Abstract. The principles of kinetic modelling of free-radical chain processes initiated in an amorphous polymer matrix are presented. The chemical modelling was based on a micellar-sponge model of the supermolecular structure, which takes into account the behaviour of the heterogeneous zones, differing in size and fluctuational dynamics of micropores forming these zones. The influence of antioxidants on chain processes is associated with the existence of conjugated reaction chains localised in various zones of chain-sponge micelles. Considerable attention is paid to the mechanism of autooxidation of polyalkenes, containing sterically hindered alkylphenols, during the induction period. The induction period preceding the oxidation of a polymer is considered as a stage involving chain co-oxidation of the antioxidant and the polymer, which follows zero- or first-order kinetics with respect to the antioxidant (alkylphenol) depending on its molecular structure. The bibliography includes 54 references.

I. Introduction

According to the morphological model of a noncrystalline polymer, developed recently,^{1–9} an amorphous polymer consists of globules occurring in close contact with one another and incorporating large numbers of sponge-like polymer chains. An intraglobule chain-sponge micelle is considered as a chemical reactor. Two types of structural zones are distinguished within a micelle. In these zones, chain units experience unequal mechanical tension; they are confined by micropores, the real traps for reactive species, which have different sizes and are characterised by different fluctuation dynamics. Consequently, non-equivalent conditions

for the excitation of generation, propagation and termination of reaction chains are developed in different zones.

The closest packing of polymer chains cannot be achieved inside the globules; the degree of their loosening remains higher than that in a θ -solvent. This is due to the fact that globules in a block polymer are joined through their shells, the latter forming a continuous spatial p-framework.^{1,2,6,8} Paracrystalline domains of this p-framework, formed from small sections of chain units, act as mechanical clamps preventing the main regions of the polymer chains inside the globules from assuming a conformation of statistical knots characterised by maximum close packing.

The combination of spatial stretching fixed by the p-framework with the flexibility of polymer chains predetermines many features distinguishing amorphous polymers from homogeneous liquids. For example, there exist indirect methods that make glassy polymers compatible with low-molecular-weight compounds, although they are not mixed spontaneously upon direct contact.⁷ Many initiators and inhibitors of chain processes, used practically, which are sufficiently volatile and have access to the inner surfaces of structural cavities in a glassy polymer can be absorbed in it but only in minor amounts. However, larger amounts of the same compounds can often be introduced into the polymer from their joint solution in a common solvent at the stage of solvent evaporation.⁷

It is known that solvent molecules can exchange places, more or less easily, with chain segments, which ensures high entropy of mixing, and an intraglobule sponge micelle is thus converted into a liquid drop of a joint solution.⁹ A non-solvent molecule of a foreign admixture, which occupies in a chain sponge the site formerly belonging to a solvent molecule, is forced to push the polymer chain units apart, thus preventing them from packing more closely and, to some extent, ordering them with respect to itself. Consequently, a non-solvent molecule introduced into the sponge forms a micropore to 'match' its size, which is larger than the micropore existing without the admixture, and thus creates room for itself. The crowded sponge is compressed and, pressing against the paracrystalline globule shell, it in turn exerts an influence on the admixture through the surface forces of the micropore walls, which encapsulate the admixture molecule. Since the elastic forces of the sponge and the dispersion forces of interaction of the micropore surface with the admixed molecule

are balanced with one another, the admixed molecule is localised within the pore and thus has more freedom to rotate.

Polymer chains that have no opportunity to form close packing within a sponge micellar structure but tend to reach the highest cohesion density, create zones containing micropores with different sizes. In the absence of admixtures, a grain is formed inside a globule bound in a framework; the grain contains narrow micropores with sizes of up to 0.5 nm, which corresponds in order of magnitude to the thickness of the polymer chain.

Such a grain (called v-zone) is separated from the walls of the p-framework cell (*i.e.* from the shell of the globule) by a spherical layer of stretched chain segments oriented in radial directions in the globule. These segments act as mechanical tension wires and fix a layer of stationary super-s-micropores, the sizes of which are close to the length of a thermodynamic segment (1.5–3.0 nm).

The presence of separate microporous zones within the p-framework cells accounts for the heterogeneous distribution of molecules of admixtures (for example, initiators, inhibitors, oxygen, etc.). The greater part of an admixture is accumulated in the internal v-grains, because the energy of sorption in the narrow v-micropores of these grains is larger than that in the ample s-micropores. As has already been noted, upon capturing an admixture, the narrow v-micropores are forced to become larger, which ensures a fairly high frequency of rotation of admixed particles. The frequency of steps of migration of the admixed particles along the micropore system also increases. This is because thermal fluctuation pulsations of the sponge v-grains hanging on the walls of the p-framework stimulate the cooperative vibrations of the chain segments of the sponge. Owing to these fluctuations, a probability appears, although only for a short period, that the size of the narrow v-micropores will increase up to that of the s-micropores. Consequently, relatively small admixture particles become fairly free to move within the sponge, which enhances exchange between the v- and s-zones.

The functioning of stationary s-micropores and fluctuation-labile v-micropores in sponge micelles has an effect on the mechanism of initiated transformations, because molecules of an initiator migrate between the s- and v-zones thus changing their steric and energy states. Consequently, their initiating ability in these two zones would be different. In fact, in narrow v-micropores, the force fields of the opposite walls overlap. Under these conditions, the initiator molecule is pushed to the bulk of the pore and is mostly located there, executing only short-term fluctuation-activated jumps. Owing to the short duration of these jumps, even if a primary radical pair arises upon occasional decomposition of the initiator molecule in the v-zone, the radicals of this pair cannot move far from each other.

To the contrary, in ample s-micropores, conditions for the dissociation of initiator molecules are much more favourable than those in narrow v-micropores. This is due not only to the presence of free space but also to the fact that the force fields of the opposite walls do not overlap and, consequently, an admixed particle spends most of the time on the pore surface as an adsorbed species rather than within the pore bulk. Under these conditions, the radicals of a radical pair formed spontaneously do not experience compression forces any longer; instead, under the action of adsorption forces, they efficiently attack polymeric molecules.

The presence of dissimilar zones also influences the fate of the polymeric radicals, which are able to decompose with rupture of the chains. It is clear that the probability of this event occurring on the surface of a compressed v-micropore is low, since this requires that a series of segments ensuring the fixing of the v-micropore walls would shift synchronously, which is possible only if the fluctuation mobility of the chain-sponge grains is very high.

At the same time, on the surface of s-micropores, the probability for the degradation of polymer radicals accompanied by chain rupture is substantially higher. This is due to the presence of free space and to mechanical stretching of the s-segments of polymer chains.

The above characteristic features of the heterogeneous structure of chain-sponge micelles constituting the matrix of a non-crystalline polymer make the problem of kinetic description of a chain process more complicated than that of a homogeneous reaction. To construct an adequate mechanism for a polymer transformation, one must take into account the heterogeneity of the system and abandon the simplified representation of the reaction medium as a structureless liquid-phase system. This resembles the situation, which arose at one time in the field of heterogeneous catalysis;¹⁰ therefore, the current problem could also be solved by design and selection of structural-kinetic models for reactions.

The modelling of chain transformations of polymers has been started with consideration of a model chain reaction of dibenzoyl peroxide (BP) with polymers of various structures (cellulose triacetate, polycarbonate, polystyrene and polyamide PA-548).^{3,9,11–13} Later, chain decomposition of polymeric peroxides has been modelled.^{5,6}

According to the views of that time on a heterogeneous reaction, a complete representation of a transformation should include: (1) a scheme for the primary reaction chains, which propagate in the ample micropores of s-zones of sponge micelles; (2) a scheme for the secondary reaction chains, which occur in the narrow micropores of v-zones; and (3) a scheme for the transfer of free radicals between the zones.

It may be expected that peculiar features of the supermolecular organisation of polymer chains will also influence the transformations of antioxidants used to stabilise polymeric materials during their processing and operation. Antioxidants have been widely employed in polymers since the polymers themselves came into universal use; however, up to now, the development of scientific views about the mechanism of their protective effect has remained within the framework of theories of homogeneous reactions.^{14–16} At the same time, the study of model chain reactions of dibenzoyl peroxide with polymers made it possible to discover significant specific features of the influence of phenolic antioxidants on this process resulting from microheterogeneity of the polymer matrix.^{17,18} In this review, we report briefly these results and analyse some important published data on the mechanism of the action of antioxidants, which have not yet been adequately explained. A structural-kinetic reaction model is developed, which discloses the physical essence of the action of antioxidants in a real heterogeneous process, polymer ageing. This model necessitates complete revision of the attitude towards the postulates, transferred from the theory of homogeneous reactions to the chemistry of polymers.

II. The mechanism of the influence of 2,6-di-*tert*-butyl-4-methylphenol on the anaerobic chain reaction of dibenzoyl peroxide with glassy cellulose triacetate and polycarbonate

1. Regularities of a model reaction

Studies of the reaction of BP with cellulose triacetate (CTA) and polycarbonate (PC)^{2,11} included measurements of the kinetics of consumption of BP ($T \leq 371$ K) and of accumulation of benzoic acid and phenyl benzoate and determination of the numbers of ruptured polymeric bonds and decomposition fragments of BP grafted to polymer chains.

Spontaneous decomposition of BP was found to occur in those structural zones of the polymer matrix in which macroradicals do not induce decomposition of BP and the related addition of the peroxide fragments to the polymer. The effective rate constant k_0 for the spontaneous decomposition of CTA or PC at 371 K is $4.8 \times 10^{-3} \text{ min}^{-1}$ (the activation energy $E_0 = 117 \text{ kJ mol}^{-1}$). The rate constant is described by the expression $k_0 = k_{0s} K_e m_s m_v^{-1}$, where m_s and m_v are masses of the s- and v-zones, respectively, k_{0s} is the rate constant for decomposition of

BP in s-micropores, and K_e is the equilibrium constant for the interzone distribution

The condition of equilibrium for the BP exchange between the zones has the following form:

$$c_s = K_e c_v \approx \frac{K_e c}{\alpha}, \quad (1)$$

where c_s , c_v and c are the concentrations of BP in s-zones, in v-zones, and in the whole sample, respectively; α is the mass fraction of sponge micelles consisting of both types of zones. This equilibrium, which ensures heterogeneous generation of radicals from the very beginning of the process, is not disturbed during the decomposition of BP, the rate of which is much lower than the rate of the interzone exchange.

Spontaneous decomposition of BP gives molecular products in high yields. These are phenyl benzoate and products resulting from the addition of radicals derived from BP to the benzene rings of PC. Benzoic acid and macroradicals with free valences located either in side groups ($R_s^\bullet$) or in the backbone ($P_s^\bullet$) are formed in a lower yield (the effective rate constant is $0.2k_0$). Decomposition of the latter is accompanied by chain rupture and by a decrease in the molecular weight of the polymer.

The terminal radicals arising upon destruction of the chain as well as the $R_s^\bullet$ radicals undergo transformations, which lead ultimately to the elimination of the free valence without formation of cross-linking bonds between the polymer chains.

The rate of accumulation of ruptured polymer chains and the variation of the concentration of breaks (n) with time during the processes involving CTA and PC are expressed by identical relations:

$$\begin{aligned} \frac{dn}{dt} &= k_n c_0 \exp(-kt); \\ n &= n_\infty [1 - \exp(-kt)]. \end{aligned} \quad (2)$$

Here, c_0 is the initial concentration of BP in the sample; k is the effective rate constant for decomposition of BP; n_∞ is the limiting concentration of the ruptured chains; the k_n constant at 371 K is $0.062k_0$ and $0.14k_0$ for processes involving CTA and PC, respectively (if the polymer contains dissolved oxygen, k_n halves, due to the oxidation of radicals $R_s^\bullet$ yielding new radicals that react with the initial benzoyloxyl radicals);

Transformations of polymer chains in the v-zones differ from those in the zones of radical generation. They do not degrade but instead, they enter into a chain reaction with BP according to a simple stoichiometric ratio

(here, the symbol r refers to a benzoyloxyl radical).

The overall process of decomposition of BP in sponge micelle zones is described by an exponential equation

$$c = c_0 \exp(-kt), \quad (3)$$

and the overall effective rate constant consists of the non-chain and chain components:

$$k = k_0 + k_c k_0 c_0.$$

The coefficients k_c in the chain component are similar for the reactions involving CTA and PC, unlike the situation occurring in liquid-phase systems: the rate of decomposition of BP in aromatic liquids is lower than that in non-aromatic liquids.

It has been found^{2,11} that the same reagents (BP molecules, polymer chain units, free benzoyloxyl radicals and macroradicals) exhibit different chemical properties in different structural zones. Three block schemes are used to describe the overall picture of

transformations occurring in polymers in the absence of dissolved oxygen.

The s-scheme describes generation of radicals and their subsequent transformations in zones of s-micropores. The process starts with the steps of formation of primary radical pairs:

The liberated primary benzoyloxyl radicals undergo further transformations:

(here, the symbols $P_s^\bullet$ and $R_s^\bullet$ refer to radicals with the free valence in the backbone and in the side groups, respectively).

The transfer of radicals from the s-zone to the v-zone in the absence of oxygen in the samples is described by the tr-scheme:

(here, the symbol A denotes the phenyl group of both the initial BP and the benzoic acid and phenyl benzoate formed). This scheme characterises the sequence of events occurring at a favourable arrangement of the species participating in this reaction bridge and surrounded by rigidly fixed chain segments, which confine s-micropores.

As a result of this s,v-transfer, the probability of which is low and which has no influence on the steady-state concentrations of s-radicals, secondary benzoyloxyl radicals $r^\bullet$ responsible for chain arylation of macromolecules appear in v-zones. The corresponding v-scheme has the following form:

(indices at the reagents are omitted, except for BP_v , the symbol $R^\bullet$ corresponds to a radical with the free valence at a side-chain group, $-\text{CH}_2^\bullet$). These reaction v-chains are terminated *via* the departure of mobile benzoyloxyl radicals to s-zones):

This v-scheme does not take into account the differences between the chemical structures of non-aromatic CTA and aromatic PC, which is consistent with experimental results; it does not also include steps of interaction of the aromatic rings of PC with light radicals and steps of decomposition

Whereas the $r_s^{\cdot}$ radical can add to the rings of PC in s-zones, this is apparently impossible in v-zones, because the rings in the v-framework cannot undergo conformational changes needed for the addition to proceed at intermediate stages.

The fact that decarboxylation of benzoyloxyl radicals in v-zones is absent for both polymers implies that one molecule of benzoic acid is formed in each unit of the chain decomposition of BP. This differs completely from the observations made for the reactions carried out in liquids in which the probability of decarboxylation of benzoyloxyl radicals is close to 100%. This distinction can be explained by the fact that rigid monomeric units in CTA and PC are fairly large and the volume of v-micropores is relatively small; consequently, the $r^{\cdot}$ radicals spend a lot of time on the rigid walls of the v-framework and thus have a good chance of abstracting hydrogen atoms from the alkyl substituents of macromolecules.

It should be noted that chain arylation of polymers decreases the total number of free phenyl groups, but this does not change the efficiency of the s, v-transfer involving them. This is due to the fact that the loss of a binuclear BP molecule is accompanied by the formation of a mononuclear benzoic acid molecule, which migrates along the system of micropores twice as fast as the molecule of BP. Hence, the probability of the interzone transfer of free valence is retained.^{2, 9, 11}

The non-equivalent reactivity of the same species in s- and v-zones, reflected in the above schemes, can be expressed in terms of the corresponding kinetic equations.

For example, the local rate of decomposition of BP in s-zones is described by the following equation

$$-\frac{dc_s}{dt} = k_{0s} c_s = \frac{k_{0s} K_e c}{\alpha}, \quad (4)$$

while that in v-zones is described by another equation

$$-\frac{dc_v}{dt} = k_3 [R^{\cdot}] c_v = k_2 [r^{\cdot}] [RH].$$

The concentration of benzoyloxyl radicals $[r^{\cdot}]$ can be found from the condition of equal rates of generation and termination of the reaction v-chains⁹

$$V_{tr} = k_4 [r^{\cdot}],$$

where

$$V_{tr} = k_1 [r_s^{\cdot}] [PhH_s] = 2\varphi k_1 \frac{[PhH_s] k_{0s} c_s}{k_{1s} [PH_s]} \quad (\text{Ref. 9}),$$

$$\varphi = \frac{k_0'}{k_0' + k_0'' + k_0'''},$$

$$[PhH_s] = 2 \frac{K_e c_0}{\alpha}.$$

After the necessary substitutions, we obtain

$$\begin{aligned} -\frac{dc_v}{dt} &= k_2 [r^{\cdot}] [RH] = \frac{k_2 [RH] V_{tr}}{k_4} = \\ &= 4\varphi \frac{k_2 [RH] k_1 K_e \alpha^{-1} c_0 (k_{0s} K_e \alpha^{-1}) c}{k_4 k_{1s} [PH_s]}. \end{aligned} \quad (5)$$

Now we pass from the local specific reaction rates in s- and v-zones to the overall reaction rate in the sample on the whole. This is calculated from the formula

$$-\frac{dc}{dt} = -\frac{m_s}{m} \frac{dc_s}{dt} - \frac{m_v}{m} \frac{dc_v}{dt}$$

where m_s , m_v and m are masses of s-zones, v-zones, and the whole sample, respectively. Taking into account the relation

$$\alpha = \frac{m_s + m_v}{m} \approx \frac{m_v}{m}$$

and Eqns (4) and (5), we obtain the following expression for the overall rate of the decomposition of BP

$$-\frac{dc}{dt} = k_0 c + k_c k_0 c_0 c = (k_0 + k_c k_0 c_0) c. \quad (6)$$

The rate of destruction, which occurs only in s-zones according to the s-scheme, is equal to

$$\begin{aligned} \frac{dn}{dt} &= k_{3s} [P_s^{\cdot}] = k_{1s} [r_s^{\cdot}] [PH_s] = 2\varphi k_{0s} c_s = \\ &= \frac{2\varphi K_e k_{0s} c}{\alpha} = \frac{2\varphi m k_0 c}{m_s} = k_n c. \end{aligned} \quad (7)$$

Both theoretical expressions, (6) and (7), are fully consistent with empirical formulae (2) and (3) and disclose the physical essence of heterophase transformations of units of polymeric-chain sponge in the inhomogeneous structural zones.

The heterophase scheme under consideration can be used equally well to explain the kinetic regularities of the formation of products of non-chain and chain reactions such as phenyl benzoate, benzoic acid and arylated macromolecules.

2. Characteristic features of the model anaerobic reaction in the presence of ionol

The non-equivalence of transformations of reagents in different structural zones of sponge micelles is also retained when ionol (2,6-di-*tert*-butyl-4-methylphenol, IH) is present as an admixture. The influence of this substance on model reactions of BP with polymers has been studied.^{17, 18}

Ionol itself influences the processes occurring in s- and v-zones in different ways. For example, ionol present in a relatively low concentration, $c_i \approx 0.05 \text{ mol kg}^{-1}$, causes virtually complete termination of chain arylation of polymers, whereas the process of initiated destruction is only slightly decelerated even at very high c_i . In the case of PC, as c_i varies from 0.023 to 0.64 mol kg^{-1} , the rate constant for destruction (k_n) decreases only by one half and then remains constant.

In terms of the theoretical model for a heterophase reaction, this is explained by the two-fold decrease in concentration of primary benzoyloxyl radicals $r_s^{\cdot}$ due to their interaction with the phenoxyl radicals arising *via* the reaction of ionol with side-chain and terminal macroradicals $R_s^{\cdot}$.

Thus, expression (7) for the rate of destruction assumes the form

$$\frac{dn}{dt} = 0.5 k_n c. \quad (8)$$

The fact that the rate constant for destruction (k_n) decreases in the presence of ionol by only 50% indicates that the efficiency of direct interaction of ionol with primary benzoyloxyl radicals in a PC matrix is extremely low. Apparently, the spatial arrangement of these reagents adsorbed on the walls of s-micropores is unfavourable for the reaction.

Figure 1 presents the results obtained by analysis of the decomposition of dibenzoyl peroxide in PC in terms of the heterophase scheme. The character of the curves describing the accumulation of ruptured polymer bonds (2–4) indicates that the limiting concentrations of the ruptured bonds decrease upon an increase in c_i , because BP is consumed in another reaction, the mechanism of which will be considered below. Here we only

Figure 1. Accumulation of broken polymeric chains during decomposition of 0.29 mol kg^{-1} of dibenzoyl peroxide at 371 K in evacuated polycarbonate films containing ionol in concentrations, $c_i / \text{mol kg}^{-1}$: 0 (1); 0.023 (2); 0.32 (3); 0.64 (4). Curves (1–4) were obtained by calculations, and the points show the experimental results.

mention that according to Eqn (8), the initial rate of the destruction, which can be found from the initial sections of curves 2–4, decreases by only one half with respect to the initial rate of the destruction of PC in the absence of ionol (Fig. 1, curve 1).

Some deviation of the calculated curve 4 from the experimental points is due to the fact that for very high c_i values, the contribution of the direct reaction between ionol and primary benzyloxy radicals

which is not taken into account, becomes noticeable. In the reaction involving CTA, this contribution is greater; however, in this case too, destruction is not terminated completely even at a high concentration of ionol, $c_i = 0.32 \text{ mol kg}^{-1}$.

In the v-zones of chain-sponge micelles, in which decomposition of BP induced by macroradicals is inhibited even at low c_i , ionol reacts with benzyloxy radicals in a completely different way. This is manifested both in a decrease in the effective rate constant (k_i) for the consumption of BP and in the fact that the synthesis of arylated macromolecules ceases.

The overall process of BP decomposition in the presence of ionol obeys an exponential kinetic law

$$c = c_0 \exp(-k_i t), \quad (9)$$

According to this equation, the k_i constant, which characterises this reaction at any degree of conversion, depends on the initial concentrations of BP (c_0) and ionol (c_{i0}). To illustrate this, several $c(t)$ dependences plotted in semilogarithmic coordinates and referring to the decomposition of BP in CTA films, are presented in Fig. 2.

It can be seen from Fig. 2 that the smallest k_i value is achieved in those samples, which have been heated in air (curve 1); in this case, k_i coincides with the constant k_0 for spontaneous decomposition of BP. For c_0 and c_{i0} ranging over the same limits but in the absence of oxygen, k_i varies in a complex manner: at low c_0 (0.02 mol kg^{-1}), it increases proportionally to c_i (Fig. 3, straight line 1), whereas at high c_0 , it sharply diminishes as c_i increases, reaches a minimum at $c_i = 0.05 \text{ mol kg}^{-1}$, and then increases again (Fig. 3, curves 2, 3 and 5).

In the presence of ionol, a catalytic branch of BP decomposition appears (Fig. 3) in which the rate of chain decomposition under the action of macroradicals is negligibly small. Firstly, this is indicated by straight line 1 in Fig. 3: in this case, chain arylation

Figure 2. Semilogarithmic plots for the curves for consumption of dibenzoyl peroxide at 371 K in aerated (1) and evacuated (2–4) cellulose triacetate films containing BP and ionol in concentrations, mol kg^{-1} : for (1), (1'), and (1'') — $c_0 = 0.02, 0.25$, and 0.63 , $c_{i0} = 0.08, 0.10$, and 0.11 , respectively; (2) — $c_0 = 0.02$, $c_{i0} = 0.027$; (3) — $c_0 = 0.66$, $c_{i0} = 0.042$; (4) — $c_0 = 0.02$, $c_{i0} = 0.27$.

Figure 3. Dependence of the effective rate constant for the decomposition of BP at 371 K on the concentration of ionol in evacuated (1–3, 5) and aerated (4) CTA (1–4) and PC (5) films containing BP in the following initial concentrations mol kg^{-1} : 0.02 (1); 0.27 (2, 4, 5); 0.64 (3).

does not make significant contribution to the decomposition of BP even when no ionol is present, because c_0 is fairly low. Secondly, this is confirmed by the fact that the accumulation of arylation products, which is followed using the UV spectra of CTA, almost ceases after BP has wholly decomposed (in the range of c_0 from 0.15 to 0.7 mol kg^{-1}) and the decomposition products have been extracted with methanol (Fig. 4). The straight line 1 in Fig. 4 corresponds to chain grafting of BP fragments to CTA in the absence of ionol, and curve 2 corresponds to the same process in the presence of ionol ($c_{i0} = 0.22 \text{ mol kg}^{-1}$). Curve 3 was constructed using measurements of the optical density at $\lambda = 333 \text{ nm}$, which is beyond the absorption spectrum of grafted BP fragments, while curves 1 and 2 were obtained by measuring the optical density at the maximum of the absorption band of these fragments ($\lambda = 284 \text{ nm}$). Complete correlation between curves 2 and 3 indicates that the formation of a minor amount of UV-absorbing products in this case is associated with grafting of only a small number of ionol groups and not of BP fragments to the polymer.

Speaking again about the reasons for the appearance of catalytic branches in the curves in Fig. 3, it should be mentioned that they refer to decomposition of BP caused by free radicals derived from ionol rather than by ionol molecules. This is why the

Figure 4. Dependence of the normalised optical density D_{∞} of arylated CTA on the concentration of BP without antioxidant (1) and in the presence of 0.22 mol kg^{-1} of ionol (2, 3). The D_{∞} values were measured at an UV radiation wavelength of 284 (1, 2) and 333 (3) nm for solutions of films in dichloromethane, after anaerobic decomposition of BP at 371 K and extraction of low-molecular-weight compounds from the films with methanol.

catalytic effect disappears completely when the polymer films contain dissolved air; the rate of decomposition of BP in aerated films is equal to the rate of its spontaneous decomposition (straight line 1 in Fig. 2 and curve 4 in Fig. 3).

Free phenoxyl cannot act as a radical carrying new chains of BP decomposition, since it ensures linear termination of chains of arylation of macromolecules. In addition, it is known that phenoxyl radicals derived from sterically hindered phenols (including ionol) are not oxidised by oxygen and dibenzoyl peroxide at 371 K.^{19–21}

The σ -complex formed upon addition of benzoyloxy to the benzene ring of ionol acts as a new initiator of the chain decomposition of BP. The formation of σ -complexes in reactions of ionol with alkyl macroradicals can be neglected, because the data presented in Fig. 4 indicate that the rate of this addition is low even at high concentrations of ionol ($c_i = 0.22 \text{ mol kg}^{-1}$).

In solutions, ionol and other sterically hindered phenols also do not add alkyl radicals,¹⁶ and their σ -complexes with benzoyloxy radicals are extremely unstable; they rapidly dissociate into the initial species, $r^{\cdot}$ and IH , and exert no influence on the rate of decomposition of BP.^{9, 19} However, admixture species in v-zones of chain-sponge micelles, unlike those in liquids, experience the effect of the overlapping surface forces from the closely spaced walls of v-micropores; consequently, these species are localised within the bulk of the pores. This favours mutual contacts between the species and hampers their dissociation. Recall that a similar structural effect of the chain sponge accounts for the decrease in the rate of dissociation of BP in narrow micropores of v-zones. For a similar reason, the stability of the ionol σ -complexes and the probability of their interaction with BP molecules migrating in v-zones increase.

These transformations of ionol can be represented by the following scheme:

The termination of new reaction chains occurs both upon the migration of benzoyloxy radicals from v-zones to s-zones (with

rate constant k_4) and in processes involving the phenoxyl radicals formed

If we consider these reactions in terms of the above scheme for the decomposition of BP, it is not difficult to find out that they do not suffice to account for the increase in the constant k_i in the region of high c_{i0} values, since both the rate of the chain reaction (k_6) and the rate of chain termination (k_7) depend on c_i in the same manner.

The linear $k_i(c_i)$ dependence in the catalytic branches of the curves (see Fig. 3) indicates that an additional route for the injection of radicals from s-zones to v-zones, which involves ionol, should be considered:

Now, taking into account both routes of the s,v-transfer of free valence (involving PhH and ionol) and the fact that the rates of generation and termination of the reaction v-chains are equal, we obtain an expression for the concentration of benzoyloxy radicals in the v-zone:

$$[r^{\cdot}] = \frac{(k_1[\text{PhH}_s] + k_5 c_{is})[r_s^{\cdot}]}{k_4 + 2k_7 c_{iv}} \quad (10)$$

When the content of ionol (c_{i0} , c_{is} and c_{iv}) is relatively high, the concentration of $r^{\cdot}$ markedly decreases, and Eqn (10) is transformed into the following expression

$$[r^{\cdot}] = \frac{k_5 c_{is} [r_s^{\cdot}]}{2k_7 c_{iv}},$$

which actually implies that $[r^{\cdot}]$ does not depend on the concentration of ionol, because during the interzone exchange of ionol, the following equilibrium is established:

$$c_{is} = K_{ei} c_{iv} \approx \frac{K_{ei} c_{i0}}{\alpha},$$

(here K_{ei} is the constant of the corresponding equilibrium). Thus, Eqn (10) assumes the following form

$$[r^{\cdot}] = \text{const } k_0 c.$$

In conformity with the extended heterophase scheme, the rate of decomposition of BP in v-zones is the sum of two terms

$$-\frac{dc_v}{dt} = k_3 [R^{\cdot}] c_v + k_6 [r^{\cdot}] c_{iv} = k_2 [r^{\cdot}] [\text{RH}] + k_6 [r^{\cdot}] c_{iv} \quad (11)$$

The contribution of the first term is significant only at very high concentrations of dibenzoyl peroxide c_0 , because ionol decreases markedly the concentration of $r^{\cdot}$. Taking this into account, the overall rate of decomposition of BP in s- and v-zones can be approximated by the expression

$$-\frac{dc}{dt} = k_0 c + k'_i c_{i0} c = (k_0 + k'_i c_{i0}) c = k_i c, \quad (12)$$

which characterises the catalytic branch of decomposition of BP associated with the influence of ionol.

Here the following important circumstance should be recalled: the initial concentration of ionol c_{i0} appears in the expression for the effective rate constant k_i as a constant parameter at any ratios of c_{i0} and c_0 (Fig. 2, straight lines 2–4). The fact that the c_{i0} is virtually invariant has been confirmed by IR spectroscopic analysis of CTA and PC films, which indicates that the intensity of IR absorbance by phenolic OH groups decreases only slightly

during the reaction.^{17,18} This invariance of absorbance (which is also typical of the reaction of ionol with BP in a polystyrene matrix⁹) implies that a mechanism for the regeneration of ionol from the main product of the transformations, Ir, is accomplished in the polymers.

The compound Ir is unstable in solutions and dissociates quickly to give benzoyloxy and phenoxy radicals.¹⁹ Apparently, molecules of this compound also dissociate in a polymer-chain sponge matrix on the walls of the fluctuationally excited v-micropores, which have become as large as s-micropores for a short period. The free radicals thus formed cause dehydrogenation of the polymer by one or another mechanism, depending on the structure of macromolecules. In the case of PC, the corresponding process can be represented in the following way:

Dehydrogenation of CTA occurs by the following scheme:

while the transformation in a carbocyclic polymer follows the scheme

The reactive species dehydrogenating the polymer should not leave their reaction cage, and the whole process, which occurs by a sort of 'latent radical' mechanism, should be accomplished over the life span of the excited state of the micropore.

The influence of other sterically hindered phenols studied by us, in particular, of the tetraphenol

and 2,4,6-tri-*tert*-butylphenol (at a relatively high concentration) on the decomposition of BP is qualitatively similar to that of ionol (Fig. 5, curves 2–4). However, their catalytic efficiency is much lower (when the concentration of BP is small, tri-*tert*-butylphenol does not accelerate its decomposition at all, curve 1), which is apparently due to the fact that the participation of these phenols in the steps in the interzone s, v-transfer of free valence is less probable. However, the results considered above clearly indicate that in the chain-micellar matrix of a polymer, the radicals with free valence on oxygen atoms add to the aromatic rings of the phenols, and the σ -complexes thus formed participate in subsequent transformations. Consequently, phenolic antioxidants act as carriers of the free valence between s- and v-zones and intrazone carriers of the reaction v-chains of the BP decomposition.

Figure 5. Dependence of the effective rate constant for the decomposition of BP at 371 K in evacuated CTA films on the concentration of 2,4,6-tri-*tert*-butylphenol (1–3) and on the concentration of phenolic groups of the tetraphenol 'Irganox-1010' (4) at c_0 / mol kg⁻¹: 0.023 (1); 0.2 (2, 4); 0.76 (3).

III. Specific features of the model reaction in the presence of bisphenol

In the presence of 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) or bisphenol 2246 (HIIH), the rate of anaerobic decomposition of BP in glassy CTA increases to even a greater degree.²² The curves describing the decomposition of BP in the presence of HIIH, plotted on semilogarithmic coordinates (Fig. 6), indicate that in this case, too, the process obeys an exponential law. However, unlike the situation with ionol, the apparent rate constant k_m for decomposition of BP in the presence of bisphenol increases in the catalytic stage proportionally to the squared concentration of the phenolic groups c_m ($c_m = 2[\text{HIIH}]$). The corresponding dependence of k_m on c_m^2 is shown in Fig. 7.

Figure 6. Influence of the concentration of phenol groups of 2,2'-bis(6-*tert*-butyl-4-methylphenol) on the transforms of the curves for decomposition of BP ($c_0 = 0.37$ mol kg⁻¹) at 371 K in evacuated CTA films. $2[\text{HIIH}]$ / mol kg⁻¹: 0.06 (1), 0.18 (2), 0.40 (3), 0.64 (4).

It can be seen that in the region of low c_m , this plot contains a very short section in which k_m decreases and a fairly extended catalytic branch. The first portion is due to the inhibition of the chain arylation of CTA; it was briefly considered in the previous Section. Here we shall discuss the mechanism of catalysis by bisphenol, the efficiency of which is much higher than that of catalysis by ionol and reaches a maximum value of

Figure 7. Influence of the concentration of the phenol groups of 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) on the effective rate constant for decomposition of BP at 371 K in evacuated CTA films at $c_0 = 0.37 \text{ mol kg}^{-1}$.

$$\frac{k - k_0}{k_0} = 16 - 17$$

at the highest concentration c_m studied. To begin with, we note that the empirical exponential law for the consumption of BP

$$c = c_0 \exp(-k_m t),$$

and the expressions for the effective rate constant

$$k_m = k_0 + k_c c_m^2$$

and for the reaction rate

$$-\frac{dc}{dt} = k_0 c + k_c c_m^2 c$$

make it possible to conclude that the chain constituent of the process obeys formally third order kinetics with respect to admixed reagents. At a high rate of the chain reaction, this alone indicates, irrespective of the mechanism of the process, that admixtures in the chain-sponge micelles of a glassy polymer are fairly mobile.

As regards the particular mechanism of the action of bisphenol 2246, it is natural to assume that its molecules, which actually consist of two ionol structures linked together, should enter into the same steps of s,v-transfer of radicals, induced decomposition of BP, and regeneration as does ionol. At the same time, the substantial enhancement of the catalytic effect and the change in the apparent order of the chain constituent of the reaction attest to an essentially different mechanism for the decomposition of BP in the presence of HIIH, which can be attributed to the specific mutual arrangement of the phenolic groups in the bisphenol molecule. This arrangement is quite favourable for the phenoxyl radical formed from bisphenol to isomerise into an intramolecular σ -complex, which, in its turn, is readily oxidised by dibenzoyl peroxide:

In view of this feature of bisphenol 2246, its specific influence on the model reaction can be explained by the fact that phenoxyl radicals and intramolecular σ -complexes derived from bisphenol do not participate in the termination of the reaction v-chains of decomposition of BP, and act as chain propagating species. Therefore, the transfer of v-benzoyloxyl radicals to s-zones occurring with the rate constant k_4 becomes the only route for the termination of the reaction v-chains.

Apparently, fast isomerisation of the phenoxyl radical into the σ -complex ($\text{IIH} \rightarrow \text{IIH}'$) also accounts for the fact that in solutions, the stoichiometric coefficient of inhibition by bisphenol 2246 and by other bisphenols containing analogous complementary phenolic groups is 2, as in the case of ionol, rather than 4, which might be expected with the assumption that the influences exerted by each phenolic group are additive.²³

With allowance for the above considerations, the following scheme can be proposed for generation, propagation, and termination of reaction v-chains:

According to this scheme, the concentration of v-benzoyloxyl radicals should be described by the expression

$$[\text{r}^*] = \frac{k_8 + k_8'}{k_4} c_{ms}.$$

If we substitute this relation in Eqn (11) and neglect the first term in this equation, which can be done because bisphenol 2246 is even a stronger acceptor of radicals than ionol,²³ we obtain the relation

$$-\frac{dc_v}{dt} = k_6 [\text{r}^*] c_{mv} = \frac{k_6 c_{mv} (k_8 + k_8') c_{ms}}{k_4}.$$

Taking into account the conditions for equilibrium in the exchange of bisphenol molecules ($c_{ms} = K_{em} c_{mv}$) and BP (Eqn 1) between s- and v-zones, we obtain an expression for the overall rate of the decomposition of BP:

$$-\frac{dc}{dt} = k_0 c + k_c c_m^2. \quad (13)$$

Eqn (13) can serve as a theoretical justification for the experimental data reported earlier.²² It confirms the kinetic non-equivalence of the catalytic effects of ionol and bisphenol 2246.

IV. Heterophase model for anaerobic chain decomposition of polypropylene hydroperoxide

The concept of heterophase chain reaction also proved to be fruitful in the analysis of ageing and stabilisation processes in polymers. Important characteristic features of autooxidation of polyalkenes and of decomposition of polymeric hydroperoxides under conditions of high and low fluctuation dynamics in a polymer-chain sponge have been rationalised in terms of this concept.⁴⁻⁶ Here, we consider the mechanism of chain decom-

position of polypropylene hydroperoxide in the absence of oxygen dissolved in the polymer.

Polypropylene (PP) differs from glassy polymers in that its amorphous phase exists in a highly elastic state even at ambient temperature. The amorphous phase consists of separate areas surrounded by crystallites. The crystalline phase ($T_{\text{melt}} \approx 438 \text{ K}$) usually accounts for 60 mass % of isotactic PP. Separate crystallites are joined in a continuous rigid framework, which imparts properties of a solid to the polymer. In samples of PP with this structure, the processes of oxidation and decomposition of admixtures occur mostly in highly elastic areas.^{14, 15}

The rigid framework of crystallites influences in some way the structure of the non-crystalline phase of PP;²⁴ however, characteristic features of the chain-micellar sponge structure of the amorphous areas are retained. It cannot be ruled out that wide s-micropores in PP are also formed as layers near the surface of crystallites;²⁴ however, the greater part of the sponge micelles must consist of flexible chains as grains with more or less narrow v-micropores. Assuming that the chain-micellar sponge in polyalkenes retains its microheterogeneous structure, one should expect that the characteristic non-equivalence of the rates of radical generation in v- and s-zones will be manifested. In fact, it has been shown^{4-6, 25} that PP contains s-zones in which hydroperoxide dissociates much more rapidly than in v-zones. A primary reaction chain generated in v-zones induces chain reaction in v-zones due to the s,v-injection of radicals, the probability of which is relatively low. In rigid PP specimens, the heterophase chemical induction stops at the instant when the hydroperoxide accumulated in s-zones is entirely exhausted.

However, in the general case, decomposition of polypropylene hydroperoxide is not terminated at this point; its heterogeneous-heterophase stage, which has come to an end, is replaced by a slower heterogeneous-homophase stage. The occurrence of the latter stage is due to the fact that in v-zones a possibility exists that v-micropores will grow up to the size of s-micropores, due to fluctuations. At this stage, the frequency of the acts of hydroperoxide dissociation is largely determined by the conditions under which the polymeric specimens were prepared and by the residual mechanical tension in them.

An adequate s-scheme for the transformation of hydroperoxide (G) based on the results reported in a number of studies^{4-6, 25} has the following form:

Here, the designation PH_s corresponds to the reactive CH groups at tertiary and secondary carbon atoms in the polymeric chains; δ is a coefficient of the yield of radicals upon dissociation of hydroperoxide; $P_s^\bullet$ are internal macroradicals; and $R_s^\bullet$ and $R_{1s}^\bullet$ are terminal macroradicals.

The probability for the transfer of a free valence from s-zones to v-zones is low, and, according to the tr-scheme, this transfer is largely accomplished by the most mobile and most reactive terminal radicals $R_s^\bullet$.

The $R_s^\bullet$ radicals, which exchange their positions within the s-framework and in the micropore bulk during vibrations ($R_m^\bullet$), are capable of reacting with CH bonds in v-zones.

Owing to this transfer of radicals, chain decomposition of hydroperoxide yielding water occurs in v-zones; this process can be described by the following v-scheme

By applying the condition of steady-state concentration of radicals to these block schemes, one can obtain a series of equations:

(a) for the concentration of the radicals translating the free valence

$$[R_s^\bullet] = \frac{\delta k_{0s} g_s}{2k_{2s}},$$

(g_s is the concentration of G in s-zones);

(b) for the rate of s,v-transfer

$$V_{tr} = k'_{tr}[PH][R_m^\bullet] = k_{tr}[R_m^\bullet] = k_{tr}k_m \frac{[R_s^\bullet]}{k_{-m} + k_{tr}} = \frac{k_{tr}k_m \delta k_{0s} g_s}{2k_{2s}(k_{-m} + k_{tr})}$$

(V_{tr} is equal to the rate of termination of the reaction v-chains, $V_{tr} = 2k_2[P^\bullet]^2$);

(c) for the concentration of radicals that attack hydroperoxide

$$[P^\bullet] = \left(\frac{V_{tr}}{2k_2} \right)^{0.5};$$

(d) for the rate of chain decomposition of hydroperoxide in v-zones

$$-\frac{dg_v}{dt} = k_1 [P^\bullet] g_v = k'_e g_s^{0.5} g_v.$$

Taking into account the facts that the current concentration of the hydroperoxide dissociating in s-zones is described by an exponential equation

$$g_s = g_{s0} \exp(-k_{0s} t),$$

and that the content of hydroperoxide in s-zones is low compared to that in v-zones, the latter being nearly equal to its concentration in the amorphous phase ($g_v \approx g$), we obtain the following expression for the rate of hydroperoxide decomposition:

$$-\frac{dg}{dt} = k'_e g_{s0}^{0.5} g \exp(-0.5 k_{0s} t) = k_e g \exp(-0.5 k_{0s} t). \quad (14)$$

Integration of Eqn (14) leads to an equation describing the curve of anaerobic decomposition of hydroperoxide:

$$g = g_0 \exp \left\{ \frac{k_e}{0.5 k_{0s}} [\exp(-0.5 k_{0s} t) - 1] \right\}. \quad (15)$$

At $t \rightarrow 0$, formula (15) is approximated by a first-order equation

$$g = g_0 \exp(-k_e t), \quad (16)$$

while at $t \rightarrow \infty$, it describes termination of the process in the presence of unconsumed hydroperoxide:

$$g_\infty = g_0 \exp \left(-\frac{k_e}{0.5 k_{0s}} \right).$$

Figure 8. Curves for the consumption of polypropylene hydroperoxide in evacuated samples at temperatures /K: 383 (1); 393 (2, 2'); 403 (3, 3'); 413 (4). Curves 2' and 3' were calculated from a first-order equation for rate constants of 2.0×10^{-4} and $4.2 \times 10^{-4} \text{ s}^{-1}$, respectively.

Eqn (15) derived theoretically is in good agreement with experimental results, which is illustrated by the data presented in Fig. 8. The effective rate constants for chain decomposition at 383, 393, 403 and 413 K are equal to 0.865×10^{-4} , 2.00×10^{-4} , 4.20×10^{-4} and $10.00 \times 10^{-4} \text{ s}^{-1}$, respectively and are described by the general formula

$$k_e = 3.9 \times 10^9 \exp\left(-\frac{E_e}{RT}\right), \quad (17)$$

where $E_e = 100 \pm 5 \text{ kJ mol}^{-1}$. The rate constants for spontaneous decomposition at the same temperatures are 1.14×10^{-4} , 2.48×10^{-4} , 5.06×10^{-4} and $10.00 \times 10^{-4} \text{ s}^{-1}$, respectively, and are described by the following formula

$$k_{0s} = 6.5 \times 10^8 \exp\left(-\frac{E_{0s}}{RT}\right), \quad (18)$$

where $E_{0s} = 93.6 \pm 5 \text{ kJ mol}^{-1}$. For comparison, curves 2' and 3' calculated from formula (16) are presented in Fig. 8. It can be seen that these curves begin to deviate from the experimental points rather early; therefore, they lead to overestimated rates at large degrees of conversion, whereas theoretical curves 2 and 3, which are in agreement with experimental results, attest to almost complete termination of the process.

It should be noted that the first adequate description of the initial stage of anaerobic decomposition of hydroperoxide, which is characterised by Eqn (16), has been given only recently.⁶ This stage has long been regarded as a stage of spontaneous decomposition of hydroperoxide.¹⁴ Later, after its chain mechanism had been proved,^{15, 26} this stage has been believed to be a superposition of spontaneous and chain reactions having a one and one half order with respect to hydroperoxide. However, in both cases the initial stage of the anaerobic decomposition of hydroperoxide was considered within the framework of a homogeneous model. Since the results obtained earlier^{4–6, 25} indicate that this process occurs by a heterophase mechanism, we shall attempt to demonstrate that the regularities of the hydroperoxide decomposition accelerated by an admixture initiator are also quite consistent with the heterophase model.

The dependence of the initial rate of hydroperoxide decomposition on the concentration of dibenzoyl peroxide present as an admixture^{15, 26} evidences that the process includes a chain constituent characterised by quadratic termination of reaction chains:

$$V_0 = k_d g_0 + k_{ind} g_0 (k_b c_0)^{0.5}, \quad (19)$$

where g_0 and c_0 are initial concentrations of hydroperoxide and BP, respectively ($c_0 < 0.05 \text{ mol kg}^{-1}$), k_d is the rate constant for spontaneous decomposition of hydroperoxide, and k_b is the effective rate constant for the decomposition of BP.

Experimental values of k_d at 365 K obtained in the absence of BP and by extrapolating dependence (19) to $c_0 = 0$ are in agreement with each other and amount to $(1.8–1.9) \times 10^{-5} \text{ s}^{-1}$. With the assumption that a polymeric medium being oxidised can be regarded as a homogeneous liquid, the following expression was proposed^{15, 26} to describe the rate of the process occurring without BP:

$$-\frac{dg}{dt} = k_d g + k'_e g^{1.5}, \quad (20)$$

The first term in this expression corresponds to spontaneous decomposition, while the second term reflects chain decomposition. At the same time, the rate constant for the chain reaction at 365 K calculated from formula (17) found by us, $k_e = 1.9 \times 10^{-5} \text{ s}^{-1}$, exactly coincides with the value of k_d in Eqn (19). In addition, Eqn (20) is at variance in its physical meaning with expression (15), which implies that the contribution of spontaneous decomposition of hydroperoxide is negligibly small compared to the contribution of the chain reaction.

Let us consider this situation in terms of a heterophase reaction mechanism. Recall that BP molecules rapidly migrate between the zones of chain sponge micelles,

and dissociate in s-zones,

The condition for the equilibrium in the interzone exchange of BP molecules has the following form

$$c_s = \frac{k_s}{k_{-s}} c_v = K_e c_v = \frac{K_e c}{\beta}, \quad (21)$$

where c_s , c_v and c are concentrations of BP in s- and v-zones and in the amorphous phase of PP, respectively; β is the fraction of the amorphous phase in the polymer, and K_e is the equilibrium constant.

Owing to dissociation of BP, benzoyloxyl radicals with a free valence on the oxygen atom are generated in s-zones of the polymeric-chain sponge. The reactivity of these radicals with respect to the hydrogen atoms in OOH groups is known to be hundreds or thousands times higher than that towards CH groups.²⁷ Therefore, at the initial stage of the process, capture of benzoyloxyl radicals by hydroperoxides should be the predominant reaction in s-zones containing hydroperoxides.

Taking these transformations into account within the above s-scheme for decomposition of hydroperoxide, it is not difficult to derive an expression for the concentration of radicals that are leaders in the s,v-transfer of valence

$$[R_s^*] = \frac{\delta k_{0s} g_s + 2 k_{bs} c_s}{2 k_{2s}},$$

as well as for the rate of s,v-transfer

$$V_{tr} = \frac{k_{tr}k_m[R_s^*]}{k_{-m} + k_{tr}} = \frac{k_{tr}k_m(\delta k_{0s}g_s + 2k_{bs}c_s)}{(k_{-m} + k_{tr})2k_{2s}}.$$

Then using the v-scheme considered above and applying the condition of equality of the rates of v-chain generation and termination $V_{tr} = 2k_2[P^*]^2$, we find the concentration of the radicals that induce the decomposition of hydroperoxide

$$[P^*] = \left(\frac{V_{tr}}{2k_2}\right)^{0.5},$$

and the rate of chain reaction

$$-\frac{dg}{dt} = k_1[P^*]g = \frac{k_1g[k_{tr}k_m(\delta k_{0s}g_s + 2k_{bs}c_s)]^{0.5}}{[4k_2k_{2s}(k_{-m} + k_{tr})]^{0.5}}. \quad (22)$$

To pass from the specific rate of decomposition of BP

$$-\frac{dc_s}{dt} = 2k_{bs}c_s \quad (23)$$

to the empirical rate dc/dt , we express the number of moles of BP in s-zones as $p_s = m_s c_s$ (where m_s is the mass of s-zones) and take into account the fact that the loss of p moles of BP in a specimen is equal to the loss of the corresponding number of moles in s-zones (oxygen completely inhibits chain decomposition of BP in polypropylene).²⁸ Then

$$-\frac{dc}{dt} = -\frac{1}{m} \frac{dp}{dt} = -\frac{1}{m} \frac{dp_s}{dt} = -\frac{m_s}{m} \frac{dc_s}{dt}.$$

By substituting expressions (23) and (21) in this equation, we obtain

$$-\frac{dc}{dt} = \frac{2k_{bs}m_s K_e c}{\beta m} = k_b c. \quad (24)$$

The effective rate constant for decomposition of BP included in Eqn (24),

$$k_b = \frac{2k_{bs}m_s K_e}{\beta m}$$

in conformity with the known formula,

$$k_b = 8.4 \times 10^{13} \exp \frac{-124000}{RT} \text{ s}^{-1}$$

is equal to $1.2 \times 10^{-4} \text{ s}^{-1}$.

This value is consistent with the statement that the parameter

$$2k_{bs} = \frac{k_b m \beta}{m_s K_e}$$

is much greater than the k_b constant, because

$$\frac{m}{m_s} \gg 1 \text{ and } K_e < 1.$$

From this it follows that in Eqn (22), the rate of radical generation due to dissociation of BP is substantially higher than that due to dissociation of hydroperoxide. According to formula (18), the rate constant for spontaneous decomposition of hydroperoxide at 365 K, k_{0s} , is equal to $2.6 \times 10^{-5} \text{ s}^{-1}$. In other words, for a fairly wide range of initial concentrations of BP, Eqn (22) is transformed into the following equation

$$-\left(\frac{dg}{dt}\right)_0 = k_{ind} g_0 (k_b c_0)^{0.5};$$

and only in the region of very low c_0 , is it extrapolated to relation (14), which also characterises chain decomposition of hydroperoxide with quadratic termination of reaction v-chains.

Thus, the heterophase scheme for hydroperoxide decomposition stimulated by dibenzoyl peroxide provides an explanation of the kinetic results obtained in previous studies^{15,26} and discloses the intimate connection between the mechanism of this process and the mechanism of non-sensitised chain reaction. In addition, this scheme makes it possible to account for the formation of water in the chain process, which has not been reflected in the homogeneous scheme at all.

V. The mechanism of the influence of ionol on the rate of anaerobic decomposition of polypropylene hydroperoxide

In an early paper,²⁹ some interesting features of the fast and slow kinetic stages in the unified process of decomposition of polypropylene hydroperoxide in the presence of ionol have been found. The researchers used low-molecular-weight syndiotactic PP ($M_n = 13\,500$), which was oxidised at 373 K, in order to accumulate hydroperoxide, by passing oxygen through its solution in chlorobenzene containing an initiator.

In the absence of oxygen, decomposition of the hydroperoxide thus accumulated occurred in two stages, the first of which was fast, while the second stage was slow. The rate of the second stage of hydroperoxide decomposition, unlike that found for PP samples oxidised in the bulk (Fig. 8), was quite measurable.

The rate of the fast stage did not depend on the concentrations of hydroperoxide and ionol. In fact, at $T = 408 \text{ K}$ and at the following concentrations of reagents, G/IH (mol litre^{-1}) 0.0078/0.001, 0.0034/0.001, 0.27/0.1 and 0.005/0.012, the rate constants k_{e1} for this stage were 19.8×10^{-4} , 15.1×10^{-4} , 19.8×10^{-4} and $18.2 \times 10^{-4} \text{ s}^{-1}$, respectively; at $T = 393 \text{ K}$ and at concentrations G/IH (mol litre^{-1}) of 0.034/0.000, 0.011/0.001, 0.0078/0.001 and 0.27/0.01, the rate constants k_{e1} were 5.01×10^{-4} , 6.3×10^{-4} , 6.41×10^{-4} and $6.13 \times 10^{-4} \text{ s}^{-1}$, respectively.

Conversely, the rate constant for the second stage k_{e2} (which is formally a first-order rate constant) depended on the initial concentration of hydroperoxide g_0 , as has also been observed in the homogeneous chain reaction; however, unlike the latter case, the constant k_{e2} did not change when ionol was present in small or medium concentrations (up to $0.05 \text{ mol litre}^{-1}$). Only at a very high content of ionol ($0.124 \text{ mol litre}^{-1}$), the rate of the second stage lost its chain constituent, and the constant k_{e2} assumed its minimum value equal to that observed in the absence of ionol and at the lowest concentration g_0 .

It was suggested²⁹ that at the first stage, hydroperoxide decomposition follows a chain mechanism, which is characterised by a specific mode of propagation of reaction chains along the polymer. However, it was not explained why the fraction of the rapidly decomposing hydroperoxide diminished from 0.8–0.9 to 0.25 upon the introduction of ionol in a concentration of up to $0.124 \text{ mol litre}^{-1}$.

From our viewpoint, the reaction studied in Ref. 29 actually follows a chain mechanism, its specific features reflecting the specific state of the reaction matrix, namely, the chain-sponge micellar structure of the oxidised PP. It should be noted that the local concentration of hydroperoxide in s-zones, g_{s0} , which appears in Eqn (14), reaches the level of saturation during the oxidation of PP. As has been found in a previous study,⁶ this is accompanied by the constant k_e reaching its maximum value, equal to $11.0 \times 10^{-4} \text{ s}^{-1}$, at 403 K. Eqn (17) makes it possible to calculate the constants k_e at 408 and 393 K (the effective activation energy E_a is 100 kJ mol^{-1}). The values of 16×10^{-4} and $5.15 \times 10^{-4} \text{ s}^{-1}$ thus obtained coincide with those found for k_{e1} in Ref. 29. This indicates that the limiting degree of filling of s-zones with hydroperoxide was achieved in the oxidation in

solution carried out in this study. This is why the rate constant for the initial stage of chain decomposition k_e was independent of the initial concentration g_0 calculated with respect to the whole specimen [Eqns (14) and (16)].

Regarding the specific character of the fast stage of the process in the presence of ionol, we recall that ionol substantially narrows the concentration range in which the fast stage occurs, but does not change the magnitude of k_{e1} . Within the framework of the heterophase model, this can be accounted for by the fact that ionol, which has no influence on the mechanism of the transfer of radicals from s-zones to v-zones, decreases the number of radicals transferred due to the appearance of the additional catalytic pathway for destruction of the hydroperoxide accumulated in s-zones.

All the foregoing can be expressed as an s_i -scheme by introducing the reactions involving ionol into the s-scheme described above:

This scheme reflects a number of characteristic features of the reactants. The reactions of ionol with alkyl radicals $P_s^\bullet$, $R_s^\bullet$ and $R_{1s}^\bullet$ were not included in the scheme, because all alkylphenols exhibit fairly low reactivities towards radicals derived from polyalkenes¹⁴ (even bisphenol 2246, which is more reactive, does not have any influence on the concentration of PP radicals, which eliminate propene during the induction period of the PP oxidation).³⁰

The scheme takes into account the interaction of phenoxyl with hydroperoxide^{15,16} and both routes known from the literature for the attack of a phenol molecule by $POO^\bullet$ radicals: to yield phenoxyl and σ -complex. In the micropores of chain-sponge micelles, unlike liquid solutions, there exist molecular force fields, which, as noted above, hamper reversible dissociation of σ -complexes and thus enable their subsequent transformations. In the present case, σ -complex is converted into the alkoxyl radical $IO^\bullet$ with a quinoid structure.

This scheme also takes into account the fact that $HO_s^\bullet$ radicals are highly reactive and interact with the polymer more quickly. Since they are adsorbed on the walls of s-micropores, the conditions for their reaction with ionol are less favourable than those of $PO_s^\bullet$ radicals.

Finally, due to the high local concentration of hydroperoxide in the s-zones of the samples used in Ref. 29, the s-scheme did not include recombination

the rate of which at the initial stage of the process is believed to be negligibly small compared to the rate of the reaction

If the condition of a steady-state concentration of radicals is applied to the s_i -scheme, it can be easily seen that the expression for the concentration of radicals

$$[R_s] = \frac{\delta k_{0s} g_s}{2 k_{2s}},$$

which has been obtained previously based on the s-scheme for the process occurring without ionol (see Section IV), also holds in the present case. The concentration of s-phenoxyl radicals corresponding to the s_i -scheme does not depend on the concentration of G_s

$$[I_s] = \frac{0.5 \delta k_{0s}}{k_{6s}} + \frac{0.5 \delta k_{0s} k_{-6s} [IH_s]}{k_{6s} k_{9s}}, \quad (25)$$

the concentration of s-peroxyl radicals is equal to

$$[POO_s^\bullet] = \frac{0.5 \delta k_{0s} g_s}{k_{9s}},$$

and the overall rate for decomposition of s-hydroperoxide is the sum of several terms,

$$\begin{aligned}
 -\frac{dg_s}{dt} &= k_{0s} g_s + k_{6s} [I_s] g_s + k_{8s} [IO_s^\bullet] g_s - k_{-6s} [POO_s^\bullet] [IH_s] = \\
 &= k_{0s} g_s + 0.5 \delta k_{0s} g_s + \frac{0.5 \delta k_{0s} g_s k_{7s}}{k_{9s}} [IH_s],
 \end{aligned}$$

the second term being much smaller than the first term characterising the spontaneous decomposition of G_s ($\delta < 1$). By integrating this expression and taking into account the condition of interzone equilibrium

$$c_{is} = \frac{K_{ei} c_i}{\beta}$$

(where c_{is} ($[IH_s]$) and c_i ($[IH]$) are the concentrations of ionol in s-zones and in the non-crystalline phase of PP, respectively, K_{ei} is the equilibrium constant, and β is the fraction of the amorphous phase in the polymer), we obtain the equation for the consumption of s-hydroperoxide with allowance for the chain contribution catalysed by ionol:

$$g_s = g_{s0} \exp [-(k_{0s} + b_i c_i) t], \quad (26)$$

where b_i is a complex constant.

When we pass to the mechanism of chain decomposition of hydroperoxide in v-zones, it is noteworthy that, according to the study discussed above,²⁹ ionol exerts no influence on the constant k_{e1} over the whole range of concentrations c_i studied and has an influence on the constant k_{e2} only at a fairly high c_i value, 0.124 mol kg⁻¹. Therefore, it was suggested²⁹ that the reaction chains of hydroperoxide decomposition are mostly realised through the migration of the free valence along the polymer chains and that the intermolecular attack of hydroperoxide by $P^\bullet$ radicals yielding free peroxyl radicals is impossible. In this case, the v-scheme considered above assumes the following form

(the $OH^\bullet$ radical arising reacts with the neighbouring CH group of the same macromolecule). This scheme corresponds to a fairly loose packing of polymer chains in the chain-sponge micellar structure.

The structural looseness, *i.e.* an enhanced volume tension of the chain sponge in the PP specimens oxidised in solution, is stabilised due to fixing of the stretched chains on the crystallite

framework. It is known that syndiotactic and isotactic PP readily crystallise; and crystallising polyalkenes do not form molecular solutions in hydrocarbons at $T < T_{\text{melt}}$.³¹ They are able to be dispersed in a liquid to some extent to form a colloidal solution, in case where polymer–polymer type molecular contacts arise in the system leading to the simultaneous formation of crystal nuclei.³²

Thus, in all probability, the PP matrix subjected to oxidation in the study considered above²⁹ consisted of disseminations of chain-sponge micelles swelled in chlorobenzene into colloidal particles reinforced by a lattice of crystallites linked to one another. The lattice of crystallites was relatively strong and did not change upon drying and heating of the suspension.

It is the framework strength of the lattice of crystallites that accounts for the stabilisation of the structural looseness of chain-sponge micelles and for the fact that the rates of decomposition of hydroperoxide in PP occurring as a colloidal suspension in chlorobenzene and in PP films are virtually identical.²⁹

The reaction v-scheme for hydroperoxide decomposition, modified with allowance for the results discussed above,²⁹ includes the same steps of generation and termination of reaction v-chains, which were considered in Section IV. Therefore, Eqn (26) presented above can be included in the expression for the rate of the chain reaction, which was proposed in Section IV:

$$-\frac{dg}{dt} = k_1[P^\cdot]g = k'_e g_s^{0.5} g = k_e g \exp[-0.5(k_{0s} + b_1 c_1)t]. \quad (27)$$

The pre-exponential factor k_e in Eqn (27) has the same structure as that in Eqn (14), and the exponential part contains an additional constant, $b_1 c_1$, associated with chain decomposition of hydroperoxide in s-zones.

Integration of Eqn (27) leads to a formula, which describes the curve for decomposition of hydroperoxide

$$\ln \frac{g}{g_0} = \frac{k_e}{0.5(k_{0s} + b_1 c_1)} \{ \exp[-0.5(k_{0s} + b_1 c_1)t] - 1 \}.$$

At $t \rightarrow 0$, i.e. in the initial stage of the reaction, this formula is transformed in a first-order equation

$$\ln \frac{g}{g_0} = -k_e t,$$

or

$$g = g_0 \exp(-k_e t),$$

which coincides with Eqn (16) and includes only the constant k_e , which does not depend on the content of ionol.

At a high degree of conversion ($t \rightarrow \infty$), this initial formula is transformed in the following expression

$$\ln \frac{g_\infty}{g_0} = -\frac{k_e}{0.5(k_{0s} + b_1 c_1)},$$

or

$$g_\infty = g_0 \exp \left[-\frac{k_e}{0.5(k_{0s} + b_1 c_1)} \right],$$

which characterises a 'kinetic step'; the larger the ionol concentration (c_1) in the samples and the more pronounced is the catalytic influence of ionol on the decomposition of hydroperoxide in s-zones, the higher is this step.

Now we shall consider characteristic features of the homophase stage of decomposition of PP hydroperoxide.

In the study discussed above,²⁹ the fast stage of the process was followed by its slow stage rather than by its kinetic termination. The rate of the slow stage remained constant at low and medium concentrations of ionol (up to 0.05 mol kg⁻¹). The fact that the rate of the reaction characterised by k_{e2} can be reliably measured, although it is relatively low, distinguishes these samples from the samples oxidised in the bulk in which the second stage of the process occurs at an extremely low rate (see Fig. 8).

In the first stage of the process, the rate of hydroperoxide decomposition in the samples, which were studied in Ref. 29, was also higher than that in PP oxidised in the bulk (the temperature being the same). Obviously, the higher reactivity of the polymer oxidised in suspension should be attributed to the loose packing of the polymer chains in the chain-sponge micellar structure.

The loose structure of the micellar material in combination with high flexibility of the polymer chains increases the degree to which v-zones (which accumulate the greater part of the hydroperoxide formed upon oxidation) are ready to undergo thermofluctuational excitation, which ensures widening of v-micropores to the size of s-micropores. Consequently, the frequency of these excitation acts increases and the probability of dissociation of hydroperoxide groups within the intensely oscillating micropores increases correspondingly.

Thermofluctuational excitation of this sort is favourable for the beginning of the second stage of hydroperoxide decomposition, which can be characterised as a heterogeneous-homophase stage. The contribution of this stage becomes predominant after heterophase s,v-transfer of radicals has ceased due to the exhaustion of hydroperoxide groups within s-zones.

There is always a certain probability of the flickering growth of v-micropores in the chain-sponge zones; this probability is especially high when the polymer occurs in the highly elastic or molten state.^{5,6} The process of generation of free radicals in this stage can be represented by the following scheme

in which the constants k_f , k_{-f} and k_{of} correspond to the heterogeneous steps of excitation, deactivation and dissociation of hydroperoxide groups conjugated with the steps of fluctuation of micropores; the symbol δ_f denotes the fraction of radicals leaving an oscillating micropore.

An equation for the rate of chain heterogeneous-homophase reaction follows from this scheme in combination with the reaction v-scheme considered in Section IV:

$$-\left(\frac{dg}{dt}\right)_c = k_1[P^\cdot]g = k_1 g^{1.5} \left[\frac{\delta k_{of} k_f}{2 k_2 (k_{-f} + k_{of})} \right]^{0.5}.$$

Taking into account the fact that the occurrence of this reaction suggests a relatively large contribution of fluctuational dissociative decomposition of hydroperoxide in v-zones, we obtain the following expression for the overall rate of decomposition:

$$-\frac{dg}{dt} = k_{d,f} g + k_{c,f} g^{1.5}, \quad (28)$$

where $k_{d,f}$ and $k_{c,f}$ are complex rate constants for non-chain and chain v-reactions, respectively.

The fact that the process actually obeys Eqn (28) is indicated by the typical dependence of the formal first-order rate constant on the initial concentration of hydroperoxide, which was found in Ref. 29:

$$k_{e2} = k_{d,f} + k_{c,f} g_0^{0.5}.$$

Note that Eqn (28) looks like Eqn (20) obtained for a homogeneous reaction; however, in contrast to the interpretation reported previously,^{15,26} it characterises the slow stage of decomposition of a polymeric hydroperoxide rather than its fast stage.

According to the data obtained in Ref. 29, the chain constituent of the rate $k_{c,f} g_0^{0.5}$ is suppressed by ionol only when its concentration is very high, $c_1 = 0.124$ mol kg⁻¹. This can be explained by the fact that ionol is extremely inert with respect to alkyl polymeric radicals $P^\cdot$ and that the probability of its interaction with $PO_i^\cdot$ and $HO_i^\cdot$ radicals, hanging on the walls of a micropore excited by thermofluctuation, is low.

VI. Specific features of the influence of ionol on the chain decomposition of polypropylene hydroperoxide in the presence of oxygen

The presence of dissolved oxygen in the oxidised PP samples containing ionol dramatically changes the situation; in this case, the heterogeneous-homophase process is brought to the fore. As shown in the previous section, this process is limited by the slow rate of heterogeneous generation of radicals, occurring directly in those structural zones of chain-sponge micelles, which accumulate the major part of hydroperoxide resulting from the oxidation of PP. The chain decomposition of hydroperoxide initiated in the absence of oxygen is decelerated by ionol only when its concentration is very high, because the reactivity of alkyl radicals towards ionol is negligibly small.

The situation changes in the presence of oxygen, which converts alkyl radicals into peroxy radicals and thus sharply increases the rate of their interaction with ionol and simultaneously switches the process to the catalytic decomposition of hydroperoxide.

An example of this change in the kinetic regime of a reaction has been reported by Chien and Boss,²¹ who studied the kinetics of hydroperoxide decomposition in films, which were prepared from a melt and then oxidised (G_1) or obtained from colloidal PP oxidised in chlorobenzene (G_2). The introduction of ionol into these specimens caused the appearance of induction periods in their oxidation carried out by heating under an atmosphere of oxygen ($P_{O_2} = 1$ atm), the duration of these periods being substantially different for the specimens prepared in different ways. The rates of hydroperoxide decomposition during the induction periods were also different. The films of the polymer oxidised in a colloidal solution were the most active. This is not surprising, since chain-sponge micelles in these films possess the most pronounced fluctuation-dynamic properties (see Section V).

Figure 9 shows the plot for the consumption of G_1 (curve 1) in samples with weak fluctuation dynamics ($T = 403$ K, $g_0 = 0.150$ mol litre⁻¹, $c_{i0} = 0.013$ mol litre⁻¹). It can be compared with the curve for the consumption of peroxy radicals (curve 2) and with the curves recorded after completion of the

Figure 9. Kinetic curves for autooxidation of PP during the induction period (1, 2) and after it (3–5) at 403 K ($P_{O_2} = 1$ atm): consumption of hydroperoxide (1); consumption of phenoxyl radicals derived from ionol (2); consumption of oxygen (3); accumulation of hydroperoxide (4); accumulation of peroxy radicals (5). The factor n for curves 1, 4 is 10; that for 2, 5 is 10^6 .

induction period for the absorption of oxygen (3) and for the accumulation of hydroperoxides and polymeric peroxy radicals (4 and 5, respectively).

During the induction period, which lasted for 350 min, the amount of oxygen absorbed did not exceed the sensitivity threshold of the analytical instrument used. In this stage, the kinetic curve for the consumption of ionol (which is not shown in Fig. 9) and the curve for the consumption of phenoxyl radicals are described by exponential equations $c_i = c_{i0} \exp(-k_i t)$ and $[I] = [I]_0 \exp(-k_i t)$, respectively, with identical coefficients $k_i = 1 \times 10^{-4} \text{ s}^{-1}$. This combination of kinetic curves implies that the condition of a quasi-steady-state concentration of phenoxyl radicals derived from ionol is ensured almost from the very beginning of the process and that phenoxyl radicals do not participate in the steps of bimolecular destruction and do not react with oxygen.

During the induction period, the concentration of $POO\cdot$ radicals was lower than the limit of sensitivity of the EPR spectrometer ($\leq 10^{-8} \text{ mol litre}^{-1}$), but when the induction period was over, it quickly reached a steady-state value of $\sim 2 \times 10^{-6} \text{ mol litre}^{-1}$, which could be measured reliably.

No analytical function has been suggested²¹ to describe the curve of consumption of G_1 ; however, with allowance for the usual 10% error in the determination of hydroperoxide concentration, a calculated curve can be constructed (curve 1 in Fig. 9), which follows an exponential law with the same k_i value that characterises consumption of ionol and phenoxyl radicals:

$$g = g_0 \exp(-k_i t) \quad (29)$$

(the value $g_0 = 0.14 \text{ mol litre}^{-1}$ was taken as the initial concentration). A transformed version of this equation plotted on semi-logarithmic coordinates is shown in Fig. 10 (straight line 1), together with the plots obtained by us, which describe the consumption of hydroperoxide in the presence of air and tri-*tert*-butylphenol. Our experiments were aimed at obtaining a more precise pattern for the scattering of experimental points, because the number of points obtained in the study cited²¹ was insufficient.

In our experiments, weighed portions of finely grained PP powder (~ 1 mg each) were oxidised in air at 413 K until the concentration of hydroperoxide was $g_0 = 0.14 \text{ mol kg}^{-1}$. Tri-*tert*-butylphenol was introduced in the oxidised powder as a solution in chloroform. After 40 min of storage, the solvent was evaporated and its last traces were removed *in vacuo*. Decomposition of the hydroperoxide was studied by heating the samples in air and using the spectrophotometric version of iodometric analysis.^{4–6, 25} The curves obtained for the consumption of hydroperoxide at phenol to polypropylene ratios of 1 : 1 and 2 : 1 by weight were identical.

The experimental points on the straight lines 2, 3, 4 and 5 (Fig. 10) were obtained at 372, 383, 393 and 403 K, respectively. For comparison, the initial section of the transform of the curve

Figure 10. Constants from the curves for the consumption of hydroperoxide in the presence (1–5) and in the absence (6) of oxygen in PP samples containing ionol (1), tri-*tert*-butylphenol (2–5) and containing no antioxidant (6) at temperatures/K: 372 (2); 383 (3); 393 (4); 403 (1, 5, 6).

for decomposition of hydroperoxide at 403 K in the absence of oxygen is also presented (straight line 6). Comparison of the scatter of experimental points in our experiments with that observed in the previous study²¹ (straight line 1) makes it possible to conclude that the use of exponential functions (29) is acceptable in all cases. The effective rate constants k_i calculated from the slopes of the straight lines 2–5 are the following: 0.85×10^{-5} , 2.0×10^{-5} , 4.26×10^{-5} and $8.5 \times 10^{-5} \text{ s}^{-1}$. They can be described by the following common expression

$$k_i = 6.0 \times 10^7 \exp\left(-\frac{E_i}{RT}\right),$$

where $E_i = 91.5 \text{ kJ mol}^{-1}$. It is significant that at 403 K, the rate constant for the decomposition of hydroperoxide in the presence of ionol k_i is equal to $1 \times 10^{-4} \text{ s}^{-1}$, which differs only slightly from the value of $0.85 \times 10^{-5} \text{ s}^{-1}$ found for the process involving tri-*tert*-butylphenol. Both of these constants are markedly smaller than the constant characterising the chain decomposition of hydroperoxide in the absence of oxygen and alkylphenol (Fig. 10, straight line 6), which is equal to $4.2 \times 10^{-4} \text{ s}^{-1}$. However, the decrease in the decomposition rate cannot be attributed to the partial reduction of hydroperoxide caused by chain oxidation of PP or by the interaction of peroxy radicals with an inhibitor, since the current concentrations g , c_i and $[I]$ are directly proportional to one another over the whole induction period. It is also significant that in this stage of the process, the chain consumption of oxygen is largely depressed (Fig. 9, curve 3), and the synchronous consumption of hydroperoxide and ionol characterised by identical exponential factor $\exp(-k_i t)$ takes place when the concentration g_0 is ten times higher than c_{i0} , *i.e.* under conditions when the formation of hydroperoxide in the steps of chain termination can by no means override the four-fold deceleration of its decomposition (Fig. 10, straight lines 1 and 6).

The kinetic law for the consumption of hydroperoxide, proposed by Chien and Boss,²¹ corresponds formally to a non-chain homogeneous reaction. However, the effective rate constant for this process falls in the range of rate constants for the heterophase stage of chain anaerobic decomposition⁶ and is many times higher than the rate constant for the heterogeneous-homophase stage of the non-chain constituent. The latter reaches only a value of $4 \times 10^{-5} \text{ s}^{-1}$ at 408 K or $1.5 \times 10^{-5} \text{ s}^{-1}$ at 393 K even for fluctuatonally active samples containing hydroperoxide G_2 ,²⁹ and in films with G_1 it cannot be reliably measured at all (Sections IV and V).

The dramatic increase in the rate of hydroperoxide decomposition in the presence of oxygen with respect to the rate of the second (homophase) stage of the anaerobic reaction is, most probably, due to oxidation of alkyl macroradicals to peroxy radicals. This process has no influence on the generation of radicals by the mechanism of thermofluctuational excitation of v-micropores but it sharply accelerates the interaction of polymer radicals with alkylphenols and results in the appearance of a new chain pathway to the decomposition of hydroperoxide. Recall that we had to introduce a new reaction in order to explain the characteristic features of the anaerobic decomposition of hydroperoxide in the presence of ionol, and this reaction was actually included in the s_i -scheme described in Section V. According to the s_i -scheme, the new chain reaction of hydroperoxide decomposition is induced by alkoxyl radicals with a quinoid structure of the six-membered carbon ring, which are formed from ionol.

The characteristic features of the decomposition of PP hydroperoxide under oxidative conditions, considered in this Section, also indicate that this new chain reaction should be taken into account. This conclusion is also confirmed by the fact, established independently, that in the specimens with G_2 , the process is accelerated by oxygen to even a greater degree. For example, it was found²⁹ that complete consumption of G_2 and of ionol-derived phenoxyl radicals under an oxygen atmosphere at $T = 393 \text{ K}$ ($g_0 = 0.156 \text{ mol litre}^{-1}$, $c_{i0} = 0.17 \text{ mol litre}^{-1}$) is

observed in approximately 20 min, whereas in samples with G_1 this occurs after 350 min, *i.e.* the half-transformation period decreases from 116 min to 5–10 min, despite the fact that G_2 decomposes at a lower temperature. The effective rate constant for the reaction under these conditions ($\sim 23 \times 10^{-4} \text{ s}^{-1}$) is markedly larger than the rate constant for the initial stage of chain anaerobic reaction in identical samples (see Section V).

Thus, the influence of oxygen leads phenomenally to the replacement of two macroscopic kinetic stages of the anaerobic process by a single stage; this is due to a substantial acceleration, which is dissimilar for G_1 and G_2 , of the ionol-catalysed decomposition of hydroperoxide in a process occurring by a chain mechanism.

The generation of the reaction v-chains under oxidative conditions occurs predominantly according to a homophase route: *via* thermofluctuational excitation of v-micropores, which accumulate hydroperoxide. Ionol, which intercepts all the reaction chains and behaves as an efficient inhibitor of autooxidation of PP, participates simultaneously in the reaction chains of hydroperoxide decomposition.

It should be emphasised that the regularities of the decomposition of PP hydroperoxide both in the presence and in the absence of oxygen considered above rule out the possibility of any significant contribution of the molecular reaction of alkylphenol with hydroperoxide (and thus preclude an increase in the probability of degenerate branching in the presence of an inhibitor). In addition, the fact that the catalytic function of ionol is retained during the whole induction period indicates that some mechanism for its regeneration exists.

Taking the above into account, the following v_i -scheme can be proposed for the transformations that occur in v-zones of chain-sponge micelles of PP beginning with thermofluctuational excitation of v-micropores.

According to this scheme, the reaction chains of hydroperoxide decomposition propagate in the same way as those in the s_i -scheme considered above, *i.e.* through intermediate formation of a σ -complex from phenol and a peroxy radical and of a quinoid alkoxyl (the rate constants for these stages are k_1 and k_2 , respectively). However, chain termination in the v_i -scheme, unlike that in the s_i -scheme, occurs on ionol and its rate (characterised by constant k_3) is directly proportional to the rate of chain propagation in the decomposition of hydroperoxide. The latter is determined by the processes characterised by rate constant k_1 . It is this direct proportionality that accounts for the fact that ionol, which sharply decreases the concentration of peroxy radicals and brings the rate of chain autooxidation of PP

to a negligibly small value, ensures the catalytic development of chain decomposition of PP hydroperoxide.

Regeneration of the initial ionol (and tri-*tert*-butylphenol) from the product of its transformation, a quinoid alcohol, should follow a pathway ensuring regeneration of ionol from the quinoid compound Ir (see Sections II and III) in the steps of thermofluctuational excitation of v-micropores. These steps occur as

'latent radical' or 'intra-cage' processes and include dissociation of the quinoid alcohol and subsequent dehydrogenation of macro-molecules:

where $\text{P}^\bullet$ is a fragment of the polymer containing a double bond. Simultaneously, partial loss of phenol should occur in the disproportionation steps occurring in parallel. In the case of ionol, this leads to a methylenequinone

which undergoes subsequent transformations, while in the case of tri-*tert*-butylphenol, this process involves elimination of *tert*-butyl radicals to give a quinone and other products

By applying the condition of steady-state concentration to the reactive species appearing in the v_i -scheme (radicals and alcohols IOH), one can derive an expression for the equality of the chain generation and chain termination rates

$$\delta_f \alpha_f k_{of} g = 2 k_3 [\text{POO}^\bullet][\text{IH}]$$

[here δ_f is the yield of radicals in the fluctuation decomposition of hydroperoxide in v -zones, and $\alpha_f = k_f / (k_{-f} + k_{of})$] and for the rate of hydroperoxide decomposition

$$\begin{aligned}
 -\frac{dg}{dt} &= \alpha_f k_{of} g + k_1 [\text{POO}^\bullet][\text{IH}] - 2 k_3 [\text{POO}^\bullet][\text{IH}] = \\
 &= \alpha_f k_{of} g + \frac{k_1 \delta_f \alpha_f k_{of} g}{2 k_3} - \delta_f \alpha_f k_{of} g = k_{ii} g
 \end{aligned}$$

The latter expression implies that this process obeys first-order kinetics with respect to hydroperoxide and zero-order kinetics with respect to alkylphenol

$$g = g_0 \exp(-k_i t)$$

The rate of the consumption of phenol, according to the v_i -scheme, is

$$\begin{aligned}
 -\frac{dc_i}{dt} &= k_1 [\text{POO}^\bullet][\text{IH}] + k_3 [\text{POO}^\bullet][\text{IH}] - k_{2f} [\{ \text{I}^\bullet + \text{HO}^\bullet + \text{PH} \}] = \\
 &= \left[k_3 + \frac{k_1 k_{3f}}{k_{2f} + k_{3f}} \right] [\text{POO}^\bullet][\text{IH}] = \\
 &= \left[0.5 + \frac{0.5 k_1 k_{3f}}{(k_{2f} + k_{3f}) k_3} \right] \delta_f \alpha_f k_{of} g = k_{ii} g
 \end{aligned}$$

By integrating the expression

$$-\frac{dc_i}{dt} = k_{ii} g$$

we obtain the equation

$$c_i = \frac{k_{ii} g_0}{k_i} \exp(-k_i t) + \text{const};$$

for the initial instant $c_i = c_{i0}$ ($t = 0$), this equation assumes the following form

$$c_i = c_{i0} - \frac{k_{ii} g_0}{k_i} [1 - \exp(-k_i t)]$$

If at $t \rightarrow \infty$, $c_i = 0$, then

$$c_{i0} = \frac{k_{ii} g_0}{k_i} \quad \text{and} \quad c_i = c_{i0} \exp(-k_i t),$$

which is in full agreement with the results obtained by Chien and Boss.²¹

As noted above, a quasi-equilibrium concentration of phenoxyl radicals in the process under consideration is established very quickly. The kinetics of their consumption is described by the theoretical formula

$$[\text{I}^\bullet] = \frac{k_3 c_i}{k_4} = \frac{k_3 c_{i0}}{k_4} \exp(-k_i t),$$

which should be valid from the instant at which a quasi-steady-state concentration of phenoxyl radicals is established until the induction period in the PP oxidation is completed. This theoretical expression, like the previous ones, describes adequately the experimental results obtained in Ref. 21. Therefore, it can be concluded that the heterogeneous-homophase chain reaction model properly reflects the empirical regularities of the oxidative decomposition of polypropylene hydroperoxide in the presence of a phenolic antioxidant.

It is noteworthy that the mechanism of partial regeneration of phenol from the quinoid alcohol formed upon its chain transformation, which is similar to the mechanism of regeneration of ionol from the product of the reaction of phenol with dibenzoyl peroxide (Section II), is apparently fairly abundant. This has been supported by an independent experiment that we have carried out with the methyl ether of the quinoid alcohol, prepared from ionol by a procedure described previously.³³

When this ether was introduced into cellulose triacetate films together with dibenzoyl peroxide, it exerted qualitatively the same influence on the rate of BP decomposition as did alkylphenols (see Sections II and III). Fig. 11 shows the linear transforms of the curves for anaerobic decomposition of BP ($c_0 = 0.66 \text{ mol kg}^{-1}$, $T = 371 \text{ K}$) at initial concentrations of the methoxy-quinoid compound of 0.08 mol kg^{-1} (straight line 1) and 0.32 mol kg^{-1} (straight line 2). Even when the difference between the initial concentrations is so large, the effective rate constant for this reaction, as has also been observed for mixtures with phenols, remains virtually unchanged during the whole process. As in systems containing phenols, the rate of the chain reaction of BP induced by polymer radicals reaches a minimum when the concentration of the quinoid ether is $\sim 0.08 \text{ mol kg}^{-1}$. At quinoid ether concentrations of 0, 0.08 and 0.32 mol kg^{-1} , the effective rate constants for the decomposition of BP were 2.7×10^{-4} , 1.5×10^{-4} and $1.58 \times 10^{-4} \text{ s}^{-1}$, whereas the rate constant for non-chain decomposition of BP was $7.5 \times 10^{-5} \text{ s}^{-1}$. Thus, the non-phenolic quinoid compound exerts a prolonged inhibitory influence on the decomposition of BP induced by macroradicals and, conversely, exhibits a catalytic effect in the concentration range in which the influence of macroradicals is suppressed. The

Figure 11. Constants from the curves for the consumption of BP at $c_0 = 0.66 \text{ mol kg}^{-1}$ and a temperature of 371 K in evacuated CTA films in the presence of 0.08 (1) and 0.32 mol kg^{-1} (2) of a methoxyquinoid ionol derivative (3,5-di-*tert*-butyl-1-methyl-1-methoxycyclohexadien-4-one).

concentration of this ether, like those of phenols, appears in the expression for the effective rate constant of the reaction of BP as a parameter. This confirms the fact that the quinoid compound is quickly transformed into the corresponding phenol by a thermofluctuation mechanism.

VII. The mechanism of the initiated chain process involving ionol during the induction period of the oxidation of polyalkenes

The data presented above make it possible to consider the chemical aspect of the inhibited oxidation of polyalkenes during the induction period from a new standpoint. A lot of experimental results and theoretical studies have been accumulated in this field; however, as a rule, they do not go beyond homogeneous reaction models.^{14–16}

One of the two methodological approaches to the solution of this problem is based on the use of initiators that have been tested in liquid-phase reactions.^{15,16} In the case of liquid-phase oxidation, this method makes it possible to determine, using relatively simple experiments, the character and specific features of the influence of a particular inhibitor on the rate of oxygen absorption and on the duration of the induction period, after which the action of the inhibitor ends.

Another approach involves investigation of the inhibited oxidation of a polymer containing no specially added initiator.¹⁴

In this Section, we consider oxidation of polymers in the presence of an initiator added as an admixture; attention is focused on the regularities of the absorption of oxygen during the induction period. The fact that oxygen absorption does occur at a certain rate during the induction period of inhibited oxidation of polyalkenes in the presence of an initiator has been long known; however, it has not yet received any acceptable explanation. Among other reasons, this is due to the fact that the rate of oxygen absorption in this stage is lower than that in the stage of the polymer oxidation itself (after completion of the induction period). In determining the efficiency of inhibitors or the rate of generation of oxidation chains, researchers have believed that it was sufficient to choose conditions under which the rate of the consumption of an inhibitor did not depend on its concentration. It has been assumed that under these conditions, slow absorption of oxygen during the induction period of the polymer oxidation can be neglected.^{15,16,28} Meanwhile, insight into the mechanism of the transformation of alkylphenols with allowance for the specific

features of functioning of the chain-sponge structure in polymers, should aid greatly the refinement of general views on the mechanism of oxidative transformations involving inhibitors.

To construct a kinetic model of the process occurring during the induction period, we used experimental data reported by Chien and Wang,²⁸ who have carried out oxidation of polypropylene, poly(but-1-ene), and poly(4-methylpent-1-ene) (under an oxygen pressure of 1 atm) using dibenzoyl peroxide as the initiator and ionol as the inhibitor. Although the workers did not consider the reason why oxygen is absorbed noticeably during the induction period, they presented, among other results, fairly detailed data on the rate of the absorption of oxygen (V) and the rate of the consumption of ionol (V_i) during this stage of the reaction.

The process of oxidation of these polymers, which are partly crystalline, involved only their amorphous regions and was limited to a very early stage, corresponding to a degree of BP conversion of 0.6% to 2%.

The values $V_i = c_{i0}/t_{\text{ind}}$ (c_{i0} is the initial concentration of ionol and t_{ind} is the induction period) measured in the temperature range between 344 and 378 K, as well as the V values remained constant for the concentrations of BP used up to the instant when the oxidation process sharply accelerated due to exhaustion of ionol.

The workers proved definitely that no chain transformation of BP proceeded under oxidative conditions and found the temperature dependence of the coefficient A

$$A = \frac{c_{i0}}{c_0 [1 - \exp(-k_d t_{\text{ind}})]} \quad (30)$$

Since the discussion was carried out within the framework of a liquid-phase model, they considered A to be a parameter characterising the influence of the inhibitor on the yield of radicals in spontaneous reaction of BP.

However, comparison of the rates of consumption of ionol and oxygen during the induction period makes it possible to give a different interpretation of this coefficient. The results of this comparison are presented in Fig. 12 in which straight lines 1, 2

Figure 12. Temperature dependences of the rates of oxygen (1, 3, 5) and ionol (2, 4, 6) consumption during the induction period of oxidation of polypropylene (1, 2), poly(but-1-ene) (3, 4) and poly(4-methylpent-1-ene) (5, 6), initiated by dibenzoyl peroxide.

and 3 plotted on the Arrhenius coordinates refer to the variation of the rate of oxygen absorption, while straight lines 2, 4 and 6 refer to the rate of consumption of ionol. These temperature dependences remain linear as c_{i0} varies from 3.4×10^{-3} to 72.6×10^{-3} mol litre $^{-1}$, which is a consequence of the fact that these rates do not depend on the concentration of ionol. The identical slopes of the straight lines characterising consumption of oxygen and ionol during oxidation of each polymer indicate that the effective activation energies of the two macroscopic processes are identical ($E_i = E_{O_2}$). In the case of PP (straight lines 1 and 2; $c_0 = 0.127$ mol litre $^{-1}$), this energy is equal to 127 kJ mol $^{-1}$, while for polybut-1-ene (straight lines 3 and 4; $c_0 = 0.376$ mol litre $^{-1}$) and for polymethylpentene (straight lines 5 and 6; $c_0 = 0.33$ mol litre $^{-1}$), it is 231.0 kJ mol $^{-1}$. The number of oxygen molecules absorbed per ionol molecule consumed remains constant over the whole temperature range studied. The V/V_i ratios are 3.65, 8.0 and 13.5 for PP, poly(but-1-ene) and poly(4-methylpent-1-ene), respectively.

It can be seen that the stoichiometric V/V_i ratio depends on the chemical structure of the polymer and can be so great that this cannot be due to oxidation of only the ionol added. Therefore, the process occurring during the induction period can be regarded as initiated chain co-oxidation of the alkylphenol and the polymer. In this case, formula (30) characterises variation of the amount of ionol consumed in the chains of its co-oxidation with the polymer per BP molecule decomposed spontaneously rather than the influence of ionol and temperature on the emergence of radicals from the 'cage' of spontaneously decomposing BP.

According to Ref. 28, the rate constant of the spontaneous decomposition of BP k_d is $8.4 \times 10^{13} \exp(-124\,650/RT)$ s $^{-1}$ in PP and poly(but-1-ene) and $7 \times 10^{13} \exp(-123\,000/RT)$ s $^{-1}$ in poly(4-methylpent-1-ene). The activation energy for the decomposition of BP ($E_d = 123$ to 125 kJ mol $^{-1}$) during the oxidation of these polymers is much less than the activation energy for their co-oxidation with ionol (172 – 231 kJ mol $^{-1}$). Therefore, the temperature dependence of A found previously,²⁸ which corresponded to an extremely low degree of BP decomposition (from 0.6% to 2% over the time t_{ind}), characterises the ratio between the rates

$$A = \frac{c_{i0}}{c_0 [1 - \exp(-k_d t_{ind})]} = \frac{c_{i0}}{c_0 k_d t_{ind}} = \frac{V_i}{V_{d0}},$$

where $V_i = c_{i0}/t_{ind}$ and $V_{d0} = k_d c_0$.

The structural-kinetic model of the co-oxidation can be constructed quite easily taking into account considerations presented in the above Sections and also the facts that the systems in question contain initially no hydroperoxide, able to decompose in v-zones of the chain-sponge matrix by the mechanism of fluctuational excitation of v-micropores, and that BP molecules decompose to give radicals in the s-zones

This s-scheme differs from that considered above by the presence of a stage of recombination of s-benzoyloxy radicals with $\text{R}_{1s}^{\bullet}$ macroradicals. This recombination was discovered in a study of the material balance of phenyl-containing compounds in the reaction between BP and PP.³⁴

According to the s-scheme suggested, the steady-state concentration of radicals that accomplish the interzone s,v-transfer of free valence is equal to

$$[\text{R}_s^{\bullet}] = \frac{\delta k_{0s} c_s}{k_{2s}}.$$

The acts of s,v-transfer themselves should occur with a low frequency, having no influence on $[\text{R}_s^{\bullet}]$ (this is ensured by the rigidity of the chain-sponge framework):

The quinoid alkoxy radicals, which appear in this way in v-zones, initiate chain oxidation of macromolecules, ionol being also involved in this process:

Here we follow the numbering of rate constants k_1 , k_3 and k_4 accepted in the previous Section. It is suggested that the steps of ionol regeneration and consumption, characterised by the rate constants for the 'latent radical' stages in the transformation of the alcohol IOH (k_{1f} , k_{-1f} , k_{2f} and k_{3f}), are also retained in this case.

Within the framework of the present heterophase scheme, the fact that the rates of generation and termination of reaction v-chains are equal is represented by the following expression

$$V_{tr} = \frac{k_{tr} k_m \delta k_{0s} c_s [\text{O}_{2s}]}{k_{2s} (k_{-m} + k_{tr} [\text{O}_{2s}])} = 2 k_3 [\text{POO}^{\bullet}] [\text{IH}]. \quad (31)$$

Assuming that these chains are sufficiently long, which permits the use of the approximate equality

$$k_5 [\text{IO}^{\bullet}] [\text{PH}] \approx k_1 [\text{POO}^{\bullet}] [\text{IH}]$$

we obtain the steady-state concentration condition for the quinoid alcohol

$$k_1 [\text{POO}^{\bullet}] [\text{IH}] = \frac{k_{1f} [\text{IOH}] [\text{PH}] (k_{2f} + k_{3f})}{k_{-1f} + k_{2f} + k_{3f}}.$$

Now we substitute the product $[\text{IOH}] [\text{PH}]$, found from the above relation, in the equation for the rate of ionol consumption

$$\begin{aligned} -\frac{dc_i}{dt} &= k_1 [\text{POO}^{\bullet}] [\text{IH}] + k_3 [\text{POO}^{\bullet}] [\text{IH}] - k_{2f} [\{\text{I}^{\bullet} + \text{HO}^{\bullet} + \text{PH}\}] = \\ &= (k_1 + k_3) [\text{POO}^{\bullet}] [\text{IH}] - \frac{k_{2f} k_{1f} [\text{IOH}] [\text{PH}]}{k_{-1f} + k_{2f} + k_{3f}} = \\ &= (k_1 + k_3) [\text{POO}^{\bullet}] [\text{IH}] - (1 - \beta) k_1 [\text{POO}^{\bullet}] [\text{IH}]. \end{aligned}$$

Then we neglect the consumption of ionol in the chain termination steps (with rate constant k_3) and find, using formula (31), the $[\text{POO}^{\bullet}] [\text{IH}]$ product for a system saturated with oxygen ($k_{-m} \ll k_{tr} [\text{O}_{2s}]$); thus

$$V_i = -\frac{dc_i}{dt} = \frac{0.5 k_{3f} k_1 k_m \delta k_{0s} c_s}{(k_{2f} + k_{3f}) k_3 k_{2s}}.$$

Taking into account the interzone equilibrium of BP [Eqn (1)], we finally obtain

$$V_i = \beta k_i c,$$

where k_i is the complex constant and $\beta = k_{3f} / (k_{2f} + k_{3f})$.

From the same heterophase scheme subject to the conditions listed above, we obtain the following expression for the rate of oxygen consumption

$$\begin{aligned} V = -\frac{d[O_2]}{dt} &= k_5 [IO^\cdot] [PH] = k_1 [POO^\cdot] [IH] = \\ &= \frac{0.5 k_1 k_m \delta k_{0s} c_s}{k_3 k_{2s}} = k_i c. \end{aligned}$$

Thus, it can be seen that the theory of heterophase transformation in a system based on a polymer containing relatively large amounts of alkylphenol and oxygen in addition to an initiator leads to the rates of the consumption of inhibitor (V_i) and oxygen (V), which do not depend on their concentrations and are directly proportional to one another:

$$\frac{V}{V_i} = \frac{1}{\beta} = \frac{k_{2f} + k_{3f}}{k_{3f}}.$$

This implies that the fact that V is substantially greater than V_i is associated with regeneration of alkylphenol. Thus, the observed increase in the V/V_i ratio from 3.65 to 13.5 means that the efficiency of regeneration (β^{-1}) increases in the sequence: polypropylene > poly(but-1-ene) > polymethylpentene and is probably a result of the increase in the number of reactive hydrogen atoms on the surfaces of thermofluotually excited v-micropores. The larger is the number of these hydrogen atoms surrounded by arising $HO^\cdot$ and $I^\cdot$ radicals, the lower is the probability of mutual disproportionation of radicals and the higher is the probability of dehydrogenation of macromolecules by the 'latent radical' mechanism.

It should be specially emphasised that regeneration of alkylphenol is exactly an 'intracage' latent radical reaction occurring over the life span of a micropore grown to the required size. The emergence of radicals from such a micropore into the bulk of v-zones of the chain sponge occurs at a negligibly low rate and has no influence on the steady-state concentrations of v-radicals. In this connection, it is also noteworthy that the temperature dependence of

$$A = \frac{c_{i0}}{c_0 [1 - \exp(-k_d t_{ind})]}$$

reported previously²⁸ is not associated with the process, considered in the same study, of thermally activated diffusional insertion of ionol into a 'cage' formed upon spontaneous decomposition of the initiator. In conformity with the concept of chain co-oxidation of ionol and polyalkene, this dependence characterises the stoichiometry of chain co-oxidation. The reaction model proposed by us reveals the structure of coefficient A , which is described by the equation

$$A = \frac{V_i}{V_{d0}} = \frac{0.5 \delta \beta k_1 k_m}{k_3 k_{2s}}.$$

The coefficient β appearing in this formula depends only slightly if at all on the temperature, which follows from the fact that the E_{O_2} and E_i values are equal for all the polymers studied.²⁸ Therefore, the main contribution to the temperature dependence of A is made by the steps of migration of the terminal macroradicals $R_s^\cdot$ from the framework walls into the bulk of s-micropores (the rate constant k_m). The size of the corresponding mediator fragment

Figure 13. Temperature dependences of coefficients A in Arrhenius coordinates for polypropylene (1), poly(but-1-ene) (2) and poly(4-methylpent-1-ene) (3).

($R_s^\cdot \rightleftharpoons R_m^\cdot$) increases in the order: polypropylene < poly(but-1-ene) < polymethylpentene; therefore it is natural to expect that the restrictions to this migration will also increase in the same sequence. The temperature dependences of coefficients A plotted on the Arrhenius coordinates indicate that the activation energy E_A increases from 50 kJ mol⁻¹ for PP to 128 kJ mol⁻¹ for poly(but-1-ene) and to even a larger value for poly(4-methylpent-1-ene) (Fig. 13).

In the absence of an adequate theoretical base, Chien and Wang²⁸ could not construct the plots presented in Fig. 13. Meanwhile, it follows from these plots that in the case of PP, the parameter A is equal to 1 at 388 K, while at 405 K, it exceeds 2 ($\ln 2 = 0.693$). It is clear that dissociation of a BP molecule cannot yield more than two free radicals; thus, an A value, larger than 2, denudes of its physical meaning the suggestion made in Ref. 28 that the coefficient A characterises the output of radicals in the steps of generation of oxidation chains.

Since the physical sense of the coefficient A has changed, the interpretation of the coefficient f , determined by the procedures used for homogeneous reactions, should also change. When the inhibitor method is used, the coefficient f is calculated from the formula

$$f = \frac{W_{i0}}{V_i} = \frac{2 \delta V_{d0}}{V_i},$$

where W_{i0} is the rate of homogeneous generation of radicals, and δ is a coefficient characterising the output of radicals in the steps of dissociation of the initiator. In this case, the parameter f characterises the number of oxidative chains terminated by one molecule of the inhibitor. At the same time, by definition, f is inversely proportional to the parameter A :

$$f \sim \frac{V_{d0}}{V_i} = \frac{1}{A}.$$

Thus, as applied to polymers, this coefficient is also a particular characteristic of the chain co-oxidation of the inhibitor with the polymer. The instant when the inhibitor in the polymer is exhausted, which is detected by a sharp increase in the rate of oxygen absorption, corresponds to the end of the co-oxidation period and to the transition to the stage of oxidation of the polymer itself.

The application of the homogeneous reaction model to the oxidation of a polymer during the induction period gives rise to some inconsistencies. Let us consider, for example, a study³⁵

dealing with oxidation of PP in the presence of ionol with dicumyl peroxide as the initiator ($P_{O_2} = 1 \text{ atm}$, $T = 388 \text{ K}$). In this study, the coefficient f was found to be

$$f = \frac{W_i}{V_i} = 1$$

(W_i is the constant rate of radical generation found by the inhibitor method, and V_i is the rate of ionol consumption). Since at a constant W_i , the inhibitor was consumed at an invariant rate, it was concluded³⁵ that all the chains were terminated at the inhibitor and that there were no side reactions leading to its consumption; and the equality $f = 1$ corresponded to one oxidation chain terminated at one ionol molecule (recall that according to the data presented in Fig. 13, $A = 1$ at $T = 388 \text{ K}$). However, the workers had to note that the f value obtained differed from the value $f = 2$, typical of the liquid phase, and they also presented a number of facts proving that bimolecular destruction of the ionol-based phenoxyl radicals ($I^\bullet + I^\bullet \rightarrow \text{products}$) occurred in the PP matrix. However, the data discussed in Section VI indicate that this mechanism is by no means consistent with the actual kinetics of the destruction of phenoxyl radicals.

VIII. Chain co-oxidation of alkylphenol with polyalkene in the absence of an initiator

We shall analyse the co-oxidation occurring in the absence of an initiator using the v-scheme considered in the previous Section and taking into account the fact that the rate of radical generation in v-zones is negligibly small. Under these conditions, initiation can occur in s-zones, which serve as a heterophase source of radicals, *via* either direct oxidation of polymer s-chains or oxidation of molecules of an inhibitor if they are sufficiently reactive.

To consider the former possibility, let us examine the s-scheme, which previously has made it possible to give kinetic description for the initial stage of autooxidation of PP in the absence of an initiator and an inhibitor.^{4,25} According to this scheme, radicals are generated in supermicropores of chain-sponge s-zones upon the interaction of the CH bonds in the polymer chains with the oxygen adsorbed on the walls of s-micropores.

Subsequent transformations of s-macroradicals occur in the same way as was described in Sections II and V

The expression for the concentration of mediator radicals, which follows from this scheme, has the form

$$[R_s^\bullet] = \frac{\delta k_{0s,p}}{2 k_{2s}} [PH_s] [O_{2s}]$$

whereas the s,v-translation of valence, involving these radicals, is described by the scheme

The scheme for the reaction v-chains of the co-oxidation of alkylphenol and polymer

is retained without changes. So is the scheme of the latent radical transformations of the quinoid alcohol IOH, which ensure partial regeneration of the initial phenol.

This combination of s- and v-schemes indicates that the macroradicals occurring within individual zones are non-equivalent with respect to oxidation and interaction with the inhibitor: in supermicropores, the rates of these processes are low, whereas in v-zones, on the contrary, they are high. This selectivity, which is associated with the predominant accumulation of low-molecular-weight compounds (including oxygen and the inhibitor) in the grains of sponge micelles filled with narrow micropores, is obviously a general phenomenon.^{1-6,11-13,25} An example of this non-equivalent behaviour has been considered in the description of the transformations of ionol in the s-chains of initiated destruction of macromolecules and in the v-chains of arylation of CTA and PC (Section II). A number of similar facts have been reported. For example, it is quite characteristic that the number of polymer chains cleaved per unit time in the oxidation of molten polystyrene at 473 K ($P_{O_2} = 150 \text{ mm Hg}$) in the presence of bisphenol 2246 as an inhibitor remains virtually unchanged over a period of 26 h.^{36,37} This phenomenon is observed during the induction period if the concentration of the inhibitor is high; in the case of a low inhibitor concentration ($c_i \rightarrow 0$), it is observed after the induction period has been completed. In the oxidation of rubber in the presence of ionol³⁸ and in the oxidation of PP in the presence of bisphenol 2246 (437 K, $P_{O_2} = 300 \text{ mm Hg}$),³⁰ the concentration of inhibitor also has no influence on the rate of the polymer destruction during the induction period.

Thus, the heterophase scheme suggested for the non-initiated co-oxidation of alkylphenol and the polymer conforms to the general features observed for the induction period of the process and takes into account the specific features of co-oxidation in a heterogeneous chain-sponge micellar matrix considered previously.

By applying the condition of steady-state concentration of radicals to each unit of the overall scheme of the process considered, it is easy to obtain an expression for the rate of the s,v-transfer of free valence

$$V_{tr} = k_{tr} [R_m^\bullet] [O_{2s}] = \frac{k_{tr} k_m \delta k_{0s,p} [PH_s] [O_{2s}]^2}{k_{-m} + k_{tr} [O_{2s}]}$$

If the polymer has been saturated with oxygen ($k_{-m} \ll k_{tr} [O_{2s}]$), this expression assumes the following form

$$V_{tr} = \frac{\delta k_{0s,p} k_m [PH_s] [O_{2s}]}{2 k_{2s}} \quad (32)$$

The V_{tr} value, which is simultaneously the rate of generation of the reaction v-chains, is equal to the rate of their termination.

$$V_{tr} = 2 k_3 [POO^\bullet] [IH]$$

Under the conditions considered, the rate of consumption of alkylphenol does not depend on its concentration but depends on the oxygen pressure:

$$V_i = -\frac{dc_i}{dt} = (k_1 + k_3) [POO^\bullet] [IH] - (1 - \beta) k_1 [POO^\bullet] [IH] \approx$$

$$\begin{aligned} \approx \beta k_1 [\text{POO}'] [\text{IH}] &= \frac{\beta k_1 V_{\text{tr}}}{k_3} = \\ &= \frac{\beta k_1 \delta k_{0s,p} k_m}{4 k_3 k_{2s}} [\text{PH}_s] [\text{O}_{2s}] = \beta k_{i,p} P_{\text{O}_2} \end{aligned} \quad (33)$$

Here $[\text{O}_{2s}] = K_{\text{O}_2} [\text{O}_{2v}] = K_{\text{O}_2} \gamma P_{\text{O}_2}$, where K_{O_2} is the equilibrium constant for the oxygen exchange between the zones, γ is the Henry constant, $\beta = k_{3f}/(k_{2f} + k_{3f})$ is the efficiency of the consumption of quinoid alcohol in the steps of regeneration of phenol (see Sections VI and VII), and $k_{i,p}$ is the complex constant.

According to this scheme, the rate of oxygen absorption

$$V = -\frac{d[\text{O}_2]}{dt} \approx k_5 [\text{IO}'] [\text{PH}] = k_1 [\text{POO}'] [\text{IH}] = k_{i,p} P_{\text{O}_2}$$

exceeds the rate of the inhibitor consumption and also does not depend on its concentration c_i .

It is these regularities that have been established back in early studies dealing with the mechanism of antioxidative stabilisation with phenols, which have been regarded as weak inhibitors. Processes involving inhibitors of this type are characterised by an approximately zero order with respect to the inhibitor, the first order with respect to oxygen, and the linear dependence of the duration of the induction period on the inhibitor concentration. The following antioxidants were studied: 2,6-bis(1,1-dimethylhexyl)-4-methylphenol (at 473 K and at $P_{\text{O}_2} = 300$ mm Hg, the value of t_{ind} increased linearly from 9.5 min at $c_i = 0$ to 373 min at $c_i = 0.20$ mol kg⁻¹),^{39,40} 2,4,6-tri-*tert*-butylphenol (the effective activation energy for the consumption of phenol in the 453–473 K range: $E_i = 151$ kJ mol⁻¹),⁴¹ 2,6-di-*tert*-butyl-4-phenylphenol ($E_i = 126$ kJ mol⁻¹),⁴¹ and a bis-phenol with spatially separated OH groups — 4,4'-methylenebis(2,6-di-*tert*-butylphenol) (the t_{ind} value increased linearly from 9.5 min at $c_i = 0$ to 250 min at $c_i = 0.025$ mol kg⁻¹).⁴¹

One more feature peculiar to the phenols listed above is that their consumption is not accompanied by the formation of water; the appearance of water becomes noticeable only at the very end of the induction period. This important fact indicates that the rates of decomposition of peroxy radicals (with evolution of OH[•]) and of the polymeric hydroperoxide formed in small amounts are negligibly small. The fact that the rates of consumption of oxygen and inhibitor remain constant over the whole induction period also implies that hydroperoxide scarcely makes any contribution to the radical generation at the stage of co-oxidation of the polymer and phenol.⁴²

The heterophase scheme accepted by us does not include reactions of decomposition of POO[•] radicals or hydroperoxide groups; this reflects the fact that the concentration of peroxy radicals sharply decreases when the polymer contains even a minor amount of an inhibitor.

Additional evidence for the chain mechanism of the co-oxidation of polyalkenes and alkylphenols is provided by the substantial deceleration of this process in the presence of dialkyl sulfides.

1. The mechanism of co-oxidation inhibited by dialkyl sulfide

Analysis of the characteristic features of transformations of antioxidants in the polymer-chain zones of sponge micelles causes one to consider the problem of the mechanism of joint action of phenolic antioxidants and dialkyl sulfides. It is known that the latter do not possess any substantial inhibitory activity but extend markedly the induction period in the co-oxidation of a polymer with a 'weak' phenol and change the kinetics of the phenol consumption.^{41,43}

The reasons for the non-additive influence of phenol and dialkyl sulfide have been considered in the literature in terms of the concept of non-radical decomposition of a hydroperoxide by a dialkyl sulfide. It is believed that dialkyl sulfide destroys hydroperoxide without formation of free radicals and thus decreases

dramatically the rate of degenerate branching of oxidation chains, the probability of which during the induction period in the presence of a 'weak' phenol is thought to be relatively high. As shown above, hydroperoxide can hardly act as a branching agent at the stage of co-oxidation, if for no other reason than its fairly low concentration. However, even in the samples in which hydroperoxide has been specially accumulated prior to the reaction, the branching factor of oxidation chains in the presence of alkylphenol is equal to zero (Sections V and VI), and the transformation reduces only to oxidative chain decomposition of hydroperoxide.

Thus, the question of the mechanism of direct interaction of dialkyl sulfide and hydroperoxide, which has not yet been ultimately resolved due to its complexity,¹⁴ becomes a separate problem. It is significant for us that dialkyl sulfide, which is not an inhibitor for the polymer oxidation itself, inhibits its co-oxidation of alkylphenol. In other words, dialkyl sulfide acts as if it extended the period during which alkylphenol is efficient. This is indicated, for example, by the character of kinetic curves for the consumption of 2,6-bis(1,1-dimethylhexyl)-4-methylphenol and bisphenol 2246 obtained for oxidation at 473 K ($P_{\text{O}_2} = 300$ mm Hg).^{14,43} It can be seen from Fig. 14 that the rates of consumption of mono-phenol (the initial concentration was 0.16 mol kg⁻¹) and bisphenol (the initial concentration was 0.08 mol kg⁻¹) in the presence of 0.08 mol kg⁻¹ of a sulfide are lower than those in the absence of the sulfide. This is observed even at the very beginning of the reaction when a change in the yield of radicals in the steps of hydroperoxide decomposition under the influence of both phenol and sulfide is out of the question. As has already been noted, influence of this sort is not manifested even at high concentrations of hydroperoxide (Sections V and VI).

In addition, we mention important results,³⁰ according to which in the oxidation of molten PP (473 K, $P_{\text{O}_2} = 300$ mm Hg), the rate of evolution of propene remains constant over 100 min in the induction period; this rate is the same in the presence of 0.025

Figure 14. Curves for the consumption of 2,6-bis(1,1-dimethylhexyl)-4-methylphenol (a) and 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) (b) during the induction period of the oxidation of polypropylene (473 K, $P_2 = 300$ mm Hg) in the absence (1, 3) and in the presence (2, 4) of 0.08 mol kg⁻¹ of didecyl sulfide.

or 0.05 mol kg⁻¹ of bisphenol 2246; it also does not change when 0.08 mol kg⁻¹ of didecyl sulfide or dilauryl thiodipropionate are introduced in the reaction mixture. In other words, under these conditions, the concentration of depolymerising terminal macro-radicals remains constant over a period of 100 min, and the process of degenerate branching involving hydroperoxide and phenol can be neglected.

At the same time, gas-chromatographic analysis has shown that the introduction of dialkyl sulfides in the PP being oxidised leads to a substantial increase in the yield of ethylene,³⁰ which indicates that sulfides interact with polymeric peroxy radicals. When dialkyl sulfides are involved in co-oxidation with PP, they do not extend markedly the induction period. However, in the presence of a 'weak' phenol, a synergistic effect is manifested, and the induction period can become much longer. The mechanism of this phenomenon can be understood by taking into account the known³⁰ fact that dialkyl sulfides react with peroxy radicals; this leads to a decrease in the concentration of peroxy radicals, which induce the chain consumption of alkylphenol.

For this purpose, dialkyl sulfide should ensure the conversion of peroxy into a polymeric alkoxy, which then reacts predominantly with the inhibitor:

With allowance for the assumptions made, the scheme for the reaction v-chains of co-oxidation of the polymer, phenol, and sulfide assumes the following form:

In the absence of phenol, the role of dialkyl sulfide reduces to its consumption with the rate constant k_6 in the transformation of peroxy radicals into alkoxy radicals, which then produce oxidisable alkyl radicals $\text{P}^\bullet$ in a stage with the constant k_7 . This results in the reduction of $\text{POO}^\bullet$. The overall sequence of reactions does not lead to a change in the concentration of peroxy radicals; therefore, the consumption of dialkyl sulfide has no influence on the rate of oxidation of the polymer. The transformation of sulfide yielding ethylene, which either follows a replacement mechanism³⁰

or occurs as a reaction of the alkoxy radical formed with sulfoxide

is not shown in the scheme. These processes seem to be energetically and sterically less favourable than the stage characterised by constant k_6 , which involves rupture of the weak peroxide bond and formation of a strong S—O bond. Therefore, the formation of ethylene can be regarded as a side process. Besides, it does not influence the kinetic picture of the co-oxidation with phenol, because $\text{R}_1^\bullet$ radicals are oxidised to peroxy radicals, which qualitatively do not differ from polymeric peroxy radicals.

The co-oxidation v-scheme under consideration includes a stage in which phenol interacts with $\text{PO}^\bullet$ radicals and terminates the reaction chains involving dialkyl sulfide. Thus, the sulfide assumes an inhibitory function, which was lacking initially.

However, when the concentration of phenol is sufficiently high, the oxidative chains predominate again due to an increase in the rates of reactions characterised by constants k_1 and k_5 . This ensures a co-oxidation route independent of the presence of dialkyl sulfide.

By applying the condition of steady-state radical concentration to the v-scheme described above and resorting to the above assumption that regeneration of phenol occurs by a latent-radical mechanism, we can obtain quite easily an expression for the rate of consumption of the inhibitor

$$\begin{aligned} V_i &= -\frac{dc_i}{dt} \approx \beta k_1 [\text{POO}^\bullet] c_i = \\ &= \frac{0.5 \beta k_1 c_i V_{tr}}{k_3 c_i + k_6 k_8 c_i c_s / (k_7 [\text{PH}] + k_8 c_i)}, \end{aligned}$$

where c_s is the concentration of dialkyl sulfide. This equation can be brought to identical forms at opposite concentration ratios

$$\frac{c_i}{c_s} \ll 1 \text{ and } \frac{c_i}{c_s} \gg 1.$$

In fact, when the concentration c_i is low, so that the inequality $k_7 [\text{PH}] \gg k_8 c_i$ holds, the second term in the denominator of the main fraction in the expression for V_i can be neglected. Conversely, if the concentration c_i is high, then $k_7 [\text{PH}] < k_8 c_i$; but the inequality $k_3 c_i > k_6 c_s$ is also valid. The final results are identical in both cases

$$V_i = \frac{0.5 \beta k_1 V_{tr}}{k_3},$$

i.e. dialkyl sulfide has no influence on the rate of the process.

However, when the ratio of concentrations is intermediate

$$\frac{c_i}{c_s} \approx 1$$

and the inequality $k_7 [\text{PH}] < k_8 c_i$ holds in combination with $k_3 c_i < k_6 c_s$, then the expression for the rate of consumption of the inhibitor assumes the following form

$$V_i = \frac{0.5 \beta k_1 c_i V_{tr}}{k_6 c_s}.$$

Consequently, within a certain time interval, the process is first order with respect to phenol, which is in agreement with Eqn (32) describing the rate of translation of radicals V_{tr} to the v-zones of sponge micelles. The rate of consumption of the 'weak' phenol decreases, since the inhibitory activity of dialkyl sulfide induced by phenol is fully manifested under these conditions. Comparison of dependences 1 and 2 in Fig. 14 indicates that the kinetic law for the consumption of the inhibitor has actually changed in agreement with the theoretical prediction, which follows from the heterophase model of the induction period of the process.

The influence of dialkyl sulfides on the duration of the induction period of the oxidation of polyalkenes mixed with bisphenol 2246, which is considered to be a strong inhibitor,¹⁴ is less pronounced. The deceleration of consumption of bisphenol is also manifested to a lesser degree than that for a weak phenol (Fig. 14, curves 3 and 4). Molecules of bisphenol 2246 differ from molecules of 'weak' phenols, on the one hand, by less efficient shielding of the OH groups by the neighbouring alkyl substituents (and, hence, their higher accessibility to attacking radicals and to oxygen molecules) and, on the other hand, by specific mutual arrangement of the benzene nuclei (see Section III). For these reasons, direct oxidation of bisphenol 2246 occurring in s-zones of the polymer-chain sponge to yield radicals is facilitated (Scheme 1).

$$\text{HIIH}_s + \text{O}_{2s} \xrightarrow{k_{0s,ii}} \text{[Intermediate 1]} \rightarrow \text{[Intermediate 2]} \rightarrow \text{[Intermediate 3]}$$

$$\text{[Intermediate 3]} \xrightarrow{\text{HIIH}_s} \text{[Intermediate 4]}$$

$$\text{[Intermediate 4]} \rightarrow \text{HIIOOH}_s \text{ (intramolecular disproportionation)}$$

$$\text{HIIOOH}_s \rightarrow \text{[Intermediate 5]} + \text{H}_2\text{O}$$

$$\cdot\text{HIO}_s + \text{PH}_s \rightarrow \cdot\text{HIOH} + \text{P}'_s$$

$$\text{P}_s \xrightarrow{k_{1s}} \text{R}'_s$$

$$\text{R}'_s \xrightarrow{k_{2s}} \text{R}'_{1s}$$

$$\text{R}'_s + \text{R}'_{1s} \xrightarrow{k_{3s}} \text{products}$$

$$\text{R}'_{1s} + \cdot\text{HIOH}_s \rightarrow \text{R}^= + \text{HIIOH}_s$$

In conformity with the s_{ii}-scheme, the steady-state concentration of mediator radicals, responsible for the interzone s,v-transfer of radicals, is

$$[\text{R}_s\cdot] = \frac{\lambda c_{\text{ii}} P_{\text{O}_2}}{2k_{2s}},$$

The transfer of free valence from s-zones into v-zones, as in the case of phenols considered previously, occurs *via* intermediate formation of active quinoid alkoxy radicals

It is known^{14, 40, 44} that in the presence of bisphenol 2246, the induction period (more precisely, the period of co-oxidation) is much longer, and the influence of dialkyl sulfides is substantially less pronounced than in the case of 'weak' monophenols. Both of these effects may be due to the specific structure of the bisphenol molecule, which ensures large probability of isomerisation of active alkoxyl into inactive phenoxyl *via* an intermediate radical of the benzyl type (Scheme 2).

$$\begin{aligned} \text{HII}\dot{\text{O}}_{\text{m}} &\xrightarrow{k'_{\text{tr}}} \text{HII}\dot{\text{O}} \cdot, \\ \text{HII}\dot{\text{O}}_{\text{m}} &\xrightarrow{k_{\text{is}}} \text{HOII} \cdot \end{aligned}$$
$$V_{\text{tr}} = k'_{\text{tr}} [\text{HII} \text{O}_m] = \frac{\delta_{\text{ii}}, \lambda c_{\text{ii}} P_{\text{O}_2}}{2k_{\gamma_s}} = \frac{\delta_{\text{ii}}}{2k_{\gamma_s}}, \quad (34)$$
$$\delta_{ii} = \frac{k_m k'_{tr}}{k'_{tr} + k_{is}} < k_m.$$

A similar isomerisation of phenoxy radicals makes a contribution to the termination of co-oxidation chains in v-zones of the polymer:

It is assumed that here, as in the case of monophenols, partial regeneration of the initial bisphenol from the quinoid alcohol HIIOH occurs by the latent radical mechanism.

Since an additional route for the termination of the reaction v-chains exists, this process occurs at a lower concentration of the peroxy radicals POO[•]. This concentration can be found from the condition of equality of the rates of v-chain generation and termination:

$$\begin{aligned}
V_{\text{tr}} &= 2k_3[\text{POO}^\bullet]c_{\text{ii}} + 2k_9[\text{HIIO}^\bullet] = \\
&= 2k_3[\text{POO}^\bullet]c_{\text{ii}} + \frac{2k_1k_9[\text{POO}^\bullet]c_{\text{ii}}}{k_5[\text{PH}]}.
\end{aligned}$$

For this reason, and also due to the fact that radicals lose their reactivity during s,v-translation [in Eqn (34), $\delta_{\text{ii}} < k_{\text{m}}$], the rate of consumption of bisphenol becomes much lower than that of monophenols [Eqn (33)].

$$V_{\text{ii}} = -\frac{dc_{\text{ii}}}{dt} \approx \beta k_1[\text{POO}^\bullet]c_{\text{ii}} = \frac{\beta k_1 \delta_{\text{ii}} \lambda c_{\text{ii}} P_{\text{O}_2}}{(2k_3 + 2k_1k_9/k_5[\text{PH}])2k_{2s}}.$$

Simultaneously, the induction period of the polymer oxidation becomes longer, and the opportunity for the synergistic action of a dialkyl sulfide decreases.

Thus, within the framework of the heterophase model, the induction period is distinguished as a macroscopic stage involving chain co-oxidation of the inhibitor and the polymer. At this stage, alkylphenol actively participates in the chain process and is mostly consumed in the steps of propagation of co-oxidation chains rather than in the steps of termination of oxidation chains. This period is finished when the concentration of the inhibitor decreases and the concentration of peroxy radicals increases to a degree at which the rate of oxygen absorption is determined only by the steps of oxidation of the polymer itself^{4–6, 25}

and by bimolecular chain termination steps

The fact that both in the presence of an inhibitor and after its complete exhaustion the oxidation process does not switch to a regime with non-degenerate (non-stationary) branchings of reaction chains is of primary importance. The transition from co-oxidation to the oxidation of the polymer itself occurs when the condition of steady-state concentration of peroxy radicals is fulfilled. This requirement is also retained when the regime of co-oxidation changes from the zero order to an apparent first order with respect to phenol following the introduction of dialkyl sulfide into the system.

It should be noted that the extension of the induction period, which accompanies the change in the regime, is often manifested quite clearly in the $t_{\text{ind}}(c_{\text{i}0})$ plots, the concentration of phenol at the inflection point in the curve being interpreted as the critical concentration corresponding to the transition from a non-stationary branched chain process to stationary oxidation.¹⁴ The fact that the stage with non-stationary branching does exist was confirmed¹⁴ by the observation that at a relatively high temperature (~ 473 K), the lifetime of hydroperoxide is limited to several seconds. However, the chain heterophase mechanism of anaerobic decomposition of hydroperoxide was not taken into account.

In the absence of oxygen, decomposition of hydroperoxide follows a chain mechanism, the contribution of spontaneous decomposition to the overall hydroperoxide consumption, as has been shown in Section IV, being negligibly small.^{5, 6} Despite the fact that according to Eqn (18), the life span of hydroperoxide within s-micropores at $T \approx 473$ K is tens of seconds, the lifetime of the main bulk of hydroperoxide in the dissociated state, which is localised in the narrow micropores of v-zones of the chain sponge is much higher. For example, it is remarkable that in the absence of oxygen at 453 K, polystyrene hydroperoxide decomposes by half over a period of 12–15 min, while under conditions of oxidation of molten polystyrene[†] at 473 or 453 K it is accumulated, together with other products, for 30 or 100 min, respectively⁴⁵ and does not decompose noticeably until it begins to react with accumulated products of the polymer oxidation. After that, the accumulation of hydroperoxide ceases, and its concentration decreases.

The data considered in the present and previous Sections indicate that the explanation of the ‘critical’ concentration of phenols proposed previously¹⁴ was inadequate. In terms of our structural-kinetic reaction model, the inflection in the $t_{\text{ind}}(c_{\text{i}0})$ curve caused by the presence of dialkyl sulfide is due to the decrease in the rate of consumption of phenol in the co-oxidation following its transition from the zero order to the first order with respect to the inhibitor, when in the absence of non-stationary branching of the reaction chains, a quasi-steady-state concentration of peroxy radicals is retained.

When the process obeys a zero-order kinetics, the rate of consumption of the inhibitor is constant

$$-\frac{dc_{\text{i}}}{dt} = V_{\text{i}} = \frac{c_{\text{i}0}}{t_{\text{ind}, \text{i}}} = \text{const}.$$

Thus, the time required for its complete consumption (*i.e.* the period co-oxidation) is equal to

$$t_{\text{ind}, \text{i}} = \frac{c_{\text{i}0}}{V_{\text{i}}}.$$

If we add the time t_0 for the propagation of reaction after the inhibitor has been exhausted to the above value, we obtain the dependence of the induction period on the initial concentration of phenol

$$t_{\text{ind}} = t_0 + t_{\text{ind}, \text{i}} = t_0 + \frac{c_{\text{i}0}}{V_{\text{i}}}.$$

The linear dependence $t_{\text{ind}}(c_{\text{i}0})$ holds over a wide range of monophenol concentrations.^{39–41} The length of the linear sections decreases appreciably in the presence of dialkyl sulfide. In this case, t_{ind} rapidly increases starting from a certain ‘critical’ $c_{\text{i}0, \text{cr}}$ value. A similar behaviour has also been observed in the presence of bisphenol 2246. In these systems, co-oxidation at $c_{\text{i}0} > c_{\text{i}0, \text{cr}}$ (and $c_{\text{ii}0} > c_{\text{ii}0, \text{cr}}$) obeys first-order kinetics and is characterised by an exponential equation

[†] In the presence of oxygen, the mechanism of hydroperoxide decomposition basically changes.

$$c_i = c_{i0} \exp(-k_i t)$$

or

$$\ln \frac{c_{i0}}{c_i} = k_i t.$$

This equation is valid until the $c_{i0,cr}$ value is attained. After that, the law for the termination of reaction chains changes, and their bimolecular termination in the subsequent steps begins:

In this case, the total induction period is characterised by the sum

$$t_{ind} = t_0 + \frac{1}{k_i} \ln \frac{c_{i0}}{c_{i,cr}}.$$

This relation holds fairly frequently.¹⁴

The above structural-kinetic model for the co-oxidation of the phenol and a polymer makes it possible to elucidate more precisely the physical meaning of the antagonistic influence of monophenol and bisphenol 2246 simultaneously introduced in a polymer.^{14, 39, 40} Although in this case, the overall content of inhibitors is larger, the induction period in the presence of these mixtures is shorter than that observed with bisphenol 2246 alone. The authors cited explained this phenomenon by a specific influence of monophenol and bisphenol on the emergence of radicals from the 'cage' of the hydroperoxide, which decomposes spontaneously. They believed that the monophenol destroys one of the radicals in a primary radical pair but prevents the destruction of the second radical; thus, the overall yield of radicals should increase. However, in the presence of bis-phenol 2246, which contains two functional groups, the yield of radicals increases to a lesser extent than in the presence of a monophenol or does not increase at all.

However, in contrast to these views, the data presented in Sections V and VI indicate that a typical monophenol, ionol, does not lead to any substantial increase in the yield of radicals from hydroperoxide. The kinetic model considered above makes it possible to give a simple explanation to the antagonistic effect.

Monophenol increases the rate of generation of co-oxidation v-chains by accelerating the injection of free valence from s-zones to v-zones of the polymeric-chain sponge. In this case, the term 'reaction cage' refers to a system of supermicropores in the structural s-zones rather than to a homogeneous environment consisting of macromolecular segments and resembling a structureless liquid.

Monophenol reacts with the mediator peroxy radical and is thus converted into a quinoid alkoxy

which cannot isomerise into the inactive phenoxyl. In this case, $\delta_i = k_m$, whereas in the reaction involving bisphenol 2246, $\delta_{ii} < k_m$ [Eqn (34)].

The competition between monophenol and bis-phenol for the s,v-transfer of radicals results in an increase in the rate of generation of the co-oxidation chains in v-zones of the polymeric matrix and thus shortens the induction period.

In conclusion, note that in the presence of sterically hindered monophenols considered in previous studies,^{41, 43} no transition to the first-order kinetics was observed over the whole range of monophenol concentrations studied. However, it cannot be ruled out that this transition would be possible in the presence of phenols in which the steric hindrance from the alkyl substituents is weaker or at a sufficiently high concentration c_i . For example, this situation can arise if the reversible dissociation of a complex of phenol with oxygen

competes with the following reaction

Diminution of steric hindrance can also be favourable for the appearance of an additional pathway to the termination of co-oxidation chains.

The reasons considered above might also account for the known fact that 4,4'-methylenebis(2-methyl-6-*tert*-butylphenol), which contains spatially separated OH groups in the molecule and is considered¹⁴ to be a weak antioxidant, is actually as effective as bisphenol 2246.⁴⁶ The termination steps mentioned above can also be among the reasons for the synergistic effect exhibited by antioxidant mixtures.

IX. Conclusion

A certain relationship between the microheterogeneous structure of the non-crystalline polymeric matrix and chemical transformations in the polymers has been mentioned in the literature long ago; this has been reflected in the polychromatic⁴⁷ (or polychromic)⁴⁸ kinetic model. However, individual studies in which this relationship was only stated, have not yet been united in a separate branch of the chemical physics of polymers. Description of kinetic polychromatism has reduced only to one or another variant of the formal mathematical scheme based on general physical views, without disclosing the in-depth causes for its origin.

It is clear that construction of adequate chemico-physical models for polymeric transformations requires inevitably that the supermolecular organisation of the polymeric reaction medium be known in detail. The microheterogeneous chain-sponge structure of polymer chains increases substantially the number of factors, which are able to influence in a particular way a chemical process involving them (compared to the number of factors influencing processes in a homogeneous liquid) and hampers the theoretical studies. Construction of structural kinetic reaction models¹⁰ is helpful in overcoming the arising difficulties (which is especially significant in the initial stage of the development of the theory).

The models for chain processes presented in this review have been constructed with allowance for the fine structure of polymer chain-sponge micelles, which contain a sponge framework possessing a certain degree of mobility. In these models, the notion of mobility is associated with the property of micropores to change their sizes under the influence of thermofluctuational motion of cooperated units of flexible polymer chains within the microporous sponge structure rather than with the abstract concept of 'molecular segmental mobility'.

The method of structural-kinetic modelling made it possible to discover important regimes of chain reactions, such as heterogeneous-heterophase and heterogeneous-homophase regimes, and to refine the concept of 'latent radical' (intracage) processes occurring inside a thermofluctuationally excited micropore, which has expanded to the size of a supermicropore.

The construction and analysis of various reaction models proved the validity of the general concept of the chemistry of the microheterogeneous polymeric-chain sponge. This concept provides extensive possibilities for further specification of the mechanism of elementary chemical steps occurring in a fluctuating sponge material. In addition, it requires that researchers change their attitude to some generally accepted views concerning the homogeneous character of non-crystalline polymers (in terms of the homogeneous model, a kinetically unstable unit, which is formed and destroyed by fluctuations, has a 'short-range' order in the arrangement of segments, and resembles the areas with a short-range order in liquids, is considered as the only structural element).⁴⁹

In particular, the interpretation of the self-acceleration stage in the oxidation of polyalkenes within the framework of the non-stationary branched chain mechanism should be rejected.

It is also believed¹⁴ that the absence of substantial deviations from the first-order kinetics indicates that the inhibitor is mostly consumed in its direct interaction with oxygen and in the steps of termination of the oxidation chains thus generated. However, in reality, as shown in our review, the greater part of phenol is consumed *via* its chain co-oxidation with the polymer, no matter what particular order — zero or first — with respect to the inhibitor is obeyed by the process.

The criterion used in the inhibitor method for determination of the rate of generation of oxidation chains in homogeneous liquids¹⁵ also loses its fundamental significance when applied to polymers. The zero order for consumption of an inhibitor in a microheterogeneous chain-sponge medium does not imply any longer, as it does in a homogeneous liquid, that the inhibitor is not involved in any step other than termination of reaction chains. The inhibitor molecules, which occur in a polymeric matrix and scavenge all the reaction chains, can liberate fairly reactive radicals, together with inactive ones. Thus, the inhibitor becomes an active participant in the co-oxidation with the polymer.

The structured character of the chain-sponge polymeric matrix also causes the need to determine separately the non-equivalent rates of radical generation, firstly, in quasi-steady-state zones consisting of relatively immobile supermicropores, secondly, in dynamically more active zones in which the oxidation chains of macromolecules propagate, and, thirdly, at the stage of the interzone transfer of radicals. Simultaneously, this gives rise to the problem of development of experimental methods for determining the rate constants for the elementary reactions, which characterise heterogeneous steps in the polymeric-chain sponge.

This review is a logical continuation of the studies performed by Academician N M Emmanuel and his school dealing with oxidation processes in the condensed phase.^{50–54}

Abstract. The data on unusual transformations of 2-isoxazolines observed in both their preparation by traditional methods and various reactions, mostly with nucleophilic reagents, are considered systematically. Possible mechanisms of these reactions are discussed. Special attention is given to the transformations of 2-isoxazolines under the action of complex organometallic compounds. The bibliography includes 78 references.

I. Introduction

Isoxazoles and their dihydro derivatives, 2-isoxazolines (hereinafter, isoxazolines), are synthetic precursors of various acyclic compounds. They are widely used in organic synthesis for obtaining β -hydroxy ketones and β -diketones, γ -amino alcohols, enoximes, enones, and β -amino enones. Owing to the versatility of the nitrile oxide method of preparing isoxazoles and isoxazolines and the latent bifunctionality of the isoxazole heterocycle, the so-called 'isoxazoline pathway'¹ developed in the last two decades has become a recognized procedure for the total synthesis of natural compounds, including antibiotics, nucleosides, alkaloids, vitamins, steroids, and prostanoids.

The use of isoxazoles in a total chemical synthesis of natural compounds and the related aspects of the preparation and transformations of isoxazoles and isoxazolines have been surveyed in a number of reviews.^{1–5}

The main attention in these reviews has been concentrated on the reductive cleavage of the heterocycle at the N–O bond. This reaction is a traditional method of realisation of the latent bifunctionality of the isoxazole ring. At the same time, after the discovery of selective reductive cleavage of the heterocycle, the reactions of isoxazolines with nucleophilic reagents, which had been earlier the subject of intense studies of the properties and transformations of the isoxazole ring, failed to attract further attention of investigators, since they did not find wide synthetic application, except for the cleavage of 3-non-substituted isoxazolines into hydroxy nitriles⁶ and of 3-substituted isoxazolines into enoximes.⁷

However, recently considerable attention has again been expressed in the transformations of isoxazolines under the action of nucleophilic reagents. The reason for this is, first and foremost, the application in modern organic synthesis (including the isoxazoline chemistry) of new reagents, in particular complex organometallic systems. The use of organometallic reagents, in which the reductive capacity is combined with their properties as bases, has led to the discovery of transformations, which are unusual for isoxazoline compounds. Information about the state-of-the-art of these unusual reactions of isoxazolines is systematised and considered in the present review.

II. Interaction of 2-isoxazolines with bases

The molecule of 2-isoxazoline (**1**) having two heteroatoms with lone electron pairs and an unsaturated C=N bond is characterised by an uneven distribution of the electron density over the ring and by the presence of potentially mobile ('acidic') hydrogen atoms at C(3), C(4), and C(5). Under the action of a base, deprotonation can occur, which is accompanied by the generation of one of the possible cyclic carbanions (**2a–e**) (Scheme 1).

3- or 4-Non-substituted isoxazoline derivatives undergo cleavage under the action of bases. It is the protons at these carbon atoms that are the most 'acidic' as regards the distribution of electron density in the isoxazoline molecule. Thus, the interaction of C(3)-non-substituted isoxazolines with bases gives the isoxazolinium anion **2a**. Upon subsequent cleavage of the N–O bond, the isoxazoline derivative is transformed into a compound with a hydroxynitrile group.^{6, 8–10}

The 3-substituted 2-isoxazolines **3** are cleaved only in the presence of strong bases. This reaction has been extensively and systematically studied by Jager et al.^{2, 7, 11–13} In the first step, a strong base abstracts the proton from the C(4) atom (4-*endo*-deprotonation) with the formation of an isoxazolinium anion of the type **2b** (Scheme 1), which is stable at $-60\text{ }^{\circ}\text{C}$ to $-80\text{ }^{\circ}\text{C}$ and cleaves at room temperature to give a non-cyclic enoximate anion and then the enoxime **4**.

Scheme 1

Various preparative methods have been developed for the cleavage of isoxazolines into unsaturated oximes with lithium diisopropylamide (LDA)^{7, 14} and dimethylsodium.¹⁵ These methods have found wide application in the synthesis of polyfunctional organic (including natural) compounds.^{3, 16–18}

If the isoxazoline contains alkyl substituents, 4-*endo*-deprotonation competes with *exo*-deprotonation; however, it has been established that the 4-*endo* proton possesses a higher acidity and is the first to be deprotonated under standard conditions for this reaction (–78 °C, LDA).¹⁸ With respect to the ease of abstraction by bases, the hydrogen atoms of *C*-alkyl-2-isoxazolines can be arranged in the following order: 3-*endo* > 4-*endo* > 3-*exo* > 5-*endo*.

Jager¹² has proposed a generalised scheme, which includes four possible pathways of transformations of the 3-substituted isoxazoline heterocycle under the action of bases (see Scheme 1). The mobility of the H(4) protons of the isoxazoline ring can be employed for the introduction of substituents into the isoxazoline molecule using the so-called ‘Jager alkylation’ method.^{7, 11–13, 17–19} Alkylation of the anions **2b** and **2e** by electrophiles is used for the modification of the heterocycle and subsequent generation of a functionalised acyclic compound from the isoxazoline derivative.^{2, 3}

Analysis of a great number of publications has revealed that an unambiguous result can hardly be achieved in reactions with bases due to a number of factors intervening. The main factors are the structure of the substrate and the nature of the base interacting

with it. The direction and ease of the isoxazoline ring cleavage depend on the particular structure of the isoxazoline derivative, in the first place, on the distribution of electron density in the molecule.^{20, 21} The presence or the absence of substituents at the carbon atoms of the heterocycle and their electronic effect on the ring eventually determines the site of deprotonation under the action of the base. Clearly substituents having polarised bonds, heteroatoms, etc., can influence critically the direction of the reaction. Such situations will be the subject of our further consideration.

III. 1,4-Cycloreversion of 2-isoxazolines

Cycloreversion of isoxazolines (degradation of the heterocycle at two bonds) often interferes with normal (usual) isoxazoline ring cleavage under the action of basic (as well as organometallic and some other) reagents normally occurring at one of the bonds of the N–O–C fragment. Two types of ring fission (in accord with the number of C–C bonds present in the heterocycle) are known for isoxazolines, *viz.*, 1,3- and 1,4-scission.

Ring fission always occurs with rupture of the bond between the heteroatoms, since this bond is the weakest in the ring. Most probably, it is the C=N–O fragment of the ring, that interacts with the reagent. For example, it has been noted that chelation of various reducing reagents (e.g., complex metal hydrides, hydrogenation catalysts, etc.) in reductive cleavage reactions occurs with the involvement of this particular fragment of the isoxazoline molecule.¹⁸ The site of the second ring fission is one of the two C–C bonds, namely: C(3)–C(4) in the case of 1,3-cycloreversion and C(4)–C(5) in the case of 1,4-cycloreversion. In the reaction with a nucleophile (with a base), the reaction center is the carbon atom carrying the most acidic proton. The site of the second fission of the ring is largely determined by the specific structure of the isoxazoline molecule, e.g., by the presence of substituents, which can affect the distribution of electron density at the ring atoms.

Thus, cycloreversion, which normally accompanies the main (usual) direction of the reaction, poses the problem of practical synthesis of hydroxynitriles from isoxazolines. The highly stereoselective reaction of isoxazoline cleavage into hydroxynitriles was

first described by Huisgen et al.⁶ for isoxazoline-5-carboxylic acid (**5a**) and 4-methylisoxazoline-5-carboxylic acid (**5b**), which produced quantitatively 3-cyano-2-hydroxypropionic and 3-cyano-2-hydroxybutyric acids upon treatment with triethylamine.⁶

R = H (**a**), CH₃ (**b**); R' = COOH.

Cleavage of other 3-non-substituted isoxazolines under the action of bases occurred in a similar way.^{22,23} Consecutive 1,3-dipolar cycloaddition of nitrile oxides to alkenes and basic cleavage of 2-isoxazolines thus formed is a rather simple, versatile and stereospecific method for preparing vicinal hydroxy nitriles.

The scope of this method has been expanded with the use of 3-substituted 2-isoxazolines **6–9**, which could generate under certain conditions either the 3-non-substituted isoxazolines **5** or the corresponding anion or radical. Thus, the photolytic or pyrolytic decarboxylation of isoxazoline-3-carboxylic acids and their derivatives **6** was accompanied by simultaneous cleavage of the heterocycle to give the β-hydroxynitriles **10**.^{24–26} 3-Triphenylmethyl-2-isoxazolines **9**,²⁷ 3-trialkylsilyl-2-isoxazolines **7**,²⁸ and 3-phenylsulfonyl isoxazolines **8**^{22,25} underwent similar cleavage. These methods turned out to be useful in the solution of a number of synthetic problems and are now widely used in the synthesis of polyfunctional compounds.^{6, 10, 25, 28–33} Compounds **5–9** behave similarly in the above reactions and, as will be shown below, the mechanisms of cleavage (cyclodegradation) of the isoxazoline heterocycle are identical. Therefore, all these reactions including the interaction with nucleophilic reagents, as well as pyrolytic and photolytic degradation, are considered in the same section.

Pyrolytic decarboxylation of isoxazoline-3-carboxylic acid derivatives devoid of aromatic substituents gives the β-hydroxynitrile **10** in a quantitative yield. However, in many cases other products form in addition to the hydroxynitriles **10**. Heating of ethyl 5-phenylisoxazoline-3-carboxylate **6a** at 120–130 °C results in the hydroxynitrile **10** (R¹ = H, R² = Ph) (65%–90%) and trace amounts of benzaldehyde. Ethyl isoxazoline-3-carboxylate **6b** (R = Ph) prepared from *trans*-stilbene gives quantitatively under identical conditions a 1 : 1 mixture of phenylacetaldehyde (**13**) and benzaldehyde (**14**), the products of cyclodegradation at the N–O bonds (the anion **11b**) and C(4)–C(5) (the alkoxide ion **12b**) (Scheme 2).²⁶

Scheme 2

The steroid isoxazoline **15** obtained from the ketone **16** gives quantitatively the hydroxynitrile **17** (1 h, 130 °C, DMF). However, at 220 °C the yield of the hydroxynitrile **17** is 30% and the yield of the ketone **16** is 60%, while in sulfolane (190 °C, 30 min) the yield of the hydroxy nitrile is as low as 10% (Scheme 3).²⁶

Upon photolysis, 5-phenyl-3-triphenylmethylisoxazoline (**18a**) and 4,5-diphenyl-3-triphenylmethylisoxazoline (**18b**) prepared from styrene and *trans*-stilbene, respectively, gave different amounts of benzaldehyde. Under these conditions, the steroid isoxazoline **19** was converted (via the radical **20**) into a mixture of the ketone **22** (up to 48%) and the hydroxy nitrile **21** (up to 5%).²⁷

Scheme 3

R = H (**a**); R = Ph (**b**).

The mechanism of cyclodegradation proposed by Kaufmann and Kalvoda^{26,27} involves generation of a cyclic carbanion **11**. Subsequent cleavage of the weakest N–O bond gives either the acyclic alkoxide ion **12** or the nitrile **13** and the aldehyde **14** as a result of synchronous heterocycle fragmentation, depending on the strength of the C(4)–C(5) bond. Thus, the cyclodegradation of the carbanion **11** may occur either consecutively: **11** → **12** → **13** + **14**, or synchronously: **11** → **13** + **14** (see Scheme 2). Apparently, the degradation of the photolytically generated radical **20** occurs by an analogous scheme.

The result of conversion of the 3-phenylsulfonylisoxazolines **8a–h** depends on the structure of the substituents at the C(4) and C(5) atoms of the heterocycle (Table 1). Thus, the reaction of phenylsulfonyl derivatives **8a–f** with sodium amalgam gives 86%–94% of the corresponding hydroxy nitriles as the sole diastereomers. It is worthwhile noting that the 3-phenylsulfonyl derivative **8f** is cleaved into the corresponding hydroxy nitrile (**10f**), while the isoxazoline-3-carboxylic acid (**23**) gives upon decarboxylation only 6-oxoheptanonitrile (**24**), the product of the cyclodegradation at the C(4)–C(5) bond:²⁵

Upon treatment with sodium amalgam, 3-phenylsulfonyl-4,5-diphenylisoxazolines **8g,h** give the same cyclodegradation products, **13b** and **14**^{22,23} as those formed upon decarboxylation of 4,5-diphenylisoxazoline-3-carboxylic acid.²⁶ The composition of the base-induced cleavage products also depends on the pH of the reaction medium: in a phosphate buffer, a mixture of hydroxy nitrile, benzyl alcohol (the product of subsequent reduction of benzaldehyde with sodium amalgam), and phenylacetaldehyde is formed. It has been noted that at pH > 10 the cyclodegradation products form predominantly, whereas at pH < 9 hydroxynitriles form (in this case, the conversion is insignificant). Since in an aqueous sodium hydroxide solution the conversion of the hydroxy nitriles prepared from the isoxazolines **8g,h** into benzaldehyde and phenylacetaldehyde was completed within several minutes, it may be supposed that the latter are the products of the retroaldol reaction of the hydroxy nitrile, since the latter is alkali-labile. However, it is very likely that both the N–O cleavage of the isoxazoline ring into the hydroxy nitrile and the competing process of cyclodegradation occur by the same mechanism, in

which the cyclodegradation is one of the pathways of stabilisation of the cyclic carbanion **11** or the acyclic alkoxide ion **12**.

The anion **11**, which has been postulated for the cyclodegradation of the isoxazoline-3-carboxylic acids **6**,^{26,27} seems to be the intermediate product in the cleavage of 3-non-substituted (**5**),⁶ 3-phenylsulfonyl- (**8**),²² and 3-trimethylsilylisoxazolines (**7**),²⁸ although direct evidence in favour of this mechanism has not been obtained yet. The generation of the isoxazolinium anion **11** from 3-phenylsulfonyl-, 3-trimethylsilyl-, and 3-carboxyisoxazolines occurs by the cleavage of the C(3)–X (X = S, Si, C) bond. It is worth noting that the identity of the products of the above reaction points to the common intermediate, which can be represented by the corresponding 3-non-substituted isoxazoline generating the anion (or the radical). If the C(4)–C(5) bond cleavage occurs and the β-hydroxy nitrile is thermally stable under the given reactions conditions, one may postulate the cyclodegradation as occurring via the intermediate formation of the acyclic alkoxide ion **12**.²⁶ An alternative mechanism of this reaction is the concerted cyclodegradation of the carbanion **11** with the formation of compounds **13** and **14**.²⁵

The cleavage of the alkoxide ion **12** must be very rapid and compete with protonation. Thus, the observed conversion of the β-hydroxy nitrile **10f** into the oxonitrile **24** under the action of a

base (170 °C) is in accord with the rapid cleavage of the C(4)–C(5) bond in the alkoxide ion.²² Presumably, in the course of decarboxylation the alkoxide anion **12** is originally generated in an excited state; such a 'hot' alkoxide ion undergoes fragmentation more easily.

If isoxazolines are considered as a latent form of β -hydroxy ketones and the process of the formation of isoxazolines and their cleavage into hydroxy ketones as the equivalent of the aldol condensation, the 1,4-cycloreversion represents, in effect, a retroaldol degradation.

Apart from the above examples of 1,4-cyclodegradation of the isoxazoline ring, when the generation of the isoxazolinium anion of type **2a** proceeds with the participation of nucleophilic reagents, an alternative way of 1,4-cycloreversion of isoxazolines is known, which represents the degradation of the isoxazoline ring without deprotonation and is accompanied by the formation of two carbonyl compounds. Such a cyclodegradation was observed as a competing process in the cleavage of isoxazolines by metal polycarbonyls.^{34–38}

In 1984–1987, preparative methods were developed for thermolytic and photolytic degradation of isoxazolines into β -hydroxy ketones in the presence of metal polycarbonyls.^{34, 35, 37} This interaction is not unambiguous, however. Thus, in the case of phenyl-substituted isoxazolines **25a,b**, the aldehydes **26** and the ketones **27** form, which are the products of retroaldol degradation of the heterocycle at the N–O and C(4)–C(5) bonds (Scheme 4). The isoxazolines containing no substituents at C(5) give, in addition to the 1,4-cycloreversion products, the corresponding β -hydroxyketones **28** or aminoenones. It was also found that 1,4-cycloreversion is the main pathway of the cleavage of isoxazolines with $\text{Mo}(\text{CO})_6$ in anhydrous media.³⁷

The yields of the products of photolytic [under the action of $\text{Fe}(\text{CO})_5$] and thermal [under the action of $\text{Fe}_2(\text{CO})_9$] cleavage of the isoxazolines **25a–i** are listed in Table 2.³⁴ The results presented can be explained within the framework of the mechanism of cyclodegradation depicted in Scheme 4. The most probable mechanism is the degradation via the intermediate **29** and its cleavage with the formation of a bipolar complex **30**, the rapid hydrolysis of

which gives the β -hydroxy ketone **28**. In anhydrous media, the cleavage occurs at the C(4)–C(5) bond. An n -donor complex **29** of isoxazoline with $\text{Fe}(\text{CO})_4$ generated photochemically from $\text{Fe}(\text{CO})_5$ or thermally from $\text{Fe}_2(\text{CO})_9$ cleaves to give the intermediates **30** or **31**, which undergo further degradation to yield the aldehyde **26** and the vinylidene complex **32** (or its protonated form **33**). Obviously, the factor facilitating the easy cleavage of the N–O bond is the delocalisation of the π - d electrons from Fe to the π^* -orbital of the C=N–O fragment of the heterocycle. In methanol (or in the presence of water), the complex **32** undergoes reduction to give the imine **34** (major pathway) or insertion of the carbonyl occurs with the formation of the vinyl isocyanate **35** (minor pathway). The isolation of a stable methyl mesyl ketimine in the case of the isoxazoline **25g** is evidence for the intermediate formation of the corresponding imine **34**. In the presence of water,

the vinyl isocyanate **35a** ($R^1 = \text{Ph}$) dissociates into the ketone **27a** via the intermediate acid **36**, and in methanol it gives 1-phenyl-vinylcarbamate **37a**. The imine **34a** is hydrolysed when treated with water (or in the presence of water) to give the ketone **27a**. Thus, the intermediates **32** (or **33**) are very labile in protic media or in the presence of trace amounts of water. The carbamate **37** can also undergo hydrolysis into the ketone **27**. The formation of the latter can also occur through consecutive transformations of the intermediates **32** (or **33**) into the imine **34**.³⁴

The nature of the substituent at the C(3) atom does not apparently influence appreciably the course of the reaction. Thus, for 3-methyl- (**25e**) and 3-phenyl-substituted (**25a**) isoxazolines the results of the reaction are comparable (Table 2). Obviously, the substitution at C(5) is the most important for the cleavage of the C(4)–C(5) bond. The absence of substituents at C(5) prevents this cleavage. Thus, for the C(5)- non-substituted 2-isoxasolines **25h,i**, the yield of the aldol degradation products, *viz.*, acetophenone **27h** and propiophenone **27i**, was about 40%, whereas the corresponding hydroxyketones **28h,i** were obtained with the yields of about 50%. Apparently, in these cases the energy barrier for the C(4)–C(5) bond cleavage is higher than that for the 3-substituted isoxazolines **25a–g**, and the degradation of the **30** (**31**) $\rightarrow$ **26** + **32** (**33**), type involving the elimination of the aldehyde molecule, competes with the cleavage via the hydroxy imine **38** into the hydroxyketone **28**. Irradiation of the isoxazolines **25h,i** with $\text{Fe}(\text{CO})_5$ in methanol does not cause the aldol-type reversion.

Reactions of isoxazolines **39a–c** having acetoxy, ethoxy, or amino groups at C(5) with metal polycarbonyls give β -amino enones **40a–c** in good yields under identical conditions (Table 3).^{34,36} The enamino ketone **40** can form from the complex **41** by cleavage at the N–O bond and subsequent elimination of the AcO- or EtO-groups to give the vinylnitrene complex (pathway *A*, Scheme 5) similar to the complex **31**. An alternative pathway for obtaining the enamino ketones **40**³³ (pathway *B*, Scheme 5), through elimination of AcOH and EtOH from isoxazolines with the intermediate formation of the corresponding isoxazoles **42** and their degradation by metal polycarbonyls has been described.³⁹ This pathway seems to be analogous to aromatisation of isoxazolines, which will be considered below. The pathway *C* depicted in Scheme 5 is analogous to the degradation of isoxazolines **25a–g** and involves the elimination of the aldehyde **26** with the formation of the vinylnitrene complex **43**, which is further converted into the ketone **44**. In the case of isoxazoline **39c** having a pyrrolidino substituent at C(5), the products of conversion by both the pathway *A* and the pathway *C* have been isolated. The direction of this reaction is also affected by the substituents at C(4) of the heterocycle. For 4,4-dimethyl-5-(pyrrolidino-2-isoxazoline (**39d**), only one pathway *C* resulting in the formation of the ketone **44d** is realised, since for $R^1 \neq \text{H}$, the elimination of the tertiary amine molecule is unlikely.

d	Me	Me	$-\text{N}(-\text{CH}_2-)_4$	20	0	72

^a Thermal treatment.

In the reactions of fused isoxazolines, *viz.*, 3-phenyl-3a,4,5,6a-tetrahydrofuro- (**45a**) and 3-phenyl-3a,5,6,7a-tetrahydro-4H-pyrano[3,2-*d*]isoxazoles (**45b**) with metal polycarbonyls, cycloreversion is the major transformation.^{35,36}

$\text{M}(\text{CO})_m = \text{Fe}(\text{CO})_4, \text{Mo}(\text{CO})_6; [\text{Fe}_2(\text{CO})_9, \Delta \rightarrow \text{Fe}(\text{CO})_4; \text{Fe}(\text{CO})_5, \Delta \rightarrow \text{Fe}(\text{CO})_4]$.

The degradation proceeds via the n -donor complex **46**, which is cleaved to give a nitrene complex **47**; its further reduction results in the enamine **48**, which is hydrolysed under the reaction conditions into the hydroxyketone **49**. An alternative pathway with the formation of the enamino ketone **50** resulting from the cleavage of the N—O bond of the isoxazoline and the C—O bond of pyran does not take place, in contrast to the cleavage of 5-ethoxy- or 5-acetoxyisoxazolines.

Similar reactions with 7*a*-morpholino- (**51a**) and 7*a*-pyrrolidino-3-phenyl-3*a*,4,5,6,7,7*a*-hexahydrobenzo[*d*]isoxazoles (**51b**) give the products **53** and/or **55**, depending on experimental conditions. With $\text{Fe}_2(\text{CO})_9$ (thermolysis) or $\text{Fe}(\text{CO})_5$ (photolysis), the degradation follows predominantly pathway *A* (Scheme 6) to give the enamino ketone **53** formed as a result of cleavage of the N—O bond and the elimination of the amine HX. Treatment of isoxazolines **51** with molybdenum hexacarbonyl in methanol gives, in addition to the products **53** and **55**, also a small amount of the oxo amide **54**. The degradation of the intermediate complex **52** at the N—O and C(3*a*)-C(7*a*) bonds can also occur via the intermediate **56**, the reduction of which and subsequent hydrolysis gives the enamino amide **57** (pathway *B*, Scheme 6). The derivative **55** is the product of methanolysis of the amido group in the compound **54**.³⁵

Scheme 6

$\text{M}(\text{CO})_n = \text{Mo}(\text{CO})_6, \text{Fe}(\text{CO})_4$.

On the other hand, the reaction of 6*a*-morpholino- (**58a**) and 6*a*-pyrrolidino-3-phenyl-3*a*,5,6,6*a*-tetrahydro-4*H*-cyclopenta[*d*]isoxazolines **58b** with $\text{Fe}_2(\text{CO})_9$ is a very slow process, and the β -enamino ketones **59** are isolated along with large quantities of the original isoxazolines. At the same time, the enamino ketone **59**, the amide **60**, and the ester **61** are readily formed with $\text{Mo}(\text{CO})_6$.³⁵

In the above examples, a dependence emerged between the direction of isoxazoline degradation and the length of the

4,5-polymethylene chain. Presumably, the composition of the products does not depend on the structure of the leaving group X. However, the cleavage of the N—O bond with simultaneous elimination of the heterocyclic amine and the formation of the enamino ketones **59** becomes the major pathway for the fused isoxazolines **58**.

It should be noted that the cycloreversion, which interferes with the degradation of 3-phenyl-substituted isoxazolines, is not characteristic of 3-alkyl-substituted ones. In the latter case, the degradation of the heterocycle under the action of metal polycarbonyls follows a traditional pattern with the formation of the corresponding hydroxy ketones and enones. A modified procedure has been proposed to block the cycloreversion, which occurs in the reaction of the 3,5-diphenyl-substituted 2-isoxazolines **25** with metal polycarbonyls, in which the reagent is the $\text{Mo}(\text{CO})_3(\text{MeCN})_3$ complex.³⁸ In this case, the proportion of the cycloreversion products **14** and **27h** formed upon cleavage of the 3,5-diphenyl-2-isoxazoline **25a** diminishes from 40% down to 4%.

IV. 1,3-Cycloreversion of 2-isoxazolines

If the 1,4-cycloreversion of 2-isoxazolines considered above represents a retroaldol degradation, the 1,3-cycloreversion is a process which is the opposite of intramolecular cycloaddition. The reaction of retro-1,3-dipolar intramolecular cycloaddition takes place primarily in the synthesis of isoxazolines from oximes.

Thus, Shotton et al.⁴⁰ observed 1,3-cycloreversion of isoxazolines in the studies of thermal cyclisation of the oximes **66a–g**. At temperatures around 300 °C, oximes yield compounds, which can be regarded as products of fragmentation of the intermediate isoxazolines undergoing 1,3-cyclodegradation.⁴⁰ These isoxazolines were isolated if the cyclisation of the oximes **66a,b** was carried out at 200 °C, and then at 300 °C they decomposed into the same products as those obtained upon thermal cyclisation of oximes at 300 °C.

Ar = Ar¹ = Ph: R = R¹ = H (**a**); R = Br, R¹ = H (**b**);
 R = H, R¹ = Me (**c**); R = Me, R¹ = H (**d**);
 R = R¹ = H: Ar = *p*-MeOC₆H₄, Ar¹ = Ph (**e**);
 Ar = Ph, Ar¹ = *p*-MeOC₆H₄ (**f**);
 R = Me, R¹ = H, Ar = Ph, Ar¹ = 2-thienyl (**g**).

Thus, upon heating at 280 °C, the benzalacetophenone oxime **66a** gives 36% of benzonitrile, 30% of acetophenone, 4% of benzaldehyde, 6% of ammonium benzoate, water, and ammonia. At first, 3,5-diphenylisoxazoline **25a** is formed from this oxime at 200 °C; further heating up to 280 °C gives the products of 1,3-(benzonitrile and acetophenone) and 1,4-cyclodegradation (benzaldehyde and acetophenone imine). The latter undergoes easy hydrolysis into acetophenone and ammonia. It is thus supposed that pyrolysis of oximes proceeds through the intermediate formation of isoxazolines with their subsequent cyclodegradation by two pathways. A scheme has been proposed for the 1,3-cycloreversion, which involves a hydride shift. It is believed that 1,4-cyclodegradation is a reductive process consisting in the transfer of the hydride ion; however, the donor of this ion has not been identified (Scheme 7). The isolation of the isoxazoline **67c** in 65% yield and the absence of cyclodegradation products in the pyrolysis of the oxime **66c** are evidence in favour of the proposed mechanism. Probably, in this case the postulated hydride shift is impossible. The reaction with the oxime **66d** gave benzonitrile (50%) and propiophenone (56%), the products of 1,3-cyclodegradation of the intermediate, isoxazoline **67d**, and its aromatisation product, 3,5-diphenyl-4-methylisoxazole. There was no 1,4-cyclodegradation under these conditions.

By analogy with the behaviour of other five-membered heterocyclic systems, the authors assumed that the both pathways of cyclodegradation (1,3 and 1,4) are cases of retro-1,3-dipolar cycloaddition. However, the dipolar ion, ⁺CH₂–CH(Ph)–O[–], formed upon 1,3-cyclodegradation, is devoid of the four π-electrons in the C–C–O bond system necessary for its conversion into an alternative canonical structure, [–]CH₂–CH(Ph)–O⁺, while in the case of the vinylnitrene **68**, the original product of 1,4-cycloreversion, such an isomerisation is very likely:

Scheme 7

For 2-methyl-1-phenyl-3-(2-thienyl)prop-2-en-1-one oxime **66g**, the corresponding intermediate product, isoxazoline **67g**, could not be isolated under the conditions of thermal cyclisation,⁴⁰ apparently due to the high susceptibility of the latter to cyclodegradation. This reaction gave only benzonitrile and the corresponding ketone **69**.

It should be noted that benzonitrile oxide and alkene, the products of cycloreversion by the third possible pathway (the so-called ‘3,5-retro-Grünanger addition’), were not identified among the products of oxime pyrolysis. Such a process did not take place in other cases either. Obviously, this process is hardly likely due to the energy gain in the direct reaction. Studies of the interaction of 3-substituted isoxazolines with bases did reveal cases of 1,3-cycloreversion. 1,3-Cycloreversion of isoxazolines under the action of bases is associated with the possibility of generating an anion at C(5) of the isoxazoline. It is known that the most acidic protons are the proton at C(3) in 3-nonsubstituted isoxazolines and the proton at C(4) in 3-substituted isoxazolines.^{7, 18} 5-*endo*-Deprotonation is not usual in this case; it can occur only in isoxazoline structures in which deprotonation at other carbon atoms is hindered, on the one hand, and which contain substituents at C(5) able to stabilise the anion formed, on the other hand. Thus, a significant increase in the proton H(5) acidity can be invoked by electron-acceptor substituents at C(5).⁴¹ Indeed, isoxazolines carrying electron-acceptor substituents turned out to be highly susceptible to such a cyclodegradation. The degradation of the cyclic carbanion **2c** generated as a result of C(5) deprotonation by the nucleophile can further proceed in accordance with the scheme:

Baranski and Cholewka⁴² observed 1,3-cycloreversion under conditions of the Nef reaction. This is the first example of such reaction. Treatment of 3,4-diaryl-5-nitroisoxazolines **70** with a stoichiometric amount of NaOMe in absolute methanol resulted in the nitrile and methyl phenylacetate; an analogous reaction with Et₃N or cyclic amines in aprotic solvents results in the nitrile and the corresponding amides.⁴²

Since it had been known that 5-nitroisoxazolines easily eliminate nitrous acid to give the corresponding isoxazoles^{43–46} (see also Section V), it has been postulated that cyclodegradation is preceded by the aromatisation of the heterocycle through the elimination of nitrous acid. The isoxazoles formed thereby can undergo further degradation by the nucleophile. However, the composition of the reaction products excluded the intermediate formation of isoxazoles. Furthermore, unlike 4-nitro-2-isoxazolines, 5-nitroisoxazolines were not subjected to aromatisation by MnO_2 .⁴⁷

The most likely mechanism of the 1,3-cycloreversion of nitroisoxazolines is believed to be the synchronous E_2 -process with transfer of the H(5) proton to the nucleophile, the cleavage of the N–O and C(3)–C(4) bonds in the intermediate **71**, and the changes in the order of the C=N and C(4)–C(5) bonds. Further transformations of the acyclic anion **72** consist in the elimination of the nitrite anion and the formation of ketene.⁴²

It has to be noted that a final choice in favour of one of the proposed alternative mechanisms is difficult to make, because it is not easy to draw a demarcation line between the ability of 5-nitroisoxazolines for aromatisation and their susceptibility to cyclodegradation. Apparently, aromatisation and cyclodegradation are competing processes, and the composition of the products is determined by both the particular structure of the substrate and the nature of the nucleophile used.

The 5-acylisoxazolines **73**, which decompose into nitriles, α -diketones, isoxazoles **74** and **76**, as well as Δ^2 -pyrrolin-4-ones **75** under the action of bases, are also susceptible to C(5)-deprotonation.^{41, 48} 5,5-Disubstituted isoxazolines are stable under these conditions due to the impossibility of C(5)-deprotonation.⁴¹

In methanol, C(5)-deprotonation of 5-acylisoxazolines **73** gives approximately 8% of the isoxazoles **74** and **75**, whereas in benzene their yield is as high as 70%. The mechanism of formation of 5-hydroxy-2-pyrrolin-4-one **75** can be represented by Scheme 8. In the presence of bases, C(5) deprotonation of isoxazoline **73** occurs with the formation of the anion **77**; this is followed by its cleavage at the N–O bond to the anion **78** and reprotonation give the equilibrium mixture $\text{74} \rightleftharpoons \text{79} \rightleftharpoons \text{75}$. The fragmentation products, the nitrile and the α -diketone, form by the same scheme either by pathway *A* or *B*. Pathway *A* seems to be more preferable than pathway *B*, for it includes a symmetrical cycloreversion via the activated complex **80**. However, it is difficult to make a choice between these pathways, since both of the corresponding transition states for **78** and **80** have similar energy.⁴⁸

Scheme 8

No deuterium exchange occurs on addition of triethylamine to a solution of isoxazolines **73** in D₂O (¹H NMR data); therefore it can be suggested that the equilibrium $73 \rightleftharpoons 77$ does not exist and deprotonation is the slowest stage of the process. The lack of direct evidence for the formation of the anion **77** allows one to suggest that degradation via pathway *C* is not unlikely. On the other hand, ignoring pathway *B* and considering pathway *A* to be the only one possible, the degradation of the isoxazoline ring to the imino diketone **79** must be more effective in benzene than in methanol, since the transition complex **78** contains a contact ion pair with triethylamine (Scheme 8).

In conformity with this assumption, the formation in a high yield of the isoxazole **76** upon the cyclodegradation of 4,5-dibenzoyl-3-phenyl-2-isoxazoline (**73a**) ($R^1 = R^3 = \text{Ph}$, $R^2 = \text{COPh}$) in the reaction with triethylamine can best be explained by the transition state **82**.⁴⁸

1,3-Cycloreversion of the 3-R-5-(4-pyridyl)isoxazolines **83a–c** resulting in the nitriles **84a–c** and 4-acetylpyridine occurs on the interaction of these isoxazolines with bases (butyllithium and dimsylsodium) and potassium selectride,^{49,50} whereas their analogues **83d,e** interact in accordance with the known schemes to give enoximes **85d,e**.^{2,3,15,51}

$R^1 = -\text{C}_6\text{H}_3(\text{OMe})_2$ (a), $-(\text{CH}_2)_4\text{COOMe}$ (b),

$R^2 = \text{pyridyl-4}$ (a–c), Ph (d), $-\text{CH}_2\text{OPh}$ (e).

It is noteworthy that the reduction of the isoxazoline **83c** with sodium tetrahydroborate results in the formation of the carbonyl-group reduction product, **86**. Upon reductive cleavage (Raney Ni, AlCl_3 , $\text{MeOH}-\text{H}_2\text{O}$), 5-pyridylisoxazolines **83a–c** and 5-phenyl(phenoxymethyl)isoxazolines **83d,e** give the β -hydroxy ketones **87**, which is typical of isoxazoline cleavage by reagents of this type.^{1,3}

The formation of different products in the reaction with nucleophilic agents from the 5-pyridylisoxazolines **83a–c** and from the 5-phenylisoxazolines **83d,e** points to the involvement of the substituent at C(5). In the case of the derivatives **83a–c**, the products of the cyclodegradation of the isoxazoline fragment form, and the ketone-nitrile 1,3-cycloreversion of 5-(4-pyridyl)-2-isoxazolines observed is similar to the cycloreversion of 5-acyl- and 5-nitro-2-isoxazolines and seems to proceed in accordance with Scheme 9:

Scheme 9

The first step in the 1,3-cyclodegradation of 5-pyridyl-2-isoxazolines **83a–c** is the generation of the anion **88** under the action of the base. Subsequent redistribution of the electron density in the isoxazoline fragment results in the cleavage of the N–O and C(3)–C(4) bonds. The formation of a stable molecule of the corresponding nitrile **84** from the N–C(3)–R fragment is the driving force of this cyclodegradation. The C(4)–C(5)–O fragment carrying originally a negative charge undergoes cyclodegradation to give the enolate anion **89** and then acetylpyridine. It should be noted that all the cases of 1,3-cycloreversion observed previously in reactions with bases seem to occur with the participation of the isoxazolinium anion, the stabilisation pathways of which depend on the specific reaction conditions and the reagents used.

The interaction of the compounds **83d,e** with butyllithium and dimsylsodium occurs via the intermediate formation of the anion of the **2b** type (see Section II), which, depending on conditions, can regenerate the original isoxazoline (BuLi , -78°C) or can be cleaved at the C(5)–O bond to form the stable enoxime **85** (dimsylsodium, 20°C).

It should be noted in conclusion that the sequence: $[2+3]$ -cycloaddition $\rightleftharpoons$ deprotonation $\rightleftharpoons$ $[2+3]$ -cycloreversion is a potentially promising method for the oxidative cleavage of the double bond with simultaneous elongation of the carbon chain at its ends (the so-called method of 'indirect carbolytic cleavage of the double bond').^{52,53}

R = H, Me; R¹ = Alk, Ar.^{56,57}

V. Aromatisation of 2-isoxazolines

The tendency toward the formation or elongation of a system of conjugated bonds via the formation of a heteroaromatic ring can be one of the reasons for the conversion of isoxazolines into isoxazoles. Another reason for such conversions is, as a rule, the presence in one of the positions of the carbon skeleton of the isoxazoline heterocycle of a substituent which represents a 'good leaving' group. These substituents can be eliminated spontaneously in the course of isoxazoline formation or under the action of reagents stimulating the elimination process.

Thus, aromatisation of isoxazolines into the corresponding isoxazoles is often observed in the reaction of 1,3-dipolar cycloaddition of nitrile oxides to enones, 1,3-diones, and their derivatives.^{54–59} Aromatisation of the cycloadducts formed as a result of the addition of the nitrile oxide dipole at the double bond of the enolic form of the β-dicarbonyl compounds **90**–**92** occurs via the elimination of the water molecule from the intermediate 5-hydroxy-2-isoxazolines of the **93**–**95** type.

R¹ = Me; R² = Me, Et;
R³ = Ph, C₆H₄NO₂, C(O)Me, COOEt, C(O)Ph.⁵⁴

Y = OAlk, Ar, thienyl-2; R = Alk, Ar.⁵⁵

Aromatisation of cycloadducts with enones is a result of an oxidative transformation.^{58,59} One can assume that the aromatisation of 4,5-diacetyl-2-isoxazoline **96** into 4,5-diacetylisoxazole **97** occurs via an identical mechanism.⁶⁰ The reaction of the nitrile oxide **98** with 5,5-dimethylcyclohex-2-enone gives the isoxazoline **99**; however, it is readily converted into the corresponding isoxazole **100** during purification on a column or on boiling in *tert*-butyl alcohol in the presence of chloranil.^{61,62}

The ease of elimination of the substituent at C(5) of isoxazoline is not only due to the effect of the reaction medium, but also due to the presence of such good leaving groups as acyloxy, alkoxy, and amino groups. Thus, an attempt to synthesise the isoxazoline **101** from the corresponding enone and nitrile oxide has led to the 5-acylisoxazole **102**.⁶³

silica gel, did not react with nucleophilic reagents, but readily converted into the isoxazoles **118**–**120** upon acid or alkaline hydrolysis. In this particular case, the aromatisation of the isoxazoline **117** occurs through the elimination of the lactam ring fragments formed upon the hydrolytic cleavage of the azlactone substituent at C(5).⁶⁸

The instability of 4- and 5-nitro-2-isoxazolines was repeatedly observed in their synthesis from nitrile oxides and nitroalkenes, when the primary product of the cycloaddition, the corresponding 2-isoxazoline, converted into the isoxazole with elimination of nitrous acid.⁴⁶ Some nitroisoxazolines formed in this reaction are rather stable under reaction conditions; however, they undergo rapid aromatisation on heating. Thus, the interaction of aromatic nitrile oxides with nitroethylene resulted in the 5-nitro-2-isoxazolines **121**, which on boiling in toluene gave high yields of the isoxazoles **122**.^{43,44}

The ability to eliminate nitrous acid differs for various substituted 4- and 5-nitroisoxazolines. Thus, 4-nitro-5-methylisoxazolines **123** aromatised upon prolonged heating, whereas the derivatives of 5-nitro-2-isoxazoline **124** aromatised spontaneously under reaction conditions.^{45,46}

The 1,3-dipolar cycloaddition of benzonitrile oxide to α -substituted nitroethylenes of the type **125** at 0 °C gives the isoxazolines **126**, which spontaneously convert at 20 °C into the isoxazoles **127** with the elimination of the nitro group.⁶⁹

The nitro group can be eliminated more readily from isoxazolines than the cyano and carboxy groups.^{70,71} Thus, the nitro group eliminates preferentially from C(5) of the 5-nitro-5-alkyl(aryl)isoxazolines **128** and **129** to give the corresponding 3,5-diaryl- (**130**)⁷² or 3,5-dialkylisoxazoles (**131**).^{72,73}

However, if the isoxazoline contains an amino group as in the case of 4-nitro-5-dimethylaminoisoxazoline **132**, it is this group that is eliminated during aromatisation.^{74,75}

The reactions of the β,β -diaminonitroethylenes **133** with nitrile oxides give the 5-amino-4-nitro-3-isoxazoles **134**, the products of elimination of one of amine molecules.⁷⁶ In the case of the 1,3-dipolar cycloaddition of the nitrile oxide to the nitroalkene **135**, the isoxazole **136** is also formed as a result of preferential elimination of morpholine.⁷⁴

The adducts of benzonitrile oxide with halonitroethylenes aromatise to give 4- and 5-nitroisoxazoles which can be explained by the ability of intermediate isoxazolines to eliminate the hydrogen halide molecule more readily than HNO_2 .⁴⁶ It should be noted that spontaneous elimination of hydrogen halide under conditions of nitrile oxide synthesis was often observed when halogenoalkenes were used as dipolarophiles.^{57,77} Hence, in some cases unstable 4- and 5-nitroisoxazoles can be obtained by cycloaddition to nitroalkenes containing a substituent group, which eliminates more readily than the nitro group.⁴⁶

The nitro group can be split off, not as nitrous acid, but as a stable compound with another substituent in the isoxazoline ring. Such an ability for elimination is useful in the synthesis of some isoxazoles. For example, in the synthesis of 3-phenylisoxazole by the nitrile oxide method, the substituents at C(4) and C(5) eliminate simultaneously from the isoxazoline **137** formed in the first stage of the reaction:⁷⁸

According to their ability for cleavage, the 2-isoxazoline substituents can be arranged in the following order: $\text{NR}_2 > \text{Hal}, \text{OR} > \text{NO}_2 > \text{CN}, \text{COOR}$.

Aromatisation of isoxazolines was observed either under conditions of nitrile oxide synthesis or under the action of reagents (predominantly acidic). Spontaneous aromatisation of isoxazolines formed as intermediate adducts of the nitrile oxide synthesis occurs with the participation of bases and if C(5) contains hydrogen, which is readily cleaved by bases. Aromatisation of amino-substituted isoxazolines occurs, as a rule, under conditions of proton catalysis.

As noted above, aromatisation of some 5-substituted isoxazolines is a very likely reason for the formation of unusual degradation products upon interaction with metal polycarbonyls (see Section III). Thus, the formation of enamino ketones upon treatment of isoxazolines with iron or molybdenum polycarbonyls^{34,39} apparently involves elimination of 5-acyloxy-, 5-ethoxy-groups, or 5-pyrrolidinyl substituents, since the corresponding hydroxy ketones must be the normal products of cleavage of the N—O bonds of isoxazolines.

The competing process of aromatisation is the reason for the conversion of 5-aminoisoxazolines into enamino ketones, the aromatisation being the major pathway in the interaction of isoxazolines with molybdenum hexacarbonyl. The tendency to aromatisation is also realised for 4,5-diacylisoxazolines. Their reactions with bases give isoxazoles in addition to 1,3-cyclodegradation products (see Section IV). In this case, aromatisation is the result of hydride shifts occurring with the participation of acyl substituents or it is analogous to the oxidative transformations of the adducts of the nitrile oxide synthesis.

The examples considered above provide evidence for the competition of the aromatisation of the isoxazolines with the reactions of 1,4- or 1,3-cyclodegradation, which is particularly true for the isoxazoline derivatives carrying good leaving groups as substituents.

VII. Synthesis of phospholipids based on oxazolines	50
VIII. Conclusion	50

Abstract. The practical significance of acylation of acetals, orthoesters, and their aza-analogues (oxazolines) in fine organic synthesis is considered. Attention is mainly focused on the application of this reaction to the design of glycerophosphatides and other types of phospholipids. The use of acylation of these geminal alkoxides and oxazolines makes it possible to optimise the strategy of the synthesis of polyfunctional ester systems. The bibliography includes 76 references.

I. Introduction

Acetals,[†] orthoesters, and other geminal alkoxides are of special interest as stable derivatives of the corresponding carbonyl compounds, which are formed at certain stages of synthetic schemes.^{1–3} In addition, they are used as effective donors of α -substituted carbocations in the formation of carbon–carbon^{1,4,5} or carbon–hydrogen^{6,7} bonds in the design of complex polyfunctional systems. In all these cases, the alkoxide fragment of the above-mentioned compounds as synthetic material is partly or completely lost.

At the same time, geminal alkoxides can also function as synthetically useful derivatives of polyhydric alcohols. This possibility was established as early as the last century, but has been introduced into routine preparative practice only in recent years. The main attention was focused on the conversion of cyclic acetals of polyhydric alcohols into complex lipids. The main results of these investigations are discussed in the present review.

II. Acetals as nucleophiles

The simplest and functionalised acetals can react with phosphorus and sulfur halides as well as with phosgene to give the corresponding α -haloethers.^{1,8,9} The mechanism of these reactions has not

[†] We use the term 'acetals' to denote geminal alkoxide derivatives of aldehydes and ketones.

been studied in detail. However, it presumably involves an electrophilic attack of the acetal oxygen by phosphorus, sulfur, or carbon to give oxonium compounds, which are transformed into α -haloethers, either directly or via several stages. Simultaneously, the eliminated alkoxy group is converted either into halophosphite (phosphate), -sulfite (sulfate), or -carbonate or into the corresponding alkyl halides. This rationalisation of the chemical nature of this process has been substantiated by studies of the interaction of acetaldehyde ethylene acetal with ethylene chlorophosphite.¹⁰

The interaction of acyclic acetals with the simplest carboxylic acid halides in the presence of Lewis acids, which also results in α -haloethers, has been reported.^{11–16}

Similarly, C–O bond cleavage occurs when acetals react with anhydrides (as had been shown long ago by Claisen¹⁷).¹⁸

The above reactions have also been studied in relation to cyclic acetals, 1,3-dioxolanes and 1,3-dioxanes. It has been established that acylation of cyclic compounds is a complex process, which normally gives a mixture of products.^{19–26}

$n = 2, 3.$

In some experiments it has been shown that ω -acyloxyalkyl chloroalkyl ethers tend to cyclise, which leads to establishment of an equilibrium, for example:²³

In addition, dehydrochlorination of these α -chloroethers has been observed.¹⁰

Acylation of ethylidene derivatives of monosaccharides with acetic anhydride in the presence of trifluoroacetic acid with subsequent hydrolysis of the acylal-acetal formed initially has been proposed by Kochetkov et al.²⁷ as a method for removing acetal protection.

This reaction was further extended to acylation of silicon analogues of cyclic acetals, 1,3,2-dioxasilacyclanes. These compounds react with acid halides to give mono- and di-acylation products.²⁸

It can be concluded that in the studies on acylation of acetals with chlorides and anhydrides of simplest carboxylic acids, interesting chemical phenomena have been observed but no new preparative methods for organic synthesis have been developed. These methods were elaborated later in studies of the reactions of acetals with chlorides of higher fatty acids in the presence of zinc chloride or other Lewis acids, for example, of the reaction of acetone diethyl acetal with myristoyl chloride.²⁹

A version of this reaction that consists in acylation of cyclic acetals is of great preparative importance. This method was used, in particular, to obtain 1,2-di-*O*-acyl-3-*O*-benzylglycerols **2**, which are important intermediates in the chemistry of lipids, based on accessible 1,2-*O*-isopropylidene-3-*O*-benzylglycerol **1** (pathway *a*).^{29,30} The acetal **1** has been traditionally employed in lipid syntheses: it was hydrolysed to the diol **3**; the latter was isolated and purified and then acylated to give the final esters **2** (pathway *b*). This synthesis required large amounts of solvents and additional reagents. The yield of the ester **2** was as low as 40%–45% with respect to the initial acetal **1**.³¹

R = C₁₅H₃₁, C₁₇H₃₅.

A new synthetic method consisting in direct acylation of the acetal **1** is much more simple and efficient, and the yields of the esters **2** obtained in this way reach 65%. This reaction is usually carried out in a small amount of ether or chloroform or without solvents.

An increase in the acylation temperature to 60 °C decreases the yields of the glycerides **2** due to partial debenzylation. It is significant that the glycerides **2** are formed not only when two moles of acid chloride per mole of the acetal **1** are used, but also at an equimolar ratio of the reagents. However, in the latter case, about half of the initial acetal does not react.^{29,30} ‡

Complete acylation of acetals can also be used for the conversion of 1,3-dioxanes, e.g. 1,3-*O*-benzylidene-2-*O*-benzylglycerol **4**, into the corresponding esters **5**.^{30,32}

R = C₁₅H₃₁, C₁₇H₃₅.

The isomeric glycerides **2** and **5** were investigated by high-resolution NMR spectroscopy. It was noted that no acyl migration along the glycerol system occurred during the synthesis.³² Thus, the practical utility of this method for target-directed syntheses of more complex lipids was demonstrated.

This method was also used in the synthesis of other natural systems such as diacyl derivatives of *S*-alkylthioglycerol **6**.³³

R = C₁₅H₃₁, C₁₇H₃₅; R' = C₁₆H₃₃, C₁₈H₃₇.

Complete acylation of the cyclic acetal **1** appears to be a two-stage process, which can be schematically presented in the following way:³⁰

The isolation of 2,2-dichloropropane is evidence in favour of this mechanism. In addition, to confirm the above mechanism, a model acetal was specially 'designed'; its structure was to ensure

‡ The benzylacetal **1** can also be converted into the ester **2** by treatment with carboxylic acids in the presence of *p*-toluenesulfonic acid. However, in a preparative sense, this procedure is more complex because it requires heating to 110 °C and removal of the H₂O and acetone formed in the process.³⁰

that the negatively charged oxygen atom (if it was generated at the first stage of acylation) comes close to the electrophile. The electrophile should 'trap' the alkoxy-anionic centre thus preventing diacylation. For this purpose, 2-dimethylamido-5,6-isopropylidenedioxy-2-thiono-1,3,2-dioxaphosphepane **7** was used as the model compound. At the first step of acylation, this compound generates alkoxy anion **8**, which, due to the proximity to the dimethylamidothiophosphoryl group, effectively interacts with it by a nucleophilic substitution mechanism. As a result, no second acylation takes place and the phosphorus framework compound **9** is formed instead of the diacylate:^{34, 35}

Orthoesters and other geminal alkoxydes are also nucleophilic and susceptible to acylation. In the studies of these compounds, some interesting chemical features have been found. Therefore, their acylation will be considered separately in the foregoing sections.

III. Synthesis of phospholipids based on glycerol acetals

Complete acylation of acetals has been investigated most extensively and thoroughly in connection with the synthesis of glycerophospholipids and their analogues. 1,2-*O*-Isopropylidene- or 1,3-*O*-benzylideneglycerols were used in these studies as the initial compounds; they were consecutively introduced into phosphorylation, direct acylation, and subsequent auxiliary transformations of the polar fragments of the molecules. It was found that acylation of phosphorylated acetals, occurring under mild conditions corresponding to the acylation of the simplest cyclic acetals, is effective, and has a broad range of synthetic applications. It is noteworthy that acylation of glycerol acetals was studied in parallel with the development of new methods for the design of a lipid-phosphorus unit.^{36, 37} These two lines of research successfully complemented each other and greatly contributed to progress in the synthetic chemistry of phosphoglycerides.

Let us consider acylation of glycerol acetals aimed at the synthesis of phosphatidic acids and their thio- and seleno-analogues. This task can be solved using accessible compounds, such as acetal phosphates **10a, b, 14** and thionophosphates **11a** as initial substances.^{29, 30, 32, 38}

R' = Et (**10a, 11, 12a, 13**), Ph (**10b, 12b**); X = O (**10, 12**), S (**11, 13**).

An increase in the molar amount of the acid chloride (more than 2 moles per mole of the acetal **10a**) has no substantial influence on the yield of the phosphates **12a**. An increase in the reaction temperature (> 50–60 °C) results in the formation of various side products. For example, in the case of the acetal **10a**, considerable amounts of ethyl carboxylates are formed, while the acetal **10b** gives 1,2-di-*O*-acyl-3-chloro-3-deoxyglycerols.³⁰

In order to elucidate whether migration is possible during the acylation, the chromatographic mobility and ¹H, ¹³C, and ³¹P NMR spectra of ethyl esters of α-phosphatidic acid **12a** and of its β-isomer **15** have been analysed. From chromatographic and spectral data it was concluded that acyl migration did not occur during the synthesis.³²

The phosphates **12a** and **15** and thionophosphates **13** obtained were transformed into phosphatidic acids **19** and their thiono-analogues; first, they were made to react with Me₃SiX and then the silyl derivatives thus formed were hydrolysed.^{29, 30, 32, 38}

An alternative method for preparing the phosphatidic acids **19** is acylation of the glycerophosphate silyl ester acetal **18**. In this case, the synthetic scheme involves preparation of amidophosphites of 1,2-*O*-isopropylideneglycerol **16**, their hydrolysis to primary phosphites **17**,⁸ and silylation of the latter. This is followed by oxidation or addition of sulfur (selenium), acylation, and desilylation.^{39, 40}

§ These compounds are often called *H*-phosphonates, which is not, in our opinion, a very adequate term.

X = O, S, Se.

In this case, as in those described above, the efficiency of acylation was found to be higher for thione derivatives than for selenone derivatives. Using the latter synthetic scheme, an optically active phosphatidic acid, 1,2-di-*O*-palmitoyl-*sn*-glycero-3-phosphate, was obtained. The synthesis was not accompanied by changes in the chirality of the glycerol system.³⁹

If required, phosphatidic acids and their thione analogues **19** can be obtained by acylation of salts of 1,2-*O*-isopropylidene-glycero-3-phosphates **20**.^{39, 40}

X = O, S.

In recent years, enzymological demands have stimulated studies of thiol analogues of natural phosphate systems. Derivatives of this kind of the series of phosphatidic acids were obtained by an elegant procedure.⁴¹

Another trend in phospholipid synthesis involving acylation of acetals is the design of natural esters of phosphatidic acids and their S-analogues. For this purpose, a preparative scheme has

been developed, which includes the initial formation of glycerol acetals with protected phosphate groups. These phosphorylated acetals are first acylated and then deprotected. Methyl, ethyl, and benzyl groups are used most frequently as protective groups in these syntheses.

The synthesis of thionophosphatidyl acyl glycols of type **22** can serve as an example.⁴²

Acylation of the phosphatoacetal **21** was carried out with a threefold molar excess of palmitoyl chloride; therefore, both the acetal group and the alcohol hydroxyl underwent acylation.

The synthesis of phosphatidyl ethylene glycol systems **22** was supplemented by the synthesis of phosphatidyl glycerol derivatives **23**. A simple method that proved to be effective was used for this purpose.⁴³

X = O, S.

Glycerophosphates with a protected phosphate group were also used to produce membrane-directed antioxidants by chemical combination of phosphatidic acids and sterically hindered phenols. In fact, phosphatidyl ionols **25** containing 4- γ -oxypropyl-2,6-di(*tert*-butyl)phenol as the protective moiety were obtained by acylation of the acetal **24** with stearoyl chloride.⁴⁴

It should be noted that the acylation does not affect the sterically hindered phenolic hydroxyl.

Synthesis of lipid phosphodiester by acylation of glycerol acetals can also be performed without protection of the free phosphate hydroxyl. For example, the phosphatidyl homocholines **27** have been effectively prepared by acylation of the sodium salt of the glycerol homocholine phosphate **26**.⁴⁵

R = C₁₅H₃₁, C₁₇H₃₅.

More complex lecithin derivatives **29** containing a hydroxy-homocholine residue were also synthesised by acylation of the phosphoacetals of type **28**.⁴⁶

Acylation was also used in the synthesis of phosphatidyl-*N*-methylethanolamines and their thione analogues **31**.⁴⁷ For this purpose, *N*-methylaminoethyl phosphate **30** was treated with an excess of palmitoyl chloride. It is noteworthy that this reaction does not involve *N*-acylation.

X = O, S.

Acylation of compounds containing phospho-rings (these compounds play a significant role in the synthetic chemistry of phospholipids) constitutes a special line of research.³⁷ For example, acylation of acetals containing six- and seven-membered rings with phosphoryl, thiophosphoryl, and selenophosphoryl groups has been carried out.^{48–51}

X = O, S, Se; *n* = 3, 4; R = C₁₅H₃₁, C₁₇H₃₅.

It should be emphasised that acylation was not accompanied by opening of the phospho-rings. The yields of the target products **33** depended on the ring size; for phosphorinanes they reached 68%, whereas for simplest phosphhepanes, they were only 25%–58%.

Fused phosphhepanes appeared to be more convenient starting compounds than their monocyclic analogues **32**. For example, phosphhepane **34** is readily and effectively converted into the lipid system **35**.⁵²

Acylation of systems **36** the rings of which contain sulfur or selenium atoms, in addition to phosphorus and oxygen atoms, has also been studied.⁴⁹ The yields of the target products **37** in this reaction were relatively low (45%–47%), which may be due to the partial acylation of the sulfide or selenide centres in the initial phosphates **36**.

V. Synthesis of phospholipids based on acetals of tri- and tetramethylolalkanes

In modern lipidology, a new trend has appeared, devoted to the study of systems derived from unusual polyhydric alcohols. Acylphosphopentaerythritols and related compounds belong to this group. Acylation of mono- and diacetals of oligomethylolalkanes has been widely used in the synthesis of these lipids.

The design of new phospholipids was preceded by studies on acylation of model systems **45** and **46** based on 2,2-dimethyl-1,3-dioxane. It was shown that the mono- and diacetals **45** and **46** are smoothly and effectively acylated, according to the method described above.^{55,56}

It was then demonstrated that mono- **47** and dithiophosphamide **48** acetals of pentaerythritol are acylated with an equal efficiency.^{55,56}

To obtain bis(dioxaphosphorinane) derivatives of diacylpentaerythritol **50**, the corresponding acetals **49** were introduced into the reaction with stearoyl chloride under standard conditions.^{55,56}

X = O, S.

The distearoyl bisphosphates **50** possess an important structural feature: they contain two phosphopropylene rings. This permits these compounds to be used in the synthesis of phospholipids containing two hydrophilic residues in their molecules.^{55,56} In recent years, lipids of this type with enriched hydrophilic fragments have attracted attention of investigators due to their peculiar behaviour in some enzymic reactions⁵⁷ and in membrane modification⁵⁸⁻⁶⁰ and also due to the prospects for their clinical application.⁶¹

The acylation reactions considered above have also been extended to the synthesis of erythritol phospholipids of the amidophosphite **51** and phosphate types **52**.⁶²

X = O, S, Se; $n = 2, 3$; R = C₁₅H₃₁, C₁₇H₃₅.

It is noteworthy that the efficiency of acylation in the case of phosphoryl, thionophosphoryl, and selenophosphoryl derivatives of erythritol is virtually identical. In this respect, trimethylol phospholipids differ from glycerophospholipids.

VI. Synthesis of phospholipids based on orthoesters

Orthoesters are classical reagents for fine organic synthesis, which are widely used in preparative practice, especially in the synthesis of heterocyclic compounds. As a rule, their transformations are associated with the formation of stabilised carbocations that are attacked by nucleophiles.^{2,3,5} The reactions of orthoesters with electrophiles have received much less attention.

The interaction of orthoesters with phosphorus and sulfur halides resulting in esters of the corresponding mineral acids has been reported.⁶³⁻⁶⁵ Reactions of orthoesters with carboxylic acids, their anhydrides, acyl chlorides, and acyl cyanides have also been described.⁶⁶⁻⁷⁰ These reactions give mixtures of esters and other products. For example, mixing of ethyl orthoformate and acetyl chloride at 20 °C results in ethyl formate, ethyl acetate, and ethyl chloride.⁶³ The use of chlorides of higher fatty acids in acylation has led to similar results.⁷¹

The interaction of acid chlorides with bicyclic orthoesters **53** proceeds in a different way; In this case, complete acylation occurs to give triesters **54**.⁷¹

R = H, Me.

This reaction has been used in the total synthesis of pentaerythritol homocholine phospholipids. To this end, phosphorylated bicyclic orthoesters **55** were converted into triacylphosphates **56** by direct acylation with palmitoyl and stearoyl chlorides.⁷¹

R' = H, Me; X = O, S; R = C₁₅H₃₁, C₁₇H₃₅.

It has been expedient to include this reaction in the scheme of the synthesis of phospholipids, because, in this case there is no need to protect three alcoholic hydroxyls prior to phosphorylation of pentaerythritol and to remove protective groups after phosphorylation.

This reaction has a wide range of synthetic applications, since both phosphate and thiophosphate compounds successfully enter into it. Its practical utility becomes even more evident from the fact that the cyclic phosphates **56** formed proved to be effective alkylating agents. Owing to this property, they were used for obtaining previously unknown pentaerythritol homocholines **57**.⁷¹

X = O, S; R = C₁₅H₃₁, C₁₇H₃₅.

Like bicyclic orthoesters of carboxylic acids, the corresponding orthoesters of phosphorous acid (bicyclic phosphites) **58** also undergo acylation. Here the electrophilic reagent attacks the oxygen atoms rather than the phosphorus atom as could be expected for an Arbuzov reaction.⁷²

R = CH₃, C₁₅H₃₁, C₁₇H₃₅.

A specific feature of the bicyclic phosphites **58** is their relative inertness in acylation in which only one acyl group is introduced into their molecules.

The resulting cyclic chlorophosphites **59** were used in the syntheses of various lipid-like compounds and other products.⁷²

VII. Synthesis of phospholipids based on oxazolines

Further extension of studies on the acylation of geminal systems has led to the involvement in this process of oxazolines, which had been barely regarded as nucleophiles before.^{3,63} Recently, it has been shown that these accessible and convenient compounds interact specifically with higher carboxylic acid chlorides to yield new types of nitrogenous phospholipids. For example, the reaction of cyclic bis(thiophosphates) of the oxazoline series **60** with stearoyl chloride gave the product of extensive acylation **61**.⁷³

R = H, Me.

In this case, as well as the oxygen atoms of the oxazolines, the nitrogen atoms were also attacked by the electrophilic acylating agent. This reaction is also unique, because it occurs as double *N*-acylation.

It should be noted that in early syntheses of *N*-monoacyl analogues of glycerophosphocholines based on D- and L-serines with the use of oxazoline protection, the introduction of fatty acid residues into lipid molecules has been carried out in two stages: deprotection in a strongly acidic medium and acylation of the amino alcohols formed with acid chlorides, anhydrides, or esters.^{74,75} The new reaction of direct acylation of oxazolines has broadened considerably the potentialities of phospholipid synthesis.

VIII. Conclusion

The main conclusion of the present review is that a new method of *O*- and *N*-acylation has been added to the arsenal of fine organic synthesis; this method can be applied to the design of lipids and other complex polyfunctional systems. The method is facile and is therefore promising. At the same time, it has a number of specific features as regards the design of synthetic schemes; in particular, it may exclude the stage of obtaining intermediate polyhydroxylic structures.

Studies of the acylation of acetals have been mostly carried out in relation to the synthesis of carboxylic acid esters. Meanwhile, this reaction is also promising for the synthesis of phosphorous acid esters and, obviously, of other types of esters. We have already mentioned the interaction of 1,3-dioxolanes with ethylene chlorophosphite, which occurs as *O*-phosphorylation of the cyclic acetal.¹⁰ Recent studies have demonstrated the possibility of conducting related phosphorylation. It is the intramolecular cyclisation of acetals **62**, the molecules of which contain a dichlorophosphite group.⁷⁶

This simple reaction is a convenient method for the synthesis of framework bicyclic phosphites of carbohydrates **63**.

The synthesis and properties of interstitial phase films

R A Andrievskii

Contents

I. Introduction	53
II. Preparation	53
III. Composition, structure, defects, and electronic structure	56
IV. Properties	61
V. Conclusion	68

Abstract. The methods of synthesis of interstitial phase films (transition metal carbide, nitride, boride, and hydride films) are described. Different versions of their chemical and physical deposition from the gas phase are compared and discussed. The available information about the structures, electronic structures, and physicochemical properties of the films (including alloyed and multilayer films) is surveyed and analysed. The bibliography includes 225 references.

I. Introduction

The term 'interstitial phases' (IP) (or interstitial alloys, interstitial compounds, and Hagg's phases) appeared more than 60 years ago in studies of the structures of the phases in transition metal–light nonmetallic element (hydrogen, nitrogen, boron, carbon, etc.) systems. Hagg¹ put forward the hypothesis that the small atoms of the light elements are inserted in the interatomic sites within typical close-packed metallic structures: face-centred cubic (FCC), hexagonal close-packed (HCP), and body-centred cubic (BCC).

The structures of typical IP of the NaCl type, in which the octahedral positions in the metallic FCC sublattice are occupied by carbon or nitrogen atoms, and of the CaF₂ type, in which the hydrogen atoms are located in tetrahedral positions of the FCC lattice, are well known from the results of neutron diffraction studies.² The structures of the borides are somewhat more complex in most cases than those of the hydrides, carbides, and nitrides, but the familiar simple relations, proposed by Hagg and based on a purely geometrical approach, proved suitable only for stoichiometric phases. Deviation from stoichiometry led in the vast majority of cases to the ordering of the nonmetallic sublattice and the formation of IP with a complex structure, the metallic sublattice of which was no longer in any way characterised by simple FCC, HCP, or BCC type packing. For this reason, as has been emphasised in the monograph of the present author and Umanskii,² the term 'interstitial phases' is mainly of historical significance. At the present time the IP include Group III–VI

transition metal hydrides, nitrides, carbides, and borides with metal-like properties, as well as certain monoxides (for example, TiO). A series of monographs (see, for example, Refs 2–21) and a multiplicity of communications have been published in collections and numerous periodicals devoted to the problems of the preparation, properties and applications of IP. However, questions concerning films have been described in the monograph literature on a very limited scale — so far as we are aware, only in a single monograph.⁷ This situation is due to the fact that IP films began to be actively investigated only during the last 10–15 years after the development of an effective method for their preparation by physical deposition from the gas phase (the so called PVD technology), although chemical deposition from the gas phase (the CVD technology) had long been known. The extensive application of such films in the tool industry and in electronics stimulated the study of the characteristic features of their synthesis and properties. As regards the number of publications, titanium nitride is the undoubted leader. In this connection, one should note the reviews^{22–28} and certain monographs on films and coatings.^{29–31} The available information on nitride, boride, carbide, and hydride films is scattered in the periodical literature and needs to be surveyed. We may also note that this problem appears of current interest also in connection with the development of studies on IP-based nanocrystalline materials.^{32, 33}

II. Preparation

We shall consider films with a thickness up to several micrometers. Thicker films and coatings will not as a rule be analysed. Table 1 presents the principal methods of preparation of IP films. The classification presented is arbitrary because, for example, many physical methods include chemical reactions and chemical procedures have been stimulated by physical influences.³² The table includes only the principal methods of synthesis (vaporisation and condensation processes in an inert medium or in the reaction medium are usually implied). Nitride films can be obtained by virtually all methods, while hydride films can be prepared only by the low-temperature methods in view of the considerable dissociation pressures of the hydrides. The carbide and boride films occupy an intermediate position.

1. Physical methods

a. Thermal evaporation

In connection with the high melting points of the majority of carbides, nitrides, and borides, the processes involving evaporation by resistive or radiation-induced heating are used compara-

Table 1. Principal methods of preparation of IP films.

Method	Principal varieties	Compound
Physical methods		
Thermal evaporation	Activated reactive evaporation	Nitrides and carbides
	Electron-beam heating	Borides and carbides
	Laser treatment	Nitrides and carbides
Ion plating	Ion arc sputtering	Nitrides and carbides
	Magnetron sputtering	Nitrides, borides, carbides and hydrides
	Ion-beam treatment; implantation	Nitrides and borides
Chemical methods		
Deposition from gas phase	Plasma-associated and plasma-activated CVD processes; electron cyclotron resonance	Nitrides, carbides, and borides
Thermal decomposition	Gaseous and condensed precursors	Nitrides and borides
Nitridation and hydridation	Low-temperature version; implantation	Nitrides and hydrides

tively rarely. Electron-beam evaporation (EBE) has been used to obtain carbide, boride, and carbidoboride (TiC/TiB₂) films.³⁴ This method has been used with heating of the substrates to high temperatures (650–1600 °C); the rate of deposition was up to 6 µm min⁻¹ and the thickness of the layers was 0.25–0.3 mm, but their hardness was relatively low (up to 20–30 GPa) owing to intense recrystallisation. Laser evaporation (LE) is also used.

The thermal vaporisation of metals and alloys in a reaction medium with simultaneous saturation by the interstitial elements (carburation, nitridation and hydridation) is more common. A version of this method — activated reactive evaporation (ARE) — is particularly well known, although the latter is ‘akin’ to ion deposition processes. Laser reactive sputtering of niobium targets in carbon-containing media for the preparation of superconducting niobium carbide films has been described.³⁵ The use of a glow discharge and of other plasma-activating processes for these purposes is known,³⁶ but the most effective variety of the ARE is arc vapour ion deposition (sputtering) (AVID).

In order to obtain IP films by the thermal vaporisation method, account must be taken of the characteristic features of this process. The compounds from which films are obtained possess in most cases wide ranges of homogeneity and vaporise predominantly (at least in the initial stage) incongruently. The possibilities of statistical-thermodynamic methods, which make it possible to estimate the rates of vaporisation and the congruently vaporising IP compositions have been examined in monographs.^{2, 19}

The vacuum vaporisation of intermetallic compounds of the type FeTi and LaNi₅ with subsequent hydridation (VViH) is also used to obtain hydride films (see, for example, Singh et al.³⁷ and Li and Cheng³⁸).

b. Ion plating

The term ‘ion plating’ was first encountered in the communication of Mattox and McDonald³⁹ for the designation of a wide range of plasma-activated PVD processes in which the surface of the support was subjected to the action of an ion stream before the deposition of the film. The excitation of an arc discharge in a

nitrogen or carbon-containing atmosphere is one of the most common variants of this technology, which has found extensive industrial application (on ‘Bulat’ type devices in our country). Metallic cathodes are used as a source of metal ions in AVID, high degrees of ionisation being attained under these conditions (from 30% to 100%), the kinetic energy of the ions is from 10 to 200 eV, and the rate of deposition may be up to 1–3 µm min⁻¹.^{40, 41}

In most cases Ar + N₂ or Ar + C_nH_m reactive working media at a pressure of ~10⁻³ mm Hg and metallic cathodes (Ti, Ti–Al, Zr, Mo, Cr, etc.) are used in AVID. The principal deficiency of AVID is the formation of the so-called drop phase as a result of the intense influence exerted by the arc on the cathode and the high probability that metal drops enter into the films deposited. Filtered AVID processes, where the drop phase can be to a large extent filtered off by means of a magnetic field, are known.^{24, 42, 43} Also known are hybrid variants of PVD, including both multi-cathode devices and a combination of AVID and magnetron sputtering (MS), which makes it possible to obtain a wide variety of types of multilayer and doped films.⁴⁴

A more flexible variety of ion deposition is MS. In magnetron sputtering, it is possible to employ not only metal and alloy cathodes but also cathodes made of IP as well as nonmetallic compounds and to reduce the temperature of the support to 100–200 °C and sometimes even below that. These factors greatly expand the possibilities for the preparation of films in amorphous and nanocrystalline states and also of supersaturated solid solutions. There are numerous variants of MS: d.c. sputtering, high-frequency sputtering, application of a bias voltage to the substrate, the use of so called unbalanced magnetrons, etc.^{24, 26, 41} However, the degree of ionisation, the kinetic energy of the ions, and the rate of deposition are in almost all cases lower than for AVID (< 10%, up to 10 eV, and < 0.1–0.2 µm min⁻¹ respectively).

Different variants of the ion-beam treatment (IBT), in which atoms are dislodged from the target by the bombardment of its surface with ion beams, have also come to be widely used. The ion beams are also employed for the treatment of the films formed. Figs 1 and 2 present two schemes for the ion-stimulated deposition of nitride films. In the first case, the metal ions are generated by bombarding a metallic target with inert gas or nitrogen ions and in the second a stream of metal atoms is generated by means of an electron-beam treatment.^{45, 46} Such methods make it possible, on the one hand, to synthesise superstoichiometric compounds⁴⁵ and, on the other, to vary the crystallisation conditions. For example, bombardment with heavy ions (320 keV Ar²⁺ or 320 keV Xe²⁺) in the deposition of TiB₂ films leads to the appearance of crystallinity even when the process is carried out

**Figure 1.** Schematic illustration of the binary ion-stimulated deposition of nitride films.⁴⁵

at room temperature.⁴⁷ Only the formation of amorphous films was observed under these conditions without an ion-beam treatment. The use of molecular dynamics methods for IBT processes has been described.⁴⁸

2. Chemical methods

a. Deposition from the gas phase

The traditional CVD technology, associated with high-temperature gas reactions of the type

has long been used to obtain wear-resistant protective layers, films, and general purpose coatings. Reactions (1)–(3) have been formulated in their final form but in fact they consist of many stages and in addition admixtures of oxygen complicate their occurrence in almost all cases. A comprehensive review of the studies devoted to wear-resistant TiN CVD coatings has been published.²⁷ Not only single-layer IP films but also multilayer and doped compositions of the type $Ti(C_xN_y)_z$, $TiC + TiN$, $TiC + Al_2O_3$, $TiC + TiB_2$, and $TiC + Al_2O_3 + TiN$ have been developed and are manufactured on the industrial scale.^{24, 27}

In most cases the temperature range for the deposition of CVD films is 900–1100 °C. Rates of deposition of 0.03–0.2 $\mu m \min^{-1}$ are typical for these conditions. The search for the possibility of reducing the process temperature, dictated mainly by the requirements of electronics and machine building, have led to the creation of different variants of physically stimulated regimes, in which plasma and laser techniques, electron cyclotron resonance (ECR), etc. are used.^{49–54} The following features are characteristic of these variants:

(1) the deposition temperature is reduced to 600–300 °C and below;

(2) the rates of deposition are 0.001–0.2 $\mu m \min^{-1}$;

(3) organometallic precursors of the type of titanium tetrakis[dimethyl (or diethyl) amides] or tetraisopropoxide — $Ti[N(CH_3)_2]_4$, $Ti[N(C_2H_5)_2]_4$ and $Ti[OCH(CH_3)_2]_4$ — having a high vapour pressure are used;

(4) compared with the usual CVD technology, these methods require special apparatus, so that their application is in most cases justified economically only in electronics.

Figure 3 presents a schematic illustration of the apparatus in which titanium tetrakis(dimethylamide) vapour and nitrogen are used and which is activated in an ECR cell.⁵¹ The initial vacuum in the apparatus is maintained with the aid of a turbomolecular pump at a level below 10^{-10} mm Hg, while the working nitrogen pressure is 10^{-4} mm Hg. The temperature of the substrate, on which a shift potential is established, amounts to ~ 100 °C. The highest rates of deposition ($\sim 6 \times 10^{-4} \mu m \min^{-1}$) and comparatively low electrical resistances of the films have been observed when a shift potential of -50 V was applied to the support. The composition of the films, monitored with the aid of XPES, proved to be as follows (at. %): Ti ~ 42 , N ~ 42 , C ~ 10 , O ~ 6 . Other schemes for the employment of ECR in order to obtain TiN films have been described. When these schemes are employed, the impurity content can be reduced by an increase in temperature but the rates of deposition remain nevertheless relatively low ($\sim 10^{-3} \mu m \min^{-1}$).^{52–54}

Figure 3. Schematic illustration of the apparatus for the deposition of TiN films using an organometallic precursor and the activation of nitrogen by means of cyclotron resonance.⁵¹

(1) turbomolecular pump; (2) nitrogen traps; (3) substrate with a device for heating and the measurement of temperature; (4) bias voltage source; (5) organometallic precursor ($T = 75$ °C); (6) supply of nitrogen; (7) cell of 90 W cyclotron resonance apparatus with a high-frequency generator and source and mains potential generators.

Examples of the synthesis of films comprising complexes of group IV and V transition metal tetrakis (dialkylamides) and ammonia at atmospheric pressure have been described.^{55, 56} Fairly high rates of deposition (0.02–0.2 $\mu m \min^{-1}$) and low temperatures (200–400 °C) were then noted and the impurity content was low; the formation of TiN , Zr_3N_4 , Hf_3N_4 , VN , Nb_3N_4 , and Ta_3N_5 was detected. Epitaxial layer-by-layer growth of TiN film at 500 °C was observed when $TiCl_4$ and NH_3 were supplied alternately to the support with injection of zinc vapour after the supply of titanium chloride.⁵⁷

It is seen from the foregoing that, in the course of the updating of the regimes in the traditional CVD technology, experimental data have accumulated and new schemes have been tested, but it is so far difficult to give preference to any one of them.

b. Thermal decomposition

The thermolysis of gaseous and condensed precursors for the preparation of IP films is used comparatively rarely. As regards titanium nitride and carbonitride films there have been indications that thermal decomposition of organometallic compounds of the type of titanium tetrakis(dialkylamides), including polymeric ones, is possible without the addition of ammonia to the reaction zone.^{49, 58}

The deposition of titanium, zirconium, and hafnium boride films by the thermolysis of borohydrides has been described in several communications (see, for example, Refs 59–62). At fairly low decomposition temperatures (100–250 °C), the formation of both amorphous and crystalline films with a fairly high metallic conductivity is observed. The latter property is particularly attractive for the employment of these films in electronics as diffusion barriers. However, owing to the high reactivity of borohydrides, so far boride films are obtained by this method mainly on a laboratory scale.

c. Nitridation and hydridation

The nitridation and hydridation methods are applied in different variants: ionic and laser implantation of nitrogen and other interstitial elements in thin metallic films (Figs 1 and 2) or surface layers,^{63–65} nitridation of surface layers in a high-frequency discharge,⁶⁶ high-temperature (400 °C) nitridation by hydrazine,⁶⁷ and hydridation of films at low temperatures including electrochemical and magnetron synthesis.^{37, 38, 60, 69} However, compared with methods for deposition from the gas phase and thermal decomposition, nitridation and hydridation have no special advantages. Hydride films may be an exception, but the characteristic features of their preparation have so far been investigated on a limited scale.

III. Composition, structure, defects, and electronic structure

The thickness of the films determines the application of the corresponding methods for their investigation.⁷⁰ This applies particularly to the study of their decomposition and defectiveness, for which many methods are employed; XPES, XRD, Auger electron spectroscopy (AES), scanning and transmission electron microscopy (SEM, TEM), Rutherford back scattering spectroscopy (RBSS), electron microprobe analysis (EMA), positron annihilation spectroscopy (PAS), secondary ion mass spectrometry (SIMS), scanning tunnelling and atomic force microscopy (STM, AFM), selected area electron diffraction (SAED), and others. In most cases, two and more methods are used to ensure the reliability of the results.

1. Composition

Table 2 presents certain results of the analysis of the composition of IP films obtained by different methods. The formulae of the films, found in a number of investigations,^{51, 52, 54, 60, 72, 75, 76} were calculated by ourselves on the hypothesis that the boron, nitrogen, oxygen, and carbon atoms are located in one sublattice (for example, in octahedral positions), while the smaller hydrogen atoms are in another sublattice (for example, in tetrahedral positions). In many cases, the synthesis of IP films is accompanied by the formation of superstoichiometric compounds. The influence of argon pressure on the boron content in diboride (TiB₂ and ZrB₂), hexaboride [(La, Ce, Sm, Y)B₆], and dodecaboride (ZrB₁₂) films obtained with the aid of MS has been examined.⁷⁷ The formation of superstoichiometric phases in the first two cases and of prestoichiometric phases in the last case was noted. This was attributed to the characteristic features of the mobility and the collision reactions of the boron and metal atoms. The formation of superstoichiometric titanium carbonitrides and boridonitrides with the aid of MS has also been reported.⁷⁸ The important question concerning the relation between the compositions of the target and the sputtered film as regards IP has not so far been considered in detail. It has been noted⁷⁸ that the depletion in carbon of a nonstoichiometric titanium carbide (TiC_{0.5}) target has been detected with the aid of MS.

In the synthesis of the usual IP, the formation of superstoichiometric phases is observed mainly in the presence of oxygen impurities, which leads to the appearance of structural (non-thermal) vacancies in the metallic sublattice.^{2, 7} The insufficiently complete attestation of the compounds listed in Table 2 precludes

Note. The following designations have been adopted: LRS — laser reactive synthesis; ECR — electron cyclotron resonance; TD — thermal decomposition; DCMRS and DCMNS — direct current magnetron reactive and nonreactive (i.e. sputtering by neutral atoms) sputtering respectively; HFMRS and HFMNS — high-frequency magnetron reactive and nonreactive sputtering respectively.

conclusions concerning the nature of the superstoichiometry of the IP films. Accurate measurements of the X-ray and pycnometric densities as well as detailed elemental and phase analyses are therefore needed. One should bear in mind that the agreement between the results of the determination of the elemental compositions of the films by various methods is not always satisfactory and this problem requires special consideration in almost every case.

Oxygen is one of the commonest impurities in IP. Fig. 4 presents the dependence of the titanium, nitrogen, oxygen, and carbon concentrations on the surfaces of TiN films on the partial pressure of oxygen in a direct current magnetron reactive sputtering (DCMRS) chamber. The plots were constructed from results obtained by the AES method *in situ*.⁷⁹ Analysis demonstrated how important is the 'vacuum hygiene' in the preparation of IP films: at an oxygen partial pressure in excess of $\sim 10^{-6}$ mm Hg (total pressure $\sim 10^{-3}$ mm Hg), a decrease in the nitrogen concentration and an increase in the oxygen impurity content are observed. A similar situation has been noted also for water vapour.

Figure 4. Dependence of the concentrations of oxygen (1), nitrogen (2), carbon (3), and titanium (4) on the surfaces of TiN films on the partial pressure of oxygen.⁷⁹

Figure 5. Variation of the contents of argon (1), neon (2), and xenon (3) in the region of homogeneity of hafnium nitride.⁴⁵

The presence in the films of inert gas atoms, entrained in the course of sputtering and implantation, is noteworthy. Fig. 5 presents the dependence of the argon, neon, and xenon contents on the composition of hafnium nitride films synthesised in accordance with the binary ion-stimulated deposition scheme (Fig. 1). The content of the inert gases increases significantly with increase in the amount of nitrogen in the superstoichiometric nitrides, the total amount of these gases being, as expected, inversely proportional to their atomic radius. The above concentration dependence may be associated with increase in the concentration of structural vacancies in the nonstoichiometric phases. An approximately similar situation has been observed also for titanium and zirconium nitrides.

Interesting possibilities of XPS in relation to the analysis of $\text{Ti}(\text{B},\text{N})_x$ films have been demonstrated by Mollart et al.⁸⁰ Fig. 6 presents the XPE spectra of the 1s states of boron and nitrogen in

Figure 6. XPE spectra of the 1s states of boron and nitrogen in nitridoboride films of different composition before annealing (a) and after annealing at 400 °C (280 min) (b).⁸⁰ (1) TiB_2N ; (2) $\text{TiBN}_{0.5}$; (3) $\text{Ti}_2\text{BN}_{0.5}$.

nitridoboride films of different composition in the initial and annealed states. The films were obtained by the direct current magnetron nonreactive sputtering (DCMNS) method using $\text{Ti}-\text{BN}$ composite targets of different composition. By employing standards for TiB , TiB_2 , BN , and B_2O_3 , it was possible to estimate with an accuracy of $\pm 30\%$ the phase compositions of different films, which agreed qualitatively with data obtained from the $\text{Ti}-\text{B}-\text{N}$ phase diagram. The XRD and AES methods proved less informative in this respect, although the latter has been recommended for the determination of the $[\text{N}]/[\text{Ti}]$ ratio in titanium nitride.⁸¹

2. Structure and defects

a. Lattice parameters and occupancy of sublattices

The IP structure began to be investigated a long time ago, but an insufficiency of results obtained on well attested objects is nevertheless still felt. It was noted above that accurate measurements of the X-ray and pycnometric densities are needed for the elucidation of the occupancy of the metallic and nonmetallic sublattices in IP. Such densities are nontrivial for low dimensionality objects such as films.

A decrease in the lattice parameter on deviation from stoichiometry has been noted for both the usual⁸² and film^{22,83} titanium nitride specimens (Fig. 7). A similar situation is characteristic also of hafnium nitride.⁸⁴ The absolute values of the lattice parameters for IP films are usually greater than for massive specimens. This is as a rule attributed to the influence of the residual stresses, the grain size, and also the presence of impurities. It is striking that the period depends on the film thickness. A decrease in the lattice parameter with increase in the thickness of TiN , NbN , and CrN films has been noted (it is particularly marked up to a thickness 50–150 nm); on the other hand, for a zirconium nitride film the lattice parameter also increases with increase in thickness.⁸⁵ The presence of an appreciable crystallographic anisotropy in the lattice deformation parameters for the substoichiometric and stoichiometric titanium nitrides is also of interest.⁸³ Thus the relations $a(200) > a(111)$ and $a(200) < a(111)$ are characteristic of $\text{TiN}_{\sim 0.55}$ and $\text{TiN}_{\sim 1.0}$ respectively. The latter relation is also observed for superstoichiometric TiN films, which has been attributed to the possible formation of a phase with a CaF_2 type structure in the form of nanocrystals.⁸⁶ However, an unambiguous treatment of these and other changes in the lattice period in IP films requires additional studies and a detailed elemental analysis.

Figure 7. Variation of the density (γ) in the region of homogeneity of titanium nitride films.³²

Dashed line—calculated results obtained, on the basis of a purely vacancy approach.

In a number of investigations, the point defects in the films were studied by positron annihilation spectroscopy.^{84, 87–89} The presence of defects of the type of vacancies, interstitial atoms, micropores, and others has been noted. However, the treatment of the annihilation characteristics in IP with different sublattice occupancy is still far from being fully understood, so that neutron diffraction studies with determination of the locations of light

atoms and of the ordering of structural vacancies might therefore 'throw light' on this problem.

Certain interesting features of the crystal structures of Ti(Si, N, O), NbN, ZrN, LaB₆, CeB₆, SmB₆, ZrB₂, and TiB₂ films (anisotropy of the lattice parameters, the influence of the film thickness on the crystallinity), as well as single crystal film deposition processes, the formation of supersaturated solid solutions, etc. have been examined in a number of investigations.^{77, 90–94} The characteristics of the ordering in IP films remain virtually little investigated, although an appreciable amount of information has accumulated for these compounds in the usual (nonfilm) form.^{2, 10, 20}

b. Residual stresses and texture

The residual stresses in IP and their structure have been thoroughly investigated and described in the literature (see, for example, Refs 22, 24–26, 83, and 95–97). The residual macrostresses are measured by an X-ray method (the so called $\sin^2\psi$ method) and many mechanical methods. It is believed that the residual stresses are due to the difference between the coefficients of linear thermal expansion of the film and the substrate and also to the characteristic features of the film growth. For the majority of PVD films, these stresses are compressive; for TiN CVD films, tensile stresses have been noted.²⁵ Appreciable compressive stresses have been detected also for TiC and TiB₂ PVD films.^{22, 93} It has been observed that the bias voltage and ion bombardment exert a significant influence on the residual stresses.^{26, 83} In the region of homogeneity of TiN, the residual stresses vary nonmonotonically, minimum stresses being characteristic of the TiN_{0.7} composition, to which the maximum hardness corresponds (see below).⁹⁵

The study of the texture of TiN CVD films revealed that the preferred orientations depend on the deposition temperature and on the molar ratio $[\text{TiCl}_4]/[\text{NH}_3](m_{\text{N}}/[\text{Ti}])$.⁹⁸ Three types of preferred orientations have been detected; the $\langle 100 \rangle$ texture is characteristic of low deposition temperatures; the $\langle 110 \rangle$ texture corresponds to moderate temperatures and low values of $m_{\text{N}}/[\text{Ti}]$; the $\langle 111 \rangle$ texture corresponds to high process temperatures and high values of $m_{\text{N}}/[\text{Ti}]$. The changes in the nature of the texture are attributed to the characteristic features of the supersaturation in the gas phase. Weber et al.,⁵² who used the ECR method to activate nitrogen, noted that the preferred $\langle 200 \rangle$ orientation was observed for TiN films when N₂ was employed, while the $\langle 111 \rangle$ texture was characteristic of the film when ammonia was employed. It has also been noted that the latter texture is manifested for titanium nitride (PVD) with a nearly stoichiometric composition (TiN_{0.88–1.0}); for compositions with a lower nitrogen content, the $\langle 311 \rangle$ and $\langle 200 \rangle$ textures predominate.⁹⁵ The influence of substrate layers (titanium nitride or carbide) on the textures of AVID carbide and nitride films respectively and also of multilayer nitride films has been analysed.^{85, 97}

The influence of film thickness and partial nitrogen pressure in PVD processes has been investigated.^{99, 100} With increase in film thickness from 1.3 to 6.8 μm , the preferred texture changed from the $\langle 200 \rangle$ orientation to $\langle 111 \rangle$; the opposite change was observed when the partial nitrogen pressure was increased, which was accompanied by a decrease in the residual compressive stresses. Such changes in texture are associated with the deformations accumulating during the deposition of the films when account is taken of the anisotropy of the surface energies of different crystallographic faces.

Figure 8 illustrates the influence of the thickness of the TiB₂ films obtained by the DCMRS method on the nature of the X-ray peaks.⁹³ The ratio of the intensities of the (001) and (101) reflections is manifested fairly clearly only for thicknesses in excess of 1300 Å. A predominantly random orientation is characteristic of thinner films (Fig. 8a), while the $\langle 001 \rangle$ texture begins to be manifested distinctly when the thickness increases.

Figure 8. Diffraction patterns for a TiB₂ film obtained at an angle of 5° .⁹³ (a) the influence of thickness; (b) film 860 Å thick; film thickness (Å): (1) 5000; (2) 2800; (3) 1800; (4) 1300; (5) 860.

The thermal stability of texture orientations in IP films has been investigated on a limited scale.

c. Grain size (of crystallites) and morphology

The study of the fine structure [the size of the crystallites (L) and microstrains (ϵ)] and also of the morphology of IP films is needed to elucidate their properties. Fig. 9 presents the (200) and (111) reflections for a titanium nitride film obtained in accordance with the ion-stimulated deposition scheme (Fig. 2).⁴⁶ The broadening of the peaks as the energy of the Xe ions is varied can be seen. The quantity L is estimated from the familiar Scherrer formula using the measured peak width at half-height level. For accurate calculations, it is necessary to take into account the contribution of microdistortions to the width of the peaks. For this purpose, use is made of different modifications of the familiar Warren–Averbach and Williamson–Hall methods.¹⁰¹

Table 3 presents certain results of the determination of the values of L and ϵ for IP films. The size of the crystallites in the films investigated is in most cases < 50 nm and they can therefore be assigned to the class of nanocrystalline (nanostructural) objects. A detailed study of the influence of the temperature of the substrate, the bias voltage, and the duration of sputtering on the value of L estimated from the width of the (111) reflection has been undertaken for TiN.¹⁰⁵ It is of interest that the influence of temperature is manifested distinctly only for a bias voltage of about -60 V, whereas at -100 and -200 V it is virtually absent in the temperature range $150–500^\circ\text{C}$. The influence of various factors on L and ϵ for the magnetron sputtering of a wide variety of targets (TiNi, TiC_{0.5}, TiB + Ti, etc.) has been described.^{78, 107} It was noted in the same investigations, in particular, that the reason for the difference between the values of L determined by the XRD

and TEM methods may be packing defects, which contribute to the broadening of the X-ray reflections and the block nature of the structure. Such differences for nanocrystalline materials are fairly frequent,¹⁰¹ which is associated with the columnar nature of the morphology of many IP films. A combination of various methods for the determination of L is therefore needed, particularly in relation to multilayer objects.⁹⁶

The presence of edge misfit dislocations with a Burgers vector $1/2 [110]$, characteristic of carbides and nitrides with the NaCl structure, has been detected in multilayer TiN, NbN, VN, and (TiV)N films, which were deposited by the DCMRS method on the (100) face of a MgO single crystal.¹⁰⁸ The relaxation of the stresses with formation of a domain structure under the influence of the differences between the lattice periods and layer thicknesses has been observed. The density of the loop dislocations fell from 5×10^{12} to $1.5 \times 10^{10} \text{ cm}^{-2}$ with increase in the temperature of the single crystal support from 550 to 850 °C, which ensured the formation of single crystal TiN films.¹⁰⁹

The morphology of the structural features of IP films may be characterised as columnar and as random with a wide range of intermediate variants. Fig. 10 presents a typical columnar structure of a TiN film obtained by the DCMRS method.¹¹⁰ In cross section, the size of the crystals reaches 200–300 nm. This photograph clearly illustrates also the presence of a residual plastic deformation of the fibres of the brittle titanium nitride in the

Figure 10. The fracture surface in a TiN film in the region of indentation by the microhardness measuring device.

The photograph was taken on a high-resolution scanning electron microscope (FEG-SEM) and has been kindly provided by Ma and Bloyce.¹¹⁰

region of the microindentation. The influence of the deposition temperature and of the shift potential on the morphology of TiN films has been described.¹⁰⁵ Depending on the deposition conditions, in cross section the form of the crystals varied from triangular to square and their size was between 50 and 500 nm, which is greater by factors of 2–4 respectively than the X-ray determinations of L (Table 3). This difference must be attributed to the approximate nature of the estimates from the Scherrer formula. Another type of fracture in TiN films obtained by the DCMRS method in apparatus with four planar nonbalanced magnetrons (a columnar amorphous structure) has been described by Effoglu et al.¹¹¹ The possibility of obtaining columnar structures by employing stronger magnetic fields was demonstrated in the same study. It is of interest that films with a noncolumnar amorphous structure had more effective mechanical and operational properties. It has also been noted that the imposition of a shift potential during magnetron sputtering promotes the elimination of the porosity of the films.¹¹²

The study of the fractures in boride films (see, for example, Refs 74, 76, 77, 113, and 114) revealed different structural types. A stone-like fracture or a 'cauliflower' type fracture with a partially manifested columnar structure is characteristic of these films, the columnar structure becoming more pronounced with increase in the nitrogen content (Figs 11 and 12). The porosity of the films is usually low or virtually absent, but it must nevertheless be taken into account in the analysis of the properties of the films. The

Figure 11. The fracture surface in a TiB₂ film obtained by the DCMNS method.¹¹⁴

Figure 12. The fracture surface in a Ti(B,N)_x film obtained by the DCMNS method.¹¹⁴

methods for the determination of porosity from electrochemical measurements in relation to TiN, Ti(B, N) , and $(\text{Ti, Al})\text{N}$ films have been described by Aromaa et al.¹¹⁵ and the general features of the macro- and micro-defects in the coatings have been analysed in a monograph.¹¹⁶ We may note that the general level of the porosities of films obtained by the IBT and HFMNS methods was from 0.003% to 0.239%.¹¹⁵ The topography of the film surfaces was investigated both with the aid of scanning electron microscopy (Figs 10–12) and (especially) scanning tunnelling and atomic force microscopy.¹¹⁷

The characteristic features of the morphology of the IP films obtained with the aid of CVD technology have been examined in a series of studies (see, for example, Refs 27, 55, and 118–120). It is important to note that, when two- or three-phase systems (compositions such as TiB_2 – TiC , SiC – TiC – C , TiN – AlN , etc.) are codeposited, nanostructural multilayer and mixed films, coatings, and layers with $L \approx 10$ – 20 nm may be obtained judging from the equilibrium phase diagrams. By virtue of the high process temperatures (~ 1000 – 1100 °C), the rates of deposition are very high (~ 1 mm h^{-1}). For the SiC – TiC – C nanocomposites, a texture in the growth of $(\text{Si, Ti})\text{C}$ crystallites with a transverse dimension of 10–15 nm in the $\langle 220 \rangle$ direction was noted; according to Raman spectroscopic data, the size of the graphite inclusions did not exceed several nanometers.¹¹⁹

Thus a wide spectrum of morphological structures, caused by the diverse influence of the deposition conditions, impurities, and other factors in the PVD and PCD processes, is characteristic of IP films. In a number of studies (see, for example, Refs 24, 26, 121, and 122), attempts were made to put forward schemes which would make it possible to predict the formation of particular structures in the PVD films. The prediction was based on the analysis of homologous deposition temperatures, the gas pressure, the shift potential, etc. Estimates of the conditions for the production of single crystal and polycrystalline formations are available for CVD films.¹²³ However, in the vast majority of cases the predictions are so far qualitative in character.

A schematic illustration of typical morphological structures is presented in Fig. 13 in relation to TiN and $(\text{Ti}_{0.5}\text{Al}_{0.5})\text{N}$ PVD films. The authors of this scheme²⁸ note that, apart from the principal factors indicated (deposition temperatures and ionic characteristics), parameters such as the composition of the plasma-forming gas, the impurities, etc. may greatly alter the nature of the morphology of the deposited films. The wide variety of factors exerting an influence, listed above, does not as yet permit an *a priori* prediction of the formation of particular morphological structures and this question requires further study.

Figure 13. Schematic illustration of typical morphological structures of TiN and $(\text{Ti}_{0.5}\text{Al}_{0.5})\text{N}$ PVD films.²⁸

(a) low deposition temperatures ($T < 500$ °C) and low energy characteristics of the ions; (b) low deposition temperatures and average energy parameters of the ions (100–500 eV) (c) high deposition temperatures ($T > 500$ °C) or low temperatures but high low-energy ion fluxes.

3. Electronic structure and chemical bonding

The electronic structure and chemical bonding in carbide and nitride films have been investigated by numerous workers (see, for example, Refs 21, 55, 56, 84, and 125–128). One of the latest communications devoted to this problem is a review.¹²⁴ The binding energies of Ti $2p_{3/2}$, B $1s$, and N $1s$ core levels have been measured^{80, 125, 127} for Ti(B,N)_x , TiB_2 , and TiN films as well as those of the Ti $2p$, N $1s$, and O $1s$ levels for TiN_x and Ti(N,O)_x films. The effective charges on the titanium, oxygen, and nitrogen atoms have been estimated.¹²⁷ The possible influence of structural defects in IP on the binding energies of the core levels and the difficulties in understanding the nature of the IP have been discussed.⁸⁴ Detailed XPES studies on cubic $(\text{Ti,Al})\text{N}$ films as well as quantum-chemical calculations made it possible to estimate the effective atomic charges and the distribution of the local density of states and to conclude that there is an ionic component in the bonds.^{124, 126} Comparison of the estimated cohesion and substitution energies in titanioaluminium nitrides and carbides showed that the formation of the latter is less probable.

Table 4 presents the experimental binding energies for the $1s$ levels of nitrogen and the levels of the metals in Group IV and V transition metal nitride films synthesised from organometallic precursors and ammonia at low temperatures.^{55, 56} These films were characterised by a low content of impurities (less than 1–2 at.% of oxygen and carbon) and by the small size of the crystallites ($L \approx 2$ – 5 nm). However, the hydrogen content, characterised by the ratio $[\text{H}]/[\text{M}]$, varied in the range 0.5–1.35. The

Table 4. The binding energies (eV), found by the XPS method, for films deposited at 200 °C.^{55, 56}

Compound	Precursor	Energy of N 1s level	Energy level of metal atom	E_M

binding energies in the films do not differ from those for the nitrides in the usual polycrystalline state^{55, 56} and it has not so far been possible to detect a possible change in the electronic structure in the nanocrystalline state.

IV. Properties

1. Electrical and optical characteristics

a. Electrical resistivity

The metal-like nature of the interstitial phases is manifested primarily in their electrical properties — a low specific resistance (ρ) and a positive coefficient of its temperature dependence ($\alpha = \Delta\rho/\rho\Delta T$). This is associated with the characteristic features of the energy spectrum of the electrons in IP and with the high concentration of carriers.^{2, 7, 17} The level of the resistivity in some of the IP (for example, stoichiometric Group IV transition metal nitrides and borides) is appreciably lower than in the corresponding metals. On the other hand, certain superstoichiometric IP, in particular nitrides, behave as semiconductors and dielectrics. The deviation from stoichiometry has a great influence on the electrical properties. Furthermore, as in the case of metals and alloys, ρ and α are greatly influenced by the overall impurity content and the defectiveness of the structure, including the grain size and the cross-section of the specimens (we have in mind the scattering of the carriers at the grain boundaries and on the outer surfaces). The study of electrical properties is a fairly representative method for the investigation of the composition and ideality of IP films, but a detailed attestation of the test objects is then of course required.

Table 5 presents the results of the determinations of ρ for IP films obtained by different methods. Not all the data are presented, but only those which are most reliable (in this sense the results for TiN are outstanding). In a number of instances, one should not overestimate the value of the information presented, since there are no detailed data on the composition, defectiveness, and thickness of the films. Nevertheless, we shall emphasise certain general characteristics of the results presented in Table 5.

1. The variation of ρ in the region of homogeneity of the IP is not monotonic. This is illustrated in Fig. 14 for TiN, ZrN, and HfN films synthesised in accordance with the ion-stimulated deposition scheme (Fig. 1).⁴⁵ The increase in ρ on deviation from stoichiometry in the decreasing direction ($n < 1$) is usually attributed to the scattering of the carriers by structural vacancies in the nonmetallic sublattice. The considerable increase in ρ for $n > 1$ is due to the transition to compounds with nonmetallic conductivity. A similar situation has been observed for yttrium and lanthanum dihydride and trihydride films.¹⁴⁶ We may also note that, on the one hand, the variation of the electron energy spectra on passing from MN to M₃N₄ has been confirmed also by quantum-chemical calculations¹⁴⁹ and, on the other, the fact that the concentration of inert gases increases in the superstoichiometric nitrides (Fig. 5). At the same time a different type of variation of ρ may be observed in the region of homogeneity, for example, ρ for tungsten nitride films diminishes on deviation from stoichiometry.¹³⁶

**Figure 14.** Variation of the resistivity in the region of homogeneity of HfN (1), ZrN (2), and TiN (3).⁴⁵

2. By comparing the overall level of the values of ρ with the available data for IP (see, for example, Refs 2, 7, and 17), one may note that results indicating a high degree of ideality and a low impurity content have been obtained only in isolated instances (TiN single crystal films¹²⁹ and extremely ideal ZrN films¹³²). This was achieved by employing single crystal supports (MgO and Si) and by the thorough maintenance of other deposition conditions (high temperatures, low ion energies, 'vacuum hygiene', etc.).

Figure 15 presents the dependences of ρ and of the width of the (200) reflection for a ZrN film on the energy of nitrogen ions.¹³² The low values of ρ were determined by the deposition temperature (not above 800 °C) and the corresponding specified generation of nitrogen ions and zirconium atoms ensuring the formation of a zirconium nitride with a nearly stoichiometric composition. The influence on ρ by various conditions in the deposition of TiN films on single crystal silicon supports with a germanium sublayer under the conditions of pulsating laser vaporisation has been analysed in detail.¹³¹

3. It has been noted⁵⁷ that minimal values of ρ have been obtained for a thickness of a TiN CVD film greater than 100–150 nm. For PVD films, the critical thickness was

**Figure 15.** Dependence of the resistivity and the width of the (200) reflection for a ZrN film on the energy of nitrogen ions.¹³²

Table 5. The resistivities (ρ) of IP films at room temperature.

30–40 nm,¹⁵⁰ although the most reliable results were obtained for a thickness of ~260 nm; a preliminary consideration of the role of the scattering of carriers at intergrain boundaries and on the film surfaces has been carried out. These questions appear to have been inadequately investigated for IP films.

4. The results presented for carbide, boride, and hydride films indicate that the optimum conditions for their preparation with an ideal structure have not so far been found. The values of ρ for annealed specimens are indicated in brackets for TiB_{~2} and ZrB_{~2} films, but one should recall that the resistivity ρ of boride single crystals may be an order of magnitude lower (see, for example, Zhurakovskii and Nemchenko¹⁷ and Serebryakova et al.¹⁸).

An important parameter reflecting the influence of purity and ideality and also containing information about the nature of the carriers is the coefficient of the temperature dependence of the resistivity (α). Table 6 presents results reflecting the influence of the conditions in the deposition of TiN films by the HFMRS method on ρ and α and superconducting characteristics. These data clearly indicate the high structural sensitivity of the electrical characteristics. We may note, that according to the results of Johansson et al.,¹²⁹ $\alpha = 6.2 \times 10^{-3} \text{ K}^{-1}$ for ideal single, crystal TiN films ($\rho = 18 \mu\Omega \text{ cm}$) (for a film ~260 nm thick, $\alpha = 6.4 \times 10^{-3} \text{ K}^{-1}$)¹⁵⁰. It has been reported in a review²² that $\alpha = (1–2) \times 10^{-3} \text{ K}^{-1}$ for the majority of the usual TiN films. A negative value of α is characteristic of the nonmetallic type of conductivity, for example, in the case of Zr₃N₄ films.⁷⁶ A different sign of α has been noted for NbN films: positive for single crystal films⁹² and negative for polycrystalline films.¹⁵¹

Table 6. The influence of the conditions in the deposition of TiN on the resistivity (ρ), the temperature coefficient of the resistivity (α), the temperature of the transition to the superconducting state (T_c), and the width of the superconductivity transition (ΔT_c) (film thickness 30–100 nm).¹⁵⁰

Temperature of support/ $^\circ\text{C}$	Bias voltage/V	$\rho / \mu\Omega \text{ cm}$	$10^3 \alpha / \text{K}^{-1}$	T_c / K	$\Delta T_c / \text{K}$
40	0	205–215	0.26	< 4.3	0.04
40	–115	120–135	0.56	< 4.3	0.04
500	0	65–70	1.02	4.84	< 0.02
500	–100	45–60	1.34	5.04	< 0.02

A detailed study of the electrical properties of epitaxial single crystal multilayer TiN–VN films has been undertaken.¹⁵² Measurements of the Hall constant (R_H) and ρ showed that r_H and hence the concentration of carriers $n = 4.5 \times 10^{22} \text{ cm}^{-3}$ is independent of the thickness of the layers, while ρ and the mobility of the carriers (m) increase sharply, like α , with decrease in thickness, starting with 6 nm. For layers more than 10–15 nm thick, the following values were obtained: $\rho \approx 30 \mu\Omega \text{ cm}$, $m \approx 5 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, and $\alpha \approx 1.6 \times 10^{-1} \text{ K}^{-1}$. Estimation of the free path length (λ) of the electrons within the framework of Drude's model and on the assumption that the Fermi surface is spherical led to $\lambda \approx 4.6 \text{ nm}$ (both for TiN and VN). These estimates are approximate because, for example, the Fermi surface for nitrides is clearly anisotropic. Nevertheless they are probable. The of the electron free path length in TiN (according to the data of Tsai et al.¹⁵⁰) is 39–96 nm (Table 6); according to Krasnovobodtsev et al.,¹³⁸ $\lambda > 40 \text{ nm}$ for stoichiometric NbC films. Unfortunately, the available information about other electrical characteristics (Hall parameters, magnetic resistance, thermo-e.m.f., etc.) for IP

films is limited and is restricted to data for TiN,^{129, 153} HfN,¹³³ and FeTiH.¹⁵⁴

b. Optical properties

Data on the optical properties of IP are important for decorative applications and also for the construction of devices for the direct conversion of energy. It is well known that in the region of homogeneity titanium nitrides have different colours: TiN_{~0.5} is metallic grey, TiN_{~0.8} is bright yellow, TiN_{~0.95–0.97} is golden yellow, and TiN_{1.0} is brown; carbon and oxygen impurities lead to the blackening and the appearance of a blue tint in the specimens. The optical properties of nitride films have been analysed in reviews on the basis of their electronic structures.^{22, 84} The change in optical properties on passing from yttrium dihydride to the trihydride is beautifully illustrated by experiments described by Huiberts et al.¹⁴⁶ and showing that the change in the hydrogen composition of the films is accompanied by a transition from mirror reflection (metal-like $YH_{<2}$) to transparency (nonmetallic $YH_{>2}$) (see also the resistivity ρ in Table 5).

The characteristics of the optical properties of nitride films are presented in Table 7. It is seen that the influence of deviations from stoichiometry is fairly appreciable. The effects associated with the influence of impurities and surface roughness have been analysed.^{55, 156} For ZrN film containing 10 at.% of oxygen, the refractive index proved to be 2.15–2.25.⁵⁵ The optical properties of TiN_xO_y films obtained by the DCMRS method on architectural glass have been analysed by Polato et al.¹⁵⁷ It has been proposed that the stoichiometry of TiN films be monitored *in situ* on the basis of spectroscopic ellipsometric measurements.¹⁵⁸

^a Determined with the aid of an ellipsometer (wavelength 622.8 nm).

^b Photon energy 2.8 eV.

Boride films are also promising for decorative applications. LaB₆ films have a characteristic violet colour, while ZrB₂ is silver-grey. On doping with nitrogen, the refractive index of the latter remains constant over a wide range of wavelengths and they are extremely corrosion resistant.⁷⁷

2. Hardness

There is no doubt that the measurement of hardness is one of the most popular methods for the investigation of the properties of films, since it is readily accessible and yields much information. However, an unambiguous interpretation of the results obtained by this method is not simple in many instances owing to the high structural sensitivity of hardness and its dependence on the method of measurement and the influence of the load, the film thickness, and the nature of the support. It is difficult to compare the absolute values of hardness and they require a careful analysis. The result of the measurement of the hardness of IP films have

Figure 16. The influence of grain size on hardness.

(a) 1 N load; film thickness 20–25 μm ; support — Ti–6Al–4V alloy;⁹⁵
(b) 0.025 N load; film thickness 1–1.5 μm ; substrate — stainless steel.¹³⁰

been discussed in a number of studies (see, for example, Refs 22–28, 76, 77, 95, 96, 114, 129, 130, and 159–164). We shall consider them for the most thoroughly investigated titanium nitride.

The influence of various factors on the hardness of TiN films is illustrated in Figs 16–18. Much attention has been devoted^{95, 129, 130} to the attestation of the objects of study and the results of these investigations are fully reliable. The familiar Hall–Petch relation, linking hardness (strength) to grain size, holds quite well for films obtained by the AVID method (Fig. 16). Admittedly, it has been noted⁹⁵ that, together with the change in grain size, the nitrogen content and the residual stresses also changed in the films (Fig. 17) and the change was nonmonotonic.

Figure 17. Variation of hardness and residual compressive stresses in the region of homogeneity of TiN.⁹⁵
For conditions, see Fig. 16a.

Figure 18. The influence of the load on the hardness of the (111) face of a single-crystal TiN film.¹²⁹ Thickness 2 μm ; substrate — MgO single crystal.

Thus, the relation presented in Fig. 16a reflects the combined influence of such factors on the hardness of the films. The results for the variation of hardness in the region of homogeneity of TiN agree with the latest data published on this question.^{16,82} It is important to stress that the relations presented in Fig. 16 have been obtained for different loads in the tests (the usual Vickers method⁹⁵ and nanoindentation.¹³⁰). The dimensional effect (the influence of the load) is illustrated in Fig. 18, where data for an ideal single crystal TiN film are presented. We may note, however, that certain data of the above studies^{95,130} do not agree with the results of other investigations, (for example, of the influence of residual stresses⁸³). The overall level of film hardness⁹⁵ does not appear very high, which is probably associated with the nature of the support and the thickness of the films in these experiments (in the discussion of the data in Table 3 above, we have already emphasised the uncertainty in the determination of L).

It follows from the foregoing that the treatment of the results of the measurement of hardness is not quite so simple. We endeavoured to collect information about the hardness of IP films and attached to them data on the conditions of preparation and measurement (Table 8). Some of the tabulated results have been estimated by means of the relation proposed by Jonsson and Hogmark.¹⁵⁹ Modelling of the hardness of films on supports as the hardness of composites in many cases leads to entirely reasonable results. The values of Knoop hardness are as a rule lower than those of Vickers hardness. The following comments are useful for a correct interpretation of the data presented in Table 8.

1. The methods and deposition regimes employed exert a considerable influence on the hardness of the films.^{77, 79, 129, 130, 169, 173, 178, 188} The deposition temperature, the shift potential, the characteristics of the ions, the temperature of the subsequent annealing, and other parameters affect the structures of the films and determine their hardness. The results^{178, 188} for TiC–NiB₂ and Ti(B,N)_x films are especially striking in this respect. In the first case, there is a considerable difference between the amorphous and crystalline states (it is not the same for individual compounds and their mixtures). For the boridonitride film, an increase in deposition temperature from 20 to 400 °C also led to an almost twofold increase in hardness. The lower hardness of ZrB₂ and Zr(B,N) films compared with that of titanium diboride and nitridoboride films is also striking. The addition of nitrogen to the former led to the disappearance of the fine columnar structure and the formation of hexagonal boron nitride with a low hardness and effective lubricating properties, which led to an appreciable increase in wear resistance.⁷⁷

2. As a rule, AVID regimes lead to higher hardness parameters compared with other methods. Thus, at the optimum nitrogen pressure and temperature of the support, the hardness of Ti₂N and TiN was respectively ~ 46.5 and ~ 42 GPa (load 0.5 N, film thickness 4–6 μm).^{189, 190} The influence of nitrogen pressure on hardness, lattice period, and half-height peak width of the (111) reflection is illustrated in Fig. 19 for TiN, (TiZr)N, ZrN, and

Figure 19. Dependence of hardness (I), lattice parameters (2), and width of the (111) reflection (3) on the nitrogen pressure.¹⁹⁰ (a) TiN; (b) (Ti–25 mass% Zr)N; (c) (Ti–50 mass%, Zr)N; (d) (Ti–75 mass% Zr)N; (e) ZrN; (I^*) (Zr–2 mass% Nb)N; (f) (Ti–21 mass% Mo)N, (I^*) (Ti–31 mass% Mo)N.

(Ti,Mo)N films. It is striking that cubic titanium nitride which has not yet attained the stoichiometric composition has the maximum hardness. The introduction of dopants into TiN (up to 50%) does not alter the general characteristics (Figs 19b and 19c), but films with a higher content of zirconium (Fig. 19d) as well as films of ZrN itself (Fig. 19e) are characterised by a single maximum in the relations presented, because the Zr₂N phase is absent from the Zr–N₂ system. The situation is more complex for (Ti,Mo)N films — in the presence of 21 mass% of Mo it resembles that for weakly doped (Ti,Zr)N films, while a body-centred cubic metallic phase appears for 31 mass% of Mo in the structure and low nitrogen contents.

3. Certain results presented in Table 8 have been obtained in nanoindentation experiments, i.e. for small loads under the conditions of continuous indentation (see, for example, Refs 130, 165, 167, and 168). These data may be somewhat lower than the usual results as a consequence of the influence of the relaxation effect, despite the fact that the influence of the support and of the load is eliminated under nanoindentation conditions (Fig. 18) and this tends to increase the results of the determination

Table 8. Hardness of IP films.

of hardness. Yet another characteristic feature of nanoindentation is the possible additional scatter of the results associated with the influence of the roughness of the surface (Figs 10–13)

4. A series of data confirm the Hall–Petch relations as regards films (see Fig. 16 and Miura et al.¹⁹¹), but this problem does not appear to have been exhausted, particularly in view of the need for a detailed structural and other attestation of the films. For example, the nanoindentation of TiN CVD films,¹⁹² deposited on a silicon single crystal at 350 °C, yielded a hardness of 12.7 GPa for a grain size of ~10 nm. This ‘record breaking’ minimal result (see also Gao et al.⁵⁰) requires an explanation. A series of data on WC films^{180, 181} also need interpretation.

5. Alloying is accompanied by an increase in hardness, which has been observed for (Ti,Al)N, (Ti,V)N, (Ti,Nb)N, (Ti,Zr)N, and (Ti,Zr)C films. The presence of oxygen leads as a rule to a decrease in hardness. The influence of nitrogen and carbon atoms is approximately additive. When (Ti,Zr)N and (Ti,Zr)C films are annealed, the spinodal decomposition in the TiN–ZrN and TiC–ZrC systems leads to the formation of a nanocrystalline two-phase structure with a high hardness.^{169, 174} This is clearly seen as regards the influence of the annealing temperature on the hardness of doped and multilayer films based on TiN (Fig. 20). The anomalous behaviour of (Ti,Zr)N films is evident.

These data also demonstrate the advantage of multilayer films compared with monolayer and doped films. Composite or multilayer films (they are also referred to as superlattices) have recently attracted much attention.^{96, 182, 193} Their high hardness and wear-resistance characteristics have been demonstrated in relation to films in a series of systems: TiC–TiB₂, SiC–TiC, B₄C–TiB₂,^{182, 193, 194} TiN–ZrN, TiN–NbN, TiN–CrN,^{85, 169, 195} Ti–VN, TiN–NbN, TiN–(Ti,Nb)N,^{96, 170} TiN–Si₃N₄,¹⁹⁶ and TiN–CN_x.¹⁹⁷ The technological prospects for the combination of CVD and PVD layers have been discussed.¹⁹⁸

Figure 21 illustrates the variation of the hardness of multilayer TiN–ZrN, TiN–NbN, and TiN–CrN films with increase in the number of layers (the overall thickness of all the films was the same and amounted to 2 μm). It is possible to specify at least four factors responsible for the increase in hardness with increase in the number of layers (with decrease in their thickness): the increase in the number of interfaces preventing the propagation of dislocations and cracks; the decrease in grain size in individual layers with decrease in their thickness; the increase in the density of noncorrespondence dislocations and the possible more favourable situation as regards residual stresses in the case of multilayer structures. The nonmonotonic variation of hardness in the case of TiN–CrN films may be attributed to the formation of (Ti,Cr)N solid solution and hence to the disappearance of interfaces, which has been confirmed by X-ray phase studies. The formation of a limited amount of solid solutions has also been detected for TiN–NbN and TiN–ZrN films even for the maximum number of layers (180) and individual nitrides continued to be detected by the XRD method. This confirms the major role of interfaces. The reasons for the high hardness of multilayer films have also been

discussed in reviews.^{28, 96} Attention has been turned to the appreciable difference between the elastic properties of the layers in superlattices.

Figure 20. The influence of annealing temperature on the hardness of monolayer (TiN, ZrN, NbN, CrN, Cr₂N), multilayer (TiN–ZrN, TiN–NbN, TiN–CrN), and alloyed [(Ti, Zr)N, (Ti,Nb)N, and (Ti,Cr)N] films.¹⁶⁹

Figure 21. Dependence of the hardness of multilayer nitride films on the number of layers.⁸⁵
(1) TiN–NbN; (2) TiN–ZrN; (3) TiN–CrN.

It is of interest that after some time (possibly several months, which could not unfortunately be established) the high hardness of the TiN–NbN and TiN–ZrN films vanished, evidently as a consequence of the diffusional dissipation of the individual layers.⁸⁵ The existence of relaxation effects in multilayer nitride films has also been noted by Hultman et al.¹⁰⁸ The problem of the stability of multilayer structures over a wide temperature range requires separate study.

The short-term high-temperature hardness of TiN, HfN, ZrN, (Ti,Al)N, and TiC–TiB₂ films has been investigated at temperatures up to 1000 °C.^{178, 199} Whereas the hardnesses of nitride films differ insignificantly up to 1000 °C (8–10 GPa), the difference for TiC, TiB₂, and TiC–TiB₂ films is more significant (for example, at 900 °C it amounts to ~20 GPa for NiB₂–20% TiC and ~9 GPa for TiB₂–50% TiC). It may be that this situation is due to the manifestation of high-temperature superplasticity in two-phase equimolar mixtures, which was observed in experiments on creep for these and other two-phase compositions based on refractory compounds (see, for example, Refs 16, 32, and 33).

It must be emphasised that the knowledge of hardness is useful for correlation with numerous properties important in the practical employment of the films. Such characteristics are determined in tests of the specimens for wear resistance, for microscratching in the study of the adhesion of the films and coatings, and for microbrittleness and cracking resistance in the modelling of disintegration under a concentrated load, etc. (see, for example, Refs 16, 24, 25, 200, and 201). However, these processes will not be considered here.

3. Other characteristics

Table 9 presents data on the elastic properties. In the analysis of these results, one should bear in mind that the absolute values of the elastic properties are influenced not only by the method of preparation, which determines the structure, texture, composition, and size of the specimens, but also by the method of measurement (see, for example, the relevant reviews^{164, 165}). For stoichiometric TiN and ZrN, the results of Torok et al.²⁰² are the most representative. They agree well with the results of the study of Portnoi et al.²⁰⁸ obtained on analogous nonporous nitride

Table 9. The normal moduli of elasticity (E), moduli of shear (G), and Poisson coefficients (ν) for IP films.

specimens prepared by the method involving, the through-saturation of the metals with nitrogen.

The nanoindentation method, involving the analysis of the form of the load-release curve, has come to be widely used in the study of elastic properties (as in the study of hardness). However, not all the results obtained by this method (for example, the data of Vancoille et al.²⁰⁷) have been reasonably interpreted. The high values of the modules of elasticity (E) for certain boridonitride films are also noteworthy.¹⁸⁸ It is likewise of interest that the decrease in the deposition temperature from 400 to 20 °C led to a decrease in E by a factor of almost 1.5 (TiBN_{0.5}). It has been noted²⁰⁷ that annealing of the films leads to an increase in their modulus of elasticity, but above 500 °C it diminishes. In the study of multilayer films, anomalies in elastic properties were not observed for the TiN–(V,Nb)N system, in contrast to hardness.²⁰⁹

The tribological and corrosion properties of IP films^{24, 25, 77, 111, 113, 115, 198, 210–215} have been the subject of numerous investigations. At the same time, problems such as those of phase equilibria and the thermodynamic, thermal, and diffusion properties have been studied to an extremely limited extent in relation to IP films.^{32, 33, 216} So far as we are aware, the available information about diffusion is limited to studies on films as barrier layers (see, for example, Ostling et al.²¹⁷ and Shin et al.²¹⁸). The thermodynamic properties and phase equilibria have been investigated for certain hydride films [VH(D)_x and PdH_x].^{219, 220} In particular, a change in the nature of the isotherms and a decrease in the critical point for decomposition have been noted in the palladium–hydrogen system for films ~50 nm thick as a possible result of the influence of nanocrystallinity on the equilibrium in this system (for films 300 nm thick, anomalies were not observed).²²⁰ On the other hand, for vanadium films 500 nm thick and with a grain size of ~50 nm, measurements of the partial and integral thermodynamic properties revealed no differences relative to the usual polycrystalline vanadium on interaction with hydrogen.²¹⁹ The emission characteristics of lanthanide boride films are discussed in a review.⁷⁷

The thermal stabilities and the recrystallisation of IP films have been studied by a series of investigators (see, for example, Refs 93, 169, 174, 195, 199, 207, and 221–223). It is well known that the formation of a granular structure and recrystallisation begin even during the deposition of the films. Fig. 22 illustrates the influence of film thickness on the grain size for various nitrides. There is an evident difference between ZrN, on the one hand, and TiN, NbN, and CrN, on the other. It may be that this is associated with the greater affinity of zirconium for nitrogen and

Table 10. The grain sizes in nitride films 2 µm thick obtained by the AVID method.²²³

Film	Grain size/µm			Energy of mixing in (Ti, M)N system /kJ mol ⁻¹
	I	II	III	
TiN	0.18±0.08			
CrN	0.16±0.08	0.17±0.05	0.18±0.04	3.4
NbN	0.14±0.03	0.04±0.01	0.08±0.02	6.1
ZrN	0.03±0.02	~0.01	0.02±0.01	32.6
AlN	0.15±0.05	0.08±0.03	~0.01	37.2

Note. The following designations have been adopted: (I) unalloyed film; (II) multilayer TiN–MN film (10–20 layers); alloyed (Ti,M)N film.

the higher energy of zirconium ions. It is of interest that the smallest grains are observed also in multilayer and doped films with ZrN (Table 10). This is also correlated with the high energy of mixing in the TiN–ZrN system. The latter characteristic is known to be related to the diffusional and recrystallisation mobilities.

The influence of film thickness, alloying, and multilayer structure on the recrystallisation of a series of nitrides has been investigated in a number of studies.^{169, 195, 221, 223} Fig. 23 illustrates this in relation to TiN and NbN. The recrystallisation of TiN and NbN begins at virtually identical temperatures, although a greater spread in size is characteristic of TiN. It is also evident that thinner films recrystallise more intensely, but in multilayer and doped structures this process is retarded, especially in the case of TiN–ZrN and (Ti,Zr)N (Table 10). Many details and the mechanism of the high-temperature behaviour of IP films require additional studies.

V. Conclusion

The available information about IP films is diverse but inhomogeneous. Most of it refers to nitrides and, in particular, to TiN. Much less is known about carbides and hydrides, borides occupying an intermediate position. However, so far as one can judge from the problems dealt with in the latest symposia on borides (Austria, August, 1996) and hydrides (Switzerland, August, 1996), there is a growing interest in boride and hydride films. The reactivity and catalytic properties of thin carbide and nitride layers are also being comprehensively investigated.²²⁴ In the present review, the author, whilst not claiming to examine all the problems of film IP, has endeavoured to emphasise certain unsolved problems and in this connection the available information about the structures and physicochemical properties of these objects appears far from complete. For example, the data on the structures of the interfaces for IP films are greatly inferior to those for metals.²²⁵ It is thought that the accumulation of new fundamental results for IP films will promote the development of the physicochemical foundations of the nanostructural materials science and the expansion of the range of their diverse applications.

This review has been written within the framework of projects supported by the Russian Fundamental Research Fund (grant No. 95-02-03518) and the INTAS program (grant No. 94-1291).

Labile products of interaction of cellulose with nitrogen oxide compounds

E V Gert

Contents

I. Introduction	73
II. Analysis of ideas concerning the preparation and isolation of cellulose nitrite	74
III. Studies on the heterogeneous <i>O</i> -nitrosation of cellulose and its products	77
IV. Heterophase structural transformations of cellulose with participation of labile nitrogen-containing derivatives	82
V. Examples of the applied importance of labile nitrogen-containing polysaccharide derivatives	88

Abstract. Data concerning the conditions and kinetics of the formation, the methods for identification and isolation, the chemical and physical properties, and the crystal structure of cellulose trinitrate are presented. The conditions governing the formation of Knecht' sorption compound and other unstable crystalline products in the cellulose–N₂O₄ system are also discussed. The primary role of labile derivatives in the manifestation of polymorphism by cellulose on its regeneration from these compounds is demonstrated. The causes of the amorphisation of cellulose, which may occur in these systems, are examined. Examples of a rational combination of several functions of the reaction medium and of the labile nitrogen-containing compound present in it in the preparation of other materials of practical importance from polysaccharides (sulfate and acetate esters and structurally and chemically modified powdered forms of cellulose) are presented. The bibliography includes 160 references.

I. Introduction

The possibilities for the chemical and physical transformation of cellulose (Cel) with the aid of nitrogen oxide compounds (N₂O₄, NO₂, N₂O₃, HNO₃) are extremely diverse. The use of these compounds in oxidation,^{1,2} nitration,^{3,4} degradation,^{5,6} bleaching,^{7,8} and structural modification^{9–12} of cellulose, the dissolution of cellulose in aprotic electron-donating organic media,^{13–15} and its conversion into various derivatives,^{16–18} fibres,^{13,19–21} membranes,^{22–24} and composite materials^{20,25} is well known. In terms of the 'universality index', nitrogen oxide compounds (in the first place N₂O₄) are superior to all known reagents which actively interact with cellulose. The nature of the transformations of cellulose on treatment with these compounds depends on the reaction conditions.

The postulated formation in the given systems of labile cellulose derivatives and their influence on the course of the transformations and the properties of the final products have long been the subject of controversy. A key chemical compound of this type is cellulose nitrite. The decrease in the stability of pyroxylin has been attributed to its presence.^{3,26} The familiar

mechanism²⁸ of the oxidation of cellulose to monocarboxycellulose, where the role of an intermediate was assigned to cellulose nitrite, has been supported² and rejected.^{1,27} The dissolution of cellulose in aprotic organic media containing N₂O₄ is to this day explained in different ways. Some investigators^{13,16–18} postulate the formation of cellulose nitrite whilst others¹⁵ believe that molecular complexes are formed. The absence of information about cellulose nitrite as an individual compound as well as the lack of reliable methods for its detection in a complex reaction medium gave to this cellulose derivative the attributes of a 'hypothetical compound' until recently.

An unstable sorption product characteristic of the given systems is the adduct of cellulose with HNO₃, the existence of which was established at the beginning of this century by Knecht²⁹ and was subsequently called Knecht's compound (KC).^{30,31} It has been suggested that the formation of KC precedes the nitration of cellulose.³ For many decades KC remained 'in the shade' and neither its chemical composition and structure nor its crystal structure have been established hitherto. Nevertheless, communications have recently appeared,^{32,34} indicating the possibility of an effective practical application of KC.

Cellulose nitrite and molecular complexes as possible alternatives to the latter have been considered in reviews^{13–15} merely in the context of their probable participation in the dissolution of cellulose. Their formation was postulated on the basis of a series of indirect experimental pieces of evidence. It was not until the 1980s that the labile products of the interaction of cellulose with N₂O₄ became the object of special comprehensive investigations and fairly extensive experimental data have now accumulated in this field. The high degree of stoichiometry of the interaction observed in this system has led to the possibility of the effective employment of X-ray diffraction for the detection of cellulose nitrite, KC, and other unstable compounds in terms of their crystalline phases in a complex reaction mixture. The primary role of labile derivatives of cellulose also in the observed diversity of the heterophase structural transformations of cellulose, which do not lead ultimately to an alteration of its chemical composition, has been elucidated. The application of new methods made it possible to overcome the 'inaccessibility' of cellulose trinitrate.

Data concerning the conditions and kinetics of the formation, the methods for the identification and isolation, the crystal structure, the properties, and the applied importance of labile nitrogen-containing derivatives of cellulose compounds should be of interest to a wide range of specialists in the field of the chemistry and physics of cellulose. The present review is the first attempt at a systematic account and survey of this scattered information.

II. Analysis of ideas concerning the preparation and isolation of cellulose nitrite

The first mention of cellulose nitrite is in the communication of Nicolardot and Chertier.³⁵ Its authors detected nitrite ester groups in the product of the interaction of cellulose with a mixture of nitrogen oxides and acetic acid (AA). The formation of cellulose nitrite was postulated in the nitration of cellulose by compositions containing nitrogen oxides in connection with the search for ways of increasing the stability of nitrocellulose.²⁶

Studies on the formation reaction of monocarboxycellulose have shown that the UV and visible spectra of cellulose treated with gaseous nitrogen oxides exhibit a series of absorption bands at 350, 341.5, 355, and 365 nm, which may be due either to HNO_2 or to cellulose nitrite. A detailed experimental test of both possibilities indicated that these bands are due to the cellulose nitrite spectrum.²⁸ A mechanism postulating that the oxidation of cellulose by nitrogen oxides proceeds via the formation of cellulose nitrite as an intermediate has been put forward.

The practical importance of cellulose nitrite was revealed by numerous studies^{13–18, 36–53} concerning the use of nitrosyl-containing compounds — N_2O_4 , NOCl , $\text{NO}[\text{SO}_4\text{H}]$, etc. — in combination with aprotic organic solvents for the dissolution of cellulose. Fowler et al.³⁶ observed that in nonpolar solvents N_2O_4 has a strong oxidising effect on cellulose, whereas in polar solvents increased swelling takes place or the polymer dissolves without appreciable oxidation. The most suitable organic components from the standpoint of the preparation and processing of the solutions proved to be dimethylformamide (DMF), dimethyl sulfoxide (DMSO), dimethylacetamide (DMA), and ethyl acetate (EA).^{15, 27} The formation of the nitrosyl nitrate form of N_2O_4 ($\text{NO}^+ \text{NO}_3^-$) in polar solvents in the presence of this isomer even in HNO_3 -free liquid N_2O_4 has been demonstrated^{54–56} the interaction of the strong electron acceptor NO^+ with the oxygen atom of the hydroxy-group of cellulose, which functions as an electron donor, is typical for these systems.^{16, 42, 44, 46} Such interaction leads to the formation of cellulose nitrite and HNO_3 , which dissolve in the reaction medium. The organic solvent binds HNO_3 , displacing thereby the equilibrium towards the formation of cellulose nitrite. Total dissolution is ensured for the molar ratio N_2O_4 :Cel = 3. When NOCl is combined with DMF, the ratio is 8.^{13, 16} In contrast to N_2O_4 , nitrosyl chloride itself interacts chemically with DMF.¹⁵ The following mechanism of the electrophilic substitution involving all the hydroxy-groups of cellulose has been proposed:¹⁶

This view is also adhered to by Ermolenko,²⁸ who postulated the formation of cellulose nitrite from its adsorption compound with the nitrosyl nitrate form of N_2O_4 .

The high sensitivity of solutions of cellulose nitrite in nitrosating compositions to water and alcohols has been noted.^{38, 39, 44–47} The regeneration of cellulose is catalyzed by the acid present in the system, which corresponds to the inversion of reactions (1) and (2). The chemical composition of the substance isolated on hydrolysis or alcoholysis hardly differs from that of the initial cellulose.^{13, 16, 44, 46} The acid present in the solution induces the depolymerisation of the macromolecules when the solution is maintained at room temperature.¹⁶ Allowing the solutions to stand in the cold (5 °C) for between 6 h and 12 days does not reduce appreciably the degree of polymerisation (DP) of

the cellulose regenerated from them. Depolymerisation occurs also during the nitrosation process.^{52, 53} The degree of depolymerisation depends greatly on the moisture content of cellulose stirring of the solutions promotes depolymerisation.⁵²

The possibility of synthesising in solution other uniformly substituted cellulose derivatives has been attributed to the formation of cellulose nitrite and to its reactivity in transesterification reactions.^{16–18, 41 43, 50} The water-soluble cellulose nitrate has been obtained by Schweiger¹⁶ as a result of heating a solution of cellulose nitrite in the N_2O_4 –DMF mixture for 70 min at 90 °C. Its degree of substitution (DS) was only 0.5. The HNO_3 accumulated in the system as a result of the nitrosation of cellulose proved to be sufficient for the reaction to occur. These results explained the observations of Clermont and coworkers,^{41–43} who carried out similar experiments and who postulated that the weakly substituted highly degraded product formed is a mixed cellulose nitrite–nitrate. At room temperature, cellulose is not nitrated in the given system. Even after the solution has been kept together with added HNO_3 for 20 h (molar ratio HNO_3 :Cel = 9), only traces of nitro-groups are detected in the precipitated product (DS = 0.04).⁴⁷

Low-molecular-mass alkyl nitrites, including those obtained by treating monohydroxylic alcohols with N_2O_4 , can be isolated after diluting the reaction medium with water, in which they are insoluble.^{44, 57} Polyol nitrites are much less stable than the nitrites of monohydroxylic alcohols,⁵⁸ which can be accounted for by the anchimeric facilitation of the hydrolytic reaction by the vicinal nitrite ester groups. For example, the nitrites of poly(vinyl alcohol) and glycerol cannot be isolated on dilution with water owing to their low hydrolytic stability in acid media. The stability of cellulose nitrite is even lower because of the extensive capillary-porous system of the fibre, which increases the area of the reactive surface. Schweiger^{16, 44} precipitated cellulose nitrite with ice water from a solution to which a strong organic base (pyridine, quinoline, or triethylamine) had been added. The role of the base consisted in inhibiting the acid catalysis of the elimination of the nitrite ester groups. The white deposit isolated was washed with ice water, hydrolysed in an acid medium, and the HNO_2 content in the liquid over the precipitated polymer was determined. The moist cellulose nitrite thus obtained may be stored for a long time in the cold without decomposition. All attempts to dry it led to decomposition. Wagenknecht and coworkers^{46, 48} precipitated and analysed cellulose nitrite in accordance with the same scheme, employing a mixture of diethyl ether (DE) and methylene chloride as the precipitant. The nitrogen content in the precipitates corresponded to a degree of substitution of 2.50–2.95 in terms of the nitrite ester groups,⁴⁶ which, together with the ease of their hydrolysis or alcoholysis, indicated the occurrence of *O*-nitrosation.

The product isolated by Schweiger^{16, 44} was identified more rigorously by Torgashov et al.⁵⁹ Analysis of the deposit for nitrogen in the nitrate and nitrite forms demonstrated that the latter predominated greatly (2.85 against 0.01 in terms of the degree of substitution). For the first time, the IR and UV spectra of a preparation of an individual highly substituted cellulose nitrite were presented. The nitrite was prepared by the following method. The fibrous deposit from which excess water had been squeezed out was dissolved in ethyl acetate cooled to 5 °C. Water was removed from the resulting solution by successive freezing and treatment with calcium chloride. Specimen films for spectroscopic study were cast on KRS-5 or quartz plates in a vacuum desiccator over P_2O_5 . The IR spectrum of such a film (Fig. 1) hardly exhibits the band due to the stretching vibrations of the cellulose OH groups (3100–3500 cm^{-1}) as a consequence of the high degree of substitution, which is 2.85. The two new intense bands at 780 and 1680 cm^{-1} correspond to the stretching vibrations of the O–N and N=O bonds in organic nitrites.⁶⁰ The low-intensity bands at 510 and 650 cm^{-1} may be assigned to the deformation vibrations of the O=N–O group.

Figure 1. IR spectra of the initial cellulose nitrite film (1) after keeping in air for 30 min (2), and after 2 min contact with ethanol (3).

An obligatory condition for the measurement of such a spectrum is the reduction to a minimum of the contact between the specimen and the moisture in the ambient medium during all the preparatory operations. In air with a relative humidity of 65%–70%, at 20 °C, the preparation decomposes, which has been clearly detected from the increase in the intensity of the absorption in the region of the stretching vibrations of the cellulose OH groups and the synchronous weakening of the spectral bands due to the nitrite ester. The weakening of the band at 1680 cm^{-1} is accompanied by its bathochromic shift. The spectrum recorded after brief treatment of the film with water or ethanol corresponds to chemically unaltered cellulose.

The results of the spectroscopic experiments have been confirmed by Grinshpan,¹⁵ who, whilst retaining Schweiger's method,¹⁶ precipitated cellulose nitrite from the N_2O_4 –acetonitrile system. According to these data, the 1660 and 1780 cm^{-1} bands were present in the IR spectrum of a film of the highly substituted product ($\text{DS} = 2.80$) and an appreciable absorption was noted in the range 3100–3500 cm^{-1} . The appearance of the latter as well as the displacement of the N=O bond stretching vibration band maximum from 1680 to 1660 cm^{-1} are most probably caused by the partial decomposition of the specimen during the experiments. Thus the presence of absorption bands at 1780 cm^{-1} and in the range 1650–1680 cm^{-1} must be regarded as specific characteristic of the IR spectrum of cellulose nitrite. This characteristic is common to all nitrite esters.^{57, 60}

The formation of cellulose nitrite in the above systems, and not of its complexes with nitrogen oxides,^{15, 27, 36, 61} has been confirmed also by the results of the analysis of the solutions for HNO_3 , the second product of the esterification reaction. The amount of HNO_3 was determined from the mass of the pyridinium nitrate precipitated when an excess of pyridine was added to a solution of cellulose in the N_2O_4 –ethyl acetate mixture. Absolute diethyl ether, which is incapable of precipitating the polymer, was used in addition to isolate pyridinium nitrate from the N_2O_4 –DMF system. According to the experimental data approximately 3 moles of HNO_3 per glucopyranose unit (GPU) of cellulose are present in the solutions, i.e. as much as should have been obtained on total esterification of cellulose.

It has been suggested¹⁴ that the presence of a strong organic base is obligatory for the *O*-nitrosation of cellulose, because cellulose nitrite can be isolated from solution only with participation of amines.^{16, 44, 46, 48} Developing further this hypothesis,

Grinshpan¹⁵ attributes to amines the role of a catalyst in the esterification of cellulose by the nitrous acid formed when the nitrogen oxides of the solvent mixture interact with water in the precipitation baths. It has been suggested that, apart from the catalytic effect, the presence of amines prevents the decomposition of HNO_3 . The cause of the high content of nitrite ester groups ($\text{DS} = 2.50$ –2.95) in the deposits isolated without the use of water was not discussed in this connection.^{46, 48}

The catalytic function of amines is confirmed, according to Grinshpan's data,¹⁵ by the procedure described in a inventor's certificate.⁶² According to this procedure, cellulose nitrite can be precipitated from solutions at the instant of formation by employing a cooled water–pyridine mixture. It was noted that the cellulose nitrite isolated from solutions incorporating an organic component with a lower proton affinity (ethyl acetate or acrylonitrile and not DMF or DMSO) is the most stable. This factor is assessed as an argument in support of the dissolution of cellulose without esterification to the nitrite. It has been stated that if an esterification had occurred, the product isolated from solution in DMF or DMSO would be more stable. However, it is evident that in the presence of amines, the proton affinity towards the solvent loses its importance and an effect of 'protection' of cellulose nitrite against water should be manifested in more hydrophobic media (of the type of ethyl acetate).

The possibility of the *O*-nitrosation of cellulose, even in the absence of amines on its dissolution in nitrosyl-containing systems with a 'dual' esterifying ability: $\text{NO}[\text{HSO}_4]$ –DMF, $\text{NO}[\text{SbCl}_6]$ –DMSO, has been assumed.¹⁵ According to the author, the anionic components of the salt-like compounds in such systems perform simultaneously the functions of esterifying agents, *O*-nitrosation acid catalysts, and stabilisers of the HNO_2 and the cellulose nitrite formed.

The following reaction equations have been presented:

The nitrite ester groups in the mixed cellulose ester formed are fairly stable.^{45, 46, 48} A substantial part of them ($DS = 1.21$) can be detected together with sulfate groups ($DS = 1.19$) in the deposits isolated at 20 °C by means of acetone without using amines.⁴⁵ On the other hand, the content of nitrite groups in the deposits obtained by similar procedures from the N_2O_4 -DMF and $NOCl$ -DMF solvent systems is very small, which, according to Grinshpan,¹⁵ confirms the absence of reactions similar to reactions (3)–(5) and the constancy of the chemical composition of the cellulose dissolved in these media. However, even if the latter possess a nitrosating activity, one cannot expect a high concentration of nitrite ester groups in the products precipitated with acetone, in which the highly substituted cellulose nitrite is readily dissolved.^{15, 57} The ability of ketones to enolise in acid media induces denitrosation and hence the deposition of the polymer. When N_2O_4 is combined with acetone, a stable solution cannot be obtained because of enolisation.

The majority of investigators^{37, 40, 41, 44, 46, 51, 52, 63, 64} attribute the dissolution of cellulose to the esterifying ability of nitrosyl-containing compounds (in the first place N_2O_4) in the absence of amines. Other views on this process have been expressed in studies^{15, 27, 36, 61} in which the postulated compositions and structures of the molecular complexes, ensuring, according to the authors, the dissolution of cellulose, are discussed. The results of the analysis of the solutions by UV,^{15, 57, 59} IR,^{15, 24, 59, 65} ^1H NMR,^{15, 51} and ^{13}C NMR^{15, 49} spectroscopic methods as well as calorimetry^{15, 63} have been treated in a contradictory manner by the supporters and opponents of the nitrite mechanism of the dissolution of cellulose. The IR spectra of the Cel- N_2O_4 -DMSO system (Fig. 2) contain evident features of the esterification of cellulose, such as the decline of the intense absorption in the range 3100–3500 cm^{-1} and the appearance of bands characteristic of the nitrite ester substituents introduced into the chain (at 1650 and 730 cm^{-1}).^{24, 57, 65} The dissolution of the model cellulose nitrite in DMSO induces a shift of the $N=O$ bond stretching vibration band maximum from 1680 to 1660 cm^{-1} , while the position of the band at 780 cm^{-1} is retained. A similar phenomenon has been observed also for low-molecular-mass nitrites in polar solvents.⁶⁶ The position of the absorption band of pentyl nitrite at 1650 cm^{-1}

remained unchanged after dissolution in CCl_4 , but was displaced to 1630 cm^{-1} after dissolution in $CHCl_3$.

Analysis of the IR spectra obtained in a number of studies^{24, 57, 65} (Fig. 2) showed that the spectrum of the Cel- N_2O_4 -DMSO system can be regarded, with some approximation, as a superposition of the spectra of solutions of cellulose nitrite and HNO_3 in DMSO. The absorption maxima of the dissolved cellulose nitrite (1660 cm^{-1}) and HNO_3 (1640 cm^{-1}) are not then resolved. For the Cel- N_2O_4 -DMSO system, they are averaged out at about 1650 cm^{-1} .

The use instead of cellulose of its analogue soluble in DMSO, namely starch, makes it possible to trace the variation of the absorption under the influence of N_2O_4 in the region of the stretching vibrations of the OH groups of the polysaccharide (Fig. 3). The addition of N_2O_4 to a solution of starch (up to 3 moles per GPU) induces a pronounced weakening of the intensity of the absorption band due to the OH groups. The bathochromic shift of this band (from 3310 to 3240 cm^{-1}) taking place simultaneously with the changes in intensity can be logically explained by the different reactivity of the reaction of the OH groups, depending on the energy of the hydrogen bonds, similar to that in the synthesis of the nitrites of other polyols.⁵⁸ A number of the most strongly bound hydroxy-groups remain free. An increase in the N_2O_4 concentration in solution also leads to a steady intensification of the spectroscopic indications of the presence of starch nitrite (bands at 1650 and 780 cm^{-1} and HNO_3 , (2100–2600, 1340 820, and 620 cm^{-1}). In the measurement of the IR spectra of solutions, it is necessary to take into account the high sensitivity of the preparation in the form of a thin liquid layer to atmospheric moisture. The increase in the intensity of the absorption band of the cellulose OH group is the spectroscopic evidence of the rapid decomposition of cellulose nitrite.

According to Grinshpan,¹⁵ the IR spectra of the Cel- N_2O_4 -DMSO system do not conflict with the hypothesis that cellulose dissolves via the formation of a Cel-organic solvent- NO_2 ternary complex. The reasons for the marked weakening of the absorption intensity in the range 3100–3500 cm^{-1} are not discussed. It is postulated that the bands at 1650 cm^{-1} (at 1640 cm^{-1} according to Grinshpan¹⁵) and 1340 cm^{-1} (Fig. 2)

Figure 2. IR spectra of a 15% solution of cellulose nitrite ($DS = 2.85$) in DMSO (1) of the Cel- N_2O_3 -DMSO (10:17:73 mass %) homogeneous system (2), and of the N_2O_4 -DMSO dissolving mixture (3) and of 11.6 mass % HNO_3 solution in DMSO (4).

Figure 3. IR spectra of an 8% solution of starch in DMSO (1) and of the same solution to which two (2) and three (3) moles of N_2O_4 per GPU have been added.

are due to the NO_2 molecules bound in a complex with DMSO. This explanation is not based on any known reference guidelines similar to those in the spectra of low-molecular-mass nitrites. For systems incorporating nitrogen oxides with different degrees of oxidation and the products of their heterolytic dissociation (nitric and nitrous acids), the controversial character of such assignments of the spectral bands is evident. The explanation of the appearance of the 780 cm^{-1} band by the formation of a nonchemical sorption compound of cellulose and anhydrous HNO_2 is likewise controversial. The latter arises in the system ‘...on homogeneous dissociation of a C–H bond in the alcoholic groups of cellulose effected with the aid of the NO_2 radical molecules’.¹⁵ The origin of the bands at 1420 , 1300 , and 940 cm^{-1} is also attributed to the formation of a stable $\text{Cel}-\text{HNO}_2$ sorption complex. However, the intensity of precisely these bands in the spectrum of a solution of starch in DMSO is appreciably higher than in the spectrum of the same solution containing N_2O_4 (Fig. 3). The explanation of a series of observations in Grinshpan’s study,¹⁵ which follows from the known similarity of certain spectral features of HNO_2 and organic nitrites, repeats essentially the hypothesis previously tested by Ermolenko²⁸ and rejected.

Philipp and coworkers,^{17,45–50} who have investigated extensively the state of cellulose in nitrosyl-containing solvent systems, allow (in the papers by Nehls et al.⁴⁹ and Philipp et al.⁵⁰) the possibility of equilibrium between the cellulose nitrite ester and its adduct with N_2O_4 via a subsidiary valence. This conclusion was based on the analysis of ^{13}C NMR spectra of the $\text{Cel}-\text{N}_2\text{O}_4-\text{DMF}$ system,⁴⁹ indicating at least partial esterification. It has been noted^{49,50} that the introduction of amines promotes a shift of the equilibrium towards full esterification and the isolation of a product similar in composition to cellulose trinitrite.

III. Studies on the heterogeneous *O*-nitrosation of cellulose and its products

A comprehensive study of cellulose nitrite became possible after a way had been found of preparation it without impurities in a dry crystalline state. It has been suggested that mixtures of N_2O_4 with aprotic organic liquids, which do not dissolve cellulose nitrite, be used for the *O*-nitrosation of cellulose.^{57, 64, 67–71} As in the preparation of solutions, the ‘driving force’ of the process is the

increased affinity of the reaction medium for HNO_3 . The use of DMF, DMSO, DMA, and ethyl acetate is possible only in the presence of an excess of N_2O_4 ($> 30\text{ vol.}\%$), which rules out the dissolution of the reaction product. Absolute diethyl ether, which does not dissolve cellulose nitrite, proved to be the most suitable organic component. Diethyl ether has a fairly high affinity for HNO_3 ^{72,73} (Table 1) and N_2O_4 ;^{74,75} it is suitable not only as a reaction medium but also as a medium for the subsequent removal of the sorbed nitrogen-containing substances from the final product. The high vapour pressure of diethyl ether ensures the ease and completeness of the drying of cellulose nitrite washed with this solvent.

In the study of the nitrosating activity of the N_2O_4 diethyl ether system it was established^{68,70} that, with increase in the

Table 1. The donor numbers (DN) of the organic solvents employed and the enthalpies of their interaction with HNO_3 ($-\Delta H$).

Solvent	DN	$-\Delta H/\text{kJ mol}^{-1}$
Pyridine	33.1	99.2
DMSO	29.8	52.5
DMF	26.6	60.2
Diethyl ether	19.2	29.8
Ethyl acetate	17.1	19.7

concentration of N_2O_4 in the mixture to $\sim 23\text{ vol.}\%$, the increase in the rate of reaction is small. This is followed by acceleration, which becomes very rapid starting from N_2O_4 concentration of $\sim 37\text{ vol.}\%$ (Fig 4). These N_2O_4 concentrations actually correspond to the stoichiometric molar compositions (1 : 2 and 1 : 1) of its complexes with diethyl ether.⁷⁵ As a consequence of the decomposition of the complexes, the system contains a certain amount of free N_2O_4 , which permeates into the bulk of the fibre much more readily than the complexes. The 1 : 1 complex is less stable⁷⁵ and more dissociated. With increase in the N_2O_4 concentration above the stoichiometric value, the nitrosation process accelerates sharply. An increase in temperature tends to decrease the stability of the complexes with ‘liberation’ of N_2O_4 and its dissociation.⁷⁵ The reaction rate increases more than might have

Figure 4. Dependence of the degree of nitrosation of cellulose on the N_2O_4 concentration in diethyl ether (reaction time 18 min, liquid modulus 50 ml g^{-1} , 0°C).

been expected solely on the basis of the temperature coefficient of diffusion.^{68,70} Taking into account the high volatility of the components of the nitrosating mixture, it was recommended^{67,68,70} that cellulose trinitrite be obtained in the presence of a higher N_2O_4 content ($\sim 50 \text{ vol. \%}$) in diethyl ether but at reduced temperatures ($\sim 0^\circ\text{C}$). The final product should be washed free of the sorbed components of the reaction medium with cooled absolute diethyl ether, the completion of the washing process being checked by means of the starch-iodine indicator. It is desirable that the preparation be dried by evacuation in the cold.

The nitrosation of cellulose takes place also in the absence of an electron-donating organic component.^{68,69} The excess N_2O_4 is capable of binding and removing from the reaction zone the HNO_3 produced, since it dissolves it with formation of fairly stable compounds.⁷⁶ The rapid intracrystallite permeation of the free N_2O_4 into the cellulose phase gives rise to a very high rate of reaction.⁶⁹ However, serious methodological, complications, associated with the occurrence of competing processes, arise in this case.⁶⁹

The combination of diethyl ether with NOCl does not allow the preparation of a highly substituted cellulose nitrite.^{57,68} The electron-donating ability of diethyl ether is insufficient to bind the hydrogen chloride formed as a side product, which is a stronger acid than HNO_3 . A mixture of chloroform with pyridine is suitable in this instance as the reaction medium. In contrast to diethyl ether, chloroform can dissolve and remove from the reaction zone the second reaction product, pyridine hydrochloride.

The sorbed components of the reaction medium can be removed from the reacted material also with water at $0-5^\circ\text{C}$ in the presence of bases such as, for example, pyridine or NaHCO_3 ($\text{pH} \sim 8.5$).^{57,69} A moist fibrous cellulose nitrite, stable in the cold and similar to the preparations isolated from solutions, is obtained.^{44,59}

Analysis of the products of the heterogeneous reaction for the nitrite and nitrate forms of nitrogen by the familiar chemical methods and also those proposed by Torgashov and co-workers,^{57,59,68} demonstrated a satisfactory agreement among the results, indicating the vast predominance of the nitrite ester groups and the possibility of the attainment of a high degree of substitution up to complete substitution. Using the gravimetric analysis of a dry preparation ($\text{DS} = 2.97$) obtained with the aid of diethyl ether from chromatographic paper (97% α -cellulose), Torgashov et al.⁵⁷ tested, apart from the conclusion about the purity of the product, the hypothesis^{15,36,61} that molecular complexes between cellulose and HNO_2 or nitrogen oxides with

different degrees of oxidation are formed in the given systems. After nitrosation, washing, drying and regeneration, the specimen retained the form of a sheet, which is most convenient for studies. The molecular mass (M) of the elementary unit of the nitrogen-containing compound obtained was found from the gravimetric results:

$$M = 162 \frac{m_1}{m_2},$$

where m_1 and m_2 are the masses of the reaction product and of the cellulose regenerated from it with water. The value $M = 249.48$ found was compared with the molecular masses of the postulated compounds (Table 2). The latter were calculated from the degree of substitution in terms of HNO_2 . The minimum discrepancy between the experimental and calculated values corresponds to cellulose nitrite ($\text{DS} = 2.97$). For the remaining variants, the discrepancy greatly exceeds the possible errors of the gravimetric method. The formation of cellulose nitrite in the given systems and not of its isomeric *C*-nitroso-compound is demonstrated by the decomposition of the preparations obtained by LiAlH_4 or CaH_2 in anhydrous diethyl ether into ammonia and chemically unchanged cellulose.⁵⁷ *C*-Nitroso-compounds are known to be readily reduced to amino-derivatives.

The visible and UV spectra of the preparations obtained are identical with the spectra of the cellulose nitrite isolated from

Table 2. The calculated molecular masses of postulated compounds of different composition.

Compound	M	Absolute deviation	Relative deviation (%)
$\text{C}_6\text{H}_7\text{O}_2(\text{OH})_{0.03}(\text{ONO})_{2.97}$	248.13	+1.35	0.5
$\text{C}_6\text{H}_7\text{O}_2(\text{OH})_3 \cdot 2.97\text{HNO}_2$	301.59	−52.11	20.9
$\text{C}_6\text{H}_7\text{O}_2(\text{OH})_3 \cdot 2.97\text{N}_2\text{O}_4$	435.24	−185.76	74.5
$\text{C}_6\text{H}_7\text{O}_2(\text{OH})_3 \cdot 2.97[\text{N}_2\text{O}_4 \cdot (\text{C}_2\text{H}_5)_2\text{O}]$	655.02	−405.54	162.5
$\text{C}_6\text{H}_7\text{O}_2(\text{OH})_3 \cdot 1.485\text{N}_2\text{O}_3$	274.86	−25.38	10.2

solution⁵⁹ and with the spectra of other organic nitrites (Fig. 5). The 4–5 band absorption in the range 330–380 nm characteristic of these compounds⁶⁶ vanishes when the preparation is treated with water or alcohol. A similar correspondence has been observed between the IR spectra of the heterogeneous interaction products and the highly substituted cellulose nitrite precipitated from solution.^{15,59} The spectrum of a solution of cellulose in DMSO presented in Fig. 2 corresponds to the preparation obtained with the aid of diethyl ether.

In a study of the crystal structure of cellulose trinitrite,^{68–70,77–80} special procedures,^{68,69,79} ensuring the protection of the specimen against decomposition throughout the X-ray diffraction measurement, were used. Oriented preparations ($\text{DS} = 2.93-2.97$) were obtained from purified and bleached flax fibres (97% α -cellulose), which had been used successfully in previous^{81,82} X-ray diffraction analyses of cellulose nitrates.

The texture X-ray diffraction pattern of cellulose trinitrite (Fig. 6), (Table 3) contains 19 independent reflections, which have been satisfactorily indexed in terms of a monoclinic unit cell with the parameters $a = 25.3 \text{ \AA}$, $b = 18.9 \text{ \AA}$, $c = 25.5 \text{ \AA}$ (fibre axis), and $\gamma = 95.8^\circ$.^{70,79} Eight chain molecules pass through the unit cell. The theoretical density of the crystallites, calculated from these unit cell parameters, is 1.36 g cm^{-3} . The experimental density (1.39 g cm^{-3}), determined pycnometrically using absolute diethyl ether, agrees satisfactorily with the calculated value. In the determination of the density, the operations involving the nitrosation of cellulose with a N_2O_4 –diethyl ether mixture and

the washing of the final product with diethyl ether were performed directly in the pyknometer.^{70, 79}

There is an evident analogy between the structures of the cellulose trinitrite crystallites and those of the 'related' cellulose trinitrate.^{81–83} Both compounds are outstanding among the crystallographically investigated cellulose derivatives having a helical chain conformation with a five-unit pitch and hence with an 'anomalous' identity period of ~ 25.5 Å. In the crystallites of other cellulose triesters as well as cellulose itself, this parameter is

determined by the length of the cellulose fragment (~ 10.3 Å) regardless of the polymorphic modification.

Distinctive features have also been noted in the formation of the crystalline phases of the incompletely substituted nitrated and nitrosated cellulose.⁶⁹ The different contents of nitrogen in specimens of highly substituted cellulose nitrate causes certain differences in the unit cell parameters.^{4, 82} Accordingly, the angular distribution of the reflections on the X-ray diffraction patterns of preparations with high but somewhat different degrees of substitution may not agree. In the case of cellulose nitrite, the dependence of the diffraction angles on the degree of substitution, the nature of the nitrosating agent (N_2O_4 or NOCl), and other factors is almost imperceptible.⁶⁹ On the diffractograms of preparations differing, apart from the degree of substitution (2.52–2.85), in the form of the initial native cellulose, the nitrosation conditions, and the conditions in the isolation of the product from the reaction mixture, the angular positions of the reflections are identical and the same as for cellulose trinitrite (Fig. 7). The above factors influence mainly the intensity and sharpness of the reflections.

For the same degree of substitution and preparation conditions, the nitrite of wood cellulose is consistently less crystalline than the nitrite of cotton or flax cellulose, since the crystal structure of its cellulose precursor is less ideal. The crystallinity of the cellulose nitrite obtained in diethyl ether, which is inert to it, is always higher than that of the preparation obtained in DMF or ethyl acetate, which do not dissolve this product solely by virtue of the excess of N_2O_4 in the system. The crystallinity of equally substituted cellulose nitrosation products increases in aliphatic carboxylic acids with increase in the length of the hydrocarbon group of the acid. The isolation of cellulose nitrite from the reaction medium with the aid of anhydrous CCl_4 or CH_2Cl_2 , which are indifferent to N_2O_4 and HNO_3 , is accompanied by a decrease in the degree of substitution and crystallinity. In contrast to diethyl ether, these liquids do not have a stabilising effect and serve merely as a 'transporting agent' in the removal of excess reactants from the polymer phase. The quite distinct individuality of the diffractogram of cellulose nitrite makes it possible to employ the X-ray diffraction method for the detection of the

Figure 7. Diffractograms for isotropic cellulose nitrite specimens. Specimen: (1) DS = 2.85, obtained from cotton cellulose in N_2O_4 –diethyl ether, isolated with diethyl ether, and dried *in vacuo*; (2) DS = 2.78, obtained from wood cellulose in N_2O_4 –ethyl acetate, isolated with diethyl ether, and not dried; (3) DS = 2.81 obtained from cotton cellulose in N_2O_4 –DMF, isolated with a water–pyridine mixture, and not dried; (4) as (3), but isolated with NaHCO_3 solution; (5) DS = 2.80, obtained from flax cellulose in N_2O_4 –caprylic acid, and not dried; (6) DS = 2.52, obtained from cotton cellulose in N_2O_4 –DMF, isolated with CCl_4 and CH_2Cl_2 in succession, and dried *in vacuo*; (7) DS = 2.75, obtained from cotton cellulose in NOCl – CHCl_3 –pyridine, isolated with a solution of pyridine in CHCl_3 , and not dried.

crystalline phase of this compound in a complex reaction mixture, where other methods are inapplicable.^{77,78}

The kinetics of the heterophase *O*-nitrosation of cellulose in organic media have been investigated taking into account the influence on the process exerted by the factors specific to the given systems.^{68,70,84,85} Together with highly crystalline cellulose, a specimen with a more accessible structure, prepared by the decrystallisation of cellulose, was employed. It was obtained by heterogeneous regeneration from cellulose nitrite under anhydrous conditions.⁸⁴ The reaction in DMF, ethyl acetate, diethyl ether, and acetic and oenanthic acids (AA and OA respectively) was investigated. The kinetic curves (Fig. 8) were obtained for the minimal value of the liquid modulus established (50 ml g^{-1}), an increase in which hardly affects the degree of esterification.

The long linear section of the curves, reflecting the constancy of the rate at which an appreciable mass of cellulose (from 40% to 90%) is converted into the nitrite, is described by the zero-order equation

$$\alpha = k_0 t,$$

where α is the degree of conversion at time t and k_0 is the rate constant.

In heterogeneous reactions, this type of relation is attributed to the constancy of the reaction surface in the conversion of a large proportion of the initial substance.⁸⁶ Bearing in mind that the capillary mechanism of the transport of the reactant predominates in cellulose fibres over the diffusional mechanism,⁸⁷ the constancy of the cross-section of the reactant flux may be represented as the migration of the reaction zone at a constant rate via a network of

Figure 8. Kinetics of the heterophase nitrosation of cellulose under various conditions.

capillaries. In this case, one has to assume that the reaction proceeds layer-by-layer with conversion of the main bulk of cellulose on the outer surface. The decrease in the area of the latter is responsible for the bending of the kinetic curve on passing to inner regions, accessible with difficulty, where truly diffusional transport plays the main role.

Taking into account the methodology of the familiar studies^{88,89} on the topochemical reactions of cellulose, the experimental data (Table 4) were expressed quantitatively with the aid of the Erofeev–Kolmogorov equation

$$\alpha = 1 - \exp(-Kt^n),$$

where K and n are constants. The reaction orders n , determined from the slopes of the modified curves, indicate that the order is in all cases limited by chemical factors. The activation energies E are also too high for diffusional kinetics.⁹⁰ However, the inconstancy of the composition of the reaction mixture and of the state of the reacting surface, characteristic of the given systems, throw doubt on the conclusion concerning the rate-limiting stage reached from the analysis of topokinetic equations. The influence of the nature of the solvent and temperature on the rate of the complex formation reaction between the liquid components^{74,75} was discussed above. The rate of the reaction depends on the nature of the organic medium even in mixtures rich in N_2O_4 (Table 4). The smallest change in the reaction surface as a result of swelling should occur during nitrosation in diethyl ether and acetic and oenanthic acids, which do not dissolve cellulose nitrite. The rate of reaction in diethyl ether, the basicity of which is higher than that of carboxylic acids, is higher than in acetic acid but lower than in oenanthic acid, although the basicities of both acids are virtually identical. This difference can be accounted for by taking into account the functional density of the medium (FDM), equal to the number of electron donors per unit volume.⁸⁴ The expression for this parameter includes the density (d , at 20 °C) and the molecular mass of the organic liquid:

$$\text{FDM} = \frac{1000d}{M}.$$

^a The fraction of cellulose reacting in accordance with the equation $\alpha = k_0 t$. ^b Determined from K/h^{-n} with the aid of the Sakovich equation: $k = nK^{1/n}$. ^c Calculation by the Arrhenius equation; the first value corresponds to the values of k_0 . ^d Values for specimens of amorphised cellulose.

The smallest number of moles per unit volume is actually a characteristic of oenanthic acid (Table 5), so that a greater fraction of N_2O_4 remains unbound in the latter compared with other media. The activation energy is higher in mixtures of N_2O_4 with acetic acid than in its mixtures with oenanthic acid (Table 4), since the dissociation of the complex is an endothermic process⁷⁴ and the FDM is higher for acetic acid. Accordingly, with increase in temperature the reaction in acetic acid is accelerated to a greater extent than in oenanthic acid. The viscosity of the medium also plays an important role; the viscosity of oenanthic acid is highest (Table 5). In mixtures of diethyl ether, acetic acid and oenanthic acid with a reduced N_2O_4 content, where the influence of the FDM is abolished by the excess of the solvent, the importance of

transport factors increases. In the least viscous, diethyl ether, the rate of reaction at a relatively low N_2O_4 concentration (20 vol. %) is higher than in oenanthic acid medium of similar composition.

The influence of the structural characteristics of cellulose on the process kinetics is manifested clearly in experiments with a decrystallised specimen.⁸⁴ As a consequence of the facilitation of mass transport, there is a significant increase in the rate constant and in the fraction of cellulose reacting at a constant rate, as the activation energy diminishes (Table 4). In DMF and ethyl acetate, which dissolve cellulose nitrite, a heterogeneous course and completion of the reaction are possible only in the presence of an excess of N_2O_4 (40 vol. % – 50 vol. %). The decrease in its concentration as a result of its consumption on nitrosation alters the nature of the interface, since the polymer swells. The reason for the hindrance of mass transport may be the formation of a gel-like layer, the viscosity of which is highest when ethyl acetate is employed.¹⁵ A distinctive feature of these systems is the acceleration of the reaction following a decrease in the N_2O_4 concentration to ~20 vol. % and its completion by the complete dissolution of the material. The baring of the reaction surface as a result of the dissolution of the reacted layer facilitates mass transport and accelerates the reaction (k_0 was estimated approximately in this case from the time for the total dissolution of the specimen).

The sensitivity of the reaction to factors which determine the transport of the reactant, the change in the properties of the reaction surface, and also the appreciably lower rate of interaction with N_2O_4 than for low-molecular-mass analogues⁹¹ conflict with the conclusion that chemical inhibition, which follows from the value $n \geq 1$, takes place. A precondition of an adequate description of the process is, in particular, that the composition and homogeneity of the polymer phase be determined at different stages of the reaction. Analysis of the corresponding diffractograms (Fig. 9) indicates convincingly the layer-by-layer course of the process, throughout which the material remains crystalline. The intensification of the reflections due to cellulose trinitrite with increase in the degree of substitution is accompanied by the

Figure 9. Dynamics of the structural rearrangement at different stages of the nitrosation of cellulose with a N_2O_4 – diethyl ether (50 : 50) mixture at 0 °C. DS: (1) 0.33; (2) 0.91; (3) 1.98; (4) 2.30; (5) 2.60; (6) 2.93.

synchronous weakening of the Cel-I reflections as far as their complete degeneration. The diffractograms of the products of the intermediate reaction stages resemble those of a mechanical mixture of the crystallites of Cel-I and its trinitrite. With the aid of ethyl acetate, which is indifferent to cellulose, it is possible to separate quantitatively a weakly substituted preparation ($DS = 1.53$) into a solution of highly substituted cellulose nitrite, and a virtually unaltered Cel-I.⁸⁴

These data, together with those examined above (Fig. 7) clearly indicate the direct formation of the triester from cellulose, i.e. a high rate of the chemical reaction proper. In the kinetic reaction regime, a nearly statistical substitution of the OH groups, inducing the diffuseness of the X-ray diffraction patterns of the partly substituted preparations, would be most probable. By definition,⁹⁰ the set of the above features makes it possible to identify the *O*-nitrosation of cellulose in electron-donating organic media as a process occurring under the conditions of strong internal-diffusion inhibition in the 'external kinetic region'. The reaction is 'displaced' on to the outer surface and proceeds in a regime simulating the kinetic regime.

The highly substituted cellulose nitrite obtained as a result of heterogeneous processes with the aid of diethyl ether is a white substance with a yellowish tint. Its form corresponds to that of the initial cellulose (fibre, sheet, powder). In a moist atmosphere, it decomposes, readily with evolution of nitrogen oxides. Its resistance to the action of moisture increases appreciably in the pressed state.⁶⁸ The decomposition process is retarded in alkaline media.⁷⁰ On ignition, cellulose nitrite burns vigorously. The enthalpies of combustion and formation of cellulose nitrite, determined calorimetrically in the absence of contact with atmospheric moisture, are respectively -2970 ± 12.5 and -391 ± 12.5 kJ mol⁻¹.⁹² The high heat of explosive decomposition (-3660 kJ kg⁻¹) and the large volume of the gases evolved on explosion (870 litre kg⁻¹) make it possible to classify cellulose nitrite as a fairly powerful explosive.

The N₂O₄- and HNO₃-free bright transparent solutions of cellulose nitrite in organic solvents are distinguished by a series of properties from the familiar solutions in nitrosating compositions.^{93–96} Their lower viscosity makes it possible to attain a high polymer concentration (up to 15%). For example, the viscosity of a 6% solution of the nitrite of sulfate cellulose (DP = 1200) in ethyl acetate corresponds to the viscosity of a 2% solution in the N₂O₄-ethyl acetate mixture.⁹⁴ A similar rule is characteristic also of solutions of cellulose nitrate incorporated in graft copolymers of cellulose. The stability of joint solutions of cellulose nitrite and synthetic and artificial polymers is higher than that of analogous systems incorporating N₂O₄ and HNO₃. The absence of N₂O₄ and HNO₃ makes it possible to employ polymeric additives sensitive to them (polyamides and rubbers), expanding the possibilities for the moulding of the composite materials.⁹⁵

Torgashov et al.⁹⁷ investigated the oxidation of cellulose nitrite ($DS = 2.80$) by N₂O₄ in carbon tetrachloride in order to test the hypothesis^{2,28} that the nitrite ester participates as an intermediate in the reaction of preparation of monocarboxycellulose. The model cellulose nitrite was oxidised much more slowly than cellulose itself. The onset of the oxidation process was preceded by an induction period of ~ 6 h, during which neither denitrosation nor oxidation took place (Fig. 10). The reaction of cellulose under the same conditions began with the accumulation of nitrite ester groups in the first ~ 10 min, after which the oxidation process developed and the content of the nitrite groups diminished.

The behaviour of the model cellulose nitrite and the nitrite formed in the Cel–N₂O₄–CCl₄ system is not equivalent owing to the formation in the latter case of HNO₃, which, together with the destabilisation of the nitrite ester, increases the electrophilicity of N₂O₄⁹⁸ and hence its oxidising capacity. If 100% HNO₃ (3 moles per GPU) is added to the reaction mixture during the oxidation of cellulose nitrite, modelling the Cel–N₂O₄ system thereby, the rate of accumulation of carboxy-groups is found to be even higher

Figure 10. Variation of the contents of carboxy-groups (*I*, *2*) and nitrite ester groups (*I'*, *2'*) in the oxidation of cellulose (*I*, *I'*) and of its model nitrite ester (*2*, *2'*) with N₂O₄ in CCl₄.

than in the oxidation of cellulose. The formation of the labile cellulose nitrite at an intermediate stage of the oxidation process exerts a strong influence on the reaction, although, according to Sykes's data,⁹⁹ cellulose nitrite does not correspond to the intermediate in the cellulose oxidation reaction in terms of kinetic parameters.

IV. Heterophase structural transformations of cellulose with participation of labile nitrogen-containing derivatives

In the structural transformations taking place in the Cel–N₂O₄ system, the attention of investigators has been drawn to the effect of decrystallisation of native cellulose as a result of treatment with N₂O₄ and subsequent washing with water or an organic liquid.^{100–106} The use of both liquid^{101–105} and gaseous^{100–106} N₂O₄ for this purpose has been discussed. The chemical composition of the decrystallised cellulose is unaltered, but the DP diminishes significantly (as far as ~ 300).^{100,101,103} The degree of decrystallisation and the accompanying degree of transformation of the native structural form into the Cel-II form were found to be extremely sensitive to the moisture content of the initial fibre and the conditions employed to perform the both stages of the process.^{100,101,105,106} Such features of the process as the brief contact (~ 15 s) between cellulose and N₂O₄, which is sufficient for attainment of decrystallisation effect, or the suitability of water for washing of the treatment products, did not fit into the framework of the established ideas^{107–109} about the mechanisms of the heterophase amorphisation of cellulose by reagents capable of inducing its intracrystallite swelling.

The interaction of cellulose with a N₂O₄ solution (18 vol. %–20 vol. %) in glacial acetic acid and subsequent washing of the fibre with the same acid ensure the formation of an amorphous structure with a capillary-porous system developed to the maximum extent and accompanied by a much smaller decrease in DP.^{12,17,110,111} The cotton cellulose amorphised in this way is superior to the initial cellulose in terms of the water-retaining capacity (WRC) almost by a factor of 7 (250% against 37%).^{12,111} Under identical conditions in hydrolysis in dilute HCl, the amorphised cellulose loses 84% of its mass, while the initial cellulose loses only 35%.^{110,111} Complete acetylation of cotton cellulose after this treatment is 25 times faster than after standard activation with acetic acid alone.^{112,113} For cellulose decrystallised directly by N₂O₄, the superiority of these and some other

parameters over the initial ones is manifested to a much smaller extent.^{112, 114–117}

X-Ray-amorphous material with a high WRC ($\sim 250\%$) and a high hydrolysability has also been obtained by treating cellulose with more dilute (6 vol. %–10 vol. %) N_2O_4 solutions in acetic anhydride or mixtures of the latter with acetic acid.^{77, 118, 119} In contrast to the conditions indicated above, these reaction conditions induced the formation of a weakly substituted cellulose nitroacetate.

Kaputskii et al.¹²⁰ explained the amorphisation of cellulose by the irreversible destruction of the crystallites as a result of the intense swelling in the $\text{N}_2\text{O}_4 \rightleftharpoons 2\text{NO}_2$ dynamic mixture. A decisive role was attributed to physical factors — sorption, condensation, dimerisation of NO_2 molecules, disjoining effect. However, it was found from the results of X-ray diffraction phase analysis that the competitive formation of two new crystalline phases takes place in the swelling stage.^{121, 122} The X-ray diffraction expression for one of them corresponds to cellulose nitrite.⁶⁹ The second, more stable phase, is characterised by a diffraction pattern typical for Knecht's compound, the familiar adduct of cellulose with HNO_3 .³⁰ The ratio of these phases in the swollen fibre depends on the moisture content in the initial cellulose, on the treatment conditions, and in particular on the access of atmospheric moisture to the reaction zone.^{69, 121} The transformation of the structure of cellulose nitrite into that of KC under the influence of atmospheric moisture can be traced from the variation of the intensities of the corresponding reflections on the diffractograms of the fibre swollen in N_2O_4 .^{121–123}

The formation of cellulose nitrite in the reaction mixture was observed by X-ray diffraction^{10, 121, 122, 124–126} before the X-ray pattern of individual cellulose nitrite became known.⁷⁸ The cellulose nitrite phase has been erroneously classified^{10, 121, 122, 124–126} as a sorption compound on the basis of generally known principles^{108, 127} of the structural reorganisation of cellulose under the action of other active nitrogen-containing reagents (ammonia, amines, HNO_3), which induce its intracrystallite swelling. These studies initiated a detailed investigation of the structural transformations possible in the given system.

Each of the above phases can be formed separately (cellulose nitrite or KC) by establishing an appropriate regime in the interaction of cellulose with liquid N_2O_4 .^{69, 128, 129} If the reaction conditions promote the removal from the fibre of HNO_3 formed and prevent the access of moisture from the surrounding medium to the reaction zone, cellulose nitrite is formed preferentially. A preparation having a typical cellulose nitrite diffractogram (Fig. 11) has been obtained by the successive treatment of air-dry cellulose (moisture content 5%–7%) for ~ 2 min with three fresh portions of N_2O_4 whilst stirring and at a high value of the liquid modulus.^{69, 129} The rapid protection of the preparation from atmospheric moisture immediately on completion of the treatment is obligatory, since otherwise the reflections of the second phase (KC) appear on the diffractogram. The crystallinity of the cellulose nitrite thus obtained is always significantly lower than that of the substance obtained in the presence of an electron-donating liquid.

The combination of N_2O_4 with an electron-donating component (diethyl ether or acetic acid) pre-determines the nitrite pathway of the reaction and a higher stability of the cellulose nitrite swollen in the reaction medium.⁶⁹ On treatment with water, the crystalline phase of the nitrite of the native cellulose is readily reconverted into the crystalline Cel-I phase (Fig. 11).^{68–70, 129} A direct relation has been traced between the degrees of crystallinity of the regenerated Cel-I and the precursor (the nitrite ester). The use of hot water or steam for the hydrolysis of cellulose nitrite tends to increase the crystallinity of the regenerated Cel-I.^{68–70} The interconversion of the crystalline phases of Cel-I and its nitrite is characterised by more clear X-ray diffraction patterns than these obtained during the familiar heterogeneous cellulose esterification processes (acetylation, nitration) and in the hydrolysis of its triesters.¹³⁰ The conclusion¹³⁰ that the lattices of the initial

Figure 11. Equatorial diffractograms for the initial flax cellulose (1), highly substituted cellulose nitrite obtained with the aid of N_2O_4 alone (2) and a N_2O_4 –diethyl ether mixture (3), Cel-I regenerated with water from specimens 2 (4) and 3 (5).

native cellulose and that after a cycle of topochemical transformations are not quite equivalent has been confirmed. On the diffractogram of the latter, the (002) reflection is displaced by $\sim 0.4^\circ$ towards smaller diffraction angles (Fig. 11).^{128–130}

The sorption-type KC is also a labile product of the interaction of cellulose with N_2O_4 .^{10, 69, 121, 123} The extremely scanty and contradictory information about its composition and structure is almost fully confined to the data in Refs 29–31, 131, and 132. This compound is formed in the reaction of cellulose with HNO_3 in the monohydrate form. As a rule, the acid concentration of 68 mass %–69 mass % is employed. The azeotropic mixture corresponding to 68.4% HNO_3 is characterised by extremal physical properties⁷⁸ and a weak nitrating activity.^{31, 131, 132} According to Gess,¹³¹ KC is an oxonium compound, being a product of the addition of HNO_3 to the oxygen of the glucoside group of cellulose. The results of calorimetric measurements¹³³ have confirmed this view.

On the basis of the analysis of texture X-ray diffraction patterns and certain assumptions, Andress³⁰ proposed a monoclinic unit cell for KC with the following parameters: $a = 12.20 \text{ \AA}$, $b = 10.28 \text{ \AA}$ (fibre axis), $c = 9.73 \text{ \AA}$, and $\beta = 53^\circ$. Somewhat later Mark¹³² assessed these data as reliable only with regard to the identity period. From the standpoint of the modern concept of the formation of cellulose adducts,^{108, 127} the crystalline phase of KC should be regarded as a result of the insertion and stoichiometric 'fixation' of HNO_3 between the least interlinked (101) planes of the three-dimensional lattice of cellulose. The movement of these planes away from one another along the large ac diagonal (cell projection) is accompanied by a decrease in the angle β without affecting significantly the (10 $\bar{1}$) and (002) planes (Fig. 12). The (101) reflection on the X-ray diffraction pattern of the new phase is displaced towards smaller diffraction angles. Andress identified this reflection as due to the (001) plane, emphasising at the same time the constancy of the (10 $\bar{1}$) and (002) interplanar spacing in the transformation of the Cel-I lattice into the KC lattice.³⁰

The KC lattice is formed in the interaction between cellulose and N_2O_4 under the conditions of the generation of HNO_3 from N_2O_4 directly in the swollen fibre.^{10, 69, 121–123} The reactions of N_2O_4 with cellulose (nitrosation of cellulose) and also with the moisture in cellulose and in the surrounding medium (hydrolysis of N_2O_4) are the sources of the accumulation of HNO_3 . For example, keeping of N_2O_4 -impregnated air-dry cellulose in an atmosphere with a moderate relative humidity (50%–60%) leads

Figure 12. Schematic illustration of the transformation of the Cel-I unit cell (a) into the KC unit cell (b) and the corresponding changes in the diffractogram.

to the formation of KC. After only 15 min of the free evaporation of nitrogen oxides from the swollen fibre, the reflections due to cellulose nitrite vanish from its diffractogram¹²¹ and the angular distribution in the reflections present^{69, 121} corresponds exactly to that indicated by Andress³⁰ for the cellulose adduct with 68.6% HNO_3 . The KC thus obtained is distinguished by an increased crystallinity and the corresponding well resolved X-ray diffraction pattern (Fig. 13). It is formed under the conditions of the decomposition of the cellulose nitrite formed initially, i.e. in a system with a weakened intermolecular interaction and an enhanced segmental mobility of the macromolecules. It is this peculiar 'chemical plasticisation' effect, that most probably creates favourable kinetic preconditions for the formation of the perfect KC crystal lattice.

It has been noted^{128, 129} that the equatorial KC diffractogram changes somewhat with time (Fig. 13). After the specimen has

Figure 13. Equatorial diffractograms for KC obtained with the aid of N_2O_4 at a relative humidity of 53%.

(1) initial diffractogram; (2) after keeping specimen 1 under room conditions for 24 h; (3) after additional treatment of specimen 2 with N_2O_4 under previous conditions.

been kept for 20 h under room conditions, the reflections at $2\theta = 11.2^\circ$ and 22.8° are displaced to $2\theta = 12.0^\circ$ and 24.0° , indicating the densification of the crystallites. Judging from the meridional diffractograms,¹²⁸ the identity period remains unchanged (10.3 Å). Additional treatment with N_2O_4 of the specimen having the modified lattice under the previous conditions restores the initial diffractogram and improves somewhat the degree of its resolution. These observations suggest that KC is polymorphic, by analogy with alkaline cellulose.¹²⁷ The inconstancy of the KC crystal structure is apparently due to the change in its composition as a result of the evaporation of 'guest' molecules. According to Mark's data,¹³² the adducts $\text{C}_2\text{H}_{10}\text{O}_5 \cdot \text{HNO}_3$ and $2\text{C}_6\text{H}_{10}\text{O}_5 \cdot \text{HNO}_3$ are characterised by identical diffraction pattern. This is attributed to the presence in the former case of an excess of HNO_3 , sorbed on the surfaces of the crystallites and not involved in the formation of the lattice. Postulating the involvement of partly oxidised cellulose macromolecules in the formation of KC, Urbanski and Zyszczyński³¹ do not reflect the chemical changes in the formula quoted: $2\text{C}_6\text{H}_{10}\text{O}_5 \cdot \text{HNO}_3 \cdot \text{H}_2\text{O}$. Their conclusion that cellulose undergoes preliminary oxidation at the sixth carbon atom conflicts with many evident experimental results.⁹ The specific feature of the structure of KC are still not understood. The possibility of increasing the amount of information derivable from the texture X-ray diffraction pattern of the KC obtained using N_2O_4 makes it possible to hope for a more rigorous quantitative description of the crystal structure of this compound.

On treatment with water, the KC crystallites are always transformed into Cel-II crystallites.^{9, 10, 131, 132} The mechanism and conditions of this transformation are on the whole similar to the usual mercerisation of cellulose.⁷⁷ The degree of the polymorphic transformation of Cel-I into Cel-II via KC reflects a measure of the involvement of the crystallites of the initial material in the adduct formation process.^{9, 10} From the standpoint of permeating capacity, N_2O_4 has considerable advantages over 68%–69% HNO_3 .^{10, 77}

The crystallinity of cellulose nitrite, and that of KC, can be logically regarded as naturally 'inherited' from the lattice of cellulose itself. In view of the lability of these derivatives, the application to them of the familiar artificial crystallisation procedures (for example, heat treatment) does not appear possible. Nevertheless, evidence for the spontaneous formation of the crystalline phases of both cellulose trinitrite^{128, 129, 134} and KC^{123, 134–138} has been obtained in experiments on cellulose known to be amorphous. The high extent of 'amorphousness' of the initial model preparation, isolated from cellulose nitrite solution by special precipitation and regeneration methods,^{139, 140} has been confirmed by the rapid and complete hydrolysability in dilute HCl. The cellulose trinitrite obtained from this preparation crystallised slowly on standing in the nitrosating medium (N_2O_4 –diethyl ether) even at 0°C (Fig. 14). Two weak reflections (instead of one), distinguishing Cel-II trinitrite from Cel-I trinitrite, are gradually outlined on its diffractogram in the range $2\theta = 24–25^\circ$.^{128, 129} A similar difference between diffractograms is characteristic also of Cel-I and Cel-II trinitrites.¹⁴¹ The decomposition of the specimens in cold water leads to Cel-II, while their decomposition by steam affords Cel-IV (Fig. 14). Instances of the formation of Cel-IV in the high-temperature saponification of stable Cel-II esters are known.¹⁴² Thus amorphous cellulose can be converted into Cel-IV via its nitrite ester, an appreciable crystallisation effect being attained. Clearly, there can be no question of this type of ordering effect in chemically unaltered amorphous cellulose using treatment with hot steam for 1 min.

The crystallisation of amorphous cellulose as KG has been observed at room temperature on treatment with 68% HNO_3 and N_2O_4 under the conditions discussed.^{123, 134–138} The use of N_2O_4 leads to an appreciably greater crystallisation effect, as in the experiments with the usual amorphous-crystalline cellulose.^{121, 128, 129} The process is extended in time, but has a distinct X-ray diffraction expression (Fig. 14). The kinetic causes of the

(1) initial amorphous cellulose; (2) and (3) trinitrite obtained from amorphous cellulose after being kept for 2 h (2) and 21 h (3) in a N_2O_4 –diethyl ether mixture at 0 °C; (4) and (5) Cel-IV regenerated with steam from specimens 2 and 3 respectively; (6) KC obtained from amorphous cellulose (by treatment with 68% HNO_3 for 4 h); (7) KC obtained from amorphous cellulose (by treatment with N_2O_4 for 1 h, relative humidity 55%); (8) and (9) Cel-II regenerated with water from specimens 6 and 7, respectively.

phase transformation are evident. The weakening of the intermolecular interactions by the formation of an adduct and due to other factors^{123, 136} stimulates crystallisation. Hitherto the formation of cellulose adducts (inclusion compounds)^{108, 127} has been traditionally treated regardless of the amorphous regions of the fibre. In relation to KC, first data have been obtained^{123, 134–138} concerning the possibility of the formation of crystallites of these compounds via a mechanism other than that¹²⁷ involving the insertion of ‘guest’ molecules in the finished lattice. Such a lattice is also produced as a result of the self-organisation of the unordered cellulose macromolecules bound to HNO_3 . The crystallinity of KC attained during the self-organisation process is ‘transmitted’ to the Cel-II regenerated from this compound with water (Fig. 14). According to the results of a series of studies,^{9, 123, 136, 138} the amorphous regions also perform a ‘mediating’ function, promoting the penetration of the reagent into the crystallites and the complete formation of a new crystalline phase. The participation of the amorphous regions in the formation of the crystalline phase of the cellulose adducts has been confirmed by the analogous experiments with alkaline cellulose.^{136–138} However, the nonrigorous stoichiometry of the interaction in this system precludes a distinct X-ray diffraction expression of the crystallisation effect of the kind observed in the case of KC.

One of the characteristic features of the heterophase transformation of cellulose on treatment with N_2O_4 into a labile chemical or sorption derivative is the high crystallinity of the final reaction product. A high crystallinity is also characteristic of various polymorphic modifications of cellulose itself, regenerated with water from these labile compounds. The manifestation of this topochemical property has been illustrated^{128, 129} by a series of diffractograms (Fig. 15), reflecting a series of consecutive transformations of cellulose on the same fibrous specimen. If the initial Cel-I specimen is used and its treatment with N_2O_4 under appropriate conditions is alternated with treatment with water, then the following topochemical transformations can be observed on the basis of clear diffraction patterns:

Figure 15. Equatorial diffractograms obtained in succession for flax cellulose (1), Knecht's compound (2), Cel-II (3), Cel-II nitrite (4), and Cel-IV (5).

Conditions in the treatment of the specimen: (1) N_2O_4 , relative humidity 53%; (2) H_2O , 20 °C; (3) N_2O_4 – $(\text{C}_2\text{H}_5)_2\text{O}$; (4) H_2O , 100 °C.

Taking into account the above specific features of the formation of labile derivatives of cellulose and of its polymorphic transformations via these derivatives, one can account for the causes of the amorphisation of cellulose, which is possible under these conditions. The type of polymorphic modification of cellulose regenerated in water from the labile derivative depends on its nature. The formation of each labile compound separately in the interaction of cellulose with liquid N_2O_4 requires particular conditions for the accumulation and distribution of HNO_3 in the system.¹²⁹ The usual conditions in the preliminary treatment,^{10, 101–105, 121} initiating both reaction paths at the intracrystallite level, lead to the regeneration of amorphous cellulose. Judging from the nature of the diffractogram (Fig. 16),^{10, 121, 129} obtained in the stage involving the interaction of cellulose with N_2O_4 , a product of the ‘copolymer type’ is formed in this case. The main bulk of the chain molecules are converted into a mixed

Figure 16. Diffractograms for isotropic flax cellulose specimens swollen in N_2O_4 (1), wood cellulose of the ‘Raycord’ brand (2), and the products of their interaction with water (3, 4). (I) KC; (II) cellulose nitrite.

derivative, losing their regular structure, which actually leads to a general disorganisation of the system (intense diffuse scattering on the diffractograms).

The uniform sequences of cellulose nitrite and KC units present in individual microvolumes form crystalline inclusions, the fraction of which is small (weak reflections against the background of diffuse scattering). The balance between cellulose nitrite and KC is unstable, the system tending to be wholly transformed into KC under the influence of small amounts of water, which actually occurs when it is absorbed from air with a humidity of 50%–60%. Only the most unstable component (cellulose nitrite) decomposes under these conditions, stimulating the formation and crystallisation of KC. On rapid decomposition by an excess of water of both labile components simultaneously, the structural imperfection of the mixed cellulose derivative is 'transmitted' to the cellulose regenerated from it (Fig. 16). The elements of order in the cellulose decrystallised in this way are contributed by crystallite formations comprising cellulose nitrite and KC, which are transformed by the action of water into Cel-I and Cel-II respectively. Weak signs of crystallite scattering by these cellulose modifications are frequently manifested on the diffractograms of the amorphised specimens, which are on the whole diffuse.^{101, 103, 114} A convincing demonstration of their presence in the amorphous 'matrix' follows from the diffractograms of the fraction of amorphised preparations which is difficult to hydrolyse.^{105, 114} The degree of decrystallisation of cellulose increases appreciably when an undried organic solvent with a high affinity for nitrogen oxides and HNO₃, for example, diethyl ether or acetic acid, is used instead of water to wash the treated fibre.^{10, 100, 101, 126} These regeneration conditions hinder the transformation of the crystalline cellulose nitrite and KC formations into the corresponding crystalline modifications of cellulose.

Brief contact (15–20 s) between air-dry cellulose and liquid N₂O₄ is favourable for amorphisation.¹⁰ A short reaction time promotes the attainment of a disordered state of the system, limiting structure formation in the rapidly formed labile products. For example, the intracrystallite swelling of cellulose in 68%–69% HNO₃ is known to be completed after ~2 min,^{9, 136} but an increase in the crystallinity of KC is observed over a period of many hours of contact between the fibre and the acid.¹³⁶

The degree of amorphisation of cellulose depends on its moisture content and on the amount of moisture absorbed from the air by the fibre swollen in N₂O₄. It has been noted¹⁰⁵ that, in order to obtain X-ray-amorphous cellulose, the fibre interacting with N₂O₄ should contain at least 5%–7% of water, i.e. should be air-dry. The formation of KC participating in the amorphisation process is not alone in being coupled with the moisture content factor. For a high moisture content in cellulose or a high humidity of air, the process can also be influenced by the formation of N₂O₃ in accordance with the following equations:

A mixture of N₂O₄ and 3%–10% of N₂O₃ is capable of effecting the transition of cellulose to the gel state or a solution.¹³ The shrinkage and conversion into a gel-like formation of a bundle of cellulose fibres on wetting both with purified N₂O₄ under the conditions of a high relative humidity of air (92%) with and a mixture of the above nitrogen oxides (for a humidity of 53%), obtained by passing NO into cooled N₂O₄, has been noted.¹²⁹ According to an X-ray photodiffractogram, the chemically unaltered cellulose regenerated from the gel with water or alcohol is an isotropic amorphous material.¹²⁹ It is remarkable that such treatment of the fibre with N₂O₄ under the conditions of moderate humidity (50%–60%) leads to the formation of the KC crystal lattice, from which textured Cel-II with a high degree of

crystallinity can be readily regenerated with water.^{10, 129} It is logical to assume the possibility of the local manifestation of the homogenisation effect for an increased moisture content in cellulose. Outwardly this may be undetectable owing to the presence of an excess of N₂O₄.

Cellulose dried beforehand is resistant to amorphisation by N₂O₄.^{105, 126} After contact with N₂O₄ and washing with water, its structure corresponds to the Cel-I modification, as for the material generated with water from cellulose nitrite (Fig. 11). However, under conditions inducing the rapid nitrosation of air-dry cellulose^{69, 129} the transformations of the 'dehydrated' cellulose on treatment with liquid N₂O₄ are extremely unusual. An idea about their dynamics is provided by the diffractograms presented in Fig. 17, which were obtained in the following readily reproducible experiment. A specimen comprising dried (105 °C, 2 h) flax cellulose fibres was treated with liquid N₂O₄ under conditions promoting esterification^{69, 129} and was rapidly isolated from the external medium. This was followed by the repeated recording of X-ray diffractograms in the range of angles 8–25 °C at an equatorial scanning rate of 2 deg min⁻¹. Thus the recording of one diffractogram after another (Fig. 17) reflects the course of the structural changes in the fibre throughout approximately 1.2 h since the start of the recording. It follows from then that the rapid intracrystallite interaction of the 'dry' cellulose with N₂O₄ is characterised by a surprisingly high stoichiometry. The new unstable crystalline phase formed in the course of several minutes is distinguished by an individual angular distribution of the diffractogram reflections and by a higher degree of order than in cellulose itself, its trinitrite, or KC. According to the subsequent diffractograms, the crystal lattice of the initial phase approaches that characteristic of cellulose trinitrite as a result of continuous transformations. In the analogous experiments with an air-dry fibre, the diffractogram of cellulose trinitrite is obtained immediately (Fig. 11).^{69, 129}

It may be postulated that a small amount of sorbed water stimulates the nitrosation of cellulose as a result of the ionisation of N₂O₄, whilst in the case of 'dehydrated' cellulose the process is extended over a period of time and it is possible to observe the diffractograms of the transition state adducts. At the same time the complex and varied nature of the interaction of cellulose with pure N₂O₄ does not rule out also other causes of the above transformations. The decisive influence of the moisture content factor on the transformations in the given system is evident, but has not been established in all its manifestations. Without taking into account this influence, seemingly identical reaction conditions may lead to different results.^{114, 138}

The effectiveness of combining N₂O₄ with glacial acetic acid in the preparation of amorphous cellulose has already been noted.^{12, 77, 110, 111} In the presence of carboxylic acids, the nitrosation of cellulose is not complicated by side reactions. According to series of X-ray diffraction features, the swelling of cellulose nitrite in carboxylic acids, (ranging from acetic to valeric) is an intracrystallite process.^{77, 80, 124} The diffractograms of the preparations swollen in the esterifying mixture show, together with the reflections due to cellulose nitrite, an average-angle reflection ($2\theta = 6-7^\circ$), which reflects the appearance in the lattice of a fairly extended (~13 Å) periodicity (Fig. 18). As a result of the displacement of the carboxylic acid from the esterified preparations by absolute diethyl ether, the above periodicity is eliminated, the swelling of the fibre diminishes appreciably, and the reflections due to the crystalline phase of cellulose trinitrite intensify. Such periodicity is also manifested when dry cellulose nitrite, prepared with the aid of diethyl ether, is acted upon by a carboxylic acid. With increase in the length of the hydrocarbon component of the acid molecule, the new interference shifts into the region of smaller angles.^{77, 88} With increase in the degree of swelling of the preparation, its intensity increases synchronously with the degeneration of the (220) and (440) reflections due to cellulose nitrite ($2\theta = 12.4^\circ$ and 24.8°) and then, as the preparation decomposes, it diminishes to zero. The variation of the intensity of the reflection

Figure 17. Dynamics of the structural rearrangement in the interaction of 'dry' cellulose with N_2O_4 .

Time elapsed from the start of the experiment to the completion of the recording of the corresponding diffractogram (min): (a) 9; (b) 18; (c) 27; (d) 36; (e) 45; (f) 54; (g) 62; (h) 72.

due to cellulose nitrite also passes through an extremum at $2\theta = 20.8^\circ$, the reflection shifting towards larger diffraction angles and becoming diffuse.⁸⁰ There is every reason to suppose that cellulose nitrite swells as a result of the insertion of the acid into the lattice between the (220) planes, the new periodicity appearing as a result of the planes 'moving apart'. Comparison of the increment in the (220) interplanar spacing with the sizes of the carboxylic acid molecules shows that this hypothesis is tenable.

Figure 18. Diffractograms of the products of the interaction of cellulose nitrite with carboxylic acids.

Specimen: (1) specimen swollen in the N_2O_4 -acetic acid esterifying mixture; (2) specimen swollen in the N_2O_4 -butyric acid esterifying mixture; (3) specimen 1 after washing with absolute diethyl ether; (4) and (5) specimens swollen in acetic and butyric acids respectively.

The regeneration of cellulose during the washing of the esterified and swollen fibre with glacial acetic acid is actually its regeneration from the additive compound of cellulose nitrite with the acid under the influence of the moisture absorbed from air.⁸⁰ As a hygroscopic substance, glacial acetic acid functions as a moisture conductor, ensuring its equal access to the amorphous and crystalline regions of the swollen fibre. Denitrosation proceeds slowly, in accordance with the statistical principle, introducing a structural disorganisation into the system. An appreciable decrystallisation effect can be attained by not allowing the decomposition of cellulose nitrite in acetic acid to go to completion, the process being stopped by washing with water, as a result of which structurally nonordered cellulose is rapidly and fully recovered from its partly substituted labile ester with an irregular structure. The direct action of water on the esterified preparation rules out the isolation of X-ray-amorphous cellulose.⁷⁷ Complete denitrosation in acetic acid gives rise to the greatest decrystallisation effect. This process, limited by the amount of sorbed moisture, can be greatly extended in time. Gert et al.¹¹¹ determined the degree of swelling of the fibre in acetic acid after the displacement of the latter with N_2O_4 from the product of the treatment of cellulose with a mixture of the above reagents, assuming that the swollen material comprises chemically unaltered amorphous cellulose. The value obtained (300%) exceeds the value of WRC (250%) established by the same gravimetric method after the displacement of acetic acid with water. The swelling of chemically unaltered cellulose in acetic acid cannot exceed its swelling in water. For the initial cellulose, the degrees of swelling are respectively 11% and 37%.^{12, 111} Evidently the swollen specimen employed for the analysis consisted of partly substituted cellulose nitrite, the decomposition of which was completed in the course of the drying of the sample.

The degree of decrystallisation of cellulose is very sensitive to the degree of swelling in the nitrosating mixture, i.e. to the mixture composition, temperature, and the reaction time.^{12, 77} Fig. 9 illustrates the effectiveness of the employment of different com-

positions of the acetic acid–N₂O₄ mixture for the decrystallisation of cellulose during 20 min interaction at the liquid modulus value of 20 ml g⁻¹. In all cases, identical conditions were maintained in the denitrosation reaction, which was stopped by the action of water. As can be seen, the use of mixture of acetic acid with 18 vol. %–20 vol. % of N₂O₄ (5 mol of acetic acid per mole N₂O₄) at 30 °C makes it possible to amorphise cellulose almost entirely. This composition actually induces the highest degree of swelling, of the cellulose nitrite formed, since it exhibits a fairly high nitrosating activity at 30 °C (Fig. 8) At the same time, the composition includes an appreciable amount of free acid (the molar ratio in the acetic acid–N₂O₄ complex is 2 : 1; melting point 2 °C).⁷⁴ It is not fortuitous that the combination of N₂O₄ with a cellulose nitrite solvent (methyl acetate) is used in such proportion to dissolve cellulose.^{1,27} The change in this composition in any direction decreases sharply the decrystallisation effect, giving rise to an extremum in the variation under discussion (Fig. 19). The same behaviour is manifested also as a lower temperature of the 20 min treatment of cellulose with acetic acid–N₂O₄ mixtures of different composition. The weakening of the nitrosating activity leads in this case to a smaller degree of decrystallisation of cellulose. A fairly rigorous correlation between the crystallinity index and the WRC of the preparations indicates that the measurements made are correct.

Figure 19. Variation of the crystallinity index (a) and the water retaining capacity (WRC) (b) of cotton cellulose as a result of treatment with N₂O₄–acetic acid mixtures of different composition.

Treatment conditions: 20 min; liquid modulus 20 ml g⁻¹, temperature 30 °C (1) and 25 °C (2).

Thus the use of the acetic acid–N₂O₄ system for the preparation of amorphous cellulose is based on the specific features of the swelling and decomposition of cellulose nitrite in acetic acid.

V. Examples of the applied importance of labile nitrogen-containing polysaccharide derivatives

In this section, we shall confine ourselves to the discussion of certain rational approaches to the preparation of materials of practical importance, based on polysaccharides with participation of their labile derivatives. This methodology is based on the

principle of the combined use of several functions of the reaction medium and of the unstable polymeric compound formed in it.

A good example is the homogeneous conversion of polysaccharides into sulfates in the DMF–N₂O₄ system by ‘generated reactants’ method.^{143–146} The sulfates of accessible polysaccharides (cellulose, dextran, mannan, chitosan) possess a biological activity, like the expensive and difficult to isolate heparin, chondroitin sulfate, etc.¹⁴⁷ The most effective procedure for the uniform conversion of polysaccharides into sulfates is the homogeneous transesterification of the nitrites with the highly toxic and corrosive SO₃ in the DMF–N₂O₄ system.^{16, 17, 50} It has been suggested^{143–146} that the usual sodium and potassium salts of the acids H₂S_nO_{2n+1} (n = 1, 2) or H₂S_nO_{3n+1} (n = 1–3), which are themselves incapable of esterifying polyhydroxypolymers and function as ‘stored’ forms of SO₃, generating the latter on being acted upon by the reaction medium, be used for the formation of sulfates in the above system. Apart from homogenising the system as a result of the formation of the nitrite ester, the presence of N₂O₄ ensures the sulfating activity of the potential source of SO₃.

Reactants stimulating sulfate formation can act as oxidants, or can participate in exchange processes, or can combine the oxidising and exchange functions depending on the type of sulfur-containing compound employed. The first role is assumed when SO₂ is converted into the sulfating complex between SO₃ and the solvent.¹⁴⁸ The role of N₂O₄ is not restricted solely to the nitrosation of the polysaccharide and the generation of SO₃. The equilibrium degree of substitution as regards sulfo-groups depends on the ratio N₂O₄/SO₃, it diminishes with increase in the ratio.

Thus, apart from the known instability of sulfate esters in relation to acid media, account must be taken also of the desulfating activity of N₂O₄, i.e. the existence in the reaction systems of equilibrium between the sulfate and nitrite ester substituents in the polysaccharide:

When salts of the acids H₂S_nO_{3n+1} are used as the source of sulfur, the reactive sulfating agent is generated (*in situ*) as a result of the exchange activity of N₂O₄ and HNO₃

The SO₃ evolved from the salts shifts equilibrium (6) towards the formation of the sulfate ester. By virtue of the homogeneity and reversibility of the process, the displacement of nitrite by sulfate ester groups takes place uniformly. The cellulose sulfates obtained dissolve fully in water even for DC = 0.2, which is not attained under any other known sulfate formation conditions.

A mixed type of the activating influence of N₂O₄ and HNO₃ is manifested in relation to salts of the acids H₂S_nO_{2n+1}:

It follows from Eqns (7) and (8) that, when salts with tetravalent sulfur are used, both exchange and oxidation reactions take place. The latter lead to heating of the system and the acceleration of the reaction. Salts with hexavalent sulfur are preferable because in this case the equilibrium is established slowly without heating, which creates ‘mild’ synthesis conditions and prevents degradative transformations of the macromolecules. The overall synthesis time is reduced as a result of the combination of the stages involving the dissolution of the starting material and its

conversion into a sulfate on simultaneous introduction of the polymer and the salt into the DMF–N₂O₄ mixture. The mannan and dextran sulfates synthesised in this way exhibit a distinct anticoagulant activity for the corresponding degrees of substitution but are not toxic even in large doses (2–5 g kg⁻¹).¹⁴⁹

Partial nitrosation of cellulose in acetic acid may be of practical interest as an effective preactivation method in the preparation of cellulose acetates.^{12, 113, 126, 150} The high reactivity of cellulose nitrite in the homogeneous transesterification reactions with acetylating agents is known.^{8, 50} The proposed activation procedure reduces to brief treatment of cellulose with a solution of N₂O₄ in glacial acetic acid and subsequent displacement of the free nitrogen oxides from the fibre by the same acid.^{112, 113, 126, 150} The traditional industrial schemes for the activation of cellulose are also based on the treatment of the fibre with acetic acid.^{107, 151} The addition of small amounts of N₂O₄ (5 vol. %) does not induce excessive swelling of the fibre, so that the activation process is achieved simply and rapidly, achieving nevertheless an appreciable increase in reactivity (Table 6). After such activation, even mercerised cellulose, characterised by a low reactivity in acetylation, is acetylated almost wholly.¹⁰⁷ By carrying out the reaction up to the appearance of a 'clear field' in acetone, it is possible to obtain partially substituted cellulose acetates (DS = 2.12–2.26; DP = 420–590) soluble in acetone, dioxane, DMF, acetic acid, and other solvents.^{126, 150} The properties of these products are similar to those of the secondary cellulose acetates obtained via a two-stage scheme: full acetylation of cellulose — partial homogeneous hydrolysis. The known methods for the direct synthesis of such materials^{151, 152} are based on the acetylation of cellulose in the presence of large amounts of H₂SO₄ (15%–25% of the mass of cellulose) and on the reaction being carried out in dioxane. The same 'chemical activation' principle (in the present instance, by conversion into a sulfate) is used. Such methods are more complex. The mixed esterification of cellulose leads to the homogenisation of the reaction mixture in early stages of the reaction and to uniformity of the substitution by acetyl groups, as a result of which the partly substituted cellulose acetate dissolves in organic solvents. In order to isolate cellulose acetate in a pure form and impart thermal stability to it,¹⁵³ a special operation involving the saponification of the sulfate ester groups is carried out. Analogous materials are prepared from partly nitrosated cellulose by means of an acetylating mixture having the usual composition and additional stabilisation procedures are not required.

In contrast to alkaline cellulose, Knecht's compound has not found a practical application. Nevertheless, when cellulose is

processed in acid media, for example, for the preparation of its powdered forms, one can employ successfully the same properties of KC as those of alkaline cellulose. These are primarily the ability to induce the polymorphic transformation of cellulose and to serve as a reactive additive 'matrix' for chemical modification in accordance with a principle similar to that underlying the xanthogenation of alkaline cellulose.

It has been suggested^{33, 154–157} that chemically unchanged microcrystalline Cel-II (MCCel-II) be obtained from native cellulose in accordance with a purely acid scheme, where HNO₃ performs the functions of both 'mercerising' and hydrolysing agents. After the interaction of cellulose with 68%–69% HNO₃, the liquid is squeezed out of the swollen fibre and the strong acid remaining in it is diluted with water to a concentration of 5%–15%, which ensures the selective hydrolytic cleavage of the fibrous system on subsequent heating. As a result of dilution, Cel-II is regenerated from KC and is then hydrolysed with the weak HNO₃ solution formed until the attainment of the 'limiting DP'. The simplicity and rationality of this scheme, eliminating the traditional mercerisation of cellulose with a solution of alkali, are evident. Furthermore, MCCel-II is obtained by the acid scheme with a lower crystallinity than the product formed by the alkaline-acid scheme.¹⁵⁶

The reverse sequence of operations also leads to the 'mercerisation' effect, i.e. treatment of the MCCel-I obtained beforehand with 68%–69% HNO₃ and then water. In this variant, there is the attractive possibility of attaining the virtually complete amorphisation of microcrystalline cellulose by increasing the duration of the reaction with 68%–69% HNO₃ to 2–4 h.^{32, 156, 158, 159} The main cause of decrystallisation is the uniform partial nitration of the microcrystalline cellulose. While possessing a low nitrating activity, 68%–69% HNO₃ is nevertheless capable of esterifying cellulose to a slight extent (DC = 0.1–0.3) under the conditions of prolonged contact. The intracrystalline character of the swelling (the formation of KC) ensures the uniformity of the substitution by nitro-groups. The product isolated by treatment with water is weakly nitrated powdered decrystallised cellulose (PDC).

Powdered celluloses obtained by the above procedures are distinguished by high specific surfaces and sorption activities. (Table 7). In terms of the retention of water and the sorption of iodine and a dye, they are greatly superior to the microcrystalline cellulose prepared in the traditional way. It has been noted that HNO₃ in the form of the monohydrate, induces (like N₂O₄) the appearance of microcracks in the cellulose fibre. Their branched network has been observed on fibre cross-sections⁷⁷ and on the lateral surfaces of PDC particles¹⁵⁸ under a scanning electron microscope. The microcracks and the low crystallinity of the materials are responsible for the manifestation of strong sorption properties. The familiar bleaching activity of HNO₃ and nitrogen oxides^{7, 8} is expressed by the high degree of whiteness of the powdered form of cellulose obtained with their aid.

The possibility of the effective employment of KC in the preparation of monocarboxycellulose, in particular its powdered forms, has been established.^{34, 156, 160} The preactivation of native cellulose with 68%–69% HNO₃ (the formation of KC) makes it possible to increase greatly the rate and uniformity of the subsequent oxidation in the same acid at a somewhat lower concentration (55%–60%). The concentration of HNO₃ is reduced in the oxidation stage in order to weaken its nitrating activity. The oxidation reaction is initiated by the generation of nitrogen oxides from HNO₃. For this purpose, sodium nitrite is introduced into the system or the reaction temperature is increased. By virtue of preactivation, the fraction of the material oxidised at a high, virtually constant rate increases by a factor of 3–5,¹⁶⁰ which makes it possible to obtain rapidly uniformly oxidised cellulose, containing up to 17 mass % of carboxy-groups (the oxidation of the sixth carbon atom in all the GPU corresponds to 25.57 mass % of COOH groups). The bound nitrogen content in the specimens is 0.28 mass %–0.46 mass %.¹⁶⁰

At elevated temperatures, the cellulose oxidation and hydrolytic decomposition reactions coincide in time. Preactivation

Table 6. Results of acetylation by the methylene chloride method of cotton cellulose activated at 20 °C with acetic acid, or the N₂O₄–acetic acid mixture followed by displacement with glacial acetic acid.

Acitvation conditions	Reaction time until attainment of clear field /min	DS of cellulose acetate	DP of cellulose acetate
Initial cellulose — native

PDC (1.3% N), obtained from MCCel-I, LT brand (Lachema Company)	95 (156)	238.0	640	150	94

^a The number in brackets characterises the water-washed final product before drying.

accelerates sharply both reactions. The hydrolysis of cellulose itself stimulates the oxidation reaction, because its products have a reductive function, promoting the formation of nitrogen oxides in the system. It is important to balance these reactions in such a way that the degree of hydrolysis does not affect negatively the yield of powdered oxidised cellulose.¹⁶⁰

Oxidation of preliminarily dispersed cellulose, for example, microcrystalline cellulose, in accordance with this scheme, should be carried out at normal or reduced temperatures, initiating the reaction by adding N₂O₄ or sodium nitrite. There are virtually no mass losses in this case. By virtue of preactivation, the reaction from its very beginning, takes place also in the crystallites themselves and not only on their surfaces, so that the final products are characterised by a low degree of structural order even for a relatively low degree of oxidation.¹⁶⁰

Abstract. The properties of short-lived metal atoms and ions in unusual oxidation states in aqueous solutions, characterised by the presence of one electron in the outer *s* or *p* orbitals (the $d^{10}s^1$ and $d^{10}s^2p^1$ configurations respectively), are discussed. The results of studies on such ions by pulse radiolysis with rapid optical detection and by the matrix isolation method in frozen aqueous solutions are presented. The nature of the dependences of fundamental characteristics of metal atoms and ions (optical transition energies, the electronic structures of various complexes, the oxidation-reduction potentials, etc.) on their positions in the Periodic System are analysed. The bibliography includes 93 references.

I. Introduction

Atoms and ions in unusual and unstable oxidation states are formed at intermediate stages of oxidation-reduction reactions occurring with participation of polyvalent metals. Despite the short time of their existence, their important role in the occurrence and effectiveness of many processes in chemistry and biology is evident. The existence of metal ions in unusual oxidation states has been postulated, and in a number of instances has been confirmed experimentally, in connection with the justification of the multistage nature of electrochemical reactions and the explanation of catalytic steps with participation of metals and the characteristic features of the mechanisms of many other oxidation-reduction processes. The above species can be obtained by pulse radiolysis in aqueous solutions in one-electron reduction or oxidation reactions of metal ions and they are investigated with the aid of optical or coulometric detection. Procedures involving the radiation-induced generation of metal ions in unusual oxidation states in inert matrices at a low temperature with subsequent study by stationary optical and EPR spectroscopic methods are also widely employed.

During the last thirty years investigators have studied in fair detail, employing the above approaches, the properties of many metal ions in unusual valence forms in aqueous media. The results of studies available by 1981 were analysed in our previous review.¹ New data, which make it possible to reach definite conclusions about the regularities in the variation of fundamental properties of metals in unusual oxidation states as a function of their position in the Periodic System, have now accumulated. The study of the chemistry of such elements has become possible as a result of advances, in the first place in radiation chemistry, and also the development of the method of pulse radiolysis.²

This review is devoted to a discussion of the properties of metals in unusual and unstable oxidation states in aqueous solutions and to the establishment of the regularities in their manifestation as a function of the position of the element in the Periodic System. The review is concerned predominantly with metal ions having one electron in the outer *s* and *p* orbitals, *i.e.* with the $d^{10}s^1$ and $d^{10}s^2p^1$ electronic configurations (copper, silver, gold, zinc, cadmium, mercury, gallium, indium, thallium, tin, lead, antimony, and bismuth).

II. Radiation-chemical preparation of atoms and ions of metals in unusual oxidation states

The radiation-chemical reduction or oxidation of metal ions in aqueous solutions is effected by the ionic and radical species which arise on decomposition of water as a result of its interaction with ionising radiation. In a general form, the latter process can be described by the following equation:

The primary radiation-chemical yields of the species in the solution volume per 100 eV of the absorbed energy for light types of radiation (γ -rays or accelerated electrons), the linear energy transfer for which is small, are presented in brackets. The hydrated electron e_{aq}^- and the hydrogen atom H formed have high reduction potentials (-2.7 and -2.3 V respectively), while the hydroxyl radical OH has a high oxidising capacity (2.9 V). For this reason, when the ratio of the potentials in their interaction with metal ions satisfies the requirement that the free energy of the system diminishes, one-electron reduction or oxidation reactions take place. For example, both processes take place in the case of Pb^{2+} ions.

Under these conditions, ions in unusual and unstable oxidation states are produced. They have the electronic configurations $d^{10}s^1$ and $d^{10}s^2p^1$ for Pb^{3+} and Pb^+ respectively.

As a rule investigators used for the study of metal ions in unusual oxidation states solutions in which predominantly reducing or oxidising species may be obtained. We shall illustrate this in relation to OH radicals. On order to obtain OH radicals, a solution is saturated with nitrous oxide. The limiting concentration of the gas under normal conditions in a neutral solution is ~ 0.05 M. As a result of the reaction

the rate constant for which is 9×10^9 litre $\text{mol}^{-1} \text{s}^{-1}$,³ virtually only hydroxyl radicals are formed in aqueous solution.

Hydrated electrons alone may be obtained only in alkaline solutions ($\text{pH} > 12$), saturated with molecular hydrogen, via the following reactions:

The pK for the second equilibrium is 9.6, *i.e.* the hydrogen atom is a weak acid. However, the rate constant for the reaction of molecular hydrogen with the hydroxyl radical is insufficiently high (3.7×10^7 litre $\text{mol}^{-1} \text{s}^{-1}$). In order to increase the rate of reaction, it is necessary to employ high hydrogen pressures, which is difficult to achieve experimentally. Furthermore, hydrogen atoms are transformed into hydrated electrons only in a highly alkaline medium, where many metal ions are precipitated in the form of hydroxides. Therefore, in order to create a reducing medium, use is made of aqueous solutions to which organic compounds — alcohols or organic acid salts — are added as hydroxyl radical and hydrogen atom scavengers. For example, when isopropyl alcohol or a formic acid salt is added, the reactions

generate only reducing species — hydrated electrons and organic radicals — on exposure to ionising radiation. The oxidation-reduction potentials (E^0) of certain organic radicals, most frequently employed in radiation-chemical studies, have been determined from measured equilibrium constants for the reactions involving the reduction of thallium ions by such radicals ($E^0 = -1.94$ V). The following values were obtained:^{4,5}

Parameter	CO_2^-	$(\text{CH}_3)_2\text{COH}$	CH_3CHOH	CH_2OH
$-E^0/\text{V}$	1.9	1.39	1.25	1.18

The presence of one electron in the outer s or p orbital of the metal atom or ion is responsible for an exceptionally high reactivity. Such species may be compared with radicals, which also have an unpaired electron. The lifetimes of metal ions belonging to the s and p blocks and having unusual oxidation states in aqueous solutions are determined by kinetic factors. The rate constants for their dimerisation or disproportionation are as a rule $10^9 - 10^{10}$ litre $\text{mol}^{-1} \text{s}^{-1}$. The preparation and study of such species in aqueous solutions are therefore associated with the employment of methods which make it possible to detect fast processes, in the first place pulse radiolysis with optical detection of short-lived products,^{1,2,6} as well as low-temperature radiolysis [usually in glassy aqueous solutions at the temperature of liquid nitrogen (77 K)]. The method involving the matrix isolation of the highly reactive species formed under these conditions makes it possible to investigate them by stationary electron spin resonance (ESR) or optical spectroscopic methods.

III. Atoms and ions of metals in unusual oxidation states in aqueous solutions

1. Copper, silver, and gold atoms

The radiation-chemical reduction of silver has been most thoroughly investigated.⁷⁻⁹ We shall deal in somewhat greater detail with the methodological features of the experiments on the preparation and study of silver atoms in aqueous solutions, because they are fairly applicable also to other metals.

In a dilute aqueous solution of a silver salt (AgClO_4 at a concentration of $10^{-5} - 10^{-3}$ M is usually employed), containing alcohol or HCOONa as the hydroxyl radical scavenger, an intense optical absorption due to the hydrated electron with $\lambda_{\text{max}} = 720$ nm is observed immediately after the application of a short electron pulse (with a nano- or micro-second duration). The decrease in this absorption is accompanied by the appearance of a new absorption band with $\lambda = 360$ nm. The rates of decrease in the intensity of the first absorption and of increase in that of the second are proportional to the concentration of the silver ions present in the solution. When the solutions are saturated with nitrous oxide, the hydrated electrons are transformed into OH radicals. The appearance of a band with $\lambda = 360$ nm is not then observed. The observed changes in the optical absorption spectra are probably caused by the reaction

This hypothesis has been confirmed by the observation of the effect of ionic strength on the rate of reaction which is of the kind expected for the interaction of species bearing unlike charges. The conductivity of the aqueous solution increases under these conditions owing to the formation of a proton.

The rate constant for the reduction of silver ions by electrons has been determined from the analysis of the kinetics of the decrease in the optical absorption due to the hydrated electron, which is described by pseudo-first-order kinetics. The rate constant was found to be 4.8×10^{10} litre $\text{mol}^{-1} \text{s}^{-1}$.⁹ In the measurement of the optical spectrum of atomic silver, it is essential to bear in mind that its absorption bands overlap with those of the hydrated electron and the organic radical, formed immediately after the application of the accelerated electron pulse and disappearing in subsequent reactions, and also with the bands due to a new species — the Ag_2^+ cluster generated in the reaction

Bearing this in mind, Ershov *et al.*⁹ exposed a deaerated AgClO_4 solution (1×10^{-4} M) containing 0.1 M isopropyl alcohol to a short 15 ns electron pulse, the absorption spectrum being measured after 0.1 μs . During the time elapsed, only 36% of the hydrated electrons were trapped by the silver ions. Allowance for the absorption due to the remaining hydrated electrons and $(\text{CH}_3)_2\text{COH}$ radicals, as well as the silver ions consumed as a result of the reduction made it possible to calculate the absorption spectrum due to Ag^0 atoms in the aqueous solution. The spectrum consists of a broad band with $\lambda = 360$ nm; the extinction coefficient (ε) is 1.6×10^4 mol litre cm^{-1} , whilst the band width at the half the height is 0.91 eV (Fig. 1).

The preparation of copper atoms in unusual oxidation states is complicated compared with the preparation of silver atoms by the fact that in aqueous solutions copper in the stable state has a degree of oxidation of +2. Solutions of copper salts in the +1 oxidation state are unstable and are readily oxidised to the +2 state. In order to increase their stability, ligands capable of forming copper(I) complexes are added to the solution. Sukhov *et al.*¹⁰ used neutral aqueous deaerated CuCl solutions ($1 \times 10^{-4} - 3 \times 10^{-3}$ M) containing 2 M NaCl. Under these conditions, copper(I) ions exist predominantly as the complexes CuCl_3^{2-} (80%) and CuCl_2^- (20%). It was observed that, after irradiation with accelerated electrons for 15 ns, the decrease in the absorption due to hydrated electrons at 720 nm is accompanied by the appearance of an absorption band with $\lambda = 380$ nm.

Figure 1. Optical absorption spectra of the atoms and ions of metals with the $d^{10}s^2p^1$ electronic configuration in water. (1) Ag^0 ; (2) Cd^+ ; (3) In^{2+} .

However, in contrast to the analogous processes described above for silver ions, the increase in the intensity of the band with $\lambda = 380$ nm is slower than the decrease in the intensity characterising the disappearance of hydrated electrons. Furthermore, the rate of destruction of the latter was proportional to the concentration of the copper(I) ions present in the solution. However, this did not affect the appearance of the new band. The kinetics of the disappearance of e_{aq}^- in CuCl solutions are described satisfactorily by a first-order equation with an effective rate constant which depends linearly on the concentration of the dissolved salt. All these features suggest that the electrons are destroyed in a reaction of the type

The calculated effective rate constant for the interaction of e_{aq}^- with monovalent copper(I) chloride complexes is $2.7 \times 10^{10} \text{ litre mol}^{-1} \text{ s}^{-1}$.¹⁰ We may note that the hydroxyl radicals formed oxidised copper(I) to copper(II). Analysis of the characteristic features of the kinetics of the appearance of the absorption band with $\lambda = 380$ nm suggests that it is due to the copper atoms formed in the decomposition of the unstable chloride complex:

The kinetics of the formation of copper atoms are described by a first-order equation with an effective rate constant of $4.7 \times 10^7 \text{ s}^{-1}$.¹⁰

About thirty years ago, it was established¹¹ that the product of the reduction of the $\text{Au}(\text{CN})_2^-$ ion by hydrogen atoms in an aqueous acid solution has an absorption band with a maximum at 260 nm, while the product of the reduction by hydrated electrons in a neutral medium is characterised by a band with a maximum at 410 nm. It has been suggested that the above absorption bands are associated with the adducts $\text{HAu}(\text{CN})_2^-$ and $[\text{Au}(\text{CN})_2] \dots e_{\text{aq}}^-$. In a later publication,¹² it was shown that reduction with formation of a product in three equilibrium forms depending on the pH, each of which is characterised by different optical absorption bands, does indeed take place in both cases.

The $\text{p}K$ is 5.9 and ~ 5.2 for the first and second equilibria respectively. It was also established that all three complexes decompose with formation of gold atoms, which have a low-intensity absorption band with $\lambda_{\text{max}} < 260$ nm. The reaction is first-order with rate constants of 6.7×10^3 and $5.3 \times 10^4 \text{ s}^{-1}$ for $\text{Au}(\text{CN})_2^{2-}$ and $\text{H}_2\text{Au}(\text{CN})_2$ respectively.

2. Zn^+ , Cd^+ , and Hg^+ ions

The formation of monovalent zinc and cadmium ions as a result of reduction by hydrated electrons of the divalent metal ions in neutral aqueous solutions was observed more than twenty years ago.^{13–15} It was found that the univalent ions have intense absorption bands at 300 nm. The results of the latest more careful experiments¹⁶ suggest that the Zn^+ ion does indeed have an absorption band with a maximum at 310 nm, while the absorption band due to the Cd^+ ion is probably at 295 nm (Fig. 1). The formation of Hg^+ ions was observed in the reduction of divalent mercury by hydrogen atoms in aqueous media.^{17,18} A feature distinguishing this species from those examined above with the $d^{10}s^1$ electronic configuration is the presence of two absorption bands with maxima at 225 and 255 nm,¹⁷ which is apparently a consequence of the splitting of the p level. The Hg^+ ion hydrolyses in solution:

The logarithm of the equilibrium constant of this reaction is 5.1.¹⁸ According to the study quoted, the hydroxo-complex HgOH is characterised by two absorption bands — at 233 and 265 nm. The presence of an additional band with a maximum at 360 nm has also been established.¹⁹ We may note an interesting feature of the formation of the Hg_2^{2+} ion by the dimerisation of Hg^+ ions. The process is complex and takes place in two consecutive reactions: in the first, the disproportionation of Hg^+ ions results in the formation of a mercury atom, while in the second the atom reacts with a Hg^{2+} ion, affording Hg_2^{2+} .

It has been shown²⁰ that HgCl_2 molecules interact with hydrated electrons:

The rate constant for this reaction ($2.7 \times 10^{10} \text{ litre mol}^{-1} \text{ s}^{-1}$) is high.

The HgCl molecules are characterised by two optical absorption bands — at 245 and 330 nm. These molecules disappear, giving rise to Hg_2Cl_2 . The formation of HgCl molecules in the reduction of HgCl_2 has been demonstrated by electron paramagnetic resonance.²¹ After γ -irradiation of frozen aqueous sulfuric acid solutions of this salt at 77 K, a signal due to the HgCl molecule is observed. Its quartet hyperfine structure is due to the interaction of the unpaired electron with the ^{35}Cl and ^{37}Cl magnetic nuclei, the nuclear spins of which are identical and equal to $3/2$, while the magnetic moments are similar. In concentrated hydrochloric acid solutions (8 M), mercury is present in the form of the complex HgCl and the reduction of the mercury ion is not accompanied by the splitting off of chloride ions.²¹ The formation of the HgBr^{22} and HgI^{23} molecules has been detected by pulse radiolysis in the reduction of the corresponding divalent mercury salts in aqueous solutions.

3. Ga^{2+} , In^{2+} , and Tl^{2+} ions and In and Tl atoms

The Ga^{3+} and In^{3+} ions are vigorously hydrolysed in aqueous solutions. It has been established that these ions and their hydrolysed forms are virtually not reduced by hydrogen atoms and the formation of the Ga^{2+} and In^{2+} ions, occurring in aqueous and neutral solutions, is a result of the interaction only with hydrated electrons.^{24–26} The absorption band maxima of the Ga^{2+} and In^{2+} ions are at 268 and 263 nm respectively. The absorption spectrum of the indium aquo-complex in the $+2$ oxidation state is presented in Fig 1. The Tl^{2+} ion has been obtained in a strongly acid medium on reduction of trivalent thallium by hydrogen atoms.²⁷ Its absorption, the maximum of which occurs at wavelengths shorter than 225 nm, has been recorded. We may note that, together with the main absorption band, an additional shoulder appears for the hydroxo-complexes of divalent gallium²⁵ and thallium^{27–30} — at 300 nm for the first complex and 360 nm for the second.

The Tl^+ ion is stable in aqueous solutions. The oxidation-reduction potential of the Tl^+/Tl^0 couple is -1.94 V, which implies

the possibility of its reduction by both hydrated electrons and hydrogen atoms in aqueous solutions. It has been shown³¹ that this does indeed take place. Fairly concentrated salt solutions and long electron pulses (2 μ s) were used in the experiments. As a consequence of the high rate of the reaction

the equilibrium constant of which is 2.3×10^3 litre mol⁻¹, the optical absorption due to thallium atoms was hardly observed owing to the intense absorption due to the Tl_2^+ species formed (a band with a maximum at 420 nm). Ershov *et al.*³² refined the characteristics of the absorption spectrum of thallium atoms. A low concentration of Tl^+ ions (1×10^{-4} M) was used for this purpose, the solution containing also isopropyl alcohol as a hydroxyl radical scavenger. The spectrum was recorded 0.7 μ s after the application of 15 ns or 0.5 μ s electron pulses. Under these conditions, the equilibrium in the last reaction is displaced to the left. It was established that the absorption by Tl^0 (Fig. 2) includes two bands — at 450 nm ($\epsilon = 5 \times 10^3$ litre mol⁻¹ s⁻¹) and at 260 nm ($\epsilon = 9 \times 10^3$ litre mol⁻¹ s⁻¹).

The In^+ ion is unstable in aqueous solutions and is readily oxidised, forming In^{3+} ions. The calculated reduction potential of indium atoms in aqueous solution proved to be -2.3 V.³³ It is identical with the potential of hydrogen atoms. This means that In^+ ions could be reduced only by hydrated electrons. Aqueous InBr solutions were used in the above study.³³ In the presence of bromide ions, univalent indium becomes more stable. It has been established that the indium atoms arising immediately after the application of a 15 ns electron pulse are characterised by absorption bands with maxima at 500 nm and at a wavelength shorter than 300 nm. After a time, the intensities of the above bands fall and new bands appear at 310 and 460 nm. The rate of appearance of the latter increased with increase in the salt concentration in solution. The above changes were induced by the reaction

the equilibrium constant of which is approximately 5×10^2 litre mol⁻¹. We may recall that, in contrast to the metal atoms and ions examined above, having the $d^{10}s^1$ configuration, indium and thallium atoms are characterised by the $d^{10}s^2p^1$ electronic configuration.

4. Pb(I) and Pb(III) ions

Lead aquo-complexes in the +1 and +3 oxidation states were obtained when Pb^{2+} ions were reduced by hydrated electrons and oxidised by hydroxyl radicals in aqueous, neutral, and alkaline aqueous solutions. The Pb^+ ion is formed on pulse radiolysis in neutral or weakly acid Pb^{2+} solutions.^{34–36} Its absorption spectrum is presented in Fig. 2. The ion has a $d^{10}s^2p^1$ outer electron shell and gives rise to a low-intensity absorption band at 320 nm ($\epsilon = 2.5 \times 10^3$ litre mol⁻¹ cm⁻¹). Divalent lead ions are readily hydrolysed in aqueous solutions. At pH 6 they already exist in the PbOH^+ form. The formation of the Pb^{3+} aquo-complex may therefore be expected only for acid aqueous solutions. Indeed the above ion is formed on oxidation of Pb^{2+} by hydroxyl radicals at pH < 4 in aqueous solutions saturated with N_2O .³⁷ Its absorption band, with a maximum at $\lambda < 220$ nm, extends into the UV region. At pH ~ 4 an additional weak shoulder is formed at 330 nm and is due to the hydroxo-complex PbOH . The pK value for the hydrolytic reaction

is 4.0. At pH > 6, an additional shoulder is also observed at 360 nm with the absorption band in the UV region.³⁸ The electrical conductivity of the solution does not change under these conditions, which suggests the following reaction:

Figure 2. Optical absorption spectra of the atoms and ions of metals with the $d^{10}s^2p^1$ electronic configuration in water (a) and the dependence of $E_{\lambda_{\max}}$ on the charge (b). (1) Tl^0 (2) Pb^+ ; (3) Bi^{2+} .

At pH 11.4, divalent lead forms the hydroxo-complex $\text{Pb}(\text{OH})_3^-$. The $\text{Pb}(\text{OH})_4^-$ species probably arises in its interaction with the OH radical:

Its absorption spectrum is characterised by a narrow band at 280 nm and a broader band at ~ 360 nm. The same species appears in the reduction of tetravalent lead in a highly alkaline solution (pH 13) by the reaction

The complex PbCl_2^+ has been obtained in the oxidation of Pb^{2+} ions (5×10^{-4} M) by hydroxyl radicals in neutral and acid aqueous solutions saturated with nitrous oxide and containing chloride ions ($> 5 \times 10^{-2}$ M).³⁹ The increase in the charge on the lead ion and the decrease in its radius compared with the Pb^{2+} ion led to the formation of a monochloride complex in the reactions

The pK values for the above equilibria are 1.2 and 2.6 respectively.

The optical absorption of the above complex includes four bands with $\lambda_{\max} = 276, 320, 380$, and 485 nm, while the extinction coefficients are respectively 6.0×10^4 , 3.1×10^4 , 3.2×10^4 , and 1.2×10^4 litre mol⁻¹ cm⁻¹.

On the other hand, the PbCl molecule did not arise on reduction of lead(II) chloride complexes by hydrated electrons even at a chloride ion concentration of 0.1 M. The following reaction occurred under these conditions;

Only in the presence of NaCl in the solution (~ 2 M) was the formation of PbCl observed (main absorption band at wavelengths less than 280 nm, additional bands at 300 and 390 nm). The instability constant of this complex (pK_i) was estimated as approximately -0.3 .³⁹

5. Bi(II) and Bi(IV) ions

Since bismuth is vigorously hydrolysed in aqueous solutions, concentrated perchloric solutions (up to 5 M) are used for its preparation in the initial Bi^{3+} form. Under these conditions, the hydrogen atoms formed after the application of an electron pulse reduce the Bi^{3+} ions to Bi^{2+} (single absorption band with a maximum at 285 nm).⁴⁰ No evidence for the possibility of the oxidation of Bi^{3+} by hydroxyl radicals and the formation thereby of Bi^{4+} ions was found. This reaction probably does not occur at all owing to the high oxidation potential of Bi^{4+} . Indeed, an estimate of this potential yields ~ 3.5 V, which is significantly higher than the potential of the OH radical (2.9 V).

Ionic Bi(II) and Bi(IV) chloride complexes have been obtained by pulse irradiation of concentrated aqueous hydrochloric acid solutions.⁴¹ The absorption due to the Bi(II) ion is characterised by two bands with maxima at 350 and 460 nm and that due to the Bi(IV) ion is characterised by bands at 270 and 370 nm.

IV. Atoms and ions of metals in unusual oxidation states in frozen aqueous solutions

The method for the preparation of metal ions in unusual oxidation states in frozen aqueous solutions is based essentially on the same reactions involving reduction by electrons, formed on ionisation of the medium, and oxidation by the hydroxyl radicals, arising in ion–molecule reactions of the positively charged H_2O^+ parent ions (see, for example, Ershov and coworkers^{42,43}). Concentrated aqueous solutions of a wide variety of electrolytes, for example, perchloric, sulfuric, hydrochloric, and other acids and their salts or alcohols, to which the metal salts investigated are added, are used for these purposes. On rapid freezing of such solutions in liquid nitrogen, transparent glasses, retaining to the maximum extent the structure of the liquid aqueous media, are formed. During exposure to ionising radiation (usually ^{60}Co γ -radiation), the metal ions are reduced by thermalised mobile electrons. The metal atoms or ions formed are stable indefinitely at 77 K. The oxidation reactions of the metals occur on raising the temperature to ~ 150 K. At this temperature, the hydroxyl radicals localised in intermolecular traps become mobile. Many atoms and ions of metals in unusual oxidation states have been obtained and investigated in this way.^{44–56}

It was found that the optical characteristics of the atoms and ions of metals with $d^{10}s^1$ or $d^{10}s^2p^1$ outer electron shells in aqueous solutions at room temperature and at the temperature of liquid nitrogen do not differ significantly. Only a 10–20 nm hypsochromic shift and some narrowing of the band are observed. The most significant results were obtained in the study of the ESR spectra of the metal atoms and ions in frozen aqueous media. Indeed, by means of the ESR method one can not only demonstrate the very fact that the atoms and ions in unusual oxidation states are formed but the structure of the paramagnetic centre, the nature of the environment, and the nature of the distribution of the unpaired electron can also be determined.

Metals usually have several isotopes, some of which may carry a nuclear spin. The paramagnetic ions formed on addition of a single electron to the outer s orbital are therefore characterised by the presence of two types of signals. The first are due to isotopes without nuclear spin and are represented in the ESR spectra by singlets in the region of the g -factor of the free electron. The second are due to isotopes carrying a nuclear spin and their ESR spectra are characterised by the presence of a hyperfine structure (HFS). Light elements (copper and silver) differ from others by the fact that the HFS constants of the ESR signals are small but sufficient for observation in the usual microwave spectrometer (magnetic field up to 300–1000 mT). For virtually all other elements, the HFS constants are so large that their resonance frequencies exceed the UHF field frequency employed in the ESR

spectrometer. Only certain components of the HFS of the paramagnetic atom or ion are therefore observed. Fig. 3 presents the ESR spectra for the Ga^{2+} and Pb^{3+} ions. The HFS constants were calculated from the positions of the high-field components of the signals by the Breit–Rabi equation.⁵⁷ Table 1 presents the characteristics of the ESR spectra for a series of paramagnetic metallic species having an unpaired electron in the outer s shell. Evidently, the g -factor exhibits a negative deviation (Δg) relative to the g -factor of the free electron, which is 2.0023. A negative deviation of the g -factor is characteristic of paramagnetic centres with an excess electron. Furthermore, one may note that Δg increases in absolute magnitude along the subgroup and diminishes along one Period with increase in the atomic number of the element. In the former cases, the charge on the paramagnetic species is constant under these conditions, but the mass of the nucleus of the element increases (compare, for example, the equal-charge series, Zn^+ , Cd^+ , Hg^+), while in the latter case the paramagnetic species have the same electronic structure within the limits of the Period, but their charge increases under these conditions (compare the isoelectronic series Ag , Cd^+ , Ga^{2+} , Sn^{3+}). The ratio $A_{\text{iso}}/A_{\text{iso}}^0$, which defines the density of the s state on the metal nucleus, increases within the limits of the equal-charge series of paramagnetic species with increase in the number of the Period. On the other hand, it diminishes within the limits of the isoelectronic series with increase in the charge on the ion.

V. Regularities in the variation of electronic properties

In the preparation and study of the properties of metals in unusual oxidation states, characterised by the presence of a single electron in the s or p orbitals, investigators always showed the greatest interest in the aquo-complexes of such metals. This is because the aquo-complexes are in fact most common and have been thoroughly investigated. The regularities in the variation of the fundamental properties of the above metals within the Periods and Groups of the Periodic System have been discovered.^{51, 54–56, 63, 64} We shall deal with some of them. Metals in unusual oxidation states are extremely unstable and exist for a short time, so that the methods for their investigation are limited with the consequent limitation of the available information about their properties. These are in the first place the characteristics of their optical absorption and ESR spectra and the properties of their electronic structures as well as the oxidation-reduction potentials which follow from them.

1. Aquo-complexes

The absorption by the atoms and ions of metals with the $d^{10}s^1$ electronic configuration in an aqueous solution in the state of an aquo-complex is characterised by a single intense UV absorption band. The position of the band undergoes a smooth hypsochromic shift in an isoelectronic series of metals with increase in the charge on the species, as can be seen for the Ag^0 , Cd^+ , In^{2+} series (Fig. 1). We may note that the absorption band of the Sn^{3+} ion, the next member of the above isoelectronic series, is at ~ 215 nm in a frozen aqueous solution at 77 K,⁵⁴ i.e. the tendency for the absorption to be displaced into the UV region with increase in the charge on the ion is continued. Furthermore, the energies of the optical transitions at the absorption band maxima ($E_{\lambda_{\text{max}}}$) increase linearly with increase in z (Fig. 4). In the subgroups, the energies increase with increase in the number of the Period. These regularities, discovered at an early stage of the study of the properties of metals,^{51, 54–56} served as a basis for the prediction of the expected values of $E_{\lambda_{\text{max}}}$ for a series of atoms and ions which at that time had not yet been obtained. Thus the positions of the absorption bands were predicted and later determined experimentally for copper and gold atoms, Pb^{3+} ions, etc.

The optical absorption of the aquo-complexes of metals in the $^2S_{1/2}$ state is due to the $2a_{1g} \rightarrow 2t_{1u}$ transition. This transition can be regarded to a large extent as the transfer of an unpaired electron from the atomic orbital of the central metal ion to the mixed np , $2s$ and $2p$ orbital. The first optical transition in the same metal atoms and ions in the gas phase corresponds to the $S \rightarrow P$ transition. This entails the splitting of the level as a consequence of spin–orbit coupling. Thus in the case of silver atoms the energies correspond-

ing to the $P_{1/2}$ and $P_{3/2}$ levels in the gas phase are respectively 338 and 328 nm. As mentioned above, in water a broad band with a maximum at 360 nm corresponds to silver atoms. This means that, on passing to an aqueous solution, the absorption band undergoes a ‘red’ shift and becomes significantly broader. For this reason, if the splitting due to spin–orbit coupling is not very marked, it is not observed. The differences between the energies of the $P_{1/2}$ and $P_{3/2}$ levels for the Ge^{3+} , Sn^{3+} , and Pb^{3+} ions in the gas phase are 0.346, 0.807, and 2.611 eV respectively.⁶⁵ If one bears in mind that the values of $E_{\lambda_{\text{max}}}$ for atoms and ions in the $^2S_{1/2}$ electronic state in aqueous solutions are in the range from 3 to 6 eV, one may conclude that the splitting of the energy levels may significantly complicate the structure of the bands in the spectra of the aquo-complexes. For elements of the Fourth and Fifth Periods, the above effect most probably leads to the broadening of the absorption bands, while in the case of the Sixth Period the splitting may prove to be considerable. Indeed, two absorption bands have been observed for Hg^+ , at 225 and 255 nm,^{17, 18} which is probably a consequence of the splitting of the p level.

The first optical transition in the aquo-complex corresponds to intracomplex oxidation. The validity of this conclusion is confirmed by the linear correlation between $E_{\lambda_{\text{max}}}$ and the $s^1 \rightarrow p^1$ excitation energies of the ions in the gas phase ($E_{s \rightarrow p}$) (Fig. 5). On the other hand, such correlation between $E_{\lambda_{\text{max}}}$ and the energy of the $d^{10}s^1 \rightarrow d^9s^2$ transition in the gas phase is not observed, which indicates that the optical transition in the aquo-complex is mainly due to the $s^1 \rightarrow p^1$ excitation.⁶³

Figure 5. Dependence of $E_{s \rightarrow p}$ for the metal ion in the gas phase on $E_{\lambda_{\text{max}}}$ for the ion in the form of an aquo-complex.

Figure 4. Dependence of $E_{\lambda_{\text{max}}}$ on the charge of the metal ion.

Analysis of spectroscopic data for the gas phase demonstrates the existence of the fundamental linear dependence of $E_{\lambda_{\text{max}}}$ on z of the type established for an aqueous medium.⁶³ The above relation has been justified theoretically⁶⁴ and equations relating the energies of the $s \rightarrow p$ transitions for hydrogen-like ions with a filled d shell to their charge have been derived. The approach is based on the familiar dependence of the energy term for a hydrogen-like ion on the charge. It is described by the Balmer formula, supplemented by relativistic corrections and the relations between the mass and the extent of spin–orbit coupling. Ultimately the following equation, relating the change of the electronic transition energy (expressed in rydbergs) for a hydrogen-like ion to its charge was obtained:

$$E_{ns \rightarrow np} = \frac{2K_n}{n^2} z + az + c, \quad (1)$$

where n is the number of the electron shell and the quantities K_n , a , and c are determined by the shielding constants for the ions and

are found numerically from the dependences of their ionisation potentials in the gas phase on the charge z . For an isoelectronic series of ions, K_n is constant. Fig. 6 illustrates the dependences of the $s \rightarrow p$ transition energies for ions in the gas phase and in aqueous solution on z . They are linear and are described satisfactorily by Eqn (1). There is a slight deviation only for the first elements of the isoelectronic series, namely for copper, silver, and gold atoms. This is probably due to a certain degree of mixing of the s and d electronic states of these atoms. The constants a and c for an aqueous medium are the same as for the gas phase, but the quantities K_n differ significantly (Table 2). The intercept produced by the extrapolation of lines 1 and 2 on the ordinate axis is the same for the gas phase and aqueous solution. The intercept is determined by the constant c in Eqn (1). The physical significance of the constant is that of the energy of the $s \rightarrow p$ transition for an ion with $z = 0$.

Table 2. The coefficients K_n , a , and c of Eqn (1) for isoelectronic ions of the elements in the Fourth, Fifth, and Sixth Periods.

Period	K_n (gas phase)	K_n (aqueous phase)	a	c
4	0.862	0.221	0.035	0.165
5	0.994	0.318	0.031	0.188
6	1.311	0.312	0.042	0.234

Using the simple linear dependence of the $s \rightarrow p$ transition energy on the charge for a series of isoelectronic ions in the $^2S_{1/2}$ electronic states, it is possible to calculate by Eqn (1) or determine graphically (Fig. 6) any fundamental characteristics for ions which have not been obtained in this electronic state in the gas phase (Table 3). The energies of the optical transitions can be determined similarly also for ions in aqueous media. However, the existence of a whole series of these (for example, the As^{4+} , Sb^{4+} , Bi^{4+} , and other highly charged cations of the succeeding subgroup) is impossible because their oxidation potentials are higher than that of the hydroxyl radical.

^a Element. ^b Energy /eV.

Experimental data on the properties of metal ions having the $d^{10}s^2p^1$ electronic configuration are limited and are in essence confined to the In^0 , Tl^0 , Pb^+ , and Bi^{2+} species. Nevertheless, it is possible to analyse the structure and positions of the optical absorption bands for the isoelectronic series of the above Sixth Period metal ions. Their optical absorption spectra and the dependence of $E_{\lambda_{\max}}$ on the ionic charge (Fig. 2) show that the absorption band on the long-wavelength side shifts to the UV region in the Tl^0 , Pb^+ , Bi^{2+} series, while $E_{\lambda_{\max}}$ increases linearly at the same time with increase in the ionic charge. For equally charged metal atoms in one subgroup (indium and thallium), a hypsochromic shift of the absorption band with increase in the number of the Period can be seen [$\lambda_{\max}$ is at 500 nm for In^0 (see Ref. 33) and at 440 nm for Tl^0 (see Ref. 32)]. Thus, similar regularities in the variation of the optical characteristics as a function of the positions of the elements in the Periodic System were observed both for the aquo-complexes of metals having one

Figure 6. Dependence of the energy of the $s \rightarrow p$ transition on the charge z of the metal ions in the Fourth (a), Fifth (b), and Sixth (c) Periods. (1) In the gas phase; (2) in aqueous solution; circles — experiment; lines — calculation by Eqn (1).

electron in the outer s orbital and for the aquo-complexes with an electron in the p orbital.

2. Hydroxo-complexes

The incorporation of one OH^- ion in the coordination sphere of the metal ion leads to the splitting of the energy levels, which entails a change in the structure of the optical absorption spectrum. Apart from the main symmetrical absorption band, characteristic of the metal ion in the form of the aquo-complex, an additional broad band on the long-wavelength side is observed, as noted above. Fig. 7 presents a schematic arrangement of the energy levels for an octahedral complex, illustrating the nature of the changes in the structures of the optical transitions for mono- and di-hydroxo-complexes. The replacement of one or two water

Figure 7. Schematic illustration of the energy levels for monohydroxo-complexes (a) and dihydroxo-complexes (b).

molecules by hydroxide ions respectively in position 1 (C_{4v} symmetry) or 1 and 4 (D_{4h} symmetry) leads to the splitting of the $2t_{1u}$ level. The existence of an additional transition in the hydroxo-complex is associated with a decrease in symmetry as a consequence of the appearance of new ligands. The $2t_{1u}$ level is split in such a way that the $2e$ level for $MOH^{(z-1)+}$ and the $2e_u$ level for $M(OH)_2^{(z-2)+}$ are determined by the interaction with water molecules and the energies of the $4a_1 \rightarrow 2e$ and $3a_1 \rightarrow 2e_u$ transitions respectively therefore change little compared with the energies $2a_{1g} \rightarrow 2t_{1u}$ transitions in the aquo-complexes. On the other hand, the $5a_1$ level for $MOH^{(z-1)+}$ and the $2a_{2u}$ level for $M(OH)_2^{(z-2)+}$ are associated predominantly with the interaction with OH^- ions, while the energies of the $4a_1 \rightarrow 5a_1$ and $3a_{1g} \rightarrow a_{2u}$ transition are respectively smaller than the energies of the transition observed in the aquo-complexes. It is noteworthy that in the monohydroxo-complex there is a possibility of the splitting or broadening of the band owing to the *trans*-effect. However, in the mono- and di-hydroxo-complexes, not only the nature of the disposition of the levels but also the energies of the corresponding optical transitions are fairly similar. For example, the same structures of the optical bands have been observed for the $TiOH^+$ and $Ti(OH)_2^0$ species.^{28–30}

Figure 8 presents the dependence of $E_{\lambda_{max}}$ on z for the $4a_1 \rightarrow 2e$ and $4a_1 \rightarrow 5a_1$ transitions for the monohydroxo-complexes of Sixth Period metals. The long-wavelength component of the optical absorption band has been recorded for the $TiOH^+$ and $PbOH^{2+}$ ions and it has been stated that the maxima are located at $\lambda < 220$ nm and $\lambda < 240$ nm respectively. For $HgOH$, use was made of the results of a study¹⁹ in which an additional absorption band, not found previously,¹⁸ had been observed at 360 nm. It is

Figure 8. Dependence of $E_{\lambda_{max}}$ on the ionic charge for metal hydroxo-complexes. (1) $HgOH^0$; (2) $TiOH^+$; (3) $PbOH^{2+}$.

seen from the figure that the linearity of the dependence of the energy at the absorption maximum on z , characteristic of the aquo-complexes, holds also for the hydroxo-complexes. The difference between the transition energies in the case of the hydroxo-complexes tends to increase with increasing z , i.e. the splitting of the $4a_1$ and $2e$ levels increases with increase in the charge and with decrease in the size of the central ion.

For the fully substituted hydroxo-complexes, containing only hydroxide ions in their coordination sphere, the structure of the optical transitions is the same (with retention of the coordination numbers) as that for the aquo-complexes. The amount of experimental data for the above complexes is insufficient to establish quantitative relations. However, it is quite sufficient to demonstrate that the nature of the regularities characteristic of the aquo-complexes is retained. Thus the values $E_{\lambda_{max}} = 380,^{66} 340,^{66} 280,^{25} 275,^{26}$ and 280 and 360 nm³⁵ have been found for the $Zn(I)$, $Cd(I)$, $Ga(II)$, $In(II)$, and $Pb(III)$ hydroxo-complexes respectively. It is seen from the data presented that the optical transition energy increases with increase in z for isoelectronic ions. It also increases for equally charged ions with increase in the atomic number of the element. The decrease in the energy of the $2a_{1g} \rightarrow 2t_{1u}$ optical transition energy when water molecules are substituted by hydroxide ions is correlated with the decrease in the ionisation potentials on passing from H_2O to the OH^- ion.

3. Halide complexes

The principal characteristics of the optical transitions in the fully substituted chloride complexes of Group II–IV metals in the $^2S_{1/2}$ electronic state have been investigated by Aleksandrov *et al.*⁵⁵ HCl solutions (6–10 M), to which salts of the test metals had been added, were employed. On freezing, they gave rise to transparent glasses. After γ -irradiation at 77 K, the reduced metal ions in the $^2S_{1/2}$ electronic state appeared and their optical absorption spectra were measured in a Dewar vessel at liquid nitrogen temperature. It was established that the structure of the optical absorption is significantly more complex than the analogous structure observed for the aquo-complexes. Two–three absorption bands are observed for the metals in the Fifth and Sixth Periods. For an isotypical electronic transition, the energy at the absorption band maximum diminishes with increase in the charge on the metal ion. As stated above, similar data have been obtained by pulse radiolysis for metal halide complexes in liquid aqueous solutions. Fig. 9 presents a schematic illustration of the energy levels for a monohalide complex having C_{4v} symmetry. Compared with the schemes examined for the aquo- and hydroxo-complexes, here additional ligand molecular orbitals (MO), made up of the πp and σp atomic orbitals of the ions X^- , are present. According to this scheme, the allowed transitions in the $M(H_2O)_5X^{(z-1)+}$ complex

Figure 9. Schematic illustration of the energy levels for monohalide complexes.

(1) HgCl^0 ; (2) TlCl^+ ; (3) PbCl^{2+} .

are $4a_1 \rightarrow 5a_1$ and $4a_1 \rightarrow 3e$, as well as the new transitions $2e \rightarrow 4a_1$ and $1b_2 \rightarrow 4a_1$.

Figure 10 presents the dependence of the optical transition energies for the monochloride complexes of Sixth Period metals — mercury, thallium, and lead, containing one additional electron, *i.e.* in the $^2S_{1/2}$ electronic state. Evidently, in contrast to the analogous relations for the aquo- and hydroxo-complexes, $E_{\lambda_{\max}}$ for the chloride complexes diminishes with increase in the degree of oxidation z . This factor permits the conclusion that the optical bands of $\text{MCl}^{(z-1)+}$ are determined by the $2e \rightarrow 4a_1$ and $1b_2 \rightarrow 4a_1$ transitions. The molecular orbitals $2e$ and $1b_2$ are predominantly due to ligand molecules, *i.e.* they are occupied by the electrons of the chloride ions. For metals in isoelectronic series, the energy of the abstraction of an electron increases with increase in the charge. This means that the $4a_1$ level, at which the electron is located, is lowered with increase in z . On the other hand, the $2e$ and $1b_2$ levels, at which the nonbonding electron pairs of the Cl ions are located, hardly change their positions. The energies of the above transitions in the $\text{MCl}^{(z-1)+}$ complexes in an isoelectronic series therefore decrease with increase in the degree of oxidation. The proposed model describes correctly the experimental dependence $E_{\lambda_{\max}}$ on z . In contrast to the aquo- and hydroxo-complexes in which an electron is transferred from the metal ion to the ligand molecules, in the halide complexes the electron is actually transferred from the ligand to the metal. This is the reason for the opposite type of dependence of $E_{\lambda_{\max}}$ on z for the chloride complexes of metals in the electronic state $^2S_{1/2}$ compared with the aquo-complexes.⁵⁵

For PbCl^{2+} , four optical absorption bands are observed.³⁹ This finding may be attributed to a relativistic effect. The allowed transitions at the $^2P_{1/2}$ and $^2P_{3/2}$ levels differ, as already stated, by 2.6 eV. As a consequence of this, each of the $2e \rightarrow 4a_1$ and $1b_2 \rightarrow 4a_1$ transitions undergoes additional splitting. The energies of all the transitions in the PbCl^{2+} complex are 4.56, 3.85, 3.20, and 2.54 eV.³⁹ The difference between the transition energies for paired groups of bands is indeed close to the expected value. For lighter elements, the splitting is significantly smaller and the relativistic effect is therefore manifested by a broadening of the absorption band.

For molecular monovalent mercury halide complexes (HgCl , HgBr , and HgI), two absorption bands are observed in each case, their positions undergoing a hypsochromic shift with increase in the mass (atomic number) of the halogen. Thus, whereas the absorption bands for HgCl are at 245 and 330 nm,²⁰ they are at 280 and 350 nm for HgBr ²² and at 320 and 360 nm for HgI .²³ Such variations in the energies are consistent with the proposed energy level scheme. Indeed, the electron affinity of halogen atoms diminishes in the $\text{Cl}-\text{Br}-\text{I}$ series, which corresponds to a rise in the positions of the $2e$ and $1b_2$ levels. When the position of the $4a_1$ level, which represents predominantly the atomic orbital of the

Figure 11. Dependence of $E_{\lambda_{\max}}$ for monovalent mercury halide compounds on the electron affinity (E_a) of the halogen atom.

(1) HgI ; (2) HgBr ; (3) HgCl .

metal, is retained, this should lead to a decrease in the energies of the $2e \rightarrow 4a_1$ and $1b_2 \rightarrow 4a_1$ transitions in the $\text{HgCl}-\text{HgBr}-\text{HgI}$ series, which does in fact occur. Furthermore, there is a strict linear relation between $E_{\lambda_{\max}}$ the above monovalent mercury halides and the electron affinity of the halogen atom (Fig. 11).

VI. Oxidation-reduction potentials

The direction and effectiveness of a reaction involving electron transfer is determined by the oxidation-reduction potentials of the reactants participating in it. The potential of the reaction between a reductant B^- and an oxidant O , *i.e.*

may be determined from the equilibrium constant of the reaction $K = k_+/k_-$ (here k_+ and k_- are the rate constants for the forward and reverse reactions). Metal ions in unstable oxidation states are extremely reactive and the rates of reactions with their participation are as a rule controlled by diffusion. The reactions are irreversible. The rate constants for the reverse reactions cannot usually be determined. For this reason, approximate theoretical and experimental methods are used to determine the oxidation-reduction potentials. In a theoretical calculation, it is postulated⁶⁷ that the energy of hydration of a metal ion in an unusual oxidation state depends on its radius in the same way as for alkali metal ions and the radius itself is equal to the average radius of the element preceding the given metal and that of the radius which follows it in stable oxidation states.

The experimental approach involves comparison of the characteristics of the reactions involving the reduction of particular metal ions by various radical reductants with known potentials. The potential is then estimated as the average of the potential of a reactant which led to the reduction of the metal ion and that of a reactant the presence of which did not lead to reduction. Problems concerning the determination of the oxidation-reduction potentials of metal ions in unusual oxidation states were discussed in greater detail in our earlier review.¹

Table 4 presents the potentials known hitherto for metal ions with the $d^{10}s^1$ and $d^{10}s^2p^1$ electronic configurations. The standard potentials of metal couples in stable oxidation states [$E^0(\text{M}^{z+}/\text{M})$] as well as the analogous oxidation reduction potentials or metal couples in the atomic state [$E^0(\text{M}^{z+}/\text{M}^0)$] are also presented for comparison. In the latter case, account was taken of the correction for the energy of their sublimation at room temperature.⁶⁸ It is striking that noble metals (copper, silver, and gold) in the atomic state ($d^{10}s^1$ electronic configurations) are very powerful reductants. This is due to the presence of unpaired electrons in their outer s orbitals.

Table 4. The oxidation-reduction potentials E^0 /V.

Element	z	$E^0(M^{z+}/M)$	$E^0(M^{z+}/M^0)$	$E^0(M^{z+}/M^{(z-1)+})$

Bi	+3	+0.22	−0.29	

In isoelectronic series of metals, one can trace a tendency towards a decrease in potential with increase in the charge of the metal ion. Fig. 12 illustrates graphically this relation. It is seen that in each of the series of the Fourth – Sixth Periods the potential diminishes with increase in z . Whereas at the beginning of the Period copper, silver, and gold atoms are fairly powerful reductants, the metal ions at the end of the isoelectronic series, namely trivalent tin and lead, exhibit the properties of powerful oxidants. Within the limits of a subgroup, *i.e.* for equally charged ions, the potential $E^0(M^{z+}/M^{(z-1)+})$ increases steadily with increase in the number of the Period. The established type of variation of $E^0(M^{z+}/M^{(z-1)+})$ in Periods and Groups makes it possible to predict or revise the potentials for metals the oxidation-reduction characteristics of which have not been investigated. Thus, by extrapolating the linear section of the relation between the potential and the charge of the Bi^{4+} cation, it is possible to determine the potential $E^0(Bi^{4+}/Bi^{3+})$. It was found to be approximately +3.5 V, which appreciably exceeds the oxidation potential of hydroxyl radicals (2.9 V). This explains the fact, mentioned above, that OH radicals are not able to oxidise Bi^{3+} ions in highly acid aqueous solutions.

Comparison of the metal potentials $E^0(M^{z+}/M^{(z-1)+})$ with the standard potentials and the potentials for the atomic state (Table 4) showed that their variations as a function of the charge z differ significantly. For one-electron oxidation ($d^{10}s^1 \rightarrow d^{10}s^0 + e^-$), a monotonic increase in the potentials with increasing z may

**Figure 12.** Dependence of $E^0(M^{z+}/M^{(z-1)+})$ on the charge z for metal aquo-complexes.

be traced for all the Periods. This means that the stability of aquo-complexes of metals in oxidation states characterised by the electronic configuration $d^{10}s^1$ increases with increase in the number of the element in the Period. On the other hand, the variations of the standard potentials of these metals are not monotonic and reflect a complex dependence of the energies of abstraction of electrons on the degree of filling of the electron shells of the element as their number increases.

If one begins with the fact that the optical transition in an aquo-complex represents intracomplex oxidation of the metal ion, one may expect that the oxidation potential $E^0(M^{z+}/M^{(z-1)+})$ is correlated with the optical transition energy $E_{\lambda_{\max}}$. Such correspondence does indeed exist (Fig. 13). The higher the value of $E_{\lambda_{\max}}$ the more difficult it is to abstract an electron from the metal ion and the higher the oxidation potential of the latter. The correlation between $E_{\lambda_{\max}}$ and $E^0(M^{z+}/M^{(z-1)+})$ for the aquo-complexes is justified when they have the same structure and retain it as the degree of oxidation is changed. A coordination number of 2 and a linear configuration of the complexes $M(H_2O)_2$ are characteristic of the elements of the copper subgroup.⁶⁹ It may be expected that the coordination number of the elements of the next subgroup (Zn, Cd, and Hg) is six, although the aquo-complex of divalent mercury may be distorted.⁶⁹ High coordination numbers (5 or 6) may also be characteristic of the trivalent aquo-complexes in the gallium subgroup. Thus aqueous solutions of indium ions contain the complexes $In(H_2O)_5OH^{2+}$ and $In(H_2O)_4(OH)$.⁷⁰ A coordination number of 6 is also characteristic of the elements of the germanium subgroup in the +4 oxidation state. Thus the most probable coordination number of the majority of the elements considered is 6. The copper subgroup is an exception and, as can be seen from Figs. 12 and 13, this fact is apparently the reason why a deviation from the linear relation between $E^0(M^{z+}/M^{(z-1)+})$ and $E_{\lambda_{\max}}$ is observed for copper, silver, and gold atoms.

**Figure 13.** Dependence of $E^0(M^{z+}/M^{(z-1)+})$ on $E_{\lambda_{\max}}$ for metal aquo-complexes.

It is noteworthy that the correlation of $E_{s \rightarrow p}$ and $E_{\lambda_{\max}}$ (Fig. 5) makes it possible to determine from the dependence of $E_{s \rightarrow p}$ on $E^0(M^{z+}/M^{(z-1)+})$ the oxidation potentials of the aquo-complexes of metals in the electronic state $2S_{1/2}$ for which there are some kind of data concerning the positions of their absorption bands. The above approach has been used widely in the case of f elements, for which the energies of the $f^n \rightarrow f^{n-1}d^1$ transitions in the gas phase are correlated with the oxidation potentials in aqueous solution.⁷¹ The potentials E^0 of processes of the type $Zn^+ + e^- \rightarrow Zn^0$ are correlated with the energies of bands

determined by transitions from the ligand orbitals ($e_g \rightarrow t_{1u}$, etc.). They should occur in the short-wavelength region ($\lambda_{\max} < 200$ nm)

Data referring to metal ions with the $d^{10}s^2p^1$ configuration are available only for elements of the Sixth Period (Tl^0 , Pb^+ , and Bi^{2+}). By analysing the data in Table 4 for these elements, one may conclude that a similar relation, involving a decrease in the potential with increase in the charge of the cation exists for them as well.

VII. Regularities in the variation of the dissociation constants of complexes

The change in the degree of oxidation of a metal ion is accompanied by a change in its charge and size. Despite the short time during which the ion exists in an unusual oxidation state, the corresponding equilibrium coordination sphere is formed in aqueous solution. The dissociation constants of isotypical complexes of metal ions, in different oxidation states, are different. The first hydrolysis constants have been determined for many ions with the $d^{10}s^1$ and $d^{10}s^2p^1$ configurations. These constants have been compared⁷² with the corresponding constants for stable valence forms of the same metals.⁷³ It was established that the nature of the variation of the hydrolysis constants is consistent with the nature of the variation of these quantities predicted by electrostatic theory^{74,75} both for isoelectronic metal ions in the usual and unusual valence forms and for the same metals in different oxidation states. The stability of a complex is known^{74,75} to be determined by the potential energy of the interaction of two ions, which is proportional to the ratio $z_M z_L / r$, where z_M and z_L are respectively the charges on the metal ion and the ligand and r is the distance between them. Fig. 14 illustrates the variation of the first hydrolysis pK with the ratio z/r , where $z = z_M$, since the charge on the ligand (the OH^- ion) is -1 and $r = r_M + r_{OH^-}$. Evidently, the pK for isoelectronic ions in stable oxidation states, having the $d^{10}s^0$ electronic configuration, decreases linearly with increase in z/r . For elements of the Fourth and Fifth Periods, the slopes of the relations are almost the same, whilst for the elements of the Sixth Period they are significantly smaller. For metals in unstable oxidation states having the $d^{10}s^1$ electronic configuration, a similar relation is observed. However, in this case pK increase with decrease in the degree of oxidation of the metal. For example, pK increases in the sequence $Hg^+ \rightarrow Hg^{2+}$, $Tl^{2+} \rightarrow Tl^{3+}$, etc. The variation of the pK for isoelectronic series of ions in stable and unstable oxidation states is described satisfactorily by the simple equation

$$pK = \frac{q}{r} z + w, \quad (2)$$

The coefficients q and w are listed in Table 5.

Figure 14. Dependence of the first hydrolysis constant on z/r .

Table 5. The coefficients q and w in Eqn (2).

Period	Electronic configuration	q	w
4	$d^{10}s^0$	-0.74 ± 0.2	14.2 ± 0.5
5	$d^{10}s^0$	-0.74 ± 0.2	14.2 ± 0.5
5	$d^{10}s^1$	-0.65 ± 0.1	10.0 ± 1.0
6	$d^{10}s^0$	-0.49 ± 0.02	7.7 ± 0.4
6	$d^{10}s^1$	0.13 ± 0.01	5.8 ± 0.2

The above characteristics of the variation of the pK with z/r agree with the concept of the decisive contribution of electrostatic interaction of the central ion and the ligand to the stability of the complex. For equally charged ions, the nature of the observed relations is more of an indication of the decisive role of the electronic structure. For example, a clear-cut sequence based on the increase in the pK with increasing atomic number of the element has been observed for the elements of the Sixth Period ($Hg^+ < Tl^+$, $Hg^{2+} < Tl^{2+} < Pb^{2+}$, $Tl^{3+} < Pb^{3+}$). However, for elements of the Fourth and Fifth Periods, the above relation is reversed ($Zn^{2+} > Ga^{2+}$, $Cd^{2+} > In^{2+} > Sn^{2+}$, $In^{3+} > Sn^{3+}$). Finally, one should note that the variation of the pK for equally charged ions in one subgroup is apparently not systematic (in particular, this was indicated earlier by Nazarenko *et al.*⁷³). Thus the pK of Group III elements diminish in the sequences $In^{3+} > Ga^{3+}$, Tl^{3+} and $In^{2+} > Ga^{2+} > Tl^{2+}$, while for Group II elements they decrease in the sequence $Cd^{2+} > Zn^{2+} > Hg^{2+}$.

Bearing in mind the regularities established in the variation of the pK with z/r in isoelectronic series of metals of one Period and also the nature of the variation of this quantity in equal-charge series, it appears possible to estimate the pK for certain ions. Thus $pK = 11.1 \pm 0.5$ and 6.0 ± 0.5 can be obtained for Cu^+ and Au^+ respectively by Eqn (2) from the coefficients q and w found for the corresponding Periods. The pK for the Zn^+ and Cd^+ ions are apparently very similar and are in the range 7–9.

Regularities in the variation of the instability constants, expected from electrostatic theory, have also been observed for the chloride complexes of metals in different oxidation states, including the unstable states with the $d^{10}s^1$ and $d^{10}s^2p^1$ electronic configurations.

Constant	TlCl	TlCl ⁺	TlCl ²⁺	PbCl	PbCl ⁺	PbCl ²⁺
pK_i	0.5	4.6	7.7	-0.3	1.5	2.6

Evidently the constants increase with increasing charge on the metal ion. For lead compounds, a nearly linear variation of pK_i with z/r has been noted.³⁹ For thallium complexes, pK_i is appreciably higher.⁷⁶ This means that the stability of the complexes is influenced significantly by the nature of the central ion.

VIII. Conclusion

The formation of metal ions in unusual oxidation states is not characteristic solely of aqueous media. They arise also in inorganic oxide glasses doped with thallium, cadmium, lead, or other metals as a result of oxidation-reduction reactions initiated by ionising radiation, light, or mechanical action (see, for example, the review of Aleksandrov *et al.*⁷⁷). The rigid structure of glasses is responsible for the indefinite stability of such ions. The decisive role of cooperative oxidation-reduction processes, the effectiveness and direction of which depend on the composition of the glass and its structure and the presence of free and multicentre bonds in it, has been demonstrated. It is important to note that a series of regularities which have been observed for aqueous solutions and are discussed in detail in the present review (for example, the distribution of electron densities and the optical transition energies in the isoelectronic and equal-charge series of metals) are characteristic also of inorganic oxide glasses. On the

one hand, this makes it possible to assume that the observed regularities in fundamental properties are common to all metals in unusual oxidation states and, on the other, one may assume their practical importance in the development of glass compositions with specified characteristics.

At intermediate stages of oxidation-reduction reactions in aqueous solutions, containing the ions of several metals, short-lived mixed clusters may arise. Thus, various monovalent ions, such as Cd^+ , Co^+ , Zn^+ , and Ni^+ , generated on pulse irradiation with electrons, can react with the Ag^+ ions present in the solution.^{16,78} The Zn^+ ion, which has a high reduction potential, enters under these conditions into a reaction with Ag^+ involving electron transfer and the formation of a silver atom. The Cd^+ and Co^+ ions, the potentials of which are close to that of atomic silver, form the mixed clusters $(\text{CdAg})^{2+}$ and $(\text{CoAg})^{2+}$. These clusters exist only for several microseconds and decompose rapidly with formation of Cd^{2+} (or Co^{2+}) and the Ag_2^+ cluster. In the case of Ni^+ , neither electron transfer in the reaction with the Ag^+ ion nor the formation of a simple mixed cluster have been established. However, silver is reduced with formation of a mixed product (possibly a larger mixed cluster), which appears when Ni^+ ions vanish. The appearance of mixed short-lived $(\text{AgTi})^+$ and $(\text{TiCd})^{2+}$ clusters was observed⁷⁹ in a study of the reactions of Ti_2^+ with Ag^+ and Cd^{2+} ions. The Pb^{2+} ion is reduced by Ti_2^+ with formation of the Pb^+ ion. The results obtained indicate the important, and sometimes the decisive, role of impurity ions as regards the direction or effectiveness of oxidation-reduction reactions.

Processes involving the reductive nucleation of metals (silver,^{9,80,81} copper,^{82,83} cadmium,⁸⁴ lead,³⁶ palladium,^{85,86} etc.) are associated with the initial stage involving the formation of ions in unusual oxidation states and with their dimerisation or disproportionation reaction. The chain of consecutive growth of clusters ultimately leads to the appearance of subcolloidal and then colloidal metal particles. The nucleation of silver in polymer membranes,^{87,88} in gelatin,⁸⁹ and on the surface of colloidal silicon⁹⁰ proceeds via a similar mechanism.

Certain special questions concerning the role of the anomalous valence forms of metals in catalysis have been examined in recently published reviews.^{91–93}

Thus the studies on the preparation of short-lived metal ions in unusual valence states initiated about 30 years ago have now developed further. The use of pulse radiolysis and also of the technique involving the matrix isolation of chemically reactive species made it possible not only to confirm the possibility of the appearance of these short-lived species in aqueous solutions at intermediate stages of oxidation-reduction reactions but also to investigate comprehensively their properties. In the subsequent period, main efforts were directed towards the comparative analysis of these properties and their changes within Periods and Groups of the Periodic System. This has been done most thoroughly for simple complexes of Group I–V metals in the electronic state $^2S_{1/2}$ in aqueous solutions. In particular, a regular feature of the variation of the fundamental physicochemical properties of metal atoms and ions with the $d^{10}s^1$ electronic configuration which had not been known beforehand was established and theoretically justified. It consists in the fact that the resistance of the aquo-complexes of the above metals to oxidation and also the energies of the first electronic transitions increase monotonically with increase in the ionic charge within the limits of an isoelectronic series. These and other regular features discovered apparently reflect a fundamental property of the elements, namely the monotonic variation of their physicochemical characteristics within the limits of one Period. The possibility of predicting new unusual valence forms of the elements and their properties on the basis of regular features already established is thereby justified.

VI. Conclusion	116

Abstract. The phenomenon of hydrogen spillover (interphase diffusion of adsorbed hydrogen), the methods for its detection, and the factors influencing it are examined. The common occurrence of the spillover and its role in various adsorption and catalytic processes, particularly in reactions involving hydrogen on multiphase catalysts, are demonstrated. The possible mechanisms of the spillover are analysed. The bibliography includes 189 references.

I. Introduction

In heterogeneous catalysis, the term spillover is applied to the transport of active species sorbed or formed on one phase to another phase which does not sorb or generate these species under the given conditions.^{1–7} The term ‘spillover’ (from spill over in English) was introduced by Boudart *et al.*¹ The phase generating the active species is called the initiator (or activator), while the phase providing sites for the adsorption of active species is known as the acceptor. If these phases are in direct contact, then the spillover is said to be primary, but when they are separated by an additional inert carrier, it is said to be secondary.

The first direct evidence for spillover was apparently obtained by Khoobiar.² WO₃ is known to be reduced by hydrogen at temperatures above 200 °C with formation of the blue oxide W₄O₁₁. On the other hand, when pure H₂ is passed over the 0.5% Pt/Al₂O₃ + WO₃ mechanical mixture, the colour changes already at room temperature. This effect is not observed on the Al₂O₃ + WO₃ mechanical mixture. This is explained by the fact that hydrogen dissociates on platinum and migrates via Al₂O₃ onto WO₃ in the form of atoms or H⁺ ions.

Measurement of the amount of adsorbed hydrogen showed that the Pt/SiO₂ + WO₃ mixture adsorbs several times more H₂ than Pt/SiO₂ without WO₃.³ The blue colour of the tungsten oxide is due to the formation of the so called tungsten bronze under the influence of the hydrogen which has passed from Pt onto WO₃ via SiO₂ (or Al₂O₃).

The so called structural sensitivity, *i.e.* the dependence of the specific catalytic activity (calculated per unit surface or per active centre) on the particle size, is often observed in heterogeneous catalysis.⁷ This leads to differences between the specific activities of supported and massive catalysts. One of the causes of this difference may be the involvement in the reaction of the initially inactive support surface as a result of the transfer onto it of active adsorbed species via spillover.

The spillover phenomenon is common in catalysis by supported metals and mixed oxides. The atoms of not only hydrogen but also of oxygen, as well as the N, CO, NCO, and certain other species may participate in spillover. The vast majority of the communications published hitherto on this topic have been devoted to hydrogen spillover. Since 1983, international conferences on spillover are being held regularly. The present review is devoted to studies on hydrogen spillover carried out mainly during the last 10–15 years.

II. Methods for the observation of hydrogen spillover

1. Chemisorption of hydrogen

The most common method for the determination of the surface area of a metal in supported catalysts, namely from the chemisorption of hydrogen, may be used for the observation of the spillover phenomenon.³ H₂ is usually chemisorbed at 200–300 °C. Analysis of extensive experimental data showed that the number of metal atoms on the surface (*N_M*) usually corresponds to the number of hydrogen atoms adsorbed on this surface (*N_H*). The review of Sermon and Bond⁵ contains tables for different supported metals (Pt, Pd, Rh, Re, Ru, Ni), from which it is seen that the ratio *N_H*/*N_M* varies in the range 0.5–2.0. With decrease in the metal particle size, the ratio becomes less than unity in most cases, although the opposite effects are also encountered. The deviations from unity are caused by the following factors: (1) the dissolution of hydrogen in the bulk of the

V V Rozanov, O V Krylov N N Semenov Institute of Chemical Physics, Russian Academy of Sciences, ul. Kosygina 4, 117977 Moscow, Russian Federation. Fax (7-095) 938 21 56. Tel. (7-095) 939 74 49 (V V Rozanov), (7-095) 939 71 68 (O V Krylov)

Received 14 October 1996

Uspekhi Khimii 66 (2) 117–130 (1997); translated by A K Grzybowski

metal; (2) a change in the crystal system in small particles; (3) the presence of a relatively large number of low-coordinated atoms in small particles; (4) a change in the degree of oxidation of the metal; (5) the spillover phenomenon.

In order to elucidate the causes of the deviation of the ratio N_H/N_M from unity, hydrogen adsorption data are compared with results obtained by other methods: from the adsorption of CO, from the broadening of X-ray diffractograms, by electron microscopy, *etc.* If all the methods other than H_2 adsorption yield identical results, the possible cause of the discrepancy may be the flow of hydrogen onto the carrier. Thus the ratios $N_H/N_M = 5-10$ on the Pt/ Al_2O_3 and Pd/ Al_2O_3 catalysts⁸ and 75 on the Pt/C catalyst,⁹ found by the H_2 adsorption method, have actually been explained by hydrogen spillover.

The additional chemisorption of hydrogen on platinum deposited on an activated charcoal, occurring with increase in the duration of exposure of the catalyst to a H_2 atmosphere, is also associated with the spillover of hydrogen from platinum to the charcoal.¹⁰

Spillover may also promote an increase in the rate of adsorption of hydrogen. This phenomenon has been observed, for example, in the adsorption of H_2 on a mixture of Co/C with activated charcoal.¹¹ On the other hand, the amount of adsorbed hydrogen is determined by the capacity of the acceptor and is independent of the concentration of Co or of another initiator (Ni, Cu, Fe).

The observation of spillover by the adsorption method is favoured by a high H_2 pressure and a high temperature.⁵ Methods involving the measurement not of the amount but of the rate of adsorption of hydrogen on the support and oxygen-hydrogen titration are varieties of the adsorption method:⁵

(water remains sorbed on the carrier). In the presence of hydrogen spillover, the number of adsorbed oxygen atoms N_O remains constant and N_H/N_O exceeds 2.

The surface hydrogen can also be titrated with olefins, which results in the formation of paraffins. It has been shown that at 100 °C the hydrogenation of pent-1-ene to pentane by the hydrogen adsorbed on Pt/ SiO_2 is very fast in the initial period, after which the rate of reaction falls.¹² It has been suggested that in the first stage the hydrogenation is effected by the hydrogen adsorbed on Pt, whilst in the second stage it is effected by the spillover hydrogen adsorbed on SiO_2 .

A gravimetric study of the adsorption of hydrogen and deuterium on the HNaY zeolite and on Pt/HNaY at room temperature showed that in the latter case hydrogen spillover from platinum to the zeolite takes place.¹³ The amount of hydrogen adsorbed on the platinum-containing zeolite exceeds by more than an order of magnitude the amount of H_2 capable of being adsorbed on the supported Pt. As expected, the increment in the mass of the specimen in the adsorption of deuterium was twice as great as in the adsorption of protium.

2. Reduction of oxides

In a mechanical mixture of a supported or unsupported metal with a reducible oxide (WO_3 , MoO_3 , Fe_2O_3 , V_2O_5 , Co_3O_4 , CuO), the degree and rate of reduction may increase by virtue of hydrogen spillover:⁴⁻⁶

As a result of spillover, the reduction temperature falls in certain cases by 200–400 °C. The studies have been carried out by gravimetric, differential thermal analysis, temperature-programmed reduction, microcalorimetric, *etc.* methods. Metals (Pt, Pd, Ni, *etc.*) are thus catalysts of the reduction of oxides. The degree of reduction can be determined from the amount of reacted hydrogen and also from the changes in certain parameters characterising the solid. In the reduction of, for example, V_2O_5

to V_2O_4 , it is possible to measure the EPR signal due to V^{4+} or the area of the bands in the phase XRD spectra of the V_2O_4 phase.

In the presence of ruthenium or iridium carbonyls, the reduction of the Co/ SiO_2 catalyst, obtained from cobalt acetate, *i.e.*

is accelerated by hydrogen spillover.¹⁴ This results in the formation of a highly disperse catalyst which accelerates the hydrogenation of CO to oxygenates.

The carbide WC, the properties of which are similar to those of Group VIII metals, can also serve as the source of spillover hydrogen for the reduction of MoO_3 .¹⁵

Sulfides can also be reduced by means of the spillover. When Ni or Co is added to WS_2 , $H_{0.05}WS_2$ is formed.¹⁶

The adsorption of hydrogen on the Pt/ WO_3 catalyst has been investigated.³ It was found that WO_3 is reduced by virtue of the adsorption and activation of hydrogen on Pt and its subsequent diffusion to WO_3 . On the other hand, on pure WO_3 the adsorption of hydrogen is not observed.

On platinum deposited on the CeY zeolite, Ce^{4+} was reduced to Ce^{3+} in the presence of adsorbed perylene, perylene serving as the bridge for the transport of active hydrogen from Pt to the zeolite.¹⁷

Hydrogen spillover has also been observed in the Pt/ ZrO_2 , Pt/ SiO_2 , and Pt/ TiO_2 systems. In certain cases, spillover is promoted by the presence of water, the molecules of which may also serve as bridges for hydrogen.

When MnO_2 deposited on a SnO_2 film is heated, reduction does not occur in a H_2 atmosphere at 500 °C. According to EPR data,¹⁸ the addition of Pd leads to the appearance of Mn^{2+} as a consequence of hydrogen spillover and the reduction of MnO_2 . However, the effect of hydrogen spillover is not easy to estimate quantitatively for the examples quoted not only because of technical difficulties but also by virtue of the characteristic features of the topochemical process. Hydrogen spillover may prove to be an essential condition for reduction only in the nucleation stage, whilst in the phase growth process the reaction may be propagated by the hydrogen interacting directly with the oxide. The degree of reduction depends also on the extent of the interface between the metal catalyst and the oxide being reduced. The reduction of oxides can therefore be regarded as confirmation of the occurrence of spillover, but it does not allow quantitative estimates.

The apparent activation energy (E_a) for the reduction of oxides under spillover conditions does not differ from E_a in noncatalytic reduction. The presence of a metal apparently promotes an increase in the amount of reactive hydrogen or an increase in the rate of nucleation (in the pre-exponential factor).⁶

One of the products of the reduction of oxides is water. According to different data, it either accelerates or retards both hydrogen spillover and the reduction process itself. This also complicates the use of the oxide reduction process for the observation of spillover.

3. The influence of spillover on catalysis

Multiphase catalysts frequently possess an enhanced activity and selectivity. This can be explained by the fact that one of the stages of a complex process occurs on one phase whilst another occurs on another phase, spillover taking place between the phases (sometimes with participation of a third phase).¹⁹ In the case of hydrogenation, the supported metal may adsorb and activate hydrogen, the support may adsorb the substance to be hydrogenated, and the reaction itself proceeds on the support surface as a result of hydrogen spillover.

For example, it has been found²⁰ that the specific rate of hydrogenation of benzene per unit mass of Pd increases by a factor of 3 when the Pd/Al₂O₃ catalyst is diluted with pure Al₂O₃. Hydrogen diffuses over distances up to 0.5 mm. At -52 °C, the degree of coverage of the Al₂O₃ surface by hydrogen may reach 3×10^{-2} .

In estimating effects of this kind, one should bear in mind that they may be accounted for by the 'trapping' by the diluent of the coke which poisons the catalyst.⁵ This is also a kind of spillover but of the organic substance and not hydrogen. It has been shown²¹ that the addition of Pt to the Ni-Mo/SiO₂-Al₂O₃ system ensures an appreciable decrease in the temperature corresponding to the removal of coke after the hydrocracking of heavy oils. When Pt was added to H-Ga silicate, an increase in the rate of aromatisation of propane and a sharp decrease in coke formation were observed.²² A similar phenomenon has been noted in the alkylation of 1,2,4-trimethylbenzene and its disproportionation to durene after the addition of Pt to montmorillonite. It has been shown by IR spectroscopy that the Lewis acid centres are then converted into Brønsted acid centres.²³⁻²⁵

The increase in the rate of hydrogenation of ethene on the Pt/SiO₂ catalyst diluted with SiO₂ or Al₂O₃ has also been attributed to hydrogen spillover.²⁶ The use of Al₂O₃ as a diluent afforded a greater increment in the rate of hydrogenation than dilution with SiO₂.

As the Pt/C catalyst was diluted with pure carbon up to a ratio of 1 : 50, its activity in the hydrogenation of benzene initially rose and then became constant.²⁷

The Pt/Al₂O₃ catalyst diluted with Al₂O₃ up to ratios ranging from 1:3 to 1:100 has been tested in the hydrogenation of benzene.²⁸ It was found that the specific activity of the catalyst per gram of Pt increases with increase in dilution up to 1 : 50. The activation energy for the reaction, which is 38.5 kJ mol⁻¹, did not change on dilution. The authors²⁸ assumed that the rate-limiting stage is not spillover but the interaction of benzene with atomic hydrogen. The rate of hydrogenation of benzene on the Pt/Al₂O₃ catalyst diluted with Al₂O₃ was equal to the sum of the rates of reaction on Pt/Al₂O₃ and Al₂O₃, but the reaction does not occur on pure Al₂O₃ in the absence of platinum.

The isomerisation of n-pentane to isopentane on the Pt/SiO₂ or H-ZSM-5 catalytic systems proceeds at a low rate, but when they are mixed an active and selective catalyst of the isomerisation reaction in the presence of hydrogen is obtained.²⁹ Oligomerisation predominates in the absence of H₂. It has been suggested that hydrogen spillover is necessary for the occurrence of hydroisomerisation.

The Pt/KA + NaY mixed catalyst exhibited a much higher activity in the hydrogenation of isobutene to isobutane than Pt/KA and NaY separately.³⁰ In this case too, hydrogen spillover accelerates the catalysis.

An appreciable increase in catalytic activity in the hydrodesulfurisation of thiophene was noted when MoS₂ (or WS₂) was mixed with PtS/γ-Al₂O₃, PdS/γ-Al₂O₃, or Rh₂S₃/γ-Al₂O₃.³¹ It has been suggested that noble metals activate hydrogen, which then migrates via the spillover mechanism onto MoS₂ or WS₂, where it participates in the hydrogenation. The addition of Ru to the Co-Mo/Al₂O₃³² or MoO₃/Al₂O₃³³ catalyst has the same effect.

The rate of hydrocracking of diphenylmethane also increases after the addition of sulfided Co-Mo/SiO₂ to an silica-alumina by virtue of hydrogen spillover.³⁴

The mechanism of the cracking of n-hexane on the Pt/H-erionite bifunctional catalyst involves hydrogen spillover.^{35,36} The hydrogen dissociated on platinum migrates onto the carrier, where a dynamic equilibrium is established between the atomic and protonated forms of hydrogen.

Organic deposits on the metal surface may also serve as a suitable 'phase' for the occurrence of spillover. It has been shown by LEED (low energy electron diffraction) that the hydrogenation of C₂H₄ on Pt and Rh single crystals takes place on top of an ethylidyne layer, which remains ordered under the reaction conditions.³⁷

The hydrogen participating in spillover can also interact with organic deposits and can ensure the removal of coke.³⁸ The isomerisation of paraffins and aromatic alkyl-substituted compounds takes place on acid catalysts and the reaction stoichiometry does not require that hydrogen participates in it. However, the introduction of small amounts of Pt and H₂ into the system accelerates the process as a result of the hydrogenation of the coke which poisons the catalyst.

In a mechanical mixture of coke-saturated Al₂O₃ with Pt-Re/Al₂O₃, the hydrogenation of coke via the spillover mechanism begins at a Re concentration of 50%.³⁹

4. Isotope methods

One of the commonest methods for the observation of hydrogen spillover is isotope exchange between D₂ and the OH groups of the carrier. An increase in the rate of isotope exchange between the OH and OD groups on Pt/Al₂O₃ compared with the rate of this process on Al₂O₃ was first observed by Carter *et al.*⁴⁰ Conner *et al.*⁴¹ studied hydrogen spillover on Pt/SiO₂ with the aid of D₂ by FTIR (fourier-transform infrared) spectroscopy. Platinum was placed at the centre of pressed Pt/Al₂O₃/SiO₂ and Pt/SiO₂ discs in order to measure the concentration gradient during spillover. Experiments were carried out also in which the spillover initiator (Pt/SiO₂) was isolated from Al₂O₃.^{42,43}

The isotope exchange between deuterium and the OH groups of a Y zeolite has been investigated by FTIR spectroscopy.⁴⁴ A two-component Pt/NaY-HNaY specimen was used for this purpose. The H-D isotope exchange on the surface of the HNaY zeolite was observed only when the latter was in direct contact with the platinum-containing component of the Pt/NaY specimen. At room temperature, the process was limited by the diffusion of deuterium and by the H-D exchange proper.

Tritium has also been used in the study of spillover.⁴⁵ Investigation of the interaction of ¹⁴C₂H₄ and ¹⁴C₃H₆ with T₂ on Pt/SiO₂ and Pt/Al₂O₃ showed that the OH groups of the support exchange with tritium under the hydrogenation conditions and that the degree of involvement of Al₂O₃ in this process is greater than that of SiO₂.

Transmission IR spectroscopy has been employed to investigate the exchange of the OH and OD groups of the Rh/Al₂O₃ catalyst in a stream of D₂.⁴⁶ The exchange of methoxylated OH groups with hydrogen on SiO₂ was observed when SiO₂ was mixed with Pt/SiO₂.^{47,48} The formation of methane as a result of the interaction of the methoxy-groups with hydrogen (demethoxylation) via a mechanism involving spillover has been noted:

(H_{sp} = spillover hydrogen).

5. The scavenger method

By adding to the system substances which interact quantitatively with hydrogen and by using sensitive methods such as, for example, EPR as indicators, it is possible to reduce greatly the threshold in the observation of the spillover effect. This has been confirmed by the results of a study on the CeY zeolite + Pt black system,⁴⁹ where Ce⁴⁺ was reduced to Ce³⁺ in the presence of hydrogen. The adsorption of perylene or anthracene led to the

appearance of radicals, readily detectable by EPR. When spillover occurs, the radicals are hydrogenated and the EPR signal vanishes.

Weakly bound H atoms, participating in the hydrogenation of benzene, have been detected by depositing *N-tert*-butyl- α -phenylnitron or 2,4,6-tri-*tert*-butylnitrobenzene, which served as 'traps' for H atoms, on Pd/Al₂O₃.⁵⁰

6. Thermodesorption methods

The temperature-programmed desorption (TPD) and temperature-programmed reaction (TPR) methods can also be used to observe the spillover of adsorbed species.⁵¹ The nonstationary temperature regime employed in these methods makes it possible to separate in time processes occurring on the surface at different rates, including processes involving the desorption of the initial substances, adsorbed in one form or another, and their conversion into other products via different pathways. In contrast to unsupported catalysts, on supported catalysts there is a possibility of the spillover of adsorbed species. This is manifested either by a simple increase in the areas of the TPD peaks due to the substances adsorbed beforehand or by the appearance of new additional peaks.

The TPD – TPR methods yield direct information about the amount of the substance which has diffused onto other phases and make it possible to calculate the coefficients of surface diffusion and the activation energy for the process.

The use of stable isotopes significantly expands the possibilities of the TPD and TPR methods in the study of the mechanism of the spillover of adsorbed species. These methods have been used to investigate hydrogen spillover on a wide range of supported catalysts: platinum,^{52–57} palladium,⁵⁸ nickel,^{52–57} and rhodium⁵² on aluminium, titanium, and silicon oxides, cobalt and molybdenum on aluminium oxide⁵⁹ and activated charcoal,⁶⁰ and platinum on zirconium oxide.⁶¹

7. Reverse hydrogen spillover

This term is frequently used to designate the reverse migration of hydrogen from the support to the metal.

In the adsorption of an olefin on 0.03% Pt/H_xWO₃ at 100 °C, hydrogen is removed from the catalyst, its amount corresponding to the ratio $N_{\text{H}}/N_{\text{Pt}} = 277$.⁵ Since H_xWO₃ is incapable of hydrogenating the olefin at this temperature, the participation of hydrogen in the hydrogenation can be accounted for by its reverse spillover from H_xWO₃ onto Pt. In H_xWO₃ + Pt/SiO₂ mixtures, where there is little contact between Pt and H_xWO₃, the reverse spillover was not observed.

The desorption of hydrogen from carbon^{11,62,63} or from the H – ZSM-5 zeolite⁶⁴ is accelerated when platinum or a metal sulfide are deposited on them. The dehydrogenation of cyclohexane under these conditions (at 450 °C) is associated with the reverse spillover of hydrogen from the support to the metal. The catalytic activity increases with increase in the initiator concentration and reaches a certain limit, which is independent of either the amount or nature of the initiator. The reverse spillover may be the rate-limiting stage in the dehydrogenation reaction proceeding via the mechanism

(X is the carbon surface and M is the metal).

Ga³⁺ and Zn²⁺ ions may play the same role of accelerators in the recombination of H atoms, because the rate of aromatisation increases on mixing Ga₂O₃ or ZnO/Al₂O₃ with ZSM-5.^{65–70} This entails the reverse hydrogen spillover from the aromatic compound, adsorbed on the zeolite, to Zn²⁺ and Ga³⁺, which accelerate the recombination of H atoms.

III. The influence of various factors on hydrogen spillover

1. The influence of water, oxygen, CO, and other compounds

Many investigators noted a significant influence of water on hydrogen spillover.^{1,3,5,71} Tungsten trioxide is reduced by hydrogen to the blue oxide at temperatures above 400 °C. If WO₃ is mixed with platinum black, the reduction temperature falls to 100 °C and, when water is adsorbed in addition, reduction begins already at room temperature. This effect can be naturally attributed to the positive influence of H₂O if, as stated above, hydrogen spillover occurs with participation of the OH groups of the support. In practice, both positive⁷¹ and negative⁷² effects of water have been observed. According to Cevallos-Candau and Conner,⁷³ water accelerates the exchange between the OH and OD groups on the support but not spillover as such.

Oxygen and CO inhibit spillover.^{74,75} Oxygen interacts with hydrogen to form water, which lowers the rate of spillover.⁶ However, the reduction of WO₃ was not observed in the WO₃ + Pt black mixture at room temperature in the presence of H₂.⁷⁶ On the other hand, the addition of oxygen to hydrogen or the adsorption of oxygen before the admission of H₂ alter the colour of WO₃, to blue, which may indicate the reduction of the oxide.

It has been shown⁷⁷ that mobile oxygen, adsorbed on the Pt/TiO₂ catalyst under the conditions of the oxidation of the latter, increases hydrogen spillover in this system.

The accelerating effect of water on the OH – OD exchange in the Pt/Al₂O₃ system in the presence of D₂ at 150 °C has been observed with the aid of chromatographic methods.⁷⁸ In the absence of platinum, no exchange was observed.

An increase in the rate of hydrogen spillover on the Pt/MoO₃ catalyst, obtained by impregnating MoO₃ with a solution of chloroplatinic acid,^{79–81} promoted a decrease in the concentration of residual chlorine on heat treatment.

2. Spillover initiators

Hydrogenation catalysts are as a rule hydrogen spillover initiators: Pt, Pd, Ni, Rh, CuCr₂O₄, etc. The presence of even very small amounts (of the order of 10^{–4}%) of a metal (Ni, Pd, Pt, W) in SiO₂ may induce an appreciable absorption of H₂ at 1000 °C (the number of atoms of the absorbed hydrogen exceeds by a factor of 100 the number of metal atoms).⁸²

The bond between hydrogen and the initiator metal should not be unduly strong and the catalyst must be sufficiently dispersed to ensure good contact between the metal and the accepting or transport phases. The activity of metals in the exchange between D₂ and the OH groups of pentasil varies in the sequence Pt > Pd > Ni, which is consistent with the greater strength of the Ni – H bond compared with the Pt – H and Pd – H bonds.⁸³

In the mixed Co – Mo – S and Ni – W – S catalysts, the hydrodesulfurising initiators of hydrogen spillover are apparently Co and Ni sulfide phases. Rh₂S₃, PdS, and PtS_x mixed with MoS₂ or WS₂ can also serve as spillover initiators.⁸⁴

The spillover initiators (donors of spillover species) do not necessarily have to be mixed with the acceptor; they can also be separated in space from the latter after the initial activation.

Special experiments have been carried out with separation in space of the source and acceptor of the spillover species.^{6,85,86} The Pt/Al₂O₃ catalyst was placed in a bulb separated from the SiO₂ acceptor by a porous partition. After activation by heating in a hydrogen atmosphere at 430 °C, the bulb with the catalyst was removed from the activation zone and ethene, ethyne, heptane, benzene, or cyclohexadiene were hydrogenated on SiO₂ at a lower temperature (200 – 270 °C) with participation of spillover hydrogen. The amount of the latter was 10¹² H atoms per gram of SiO₂. Such an activated SiO₂ specimen retained its activity in the C_nH_m + H₂ reaction for a long time, whereas on nonactivated SiO₂ the above mixture did not react. Hence it follows that

hydrogenation proceeds mainly with participation of hydrogen from the gas phase on centres created by virtue of spillover. Careful analysis demonstrated the absence of the Pt impurity in SiO₂ after spillover.

Cumene was cracked similarly on SiO₂ after its initial activation by the spillover hydrogen generated by the Pt/Al₂O₃ system.⁸⁷

Similar results were obtained with the aid of Al₂O₃ activated by the spillover hydrogen flowing from the Pt/Al₂O₃ catalyst.^{6,88} A similar activation but at a lower temperature may be ensured by Ni/Al₂O₃.

3. Hydrogen acceptors

In many cases, the final result of hydrogen spillover is the formation of new hydroxy-groups. Consequently oxygen ions may serve as acceptors of hydrogen atoms or ions:

or

or

On oxides coated with a hydroxyl layer, structural defects serve as acceptor centres. Carbon is also a good acceptor.

It was already stated above that adsorbed unsaturated compounds and the metal oxides themselves may function as acceptors of H atoms. If protons participate in the spillover, then the effectiveness of the acceptors is determined by their proton affinity,⁸⁹ which varies in the sequence water = methyl alcohol > n-butyl alcohol > *tert*-butyl alcohol ≫ dibutylamine.

4. Promoting agents

Transport bridges or phases may serve as mediators for the transfer of H atoms from the donor to the acceptor. In one of the first studies on spillover,⁹ it was found that the transport of hydrogen on the Pt/C catalyst is accelerated by carbon contaminations, which are produced after the isomerisation or hydrogenolysis of neopentane. The carbon contaminations act as bridge between Pt and C. Their combustion inhibits the spillover. Above it was already stated that perylene also serves as a bridge for the transport of H atoms between Pt and the CeY zeolite.^{10,17} Such bridges may be water and the OH groups of the support. There are data showing that SiO₂ plays more effectively the role of a bridge for the transport of H atoms than Al₂O₃. In the hydrogenation of ethene on the Pt/SiO₂ + H_xWO₃ system, the WO₃ phase transfers hydrogen to C₂H₄. Carbon functions as a bridge in the Pt/C catalyst.

IV. Kinetics of hydrogen spillover

1. The number of hydrogen spillover adsorption centres

Measurement of the excess amount of adsorbed hydrogen compared with the amount necessary for monolayer coverage of the metal surface makes it possible to determine the number of support centres participating in spillover. The study of the adsorption of H₂ on Pt/Al₂O₃ at 250–300 °C by a volumetric method showed⁹⁰ that the number of spillover centres N_{H} is 10¹² cm⁻². Data for the TPD of hydrogen on a similar catalyst yielded $N_{\text{H}} \approx 2 \times 10^{12}$ cm⁻².⁵⁷ A similar value (1.5×10^{12} cm) was obtained by NMR in experiments on the adsorption of H₂ on Pt/SiO₂ at room temperature.⁹¹ Thus the number of centres N_{H} on oxides corresponds to ~1% of the total number of surface centres, which is much less than the number of OH groups on the surface.⁶

On Pt/C, N_{H} is much greater — from 10¹³ to 10¹⁶ cm⁻² (or from 0.01 to 10 formal monolayers).^{9–11}

In experiments where the Pt/SiO₂ source of spillover was isolated from Al₂O₃, it was shown that, under the conditions of the OH–D₂ exchange, hydrogen is transferred over a distance of

1 cm in several minutes.⁴² In the hydrogenation of C₂H₄ on the Pt/SiO₂ + SiO₂ system, the induction of activity on the SiO₂ surface requires prolonged exposure in H₂ (more than 17 h at 400–460 °C) and is characterised by an activation energy of 117 kJ mol⁻¹.⁴³

2. Kinetics of catalytic reactions occurring under the conditions of hydrogen spillover

The kinetics of the chemisorption of hydrogen on Pt/Al₂O₃ have been investigated.^{57,91} It was found that the amount of absorbed hydrogen is proportional to the square root of the adsorption time and that surface diffusion is apparently the rate-limiting stage.

When the hydrogenation reaction proceeds under stationary conditions, the overall activity of the supported metal greatly exceeds (by 1–2 orders of magnitude) the activity of the acceptor-diluent. Spillover should not therefore influence significantly the rate of hydrogenation. The situation is different when hydrogen and the substance hydrogenated are adsorbed on different phases. Spillover exerts a major influence on the kinetics also when the surface is reduced and the active centres are formed with participation of hydrogen arriving from another phase. Delmon⁷⁹ called this phenomenon ‘remote control’.

It was found⁹² that two kinds of spillover hydrogen exist on Pt/Al₂O₃ at 450 °C — irreversible and reversible. The rate of aromatisation of n-hexane is proportional to the surface concentration of irreversible spillover hydrogen, while the rate of hydrocracking and isomerisation is proportional to that of reversible spillover hydrogen.

A mathematical model of spillover has been examined by Edvinsson *et al.*⁹³ It was postulated that the reaction proceeds on the metal serving as the source of spillover species and that the carrier stores these species and interacts with the metal via the spillover and reverse spillover mechanisms. The application of the cyclic modulation method made it possible to discriminate between processes occurring with and without the participation of spillover.

According to a similar model proposed by Nam and Silverston,⁹⁴ there are two regions in the catalysts: active (metal) and inactive (carrier). Dissociative adsorption, the reaction, and recombination desorption take place in the active region. The dissociated species migrate to the inactive part, which serves as a reservoir for the latter, and conversely. The model predicts that, in the absence of spillover, the yield should monotonically decrease with increase in modulation frequency, whilst in the presence of spillover it should pass through a maximum.

Mathematical analysis of the overall kinetic model of a two-stage reaction at a surface incorporating sites of two types with different heats of adsorption showed that the spillover of the adsorbed species between these sites may lead to both an increase and a decrease in the rate of the chemical reaction.⁹⁵ In the oxidation of carbon monoxide on such a heterophase surface, the kinetic coupling of the reaction, induced by CO spillover, leads to an appreciable alteration of the temperature dependence of the reaction rate and also to the appearance of superadditive activity at low temperatures.⁹⁶

3. Determination of diffusion coefficients

The TPD,⁵⁷ adsorption,⁹⁷ electron microscope,⁹⁸ and NMR^{91,99} methods have been used to determine the diffusion coefficients of hydrogen. A table of the diffusion coefficients D_{H} for a series of oxides has been published in a review⁵. At room temperature, $D_{\text{H}} = 10^{-10}$ cm² s⁻¹ on CeY.¹⁷ At 50 °C, $D_{\text{H}} = 10^{-16}$ cm² s⁻¹ on WO₃ and 10^{-13} cm² s⁻¹ on MoO₃.⁹⁷ At 100 °C, $D_{\text{H}} = 10^{-14}$ cm² s⁻¹ on carbon and SiO₂, while the activation energy is $E_{\text{D}} = 65$ kJ mol⁻¹.⁹⁸ At 400 °C, $D_{\text{H}} = 10^{-15}$ cm² s⁻¹ and $E_{\text{D}} = 119$ kJ mol⁻¹ on Al₂O₃ and diffusion takes place over a distance up to 200 nm from the Pt particles.⁹⁸

According to NMR data, 10¹² hydrogen atoms participate in the spillover on Pt/SiO₂ over each square centimetre of the SiO₂ surface⁹¹ and, since the average distance between the Pt particles

on the catalyst is 180 nm, the spillover extends over a distance of at least 90 nm.

Data on the kinetics of the exchange between the OH groups of the support and D_2 are usually employed for the determination of D_H . For this purpose, it is necessary that the direct exchange without the participation of the metal should be negligible, that the migration on the support should be the rate-limiting stage, and that the surface diffusion should differ from the bulk-phase diffusion.¹⁰⁰

If the surface concentration of H atoms on the initiator metals c_H is constant, then D_H can be calculated by the equation⁵⁷

$$Q = c_H I_0 \sqrt{\pi D_H t},$$

where Q (atoms g^{-1}) is the number of species which have diffused onto the support during the time t and I_0 ($cm\ g^{-1}$) is the perimeter of the metal particles. At 400 °C, $D_H = 9.3 \times 10^{-11}\ cm^2\ s^{-1}$ on Rh/SiO₂, $1.7 \times 10^{-10}\ cm^2\ s^{-1}$ on Rh/Al₂O₃, $2.2 \times 10^{-10}\ cm^2\ s^{-1}$ on Rh/ZrO₂ and $8.0 \times 10^{-10}\ cm^2\ s^{-1}$ on Rh/CeO₂.¹⁰⁰

Significantly higher hydrogen diffusion coefficients are also encountered. For example, it has been found⁷³ that $D_H = 10^{-3}\ cm^2\ s^{-1}$ on Pt/SiO₂ at 200 °C. Such appreciable differences between the diffusion coefficients are most probably associated with differences not taken into account under the experimental conditions.

V. The mechanism of hydrogen spillover

1. The surface and gas-phase pathways to spillover

The question of the possible transfer of hydrogen atoms during spillover not along the surface but through the gas phase arose already in the first studies. According to the data of Dmitriev *et al.*,¹⁰¹ in the isotope exchange between deuterium and surface OH groups of the HNaY zeolite the activated deuterium is transported not through the gas phase but along the surface of the support separating the spillover initiator (Pt) and the zeolite.

Gadgil and Gonzales¹⁰² investigated the adsorption of the hydrogen atoms obtained in the high-temperature heating of tungsten in a H₂ atmosphere. It was found that the rate of adsorption is low and independent of the type of carrier, which most probably constitutes evidence against the transfer of H atoms through the gas phase. The study of the adsorption of hydrogen atoms generated in a microwave discharge¹⁰³ on Pt/TiO₂ showed that F centres, capable of effecting the hydrogenation of ethene, are formed in TiO₂ under the influence of these atoms. The low rate of adsorption of H atoms on the Pt/zeolite system is due to the fact that only the outer surface of the catalyst interacts with these atoms.¹⁰⁴

The conversion of CO into methane in a two-bed reactor, the lower section of which contained the Pt/zeolite X catalyst in a stream of H₂ in a stationary bed while the upper section contained the Ni/zeolite X in a stream of CO + H₂, occurred at a much higher rate than in the absence of platinum.¹⁰⁵ The authors did not reach a definite conclusion about the transfer of hydrogen atoms through the gas phase, noting the possibility of their diffusion through the glass lattice separating the two beds.

If SiO₂ is treated with hydrogen at a temperature above 800 °C in the presence of various metals but without being in contact with them, then the siloxane bridges Si—O—Si are converted into S—H groups.¹⁰⁶ This phenomenon has been explained by the transport of the metal on SiO₂ with participation of water vapour. In terms of their activities, the metals can be arranged in the sequence Ta > Ni > Pt > W.

Hypotheses concerning the gas-phase transport of H atoms at relatively low temperatures have been put forward in only a few investigations. In the study of Baumgartner *et al.*,¹⁰⁷ these hypotheses were based on experiments involving the reduction of anthracene and anthraquinone adsorbed on SiO₂ separated in space from the source of hydrogen — Pd/SiO₂. Rodriguez and Baker¹⁰⁸ concluded that at room temperature and a pressure of 0.2 mm Hg atomic hydrogen is transferred from metal sulfides

(MoS₂, FeS₂, or FeS) through the gas phase onto a graphite surface separated from them. However, since the desorption of hydrogen atoms at low temperatures is thermodynamically unfavourable, one cannot rule out that hydrogen is transferred from the source to the acceptor not directly but in the form of other species (OH, H₂O, *etc.*) in these cases too.

2. The mechanism of the diffusion of hydrogen on an oxide surface

One of the first studies on the spillover mechanism was undertaken by Conner *et al.*,⁴¹ who used for this purpose FTIR spectroscopy *in situ*. The diffusion of the deuterium adsorbed on Pt/SiO₂ from Pt to the carrier was followed from the exchange between D atoms and the OH groups of SiO₂. It was postulated that the process proceeds in accordance with the scheme

The heat of adsorption of H₂ on Pt was 115 kJ mol⁻¹ and the activation energy was 67 kJ mol⁻¹. The heat of adsorption of H₂ on SiO₂ was smaller — 12.5 kJ mol⁻¹. Thus the transfer of deuterium from platinum to the support is an endothermic process and spillover occurs by virtue of the existence of a high deuterium concentration gradient at the interface between Pt and the support. However, it is possible that the heats of adsorption of H₂ on the real spillover centres greatly exceed 12.5 kJ mol⁻¹. Under the experimental conditions, the ratio of different forms of deuterium was

$$PtD : D_{sp} : OD = 1 : 5 : 600 \quad (D_{sp} = \text{spillover deuterium}).$$

It has been postulated that the spillover on SiO₂ takes place via the formation of associative complexes with participation of pairs of OH groups (vicinal or geminal).⁴³

Analysis of diffuse scattering IR spectra showed¹⁰⁹ that the adsorption of H₂ (D₂) on 10% Pt/TiO₂ at a low temperature results in the appearance of a new broad absorption band at ~ 3000 (2300) cm⁻¹. The authors assigned it to the OH (OD) groups at the metal–support interface. This band is thermally unstable and at room temperature the OH and OD groups are readily involved in exchange with D₂ and H₂ respectively.

The involvement of the OH groups of the HNaY zeolite in the spillover of deuterium in the HNaY + PtNaY system has been demonstrated by FTIR spectroscopy *in situ*.^{110, 111}

Under the conditions of the hydrogenation of ethene on Pt/Al₂O₃, the ethene reversibly adsorbed on the support reacts with the hydrogen arriving from platinum via the spillover mechanism.¹¹² Methylation of the support hydroxyls with diazomethane greatly reduces the rate of the reaction. The Pt/Al₂O₃—OCH₃ system formed after modification is at least ten times less active than Pt/Al₂O₃ and the hydrogenation reaction is propagated only by the metal on which ethene is strongly adsorbed. This demonstrates the need, in principle, for the spillover of hydrogen in order that the given reaction may be catalysed.

The majority of investigators hold to the view nowadays that hydrogen atoms participate in spillover.^{17, 101, 113} It has been found¹⁷ that the rate of disappearance of the EPR signal of perylene corresponds to the rate of adsorption of H₂ by the Pt/CeY system. We may note that the direct detection by EPR of H atoms on the majority of supports is possible only at temperatures below -170 °C. Careful analysis of the form and magnitude of the shift in the ¹H NMR spectra made it possible to establish¹¹³ that hydrogen migrates on the SiO₂ surface in the form of the H[•] radical species. The hydrogen radical species adsorption centres may be either F centres or the (SiO)- or Si-groups.

It has also been postulated that spillover proceeds via a proton mechanism.^{71, 89, 114} This is indicated by the correlation between the rate of spillover and the proton affinity of the promoting agent,^{71, 89} which may solvate the diffusing proton: $\text{H}_2\text{O} \gg \text{CH}_3\text{OH} > \text{C}_2\text{H}_5\text{OH} > \text{n-C}_3\text{H}_7\text{OH} > \text{n-C}_4\text{H}_9\text{OH}$. In the presence of all these promoting agents, the rate of spillover was independent of the specific surface of the supported Pt, while in the presence of CH_3COOH , which has a low proton affinity, such dependence was observed. In the latter case, the rate of reaction may be determined by the rate of solvation of the proton.

Bianchi *et al.*,⁴⁷ who investigated the hydrogen transfer from the Pt/ Al_2O_3 catalyst to a methoxylated silica gel (Aerogel), even postulated the involvement of H_3^+ species in spillover on the basis of kinetic data.

The adsorption of hydrogen on Rh/ TiO_2 has been investigated by NMR.^{74, 115, 116} Hydrogen was adsorbed in two forms: the reversible form bound to the support and the irreversible form bound to the metal. According to NMR data, hydrogen bound covalently to Pt is present at the Pt/ SiO_2 surface.⁹¹ Paramagnetic hydrogen, which reduces the relaxation time of the Si—OH bonds, participates in spillover. On Pt/ SiO_2 , two hydrogen NMR signals were also found: one corresponded to the Pt—H bond and the other to the spillover hydrogen located at the same sites as the hydrogen of the OH groups.¹¹⁷

The study of the exchange between D_2 and the OH groups of conducting supports on which platinum had been deposited failed to reveal appreciable differences between *n*- and *p*-semiconductors,¹¹⁸ which permitted the conclusion that uncharged species are involved in spillover.

The rate of the $\text{H}_2 + \text{D}_2$ exchange on Pt or Pd, deposited on a zeolite with a modulus of 30, exceeded by several orders of magnitude the rate of exchange between D_2 and OH groups.⁸³ Thus the activation of D_2 does not limit the gas-phase exchange. Spillover of hydrogen should include the interphase transfer of the activated D_2 , the migration of D on the surface, and recombination.

According to the data of Parera *et al.*,³⁸ the H—D exchange on Rh/ Al_2O_3 proceeds in two stages: rapid spillover from Rh to Al_2O_3 takes place in the first stage, while the second involves a slow exchange between the spillover hydrogen and the OH groups of Al_2O_3 .

Information about the number of spillover centres may be obtained from data¹¹⁹ on the adsorption of H_2 on Pt/ Al_2O_3 —Cl, Al_2O_3 , and their mixtures at 500 °C. The presence of chlorine alters the rate of spillover. For a certain chlorine content, maximum spillover is observed:

The rate-limiting stage is the surface migration of H atoms. The above scheme shows that, in the presence of a low chlorine content, the number of spillover centres increases, diminishing in the presence of a high chlorine content. When all the OH groups have been replaced by Cl, the protons lose their mobility owing to the absence of surface OH groups.

According to NMR data, the hydrogen adsorbed on the $\text{CuO} + \text{Cr}_2\text{O}_3$ system is capable of hydrogenating isoprene to isobutene. This hydrogen does not enter into the composition of the OH groups and does not exist on pure Cr_2O_3 . It apparently arises from the metallic copper formed under the reaction conditions.¹²⁰

It is generally believed that the first stage of the process is the homolytic rupture of the H—H bond on the metal regardless of the involvement of hydrogen atoms or H^+ ions in the spillover.

Different investigators postulate that one of two stages may limit the spillover: either the surface diffusion on the acceptor or the transfer of species from the initiator to the acceptor. Since the activation energies for these elementary stages may be different, the variation of temperature may entail also a change in the rate-limiting stage of the spillover.⁸⁵ The cause of the change in the rate-limiting stage may be also the presence at the surface of spillover promoting or inhibiting agents. A more common view is that spillover is limited by the diffusion at the support surface.⁶

3. The mechanism of the diffusion of hydrogen into the bulk phase of oxides

When small amounts of Pt or Pd are added to the oxides WO_3 , MoO_3 , or V_2O_5 , in the presence of hydrogen, tungsten (H_xWO_3),^{5, 6, 121} molybdenum (H_yMoO_3),^{6, 122–127} and vanadium ($\text{H}_z\text{V}_2\text{O}_5$)¹²⁸ bronzes are formed. They exhibit a catalytic activity in the hydrogenation of ethene, the rate-limiting stage of which may be the reverse spillover of hydrogen on Pt, where the hydrogenation reaction actually occurs.⁶

According to X-ray diffraction data, the initial monoclinic structure of WO_3 is converted into the cubic structure of $\text{H}_{0.4}\text{WO}_3$ as a result of hydrogen spillover. Hydrogen atoms occupy the hexagonal vacancies in WO_3 . The diffusion coefficient of hydrogen in the tungsten bronze is $1 \times 10^{-7} - 7.9 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ at room temperature.^{99, 122}

The study of the interaction of H_2 with the (100) face of MoO_3 at a very low pressure ($10^{-5} - 10^{-8} \text{ mm Hg}$) showed¹²³ that the monoclinic bronze $\text{H}_{1.6}\text{MoO}_3$ is formed in three stages: (1) initiation, (2) a stage characterised by a constant rate of absorption of H_2 , and (3) the concluding stage of the formation of the new phase in which the rate of absorption of hydrogen diminishes. The spillover of H_2 from Pt is observed only in the first stage. Under these conditions, hydrogen permeates into the near-surface layers of the oxide. It then reacts with the oxide without the participation of Pt. The diffusion coefficient of H atoms in the second stage is 7–10 orders of magnitude higher than the coefficient usually observed in spillover.

The rate of hydrogenation of ethene on Pt/ H_yMoO_3 increases with increase in the Pt concentration.¹²⁴ According to other data, the $\text{H}_{1.6}\text{MoO}_3$ bronze may catalyse the hydrogenation of C_2H_4 also in the absence of Pt.¹²⁵ The initial rate of reaction at 160 °C on $\text{H}_{1.6}\text{MoO}_3$ is approximately the same as on Pt/ H_yMoO_3 . In the course of the hydrogenation of C_2H_4 by the hydrogen entering into the composition of the $\text{H}_{1.6}\text{MoO}_3$ bronze, the latter is converted into $\text{H}_{0.9}\text{MoO}_3$, which has a different structure. In the presence of hydrogen in the gas phase, the bronze did not undergo structural changes. The activation energy for hydrogenation was 54 kJ mol^{-1} and was close to the activation energy for the diffusion of H atoms in the bronze.¹²⁵

On Pt/ $\text{H}_y\text{VMoO}_{5.5}$ with $2.85 < y < 3.31$, the spillover hydrogen forms with the surface a very weak, apparently physical, bond with $\Delta H < 12.5 \text{ kJ mol}^{-1}$ or is occluded between the oxide layers.¹²⁸ When $y = 5.85$, the heat of adsorption of hydrogen is $127.6 \text{ kJ mol}^{-1}$.

The vanadium bronze $\text{H}_{3-3.8}\text{V}_2\text{O}_5$ is X-ray-amorphous and, in contrast to the tungsten and molybdenum bronzes having metallic conductivity, exhibits a semiconductor conductivity.¹²⁹

The reversible adsorption and removal of hydrogen occur also on heteropolyacids (HPA) and heteropolysalts formed from molybdenum and tungsten oxides. This process has been investigated by the temperature-programmed reduction (TPR) and IR spectroscopic methods in relation to the system $\text{H}_3\text{PMo}_{12-x}\text{W}_x\text{O}_{40} + \text{Pd/C}$.¹³⁰

It was found that H_2 is absorbed already at room temperature, while water is evolved at a higher temperature. At 300 °C, the absorption of H_2 and the exchange between H_2 and D_2 take place also in the absence of Pt. The process includes two stages: (1) rapid dissociation of H_2 with the initial formation of atoms and then H^+ ions, diffusing into the bulk of the HPA, and (2) slow interaction of H^+ with the O atoms in the bulk phase. The rate of oxidation of H_2 depends little on the specific surface of the HPA.

The salt $\text{Ag}_3\text{PW}_{12}\text{O}_{40}$ exhibits an appreciably higher catalytic activity in the isomerisation of but-1-ene in the presence of hydrogen than the heteropolyacid $\text{H}_3\text{PW}_{12}\text{O}_{40}$.¹³¹ It was also found that the reactivity of the salt increases with increasing H_2 pressure, whereas that of the acid is independent of this parameter. Protons of two types have been detected in the system by NMR: some of them are manifested only in the presence of H_2 in the gas phase, whilst others are present at the surface of the salt also when the system is evacuated. The reversibly bound hydrogen is evidently formed on silver and then diffuses to the organic molecule and participates in catalysis.

The oxidation of methane to CO_2 and H_2O on the $\text{Pt/V}_2\text{O}_5$ catalyst with a very low Pt content (0.15%) has been investigated by scanning calorimetry *in situ*.^{132, 133} When $\text{Pt/V}_2\text{O}_5$ is heated to 550 °C, the stable V_2O_4 phase is formed, which can be detected from the heat of the reversible phase transition between the monoclinic and tetragonal forms of V_2O_4 , occurring at 68 °C. The stable phase proved to be completely inactive in catalysis at 275 °C.

On the other hand, the reduction of the catalyst with methane at 275 °C leads to the formation of a metastable reduced vanadium oxide phase. Under these conditions, 20%–25% of oxygen is removed from the specimen and the effective stoichiometric formula of the oxide becomes close to V_2O_4 . However, the heat of the reversible transition from the monoclinic to the tetragonal form is not then observed. The stable catalytic activity of the metastable phase is retained when the specimen is cooled to 185 °C. The temperature of its reoxidation with oxygen is higher by almost 200 °C than for the stable phase. The low-temperature (50–350 °C) stage of the oxidation of the metastable phase is then characterised by an anomalously high heat of reaction ($\Delta H = 335\text{--}502\text{ kJ mol}^{-1}$). On heating, the metastable phase is converted into the stable phase with evolution of a large amount of heat.

The study of the $\text{Pt/V}_2\text{O}_5$ surface by the XPS method showed that vanadium atoms in the V, IV, and lower valence states are present after catalysis at the surfaces of both the stable (weakly active) and metastable (highly active) V_2O_5 phases. The surfaces of the active and inactive phases differ little in composition. As regards the state of Pt, according to XPS data the appearance of catalytic activity in $\text{Pt/V}_2\text{O}_5$ after heating in methane coincides in time with the disappearance of the oxidised forms of Pt (the binding energy is $4d_{5/2} = 317.1\text{ eV}$) and the appearance of metallic Pt (binding energy 314.1 eV).

Thus CH_4 dissociates on platinum particles in the course of its oxidation on the $\text{Pt/V}_2\text{O}_5$ catalyst.

Hydrogen atoms diffuse via the spillover mechanism to the V_2O_5 phase and reduce it to the nonequilibrium form V_2O_4 .

The nonequilibrium V_2O_4 phase facilitates the transport of oxygen to the $\text{Pt/V}_2\text{O}_5$ interface, in the vicinity of which methane is oxidised. The O_2 and CH_4 adsorption centres are probably separated.

Similar processes occur in the oxidation of hydrocarbons on the $\text{Pt/CeO}_2/\text{Al}_2\text{O}_3$ catalyst used in automobile catalytic converters.¹³⁴ Hydrogen is split off from the hydrocarbon being oxidised, diffuses into the bulk of CeO_2 , and reduces it to a lower oxide form. The reduction of CeO_2 in the Ni/CeO_2 system has been investigated in detail by the TPR, NMR, EPR, and IR spectroscopic methods.¹³⁵ At 400 °C, each gramme of CeO_2 is capable of absorbing up to 3.4×10^{20} hydrogen atoms ($\text{H/Ce} = 0.1$). This hydrogen hydrogenates isoprene at room temperature. Pure CeO_2 is inactive in hydrogenation, but the amount of hydrogen extracted by isoprene from the Ni/CeO_2 system is greater than would have been the case for the ratio $\text{H/Ni} = 1$. It is also possible that Ni^{2+} diffuses within the CeO_2 .

The results of experiments on the synthesis of methanol on a mixture of Cu/SiO_2 with ZnO/SiO_2 suggested that hydrogen diffuses from the Cu to the ZnO phase under the reaction conditions.¹³⁶ It is postulated that H atoms are formed on decomposition of the HCOO complex on Cu and migrate to ZnO, which serves as a reservoir for the reverse hydrogen spillover. According to IR spectroscopic data, ZnO is partly reduced in the course of the hydrogen spillover from Cu to ZnO.¹³⁷ The electrical conductivity of ZnO in its mixture with Cu increases under these conditions, which, according to Barrett *et al.*,¹³⁸ is associated with the intercalation of hydrogen and the formation of ZnOH_x . The diffusion of H atoms from the Cu to the ZnO phase has been demonstrated also by the direct neutron diffraction method.¹³⁹ A ZnO superlattice with an ordered arrangement of H atoms is then formed.

On the $\text{Cu/SiO}_2 + \text{ZnO/SiO}_2$ mixture, the yield of methanol from $\text{CO} + \text{H}_2$ was higher than on the separate components.¹⁴⁰ The authors explain such synergism by hydrogen spillover.

The study of the adsorption of hydrogen on the Cu/SiO_2 , Ru/SiO_2 , and Cu-Ru/SiO_2 catalysts led to the conclusion¹⁴¹ that atomic-like hydrogen participates in the spillover from Ru to Cu through SiO_2 .

TiO_2 is an effective hydrogen transferring agent. Its addition to the CuO-TiO_2 system greatly increases the activity and selectivity of the catalyst in the synthesis of methanol.¹⁴² The addition of Pd has the same effect.¹⁴³

Co^{2+} ions present in the NaY zeolite are reduced by hydrogen in the presence of Pd, provided that Co^{2+} and Pd^{2+} are in the same sodalite cavity.¹⁴⁴

4. The strong metal – support interaction

The strong metal – support interaction (SMSI), inducing a change in the adsorption and catalytic properties of the carrier and the deposited metal, is as a rule observed in the reduction of an oxide carrier. This effect was named by Tauster and Fung,¹⁴⁵ who investigated the changes in the properties of TiO_2 on deposition of Pt. Under these conditions, the catalytic activity of the system in the Fischer – Tropsch synthesis is retained and even increases, although its adsorption capacity in relation to H_2 and CO falls.

The SMSI effect has been noted in the interaction of Pt, Pd, Ru, Rh, Ir, Ni Au, and Ag with TiO_2 , TiO , Ti_2O_3 , V_2O_5 , V_2O_3 , Ta_2O_5 , Nb_2O_5 , etc.⁵ The mechanism of the effect has been usually investigated in relation to the Pt/TiO_2 system. It is generally believed that the SMSI effect is induced by the reduction of the carrier as a result of the spillover of hydrogen from the metal to the carrier.

In certain cases, the SMSI is accompanied by the formation of alloys or intermetallic compounds. Convincing evidence for the formation of the Pt_3Ti phase in the high-temperature reduction of Pt/TiO_2 has been obtained.¹⁴⁶ An electron microscope study of the Pt/TiO_2 system showed that the spillover of hydrogen entails the partial coating of the deposited Pt with titanium oxide. At temperatures above 550 °C, TiO_2 is reduced to Ti_4O_7 . At a lower

temperature (300 °C), the formation of Ti^{3+} was observed.¹⁴⁷ The Ti^{3+} EPR signal vanishes on evacuation, but reappears after the admission of H_2 even at room temperature.

Thus at a low temperature the spillover results in the formation of the $\text{Ti}^{3+} + \text{OH}^-$ pair, whilst at high temperatures it gives rise to the bulk-phase reduction of the oxide.

In the spillover of hydrogen on Rh/TiO_2 , the amount of adsorbed hydrogen corresponded to the ratio $N_{\text{H}}/N_{\text{Rh}} = 3$. According to NMR data, Ti^{3+} centres participate in the diffusion of H atoms.¹⁴⁸ The adsorption of H_2 on Rh/TiO_2 (rutile) has been studied by the TPR, IR spectroscopic, EPR, and NMR methods,¹⁴⁹ showing that hydrogen is adsorbed at room temperature in two forms — strong and weak. The weak form participates in the reverse spillover and in the reduction of the support surface:

On anatase, such a process does not take place. The mechanism of hydrogen spillover is described by the following scheme:

where $[\]$ is a vacancy and H_{met} is metallised hydrogen. At 300 °C, hydrogen diffuses into the bulk of TiO_2 . Similar processes have been observed also on Pt/TiO_2 and Pd/TiO_2 .^{150, 151}

The valence state not only of the carrier but also of the metal may change as a result of the SMSI.¹⁵² In the Ni/TiO_2 system at 450 °C, large Ni particles interact with the carrier Ti^{3+} ions via spillover and the catalytic activity of such a two-phase system increases in the Fischer–Tropsch synthesis. However, at 650 °C a proportion of Ni migrates to the near-surface TiO_2 layers in the form of Ni^{n+} ions.

The increase in the electrical conductivity of TiO_2 in a hydrogen atmosphere after the deposition of Pt, Rh, or Ni was also accounted for by hydrogen spillover.^{153–155} An increase in electrical conductivity initially of the TiO_2 bound to Pt and then also of TiO_2 without Pt was observed in the $\text{Pt}/\text{TiO}_2 + \text{TiO}_2$ mixture in the presence of hydrogen. It is postulated that hydrogen diffuses to TiO_2 in the form of protons.

After heat treatment in hydrogen, the RhNb_2O_4 phase is formed in the $\text{Rh}/\text{SiO}_2 + \text{Nb}_2\text{O}_5$ system.¹⁵⁶ Hydrogen dissociates on Rh also after spillover to the Nb_2O_5 phase, reducing the latter.

When TiO_2 or Cr_2O_3 is added to the Rh/SiO_2 catalyst, the oxides partly ‘creep’ onto the Rh surface. According to TPR data, spillover hydrogen is adsorbed on the oxides and partly reduces them. With increase in the coverage of the rhodium surface by the oxides, the catalytic activity of the system in the hydrogenation of CO also increases.¹⁵⁷ It has been suggested that the dissociation of CO with participation of hydrogen takes place on an active centre incorporating Rh and a partly reduced titanium or chromium cation.

Ni/Mo_x catalysts, in which Ni is in the form of very small clusters (less than 2 nm) and the Ti, Zr, and Nb oxides are partly reduced, have been obtained by sputtering mixtures of a nickel salt with titanium, zirconium, or niobium salts.¹⁵⁰ The SMSI effect, occurring with participation of spillover hydrogen, has been observed in the formation of such catalysts. The catalysts obtained exhibit a high activity in the hydrogenation of CO_2 .

The SMSI effect has also been observed when Pt/TiO_2 was acted upon by hydrogen at 500 °C.¹⁵⁹ It has been suggested that a Pt–Ti alloy is formed in this system.

It has been demonstrated by the XPS method that heating of $\text{Ni}/\text{Al}_2\text{O}_3$ in a H_2 atmosphere leads to the SMSI, $(\text{Al}_x\text{O}_y)_n$ aggregates ‘creeping’ onto the surface of the deposited Ni.¹⁶⁰ Heating in O_2 or CO returns the metal to the initial state.

The coating of the catalyst by the carrier, accompanying the SMSI effect, has been noted in the interaction of methane with the $\text{MoO}_3 + \text{SiO}_2$, $\text{V}_2\text{O}_5 + \text{SiO}_2$, and $\text{Fe}_2\text{O}_3 + \text{SiO}_2$ systems subjected to a preliminary mechanochemical treatment.¹⁶¹ Electron microscope and electron diffraction studies have shown that, as a result of such treatment, the particles of the reduced oxides MoO_x and VO_y and also of metallic Fe are enclosed within a SiO_2 shell. It may be that the increased mobility of hydrogen in the mechanochemical treatment leads to the appearance of effects resembling SMSI.

5. Synergism in catalysis

The phenomenon of synergism, *i.e.* of the non additive increase in activity in mixtures of catalyst components, has been often investigated in relation to the hydrodesulfurisation process on the $\text{Co}(\text{Ni})\text{--Mo}(\text{W})$ catalyst. Delmon¹⁶² gave the first explanation of this phenomenon, postulating that the Co--Mo--S catalyst consists of two phases. According to the model of contact synergism which he proposed,^{163, 164} hydrogen is activated on the Co_9S_8 or NiS phase, while the sulfur compound being hydrogenated (for example, thiophene) is activated on the MoS_2 phase, hydrogen spillover occurring between the two phases. In a later model,¹⁶⁵ it was postulated that hydrogen spillover takes place between the CoS_2 and CoMoS phases.

The view that, whilst present in the real catalyst, the Co_9S_8 and NiS sulfide phases do not apparently play decisive roles in hydro-treating has predominated recently.^{166–176} The formation of a ‘ Co--Mo--S ’ phase, in which the Co atoms are located on the side faces or edges of MoS_2 microplates, has been observed by various physical methods (EXAFS, NMR, XRD phase analysis, *etc.*). The coordination number of Co is IV or V according to EXAFS data. Such an optimum ratio is attained when the Co atoms are located on the edges of MoS_2 microcrystallites.

Data obtained by Mössbauer spectroscopy^{177, 178} have shown that the same CoS species are formed under sulfiding conditions on the $\text{CoMo}/\text{Al}_2\text{O}_3$ catalyst as on $\text{Co}/\text{Al}_2\text{O}_3$, while on the CoMo/C catalyst the same CoS species are formed as on Co/C . This fact throws doubt on the hypothesis of the important role of the ‘ Co--Mo--S ’ phase. The MoS_2 phase is then regarded as a simple diluent. At the same time, it has been justly suggested that the CoMoS/C system may differ from $\text{CoMoS}/\text{Al}_2\text{O}_3$.¹⁶³ The Co/C catalyst exhibits an activity which is only three times lower than that of CoMoS/C .¹⁷⁹ The activities of the $\text{Co}/\text{Al}_2\text{O}_3$ and $\text{CoMoS}/\text{Al}_2\text{O}_3$ catalysts differ to a much greater extent.

As already mentioned, the Co atoms in the Co--Mo--S system are located on the edges of the MoS_2 microcrystallites.¹⁸⁰ The Co_9S_8 phase also exists, but its positive role is associated not with hydrogen spillover but with its additional function as a support for the Co--Mo--S phase.

The mechanism of the hydrodesulfurisation of thiophene on the $\text{Co}/\text{Al}_2\text{O}_3$, $\text{Mo}/\text{Al}_2\text{O}_3$, and $\text{CoMo}/\text{Al}_2\text{O}_3$ catalysts has been investigated by the TPD, TPR, and H–D exchange methods.¹⁸¹ On $\text{Mo}/\text{Al}_2\text{O}_3$ and $\text{CoMo}/\text{Al}_2\text{O}_3$, the TPR spectra of thiophene, tetrahydrothiophene and butanethiol proved to be very similar. At the same time, on the last catalyst the peaks due to the reaction products were displaced towards the region of low temperatures, which indicates higher rates of their formation. The TPR spectra of the same initial compounds on $\text{Co}/\text{Al}_2\text{O}_3$ differed sharply: no peaks corresponding to the majority of the main reaction products were observed on them. In contrast to $\text{Mo}/\text{Al}_2\text{O}_3$, hydrogen was present on the $\text{Co}/\text{Al}_2\text{O}_3$ and $\text{CoMo}/\text{Al}_2\text{O}_3$ surfaces in a weakly bound form.

The results obtained confirmed the view that thiophene (or its derivatives) are adsorbed on the MoS_2 anionic vacancies while hydrogen is activated on cobalt sulfide. Hydrogen may be transferred by means of spillover if the Mo and Co centres belong to different phases or via migration if these centres form part of the composition of a single phase. Presumably the hydrogenation–dehydrogenation reactions occur on centres of one type, whilst desulfurisation takes place on centres of another type.

Much interest has been shown recently in solid superacids of the type of $\text{ZrO}_2\text{--SO}_4^{2-}$, capable of catalysing a series of most important organic reactions of the acid type. The addition of Pt may improve the catalytic properties of superacids and, in particular, may increase their resistance to poisoning by coke, since the latter is hydrogenated by the spillover hydrogen.^{182–184} Analysis of the IR spectra showed that new proton centres are formed in place of the acid Lewis centres under these conditions. Molecular hydrogen dissociates on Pt and the H atoms formed migrate via spillover to $\text{ZrO}_2\text{--SO}_4^{2-}$. It has been suggested that the H atom gives up an electron on Lewis centres, being converted into a H^+ ion, which is stabilised by the nearest surface O^{2-} ion. The rate of the skeletal isomerisation of butane on such a catalyst is much higher than on the $\text{ZrO}_2\text{--SO}_4^{2-}$ catalyst without Pt.

The hydrogenation of CH_3OH , $(\text{CH}_3)_2\text{O}$, $\text{C}_2\text{H}_5\text{OH}$, $\text{C}_3\text{H}_7\text{OH}$ and HCOOH on the $\text{Ni}/\text{Al}_2\text{O}_3$ catalyst has been investigated by the TPR method.¹⁸⁵ It was found that the rate of formation of methane from all five compounds is the same and close to the rate of hydrogenation of the CH_2O fragment formed from the adsorbed CO and H_2 . Thus in all cases hydrogenation has the same rate-limiting stage, which may be the spillover of hydrogen from Ni to the organic molecule adsorbed on Al_2O_3 .

In the hydrogenation of CO on $\text{Ni}/\text{Al}_2\text{O}_3$ mixed with Pt/SiO_2 (or $\text{Ru}/\text{Al}_2\text{O}_3$), carbon monoxide is adsorbed on Pt, while hydrogen migrates via the spillover mechanism from Ni to Al_2O_3 .¹⁸⁶ Data obtained by the TPD method have shown that the products are desorbed from the H_2CO complex. In the absence of the second component, such a complex is not formed on Pt/SiO_2 . The independence of the rate of its formation of the Ni concentration indicates the formation of this complex on the support.

The H_2CO complex was also detected by the TPR method in the conversion of CO into methane on the $\text{Ni}/\text{SiO}_2 + \text{Al}_2\text{O}_3$ mixture.¹⁸⁷ The rate of spillover increased with improvement of the contact between the particles and with increase in the nickel concentration.

VI. Conclusion

Thus the phenomenon of hydrogen spillover, common in heterogeneous catalysis, has been observed mainly in multiphase systems. Hydrogen is activated on one of the phases, frequently the metallic phase (although this may occur also on certain transition metal oxide or sulfide phases) and then diffuses to the other phase, which in the absence of the activator phase is inactive or its activity is low in relation to the adsorption of hydrogen. The spillover hydrogen on the second phase may be detected by physical methods (EPR, NMR, neutron diffraction, etc.) and also from the change in the properties of the phase (for example, as a result of the reduction of oxides) or by virtue of the manifestation of new catalytic properties by the heterogeneous system.

The spillover phenomenon is not only of theoretical but also of considerable practical importance. The elucidation of the nature and rules governing spillover may promote a rational solution of the problem of the construction of multiphase catalysts. For this purpose, information is needed about the adsorption properties of each phase and also about the characteristic features of the interphase diffusion of hydrogen and its diffusion along individual phases. It appears that in catalysis different reactants are frequently activated on different phases and the catalytic reaction is effected as a result of interphase diffusion. It has been shown^{19,188} that the high activity and selectivity of multiphase oxide catalysts in oxidation reactions can be explained precisely by the occurrence of individual stages on different phases and by the diffusion (spillover) of oxygen between the phases.

This claim is probably even more valid in relation to catalytic reactions with participation of hydrogen. Hydrogen atoms or ions are more mobile than oxygen and may diffuse more easily. The so called 'bifunctional' catalyst, consisting of the supported metal, on which hydrogen is activated, and an oxide (frequently with distinct acid properties — for example Al_2O_3 and zeolites),

adsorbing or activating the component to be hydrogenated are widely used in catalytic reactions involving hydrogen. The role of interphase diffusion in such systems has been examined by Weisz.¹⁸⁹ Hydrogen spillover plays an important role in catalytic processes such as reforming, hydrogenation of unsaturated compounds, synthesis of methanol, isomerisation of hydrocarbons, and hydrodesulfurisation.

The mechanism of the hydrodesulfurisation reaction on the CoMo, NiMo, or NiW sulfide catalysts has been vigorously discussed in the literature. On the one hand, fairly numerous data indicate that multiphase catalysts are needed for the occurrence of this reaction. On the other hand, the idea that this requires not so much a multiphase system as the presence of centres with nonidentical functions, which can in general enter into the composition of the same phase, has been expressed recently with increasing frequency. However, in any variant it is essential to know the mechanism of the transport of hydrogen (or other adsorbed species) between such centres.

There is as yet no unanimous view about the mechanism of hydrogen spillover. The majority of investigators postulate that the initial stage of the spillover is homolytic dissociation of hydrogen on the metal phase (or an oxide or sulfide). However, the question in what form and by what mechanism hydrogen atoms pass from one phase to another remains controversial. It has been suggested that surface diffusion of the adsorbed species predominates, but in certain individual instances diffusion through the gas phase is not ruled out. The considerable scatter of hydrogen diffusion coefficients in spillover on various catalysts apparently indicates the diversity of the nature of the diffusing species and spillover mechanisms.

The nature of the hydrogen acceptor centres on the surfaces of oxides has been little investigated. It was indicated above that the number of hydrogen acceptor centres is as a rule small (usually less than 1% of the total number of surface sites). In this case, the question arises what role is played in spillover by the remaining centres, such as O^{2-} ions or OH groups. What is the ratio of the heats of adsorption of spillover hydrogen on the activator and on the acceptor centres? How do the kinetics of the reactions change in the course of the migration or spillover of adsorbed species of one or several types?

These and many other questions concerning the spillover mechanism have so far not been analysed in depth either theoretically or experimentally.

Further detailed investigations of spillover with quantitative estimation of factors such as diffusion coefficients, the number of spillover initiator and acceptor centres, and the bond energies between hydrogen and these centres are needed.

This review has been written with support by the Russian Fundamental Research Fund (Grant No. 95–03–08429a).

VI. Biological activity of azafluorene derivatives	135

Abstract. Data on the chemistry of azafluorenes (indeno[1,2-b]pyridines) for the last two decades are summarised. Methods of synthesis of all isomeric (as regards the position of the nitrogen atom) azafluorenes are considered. The main reactions of azafluorenes are analysed, their reactivity is determined by the presence and mutual influence of two different conjugated fused rings (benzene and pyridine) and the mode of fusion of the indene and pyridine fragments. The principal conversions of substituents at different positions of the azafluorene system are considered. Evidence is presented on the natural occurrence of azafluorenes, the biological activity of their synthetic derivatives, and on the structure and physicochemical properties of azafluorenes and their derivatives. The bibliography includes 204 references.

I. Introduction

The chemistry of isomeric azafluorenes (indeno[1,2-b]pyridines) has been discussed in two reviews,^{1,2} which summarise the data published mostly before 1975. It should be noted that these reviews dealt mainly with the chemistry of 2-azafluorene, and an extreme scarcity of data on isomeric 1- and 3-azafluorenes has been mentioned (1-azafluorene was first obtained as late as 1975). A large body of evidence has been accumulated in the current literature over the last two decades concerning the development of general methods of synthesis of these tricyclic fused systems together with in-depth analysis and comparison of reactivity of isomeric azafluorenes, and a search for promising biologically active derivatives among newly synthesised compounds. Considerable recent interest in azafluorenes has been stimulated by the discovery in mid-1980s of numerous plant alkaloids having mostly the structure of 4-azafluorenone. Moreover, there is evidence in both scientific and patent literature on the manifestation of antihistamine, neurotropic, antibacterial, antioxidant, and pesticide activities by azafluorene derivatives.

Uspekhi Khimii 66 (2) 131–150 (1997); translated by R L Birnova

This review presents and discusses the data on the strategy of synthesis of azafluorenes and their conversions involving the benzene, pyridine, and cyclopentadiene rings, which constitute the azafluorene system and exert a mutual influence on the chemical properties of these compounds. Data on the natural occurrence of azafluorenes and the biological activity of their synthetic derivatives are also generalised.

II. Structure and physicochemical properties

All of the isomeric (as regards the position of the nitrogen atom) unsubstituted azafluorenes (**1–4**) and azafluorenones (**5–8**)^{1–4} the structure of which is given below, have now been described:

1–4: Z = CH₂; **5–8:** Z = C=O.

Quantum-chemical calculations have been performed^{5,6} for the distribution of π -electron density and localisation energy of the protonated forms of 1-, 3-, and 4-azafluorenones. According to these calculations, electrophilic substitution must occur at the phenylene ring, presumably, at C(7). The luminescence spectra of unsubstituted azafluorenes, their 9-oxo-derivatives, and 9-arylidenes azafluorenes have been studied.^{7–9} Thus, the UV spectra of 1- and 4-azafluorenes display a bathochromic shift of the α^* -absorption band, a hypsochromic shift of the p -band, and an increase in intensity of the α^* -band as compared with fluorene. In the case of 2-azafluorene, a hypsochromic shift of these bands is accompanied by a decrease in their intensity and a bathochromic shift of the α -band occurs. It is concluded that the α^* - and p -bands for 1- and 4-azafluorenes, like for fluorene, possess fluorescent character, while in the case of 2-azafluorene, this property is inherent in the α -band. Unlike other isomeric azafluorenes, 3-azafluorene is unstable and undergoes rapid photoconversions in the light.

The ^{13}C and ^1H NMR spectra of azafluorenes **1–4** have been studied.^{3, 10–12} The ^1H NMR spectra of a series of 9-arylidene-2-azafluorenes were also studied with the use of shift-reagents.⁸

The IR spectra of azafluorenes do not contain specific absorption bands and are mostly used in studies on the synthesis of derivatives of these compounds to confirm the presence and position of substituents. The carbonyl group in the azafluorene-9-ones **5–8** absorbs in the characteristic region, i.e., at $1715\text{--}1735\text{ cm}^{-1}$. The IR spectra of 1,4-dihydro-4-azafluorenes,¹³ particularly those containing electron-withdrawing substituents at C(3), were studied in more detail.^{14, 15}

X-Ray analysis of 1,3,9-triphenyl-4-azafluorene have shown that the torsional angles between the planes of the azafluorene and phenyl rings are equal to 8.4° , 55.4° , and 44° , respectively.¹⁶ According to the X-ray data, the azafluorene polycycle of 9-benzylidene-1-azafluorene is not absolutely flat, since the angle between its two six-membered rings is 4.1° .¹⁷ The exocyclic carbon atom, C(10), of the fulvene fragment is above the plane of the five-membered ring, the corresponding torsional angle is 4° . The carbon atom of the phenyl substituent bound to C₁₀ deviates from the plane of the five-membered ring even more, the corresponding torsional angle is as much as 8.5° . The phenyl substituent is turned by 65° relative to the mean plane of the azafluorene skeleton, which confirms that through-space charge-transfer complexes can form in the case where the nitrogen atom occupies position 1 in the azafluorene fragment.¹⁸

There are no quantitative data on the basicity of the pyridine fragment and the CH-acidity of the methylene group of azafluorenes. The quantum-chemical characteristics of alkyl- and nitro-substituted 4-azafluorenones have been considered.¹⁹

A systematic study of the electron impact-induced mass spectra of azafluorenes and their derivatives has been carried out.^{3, 20–28} It has been shown that fragmentation of the unsubstituted azafluorenes **1–4** is virtually independent of the position of the nitrogen atom. The mass spectra of these compounds contain molecular ions as the most abundant peaks, while the characteristic pathways of their fragmentation are determined by the mode of elimination of the hydrogen atom and the HCN molecule. Fragmentation of the azafluorenones **5–8** is characterised by the elimination of the CO molecule, which is most intense for 1- and 4-azafluorenones. In the case of substituted azafluorenones, the character of fragmentation is determined by the nature of the substituent. Quantum-chemical calculations were used to estimate the probability of electron impact-induced rearrangement of azafluorenes and their derivatives.²⁷

III. Occurrence in nature

The first plant alkaloid with the azafluorene structure was isolated in 1976 from the arboreal part of the plant *Onychopetalum amazonicum*.²⁹ This alkaloid (onychin, **9**) was initially identified as 4-methyl-1-azafluoren-9-one. However, the synthesis of the isomeric ketones³⁰ has established that onychin is in fact 1-methyl-4-azafluoren-9-one. The ^1H and ^{13}C NMR spectra of this alkaloid have been studied in detail.³¹

9, Onychin

10, Eupolauridine

Recent studies of the plants of the Annonaceae genus have revealed 14 alkaloids having the structure of methoxy- and hydroxy-substituted 4-azafluorenones;^{32–35} methods for the synthesis of some of these compounds have been proposed.^{36–45} Several alkaloids of more complex structure also incorporate azafluorenes as fragments, cf., e.g., eupolauridine (**10**).⁴⁶ It should

be noted that 4-azafluorene was first isolated from tarry coal coking products;⁴⁷ some of its derivatives have been recently identified by chromatographic methods in the atmosphere in the vicinity of coal-tar chemical plants.⁴⁸

IV. Methods of azafluorene synthesis

The known methods of azafluorene synthesis can be divided into three main groups. The first of them makes use of degradation of nitrogen-containing fused compounds into tricyclic azafluorenes. The principle exploited in the second group is the increase in the number of fused rings by annelation of the heterocycle to the bicyclic system (indene). The strategy of the third group methods entails various reactions of intramolecular cyclocondensation of aryl- or aroyl pyridines with involvement of substituents.

1. Oxidative degradation of azafluoranthrenes and azaphenanthrenes

The first 1- and 4-azafluorenones derivatives were obtained by oxidation of substituted azaphenanthrenes with potassium permanganate.^{49, 50}

Similarly, several azafluoranthrenes were converted with low yields into these azafluorenones.^{51, 52} Later,³ the 1- and 3-azafluorenones **5** and **7** were isolated with a total yield of 12% from the products of oxidation of 2-azaphenanthrene with potassium permanganate.

An effective two-step procedure has been proposed for the synthesis of 1- and 4-azafluorenones by oxidation of the corresponding azaphenanthrenes azaphenanthrenequinones (yields 48%–80%) with iodine pentoxide.⁵³ They smoothly rearrange into azafluorenones (yields 70%–88%) on heating in aqueous solution of alkali. The limitation of this method is that some of the original azaphenanthrenes are difficult to obtain. For example, 2-azaphenanthrene is obtained from 2-formylnaphthalene in four steps.

2. Condensations involving indane derivatives

The strategy of formation of azafluorene systems based on the indane derivatives entails several approaches differing in the number of components used, the source of nitrogen needed for the formation of the heterocycle (ammonia, β -aminocrotonates, β -aminoalkanoic acids, amino- or alkylamino-derivatives of indane) and, finally, the type of heterocyclocondensation.

The condensation in a three-component system, indane-1,3-dione (**11**)–aminocrotonate–aldehyde, is the most efficient and

widely used for the synthesis of 1,4-dihydro-4-azafluorenes.^{54–59} The resulting dihydroazafluorenes (**12**) can be then easily aromatised with oxidants or, in some cases, under UV irradiation.^{60–63}

R = H, Me, Ar; R' = OMe, OEt, SMe, SEt, SCH₂Ph.

Apparently, the first step is the reaction of the aldehyde with the activated methylene group of the indane-1,3-dione **11** resulting in the intermediate 2-arylidene-(or 2-alkylidene)indanedione. The latter must be then converted into the polycycle **12** as a result of [3 + 3]-cyclocondensation. Indeed, this pathway has been confirmed experimentally^{64–69} for the condensation in a two-component system: arylidenediones (**13**)–aminocrotonates.

If ammonia and esters (or amides) containing an activated α -methylene group are used in condensation with arylidenediones, the hexahydro derivatives of 4-azafluorene-3,9-diones (**14**) are formed with yields of up to 80%.

R = CN, COOEt, COOMe, COOPh; R' = OEt, NH₂;
Ar = Ph, C₆H₄Cl-4, C₆H₄Me-4.

By varying the methylene component, fully aromatised azafluorenes can be obtained in this condensation. Thus, in the reaction of the arylidenedione **13** with 1-phenacylpyridinium bromide the good leaving azinium group favours the formation of the aromatic indenopyridinium structure **15**.^{55,70} This procedure was used in the synthesis of many 1,3-diaryl-4-azafluorenes **15**.

On going from indanones to the indanylidenes **16**, as components of the condensation with aldehydes and ammonia, one can obtain substituted azafluorenes **17**, e.g., cyanohexahydro-2-azafluorene-3-one.⁶⁸

Ar = Ph, C₆H₄NO₂-4.

The use of nitrogen-containing components in the form of nitriles, amines, or amides has made it possible to pass to the condensation of two-component systems.

3-Dicyanomethyleneindanone (**18**) possessing an active methylene group forms upon interaction with diarylformamidines the derivatives **19**, which further convert into 3-arylamino-substituted 2-azafluorene-9-ones **20** as a result of cyclisation and Dimroth rearrangement.⁷¹

R = H, 2-Me, 2-Cl, 2-Pr, 2-MeO, 4-Me, etc.

2,3-Dihydroxy-2-azafluorene-3-one derivatives **21** can be obtained by heating (3-oxoindanylidene) cyanoacetamide with orthoesters.⁷² The stage of intramolecular heterocyclisation must be preceded by condensation with the formation of 2-methyleneindanone, with the same substitution pattern.

R = H, Me, Ph.

2-Indanones enter into [2 + 4]-cyclocondensation on heating with ethyl 2-benzyl- or 3-methylaminopropionate to give high yields of tetrahydro-1-azafluorene-4-ones.^{73,74}

R¹ = H, Ph; R² = Me, CH₂Ph.

The amino group initially introduced into the C(3) position of indan-1-one allows the construction of 4-azafluorenes with the dihydropyridine ring (**22**). These indanone derivatives enter into [3 + 3]-cyclocondensation, e.g., with diethyl dicyanosuccinate.⁷⁵

[3 + 3]-Heterocyclisation occurs in the case of iminophosphoranes **23** and α,β -unsaturated ketones or aldehydes. This gives in the aromatic 4-azafluorenes **24**.⁷⁶

R = Buⁿ, Ph; X = CH₂, CO;
R¹, R² = H, Me, Ph.

Several intramolecular cyclisations of one-component systems are known. 1-Azafluorene (**1**) was obtained by thermal cyclisation of the polymethinium salt of 2-dimethylaminoindene (**25**) in the presence of ammonium acetate.⁴

The isomers of the alkaloid onychin (**9**), two methyl-substituted 1-azafluorenones and two methyl-substituted 4-azafluorenones, were obtained by oxidative thermolysis of 1(2)-but-2-enyloxyiminoindanes **26**.³⁰ In the former case, a mixture of

R = OCH₂CH=CHMe.

4- and 2-methyl-1-azafluorenes (**27a**) was formed from the 2-substituted derivative **26a** in a 38% yield; in the latter, a mixture of 1- and 3-methyl-4-azafluorenes (**27b**) was formed from the 1-substituted derivative **26b**.

The dienol phosphate **28** is converted into the tetrahydro-1-azafluorene **29** under the action of sodium hydrogen-carbonate.^{77, 78}

An analogous electrophilic cyclisation was used to convert the β -keto ester **30** into the substituted hexahydro-1-azafluorene (**31**).⁷⁹

Azafluorene systems can be formed by intramolecular heterocyclisation of indan-1(3)-ones with 3-phenylamino substituents at C(2).⁸⁰ This procedure was used to obtain partially hydrogenated 4-azafluorenones from 1-indane-1,3-diones having an α -amino-methyl-substituted fragment of propiophenone at C(2).

R = Ph.

1,5-Diketones smoothly form a pyridine ring in reactions with primary amines; therefore, the principle of heterocyclisation has been successfully applied to the synthesis of azafluorenes. Thus, cyclisation of 2-(3'-oxoalkyl)-substituted indanediones (**32**) has been used to synthesise dihydro derivatives of 4-azafluorenone **33** with yields of up to 84%.⁸¹ In this case, the formation of azafluorenes is accompanied by cyclisation into the substituted dihydrofluorenones **34**, which is suppressed in aprotic solvents. When the methyl group at C(2) of indanone is substituted for bromine, the azafluorene system is not formed at all.

R = CO₂Et, COMe; R¹ = OH, NH₂

Boiling of 2-(3-oxo-3-phenylpropyl)indan-1-one^{82, 83} or bis-(1-oxoindan-2-yl)methanes in ethanol with a twofold excess of $\text{NH}_2\text{OH} \cdot \text{HCl}$ results in 4-azafluorenes or indene[1,2-*b*]azafluorenes.⁸²

$R = \text{H, Me, Ph.}$

Until now, compounds of the 3-azafluorene series could not be obtained from indanone derivatives. Despite successful application of the approach discussed to the synthesis of some derivatives of 1- and 2-azafluorenes, this procedure seems to be of preparative importance in the synthesis of 4-azafluorene derivatives.

3. Intramolecular condensations of substituted aryl- and benzoylpyridines

The availability of diverse pyridine derivatives has offered broad possibilities for synthesising all isomeric azafluorenes based on them and varying the nature and position of substituents. The methods considered in this section are mostly based on cyclisation of aryl- or aroylpyridines with benzene or pyridine rings substituted in the ortho-position. The pioneering study of this kind,⁸⁴ which was followed by numerous analogous investigations,^{45, 52, 85–87} reported on the acid-catalysed cyclisation of 2,6-dimethyl-4-phenylpyridine-3,5-dicarboxylic acid to the azafluorenone 35.

Analogous cyclisation of the corresponding phenylpyridine-carboxylic acids,^{85–88} respective acid chlorides,⁸⁹ nitriles and esters,^{45, 46, 90–92} resulted in a vast number of 2- and 4-azafluorene derivatives. Sulfuric⁸⁴ and polyphosphoric acids,^{45, 92–94} aluminium chloride,⁹⁵ and some other compounds⁹⁶ were used as condensing agents. Thus, 3-azafluorene derivatives have been obtained from phenylpiperidinic acids by converting them into acid chlorides followed by cyclisation in the presence of AlCl_3 .⁹⁵

$R^1 = \text{Me, CH}_2\text{Ph; } R^2 = \text{H, Me, Et.}$

The cyclisation of 4-phenylpyridine-3,5-dicarboxylic acid in the presence of hydrofluoric acid is worth noting.⁹⁵ This reaction gives 9,9-difluoro-1,3-dimethyl-4-trifluoromethyl-2-azafluorene 36 instead of the expected azafluorene-9-one with a carboxylic group at C(4).

Methods have been proposed for synthesising the azafluorene alkaloids 37a,b^{41, 45} and 38³⁵ by cyclisation of the corresponding pyridine derivatives, which had been prepared from benzoylacetates as shown in the schemes given below. It has been found that the alkaloid 37b possesses antifungal activity.⁹³

PPA = polyphosphoric acid.

Synthesis of azafluorenes by thermal cyclocondensation of pyridinecarboxylic acids has the following limitations: multi-stage of synthesis of the starting compounds and, in the case of 1- and 3-azafluorenone derivatives (the former has not been prepared by this method thus far), the high probability of a side-process, decarboxylation of derivatives of α - and β -pyridinecarboxylic acids.

Substituted phenylpyridines having an aroyl group in the ortho-position can also be used in the acid-catalysed thermal cyclisation.^{3, 96, 97}

Similar cyclisations occur successfully in the case of piperidine derivatives. For example, a number of 9-phenyl-tetrahydro-2-azafluorenes have been obtained, one of which (**39**, R = Me) is used as an antihistamine drug.^{89, 98–101}

R = Alk, Ph.

The *o*-amino group served as a leaving group in the radical intramolecular cyclisation of 3-benzoylpyridine.^{102, 103} UV-irradiation or heating of 3-(2-aminobenzoyl)pyridine in the presence of copper, silver, zinc, or iron gives a mixture of 4- and 2-azafluorenones (**6** and **8**) in approximately equal amounts (total yield 50%–60%).

A series of 2-, 3-, and 4-azafluorenones substituted in the benzene or pyridine ring have been synthesised by photochemical decomposition of diazonium salts obtained from *o*-aminobenzoyl derivatives of pyridine.¹⁰⁴

R¹, R², R³ = H, Me, F, Cl.

The yield of azafluorenones varied from 25% to 74% depending on the nature of substituents, concentration of diazonium ions and reaction sensitisers (2,2'-dipyridyl complexes with ruthenium or copper). With sensitisers, the formation of benzoylketones as by-products decreased sharply. Radical cyclisation to azafluorenones when the diazonium ion is localised in the pyridine ring (particularly, in the α -position), is less effective. This method can be considered as general, although it has a number of disadvantages, such as the multi-stage synthesis of the starting compounds and the non-selectivity of the cyclisation step characteristic of radical processes.

Wentrup *et al.*^{3, 105} have carried out an original conversion of 3- and 4-benzoylpyridines into azafluorenes via hydrazones and diazomethanes, which were subjected to thermolysis *in vacuo*. Under pyrolysis conditions, as was demonstrated in experiments with radiolabelled carbon atoms,^{3, 106} the carbenes formed result in expansion of the benzene and/or pyridine ring with subsequent cyclisation to azafluorenes.

In the case of phenyl-3-pyridyldiazomethane, a 1.3 : 1.0 mixture of 1- and 3-azafluorenes is formed in a total yield of 42%, while the pyrolysis of 4-pyridyl-substituted diazomethane gives only 2-azafluorene (68% yield). 4-Azafluorene cannot be obtained by this route.

Serious drawbacks of this method (multi-stage synthesis, the formation of mixtures of azafluorenes, and the necessity to perform pyrolysis in high vacuum) do not allow its use for preparative purposes.

A general procedure for the preparative synthesis of all isomeric azafluorenes (including alkyl- and aryl-substituted ones) has been developed in our laboratory.^{107–115} The number of stages in this method depends on the procedure used for obtaining the synthon with a predetermined position of substituents.^{109–118} At the final stage, the azafluorene precursor, viz., the alkyl-substituted phenylpyridine, is subjected to vapour-phase heterocyclisation at 520–540 °C on an industrial catalyst K-16 (a mixture of metal oxides). With 1,2,5-trimethyl-4-piperidone **40** as the starting material, 3-methyl-2-azafluorene **41** was obtained by this method;¹⁰⁸ some other 2-, 3- and 4-azafluorenes with different positions of methyl and phenyl substituents were also obtained.^{109, 112–115}

R = Me; R¹ = H, Me; Ar = Ph, C₆H₄Me-4, C₆H₃Me₂-2,4.

However, the attempts to obtain 1-azafluorene derivatives from the corresponding γ -piperidones have so far been unsuccessful.

A two-stage synthesis of 4-azafluorene derivatives **42** consisting in nucleophilic arylation of pyridine, 3-picoline, and lutidines with subsequent heterocatalytic dehydrocyclisation of alkylphenylpyridines is highly efficient.^{109, 116}

R¹–R⁵ = H, Me; Ar = Ph, C₆H₄Me-2, C₆H₄Me-4, C₆H₃Me₂-3,4.

Dehydrocyclisation of 3-methyl-2-phenylpyridine or 2-*o*-tolylpyridine gives 4-azafluorene with equal yields (~20%) irrespective of what ring, pyridine or benzene, is involved in ring closure with involvement of the methyl group. However, this two-stage modification does not permit one to obtain azafluorenes with any other position of the nitrogen atom.

The most common approach is the one, in which all the necessary methyl(phenyl)-substituted pyridines are synthesised by the Chichibabin method (with yields of up to 55%) using vapour-phase heterocatalytic cyclisation of carbonyl compounds with ammonia on a cadmium-calcium phosphate catalyst (CCP).^{111, 117–120} These pyridines are then subjected to dehydro-

cyclisation on oxide catalysts into all kinds of isomeric azafluorenes **1–4** and their alkyl-substituted in pyridine ring homologues.

R = H, Me.

Thus, comparison of the known methods used to synthesise azafluorenes reveals that the most effective (particularly, for preparing 1- and 3-azafluorenes) is the two-stage procedure based on the synthesis of phenylpyridines by Chichibabin's reaction and their subsequent dehydrocyclisation. The low yields of azafluorenes (20%–40%) at the stage of dehydrocyclisation are compensated for by the high selectivity of the process, and recycling of unconsumed phenylpyridine allows one to obtain azafluorenes in quantitative yields.

V. Transformations of azafluorenes

The chemical properties of azafluorenes and their derivatives are determined by the following factors: (1) the presence of two conjugated, fused cycles of different nature (benzene and pyridine) in one molecule; (2) the order of fusion of the indene and pyridine fragments; (3) the position and nature of functional groups in the case of substituted azafluorenes.

1. Reactions at the benzene nucleus

a. Electrophilic substitution

Among the reactions of electrophilic substitution, only nitration and bromination have been studied. In the nitration of unsubstituted azafluorenes,^{25, 97, 121} azafluorenes,^{6, 25, 97} and 4-azafluorenone *N*-oxide¹²² the 7-nitro derivatives **43** are always isolated as the main product irrespective of the position of the nitrogen atom in the original polycycle. These experimental results confirm the preferential orientation of electrophilic substitution inferred from quantum-chemical calculations for 1-, 3-, and 4-azafluorenes.^{5, 6}

R = H, Me; Z = CH₂, CO, CHNHA₂.

The nitro group is readily reduced (with Zn·Hg or SnCl₂ in HCl) into the amino group.⁹⁰ Carbonylation of 7-nitro-1-azafluorene in the presence of selenourea gives a mixture of 7-amino- and 7-carbamoyl-1-azafluorenes.¹²³

Bromination of 1- and 4-azafluorenes **5** and **8** in the benzene ring has been performed with bromosuccinimide (BSI) in 70% H₂SO₄ at 50 °C. This reaction gives 7-bromo-, 5,7-dibromo-, and 5,6,7-tribromo derivatives, which is in a good agreement with the calculated reactivity indices.⁵ The use of molecular bromine requires more drastic conditions: 100% H₂SO₄, 150–170 °C, autoclave.⁵

b. π -Complex formation

Nesmeyanov *et al.*^{124, 125} have studied the interaction of azafluorenes with chromium, molybdenum, and tungsten carbonyls. It has been found that only 4-azafluorene forms arenechromotricarbonyl π -complexes with the benzene ring, whereas 1-azafluorene forms mixtures of π - and n -complexes (yields 5% – 30%).

2. Reactions at the pyridine nucleus

a. Quaternisation and complex formation

The reactivity of the pyridine fragment in azafluorenes is typical of pyridine itself. Azafluorenes easily quaternise to give *N*-alkyl halides, picrates, *N*-phenacyl halides, and complexes with BF_3 .^{126–140} They also form *N*-donor complexes with copper and silver salts.¹³¹ With metal carbonyls^{124, 125} 2- and 3-azafluorenes form only n -complexes. In the case of azafluorenones, the yields of quaternary salts decrease,^{6, 126–128} apparently, due to the lower basicity of the pyridine fragment.

b. Deprotonation of azafluorenium salts

Quaternised azafluorenes contain in their five-membered ring the methylene group with high CH-acidity, which is readily deprotonated by basic reagents. For this reason, deprotonation of azafluorenium salts is used to obtain indenopyridine anhydrosalts containing cyclopentanpyridine fragments. The latter comprise a 10π -electron nonbenzoid aromatic system and belong to the pseudoazulene series, the isoelectronic analogues of azulene. A comprehensive review on the methods of synthesis of these azafluorene derivatives and their reactivity has been published recently.¹³²

c. Oxidation

Interaction of azafluorenes and azafluorenones with hydrogen peroxide results in *N*-oxides,^{52, 109, 126, 133} which can be easily deoxygenated to free bases on heating with PBr_3 .¹²²

Oxidation of quaternary indenopyridinium salts with air or potassium ferricyanide in alkaline media gives indenopyridones.^{134, 135} The oxogroup in the α -pyridone fragment of the azafluorenediones **44** is converted into the ether group under the action of trialkylchlorosilanes and can be substituted for the halogen.⁹³ The latter is substituted for amino groups with amines under pressure.⁴⁵ The amino derivatives **45** can also be obtained from carbamoylafluorenes by Hoffmann rearrangement.

Deep oxidation of the 2-azafluorenone **6** by ozonolysis with subsequent treatment with hydrogen peroxide results in the oxidative cleavage of the tricyclic azine with the formation of cinchomeric and phthalic acids.³

d. Arylation and benzylation

Arylation of the 2-azafluorene **41** with phenyllithium¹⁰⁹ gives its 1-phenyl derivative **46** in low yield. The efficiency of nucleophilic substitution increases when the azafluorene *N*-oxide is used. Benzylation of the azafluorene *N*-oxide or methiodide with benzylmagnesium halides also occurs at the free α -position of the pyridine ring.^{109, 136}

e. Hydrogenation

Catalytic hydrogenation of azafluorenes with platinum,¹¹⁰ nickel, and rhenium heptasulfide¹³⁷ is carried out at high pressure and is accompanied by partial or complete reduction of the pyridine ring.

R = H, Me; Z = CH_2 , CHOH , CO .

In the case of rhenium heptasulfide, *N*-alkylation may occur if the hydrogenation is performed in an alcohol. The dihydro derivatives of 2-azafluorene **48** are reduced on platinum, nickel, or palladium into tetra- and hexahydro derivatives at atmospheric pressure.^{98–100, 136}

2-Azafluorenes are reduced with sodium in ethanol to indanopiperidines.^{110, 138} The stereochemistry of these hexahydro derivatives has been studied by ¹H NMR.^{138–140}

The azafluorene methiodides **49** are smoothly reduced with sodium borohydride to tetrahydro derivatives.^{6, 141–143} The residual double bond is usually localised in the β,γ-position relative to the nitrogen atom irrespective of the mode of fusion of the pyridine fragment with the cyclopentadiene ring.

Z = CO, CH₂; X = CH₂, CHOH.

Reduction of the 4-azafluorenonium perchlorate (**50**) with sodium borohydride gives 4,4a-dihydroxy derivatives (**51**). However, when lithium aluminium hydride is used, products of nucleophilic recyclisation of the pyridine ring are formed along with the derivative **51**.¹⁴³

R = COOEt; R¹ = OH, NHMe.

Reduction of azafluorenium cations with sodium hydrosulfite results in indanopiperidine.¹⁴²

f. Hydrolysis of 1,4-dihydro-4-azafluorenes

These compounds are decyclised upon acid hydrolysis with the cleavage of the N–C bond in two directions followed by elimination of the amine fragment (route A) or recyclisation into indenopyridones **53** (route B).^{81, 144–150}

R¹ = H (27% yield), CHR¹COMe (18% yield).

The cleavage of the N–C(4a) bond occurs more easily. Similar hydrolysis of 1,9a-dihydro-4-azafluorenone **54** gives 1,9a-dihydrofluorenone and substituted indanedione.^{81, 114, 146}

R = CO₂Et; R¹ = OH (10% yield), NH₂ (12% yield).

g. Other reactions

The thermal reaction of 4-azafluorene with ethyl diazoacetate results in indenoazepine (**55**).¹⁵¹ Apparently, the initial addition of the carbene to the double bond of the pyridine ring is followed by its expansion and dehydrogenation.¹⁵²

R = COOEt.

3. Syntheses involving the methylene group

a. Oxidation

The azafluorenes **1–4** are readily oxidised to the azafluorene-9-ones **5–8** with KMnO_4 or $\text{Na}_2\text{Cr}_2\text{O}_7$ in CH_3COOH (yields 40%–60%).^{112, 116, 153} The oxidation with oxygen in the presence of the Rodionov catalyst¹⁵⁴ or an alkali in DMSO¹¹⁷ increases the yield of ketone up to 80%–90%. An exceptional tendency of 3-azafluorene to oxidation (unlike that of its isomers) has been exemplified by its quantitative conversion into a stable 9-oxo derivative by mere bubbling of air through its hexane solution.⁶ Methyl- and styryl-substituted azafluorenes are oxidised to azafluorene-9-one carboxylic acids with KMnO_4 or SeO_2 .^{108, 155} The thermal (180–220 °C) decarboxylation of these acids has been studied.^{50, 51, 64, 84}

b. Halogenation

Hydrogen atoms and the hydroxyl group at C(9) of azafluorene (**56**) are readily substituted for halogen on treatment with BSI, carbon tetrachloride (in aqueous alkali in the presence of triethylbenzylammonium salt), thionyl chloride, and hydrogen halide.^{89, 153, 156–160} It is remarkable that under halogenation conditions, 9-chloro azafluorenes (**57**) dimerise on heating.¹⁵⁶

9,9-Diiodo-1-azafluorene is formed as the sole product on attempted carbonylation of 1-azafluorene-9-ol in the presence of hydrogen iodide and rhodium iodide.¹²³ Halogen derivatives are readily reduced with zinc in ethanol¹⁶¹ and halogen atoms are smoothly substituted by nucleophiles. Thus, the interaction of 9-bromo-4-azafluorene with NH_3 and amines gives the corresponding 9-aminoazafluorenes **58**.^{157, 162} Some of them are promising as inhibitors of lipid peroxidation.

Hal = Cl, Br; R = H, Me;

$\text{R}^1 = \text{NH}_2$, N -methylpiperazine, N -benzylpiperazine, $\text{N}(\text{CH}_2\text{CH}_2\text{R}^2)_2$, where $\text{R}^2 = \text{OH}$, OCOEt , OCONH_2 .

c. Condensation with aldehydes and ketones

Aromatic and heteroaromatic aldehydes easily couple with azafluorenes at the methylene group in the presence of bases to give 9-arylidene derivatives.^{117, 153, 163–170} In some cases, the geometric isomers of these benzopyridofulvenes could be separated chromatographically which made it possible to establish their molecular structure (using X-ray structural analysis) and to relate their physical and spectral characteristics with their (*Z*)- or (*E*)-form.^{8, 17, 18, 168}

Ar = Ph, $\text{C}_6\text{H}_4\text{R}$ (where R = Br, Cl, OMe, OH, NO_2 , NMe_2),

2-, 3- and 4-Py, 3-Py·MeI.

The influence of the position of the nitrogen atom in the pyridine fragment and the structure of the aromatic aldehyde on the ratio of (*Z*)- and (*E*)-isomers of 9-arylideneazafluorenes has been investigated. A possibility has been established of intramolecular through-space interaction (of the charge-transfer complex type) between the arylidene fragment and the unshared electron pair of the nitrogen atom, which can occur only in the case of 1-azafluorene derivatives.^{8, 168} 9-Alkylideneazafluorene derivatives have been prepared.¹⁶⁷ Ketones (e.g. benzophenone) also interact with azafluorenes.¹⁶³ If these condensations are carried out in the presence of air, considerable amounts of azafluorenes and 1,2-di(azafluorenylidene)ethanes are formed.^{161, 166} The methyl groups at the α - and γ -positions of the pyridine ring of azafluorene are also active as regards condensation with aromatic aldehydes, which allows synthesis of compounds of the stilbene type.^{108, 155, 163} In some cases, arylazafluorenyl ethyl alcohols¹⁶⁶ and cyclisation products of α -styryl derivatives, 3-azafluoranthenes were isolated.¹¹⁴ A series of carbocyanine dyes have been synthesised with involvement of the 3-methyl group of 2-azafluorene.¹⁶⁹

Under conditions of phase-transfer catalysis, the azafluorenes **1–4** couple with aromatic aldehydes (NaOH , CCl_4) with the formation of (*Z*)- and (*E*)-isomeric spiro(azafluorene-9,2'-oxiranes) **59**.¹⁶¹

The side products of this reaction are 9,9-dichloro- and 9-benzylideneazafluorenes as well as bi(azafluorenylidene)s-9). The latter are easily formed in the alkaline dehalogenation of 9,9-dihalogenoazafluorenes.^{146, 153} The use of benzene as the organic phase results in phenyl(azafluorenyl-9)methanol (**60**), which can be also obtained by the reaction of benzaldehyde with azafluorene in the presence of phenyllithium.¹⁷⁰

d. Acylation and alkylation

The azafluorenes **1–4**, like fluorene, are acylated at C(9) with acetic anhydride,¹⁷¹ acyl chlorides,^{130, 183} and alkylcarboxylic acid esters in the presence of alkali metals.^{170, 172} However, unlike 9-acylfluorenes, acyl derivatives of azafluorenes occur as enols

61, which seems to be assignable to the higher CH-acidity of azafluorenes.

R = Me, Et, Ph, , PhCH=CH, PhOCH₂.

Spectroscopic studies have shown that in the crystalline state as well as in polar and aprotic solvents 9-formyl-4-azafluorene exists in the enolic form, whereas in nonpolar and protic solvents, it is a mixture of aldehyde and enolic forms.¹⁷³

Reactions of alkyl halides and acid chlorides with arenochrometricarbonylazafluorenes under deprotonation conditions have been studied.^{124, 125} It has been shown that π -complexes **62** are alkylated at C(9) and N-donor complexes **63** are acylated analogously, with the formation of enol acetates **64**.

Treatment of 1-acyl-1-azafluorenium chlorides (**65**) with bases in benzene is accompanied by the formation of unstable, deep-coloured 1-acyl-1*H*-indenopyridines. Under the action of BF₃ they undergo a 1 $\rightarrow$ 3 acyl shift and are quantitatively converted into 9-acylindenopyridines, which exist in the enolic form stabilised by an intramolecular hydrogen bond.¹³⁰ No acyl shift occurs in the case of isomeric azafluorenes.

R = Me, Ph, C₆H₄NO₂-4.

Aralkylation of 4-azafluorene has been carried out at C(9) using a mixture of veratryl alcohol and veratraldehyde in the presence of KOH.¹⁶⁵

2- And 4-azafluorenes are readily alkylated under conditions of the Michael reaction²¹ and are cyanoethylated with acrylonitrile in the presence of the Rodionov catalyst.^{114, 154, 174, 175} The

9,9-bis(cyanoethyl)azafluorenes (**66**) obtained are then hydrolysed to dibasic acids thus which give after esterification entered into the Dieckmann condensation to spiro(azafluorene-9,1'-cyclohex-3-enes) (**67**). Analogous spiro-compounds are formed in one step with 20%–54% yields when esters of α,β -unsaturated acids react with azafluorene in the presence of potassium.¹⁷⁶

e. Reactions of 9-methylene derivatives of azafluorenes

9-Hydroxymethyleneazafluorenes (**68**) are converted by nucleophiles (ammonia or amines) into 9-aminomethylene derivatives (**69**), whereas with hydroxylamine, they form a stable 9-formyl-azafluorene oxime.¹⁷²

9-Aminomethylene-4-azafluorene **70** exists as enamine and two tautomeric imines. Quantum-chemical calculations as well as UV and IR spectral data indicate that this compound has the enamine structure.¹⁷⁷

Its nitrosation gives the 2-azafluorenone oxime. Dichlorocarbene adds to the exocyclic C=C bond of the compound **70** to give the spirocyclopropane derivative **71**.

Acylation of the enamine **70** gives normal mono- or diacetyl derivatives.

Nitration of benzyldeneazafluorene (**72a**) with acetyl nitrate results in the substitution of hydrogen at C(10) with the formation of 9- α -nitrobenzyldeneazafluorenes (**73**) as (*Z*)- and (*E*)-isomers in a ratio of 1 : 2.5; these compounds can be reduced the oxime **74** or amine **75**.¹⁷² Condensation of the latter with aldehydes smoothly gives Schiff's bases with the *S-trans*-configuration of the azadiene fragment.¹⁷⁸ Thermolysis of these imines in the presence of BF_3 gives the original compound, **72a**.

The exocyclic double bond of benzopyridofulvenes of the **72a,b** type is readily reduced with lithium aluminium hydride¹⁶³ or a mixture of benzyl alcohol with KOH at 200 °C.¹⁶⁵ In the case of pyridylmethylenazafluorene, catalytic hydrogenation over Re_2S_7 also occurred at this bond and did not affect the pyridine rings.¹⁷⁹

The latter finding suggests that the substrate is coordinated at the acidic centres of rhenium heptasulfide through the π -excessive fulvene fragment rather than through the pair of unshared electrons of the nitrogen atom. Calculations on this type of fulvene system provide support for the localisation of the negative charge at the carbon atoms of the exocyclic double bond.^{8,17} The bromine molecule readily adds at this double bond in the compounds **72a,b** to give dibromo derivatives **76**.

The pyridylmethylenazafluorene **72b** forms a double salt with bromoacetophenone, which generates a double ylide under the action of bases. This ylide adds only one molecule of ethyl-acetylenedicarboxylic acid (EADC) and only at the pyridyl radical to form the adduct **77**; the phenacyl substituent at N_4 of the azafluorene skeleton is split off in the process.¹⁷

The Wagner hydroxylation of the exocyclic $\text{C}=\text{C}$ bond results in the glycol.^{180, 181}

2-(9-Hydroxyazafluoren-9-yl)propionic and (9-hydroxyazafluoren-9-yl)acetic acids or their esters **78** were converted via 9-methylene derivatives into dispirobis(4-azafluorene)-9-1',3'-cyclobutanes **79**.^{161, 182}

4. Syntheses involving the carbonyl group of azafluoren-9-ones

a. Condensation with amines and CH-active compounds

The azafluorenones **5–8** give oximes, hydrazones, semicarbazones,^{2, 6, 45, 183} and Schiff's bases **80**.^{116, 184}

Higher yields of the latter compounds have been achieved with the use of BF_3 as the catalyst. The dependence of the ratio of the configurational *Z,E*-isomers of the ketimines **80** on the nature of the amine component used for condensation was studied by ^1H NMR. An alternative synthesis of arylazomethines of the type **80** has been carried out by condensation of azafluorenes with *p*-nitrosoanilines followed by reduction of the intermediate nitrones with zinc in ethanol.^{158, 184}

The Schiff's bases **80**, like the original azafluorenes, add dialkyl phosphites to give the corresponding 9-azafluorenyl-phosphonates.¹⁸⁵ 9-Iminoazafluorenes were converted into 9-amino derivatives with Zn(Fe) in AcOH or Ac_2O ,^{19, 45} NH_2-NH_2 (Raney Ni)¹⁸³ or LiAlH_4 .¹⁸⁴

Under alkaline conditions, azafluorenes condense with acetophenone to give 9,9-bis(phenacyl)- and 9-phenacylidene derivatives **81**.^{180, 181}

b. Reduction

Heating of azafluorenes with hydrazine hydrate in an autoclave results in the reduction of the oxo-group to the methylene group in high yield.^{3, 92, 186} In lower yields azafluorenes are formed on reduction with zinc amalgam in hydrochloric acid.³ Sodium borohydride reduces azafluorenes only to alcohols¹⁴²⁻¹⁴⁴ which are smoothly esterified with acid anhydrides¹⁸⁷ and acid chlorides.¹⁴¹

c. Interaction with organometallic compounds

Azafluorenes react with phenyl- and methyl lithium and with benzylmagnesium chloride to give the ordinary products of nucleophilic addition, i.e., the corresponding tertiary alcohols.¹⁸⁷ The yield of alcohols depends on the position of the nitrogen atom and the presence of substituents.^{141, 142} These alcohols are easily dehydrated in acid media or in the presence of P_2O_5 .^{165, 167, 187} In the presence of zinc, the esters of α -bromocarboxylic acids add to the $\text{C}=\text{O}$ group of azafluoren-9-ones to give the corresponding 9-substituted azafluoren-9-ols.¹⁶¹

5. Cyclisation reactions involving substituents

a. Synthesis of spiro-coupled derivatives

Heating of β -(9-hydroxy-2-azafluoren-9-yl)propionic acid in acid media results in cyclisation to the spiro lactone **82**.¹⁵⁴

9-Phenacylideneazafluorenes **83** and 9-hydroxy-9-phenylethynylazafluorenes **84** also enter into acid-catalysed cyclocondensation to give spiro compounds of the type **85** with indanone fragments.^{180, 181} Condensation of the phenacylidene derivative **83** with hydrazine gives a spiro-fused pyrazoline **86** in quantitative yield.¹⁸⁰

9-Diazo-4-azafluorene (**87**) gives spiro(4-azafluorene-9,3'-3*H*-pyrazole) (**88**),¹⁸⁸ the product of cycloaddition of EADC, and an analogous spiro-compound **89** with dehydroxybenzene.¹⁸⁹ Dimethyl fumarate reacts with tosylhydrazide **90** on boiling in benzene in the presence of sodium alkoxide to give spiro(4-azafluorene-9,3'-cyclopropane) (**91**).¹⁸⁸

$\text{R}^1 = \text{COOMe}, \text{Ph}, \text{CHO}, \text{SiMe}_3, \text{CN};$
 $\text{R}^2, \text{R}^3 = \text{H}; \text{R}^4 = \text{COOMe}.$

Similar compounds were obtained upon interaction of the derivative **87** with certain unsaturated compounds.¹⁹⁰ In the case of cyclohexanone, spiro(4-azafluorene-9,2'-cycloheptanone) (**92**) was isolated.

Treatment of the diketone **93** with hydrazine results in spiro(4-azafluorene-9,5'-diazepine) **94**.¹⁹¹

Intramolecular cyclodehydration of 9-(pyridazin-4-yl)azafluorenol (**95**) gives spiro{4-azafluorene-9,5'-indeno[1,2-*c*]-pyridazine} (**96**).¹⁹¹

b. Annellation of the benzene ring

In the presence of potassium the diester of a dibasic acid of the azafluorene series **97** gives two cyclocondensation products, viz., **98** and **99**.¹⁶²

Only one cyclisation product **100** has been obtained in low yield from 7-amino-2-azafluorene by the Skraup reaction.¹⁶⁴

4-Azafluorene condenses with 1,2,5-trimethyl-4-piperidone in the presence of KOH to give an unstable product, which was dehydrogenated without isolation into 9-pyridyl-4-azafluorene **101**.¹⁵⁷ The latter was converted into pyridoazafluoranthene by catalytic dehydrocyclisation.

c. Annellation of the pyridine ring

3-Methyl-*N*-phenacyl-2-azafluorenium bromides (**102**) cyclise under condition of the Chichibabin reaction into indenoindolizines (**103**, **104**).^{127, 128}

$\text{R} = \text{COMe}, \text{COPh}$; $\text{R}^1 = \text{Me}, \text{Ph}$; $\text{Z} = \text{CH}_2, \text{CO}, \text{C}(\text{OH})\text{Ph}$.

However, in the case of the 1-azafluorenium this reaction does not take place, and stable anhydro bases **105** are formed instead.^{121, 130}

$\text{R} = \text{Ph}, \text{C}_6\text{H}_4\text{NO}_2-4$.

Nevertheless, the latter were successfully converted into indenoindolizines **106** by thermolysis *in vacuo*.

Isomer-*N*-phenacyl azafluorenium bromides enter into 1,3-dipolar cycloaddition reactions with EADC to give indenoindolizines **107** and **108** with different fusion of the rings.^{6, 127, 128}

$\text{Z} = \text{CH}_2, \text{CO}, \text{C}=\text{CHPh}$.

The quaternary salts of 2- and 4-azafluorenium are deprotonated in the presence of benzoyl chloride to give dimers (in low yields) in the form of *NH*-diazafuoranthenes **109**.¹²⁸

$R^1 = \text{COPh}$; $R^2 = \text{H, Me}$.

1-Acetylamino-2-azafluorenone was converted into 3*H*-3,4-diazafuoranthene-2-one on heating in DMF in the presence of potassium alkoxide.⁴⁵

Condensation of diethyl oxalate with the alkaloid onychin (**9**) gives ethyl(9-oxo-4-azafluorenyl)pyruvate (**110**).⁴⁵ Its heating with ammonia results in 1,6-diazafuoranthene-2-carboxamide (**111**). The latter was converted by a two-step procedure into the alkaloid eupolauridine (**10**); it could also be obtained by an independent synthesis from the compound **112**, the product of condensation of onychin (**9**) with formaldehyde and dimethylamine.

Polycyclic heterocycles **113** and **114** were obtained on heating of 9-(2-chlorobenzylidene)-2-azafluorene in the presence of alkali.¹⁶⁴

Cyclisation of 1-benzyl-1,2,3,4-tetrahydro-2-azafluorene in orthophosphoric acid resulted in a structural analogue of morphine **115** in a low yield.¹³⁶

VI. Biological activity of azafluorene derivatives

Azafluorene derivatives display a broad spectrum of biological activities which gives a strong impetus to the synthesis and further biotesting new compounds of this series. 2-Methyl-9-phenyl-1,2,3,4-tetrahydroxy-2-azafluorene (**39a**) has been introduced into clinical practice as an antiallergic drug.^{100, 192} Some of its analogues manifest potent spasmolytic, adrenolytic, anaesthetic, and antihistamine activity.^{2, 193}

Dihydro- and hexahydro-derivatives of 2-alkylaminoalkyl-9-phenyl-2-azafluorene possess antiarrhythmic and bactericidal activities.¹⁰¹

4-Azafluorene-*N*-oxide inhibits the effects of adrenaline and secretion of gastric juice.¹³³ 1,4-Dihydro-derivatives and 9-amino-derivatives of 4-azafluorene **58a** exhibit a vasodilator activity and manifest the properties of peroxidation inhibitors.^{194–196}

As follows from the review of antiviral preparations,¹⁹⁷ alkyl-, carboxy-, and cyano-derivatives of 1-azafluorene have been recommended as antiinfluenza drugs. Derivatives of 1,2,4,9a-tetrahydro-1-azafluorene-3-carboxylic acid are considered as simple analogues of ergot alkaloids.^{73, 74, 198, 199} 1-Azafluorene and its 9-hydroxy-derivative methiodides display a broad spectrum of antibacterial activities.¹²⁶ Several tetrahydro-2-azafluorenes **116**¹⁴¹ and 9-substituted 1-azafluorenes (semicarbazones, tosylhydrazones, and arylidene-derivatives) are characterised by neurotropic activity and low toxicity.²⁰⁰ The results of antitumour assay of certain azafluorenones have been documented.^{201, 202}

Azafluorene derivatives exhibit a pesticide activity and regulate plant growth and development.^{17, 203, 204} An extensive body of evidence concerning the diverse biological activities of these compounds has also been accumulated in the patent literature over the recent years; these data are not considered in the present review.

It should be emphasised that 9-substituted azafluorenes incorporate a fragment of a potentially pharmacophore ('magic') group **117**, which is present in the molecules of numerous drugs affecting biological systems via cholinergic, adrenergic, and histamine receptors.²⁰²

117

It may therefore be expected that a search among these azafluorene derivatives for compounds endowed with a high biological activity is a very promising approach.

In conclusion, the authors express the hope that the review presented will provide further impetus to the expansion and intensification of studies into the chemistry of azafluorenes and will generate professional interest among scientists in related fields (pharmacologists, biochemists, etc.) in this group of heterocyclic compounds, which has currently become chemically available.

V. Addition to the double bond in 2,3-dihydrofurans	160

Abstract. Published data on the synthesis of heterocyclic compounds based on 2,3-dihydrofuran and its derivatives are surveyed, described systematically, and analysed for the first time. The bibliography includes 206 references.

I. Introduction

2,3-Dihydrofuran and its derivatives are representatives of cyclic vinyl ethers (ethers of enols). They are highly reactive and readily undergo various chemical transformations. Vast information on the chemistry of 2,3-dihydrofuran and its derivatives is available; however, no review papers on this topic have been published so far. Only two monographs^{1,2} contain some data concerning the chemistry of compounds of the 2,3-dihydrofuran series including a few examples of chemical transformations of 2,3-dihydrofurans.

2,3-Dihydrofuran and its derivatives incorporate a reactive double bond and, hence, they readily enter into various addition reactions. Among them, cycloaddition and addition of azoles or azines are especially interesting. Compounds obtained in these reactions, the molecules of which incorporate tetrahydrofuryl groups and residues of pyrimidine derivatives or derivatives of other nitrogen-containing heterocyclic systems, exhibit a broad spectrum of biological activity. Some of them have been found to be effective antitumour preparations.

Since 2,3-dihydrofurans are cyclic vinyl ethers, they readily undergo recyclisation reactions and are thus converted into other cyclic systems. It is also noteworthy that hydrogen atoms in 2,3-dihydrofurans are capable of being substituted by various fragments under mild conditions.

The data surveyed in our review are classified according to the types of reaction into which 2,3-dihydrofuran and its derivatives enter. In Section II, [2 + 1]-, [2 + 2]-, [3 + 2]-, [4 + 2]- and some other cycloaddition reactions involving compounds of the 2,3-dihydrofuran series are considered successively. Section III is devoted to the transformations of 2,3-dihydrofurans according to recyclisation reaction routes. The reactions involving substitution of hydrogen atoms in the molecules of 2,3-dihydrofuran and

its derivatives are discussed in Section IV. Section V includes the available data on the addition of various reagents to the double bond in 2,3-dihydrofurans.

II. Cycloaddition reactions

1. [2 + 1]-Cycloaddition

In the studies on the interaction of carbenes with 2,3-dihydrofuran and its derivatives two main methods are used for the generation of these highly reactive species (from gem-polyhalo-derivatives and from diazo compounds).

The reaction of 2,3-dihydrofuran **1** with ethyl trichloroacetate in the presence of sodium methoxide gives 6,6-dichloro-2-oxabicyclo[3.1.0]hexane **2a**, which is converted into 2,3-dichloro-5,6-dihydro-2*H*-pyran **3** on heating to 60 °C (yield 90%).³

The reaction of the compound **1** with bromoform, carried out in *tert*-butyl alcohol in the presence of potassium *tert*-butoxide at 20 °C, afforded, instead of the expected 6,6-dibromo-2-oxabicyclo[3.1.0]hexane, the product of its isomerisation and interaction with the solvent, namely, 3-bromo-2-*tert*-butoxy-5,6-dihydro-2*H*-pyran **4** (yield 21%).³

The reaction of 2,3-dihydrofuran **1** with trihalomethanes in the presence of aqueous sodium hydroxide and benzyltriethylammonium chloride (BTEAC) (the Rodionov catalyst) has also been carried out.⁴

In the case where dichlorofluoromethane was used, in addition to the cyclopropane derivative **2b**, di(3-fluoro-5,6-dihydro-2*H*-pyran-2-yl) ether **5** arising from a rearrangement product similar to **3** was isolated in 40% yield.

Cl 71 (**2a**)

F 30 (**2b**) + 40 (**5**)

6,6-Dibromo-2-oxabicyclo[3.1.0]hexane **6**, formed upon treatment of 2,3-dihydrofuran **1** and carbon tetrabromide with methyllithium under an inert atmosphere, reacts with styrene to give a mixture of isomers of the cyclobuta[b]pyran derivative **7** (yield 24%).⁵

A mixture of *exo*-6-bromo-*endo*-6-fluoro-2-oxabicyclo[3.1.0]hexane **8** (yield 25%) and the ether **5** (yield 35%) was obtained by the reaction of 2,3-dihydrofuran with dibromofluoromethane in the presence of sodium hydroxide and BTEAC.⁵

The bromofluoro-derivative **8** reacts with styrene or α -methylstyrene in the presence of methyllithium to give a mixture of *exo*- and *endo*-isomers **9a,b** (yield 54%), whereas the reaction of **8** with dienes **10** under the same conditions leads to a mixture of *exo*- and *endo*-isomers **11a,b** (yield 57%–80%) and compound **12**.⁵

Christl and Braun⁵ have proposed a scheme for the formation of the bicyclic systems **9** and **11** (using compounds **9** as an example) *via* the intermediate formation of cyclic 1,2-diene **13** and biradical **14**.

Refluxing of ethyl diazoacetate with an excess of 2,3-dihydrofuran **1** or 5-methyl-2,3-dihydrofuran **15** in the presence of copper(II) sulfate has led to 2-oxabicyclo[3.1.0]hexane derivatives **16** (yields 76% and 79%, respectively).⁶

R = H, Me.

The compound **1** reacts with methyl diazoacetate in the presence of a ruthenium catalyst even at 20 °C to afford methyl 2-oxabicyclo[3.1.0]hexane-6-carboxylate **17** (yield 62%, *E*:*Z* isomer ratio 97:3).⁷

By treatment with aqueous potassium hydroxide in the presence of a crown ether, chloro(methoxy)methyl *p*-tolyl sulfone **18** has been converted into carbene **19**, which was introduced *in situ* into the reaction with 2,3-dihydrofuran **1**; *endo*-6-methoxy-*exo*-6-(tolyl-*p*-sulfonyl)-2-oxabicyclo[3.1.0]hexane **20** was thus synthesised in 48% yield.⁸

Oxidation of the enol ether **1** with dimethyldioxirane **21** at room temperature leading to 2,6-dioxabicyclo[3.1.0]hexane **22** can also be regarded formally as [2+1]-cycloaddition.⁹

2. [2+2]-Cycloaddition

In 1973, Huisgen and Steiner¹⁰ studied the reaction of 2,3-dihydrofuran **1** with tetracyanoethene and determined its rate constant ($k_2 \times 10^3 = 22.6 \text{ litre mol}^{-1} \text{ s}^{-1}$). They suggested that this reaction involves the intermediate formation of a biradical or a zwitterion.

Fries and Gollinck¹¹ believe that the reaction of 5-methyl-2,3-dihydrofuran **15** with tetracyanoethene at –20 °C affords the zwitterion **23**, which is converted into the final adduct at 20 °C.

Photochemical reaction of the enol ether **1** with cyclopent-2-enone results in the formation of three products of [2+2]-cycloaddition: *exo*-**24** (head-to-tail), *endo*-**25** (head-to-tail) and *exo*-**26** (head to head), in 99% overall yield. The ratio of the isomers **24** : **25** : **26** = 75 : 3 : 22.¹²

When a mixture of the enol ether **1** and diphenylacetylene is irradiated with the light of a low-pressure mercury lamp for 3 days, two compounds are formed: 6,7-diphenyl-2-oxabicyclo[3.2.0]hept-6-ene **27** (yield 11%) and compound **28** resulting from the addition of the adduct **27** to the second diphenylacetylene molecule (yield 5%).¹³

By thermal condensation of dihydrofurans **1** or **15** with dimethyl acetylenedicarboxylate, one can obtain [2+2]-cycloaddition products **29**, which are converted into 2,3-dihydrooxepine derivatives **30** on prolonged keeping at 200 °C.¹⁴

R	Catalyst	Solvent	T / °C	Time / h	Yield (%)	
					29	30
H	Pr ₂ NEt	PhMe	110	1	39	—
Me	Pr ₂ NEt	PhMe	60	1	41	—
Me	Pr ₂ NEt	DMF	60	0.5	85	—
Me	Pr ₂ NEt	DMSO	60	0.5	95	—
Me	—	PhMe	200	12	—	85

In the opinion of Fries and Gollinck,¹⁵ the reaction of enol ether **15** with dimethyl acetylenedicarboxylate is reversible and occurs *via* the formation of the intermediate bipolar ion **31**.

Treatment of dibromomethylenecyclobutane with butyllithium affords 1-lithio-2-bromocyclopentene, which eliminates lithium bromide under the reaction conditions being thus converted into cyclopentyne, which enters *in situ* into a [2+2]-cycloaddition reaction with the enol ether **1**; this leads to adduct **32** in 35% yield.¹⁶

The compound **1** reacts smoothly with diphenylketene at 0 °C to give 7,7-diphenyl-2-oxabicyclo[3.2.0]heptan-6-one **33** in a quantitative yield.¹⁷

A study of the rate of [2+2]-cycloaddition of diphenylketene to various enol ethers has shown that the compound **1** reacts with the ketene 350 times faster than 2,3-dihydropyran and 20 times faster than ethyl vinyl ether.^{18, 19}

The enol ether **1** readily reacts with phenylketene to give 7-phenyl-2-oxabicyclo[3.2.0]heptan-6-one in 80% yield; the latter is converted into the naphthofuran derivative **34** (yield 30%) on treatment with toluene-*p*-sulfonic acid.²⁰

The reaction of the enol ether **1** with ketene **35** results in the formation of adduct **36** (yield 80%), treatment of which with toluene-*p*-sulfonic acid gives compound **37** in 70% yield.²⁰

Various heterocyclic compounds have been synthesised based on 7-chloro-7-phenyl-2-oxabicyclo[3.2.0]heptan-6-one **38**, which is formed in 75% yield upon [2 + 2]-cycloaddition of the enol ether **1** to chloro(phenyl)ketene **39**. For example, a mixture of lactones **40** and **41** was obtained in 45% overall yield, and bicyclic lactone **42** was prepared as a mixture of *cis*- and *trans*-isomers in a ratio of 1 : 1.6.

The reactions of the enol ether **1** with ethoxy(triphenylsilyl)ketene **44** and its sulfur-containing analogue **45** follow essentially dissimilar pathways. Whereas the interaction of the enol ether **1** with the ketene **44** affords only the [2 + 2]-cycloaddition product **46** (yield 85%),²² in the case of the ketene **45**, two compounds are formed: adduct **47** (yield 5%) and 7-triphenylsilyl-2-oxa-8-thiabicyclo[3.3.0]octan-6-one **48** (yield 14%).²³

Ketene **49** arising upon treatment of succinimidoacetyl chloride with triethylamine enters into the [2 + 2]-cycloaddition reaction with the enol ether **1** leading to 7-succinimido-2-oxabicyclo[3.2.0]heptan-6-one.²⁴

Two compounds have been obtained in the reaction of 2,3-dihydrofuran **1** with ketene **50**, prepared by treating phthalimidoacetyl chloride with triethylamine, namely, compound **51** resulting from [2 + 2]-cycloaddition (yield 40%) and 2-oxabicyclo[3.2.0]hept-6-ene derivative **52** ($\text{R} = \text{H}$, yield 7%) arising *via* acylation of the enol form of the adduct **51** with the initial acyl chloride.²⁵

The reaction of 3-benzyloxycarbonyl-2,3-dihydrofuran with ketene **50** affords only compound **52** ($\text{R} = \text{COOCH}_2\text{Ph}$, yield 28%).²⁵

As expected, the interaction of the enol ether **1** or 3-benzyloxycarbonyl-2,3-dihydrofuran with dichloroacetyl chloride in the presence of triethylamine gives only the products of [2 + 2]-cycloaddition **53**.²⁶

R	T / °C	Time / h	Yield (%)
H	20	2.5	55
COOCH_2Ph	0	1	53

Ketene **54** generated from indane-1-carboxylic acid chloride by treating it with triethylamine under an inert atmosphere has been made to react *in situ* with the enol ether **1** according to the [2 + 2]-cycloaddition route; this has led to the spiro-compound **55**.

Prolonged refluxing of the cycloaddition product **55** in chloroform in the presence of polyphosphoric acid results in its recyclisation yielding compound **56**.²⁷

When the enol ether **1** and benzonitrile are irradiated with light from a 70-W low-pressure mercury lamp through a quartz filter under an inert atmosphere, [2 + 2]-cycloaddition reaction takes place giving rise to 1-cyano-3-oxatricyclo[5.4.0.0^{2,6}]undeca-8,10-diene **57** in 20% yield.²⁸

Gilbert *et al.*²⁹ managed to accomplish [2 + 2]-cycloaddition of the enol ether **1** to naphthalene by irradiating a mixture of the initial compounds with the light from a 125-W medium-pressure mercury lamp. Adducts **58** and **59** were obtained in this way in a low overall yield (5%).²⁹

When compound **60** is exposed to the radiation of a high-pressure mercury lamp in the presence of compound **1** or **15**, a mixture of two products **61** and **62** is obtained in each case. The researchers³⁰ believe that the compounds **61** are formed *via* an intermediate *endo*- π -complex, whereas the compounds **62** arise *via* an *exo*- π -complex.

R	Yield (%)	
	61	62
H	2	8
Me	14	77

When the enol ether **1** is made to react with methyl 2-pyrone-5-carboxylate, two diastereomeric products of [2 + 2]-cycloaddition, **63a** and **63b**, are formed.³¹

At 50 °C and under a pressure of 12 kbar, *N*-tosylimine **64** undergoes [2 + 2]-cycloaddition to the enol ether **1**, which affords adduct **65** as a mixture of *cis, cis*-, *trans, cis*-, and *cis, trans*-isomers in 80% overall yield; the individual *cis, cis*-isomer was isolated from this mixture in a yield of 35%.³²

The irradiation of 5-methyl-2,3-dihydrofuran **15** and acetaldehyde with the light from a medium-pressure mercury lamp results in the formation of compound **66** as a mixture of isomers **66a** (yield 36%) and **66b** (yield 27%).³³

Japanese investigators³⁴ carried out [2 + 2]-cycloaddition of 2,3-dihydrofuran to benzaldehyde by irradiating the initial compounds with a high-pressure mercury lamp (450 W) under a nitrogen atmosphere at 0 °C for 6 h. They obtained a mixture of (1*SR*, 5*RS*, 7*SR*)- and (1*SR*, 5*RS*, 7*RS*)-7-phenyl-2,6-dioxabicyclo[3.2.0]heptanes (**67a,b**, Ar = Ph).

When this reaction has been carried out on exposure to the radiation of a 150-W high-pressure mercury lamp, the ratio of the isomers **67a** and **67b** has been found to depend on the nature of the aromatic aldehyde used.^{35, 36}

Ar	Time / h	Yield (%)	Ratio 67a : 67b
Ph	11	50	7 : 1
2-MeC ₆ H ₄	16	94	15 : 1
2,4,6-Me ₃ C ₆ H ₂	8.5	97	20 : 1
2-Me-4,6-(Bu ^t) ₂ C ₆ H ₂	24	28	20 : 1

The rate and diastereoselectivity of the cycloaddition reaction involving the enol ether **1** were found to be higher than those in the case of cyclopentene.³⁵

The diastereoselectivity of [2 + 2] cycloaddition of the enol ether **1** to aromatic aldehydes is completely reversed when the electronic configuration of the excited triplet form [3(*nπ**) – 3(*ππ**)] changes: in the case of 2,4,6-trimethylbenzaldehyde, the diastereomer **68a** is formed predominantly, while in the case of aldehydes of the naphthalene series, the diastereomer **68b** predominates.³⁷

R	Yield (%)	Ratio 68a : 68b
Me	76	55 : 45
2,4,6-Me ₃ C ₆ H ₂	97	2 : 98
α-Naphthyl	55	98 : 2
β-Naphthyl	53	98 : 2

2,6-Dioxabicyclo[3.2.0]heptane derivatives **69** have been synthesised by [2 + 2]-cycloaddition of the enol ether **1** or **15** to acetone occurring on exposure to radiation of a medium-pressure mercury lamp.³³

R = H (95%), Me (30%).

A similar reaction involving hexafluoroacetone affords adduct **70**. It has been found that the reaction temperature and the nature of the solvent exert a substantial influence on the selectivity of the process, on the degree of conversion, and on the yield of the adduct **70**.³⁸

A. Temperature dependence of the selectivity and the yield of **70**.

T / °C	Yield (%)	Selectivity (%)	Conversion of 1 (%) (in heptane)
–5	39	39	100
–10	45	46	99
–15	56	75	74
–20	57	81	71
–62 (6 h)	62	62	100

B. Solvent dependence of the selectivity and the yield of **70**.

Solvent	Yield (%)	Selectivity (%)	Conversion of 1 (%)
Et ₂ O	24	70	34
CHCl ₃	27	27	100
PhMe	50	51	98
Heptane	57	81	71

The irradiation of a mixture of the enol ether **1** and 1,3,3-trimethyl-1,2-dihydronaphthalene-2-thione **71** with an RPR lamp ($\lambda = 350 \text{ nm}$) has led to two compounds: [2 + 2]-cycloaddition product **72** and compound **73** resulting from the interaction of one molecule of the enol ether **1** with two molecules of the initial naphthalene derivative **71**.³⁹

The formation of the compound **73** was explained³⁹ in terms of a scheme involving the generation of biradicals **74** and **75**.

4,5-Dimethyl-2,3-dihydrofuran has been photooxidised by irradiation with a filtered light ($\lambda = 500\text{--}595 \text{ nm}$) of a 150-W lamp under an oxygen atmosphere in the presence of tetraphenylporphyrin or Bengal Rose. Among other products, 1,5-dimethyl-2,6,7-trioxabicyclo[3.2.0]heptane **76**, which can formally be regarded as resulting from the [2 + 2]-cycloaddition of oxygen to the double bond, is formed in 48% yield.

Cyclocondensation of the enol ether **1** with cephalosporin **77** in the presence of palladium acetate and ethyldiisopropylamine has led to compound **78**, which was separated into two isomers **78a** and **78b** (overall yield 73%, ratio of isomers 1.8 : 1).⁴¹

Ar = C₆H₄OMe-4.

3. [3 + 2]-Cycloaddition

Esters of 2-diazobut-3-enoic acid **79** decompose in the presence of various catalysts to give the corresponding carbenes; however, the primary products arising upon the addition of these carbenes to the double bond of 2,3-dihydrofuran **1** undergo a rearrangement affording regioisomers of 2-oxabicyclo[3.3.0]octene, which contain the ester group in the 6-position (**80a**) or in the 8-position (**80b**)^{42,43} and are formally the products of [2 + 3]-cycloaddition of the diazo derivative **79** to dihydrofuran.

R	Catalyst	Solvent	Yield (%)		Ref.
			80a	80b	
Me	Rh ₂ (OC ₈ H ₁₇) ₄ Et ₂ AlCl	Pentane	66	—	42
	Rh ₂ (OAc) ₄	CH ₂ Cl ₂	—	40–42	42, 43

2,3-Dihydrofuran **1** reacts in a similar way with some other diazo compounds.

The influence of the reaction conditions on the yield of the product **81** resulting from the interaction of the enol ether **1** with 2-diazocyclohexane-1,3-dione in the presence of Rh₂(OAc)₄ has been studied.⁴⁴

When the reaction is carried out without a solvent with boiling (2 h) or at 25 °C (4 h), compound **81** is formed in 84% yield. The nature of the solvent used in this reaction (25 °C, 24 h) has a substantial influence on the yield of the compound **81**.

Solvent	C ₆ H ₅ F	THF	PhH	CH ₂ Cl ₂	MeCN
Yield of 81 (%)	70	61	48	43	20

Thermal cyclocondensation of the enol ether **1** with diazo compounds **82** has given rise to furo[2.3-*b*]-2,3-dihydrobenzofuran derivatives **83** (yields 45%–56%).⁴⁵

X ¹	X ²	X ³	X ⁴
H	Cl	H	Cl
OMe	Cl	H	Cl
Br	H	Br	H

The reaction of the enol ether **1** with carbamate **84**, containing an allyl radical, in the presence of 2-methylpropane-2-thiol gave a mixture of *exo*- and *endo*-isomers of adducts **85** (in a ratio of 1 : 3) in 52% overall yield.⁴⁶

Perfluorinated heterodiene **86** reacts with the enol ether **1** at 20 °C to give the stable bipolar ion **87** in a yield of 48%. The latter undergoes [3 + 2]-cycloaddition to a further molecule of the enol ether **1**, which affords a bis-adduct, namely, 7,7,14,14-tetrakis-(trifluoromethyl)-3,10-dioxo-1,8-diazatetracyclo[6.6.0.0.2⁶0^{9,13}]-tetradecane **88** (yield 17%).⁴⁷

The [3 + 2]-cycloaddition of 2,3-dihydrofuran **1** to 1,4-dichloro-1,4-bis(trifluoromethyl)-2,3-diazabuta-1,3-diene **89** is accompanied by a rearrangement of this dichloroazine and yields compound **90** resulting from the 1,3-dipolar cycloaddition of the arising nitrilimine CF₃C=N⁺–N[–]CCl₂CF₃.⁴⁸

Clarke *et al.*⁴⁹ have suggested that the interaction of the compound **91** with 5-methyl-2,3-dihydrofuran **15** leads to the furanopyrrole derivative **92** (yield 35%). Apparently, this process also involves the intermediate formation of the corresponding nitrilimine.

The spiro-compounds **93** and **94**, containing each two dihydrofuran fragments, are formed in the condensation of dihydrofuran derivatives **95** with acetoacetates or with 5,5-dimethylcyclohexane-1,3-dione in the presence of manganese(III) acetate under an inert atmosphere.⁵⁰

R^1	R^2	Yield 93 (%)
COOEt	Et	37
COOEt	CH_2Ph	40
SO_2Ph	Et	26

Enol ethers **1** or **15** react with acetoacetates or with pentane-2,4-dione under the same conditions to give compounds with a different structure — 1,5-dioxabicyclo[3.3.0]octane derivatives **96**.⁵⁰

R^1	R^2	R^3	Yield 96 (%)
Me	OEt	COOEt	51
H	OEt	COOEt	53
H	OCH_2Ph	COOCH_2Ph	56
H	Me	MeCO	26

Tricyclic compound **97** has been obtained in 40% yield by cyclocondensation of the enol ether **15** with 5,5-dimethylcyclohexane-1,3-dione.⁵⁰

Kraus *et al.*⁵¹ showed that the cyclocondensation of the compound **1** with esters of oxoacids or with cyclic diketones can be carried out in the presence of silver carbonate in boiling acetonitrile under an inert atmosphere. For example, compounds **98** (yield 50%) and **99** (yield 60%–76%) were prepared from the enol ether **1** and ethyl acetoacetate and cyclohexane-1,3-dione, respectively.

The yield of compound **100** resulting from the photochemical reaction (high-pressure mercury lamp) of 2,3-dihydrofuran **1** with 1,2-naphthoquinone depends markedly on the polarity of the solvent in which the process is conducted. In fact, in nonpolar benzene ($D = 0.00$), the yield of the compound **100** is only 6%, whereas in acetonitrile ($D = 3.37$), the yield reaches 58%.⁵²

When epoxide **101** is irradiated with a low-pressure mercury lamp (60 W, $\lambda = 254\text{ nm}$) through a quartz filter under an inert atmosphere, it gives rise to carbonylylide **102**, which enters into 1,3-dipolar cycloaddition to 2,3-dihydrofuran **1** to give adducts **103a,b** as pairs of diastereomers (yields 21% and 5%, respectively).⁵³

Reactions of [3 + 2]-cycloaddition of various 1,3-dipoles to 2,3-dihydrofurans have been studied fairly well. For example, 1,3-dipolar cycloaddition of the enol ether **1** to nitrones **104** proceeds according to the 'head-to-head' type and yields a mixture of *endo*- and *exo*-isomers **105a,b**.⁵⁴ The ratio of the isomers depends on the nature of the group R in the nitrone.

R	Ratio 105a : 105b
PhCO	52:48
Ph	22:78

Cycloaddition of the enol ether **1** to pyrroline *N*-oxide occurs stereoselectively; the reaction products consist predominantly of the diastereomer **106a** (yield 91%), only a small amount of the diastereomer **106b** being formed (yield 3%).⁵⁵

The first study devoted to the 1,3-dipolar addition of *N*-oxides of aliphatic, aromatic, and heterocyclic carboxylic acid nitriles to 2,3-dihydrofuran was published in 1962.⁵⁶ The nitrile *N*-oxides were generated by two methods: by treating hydroximoyl chlorides **107** with bases and by dehydration of primary nitro compounds through the action of phenyl isocyanate in the presence of triethylamine. Nitrile *N*-oxides were introduced *in situ* into the reaction with 2,3-dihydrofuran. The cycloaddition occurred according to the 'head-to-head' type and gave adducts **108**.

The conditions under which the nitrile *N*-oxides were generated and the yields of the adducts **108** are presented in Table 1.

Some 3a,4,5,6a-Tetrahydrofuro[2,3-*d*]isoxazoles **108** containing substituents in the 3-position have been synthesised by the cycloaddition of the enol ether **1** to the *N*-oxides of aliphatic carbonitriles, prepared by treatment of hydroxamic acid chlorides **107** with sodium carbonate in water (*a*)⁵⁷ or with triethylamine in ether (*b*).^{58–61}

R	Yield (%)	Ref.

Me	—	59
Ph	—	60
2,4-Cl ₂ C ₆ H ₃	—	61

Harada *et al.*⁶² described another method for the generation of benzonitrile *N*-oxide, which involves successive treatment of phenylnitromethane with sodium methoxide and acetyl chloride, and proposed a mechanism for this process. The resulting *N*-oxide was introduced *in situ* into the cycloaddition reaction with 2,3-dihydrofuran **1**.

Table 1. Conditions of reactions of 2,3-dihydrofuran **1** with nitrile *N*-oxides and yields of adducts **108**.

Substrate	Reaction conditions	Yield of 108 (%)

The 1,3-dipolar cycloaddition of anthracene-9-carbonitrile *N*-oxide **109** to 2,3-dihydrofuran **1** or to 4-methoxycarbonyl-2,3-dihydrofuran has been used to prepare the corresponding adducts **110**.⁶³

R = H (61%), COOMe (31%).

Thorough investigation of 1,3-dipolar cycloaddition reactions involving 2,3-dihydrofuran **1** and benzonitrile and 2,4,6-trimethylbenzonitrile *N*-oxides has shown that these reactions are highly regioselective and that the 'head-to-head' coupling giving adducts **111** is the main reaction route. Only slight amounts of products **112** resulting from the 'head-to-tail' addition were isolated.⁶⁴

Ar	Ratio 111 : 112
Ph	99.4 : 0.6
2,4,6-Me ₃ C ₆ H ₂	99.5 : 0.5

The same investigators⁶⁴ also found that the enol ether **1** reacts with nitrile *N*-oxides 1.8 times more rapidly than cyclopentene. They attributed this result to the resonance interaction of the double bond with the electron pair on the oxygen atom, which leads to an increase in the electron density on the carbon atom in the 4-position of the enol ether and to an increase in the electrophilicity of the double bond.

The carbonitrile *N*-oxides of the furan series **113** react with the enol ether **1** stereospecifically to give adducts **114** (yields 71%–85%).⁶⁵

R = H, NO₂, 4-O₂NC₆H₄.

The 1,3-dipolar cycloaddition of 2,3-dihydrofuran **1** to the carbonitrile *N*-oxides of the pyrazine series (**115**, **116**) or of the pteridine series (**117**) has made it possible to synthesise adducts **118**, **119**, or **120**, respectively.⁶⁶ The reactions were carried out under an inert atmosphere.

R = COOEt (60%), CN (10%).

The enol ether **1** enters into cyclocondensation with tributylstannyl iodoacetate or α -iodopropionate **121** in the presence of azobisisobutyronitrile (AIBN) in boiling benzene to give 2,8-dioxabicyclo[3.3.0]octan-3-one **122** (R = H, yield 78%) or its 4-methyl-derivative **122** (R = Me, yield 72%). The latter compound is formed as a mixture of diastereomers in a ratio of 1 : 1.^{67,68}

R = H, Me.

4. [4 + 2]-Cycloaddition

Two [4 + 2]-cycloaddition products as mixtures of two isomers (**123a,b** and **124a,b**) and [3 + 2]-cycloaddition product **125** have been obtained by the reaction of the enol ether **1** with tropolone under an elevated pressure. The product ratio (**123** + **124**) : **125** is pressure-dependent.⁶⁹

123a: X = O, Y = CH₂;

123b: X = CH₂, Y = O.

Published studies indicate that [4 + 2]-cycloaddition of 2,3-dihydrofuran or its derivatives to esters of 2-pyronecarboxylic acids can be carried out under irradiation with actinic light, in the presence of catalysts, or it can be induced thermally.

The thermal condensation of the enol ether **1** with methyl 2-pyrone-5-carboxylate and the condensation induced by UV radiation afford different products. When the initial compounds were kept in benzene at 60–80 °C, methyl 9-oxo-3,8-dioxatricyclo[5.2.2.0^{2,6}]undec-10-ene-11-carboxylate **126** was obtained as a mixture of two isomers (*endo*, yield 25% and *exo*, yield 38%),⁷⁰ whereas the photochemical reaction, in which the orientation of the addends was opposite, afforded methyl 8-oxo-3,9-dioxatricyclo[5,2,2,0^{2,6}]undec-10-ene-10-carboxylate **127**.³¹

In the presence of lanthanide shift-reagents, the cycloaddition of enol ether **1** to methyl 2-pyrone-3-carboxylate occurs smoothly give products in high yields. When the reaction is carried out at 20 °C in the presence of Eu(hfc)₃, adduct **128** can be obtained in a yield of 93%–96%.^{71–73} In the reaction carried out at 0 °C for 0.5 h under an argon atmosphere in the presence of Yb(OTf)₃, the yield of the product was 93%.⁷⁴

However, the thermal reaction (DMSO , $70\text{--}80^\circ\text{C}$) in the absence of a shift-reagent afforded the adduct **128** in a yield of only 41%.⁷¹

Compound **129** is formed in 96% yield upon the [4+2]-cycloaddition of the enol ether **1** to the 2-pyrone derivative **130** in the presence of $\text{Eu}(\text{hfc})_3$.⁷⁴

The kinetics of the [4+2]-cycloaddition of various unsaturated compounds to dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate have been studied.⁷⁵ It was found that the reaction involving the enol ether **1** occurs 180 times faster than that with 2,3-dihydropyran and 6 times faster than the reaction involving ethyl vinyl ether or cyclopentene.

Heating of the enol ether **1** with pyranono[3,4-*b*]indole **131a,b** in the presence of Pd/C in a sealed tube has given carbazole derivatives **132a** (from **131a**, yield 58%) or a mixture of isomers **132b** and **133** (from **131b**, yield 85%, ratio 5 : 4).

Evidently, the first stage of this process is [4+2]-cycloaddition, which is not regioselective in the case of the phenyl-substituted derivative **131b**. The resulting adducts **134a,b** and **135** lose a CO_2 molecule and thus generate indole-2,3-quinodimethane derivatives **136a,b** and **137**, which undergo a 1,5-sigmatropic H-shift, which leads (after cleavage of the tetrahydrofuran ring) to the final products **132a,b** or **133**.⁷⁶

The Diels–Alder condensation of the vinyl-substituted dihydrofuran **138** with *N*-phenylmaleimide or with 4-phenyl-1,2,4-triazoline-3,5-dione has given the corresponding adducts **139** (yield 21%) or **140** (yield 38%).⁷⁷

The [4+2]-cycloaddition of methyl (*E*)-3-(2,3-dihydro-5-furyl)acrylate **141** to 4-phenyl-1,2,4-triazoline-3,5-dione is highly stereoselective and affords almost exclusively the *trans*-isomer of the adduct **142** (*E* : *Z* ≥ 95 : 1, yield 88%).⁷⁷

The cyclotrimer of *N*-methylethaniline **143** reacts with 2,3-dihydrofuran in the presence of titanium(IV) chloride giving rise to 2,3,3a β ,4,5,9b β -hexahydrofuro[3,2-*c*]quinoline **144** (yield 16.8%).⁷⁸

The first stage of the interaction of enol ethers with azomethines is obviously the [4+2]-cycloaddition involving the phenyl substituent. This is followed by the 1,3-shift of hydrogen, which restores the aromatic system and results in the formation of tetrahydroquinoline derivatives.

In the first study⁷⁹ devoted to the interaction of enol ethers with azomethines, the reaction of 5-methyl-2,3-dihydrofuran **15** with azomethines of the general formula $\text{ArN}=\text{CHR}_1$ in the presence of $\text{BF}_3 \cdot \text{Et}_2\text{O}$ was studied. The authors reported that this process is exothermic and is completed at ambient temperature. The reaction proceeds stereospecifically and affords compounds **145** or **146**.

R	R ¹	Yield (%)
H	Ph	81.3
MeO	Ph	70.3
H		61.5

However, more recently,⁸⁰ it was shown that the reaction of the enol ether **15** with azomethines **147** is non-stereospecific and results in the formation of mixtures of diastereomers **148a,b** in a ratio of 1 : 1.

$\text{Ar} = \text{Ph}, 2\text{-ClC}_6\text{H}_4$.

When the enol ether **15** reacts with the azomethines $\text{PhN}=\text{CHC}_6\text{H}_4\text{NO}_2$ in benzene in the presence of $\text{BF}_3 \cdot \text{Et}_2\text{O}$ at 20 °C for 4 h, a mixture consisting of equal amounts of *cis*-**148a** and *trans*-*dl*-2,3,3a,4,5,9b-hexahydro-9b-methyl-4-(*o*-nitrophenyl)furo[3,2-*c*]quinoline **148b** ($\text{Ar} = \text{C}_6\text{H}_4\text{NO}_2$) is also formed.⁸¹ A detailed study of the reactions of the enol ether **15** with azomethines of the general formula $\text{ArN}=\text{CHC}_6\text{H}_4\text{OR}$ **149a–c** has shown that, depending on the nature of Ar, the process yields either one or two pairs of diastereomers.

149a, **150**, **153**, **156**, **159**: $\text{X} = \text{Y} = \text{O}$, $n = 2$, $\text{R} = \text{Me}$;
149b, **151**, **154**, **157**, **160**: $\text{X} = \text{NAc}$, $\text{Y} = \text{CH}_2$, $n = 2$, $\text{R} = \text{H}$;
149c, **152**, **155**, **158**, **161**: $\text{X} = \text{Y} = \text{CH}_2$, $n = 1$, $\text{R} = \text{Me}$.

For example, two pairs of diastereomers are formed in the reactions of dihydrofuran **15** with each of compounds **149a**,⁸² **149b**,⁸³ or **149c**. The overall yield of reaction products **150**, **153**, **156**, and **159** is 15%, that of **151**, **154**, **157**, and **160** is 48%, and that of **152**, **155**, **158**, and **161** is 64%.

On the other hand, the reactions between the enol ether **15** and the Schiff's bases **162a**,⁸² **162b**,⁸³ or **162c**⁸³ resulted in the formation of only one diastereomer pair.

162a, **163**, **166**: $\text{X} = \text{Y} = \text{O}$, $n = 1$, $\text{R} = \text{Me}$;
162b, **164**, **167**: $\text{X} = \text{CH}_2$, $\text{Y} = \text{NAc}$, $n = 1$, $\text{R} = \text{H}$;
162c, **165**, **168**: $\text{X} = \text{NAc}$, $\text{Y} = \text{CH}_2$, $n = 1$, $\text{R} = \text{H}$.

The overall yield of the two isomers **163** and **166** was 45%, that of the compounds **164** and **167** was 48%, and the yield of **165** and **168** was 45%.

Similar stereochemical results have been obtained in another study⁸⁴ of the interaction of the enol ether **15** with Schiff's bases **169a,b** and **176**.

169a, 170, 173: R = H; **169b, 171, 174:** R = OH; **169c, 172, 175:** R = OMe.

The overall yield of the diastereomers **170** and **173** was 81%, that of **171** and **174** was 47%, and the yield of **172** and **175** was 46%.

Acenaphthene derivatives **177a** and **177b** were obtained in an overall yield of 42%.

On heating with sulfur, the diastereomers **163** and **166** are converted into the quinoline derivative **178** in 70% yield.⁸³

The reaction of *N,N'*-bis(*p*-methoxybenzylidene)-*p*-phenylenediamine with two moles of the enol ether **15** affords compound **179** in 32% yield.⁸³

Adduct **180** has been synthesised in 33% yield by the cycloaddition of the enol ether **15** to *N*-benzylidene-4-aminopyridine in the presence of acetic acid at ambient temperature.⁸⁵

The stereochemistry of the reaction of the enol ether **1** with azomethines **181**, containing various substituents in the 4- or 2-positions of the benzene ring, has been studied.⁸⁶ The results obtained imply that this reaction proceeds non-stereoselectively, the isomers **182a** being usually formed in somewhat larger amounts than the isomers **182b**. The nature of the substituents R in the 4-position of the benzene ring exerts only a slight influence on the ratio between the diastereomers **182a** and **182b**, except for azomethines in which R = 4-OMe and R = 2-NO₂. In the latter case, only one isomer was obtained.

R	181	182	Yield (%)	
			182a	182b
H	H	H	31	23
4-Me	8-Me	8-Me	27	26
4-OMe	8-OMe	8-OMe	15	33
4-Cl	8-Cl	8-Cl	38	31
4-NO ₂	8-NO ₂	8-NO ₂	36	31
2-NO ₂	6-NO ₂	6-NO ₂	41	—

When various Lewis acids are used as catalysts in the reaction of the enol ether **1** with *N*-benzylideneaniline, the yields of the adducts **183** vary over a wide range.⁸⁷

Catalyst	EtAlCl ₂	ZnCl ₂	SnCl ₄	BF ₃ · Et ₂ O	AlCl ₃	TiCl ₄
Yield (%)	80	73.1	71.2	68.9	60.3	29.3

Japanese researchers⁸⁸ have studied the cycloaddition of the enol ether **1** to azomethines **184** in the presence of tin(IV) chloride and proposed a scheme for the formation of diastereomeric pairs of products **185**.

185a: R = H, R¹ = Ar; **185b:** R = Ar, R¹ = H.

Ar	Time /h	Yield (%)	
		185a	185b
2-Furyl	25.5	4.5	13
2-Thienyl	42.5	8.1	8.3
2-Pyridyl	48	17	—

The reaction of the enol ether **1** with *N*-benzylideneaniline in the presence of montmorillonite K10/Fe(III) occurs ambiguously: apart from the normal cycloaddition product **186** (yield 81%), the [2 + 2]-cycloaddition product, namely, 6,7-diphenyl-2-oxa-7-azabicyclo[3.2.0]heptane **187** is formed (yield 7%).⁸⁹

When the reaction of the compound **1** with azomethines **188** has been conducted in the presence of methanol and with Lewis acids as catalysts, together with the diastereomers **189a,b**, which are the normal reaction products, compounds **190** were obtained.⁹⁰

R = Ph, PhCO.

The reaction of isoquinolinium salt **191** and the enol ether **1** gave adduct **192**, which was converted into 4,5-dioxo-2,3,4,5-tetrahydronaphtho[1,2-*b*]furan **193** in four steps without isolation.⁹¹

The interaction of the enol ether **1** with 1,2,4-triazine derivatives **194** begins with [4 + 2]-cycloaddition giving the corresponding adducts. Under reaction conditions (refluxing in chloroform), the adducts **195** formed in the first stage eliminate a nitrogen molecule and thus generate bicyclic compounds **196**, which then undergo cleavage of the five-membered ring and are converted into the pyridine derivatives **197**.⁹²

Compound	R ¹	R ³	Time /h	Yield (%)
197a	COOEt	COOEt	49	77
197b	Ph	COOEt	46	55
197c	COOEt	NHCOMe	120	67
197d	COOEt	Me	45	80

On heating in a sealed tube, the enol ether **1** reacts regioselectively with 1,2,4-triazine derivatives **194b** with the retention of the tetrahydrofuran ring to give compound **198**, which reacts regioselectively with another molecule of the enol ether **1** under the reaction conditions, and compound **199** is formed as the final reaction product (yield 69%).⁹²

1,2,4-Triazine **194e** ($R^1 = \text{H}$, $R^2 = \text{Ph}$, $R^3 = \text{COOEt}$) also reacts with two molecules of the enol ether **1** when heated in a sealed tube; this reaction affords compound **200** in 68% yield. However, in this case, orientation of the first added molecule of the enol ether **1** is opposite.⁹²

It is of interest that the same reaction carried out in boiling chloroform affords all three possible regioisomers **200**, **201**, and **202** in 64%, 10%, and 10% yields, respectively.⁹²

The adducts **204** obtained by heating the compound **1** with 1,3,4-oxadiazin-6-one derivatives **203** eliminate a nitrogen molecule under the reaction conditions, and the ketenes **205** thus generated react with a further molecule of the enol ether **1** giving finally bicyclo[3.2.0]heptan-6-one derivatives **206** as mixtures of diastereomers (yields 42% and 58%).⁹³

R = Ph, PhCH₂.

Ethyl *E*-3-(tolyl-*p*-sulfonylazo)but-2-enoate **91** reacts with 5-methyl-2,3-dihydrofuran **15** according to the [3 + 2]-cycloaddition reaction pattern.⁴⁹ However, the same heterodiene **91** reacts with 2,3-dihydrofuran also according to the [4 + 2]-cycloaddition scheme to give two diastereomers **207a,b**, one of which (**207b**) was isolated in a yield of 31%.⁴⁹

Trimethylmethane enters into the reaction with the enol ether **1** at 20 °C affording a mixture of isomeric 2,9-dioxabicyclo[4.3.0]non-3-ene derivatives **208a,b** (yield 73%, ratio **208a** : **208b** = 1 : 4).⁹⁴

a: R = H, R' = OH

b: R = OH, R' = H

β-Methoxystyrene reacts with the enol ether **1** upon irradiation with the visible light in the presence of tetraphenylporphyrin to give aldehyde **209** (yield 13%), which is converted into the furobenzofuran derivative **210** on treatment with dilute sulfuric acid. Matsumoto and Kudora⁹⁵ proposed the following scheme for the formation of the compounds **209** and **210**:

2,3,3a,7a-Tetrahydro-4*H*-furo[2.3-*b*]pyran and its derivatives **211** have been prepared by heating the enol ether **1** (or **15**) with acrolein or with methyl vinyl ketone in the presence of hydroquinone.⁹⁶

The [4 + 2]-cycloaddition of 5-methoxy-4-methyl-3-phenyl-2,3-dihydrofuran **212** to acrolein has been carried out⁹⁷ at 25 °C, which has led to the *cis*-isomer of 1α-methoxy-6α-methyl-7-phenyl-2,9-dioxabicyclo[4.3.0]non-3-ene **213**.

Diastereomeric compounds **214a,b** have been synthesised from the enol ether **1** and aldehydoesters at 25°C .⁹⁸

R	R ¹	R ²	Time /h	Yield (%)	Ratio 214a : 214b
H	H	OH	200	60	3 : 1
Ac	H	AcO	8–40	85	1 : 2
	H		40	86	1 : 2

α,β -Unsaturated ketones **215** containing the bulky COOBu^t group also react fairly readily with the enol ether **1** at 20°C giving adducts **216**.⁹⁹

R	Et	PhCH ₂ CH ₂	C ₆ H ₁₁	Ph	4-BrC ₆ H ₄
Time /h	10	15	20	17	3
Yield (%)	40	36	54	70	79

The reaction of the enol ether **1** or 5-(1-hydroxy-1-methyl-ethyl)-2,3-dihydrofuran with 3-phenylsulfonylbut-3-en-2-one **217** has been reported.¹⁰⁰

R	Time /h	Yield (%)
H	2.5	86
C(Me) ₂ OH	1	50

An unexpected result was obtained when the ketone **217** was made to react with 5-cyano-2,3-dihydrofuran **218**. Instead of a [4 + 2]-cycloaddition product, spiro-compound **219** was isolated in 35% yield.¹⁰⁰

The reaction of 2,3-dihydrofuran **1** with 4-ethoxy-1,1,1-trifluorobut-3-en-2-one **220** occurs regioselectively but non-stereoselectively; this reaction leads to a mixture of diastereomers of 4-ethoxy-6-trifluoromethyl-2,3,3a,7a-tetrahydro-4H-furo[2,3-b]pyran **221** in 68% yield.¹⁰¹

The [4 + 2]-cycloaddition product **222** has been synthesised in 86% yield by the reaction of the compound **1** with heterodiene **223**.¹⁰²

Heating of the enol ether **1** with heterodiene **224** has given compound **225** as a mixture of diastereomers.¹⁰³

R	R'	Yield (%)
OAc	H	50
H	OAc	12.5

A more complex picture is observed when the enol ether **1** is introduced into the reaction with unsaturated ketones **226**. Depending on the nature of substituents in the ketone molecule, the process gives either adduct **227a** or a mixture of adducts **227a** and **227b** and compounds **228a** and **228b** resulting from their transformations.¹⁰⁴

R	R ¹	R ²	T / °C	Time /h	Yield (%)
Ac	Ac	Ac	55	6	54 (227a) + 36 (228a)
H	H	Ac	85	29	90 (227a)
COOEt	Ac	COOEt	55	8	32 (227a) + 49 (227b) + 8 (228a) + 4 (228b)

The researchers cited¹⁰⁴ explained the formation of the compounds **228** from the adducts **227** in terms of the following scheme:

The reaction of the enol ether **1** with methyl vinyl ketone **229** in the presence of zinc chloride proceeds *endo*-selectively and gives rise to compound **230** (yield 89%).¹⁰⁵

In the absence of zinc chloride, this reaction needs to be carried out in a sealed tube at 85 °C for 20 h.

Treatment of diketone **231** with lithium methoxide and then by acetyl chloride affords the *O*-acetyl derivative **232**; on boiling in the enol ether **1**, this compound eliminates *N*-acetylpiperidine and is thus converted into a new diketone, compound **233**, which reacts with the enol ether **1** giving tricyclic compound **234** (yield 48%).¹⁰⁶

Compound **235** has been prepared by condensing the enol ether **1** with cyclohexane-1,3-dione and formaldehyde in the presence of proline. It is clear that the interaction of the diketone and formaldehyde results in the intermediate formation of heterodiene **236**, which undergoes [4+2]-cycloaddition to the enol ether.¹⁰⁷

When heterodiene **237** is heated with the enol ether **1** in a sealed tube for a long period, two diastereomeric adducts **238a** and **238b** are produced (yields 60% and 10%).¹⁰⁸

The [4+2]-cycloaddition of the enol ether **1** to compound **239** has led to adduct **240** (yield 61%).¹⁰⁹

Of the two heterodiene systems, present in the compound **241**, C=N–C=O and N=C–C=O, the system that incorporates the carbon–oxygen semicyclic double bond is involved in the cycloaddition with the enol ether **1** affording adduct **242** in 90% yield.¹¹⁰

Nitroalkene **243** enters into Diels–Alder condensation with 2,3-dihydrofuran **1** on heating in DMF, the [4+2]-cycloaddition product **244** being formed in 80% yield.¹¹¹

2,3-Dihydrofuran **1** and 1,2-naphthoquinone exposed to the radiation of a high-pressure mercury lamp ($\lambda = 340$ nm) interact following the [4+2]-cycloaddition pattern; this affords a mixture of two isomeric adducts **245** and **246**. A crucial influence on the yield of the adducts is exerted by the polarity of the solvent used. When the reaction is conducted in non-polar benzene ($D = 0.00$), the overall yield of the compounds **245** and **246** is 55%; in the case where acetonitrile ($D = 3.37$) is used, the overall yield of the adducts is only 4%.⁵²

The reaction of the compound **1** with dimethyl acetals **247** in the presence of trimethylsilyl trifluoromethanesulfonate and aluminium chloride involves the intermediate formation of the oxonium ions **248**, which are converted into the diastereomers of compound **249** under the reaction conditions.¹¹² This process can only formally be classified as cycloaddition.

Similarly, 'formal cycloaddition' of the enol ether **1** to oxime **250** (treatment with sodium carbonate at room temperature) affords 3-acetyl-4*a*,5,6,7*a*-tetrahydro-4*H*-furo[3,2-*e*]-1,2-oxazine **251**.¹¹³

5. Other cycloaddition reactions

2,3-Dihydrofuran **1** has been made to react with phenyl isocyanate in the presence of bis(cyclooctadiene)nickel (COD)₂Ni and tricyclohexylphosphine at a low temperature; this gave organometallic compound **252** in 93.5% yield. The latter reacts with carbon monoxide or with 1,2-bis(diphenylphosphino)ethane resulting in the formation of furopyrrrole derivative **253** or organometallic compound **254** (yields 63.8% or 62%, respectively).¹¹⁴

Three compounds: *exo*-isomer **255**, *exo*-isomer **256**, and *endo*-isomer **257**, have been isolated in 2 : 1 : 3 ratio from the products of the photochemical reaction of 2,3-dihydrofuran **1** with anisole.¹¹⁵

A totally different picture is observed in a photochemical reaction of 2,3-dihydrofuran **1** with the anisole derivative containing an electron-withdrawing cyano-group in the 2-position. The bicyclo[6.3.0]undecatriene derivative **258** is the primary reaction product, which isomerises upon irradiation into tricyclic compound **259**. An equilibrium shifted toward the compound **259** is established under the reaction conditions. The latter compound is converted into the bicyclic compound **258** on heating.¹¹⁶

The reaction of 1,3-dialkylimidazolidines **260** with the enol ethers **1** or **15** in the presence of trifluoroacetic acid has led to octahydrofuro[3,2-*f*]-1,4-diazepine derivatives **261**.¹¹⁷

R	R'	Time /h	Yield (%)
H	Me	22	41
H	Bu	139	35
Me	Me	23	20

The reaction of 5-methyl-2,3-dihydrofuran **15** with 3-substituted oxazolidines **262** in the presence of Lewis acids is accompanied by expansion of the oxazolidine ring and results in the formation of 4-*R*-8*a*-methylperhydrofuro[3,2-*f*]-1,4-oxazepines **263** in 50% – 75% yields.^{118, 119}

III. Recyclisation reactions

Two methods have been proposed for the synthesis of tryptophol derivatives **264**. The first method involves heating of a mixture of the enol ether **1** and arylhydrazine in dioxane for 6 h. The indole derivatives **264** are obtained without isolation of the intermediate hydrazones.^{120–122}

R	R'	Yield (%)	Ref.
H	H	30	55
5-Me	H	40	55
7-Me	H	20	55
7-MeO	H	25	55
H	Me	32	55
H	Ph	45	56
7-cyclo-C ₃ H ₅	H	25	56
7-Et	H	—	57

According to the second method, tryptophol derivatives **265** are prepared in two stages. Arylhydrazones **266** are obtained initially from the enol ether **1** and the corresponding arylhydrazines; then the arylhydrazones are cyclised by heating in the presence of zinc chloride under an inert atmosphere to give the target compounds **265**.^{123–125}

R	R'	Yield of 265 (%)	Ref.
H	7-I	48	123
6-F	7-I	—	124
6-F	7-Br	48	125

It has been shown¹²⁶ that the reaction of the compound **1** with 2,3-dimethoxyphenylhydrazine in the presence of hydrogen chloride at 4 °C affords two products, namely, arylhydrazone **267** (yield 42.5%) and the hydrazine derivative **268** (yield 42.5%).

When the resulting mixture of **267** and **268** is heated under an inert atmosphere in the presence of zinc chloride, the compounds cyclise leading to only one product, 3-(2-hydroxyethyl)-6,7-dimethoxyindole, its yield being as low as 10%.¹²⁶

Cyclocondensation of ethyl 5-methyl-2,3-diphenyl-2,3-dihydrofuran-4-carboxylate with 2,4-dinitrophenylhydrazine in the presence of H₂SO₄ at 20 °C has led to 2-(2,4-dinitrophenyl)-6a-methyl-4,5-diphenyl-hexahydrofuro[2,3-*c*]pyrazol-3-one **269** in 18% yield.¹²⁷

The pyrazole derivatives **270** have been prepared by recyclisation of 4,5-bis(methoxycarbonyl)-2,3-dihydrofurans **271** with hydrazine hydrate.¹²⁸

R	R'	Reaction conditions	Yield (%)
H	OMe	20 °C	59
H	NHNH ₂	boiling	90
Me	NHNH ₂	boiling	77
Et	NHNH ₂	boiling	87

The reaction of 4-acetyl-5-methyl-2,3-dihydrofuran with hydrazine, phenylhydrazine, or tosylhydrazine has led to compounds of the pyrazole series **272**.¹²⁹

R	H	Ph	SO ₂ C ₆ H ₄ Me-4
Yield (%)	54	47	62

The reaction of the enol ether **1** with toluene-*p*-sulfonyl azide affords imine **273**, which is recycled to 4-amino-3,5-bis(3-hydroxypropyl)-1,2,4-triazole **274** (yield 88%) on heating with hydrazine hydrate in toluene.¹³⁰

4-(Trihalomethylcarbonyl)-2,3-dihydrofurans **275** recycle on treatment with hydroxylamine in the presence of pyridine even at 0 °C to give 5-hydroxy-4-(2-hydroxyethyl)-5-trihalo-methyl-2-isoxazolines **276**.¹³¹

X = F (a), Cl (b).

The trifluoroacetyl derivative **275a** is more reactive. Its reaction is completed over a period of 5 h giving rise to compound **276a** in 90% yield. The compound **275b** reacts over a period of 12 h to give **276b** in 85% yield.¹³¹

On heating with selenium in 1-methylnaphthalene, compounds **277** containing both furan and 2,3-dihydrofuran rings are converted into benzofuran derivatives **278**.¹³²

Condensation of methyl 5-methyl-2,3-dihydrofuran-4-carboxylate **279** with resorcinol in the presence of sulfuric acid gives 7-hydroxy-3-(2-hydroxyethyl)-4-methylcoumarin **280**.¹³³

The 2,3-dihydrofuran **279** reacts with 1-naphthol in the presence of 80% sulfuric acid to afford the benzocoumarin derivative **281**.¹³³

In the presence of hydrochloric acid, 2,3-dihydrofuran **1** reacts with 2,2-dimethylpropane-1,3-diol at room temperature, and the 1,3-dioxane derivative **282** is formed in 83% yield.¹³⁴

A sulfur-containing analogue of the compound **282** (compound **283**) has been synthesised in 43% yield by the reaction of the compound **1** with propane-1,3-dithiol in the presence of boron trifluoride etherate followed by treatment of the reaction product with triethylamine.¹³⁵

It has been reported¹³⁶ that the reaction of the salt **284** with 2,3-dihydrofuran **1** and propane-1,3-dithiol leads to compound **285**.

IV. Substitution of hydrogen atoms in 2,3-dihydrofurans

Photocatalytic heterogeneous dehydrodimerisation of the enol ether **1** in the presence of zinc sulfide and water results in the formation of bi(2,3-dihydrofuran-3-yl).¹³⁷

When 2,3-dihydrofuran **1** reacts with 5-iodo-2,4-dimethoxypyrimidine in the presence of palladium acetate, tributylamine, sodium acetate, and a phase transfer catalyst, the hydrogen atom in the 2-position of the enol ether is substituted, and the double bond in the dihydrofuran ring partly isomerises.

This gives two compounds **286** (yield 55%) and **287** (yield 26%).¹³⁸

Two compounds **288** and **289** in an overall yield of 68% and in a ratio of 3 : 4 have also been synthesised by the reaction of the dihydrofuran **1** with 5-iodouracil in the presence of palladium acetate, tributylamine, and triphenylphosphine.¹³⁸

If triphenylarsine is used in this reaction instead of triphenylphosphine, the compounds **288** and **289** are formed over a period of 3 h at 50 °C in 58% overall yield and in a 2 : 3 ratio.¹³⁸

The reaction of 5-iodouracil with the 2,3-dihydrofuran derivative **290** in the presence of Pd(OAc)₂, Bu₃N, and Ph₃As under an inert atmosphere occurs stereoselectively and affords 5-(5-hydroxymethyl-2,5-dihydrofuran-2-yl)uracil **291** in 58% yield.¹³⁸

In order to prepare initial compounds for the synthesis of 2',3'-deoxy-*C*-nucleosides, the reaction of 5-iodo-2,4-dimethoxypyrimidine with 2(*R*)-(triphenylmethoxymethyl)-2,3-dihydrofuran **292** has been studied. By varying reaction conditions, Zhang and Daves¹³⁹ prepared compounds **293** and **294** in various proportions.

Reaction conditions	Yield (%)	
	293	294
Pd(OAc) ₂ , Et ₃ N, Bu ₄ N ⁺ Cl ⁻ ; H ₂ O, DMF, N ₂ , 20 °C, 20 h	56	31
Pd(OAc) ₂ , Ph ₃ As, Et ₃ N, MeCN, N ₂ , 75 °C, 10 h	18	59

The reaction of 5-iodo-2,4-dimethoxypyrimidine with 2(*S*)-(triphenylmethoxymethyl)-2,3-dihydrofuran **295** also led to two isomers **296** and **297**, the ratio between them being dependent on the reaction conditions.¹³⁹

The reactions involving the compound **295** were carried out under the same conditions as those with the isomer **292**. The compounds **296** and **297** were obtained in the following yields: in water and DMF at 20 °C, 53% and 30%; in MeCN at 75 °C, 20% and 58%. When the reaction of the isomer **295** with the iodo-derivative was carried out in the presence of Pd(OAc)₂, Ph₃P, and Ag₂CO₃ in MeCN at 75 °C for 10 h under a nitrogen atmosphere, only the isomer **296** was formed in 40% yield.¹³⁹

In the presence of butyllithium, 2,2-dimethyl-2,3-dihydrofuran reacts with 1,6-dioxaspiro[4.5]dec-3-en-2-one **298** to give the lithium derivative **299** arising due to the substitution of the hydrogen atom in the 5-position of 2,2-dimethyl-2,3-dihydrofuran. In the presence of camphorsulfonic acid, the lithium derivative **299** undergoes a rearrangement being thus converted into two compounds **300** and **301** (overall yield 15%, ratio 1 : 1).¹⁴⁰

V. Addition to the double bond in 2,3-dihydrofurans

The addition product **302** has been synthesised in 40% yield by the reaction of 5,8-dihydroxy-1,4-naphthoquinone with 2,2-dimethyl-2,3-dihydrofuran in the presence of boron trifluoride etherate in acetic acid.¹⁴¹

The 2,3-dihydrofuran derivatives **303–305** containing ω-hydroxyalkyl groups in the 5-position undergo spirocyclisation under the conditions of intramolecular addition–oxidation in the presence of Re₂O₇ under an inert atmosphere followed by treatment with sodium peroxide.

<i>n</i>	1	2
Yield (%)	18	48

Ketones **306**, which are the addition products formed from the enol ether **1** and compounds **307**, are converted on heating into the perhydrobenzofuran-6-one derivatives **308** (yields 48%–50%).^{143, 144}

R = H, Me.

The tetrahydrofuran derivative **309** has been prepared from the enol ether **1**, 1-chloro-2-methylprop-2-ene, and di(2-pyridyl) disulfide (yield 6%).¹⁴⁵

a) 3-ClC₆H₄CO₂H; b) KH, THF, Bu₄N⁺I[−]; c) O₃, CH₂Cl₂, Ph₃P, −78 °C; d) H⁺, MeCN, H₂O; e) (2-C₅H₄NS)₂, Bu₃P, CH₂Cl₂, 0 to −20 °C, 1.5 h.

The reactions of 2,3-dihydrofuran **1** with uracil or its derivatives **310** containing various substituents in the 5-position have been studied in most detail. The influences of the substituents in the 5-position, of the catalysts and solvents used, and of the reaction temperature and time on the yields of the addition products have been studied. Table 2 presents the substituents R in the initial and final compounds, conditions under which the reactions were conducted, and the yields of the resulting compounds **311**.

Table 2. Conditions of reactions^a of uracil derivatives **310** with 2,3-dihydrofuran **1** and yields of addition products **311**.

^a At temperatures above 100 °C, the reactions were carried out in an autoclave.

Under certain conditions, the reactions of the uracil derivatives **310** with excess enol ether **1** have led to the corresponding 1,3-di(tetrahydrofuran-2-yl)uracil derivatives **312** (Table 3).

Yet another approach to the synthesis of the compounds **311** and **312** has been developed. According to this approach, 2,3-dihydrofurans **1** and bis-ethers **313**, prepared from the corresponding uracil derivatives **310**, are used as the initial compounds (Table 4).

R¹ = CMe₃, SiR₃², SnR₃² (R² = Alk).

The reaction of equimolar amounts of the dihydrofuran **1** and the compound **310** with Me₂SiCl₂ in DMF and CH₂Cl₂ at 20 °C for 6 h gives adduct **311** (R = F) in 84% yield. If the compounds **310** and **1** in a ratio of 1 : 2 react at 20 °C for 30 h, the reaction leads to a mixture of the compounds **311** (R = F) and **312**

^a Compound **312**.

(R = F), their yields being 40% and 41%, respectively.¹⁸⁶ The interaction of 5-fluorouracil with the compound **1** and Me₂SiCl₂ in the presence of triethylamine in CH₂Cl₂ at 20 °C for 6 h affords the compound **311** (R = F) in 98% yield.¹⁸⁷

By successive treatment of a mixture of dimethoxy-derivatives **314** and the dihydrofuran **1** with hydrogen chloride and with sodium carbonate, compounds **315** have been prepared.¹⁸⁸

R H Me Br I
Yield (%) 86 40 31 33

5-Fluorothiouracil **316** adds to the compound **1** in the presence of triethylamine hydrochloride in boiling acetone giving 5-fluoro-1-(tetrahydrofuran-2-yl)thiouracil **317** in 65% yield.¹⁸⁹

A method for the synthesis of 3-[4-(5-fluorouracil-1-yl)tetrahydrofuran-3-yl]tetrahydrofuran **318** (yield 16%) has been patented.¹⁹⁰ The method involves the reaction of the dihydrofuran **1** with the bis-ether **313** ($\text{R} = \text{F}$, $\text{R}^1 = \text{SiMe}_3$) in the presence of aluminium chloride followed by treatment of the reaction product with water at pH 4.¹⁹⁰

2-Morpholinotetrahydrofuran has been obtained by the addition of morpholine to the compound **1** in the presence of the $\text{Pd}(\text{SCN})_2/\text{P}(\text{OPh})_3$ catalyst at 20 °C for 15 h.¹⁹¹

2-Nitroimidazole adds to the compound **1** in the presence of toluene-*p*-sulfonic acid.¹⁹²

The addition of methyl 5-cyanomethylimidazole-4-carboxylate di(*p*-nitrophenyl) phosphate to 2,3-dihydrofuran **1** on heating in an autoclave occurs non-regioselectively and gives two compounds **319** and **320** (yields 50% and 20%).¹⁹³

2-(1,2,4-Triazol-1-yl)tetrahydrofuran has been prepared in 90% yield by the reaction of the dihydrofuran **1** with 1,2,4-triazole in the presence of 4- $\text{MeC}_6\text{H}_4\text{SO}_3\text{H}$ in DMF.¹⁹⁴

2-(Benzotriazol-1-yl)tetrahydrofuran has been obtained in a quantitative yield by refluxing the compound **1** with benzotriazole in tetrachloromethane for 5 h.¹⁹⁵

Purine derivatives **321** containing substituents in the 6-position have been made to react with dihydrofuran **1** in the presence of organic sulfonic acids; this reaction afforded addition products **322**.¹⁹⁶⁻¹⁹⁸

2,6-Dichloropurine adds to the dihydrofuran **1** in the presence of toluene-*p*-sulfonic acid to give 2,6-dichloro-9-(tetrahydrofuran-2-yl)-9*H*-purine **323** in 88% yield.¹⁹⁹

By the reaction of 2-benzyloxymethyl-2,3-dihydrofuran **324** with 6-(trimethylsilylamino)purine at ambient temperature in the presence of tin(IV) chloride, compound **325** has been synthesised in 53% yield.²⁰⁰

Refluxing of the compound **1** with 1-bromopyrrolidine in tetrachloromethane leads to 3-bromo-2-pyrrolidinotetrahydrofuran **326** in 29% yield.²⁰¹

A fairly complex picture has been observed when 2,3-dihydrofuran **1** has been introduced in the reaction with 1-substituted benzotriazole derivatives.

When the enol ether **1** is heated with 1-pyrrolidinomethylbenzotriazole **327** in the presence of toluene-*p*-sulfonic acid in a sealed tube, a mixture of two pairs of diastereomers **328a,b** (yields 19% and 24%) and **329a,b** (yields 3% and 53%) is formed.²⁰²

The reaction of 2,3-dihydrofuran **1** with benzotriazole derivatives **230** under the same conditions gives rise to the normal addition product as a mixture of four isomers (2*R*, 3*S*, 6*R*)-**331a**, (2*S*, 3*S*, 6*R*)-**331b**, (2*R*, 3*R*, 6*R*)-**331c**, and (2*S*, 3*R*, 6*R*)-**331d**.²⁰²

A mixture of four isomers of compound **332** has been obtained by heating the dihydrofuran **1** with 1-(α -ethoxybenzyl)benzotriazole **333** in a sealed tube.²⁰³

Tetrahydrofuran derivatives **334**, containing an uracil residue in the 4-position, have been synthesised by treating the adducts **335**, prepared by the addition of phenylsulfonyl chloride to dihydrofurans **336**, with *N*-trimethylsilyluracil in the presence of tin(IV) chloride.²⁰⁴

R = H, CH₂OSiPh₂Bu^t.

The reaction of 2,3-dihydrofuran with tetrahydrothiophene and thionyl chloride in sulfur dioxide has led to salt **337**, which was converted into the chloride of the hydroxy-derivative **338** through the action of water; the compound **338** was characterized as the corresponding picrylsulfonate (yield 19.5%).²⁰⁵

4-Formylpyridine oxime reacts with the compound **1** and bromine in THF to give the pyridinium salt **339** (yield 74%).²⁰⁶

A similar interaction of pyridine derivatives **340** with halogens and the dihydrofuran **1** resulted in the formation of salts **341**.²⁰⁶

V. Conclusion	183

Abstract. The current views on the nature of the intermolecular interaction and the interchain organisation of polymers in the rubber-elastic state are described. The possibility of representing the system of intermolecular interactions by an infinite network of physical links (the physical network model) is considered. Polymeric physical networks are compared with associated species formed in low-molecular-mass organic compounds containing localised intermolecular interaction centres. The principal physical properties of polymers are analysed on the basis of the physical network model. The bibliography includes 280 references.

I. Introduction

The science of the structures of amorphous polymers has a long history. The fundamental ideas about the nature of the elasticity of elastomeric networks, introduced in the 1930s by Mark, Guth and Kuhn¹ and based on the model of overlapping statistical coils,^{2–4} made it possible to account for many thermodynamic and mechanical properties of elastomers. In the 1960s an attempt was made to re-examine the existing ideas about the structures of amorphous polymers on the basis of Frenkel's concept⁵ of the existence of a quasi-crystalline short-range order in liquids. Kargin, Kitaigorodskii, and Sloninskii put forward the hypothesis of the 'packet' structure of amorphous polymers.⁶ According to this model, the principal structural element of this system is not the macromolecule proper but an intermolecular packet consisting of several macromolecules in the uncoiled conformation arranged in parallel.^{7–9} However, the packet model encountered extremely serious objections. Flory² demonstrated theoretically that the volume effects in the polymer vanish with increase in the concentration of the solution and that the macromolecule in a block has the form of an unperturbed statistical coil. Calculations by the Monte Carlo method yield the same result:^{10–12} modelling of the conformations of nonintersecting chains showed that the gradual filling of a limited volume makes it possible to attain a

packing density of the segments which corresponds to the density of the block polymer with retention of the Gaussian coil conformation. Conformational analysis of macromolecules on the basis of the rotational-isomeric model^{3,4,13} also led to the conclusion that the macromolecule, having a Gibbs free energy minimum, should contain a fairly large number of bonds in the gauche-position. Convincing evidence in support of the amorphous polymer model, consisting of self-intersecting random coils, was obtained with the aid of the small angle neutron scattering technique.¹⁴ Direct measurement of the neutron diffraction in deuterated specimens of vitreous polystyrene^{15–17} and poly(methyl methacrylate)¹⁸ and also in a polyethylene melt^{18–20} showed that the mean square dimensions of the macromolecules in a block and in dilute ideal solutions are the same within the limits of ~10%.

All this led not only to the complete rejection of the 'packet' model but also to the denial by many investigators of the very possibility of the formation of any kind of structures in amorphous polymers. This conclusion cannot of course fail to give rise to objections. The set of accumulated experimental data shows that an ideal polymer, having the form of a structureless liquid consisting of self-intersecting random coils, is an exception rather than the rule. Indeed, the mechanical behaviour of network elastomers corresponding to this model occurs only under special conditions: when they are in a swollen state or for extremely small elongations.²¹ In other cases, deviations from the predictions of the theory of rubber elasticity are observed. This is evidently associated not only with the imperfection of the theory itself^{22–25} but also with the lack of correspondence between the structures of real networks and the structureless polymer model.^{26–28}

It is essential to mention the structural inhomogeneity of polymers at the molecular (compositional),²⁹ topological, and supermolecular (inhomogeneity arising from fluctuations and morphological and microphase formations) levels. One should also bear in mind that the range of polymers employed in practice is extremely wide and includes systems such as thermoreversible gels, block copolymers, interpenetrating polymer networks, and polyelectrolytes.

In the present review, an attempt is made to describe the current ideas concerning the structures of polymer systems in the rubber-elastic state and to analyse on the basis of the physical network model the principal physical properties of polymers of this kind.

II. Intermolecular interaction in a 'structureless' polymer system

First of all, we shall consider the structureless model of the structure of a polymeric body in which the only factor taken into account is the presence of long chains and the only form of intermolecular interaction (IMI) is repulsion due to their mutual impermeability.

1. The topological network model (entanglements network)

The simplest and at the same time the most evident feature of a 'structureless' system is the topological limitations induced by the fact that the chains cannot intersect. As early as 1944, it was observed that the modulus of elasticity of vulcanised butyl rubber differs from the values calculated on the basis of the kinetic theory of rubber elasticity.³⁰ This was attributed to the presence of three kinds of network defects: ends, loops, and entanglements. The latter exist in the network before cross-linking, cross-linking merely leading to their fixation and imparting to them the ability to be manifested as additional nodes.

The first studies on natural rubber already revealed the reversibility of its deformations, which is manifested when the period during which the specimen is maintained under load is fairly short.³¹ This effect was explained by the intertwining of the molecules with formation of entanglements, which in the course of a short time act similarly to chemical cross-links. Later several characteristic features of the mechanical behaviour of polymers, caused by the interchain interaction, were observed. These include the characteristic inflection in the plots of the viscosity of polymer melts and solutions against their molecular mass and concentration, the existence on the thermomechanical curves of a plateau corresponding to the quasi-equilibrium rubber-elastic state, and the presence of a long-time region on relaxation time spectra. The terms 'entanglements' (coupling), 'temporary cross-linking' and 'physical network' are employed in the literature for the description of these phenomena.

The first systematic studies on the physical network in elastomers were carried out by Tobolsky.^{31–33} As early as 1946, a model was proposed for a network elastomer, according to which the nodes may be disrupted by thermal fluctuations and then reformed.³¹ In this case, there is a possibility of a characteristic viscoelastic behaviour of the elastomer: an elastic response on rapid application of a load and viscous flow and relaxation of stress on slow application of a load. An attempt has been made in a monograph³³ to arrange systematically the viscoelastic properties associated with the appearance of an entanglements network and to estimate the length of the chains between the entanglements on the basis of the theory of rubber elasticity.

Several reviews have been devoted to the problem of entanglements as a specific form of intermolecular interaction in polymers.^{34–37}

Although the existence of chain entanglements appears entirely evident, no one has succeeded in observing them directly. The deviation of the real elastic properties of an elastomer from those predicted by the classical theory of rubber elasticity is usually regarded as evidence for topological limitations. However, the existence of topological limitations does not yet imply that the entanglements are indeed in regions where the chains are entangled and intertwined. In this connection, several theoretical attempts were made to estimate the probability of the formation of an entanglement on the basis of the geometrical chain parameters. Thus Hoffmann³⁸ attempted to estimate the molecular mass of the chain section between entanglements. He suggested that the entanglements represent the type of intermolecular contacts in which one chain forms a loop around another. The calculation was performed for a polymethylene chain subject to the condition that the loops are formed by four–six methylene groups and taking into account the geometrical relations in a tetrafunctional node. According to the calculation, the number of bonds between entanglements should be 175, which agrees with experiment.

Other attempts to estimate the distances between the entanglements on the basis of geometrical considerations led to different results. Thus it has been found that in a chain comprising 700 units a loop may be formed by a sequence incorporating not less than 30 units.³⁹ The calculation of the density of the entanglements network in the form of loops, carried out using the van der Waals volumes of the molecules and the molecular packing coefficient, led to the conclusion that the effective distance between the loops must be such that the mass of this section would be several times greater than the mass-average molecular mass of the usual polymer.⁴⁰ It was also shown that the formation of loops is unfavourable on thermodynamic grounds as well. Frank-Kamenetskii and Vologodskii (see their review⁴¹) estimated the probability of the formation of loops and rings with a complex configuration. These results are especially important in the consideration of the topological structure of network polymers.

2. The properties of polymers associated with the topological limitations to chain conformations

Allowance for the topological limitations to conformations implies in the first place the abandonment of the hypothesis of phantom chains. The partition function of a network with non-intersecting chains cannot be calculated directly. Various models have therefore come to be widely employed. In particular, it has been suggested that account be taken of the limitations to the number of chain conformations by examining the statistical properties of the chain in the form of an external potential having the form of a 'box' or 'tube'^{42,43} or by introducing the concept of sliding links.^{34,44} It was proposed that the effect of neighbouring chains be modelled on the basis of the elastic potential of the attraction to the equilibrium position — channel.⁴⁵ Another version of the modelling of topological limitations is the approach, which may be called the 'chain in the entanglements lattice'.²⁵ It is usually assumed that the deformation of the surroundings of the chain, modelled by a tube, channel, or entanglements lattice, is of the affine type. The model parameter is as a rule the size of the tube linked in one way or another to the concentration of entanglements. When account is taken of topological limitations, one has in mind small deformations, which makes it possible to analyse the network elastic potential constant W in the form of the Mooney–Rivlin equation:

$$W = C_{100}(I_1 - 3) + C_{010}(I_2 - 3), \quad (1)$$

where C_{ijk} are elastic constants, I_k the invariants of the deformation tensor with $I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2$ and $I_2 = \lambda_1^2\lambda_2^2 + \lambda_2^2\lambda_3^2 + \lambda_3^2\lambda_1^2$, λ_i is the elongation of the specimen along the i th coordinate axis.

An attempt was also made to construct a theory of the elasticity of a chemical network with entanglements over a wide range of degrees of deformation.⁴⁶ The slip link and tube models have been used for the description of topological limitations under the conditions of small and large deformations respectively. The expression obtained for the free energy of deformation includes two terms:

$$\begin{aligned} \frac{F}{kT} = & \frac{1}{2} N_c \left\{ \frac{(1 - \alpha^2) \sum_{i=1}^3 \lambda_i^2}{1 - \alpha^2 \sum_{i=1}^3 \lambda_i^2} - \lg \left(1 - \alpha^2 \sum_{i=1}^3 \lambda_i^2 \right) \right\} + \\ & + \frac{1}{2} N_s \left\{ \sum_{i=1}^3 \left[\frac{\lambda_i^2 (1 + \eta)(1 - \alpha^2)}{(1 + \eta \lambda_i^2)(1 - \alpha^2 \sum_{i=1}^3 \lambda_i^2)} + \lg(1 + \eta \lambda_i^2) \right] - \right. \\ & \left. - \lg \left(1 - \alpha^2 \sum_{i=1}^3 \lambda_i^2 \right) \right\}, \quad (2) \end{aligned}$$

where N_c and N_s are the numbers of chemical cross-links and entanglements respectively and α and η are parameters characterising the extensibility and slip of the chains respectively.

The first term of Eqn (2) corresponds to the deformation of the chemical network and the second to that of the entanglements

network. The parameter N_s is determined from the rubber elasticity plateau modulus and the parameters α and η for real networks have values of about 0.1 and 0.2 respectively.

An attempt has been made to use the replica method to estimate the contribution of the inhomogeneity of the spatial distribution of the density of chemical cross-links to the free energy of the network⁴⁷ and it was concluded that the free energy and hence the mechanical properties of the polymer depend little on the microscopic details in the distribution of cross-links.

Flory proposed⁴⁸ that the entanglements be modelled as limitations to the number of fluctuations of the network nodes. In this model, it is assumed that the stress consists of the stresses due to the phantom chemical network (σ_c) and the stress associated with entanglements (σ_s). The ratio of the contribution of the entanglements to that of the phantom network is defined by the equation

$$\frac{\sigma_s}{\sigma_c} = \frac{\mu}{v} [\lambda K(\lambda_1^2) - \lambda^2 K(\lambda_2^2)] \frac{1}{\lambda - \lambda^{-2}}, \quad (3)$$

where μ and v are the concentrations of the entanglements and active chains respectively, $\lambda_1 = \lambda$, $\lambda_2 = \lambda^{-1/2}$, and

$$K(\lambda^2) = B \left[\frac{B}{B' + 1} + \frac{(\lambda^2 B' + B)(x\lambda^{-2} + B^{-1})}{x} \right].$$

Here

$$B = \frac{(\lambda - 1)(\lambda + 1 - \xi\lambda^2)}{(1 + g')^2}, \quad g = \lambda^2[x^{-1} + \xi(\lambda - 1)],$$

$$B' = \frac{\partial B}{\partial \lambda^2}, \quad g' = \frac{\partial g}{\partial \lambda^2},$$

x is the ratio of the mean square distance between the ends in the phantom network to the mean square fluctuations of the position of the node in the network with limitations, and ξ is a parameter determining the degree of nonaffinity of the change in the limitations domains on deformation.

Theories of the swelling of polymer networks with allowance for topological limitations⁴⁹ and birefringence⁵⁰ have been developed on the basis of Flory's model.⁴⁸ The experimental data on the mechanical properties, swelling, and birefringence of polydimethylsiloxane networks agreed satisfactorily with Flory's model.^{51–54} This model has been used⁵⁵ to determine the contribution of the molecular parameters to the local deformation and orientation. Subsequently attention was turned to the fact that the nature of the topological limitations should depend on the way in which the network is formed. The proposed lattice model made it possible to take into account the influence of the cross-linking conditions.^{56,57}

The complexity of allowance for the topological limitations to the number of chain conformations stimulated interest in the construction of more rigorous models⁵⁸ and also in the investigation of network structures by means of a computer experiment. The influence of entanglements on the fluctuation of a network node has been investigated.⁵⁹ A rank 1 micronetwork with a node functionality of 3 and fixed ends having a length equivalent to 40 units was examined. Some of the predictions of Flory's model were confirmed, but the parameter x depended linearly on the number of units, whereas according to the above model a quadratic law should have held.

The Monte Carlo method has been used to model phantom networks and networks with nonintersecting chains in order to analyse the dependence of the number of elastically active chains, the form factor, and the cyclic rank on the structure of the network and their relation with the modulus of elasticity and the swelling parameters.^{60–62} The topological limitations were taken into account by introducing δ -multipliers, which differentiate the permissible states of the network, into the integrated expressions for the partition functions and the probability of the Markov chains. It was found that in the region of extension the elastic

behaviour of the model network obeys satisfactorily the Mooney–Rivlin equation.

It appears evident that the dynamic properties of polymers over a long time interval are controlled by the entanglements. For example, the relaxation of stress in uniaxially extended polystyrene has been investigated by the small angle neutron scattering method at a temperature above the glass transition temperature.⁶³ It was found that over a short time interval, the relaxation proceeds only on a small scale, in conformity with Rouse's model. If the time interval is long, the relaxation slows down but it is a large scale process. This is followed by the third stage, in which relaxation is independent of the degree of scattering. This stage is attributed to the unwinding of the entanglements.

The ideas concerning the presence of topological limitations have served as a basis of the 'tube' model — the reptation mechanism of the diffusion of macromolecules in concentrated systems.^{64–66} The characteristic break in the curves relating the spin–spin and spin–lattice relaxation of protons to the molecular mass of polydimethylsiloxanes has been explained by the presence of entanglements.^{34,67} Detailed study of the curves for the decrease in free induction in linear and weakly cross-linked polymers^{68,69} also indicated, according to the authors, the presence of a network of entanglements for a molecular mass of the polymer of the order of 10^5 . However, the mechanism of the diffusion of macromolecules was then interpreted within the framework of Rouse's theory: the 'tube' is not manifested in the time interval within which the NMR method operates.

The molecular mass of the chain section between the entanglements nodes (M_e) is usually estimated from the quasi-equilibrium modulus on the rubber elasticity plateau. These data have been presented in a series of books and reviews.^{34,70–74} We may note the existence of a correlation between M_e and the parameters of the chain rigidity, which are estimated, in particular, from the dimensions of the macromolecular coil in a θ -solvent.^{72,73}

In contrast to linear polymers, the topological entanglements in network polymers influence not only the dynamics but also the equilibrium mechanical properties of the specimens. The equilibrium modulus of shear consists of two components above the glass transition temperature: σ_x , determined from the classical theory of rubber elasticity, and σ_n , associated with the topology of the network.^{22,70} The fraction of the 'topological' component then depends on the degree of cross-linking for with low degree of cross-linking networks.⁷⁵ The contribution of trapped entanglements is manifested not only on deformation but also on swelling. Thus the dependence of the rate of transverse relaxation of protons δ in cross-linked polydimethylsiloxane on the degree of swelling q is divided into two characteristic regions.⁷⁶ In the region of low degrees of swelling, the main contribution to the $\delta(q)$ relation comes from the dispersion of the chains in the solvent. For high values of q , the rate of transverse proton relaxation begins to increase and tends to a limit. Effects associated with the presence of trapped topological entanglements are then manifested.

The study of the physical (mainly dynamic) properties of polymers and polymer blends from the standpoint of the reptation models is being continued.^{77–80} A continuously growing number of results, which do not fully agree with the model of reptation diffusion and indicate the need to correct the structureless model of a polymeric body, are being accumulated in this connection. Thus as early as 1975 analysis of the rheological properties of monodisperse and polydisperse polymers led to the conclusion that 'the characteristic features of the viscoelastic properties of high-molecular-mass polymer blends are incompatible with the concept of a single network of randomly entangled macromolecules of different lengths'.⁸¹

Evidently it is necessary to take into account the real structure of the polymer, at any rate to the extent that the intermolecular interactions are manifested in liquids.

III. Localised intermolecular interactions and their role in low-molecular-mass liquids and polymers

1. Intermolecular interactions and their manifestation in low-molecular-mass systems

In order to elucidate the nature of the physical bonds arising from intermolecular interactions and promoting the formation of physical networks in polymer systems, it is possible to employ, as simple models, low-molecular-mass organic compounds in which there are strong intermolecular interaction centres, namely oxygen-containing (hydroxy-, carboxy-, ester, and other groups), nitrogen-containing (amide, amine, and other groups), halogen-containing, sulfur-containing, and other atomic groups capable of undergoing dipole–dipole interactions and of forming hydrogen bonds. Evidently in a condensed state the molecules of such organic compounds are linked to one another by a system of intermolecular interactions into associated species, the topology of which may be most diverse depending on the number (n) and functionality (F) of the IMI centres, their disposition (terminal, central), and the conformational features of the compounds (especially polyatomic ones), including the barriers to internal rotation. The functionality of an IMI centre should be understood as the number of bonds which may be formed one by such centre. For example, the hydroxy-group has the functionality $F = 2$, since it forms two hydrogen bonds — one at the O atom and the other at the H atom. Evidently for $F > 2$ the formation of associated species of the physical network type becomes probable, whereas for $F < 2$ only discrete structures with limited dimensions may arise.

The very fact of the association of organic liquids and in many instances also the topological characteristics of the associated species formed have long been established.^{5,82} In the light of the problem of physical networks, the association of low-molecular-mass organic liquids is of definite interest: its study may help to discover a correlation between the parameters characterising the initial organic molecule as an elementary structural unit in a system of intermolecular bonds and the parameters of the system itself (the physical network). The nature of the IMI centres, their number and functionality, their positions, their intramolecular environment, and their mobility (the barrier to the internal rotation of an atomic group which is a carrier of the IMI centre) belong to the first group of parameters. The average concentration of intermolecular bonds ν , formed at a given temperature T , the average lifetime of the bonds τ , the form of the function $\nu = f(T)$, and the topological type of the IMI system must be assigned to the second group.

Calculations based on the model of volume pair interactions, resorting to data on the frequencies of the atomic vibrations, the frequencies of pair collisions, and the heats of vaporisation, are used for the rough estimation of the parameters $\nu = f(T)$ and τ .^{82,83}

The correlations observed in suitably selected comparison series, which include a large number of organic compounds, serve as the starting point for further systematic analysis of the physical properties of organic compounds. This results in the possibility of establishing which physical properties depend, and to what extent, on the IMI system (the physical network). Properties such as the boiling and melting points and the molecular packing coefficient K_p depend on the intermolecular interactions to the greatest extent. The molecular packing coefficient is determined by calculation⁸⁴ from data on the volume radii and interatomic distances in the molecule, the van der Waals volume of the molecules (V_v), and the molar volume (V_m) calculated from the density and the molecular mass of the substance.^{40,74} By using different comparison series of organic compounds, it is possible to discover the regularities and characteristic features in the formation of the physical networks themselves from the regularities in the variation of the physical properties.^{85,86}

The fundamental studies,^{40,87–89} in which K_p and V_v were calculated and a comparative analysis of these parameters was

carried out in relation to polymers and low-molecular-mass compounds, must be noted.

The results of the analysis of a representative set of data, including about 3000 organic compounds, are presented below.^{85,86} This series includes the homologous series of mono-, di-, tri-, and, in isolated instances, also tetra-functional organic compounds with hydroxy-, carboxy-, nitrile, amide, ester, halide, and other functional groups, which occur in polymers to different extents.

a. Analysis of the set of data on the physical properties of low-molecular-mass organic compounds

Almost all the physical properties of organic compounds are related in one way or another to the strength of the intermolecular interaction. Evidently, the dependence of physical properties on the intermolecular interaction is multiparametric and, even in a series of organic compounds with isotypical IMI centres, for example in homologous series, the variation of several parameters at once is observed. The analysis of physical properties may therefore be successful only if the set of data is sufficiently representative to ensure the possibility of combining organic compounds into large systematic comparison series and of carrying out a multiprogram comparison.

The initial set should include at least several thousand compounds.⁸⁵ Only the boiling point T_b (as a rule at atmospheric pressure), the melting point T_m , and the density (in the vast majority of cases only at room temperature) have been determined for such a number of organic compounds. Other important physical properties, which depend on the intermolecular interactions just as strongly, for example, the viscosity η and the heat of vaporisation ΔH_e , have been measured for by no means all compounds. The quantities T_b , T_m , and K_p have therefore been used as the basic physical properties for systematic analysis, while the parameters η , ΔH_e , and others have been used only in those cases where this appeared possible.⁸⁵

The quantities T_b and T_m are determined by the intensity of the intermolecular interaction at the opposite ends of the temperature range of the existence of organic compounds in the liquid state. The correlation between T_m and the IMI parameters is then complicated in many instances by crystallisation *i.e.* by the appearance of long-range order, which naturally may introduce errors into the analysis of the regularities in the intermolecular interaction unless this factor is specially taken into account. In this sense, the analysis of T_b is more correct.

When the coefficient K_p is employed, one must take into account its very high sensitivity to the shape of the molecules (conformational set). Therefore, in selecting the comparison series, it is essential to fix the shape factor and to compare only molecules with isotypical conformational characteristics.

The selection of the argument for the functions T_b , T_m , K_p or others plays a special role in the analysis of the set of data on physical properties. The van der Waals molecular volume V_v has been proposed as the universal argument.⁸⁵ This choice is justified in the following way. Strong intermolecular interactions of the type of dipole–dipole interactions and hydrogen bonds always occur against the background of weak dispersion forces, the overall energy of which is approximately proportional to V_v . Strong intermolecular interactions are localised strictly within the limits of a definite atomic group. For fairly high values of V_v , the contributions of the 'background' and localised intermolecular interactions are comparable. Therefore, in order to discover the correlations and regularities actually associated with the strong intermolecular interactions, it is necessary to differentiate the latter taking into account the 'background'. Such differentiation can be achieved by analysing relations of the 'physical properties (T_b , T_m , K_p , etc.) – V_v ' type, provided that one assumes, to a rough approximation, that the magnitude of the 'background' is proportional to V_v and the contribution of strong intermolecular interactions for a fixed number of atomic carrier groups in the molecule is independent of V_v .

b. The role of the intermolecular interaction energy

The energy of the intermolecular interaction of functional groups (E), the values of which were estimated from the heats of vaporisation⁹⁰ (ΔH_v) of the corresponding organic compounds containing groups of the given type, are presented in Table 1. Figs 1–3 present the correlations of T_b , T_m , and K_p with V_v in homologous series of organic compounds having the corresponding functional groups. In order to reduce to a minimum the differences between the molecular shapes, only homologues with linear (unbranched) aliphatic chains and functional groups located at the ends of the chains are presented in the figures. Comparison of the data in Figs 1–3 and Table 1 permits the conclusion that the molecular packing density is the physical property which is most sensitive to the strength of the intermolecular interactions estimated in terms of the energy E . The disposition of the $T_b(V_v)$ curves in Fig. 1 is also consistent with the variation of E in Table 1.

The correlation between the $T_m(V_v)$ relation (Fig. 2) and the IMI intensity is complicated by a series of factors, the most important of which is the molecular shape and, for molecules of identical shape — their symmetry. The role of symmetry can be clearly seen on comparing the $T_m(V_v)$ relations for the even and odd members of homologous series: the even members are always characterised by higher T_m . This indicates a high significance of the contribution of the associative structures with a regular disposition of molecules to the establishment of long-range order

Figure 1. Dependence of the boiling point T_b (in °C) on the van der Waals volumes of the molecules of organic compounds: (1) aliphatic hydrocarbons; (2) monocarboxylic acids; (3) 1-chloro-compounds; (4) compounds dichloro-substituted at chain ends; (5) 1-iodo-compounds; (6) compounds diiodo-substituted at chain ends; (7) 1-fluoro-compounds; (8) compounds difluoro-substituted at chain ends; (9) 1-bromo-compounds; (10) compounds dibromo-substituted at chain ends; (11) amides; (12) nitriles; (13) dinitriles; (14) amines; (15) diamines; (16) aldehydes; (17) dialdehydes; (18) alcohols; (19) glycols; (20) monocarboxylic acid esters; (21) dicarboxylic acid esters; (22) ethers. The dashed curves refer to the $T_b(1)$ ordinate, the continuous curves without arrows refer to the $T_b(2)$ ordinate, and the continuous curves with arrows refer to the $T_b(3)$ ordinate.

Table 1. The energies of the intermolecular interactions of functional groups of different types.

Group	$E/\text{kJ mol}^{-1}$	Group	$E/\text{kJ mol}^{-1}$

—I	20.1		2.1
	18.4		

^a The value which does not refer to localised intermolecular interactions but characterises the energy of the dispersion interaction.

on passing from the liquid to the solid state. The contribution of the IMI strength (Table 1) is manifested against this background only as a trend: alcohols, acids, and especially amides, characterised by the highest values of E , occupy a higher position also on the T_m scale. This trend can be seen more distinctly in the region of $V_v > 150 \text{ Å}^3$, where the contribution of the molecular symmetry factor diminishes significantly, which may be inferred from the decrease in the amplitude of the T_m oscillations in the consecutive alternation of even and odd members of the homologous series.

When the molecules contain two functional end groups — carriers of localised IMI centres (see, for example, the data for glycols), the $T_m(V_v)$ curves are sharply displaced upwards relative

Figure 2. Dependence of the melting point T_m (in °C) on the van der Waals volumes of the molecules (for the designation of the curves, see Fig. 1). The dashed curves and points 7, 10, and 15 refer to the $T_m(1)$ ordinate, points 4, 6, 13, and 14 refer to the $T_m(2)$ ordinate, and the continuous curves with arrows refer to the $T_m(3)$ ordinate.

Figure 3. Dependence of the molecular packing coefficient K_p on the van der Waals volumes of the molecules (for the designation of the curves, see Fig. 1). The dashed curves refer to the $K_p(1)$ ordinate, the continuous curves without arrows refer to the $K_p(2)$ ordinate, and the continuous curves with arrows refer to the $K_p(3)$ ordinate.

to the curves for the monofunctional analogues. First of all, this is caused by the increase (doubling) of the average concentration of nodes. The sharp increase in the amplitude of the T_m oscillations for the even and odd compounds indicates the establishment of long-range order: the molecules are arranged in parallel and this arrangement is fixed by the strong terminal intermolecular bonds.

c. The role of molecular shape

Comparison of the IMI-dependent physical properties of molecules with similar values of V_v and E but having different shapes (conformational sets) makes it possible to estimate the contribution of this factor to the formation of the IMI system. As regards organic compounds containing one functional group in the molecule, the analysis leads to the following conclusions.

The molecular shape plays an important role in the formation of associated species both as a purely geometrical factor, promoting (or hindering) close packing and as an intramolecular factor which determines the degree of shielding of the IMI centre by 'inert' substituents. Comparison of the physical properties of isomers of the type $\text{CH}_3(\text{CH}_2)_2\text{CH}_2\text{R}$ (I) and $(\text{CH}_3)_3\text{CR}$ (II), where $\text{R} = \text{OH}$, COOH , Hal , or any other functional group is the carrier of the IMI centre, serves as the simplest illustration. The volumes V_v of different isomers are identical, while the equality of E for the pairs being compared holds owing to the identity of the functional groups. The type (I) linear isomers have a cylinder-like shape, while the type (II) branched isomers have a sphere-like shape. In all cases, the transition from (I) to (II) is accompanied by a sharp rise in T_m in the region of low temperatures, by a decrease in T_b in the region of high temperatures, and by a decrease in K_p in the intermediate region. The shape of type II molecules can exert a dual influence on K_p . On the one hand, it may act as a geometrical factor (the close packing of spheres is looser than that of cylinders). On the other hand, it may also prove to be an intramolecular factor: the shielding of the group R by CH_3 side groups prevents the optimum mutual approach of the groups R of neighbouring molecules, the associative linkages are

weakened, and the packing becomes loosened owing to the decrease in the intensity of the field of intermolecular tightening forces. The occurrence of shielding is confirmed by an appreciable decrease in the heat of vaporisation ΔH_e on passing from form I to form II.

The role of molecular shape at low temperatures is determined by the ability of the system to form regular structures (long-range order). Cooperative intermolecular interactions in such structures lead to a sharp increase in their average lifetime τ up to values comparable to the observation times, which is interpreted as the transition from the liquid to the solid (nonfluid) state. Under these conditions, intramolecular energy barriers, *i.e.* barriers to the rotation of atomic groups around bonds (E_r), as well as the energy barrier to the dissociation of associative (intermolecular) bonds (E), contribute significantly to τ . In essence, the shape of a polyatomic molecule of an organic compound should be understood as a dynamic concept — as the set of conformations characteristic of the given molecule and controlled by the values of E_r .^{91–95} The quantities E_r increase with increase in the number of branches and reach values comparable to E_r . For example, the $\text{CH}_3-\text{C}(\text{CH}_3)_3$ bond is characterised by the quantity $E_r = 19.6 \text{ kJ mol}^{-1}$. In the light of this approach, factors associated with molecular shape, namely symmetry, regularity of the alternation of atomic groups in the molecule, and the values of E_r , should exert, together with E , a decisive influence on T_m . The transition from form I to form II is accompanied by an increase in E_r and in molecular symmetry, which is evidently the actual cause of the sharp increase in T_m .

The replacement of single by multiple bonds in the molecule of an organic compound causes a sharp depletion in the conformational set owing to the extremely marked increase in E_r , which actually leads to the prohibition of rotation about the multiple bond. This entails a corresponding change in the molecular 'shape' and in the physical properties sensitive to the given factor. Comparison of the properties of certain representatives of the classes of acids, alcohols, and aldehydes may serve as a typical illustration (Table 2). The values of E for these compounds are presented in Table 1.

The change in molecular shape in the examples presented, associated with the introduction of multiple bonds, leads to an increase in the molecular packing density: K_p increases on a scale

Table 2. Comparison of the properties of certain typical acids, alcohols, and aldehydes.

Formula	$V_v/\text{\AA}^3$	$K_p^{20^\circ\text{C}}$	$T_m/^\circ\text{C}$	$T_b/^\circ\text{C}$
$\text{CH}_3(\text{CH}_2)_2\text{COOH}$	89.5	0.585	−5.3	163.5
$\text{CH}_3\text{CH}=\text{CHCOOH}$	85.5	0.613	15.5	169
$\text{CH}_3\text{CH}(\text{CH}_3)\text{COOH}$	89.5	0.581	−46.1	154.7
$\text{CH}_2=\text{C}(\text{CH}_3)\text{COOH}$	85.4	0.600	16	163
$\text{CH}_3(\text{CH}_2)_2\text{CH}_2\text{OH}$	87.9	0.578	−89.5	112.4
$\text{CH}_3\text{CH}=\text{CHCH}_2\text{OH}$	83.9	0.597	< −30	121.2
$\text{CH}_3(\text{CH}_2)_2\text{CHO}$	82.2	0.550	−97.1	74.8
$\text{CH}_3\text{CH}=\text{CHCHO}$	78.2	0.569	−69.0	102.2

comparable to the effect associated with the replacement of the relatively 'weak' $-\text{CHO}$ group ($E = 18.0 \text{ kJ mol}^{-1}$) by the very strong $-\text{COOH}$ group ($E = 45.1 \text{ kJ mol}^{-1}$). The increase in packing density is apparently the main cause of the upward shift of both transition points, T_m and T_b , on the temperature scale.

The closure of the chain of functional organic compounds to form a ring also leads to the depletion of the conformational set. Organic compounds with linear and cyclic hydrocarbon chains are characterised by a higher molecular packing density than linear compounds (for $V_v = \text{const.}$). The introduction of multiple bonds into rings increases still further the compaction effect, evidently

owing to the development of additional conformational limitations.

Transition to aromatic cyclic compounds, the molecules of which have a disc shape, extremely favourable for the establishment of the closest packing, does indeed promote a still greater increase in K_p . As an example, one may compare benzene and pentane. Despite its somewhat smaller molecular volume (V_v), benzene has a significantly greater molecular packing density than pentane and hence higher values of T_m and T_b . Cyclopentane, the molecules of which have a similar volume ($V_v = 91.5 \pm 6 \text{ \AA}^3$), occupies, as should have been expected, an intermediate position between benzene and pentane as regards K_p , T_m , and T_b . On passing from pentane to benzene, ΔH_e increases by 6.3 kJ mol^{-1} .⁹⁰ Therefore, in order to discover the actual contribution of molecular shape it is necessary to include in the comparison series an organic compound the molecule of which has a shape similar to that of pentane and ΔH_e higher by 6.3 kJ mol^{-1} than in the case of the latter. Such a compound may be, for example, butyraldehyde (Table 2). It was found that the introduction of the aldehyde group ($E = 18 \text{ kJ mol}^{-1}$), resulting in an increase in ΔH_e by 6.3 kJ mol^{-1} compared with pentane whilst retaining the linear molecular shape, does not lead to an increment in the packing density comparable to that arising on passing from the linear to the disc shape.

Thus the literature data on the properties of organic compounds make it possible to obtain important information for the understanding of the nature of the intermolecular interaction. A more complete study of the intermolecular interaction requires the application of a wide range of experimental methods, among which the traditional approaches occupy an important place:^{5, 82} spectroscopy, measurement of relative permittivity, Rayleigh light scattering, X-ray diffraction, rheology, and thermophysical measurements. Certain new developments^{83, 96, 97} have been designed for the direct experimental determination of the parameters of the IMI system as a physical network — both statistical and with elements of a regular structure. Among these, the main place is occupied by the EPR method in the spin-probe version, which makes it possible to infer from the form of the EPR spectra of nitroxyl radicals in the 3-cm range (without transfer of saturation) the degree of development of a physical network of short-lived associative bonds (τ is 5×10^{-11} to 10^{-7} s) and its evolution as a function of temperature. The spin-probe correlation time is regarded as a measure of the retardation by the physical network of the reorientation process in the magnetic field of the spin-carrying atomic group.

The precision thermomechanical method (sensitivity of 5×10^{-4} mm in terms of deformation), which makes it possible to record the abrupt thermal expansion of the substance at a temperature several degrees below T_m , is also used, provided that the possibility of the formation of a network of physical bonds arises in the system by virtue of the relatively high functionality of the test molecules.

2. Manifestation of intermolecular interactions in polymer systems

a. Molecular packing coefficient in polymer systems

The question of the role of molecular shape and barriers to internal rotation acquires special importance when the information about intermolecular interactions, obtained in the study of low-molecular-mass organic compounds, is transferred to polymer systems. Evidently the repeatability of the shape of the polymer unit as a factor influencing the packing density (and hence the intermolecular interactions and the properties of the polymer depending on the latter) is hindered by the limitation to mobility due to the linking of the units in the chain. This limitation is greater the higher the corresponding barriers to rotation. On the other hand, the limitation to mobility leads to the cooperation of the intermolecular interactions, to an increase in the stability of the IMI system (physical network), and ultimately to an increase in the molecular packing density. Comparison of the set of

properties of polymeric and high-molecular-mass objects, modelling the individual fragments of the macromolecules, yields additional information about the cooperation between the intermolecular interactions in polymers.

In polymers, the units carrying localised IMI centres are linked by covalent bonds. This makes it possible to predict a series of differences between the physical networks in polymers and the similar networks in low-molecular-mass organic substances. Firstly, the degree of cooperativeness of neighbouring physical nodes is greater in polymers, which may be manifested by a sharp increase in their average lifetime τ (by an increase in stability). Secondly, as a result of the linkage of the IMI centres, steric hindrance to their mutual translational approach inevitably arises, which decreases the average concentration of nodes.

Consequently, for identical initial concentrations of the same IMI centres ($2v_0$) in low-molecular-mass organic compounds and in polymers, the nodes of the physical network formed in the latter are more stable (τ is greater), but their concentration v is reduced.

It is noteworthy that the volumes V_v of polymers listed in Table 3 refer to the repeat unit, so that the average volume of the macromolecule is equal to the product nV_v , where n is the average number of units in the polymer chains.

It follows from Table 3 that the molecular packing density of the polymer chains is influenced by the same factors as those influencing the packing density of low-molecular-mass organic compounds (it increases with increase in the IMI intensity and with increase in the barriers to internal rotation, responding to changes in the shape of the macromolecules), but to a much smaller extent. Indeed, the highest and lowest values of K_p [0.684 for poly(vinyl alcohol) and 0.627 for poly(dodecanyl methacrylate)] differ by only 5–6 units in the second digit after the decimal point. On the other hand, if polypropylene ($K_p = 0.669$), the macromolecules of which have exactly the same shape as those of poly(vinyl alcohol), and not the molecules of 'comb-shaped' poly(dodecyl methacrylate) with their outstanding shape, is chosen as the starting point for the calculation, then the difference between the values of K_p is not more than two hundredths.

For low-molecular-mass analogues, the difference between the molecular packing coefficients reaches 0.05 when the limiting value for a hydrocarbon ($K_p = 0.600$ – 0.610) is compared with $K_p = 0.662$ for a dihydric alcohol. If the dihydric alcohol is replaced by a trihydric alcohol, the difference between the values of K_p almost doubles.

It must be assumed that the contribution of the molecular shape factor to the molecular packing density of polymers is significantly greater than for monomers. For this reason, the monotonically constructed hydrocarbon chains $-(CH_2)_n-$ have a fairly dense packing ($K_p = 0.677$) even in the absence of large tightening forces ($E \approx 4.2 \text{ kJ mol}^{-1}$ per CH_2 group). The infringement of the monotonic construction as a result of the appearance of bulky side groups $[-CH_3, -Cl, -OCOCH_3, -COO(CH_2)_nH]$ or the insertion of $-O-$ groups into the hydrocarbon chain, not compensated adequately by tightening forces ($E \leq 16 \text{ kJ mol}^{-1}$), impairs the packing. The compensation phenomenon may be followed in the series of poly(alkylene oxides) (increase in K_p as the $-O-$ groups with $E = 6.3 \text{ kJ mol}^{-1}$ accumulate) and on passing from the $-(CH_2)_n-$ polymer to macromolecules with $-CN$ and $-OH$ side groups ($K_p = 0.677$, 0.681, and 0.684 respectively). When the most bulky $-COO(CH_2)_nH$ substituents are introduced, the packing becomes looser with increase in n not only owing to the operation of the geometrical factor (the shape of the macromolecules) but also because of the characteristic features of the side fragment itself: in relation to low-molecular-mass analogues — dibasic acid esters — the role of the displacement of the IMI centre ($-COO-$) from its position at the end of the molecule to its centre, which leads to a significant increase in K_p , can be clearly traced.

The role of barriers to internal rotation is more marked in polymers than in their low-molecular-mass analogues. Thus, on passing from poly(alkyl acrylates) to poly(alkyl methacrylates), K

Table 3. Comparison of the properties of certain polymers and their low-molecular-mass analogues.

^a Glycerol is not an exact structural analogue of the polymer chain fragment of poly(vinyl alcohol), demonstrating merely the role of the accumulation of hydroxy-groups in the molecule.

increases sharply (from 0.662 to 0.682 for the first members of the corresponding homologous series) owing to the appearance of the methyl side group, which inhibits internal rotation.

b. Network of localised physical bonds

If the polymer contains functional groups capable of forming strong intermolecular bonds, then the latter are a direct source of the appearance of a physical network. According to Flory's classification,⁹⁸ the networks formed by intermolecular physical bonds give rise to an unusual kind of polymer gels, although the difference between polymers with chemical and physical networks is in this instance purely quantitative. In particular, the classical polymer specimen with a chemical network — rubber vulcanised with sulfur at elevated temperatures — possesses the characteristic properties of a polymer with a physical network, namely the capacity for the relaxation of stress and creep, as a consequence of the occurrence of exchange reactions involving polysulfide bonds.^{99, 100}

The dipole — dipole and inductive interactions of the —CN groups in polyacrylonitrile and its copolymers — butadiene-nitrile rubbers — is an example of strong intermolecular interactions leading to the appearance of a physical network. The high dipole moment of nitrile groups makes them capable of forming dimers of the type

with an energy ranging from 19 to 38 kJ mol⁻¹ according to various estimates.¹⁰¹ In the low-molecular-mass analogue of polyacrylonitrile, namely acetonitrile, between 70% and 90% of

the substance is in the associated state. By virtue of the presence of a network of dipole — dipole bonds, polyacrylonitrile has marked rubber-elastic properties above the glass transition temperature and the reversible deformation (before break) may reach 350%.¹⁰¹ In butadiene — nitrile rubbers, an unusual relaxation π -transition corresponds to the disruption of the network of dipole — dipole interactions.^{102, 103}

Another kind of strong intermolecular interaction in polymers is hydrogen bonding. The appearance of hydrogen bonds in polymers is usually caused by the presence of the following functional groups: amides (—CONH) (polyamides, polyester-amides, acrylamide or methacrylamide copolymers), urethane (—COONH) (polyurethanes, oligodiene urethaneepoxides, *etc.*), carboxy- (—COOH) (copolymers of acrylic and methacrylic acids), and hydroxy- (—OH) [poly(vinyl alcohol), cellulose]. The presence of hydrogen bonds in the polymer is deduced from the shift of the absorption frequencies in vibrational spectra,^{104, 105} from the change in the chemical shifts and relaxation times in NMR spectra,¹⁰⁷ and also from the change in the relative permittivities and other indirect data,¹⁰⁸ including the deviation of certain characteristics of monomers from the additive values calculated from atomic group increments.⁷⁴

Numerous studies devoted to polyamides^{105, 106, 109} demonstrated the presence of a strong hydrogen bond in these polymers. Up to 99% of the amide groups form hydrogen bonds in polyamides of certain types. Hydrogen bonds have been detected also in polyurethanes.^{110–112} According to a number of investigators,^{113, 114} hydrogen bonds actually play a role as decisive factor in the mechanical and strength properties of these poly-

mers. Thus comparative study of the IR spectra and viscosities of oligourethane epoxides with different concentrations of urethane and epoxide groups demonstrated that hydrogen bonds are the most important factor responsible for their rheological properties, in particular for the anomalously high viscosity.^{115, 116}

The energy of hydrogen bonds depends on the geometry and nature of the substituents in the groups involved in their formation.^{116–118} Thus it has been shown that aromatic substituents prevent the formation of hydrogen bonds.¹¹⁶ Their replacement by aliphatic substituents leads to partial restoration of the interaction. The high energy of hydrogen bonds imparts to polymers, capable of forming them, all the characteristic features of polymers with a physical network. In particular, the occurrence of transitions in the temperature variation of the modulus of elasticity^{119–121} and the ability to form physical gels^{122–126} have been noted. The physical gels formed *via* hydrogen bonding possess quasi-equilibrium elasticity,¹²⁷ which may be described in terms of the theory of rubber elasticity for sufficiently short observation times. In this instance, the influence of gel formation conditions and of the type of solvent affects the elasticity constant of the gel. The application of a mechanical load leads to partial disruption of the hydrogen bonds, which is reflected in the IR spectra^{108, 121} and is manifested outwardly by the relaxation of stress. In those cases where the groups forming hydrogen bonds are located close to one another in the chain, as happens, for example, in segmented polyurethanes, there is a possibility of the appearance of associated species capable of giving rise even to microphase layer formation. The polyfunctional nodes of the physical network arising under these conditions are especially strong, which imparts the properties of a thermoelastoplastic to the polymer.

Associated species with similar properties may arise also when the polymer contains groups capable of forming bifunctional hydrogen bonds. Thus a polymer in which some of the units form bifunctional hydrogen bonds *via* the COOH- and NHCO-groups has been obtained by the interaction of polybutadiene with 4-(4'-carboxyphenyl)-1,2,4-triazine-3,5-dione.^{125, 126} The formation of associated species leads to the appearance on the corresponding plot of an equilibrium elasticity section with a positive temperature coefficient.

Polyelectrolyte complexes, obtained on mixing aqueous solutions of oppositely charged electrolytes, represent a special class of intermolecular interactions.^{128, 129} A characteristic feature of the thermoreversible gels formed under these conditions is that their modulus and degree of swelling depend on the pH of the medium and on the concentration of low-molecular-mass counterions. By altering the external conditions periodically, it is possible to vary the concentration of the intermolecular bonds and to induce either the contraction or elongation of the specimen,¹³⁰ *i.e.* it is possible to transform chemical energy directly into mechanical energy.

3. Local order and complementary sequences of units

A substance in the polymeric state may form a physical node not only as a result of strong intermolecular interactions, but, as mentioned above, also as a result of the cooperation of weak dispersion bonds. Such interaction leads to the appearance of a short-range order region in the polymer. Although numerous studies have been carried out on the problem of the ordering of polymers in the amorphous state (see, for example, Boyer¹³¹), this question continues to be controversial, mainly because many experimental results used to demonstrate the existence of local order are in principle susceptible also to a different interpretation. This applies mainly to studies on the electron microscopy of polymer films.^{132–136} The existence of local order is indicated, according to a number of workers,^{137–139} by the presence of several distinct 'intermolecular' maxima on wide angle X-ray diffractograms for both noncrystallising polymers above and below the glass transition temperature (T_g) and for crystallising polymers (polyethylene, poly-4-methylpent-1-ene) in the

melt.^{140, 141} The anomalous variation of the heat capacities of polyethylene and polypropylene melts is attributed to the reversible disintegration and restoration of short-range order regions of the smectic type, characteristic of liquid crystals.¹⁴² Convincing data supporting the existence of short-range segmental order in melts of different polymers have been presented in a series of studies.^{143–146} Analysis of the differential curves for radial distribution functions, obtained by electron and X-ray diffraction methods, revealed the existence in melts of crystallising and noncrystallising polymers of sections with a quasi-parallel arrangement of segments with a structure of the liquid crystal type. The dimensions of these sections reach 20 Å in the direction of the long axis of the macromolecule and 30 Å in the perpendicular direction. This result has been confirmed by a careful analysis of the curve for the second moment of the radial distribution function plotted on the basis of X-ray diffraction measurements for a linear polyethylene melt.¹⁴⁷ Three well resolved intermolecular maxima with a periodicity of ~ 5 Å have been observed. Measurements of the osmotic pressures of the solutions and of the heats of solution of polyisobutylene in various solvents permitted the conclusion^{148, 149} that a residual order, corresponding to a degree of crystallinity of the order of $\sim 10\%$, exists in this X-ray-amorphous polymer.

Analysis of the dielectric properties of poly(ethylene terephthalate) in the rubber-elastic state and of polyisobutylene, as well as calculations of the conformations of the macromolecules of these polymers has shown that quantitative agreement between the theoretical dipole moments and other dielectric characteristics is achieved only on the assumption that ordered sections are present in the arrangement of chain segments with a quasi-crystalline structure.^{150, 151} A characteristic feature of the dependence of the most probable relaxation time τ of the dipole-segmental polarisation on temperature is the fact that the slope of the $\lg \tau = f(1/T)$ curve changes within a comparatively narrow temperature range where $T \gg T_g$. This 'liquid-liquid' type transition, observed in many polymers,¹⁵² apparently indicates the cooperative nature of the motion of the segments at $T > T_g$ and its loss above the transition temperature.

The presence of ordered structures has been observed by the light scattering method in vitreous poly(methyl methacrylate)¹⁵³ and by small angle X-ray diffraction in vitreous extended poly(methyl methacrylate), polystyrene, and poly(vinyl acetate).¹⁵⁴ The density of the ordered sections is found to be close to that of the crystal.¹⁵³ Order among the chains in the amorphous regions of linear polyethylene can be observed by pulse ^2H NMR.¹⁵⁵

The idea that highly dense fluctuations (clusters) occur in amorphous polymers served as the basis of the cluster model of the structure of vitreous bodies and of the vitrification process.^{155–157}

A survey of experimental data on the structures of flexible-chain polymers in the amorphous state permitted the conclusion that the appearance of local order is a characteristic feature of the structures of amorphous polymers in the melt.^{158, 159} The approximate agreement between the experimental curve for neutron scattering by deuterated polymer chains and the theoretical curve calculated on the basis of the Gaussian model^{16, 18} does not conflict with the idea that small sections with an ordered arrangement of the segments are present subject to the condition that the distribution of such sections within a macromolecular coil is Gaussian. This claim appears entirely reasonable, particularly since experiment has shown that even strong local interactions, such as chemical cross-linking, do not give rise to an appreciable disturbance of the conformational state of the molecule as a whole.¹⁴ However, this view is not generally accepted and the question of the structures of amorphous polymers remains controversial.^{160–164}

At the same time the existence of local order in a whole series of polymers is unquestionable. For example, complementary syndiotactic sequences of one poly(methyl methacrylate) chain form stable stereocomplexes with isotactic sequences of another chain, which are so strong that this leads to the appearance of

strong physical network nodes,¹⁶⁵ although the bond energy corresponding to each interacting atomic group is only several kJ mol⁻¹.

We may note that the probability P_n of the formation of a complex of n linked groups (of a n -block) is significantly greater than the probability of its formation from isolated groups.¹⁶⁶ Indeed elementary calculation has shown that in the former case $P_n = 1 - (1 - \alpha)^n$, where α is the probability of the formation of a single bond (the complex exists so long as at least one bond remains unbroken), while in the latter case $P_n = \alpha^n$ (the complex exists provided that all n bonds have been formed). Since $\alpha < 1$, the difference is evident.

Similar stereocomplexes arise between the macromolecules of atactic polystyrene.¹⁶⁷ Solvent molecules may participate in their formation, which leads to the formation of thermoreversible gels in 'good' solvents. The structure of these complexes resembles that of a liquid crystal and their fusion is manifested as a temperature transition on differential thermal analysis curves. The temperature transitions in emulsion poly(vinyl chloride) above the glass transition temperature are apparently of a similar nature.¹⁶⁸ Sequences of stereoregular units participate in the establishment of local order, which gives rise to the appearance on the X-ray diffraction patterns of reflections corresponding to a degree of crystallinity of the order of several per cent.¹⁶⁹

The formation of regions with local order in atactic polymers is a special case of the crystallisation of copolymers. As mentioned in a monograph,¹⁷⁰ chemically identical but isomeric units impart a distinct copolymeric character to the crystallisation behaviour of the macromolecule. For this reason, when the crystallisation temperatures of the components of a copolymer or of the isomers of a homopolymer differ sufficiently, then in the range between the melting points of the individual components the units of the higher-melting component exhibit a tendency towards ordering and hence towards the formation of a physical network. The degree of ideality of the crystal structure depends on the ability of the units of the copolymers to become arranged in the form of blocks.¹⁷¹ The possibility of regulating the mechanical properties of the polymer over a wide range appears in this instance. In particular, it has been shown¹⁷² that the thermoviscoelastic properties of ethene-propene polymers can be deliberately varied by altering the diameters of the nodes of the physical network formed by the microcrystallites of the ethene blocks.

The stability of the physical nodes and the mechanical behaviour of the system depend on the degree of local order and on the ideality of the local structure, which may consist of a wide range of formations — from fluctuation regions of the liquid crystal type up to fully regular microcrystallites. The temperature-time conditions in the preparation of specimens influence in their turn the ideality of the local structure and hence are capable of altering the relaxation characteristics of the physical network.¹⁷³

4. Fluctuation inhomogeneity and microphase separation

The inhomogeneity of the supermolecular structure of polymers, understood in a broad sense, is an evident consequence of the molecular inhomogeneity of the polymers and copolymers themselves, arising in the stage involving their synthesis, modification, and cross-linking. First of all, the inhomogeneity is manifested as density and molecular mobility fluctuations, which is recorded by various structure-sensitive methods.^{132, 174–179} Microinhomogeneity can arise also in the stage involving the segregation of polymers as a consequence of the molecular mass distribution and spontaneous fractionation of the macromolecules on coagulation of the latex.¹⁸⁰

Owing to the fluctuations in the concentration of the vulcanising agent, during the cross-linking of elastomers regions differing in the degree of cross-linking and hence in the mobility of their constituent chains appear. This can be detected, for example, by high-resolution ³C NMR.^{181, 182} It has been suggested¹⁸³ that the cooperative relaxation of such densely cross-linked microregions of a network polymer is one of the slowest processes. It may be

that similar processes have been observed in the study of polymer-oligomer blends:¹⁷⁹ according to pulse NMR data, a true equilibrium is established in such systems in the course of tens and perhaps hundreds of hours.

In those cases where the inhomogeneity is of fluctuation type and is not accompanied by microphase layer formation, the difference between the mobilities of chain sections belonging to different regions is small and the physical nodes produced have a comparatively low energy. Such inhomogeneities appear mainly in the form of small relaxation transitions on the temperature variations of the modulus and coefficient of mechanical losses.¹⁸⁴ The situation is different when one is dealing with block and graft copolymers.^{113, 114, 185} The vitreous or crystalline domains of rigid blocks formed as a result of microphase separation represent a kind of polyfunctional physical nodes. Their energy is sufficiently high for the systems to behave like cross-linked rubbers below the melting points of the rigid blocks. Despite the fact that block copolymers are as a rule two-phase systems, the concept of a physical network is apparently applicable to them. At any rate, this claim is valid for a low content of rigid blocks when they still do not form a continuous phase. This is indicated, in particular, by the fact that below the melting points of the rigid blocks such systems have the characteristic properties of an elastomer and the principle of the temperature-time superposition is applicable to them,¹⁸⁵ extending also to temperatures above the melting point of the rigid blocks. However, the rigid blocks must then be characterised by employing an intrinsic reduction temperature. Since the dimensions of the domain are small, it can be regarded, subject to certain assumptions, as a polyfunctional physical node.

The concept of a physical network is used also in the analysis of the mechanical behaviour of more complex systems of block-copolymeric ionomers.¹⁸⁶ These thermoelastoplastics have two physical networks. In weakly sulphurised three-block copolymers of the 'styrene-(ethene-butene copolymer)-styrene' type, one network is made up of rigid polystyrene domains and the other consists of ionic clusters distributed within the polystyrene blocks. An intrinsic temperature transition is characteristic of each network. It is noteworthy that, by virtue of their ability to associate, ionomers exhibit a very distinct tendency to form a physical network. Thus the interaction of butadiene-2-methyl-5-vinylpyridine copolymers with monohalides yields, for a vinylpyridine group content as low as 6%, a product with the properties of a thermoelastoplastic, namely a high strength and elasticity,²⁷ which has been attributed to the association of the ionised vinylpyridine groups to form ionic clusters.

At high concentrations of rigid blocks in block copolymers, the domains form a continuous vitreous polymer phase, whereupon the concept of a physical network loses its significance. This applies also to systems such as interpenetrating polymer networks (IPN),^{187, 188} although the theory of rubber elasticity may be used for the analysis of the network structure in the IPN formation stage.

5. Physical gels. Models of the formation of physical gels

The most important characteristic of elastomers with a physical network, which differentiates them qualitatively from locally homogeneous elastomeric systems, is the ability to form thermoreversible physical gels. The range of questions related to the formation, structure, and properties of physical gels is extremely wide. A series of detailed reviews and monographs have been devoted to various aspects of this problem.^{189–191} In the present section, we shall therefore confine ourselves to questions concerning mainly gels arising as a result of a local intermolecular interaction and which have a direct bearing on the topic of the present review.

There are various views on the causes of the transition of a polymer to a gel-like state. Thus Papkov's concept of gel formation¹⁹¹ is based on the idea of the formation of a gel solely in the region of phase separation, the completion of which is prevented by the high viscosity of the concentrated polymer phase. The gel must therefore be regarded as a nonequilibrium

two-phase system with incomplete layer formation. However, it is difficult to agree with this view. Thermoreversible gels may be formed also under equilibrium conditions. Furthermore, there are fairly numerous examples of the existence of homogeneous physical gels.¹⁹² It is well known that phase separation may occur in the course of the chemical cross-linking of the elastomer also in a thermodynamically good solvent (*v*-syneresis).^{22,70}

Thus gel formation is caused by a local interaction between the macromolecules and phase separation should be regarded as its consequence and not conversely. The gel formation process may be divided into two stages.¹⁹² In the first stage, the formation of weak bonds leads to the appearance of stable aggregates or 'swarms' of molecules.^{192,194} The second stage consists in the binding of the aggregates to one another in the course of their growth and in the formation of a three-dimensional structure. The appearance of hydrogen bonds between gelatin molecules may be the main cause of the formation of aggregates, but in gel formation the nodes are not local bonds but ordered chain sections linked by hydrogen bonds.¹⁹³ This mechanism apparently applies also to other biopolymers.¹⁹⁵

At the same time, there is a region where Papkov's concept of gel formation is fully applicable. In particular, this concerns gels with a nonequilibrium structure formed *via* the spinodal decomposition mechanism. It has been shown¹⁹⁶ that there is a definite solution concentration above which a continuous phase, typical for the spinodal decomposition mechanism, may arise. Spinodal decomposition which has not been brought to the stage involving the complete separation of the system into two coexisting phases may be the cause of the polymer solution setting to a gel. Examples of the application of the theory of spinodal decomposition to gel formation have been published.^{197–200} Thus, in aqueous solutions of poly(vinyl alcohol)¹⁹⁹ and in the poly(vinyl chloride)– γ -butyrolactone system,²⁰⁰ gels are formed in the early stages *via* the spinodal decomposition mechanism.

A special case of the formation of thermoreversible gels is phase separation of the 'liquid–crystal' type, which proceeds *via* a mechanism involving the creation and growth of nuclei. The microcrystallites formed may become the nodes of the physical network of the gel. For example, there are experimental data on the formation of a poly(vinyl chloride) gel with nodes in the form of microcrystallites.²⁰¹ At the same time, it is essential to note that crystallisation as such is not a necessary condition for the formation of a gel. In particular, poly(vinyl alcohol) in an aqueous glycerol mixture affords crystalline gels, whereas in ϵ -methylpyrrolidone it gives rise to amorphous gels.

Single-phase gels are formed as a result of the appearance of the nodes of a three-dimensional network under the conditions of local interactions of the macromolecules with one another. Thus the formation of gels has been noted in cellulose triacetate–nitromethane and cellulose diacetate–tetrachloroethane systems at room temperature.¹²⁶ In the first case, the three-dimensional network arises as a result of the dipole–dipole interactions between the acetate groups, whilst in the second it is a consequence of the formation of hydrogen bonds between the hydroxy-groups.

Interest in the problem of the formation of gels as a result of local intermolecular physical bonds arose after gels of atactic polystyrene were observed in carbon disulfide below room temperature.^{167,202–204} It was found that the heat of gel formation in such systems is from 6 to 26 kJ mol^{−1} which is much less than the heat of formation of isotactic polystyrene gels (113 kJ mol^{−1}), which are known to be crystalline. The nature of the bonds ensuring the formation of gels in these systems has not been fully elucidated. A characteristic feature of such gels is that they are formed also in 'good' (in the thermodynamic sense) solvents. There is a view that gel formation is caused by the appearance of stable stereocomplexes involving solvent molecules.^{167,204}

Another view on the gel formation mechanism in polystyrene solutions²⁰⁵ is that this transition is common to all atactic polymers and occurs as a result of the local 'fusion' of segment–segment contacts *via* the Frenkel' mechanism.⁵ The formation of

gels as a consequence of local intermolecular interaction has been demonstrated in relation to poly(butyl methacrylate).^{206,207} The network nodes in such gels consist of locally ordered regions in which 'suspended' butyl ester side groups participate. Comparison of the enthalpy of the physical cross-linking (37 kJ mol^{−1}) with the enthalpy of the intersegment contact (6 kJ mol^{−1}) shows that six segments participate simultaneously in the formation of a single cross-link. This transition has been recorded by dielectric spectroscopy also in the absence of a solvent.²⁰⁶

The formation of oligocarbamide gels in organic solvents is distinguished by interesting features.²⁰⁸ Whereas the acceleration of the formation process on reduction of temperature is characteristic of other thermoreversible gels, in the given instance acceleration takes place when the temperature is increased. This is explained by the fact that the parallel arrangement of the molecules, treated as rigid rods the required increased mobility of which is attained at temperatures close to T_m , is the decisive stage of the process. In this case, the gel formation process is characterised by the competition between the decrease in the number of physical cross-links with increase in temperature and the appearance of new bonds as a consequence of a more ideal molecular packing.

Analysis showed that in most cases the gel formation process is based, regardless of the phase state, on intermolecular interactions promoting the appearance of a three-dimensional network structure. Many studies have been devoted to polymer gels as networks with nodes of a physical nature.^{209–215} Particular attention was then turned to the nature of the node (microcrystal, another microphase formation, cluster comprising chain sections, *etc.*),^{209,210} its functionality,^{211,212} and the thermodynamics and kinetics of the formation of physical network nodes.^{213–215}

Ferry was one of the first to attempt a theoretical description of the formation of a physical gel.²¹⁶ He began with the analogy between the formation of three-dimensional physical and chemical networks. The Flory–Stockmayer theory was applied to thermoreversible gels.² Assuming that the formation of an infinite three-dimensional network requires the formation of 1–2 bonds per macromolecule, Ferry showed (in good agreement with experiment¹⁹³) that the critical concentration for the formation of a gelatin gel is 1%. A relation between the melting point of the gel and its concentration c was found:²¹⁷

$$\ln c = -\frac{\Delta H}{RT} + \text{const}, \quad (4)$$

where ΔH is the enthalpy of formation of a bond in the gel network and T_m is the melting point.

This relation agrees well with experimental data for gelatin gels, but in the case of readily crystallising gels the relation between the melting point and the concentration is described better by the equation²

$$\frac{1}{T_m} = \frac{1}{T_{m0}} + \frac{R}{\Delta H} (V_1 - k_1 v_1^2) \frac{V_0}{V_1}, \quad (5)$$

where T_m and T_{m0} are the melting points of the polymer in the presence and absence of a solvent respectively, k_1 is the interaction parameter, V_1 and v_1 are the molar volume and the volume fraction of the solvent respectively, and V_0 is the volume of the monomer repeat unit.

A theory has been proposed for the description of the sol–gel transition.²¹⁸ Its essence is as follows. The free energy of the polymer–solvent system is represented by the sum of two terms: $F = F_h + F_b$, where F_h and F_b are the free energies of mixing and formation of the nodes respectively. The critical gel formation concentration is calculated with the aid of the Flory–Stockmayer criterion:

$$\varphi = \frac{1 + \exp(-kT\Delta F_b)}{lf^2}, \quad (6)$$

where l is the number of freely jointed segments in the polymer chain and f is the fraction of segments capable of forming a physical node.

The theoretical curve for the sol–gel transition, calculated from the equation presented, as well as the phase diagram plotted on the basis of the equation of state agree well with experimental data for gelatin gels.

The majority of modern theories of the formation of thermoreversible gels are based on the Flory–Rehner theory of the swelling of polymer networks,² according to which the free energy of the swollen network is represented by the sum of the free energy of mixing of the monomer with the solvent and the elastic energy of the network. According to this theory, the swelling pressure of the gel may be described by the equation

$$P = -\frac{RT}{V_1} [\ln(1 - v_2) + v_2 + \chi v_2^2] - \sigma_v(v_2), \quad (7)$$

where V_1 is the molar volume of the solvent, v_2 the volume fraction of the polymer in the swollen gel, χ the polymer–solvent interaction parameter, and $\sigma_v(v_2)$ the volume modulus of elasticity.

Eqn (7) does not describe by itself the formation of a physical gel. Analysis of experimental data on the swelling of gel-forming polymers led to the conclusion²¹⁹ that the phase transition and the collapse of the physical gel may be described if the interaction parameter χ in Eqn (7) is assumed to depend on v_2 :

$$\chi = \chi_1 + \chi_2 v_2 + \chi_3 v_2^2 + \dots,$$

where χ_i are experimentally determined coefficients. In particular, $\chi = 0.505 + 0.37 v_2 + 0.29 v_2^2$ for a solution of polystyrene in cyclohexane. The postulate that the interaction parameter χ be expressed as a function of v_2 had been put forward also earlier.²²⁰ However, on the whole the above theory must be regarded, despite its qualitative agreement with experimental data on the swelling and phase separation in physical gels, as semiempirical.

Tanaka's theory appears to be logically more complete.^{221, 222} It considers a solution of a polymer each unit of which is capable of forming a physical bond with a unit of another molecule. The polydisperse molecular aggregate arising as a result of the interaction is called a cluster. The free energy of the system consists of the Flory–Huggins free energy of mixing ΔF_{mix} and the free energy of formation of the clusters F_{cl} :

$$F = F_{\text{cl}} + \Delta F_{\text{mix}}, \quad (8)$$

$$F_{\text{cl}} = \sum_{m=1}^{\infty} N_m \mu_m^0, \quad (9)$$

where N_m is the number of clusters in which m molecules are bound and μ_m^0 is the chemical potential of the cluster.

By employing the standard Flory – Huggins procedure for a lattice model, Tanaka calculated the distribution with respect to the number of clusters and obtained an expression for the chemical potential of the solvent. The phase diagram of the system is qualitatively consistent with the experimental data for atactic polystyrene gels.

As a development of the above approach, the case where the gel is formed as a result not only of pair interactions but also as a result of the simultaneous interaction of the segments of several molecules was examined.²²³ This permitted a better description of the weak dependence of the critical gel formation concentration on the molecular mass.

The next step was the formulation of a theory, by Khokhlov,²²⁴ of the swelling of polymer networks in a large amount of solvent, taking into account long range interactions. It was suggested that the free energy of a defect-free network be described by the following expression:

$$F = \frac{NT}{m} \left[\frac{dx^2 + dy^2 + dz^2 - 3}{2} - \frac{2}{f} \ln(dx dy dz) \right] +$$

$$+ NT \left[\frac{Bn_0}{dx dy dz} + \frac{Cn_0}{dx^2 dy^2 dz^2} \right], \quad (10)$$

where N is the total number of units in the network, m the average number of units in the chain between two neighbouring branching points, n_0 the average concentration of the polymer under the initial (θ -state) conditions, B and C are the second and third virial coefficients for the interaction of monomer units, f is the functionality of the branching points, and dx , dy , and dz are the relative deformations of the network along the x , y , and z axes compared with the state at the start of the readings.

The first term describes the free energy of the deformation of the network and the second the free energy of the interaction of the monomer units. In essence, this formula differs from the corresponding formula in Flory's classical theory only by the choice of the start of the readings: here the θ -state was selected as the initial state, whereas in Flory's theory the state of the network in the absence of a solvent is assumed to be the initial state.

Within the framework of Khokhlov's theory, an explanation was obtained for the phenomenon of the collapse of polymer networks, first observed experimentally in 1978 in relation to polyacrylamide gels swelling in an acetone–water mixture.²²⁵ This phenomenon consists in a sharp, frequently abrupt, decrease in the size of the specimen on reducing the temperature or on improving the quality of the solvent. Analysis of the collapse of uncharged networks²²⁵ has shown that it is a consequence of a coil–globule transition in the subchains constituting the network. Such a transition may be both a discrete jump (if the chains are sufficiently rigid or if the specimen is subjected to uniaxial extension) or it may be continuous but extremely sharp.

Experimental and theoretical studies of the collapse phenomenon were developed further.^{226–233} Examination of the elastic properties of swollen polymer networks led to the conclusion that the extension of collapsed networks can induce their transition to the swollen state.²³⁴ An expression was obtained for the stress in a swollen deformed network:

$$\tau = \frac{n_0 T}{m} \left(\sigma - \frac{\alpha^2}{\sigma} \right), \quad (11)$$

where σ is the relative deformation along the z axis and α the relative deformation along the x and y axes.

On slow extension, a jump is observed in the $t(\sigma)$ relation. An experimental test showed,²³⁵ that, for a certain solvent composition and temperature, the gel sucks in spontaneously an enormous amount of the solvent during the extension process and that in an uncharged gel the dependence of the degree of swelling on the applied stress is continuous, whereas in a charged gel the transition to the swollen state takes place abruptly.

6. The properties of polymers in the presence of an effective intermolecular interaction

As already stated above, the deformation of polymer systems does not alter the internal energy if the only type of intermolecular interaction is repulsion due to the mutual in penetrability of the chains. Other types of intermolecular interaction may induce a change in the internal energy on deformation.

In the simplest case, the intermolecular interaction potential may be represented as the sum of the potentials of the central and orientation interactions. The orientation interaction potential is then described by the expression²³⁶

$$P(v) = \frac{B}{2} (3 \cos^2 v - 1), \quad (12)$$

where v is the angle between the directions of the interacting segments and B is a constant.

The interaction of segments of this type can be most simply taken into account by the average field method.²³⁷ The expression obtained for the corresponding elastic potential has the form of a

series in powers of N^{-1} . Calculations have shown²³⁸ that the deviations from the predictions of the theory of entropic elasticity for not unduly open networks can be explained precisely by orientation effects. A quantitative procedure for the determination of the parameters of the orientation of elastomers using the wide angle scattering of X-rays has been proposed.²³⁹ An approach which makes it possible to estimate the contribution of the intermolecular interaction to the relation between orientation and deformation was developed in the same study. Apart from the traditional double refraction method, pulse NMR²⁴⁰ and ^1H NMR (molecular probe spectroscopy)^{241, 242} are also used to estimate the degree of orientation order. An important feature of the orientation order on extension is the orientation phase transition of the liquid crystal type induced by the extension.^{243–249}

In contrast to the orientation interaction, local intermolecular interactions of the physical network type are disrupted in the deformation process. The relaxation of stress in deformed elastomers has been accounted for^{102, 250, 251} by the disruption process and subsequent rearrangement of the physical network. It was assumed that the dependence of the lifetime of a physical node on the stress is described by the familiar Zhurkov disruption law.

A simple mathematical model, based on the physical network concept, which makes it possible to describe qualitatively a wide class of phenomena, including equilibrium and non equilibrium properties, has been proposed.^{247, 248} It is assumed that the concentration of physical nodes diminishes exponentially in the deformed state:

$$v = v_e + (v_0 - v_e) \exp(-kt), \quad (13)$$

where v_0 and v_e are the initial and equilibrium concentrations of the physical nodes. The constant k is expressed by Eyring's procedure taking into account the force due to the deformation of the chains. In this sense, the approach is close to Bartenev's idea, because Eyring's equation may serve as a formal justification of Zhurkov's equation.

Despite the semiempirical nature of the model described, the results obtained with its aid agree well qualitatively with a whole series of experimental facts.

A more rigorous model²⁴⁹ describes the influence of the rearrangement the physical network in a chemically cross-linked elastomer on its equilibrium elasticity and mechanical losses. This model presupposes that the chains contain singular points, between which operate attractive forces with a small radius of action. The calculation of partition functions taking into account additional approximations, associated with the low concentrations of the interacting points, yields the following expression for the stress tensor:

$$\sigma_{kn} = \sigma_{kn}^{(0)} + \frac{3kT}{V} \sum_{i < j} W_{ij} \frac{r_{ijk}^0 r_{ijn}^0}{b_{ij}^2}, \quad (14)$$

where $\sigma_{kn}^{(0)}$ is the stress tensor of the Gaussian network in the absence of physical bonds, r_{ijk}^0 are components of the radius-vector between the i th and j th points in the Gaussian network in the absence of interaction, b_{ij}^2 is the square of the deviation, averaged over the network, of the reciprocal radius-vectors of the interacting points from their positions in the network without interaction, and W_{ij} is the probability of entanglement between the i th and j th points:

$$W_{ij} = q \frac{P_{ij}}{1 + qP_{ij}}, \quad (15)$$

where P_{ij} is the Gaussian distribution of the radius-vectors and q is a characteristic of the intensity of the interaction.

Analysis of Eqn (14) for uniaxial deformation showed that the model examined describes qualitatively the known deviations of the experimental relations from the predictions of the classical theory of rubber elasticity.

IV. Thermodynamic model of the deformation of elastomers in the presence of a physical network

As shown above, ideas concerning the physical network are widely used for the qualitative explanation of the processes associated with the alteration of the supermolecular organisation of polymers due to intermolecular interaction. Here the intermolecular interaction is modelled by physical nodes — formations similar to chemical cross-links but with such a low disruption energy that they can be disrupted and reformed as a result of thermal motion. The average concentration of such nodes may vary during the deformation of the specimen, in contrast to chemical nodes.

In the rubber-elastic state, such systems have specific properties determined, on the one hand, by the presence of entropic elasticity and, on the other hand, by the possibility of a change in the parameters of the equation for rubber elasticity on deformation. The existence of quasi-equilibrium rubber elasticity in systems with a physical network constitutes a most important experimental fact, indicating the occurrence in the systems of at least two kinds of fluctuations of the thermodynamic parameters with different time scales.

The first short-term type of fluctuations corresponds to the establishment of equilibrium in the chains constituting the physical network; the second, long-term type of fluctuations is associated with the rearrangement of the physical network itself. The marked difference between the time scales of thermal fluctuations makes it possible to employ a two-level thermodynamic model for a qualitative analysis of the behaviour of such a system.

Knowing the thermodynamic characteristics of the two-level system, it is possible to determine the thermodynamic properties of this system for constant values of the parameters of the second level and when additional information is available about the second level. One can also take into account the process involving the rearrangement of the supermolecular organisation, provided that the thermodynamic properties of the system with a constant supermolecular structure are known.

Such an approach constitutes the basis of the thermodynamic model of the deformation of polymers developed by the authors of the present review.^{252–261}

1. A two-level model of the physical network

In the formulation of the problem of the deformation of a polymer system, a logical difficulty arises, associated with the fact that the deformation of the physical network may entail not only a change in the concentration of the physical nodes but also a rearrangement of the network at constant concentration. If there are no chemical nodes, a change in the size of the undeformed specimen, *i.e.* plastic deformation, is observed. The components of the specimen deformation tensor cannot therefore play the role of external parameters in this instance.

When the state of a physical network is examined in terms of equilibrium statistical thermodynamics, it is postulated that the deformation of the physical network chains remains constant regardless of the way in which the deformation of the specimen varies under these conditions.

However, it is natural to suppose that when extension from the undeformed state takes place over a period sufficiently short compared with the characteristic times of the rearrangement of the network, then the chain deformation parameters actually coincide with the specimen deformation parameters. The justification of this hypothesis follows from the following simple considerations. The rearrangement of the physical network results in a nonaffine migration of the centres of mass of the macromolecules, compared with the deformation of the specimen as a whole. By virtue of the close packing and the mutual impermeability of the chains, the latter occurs as a result of reptation, the characteristic time of which is known to exceed greatly the time required to attain conformational equilibrium.⁶⁵ Thus, if the lifetime of the physical node is short and the rate of extension is

fairly high, then the equilibrium concentration of the nodes is established for a specified deformation of the chains, which differs little from the deformation of the specimen.

When elastomers contain both chemical and physical nodes, the processes involved in the rearrangement are 'frozen' by the chemical network, as a result of which the chain and specimen deformation parameters must be regarded as identical.

These hypotheses made it possible to obtain an expression for the free energy of a deformed network with a constant number of nodes and also expressions for the average number of nodes of the i th type (having an energy E_i) and an arbitrary stress.

The concentration of nodes g is defined by the following equation:^{252, 259, 261}

$$g = nY(D) = n \frac{D \exp D - \exp D + 1}{(\exp D - 1)^2}, \quad (16)$$

where n is the maximum possible concentration of physical nodes and

$$D = \frac{\Delta E}{kT}. \quad (17)$$

Here ΔE is the free energy of formation of a node, including also the free energy $\psi(\lambda)$ of the deformation of the chains attached to the given node.

The form of the $Y(D)$ relation is illustrated in Fig. 4. Evidently the fastest decrease in the concentration of nodes occurs within a narrow region near $D = 0$, i.e. when the free energy of the deformed chains and the energy required to disrupt a node are equal. This condition determines the characteristic temperature of the disruption of nodes for a given deformation and the characteristic deformation on disruption at a given temperature.

The conventional stress is described by the equation

$$\sigma(\lambda) = 2nY(D) \frac{d\psi(\lambda)}{d\lambda}. \quad (18)$$

The qualitative form of this relation for a network without chemical nodes is shown in Fig. 5 (curve 1). The point λ_0 , at which the stress decreases rapidly, corresponds to the condition $D = 0$ in Fig. 4.

The curve $\sigma(\lambda)$ corresponding to equilibrium conditions has an extremum and bounds the region of the permissible non-equilibrium states of the system for which

$$\sigma > \frac{d\psi}{d\lambda}.$$

In other words, the specimen can exist only in states which correspond to points which are not located below curve 1 in Fig. 5. The boundary points on the ascending section of the curve then refer to equilibrium states and those on the section of the curve with $\lambda > \lambda_k$ refer to pseudoequilibrium states.

Figure 4. The form of the function $Y(D)$ [Eqn (16)].

Figure 5. Dependence of σ on λ for noncross-linked (1) and cross-linked (2) polymers (for the explanation, see text).

As can be seen from the figure, the region of permissible states for a specified stress consist of two sections: $[1, \lambda_1]$ and $[\lambda_2, \infty]$. In the absence of thermodynamic fluctuations, the deformation process would end with transition to the equilibrium state λ_1 , since the transition to the non equilibrium region $[\lambda_2, \infty]$ requires that an energy barrier be overcome. However, by virtue of the fluctuations, small fragments of the medium can receive an amount of heat sufficient for transition to the state λ_2 , which leads to irreversible deformation. If the relaxation time of the material to the equilibrium state λ_1 is short compared with the characteristic lifetime of the fluctuations, then in the course of a certain period the specimen is in a state close to equilibrium with a deformation λ_1 and possesses virtually irreversible elasticity. On the other hand, if the external stress exceeds the value corresponding to the maximum on the curve ($\sigma > \sigma_k$), then plastic deformation arises immediately after the application of a load.

Thus the equilibrium theory makes it possible to separate two qualitatively different levels of loads for an elastomer in which there is a physical network. At the first level, for $\sigma < \sigma_k$, there is a possibility of quasi-equilibrium elasticity, while at the second, for $\sigma > \sigma_k$, the disruption of the physical network begins immediately during the deformation process. This feature has become the basis of a method for the determination of the thermodynamic parameters of the physical network nodes from the temperature dependence of their concentration. The concentration of the nodes is calculated from the quasi-equilibrium stress for $\sigma < \sigma_k$, found in experiments on extension at a constant rate or in experiments involving the measurement of creep.

This method has been used in the study of the deformation of elastomers of two classes differing in the mechanism of the formation of physical nodes. The elastomers of the first class consisted of copolymers with functional groups capable of forming fairly strong intermolecular hydrogen bonds.^{259, 261, 262} The objects of study were poly(nonyl acrylate) and its copolymers with acrylamide.²⁶³ The possibility of the formation of physical network nodes in these polymers is attained as a result of the formation of strong hydrogen bonds between the acrylamide or acrylic acid units.

Stereoregular polybutadiene, in which physical network nodes may be formed as a result of the interaction of complementary sequences of stereoregular units, is a representative of elastomers of the second class. Noncross-linked industrial stereoregular SKD polybutadiene and a rubber cross-linked with tetramethylthiuram disulfide were chosen for study.^{257, 261, 264} Acrylamide copolymers were tested under creptation conditions, acrylic acid copolymers were tested in a stress relaxation regime and a regime with extension at a constant rate, while polybutadiene copolymers were tested in a regime 'extension at a constant rate—relaxation at temperatures from -40 to 160 °C'.

It was established that, as the concentration of functional groups increases, there is some increase in the energy of the

physical node due to the change in the nature of the distribution of the functional groups in the chain. Studies by the ^{13}C NMR method showed that the probability of the formation of blocks increases with increase in concentration. The energy of the physical nodes also increases after the additional chemical cross-linking of the elastomer. It was found by ^{13}C NMR relaxometry that this is induced by the decrease in the mobility of fragments of the polymer chains.

An anomalous deformation behaviour is characteristic of elastomers with a physical network: when they are extended at a constant rate, the increase in deformation is sharply retarded after the attainment of a certain deformation up to its complete cessation. In certain cases, the stress can actually fall. In this region, the initial structure is disrupted, which is accompanied by a series of effects such as the appearance of turbidity, a decrease in the Poisson coefficient and the formation of a 'neck', and the appearance of 'string'. On further extension, the stress begins to increase so long as the specimen does not disintegrate, provided that a sufficient number of chains bound in a network retained in the elastomer.

In the presence of chemical nodes, the equation for a conventional stress in the physical network assumes the form

$$\sigma = 2 [nY(D) + n_{\text{chem}}] \frac{d\psi}{d\lambda}, \quad (19)$$

where n_{chem} is the concentration of chemical network nodes.

As can be seen from Fig. 5 (curve 2), the deformation curve has two extrema — a maximum and a minimum. This means that in a certain region two stable states may arise with deformations λ_1 and λ_2 and one pseudo-equilibrium state with a deformation λ_0 for identical values of the conventional stress. Consequently, under these conditions there is a possibility of the separation of the system into regions with different concentrations of the physical nodes and with different degrees of deformation, which is characteristic of a first-order phase transition.

The phase separation arising on deformation of an elastomer with a physical network may explain the characteristic form of the relation $\sigma(\lambda)$ for such systems under the conditions of extension at a constant rate. The section corresponding to a retarded growth of stress on the experimental curves may be compared with the section of the theoretical relation $\sigma(\lambda)$ located between points λ_1 and λ_2 , on which a constant stress should be retained as a consequence of the phase separation on equilibrium deformation.

Under real conditions at a constant rate of deformation, phase separation does not go to completion. For this reason, only a retardation of the growth of stress and not the attainment of a plateau are observed on the experimental curves in most cases. Nevertheless, the observation of the deformation-induced separation into layers with formation of 'string' or a 'neck' in many real polymers in the region corresponding to the section $\lambda_1 < \lambda_0 < \lambda_2$ in Fig. 5 is evidence in support of the validity of the approach under discussion. Furthermore, it is apparently possible to draw an analogy between the deformation-induced separation and the well known phenomenon of the forced elasticity of vitreous polymers. A vitreous polymer can be regarded in a certain sense as a dense-network polymer with physical nodes, because the mobility of chain elements not exceeding in size the kinetic segment is retained below the glass transition temperature. These short chains, whose length corresponds to several units, possess mainly energetic and not entropic elasticity. At the same time, it is quite possible to select for them an expression describing the potential $\psi(\lambda)$. Since it has been shown that the specific form of the potential is unimportant, the relation illustrated in Fig. 5 is qualitatively preserved. The role of the chemical network can be assumed in this case by the network of entanglements, the lifetime of which exceeds by a large factor the lifetime of the low-energy physical nodes constituting the quasi-network of the vitreous polymer. The condition $n > n_{\text{chem}}$ is then known to hold.

The phenomenon of forced elasticity is best illustrated by the deformation-induced layer formation effect. In the first place, the

deformation curve itself, corresponding to forced elasticity, has a distinct horizontal section and sometimes even a bend,^{265, 266} which is fully consistent with Fig. 5. The reversibility of forced elasticity also fits well within the theoretical framework. Finally, the appearance on the $\lambda_1 < \lambda_0 < \lambda_2$ section of 'silver' cracks, which are not cracks in the usual sense but represent layered microregions in the polymer, is also consistent with the concept of deformation-induced separation. In the 'silver' cracks, there is a loosened material with extended chains and a deformation λ_2 , which actually represents a new phase. The chains of the remaining material belong to another phase with a deformation λ_1 . In the course of the cold drawing process, the phase volumes virtually undergo a redistribution: the fraction of the material with the deformation λ_1 diminishes and that of the material with the deformation λ_2 increases. This process continues until the 'neck' has grown by the overall length of the specimen; the phase with the deformation λ_1 then vanishes. Next follows a process in which the chain deformation in the oriented phase increases. The deformation remains fully reversible and, after heating, the specimen again assumes its initial shape.

Naturally, forced elasticity is strictly speaking a nonequilibrium process and all the considerations quoted above must be regarded not as a rigorous theoretical justification but only as an analogy. At the same time, the possibility of an adequate description of the observed phenomena with the aid of this type of extension of the equilibrium theory indicates that it is entirely reasonable.

2. The form of the thermomechanical curve in the region of the rubber elasticity plateau

The proposed equilibrium theory of the deformation of elastomers has served as the basis of the description of thermomechanical curves for linear polymers in the temperature range $T > T_g$.²⁶⁷

The thermomechanical curves for polymers are traditionally analysed on the basis of the concept of a spectrum of relaxation times and their temperature dependence.^{251, 268} An important relation, namely the Williams–Lundell–Ferry (WLF) formula, is actually based on this. The relation between the extent of the rubber elasticity plateau (the temperature range between the glass transition temperature T_g and the flow temperature T_f) and the molecular mass, first obtained by Kargin and Slonimskii²⁶⁹ as early as 1948, can also be accounted for on the basis of a fairly simple model of the relaxation of polymer chains. However, this approach has not so far made it possible to interpret even qualitatively the influence of the molecular mass distribution (MMD) on the form of the thermomechanical curve.^{270, 271} When the WLF equation is used, the temperature dependences of the rates of deformation of polymers with any MMD are of the same kind and the thermomechanical curves differ only in the derivative of deformation, which depends on the average molecular mass.²⁶⁷ Indeed, it has come to be assumed²⁶⁸ that the viscosity of polymer solutions and melts depends on the weight-average molecular mass (or even the molecular mass averaged with respect to higher MMD moments). At the same time, experiment shows that the difference between the deformation curves of polymers with different MMD is qualitative.²⁶⁷

The concept of a network of physical nodes has been used²⁶⁷ for an adequate description of the temperature dependence of the deformation of the polymer in the region of the transition from vitrification to flow.

The theory of the relation between the molecular mass of the polymer and T_f has been based on the dependence of the viscosity on the molecular mass.²⁷² The start of the increase in the derivative of deformation as a function of temperature ($d\varepsilon/dT$) is believed to be a characteristic indication of the transition from the rubber-elastic to the viscofluid state. The application of this feature to a network of physical bonds leads to the conclusion that the increased $d\varepsilon/dT$ is caused by the sharp diminution of the network modulus induced by the disruption of its nodes as a consequence of a rise in temperature. The flow of a polymer

system (at a definite rate of application of a load) begins when the cross-linking index becomes 1.

According to Eqn (16), the concentration of the physical network nodes in the polymer system depends on temperature and the applied force. If the number of nodes is referred to the number of chains N and account is also taken of the fact that the breakdown of the network occurs for fairly large values of D in absolute magnitude, then we obtain the following expression for the critical cross-linking index with respect to physical nodes, *i.e.* for the criterion of the transition to flow:

$$\ln M = D. \quad (20)$$

Bearing in mind that the flow temperature T_f is the same as the glass transition temperature T_g when the molecular mass of the chain is equal to the mass of the segment M_0 , we obtain from Eqns (17) and (20)

$$\ln M = \ln M_0 + \frac{\Delta E}{RT_g} \frac{X}{1+X}, \quad (21)$$

where

$$X = \frac{T_f - T_g}{T_g}.$$

We may recall that the energy term in Eqn (21) takes into account also the intensity and duration of the application of a force to the system. Thus the equation obtained makes it possible to analyse the relation between the temperature of the transition of the system to the viscofluid state, the nature of the load applied to it, and the molecular mass of the polymer.

The relation between the flow temperature and the molecular mass for a series of polymers in terms of the variables of Eqn (21) is presented in Fig. 6. Evidently the equation describes satisfactorily the experimental data. The intercept on the ordinate axis slightly depends on the nature of the polymer (polybutadiene, polyurethanes, polyacrylonitrile) and is close to 3. This means that the molecular mass of the chain section between the physical network nodes is approximately the same and equal to the value for the Kuhn segment in the vicinity of the glass transition temperature of any polymer.^{74, 273} This conclusion is fully consistent with the physical significance of the α -transition: the segmental motion of polymer chains ceases to be inhibited when the length of the chain section between the nodes of the network of physical bonds becomes greater than the Kuhn segment. At the same time the multiplier

$$A \approx \frac{\Delta E}{RT_g}$$

Figure 6. Relation between the flow temperature and the molecular masses of linear polymers in terms of the variables of Eqn (21): (1) polybutadiene; (2) and (3) polyurethanes with different structures; (4) polystyrene.

in Eqn (21) proves to be constant^{272, 273} and almost independent of the type of polymer (the glass transition temperature): $A \approx 17$. Thus Eqn (21) is universal.

Figure 7 presents thermomechanical curves for polybutadienes with different polydispersity parameters.²⁶⁷ Evidently the temperature dependence of the deformation is extremely sensitive to the nature of the MMD. In conformity with the considerations presented above, an increase in temperature induces a decrease in the cross-linking index of the polymer chains and an increase in the fraction of elastically inactive chains of the physical network and in the sol fraction. If the system consists of chains with one length only, then the gel–sol transition occurs at the flow temper-

Figure 7. Thermomechanical (dilatometric) curves for polybutadienes with different polydispersities characterised by $M_w/M_n = 1.24$ (1), 3.50 (2), and 9.50 (3). $M_n = 1.45 \times 10^5$.

ature T_f . In this case, the dependence of the proportion of the sol fraction (more precisely of the fraction of elastically inactive chains) ϕ on temperature can be conveniently described using the Dirac δ -function, the integral of which is zero for negative values of the argument and unity for $T - T_f > 0$. Taking this factor into account in the case of a polymer consisting of a set of polymer chains characterised by a distribution function $\omega(M)$, the temperature dependence of the fraction of the elastically active chains ϕ can be described by the equation

$$\phi(T) = \int_0^{\infty} \omega(M) dM \int_{-\infty}^{\Delta M} \delta(t) dt, \quad (22)$$

where $\Delta M = T - T_f(M)$.

The function $\phi(T)$ varies from 0 for $T < T_f$ in the lowest-molecular-mass fraction in the given polymer system to 1 for T_f in the highest-molecular-mass fraction. Thus $\phi(T)$ is an integral function of the MMD when it is constructed not in terms of temperature but in terms of the corresponding molecular masses. We may recall that the relation between temperature and molecular mass is defined by condition (21). Accordingly, the derivative $d\phi(T)/dT$ becomes a differential function of the MMD.

Eqn (22) makes it possible to relate the MMD function to the thermomechanical curve for the polymer if the model is based on the concept of a network of physical bonds. This relation can be formulated in the simplest case as the equation

$$\frac{d\varepsilon}{dt} = \frac{\sigma - [1 - \phi(T)]E\varepsilon}{\eta} \quad (23)$$

or, when account is taken of the linear increase in temperature as a function time,

$$\frac{d\varepsilon}{dt} = \frac{\sigma - [1 - \varphi(T)]E\varepsilon}{\eta q} = \frac{\sigma/E - [1 - \varphi(T)]\varepsilon}{\tau q}, \quad (24)$$

where ε is the deformation, σ the stress, E the modulus of a hypothetical polymer with an infinitely large molecular mass, η the viscosity, $\tau = \eta/E$ the relaxation time, and q the rate of scanning the temperature.

So long as $\varphi(T) < 1$, the deformation occurs in a stationary regime, provided that its rate is sufficiently low. On the other hand, if the rate of deformation is high, a deformation-induced inhomogeneity of the system arises, as mentioned above, which requires a more complex analysis.

Thus the stationary deformation ε_{st} is a measure of the change in the quantity $\varphi(T)$, which increases with increase in temperature:

$$\varepsilon_{st} = \frac{\sigma}{E[1 - \varphi(T)]}. \quad (25)$$

As soon as $\varphi(T)$ reaches unity, the increase in deformation begins to be determined by the differential equation (24), in which the part of the second term enclosed in brackets is 0. At this instant, the decisive factor becomes the temperature dependence of the relaxation time (viscosity) of the system. Thus Eqn (25) establishes a direct relation between the deformation of the polymer system and the integral MMD function $\varphi(T)$.

This conclusion is illustrated by the experimental data in Refs 267 and 275. The approach described made it possible to put forward a method for the determination of the MMD based on the analysis of the temperature variation of the deformation of polymers in the region of the rubber elasticity plateau.²⁷⁵

V. Conclusion

As shown by numerous studies on the structures and properties of polymer systems, a very broad spectrum of intermolecular interactions, ranging from a weak dispersion interaction to a strong dipole–dipole interaction, may be manifested in them. A feature especially characteristic of polymers is that the interaction may involve a fairly large number of bonds (chain units). The presence of long chains predetermines the possibility of the formation of a network of physical bonds, which is reflected in most diverse ways in the properties of polymers.

The physical network model is applicable to the description of the properties not only of systems in which the nodes are formed via hydrogen bonds or a dipole–dipole interaction but also of the properties of crystallising polymers in the rubber-elastic state and also polymers with a complex phase structure, where very dense fluctuations (clusters) may play the role of the microphase. All these formations may serve as physical nodes. Thus the physical network model is in essence applicable to any polymers and polymer systems.

As in any model approach, certain properties of the system are in this instance treated as absolute, their role is over estimated, and other properties are not taken into account. A criterion of the validity of this approach may be its successful application in the solution of the relevant problems. Certain examples of the use of the physical network model in the equilibrium variant have been described.^{255, 258, 259, 276–278} Evidently the theory should answer the question how the structure and properties of the physical network itself vary with time and on what basis one can describe the time variations of the properties of polymer systems. The reptation model of the diffusion of polymer chains is extremely fruitful in this sense. However, it does not take into account the entire diversity of the types of intermolecular interactions in polymers. Certain attempts to take into account this factor theoretically in the study of the dynamic characteristics of

polymer systems have been undertaken.^{261, 279, 280} However, on the whole the problem formulated still awaits its solution.

Abstract. Published data on the methods for synthesis, reactions and natural occurrence of imidazo[1,2-*a*]pyrazines are surveyed. Some other properties and applications of these compounds are also considered. The bibliography includes 273 references.

I. Introduction

The class of imidazo[1,2-*a*]pyrazines (subsequently referred to as imidazopyrazines) comprises heterocyclic compounds based on a fused bicyclic system with a bridgehead nitrogen atom.

Although these compounds are seemingly simple, they have not been known until recently. The first representative of this class was described only in 1957.¹ However, during the next four decades, the chemistry of imidazopyrazines developed very intensely. Certainly, the attention of researchers was mainly focused on the elaboration of convenient methods for the synthesis of imidazopyrazines and on investigation of their chemical properties, physical properties, comprehensive spectroscopic characteristics and practical applications. A tremendous role in the development of the chemistry of imidazopyrazines belongs to the discovery of several imidazopyrazine-type luciferins that are responsible for the bioluminescence of various sea organisms. This discovery was followed by studies dealing with the elucidation of the structure of these luciferins and of the mechanisms of their bio- and chemiluminescence; these studies differed markedly from those described in traditional publications in the chemistry of imidazopyrazines. Synthesis of the so-called 'azacyclols' (products of cyclisation of activated esters of tripeptides) and other imidazopyrazines containing amino-acid residues as structural fragments was also significant. These studies can be regarded as an impor-

tant link between the chemistry of imidazopyrazines, cyclic peptides and lysergine alkaloids.

The three general lines of research listed above have developed quite independently. If we formally judge the integrity of a field of investigation by the existence of scientific reviews, we find that the published reviews cover mostly the chemistry and the luminescence properties of imidazopyrazine-type luciferins (see, for example, Refs 2–4). To the best of our knowledge, the topic under consideration has been surveyed more broadly only in one review,⁵ which was published in 1979. The above facts stimulated the author to compose a review devoted to the chemistry of imidazo[1,2-*a*]pyrazines. Related fused heterocyclic systems, for example, imidazo[1,2-*a*]quinoxalines,⁶ are not analysed in this review, due to their specific properties and special approaches required for their synthesis. The main purpose of this review was to discuss the methods for synthesis and reactions of imidazopyrazines (*i.e.* purely chemical aspects), whereas in considering their physicochemical features (spectra, structure, reaction kinetics, *etc.*) and practical applications, the author intended to provide readers with only a grasp of the data available from the literature.

II. Natural occurrence

As early as 1917, a bioluminescence reaction was discovered that involved luciferase and a luciferin with an unknown structure, which was isolated from sea crustacean of the genus *Cypridina*.⁷ The structure of luciferin **1** was determined in the middle 60s by high-resolution field desorption mass spectrometry (MS), NMR and amino-acid analysis and was confirmed by its total chemical synthesis.^{8–13}

The molecule of coelenterazine **2** also incorporates the imidazopyrazine fragment.^{14–16}

R = H (**2**), SO₃H (**3**).

Coelenterazine, in turn, is a prosthetic group of the luminescent protein aequorin,^{16,17} which was first isolated from *Aequorea* medusas.¹⁸ Coelenterazine is usually called '*Oplophorus* luciferin', because it can be isolated fairly conveniently from the shrimps *Oplophorus spinosus*. In general, this compound proved to be fairly abundant in the sea fauna. So far, coelenterazine has been found in the tissues of phosphorescent sea organisms, which belong to at least six different classes and range from the relatively primitive radiolaria to fishes.^{19–30}

The third known luciferin, which accounts for the bioluminescence of the cephalopoda mollusks *Watasenia scintillans*,^{15,31,32} is coelenterazine disulfate **3**.

III. Synthesis

1. Construction of an imidazole ring based on pyrazine derivatives

The strategy involving synthesis of an imidazole ring, when a pyrazine ring is already present in the molecule, is most widely used for the synthesis of imidazopyrazines. This approach proved to be especially useful for the preparation of luciferins.

Depending on the nature of functional groups involved in cyclisation, several particular approaches can be distinguished.

The earliest approach to the synthesis of imidazopyrazines was based on cyclisation of *N*-(β-hydroxyethyl)aminopyrazine **4** under the action of thionyl chloride¹ to give 5,6-diphenyl-2,3-dihydroimidazo[1,2-*a*]pyrazine **5**.

Chlorodihydroimidazopyrazines **6a–c** were prepared in a similar way.^{33,34}

6	R ¹	R ²	Yield (%)	Ref.
a	H	Cl	46	33
b	H	H	89	34
c	Me	H	45	34

Cyclisation of oxo-derivatives, obtained by oxidation of hydroxy-derivatives, in the presence of trifluoroacetic anhydride can be regarded as a modification of this method. 2,3-Dehydro-derivatives of compounds **6** were prepared in this way.^{33,34} The scheme for the synthesis of imidazopyrazine analogues of nucleosides, for example, compound **7**,^{35–37} also includes a stage of cyclisation of β-oxoalkylamines involving the N(1) atom of the pyrazine ring (Scheme 1).³⁷

The use of *N*-(β-oxoethyl)aminopyrazine for the preparation of an analogue of 2,3-dihydroimidazopyrazine **5** devoid of phenyl substituents (yield 7%) has been reported.³⁸ The initial compound was introduced in the reaction as diethyl acetal, which was hydrolysed *in situ*.

Total synthesis of the luciferin **1** has been carried out according to Scheme 2.^{10,39}

It is noteworthy that beginning from ethioluciferin **8**, the intermediates were not isolated and purified. The yield of the luciferin **1** obtained from ethioluciferin **8** was very low, < 1%.

Construction of an imidazole moiety based on α-oxoacids has also been used to prepare the natural coelenterazine (Scheme 3).⁴⁰ Two modifications of this method were described; according to procedure *A*, α-oxoacid **10** and aminopyrazine **11** were kept in a Bu^tOH–dioxane mixture at 140 °C for 25 min, which gave coelenterazine **2** (yield 49%) together with its dehydro-derivative **12** as a side product (yield 8.4%). According to procedure *B*, a mixture of the initial compounds **10** and **11** was kept in pyridine at 80 °C for 5 h, and this led to a pyrazinyl amino acid **13** in a yield of 49%. Treatment of the latter with a dehydrating agent (for example, Ac₂O) and then by NaBH₄ yielded the coelenterazine **2**.

Scheme 3

The synthesis of compounds **14a** and **14b** (Scheme 4) in which an ester is used as the dicarbonyl component can be regarded as a specific case of the latter approach.⁴¹

Scheme 4

Where CSA is camphorsulfonic acid.

This approach has received no further development for the synthesis of luciferins or simpler imidazopyrazines.

The procedure for the synthesis of the luciferin **1** was markedly improved when a racemic α -oxoaldehyde, namely, 3-methyl-2-oxopentanal **15** was used in the reaction,^{42,43} instead of the optically active α -oxoacid **9**. As a result, the yield of the luciferin increased to 30%. It is clear that the product obtained in this way exhibited no optical activity. Nevertheless, its bioluminescent activity proved to be nearly the same as that of the natural luciferin.

The same method based on condensation of aminopyrazines with glyoxals^{42–45} made it possible to achieve impressing results in the synthesis of the coelenterazine **2** and its analogues.^{15,41,46–53} The fruitfulness of this approach is clearly demonstrated by the diversity of compounds **16** and bridged analogues of coelenterazine **17** synthesised in this way. The structures of these products are presented in Tables 1 and 2. The bridged analogues **17** are formed in relatively low yields (normally ~10%), whereas the yields of compounds **16** reach 85%.

It can be seen from the above that considerable progress has been achieved in the chemical synthesis of coelenterazine, *Cypridina* luciferin and their analogues. Apparently, it should be expected that this line of research will be further developed. Nevertheless, another trend has appeared, and in the near future it may become a significant alternative to the chemical synthesis: recently, a synthesis of coelenterazine based on genetic engineering technique has been patented.⁵⁴

The method based on the use of α-oxoaldehydes was found to be also convenient for the synthesis of simpler analogues of *Cypridina* luciferin, compounds **18**,^{42–45} as well as of more complex derivatives **19**, which are used as probes for chemiluminescent immunoassay.⁵⁵

Another approach, which is based on cyclisation of pyrazinyl amino acids, their esters and amides and is similar to that shown in Scheme 1, also gives good results in the preparation of compounds **18**.^{56–58}

R¹ = H, Me, Ph; R² = H, Ph;
R³ = OH, NH₂, OMe, OEt; R⁴ = H, Me.

The method in which aldehydes (as adducts with NaHSO₃) and KCN are used as building blocks for the imidazole fragment has found limited application. For example, it was used to prepare compound **18** (R¹ = R² = H); 3-aminoimidazo[1,2-*a*]pyrazine was formed as a side product.⁵⁹

The method involving α-halocarbonyl intermediates (a special case of the Chichibabin reaction) has found the widest use in the synthesis of simple imidazopyrazines.^{33, 34, 37, 60–87} Generally, this process can be represented by the following scheme:

If the α-halocarbonyl compounds are unstable (in particular, during storage), they can be introduced in the reaction mixture as the corresponding acetals and hydrolysed directly prior to the addition of 2-aminopyrazine **20** (see, for example, Refs 86 and 87). This synthesis is carried out in polar solvents (lower aliphatic alcohols or DMF) and usually with heating, but sometimes at room temperature. To bind the hydrogen halide liberated in the process, Na₂CO₃ or NaHCO₃ is added to the reaction mixture (before mixing of reactants or after completion of the reaction). A large number of imidazopyrazines **21** have been synthesised in this way; some examples are listed in Table 3.

In contrast to the approach described above, the method involving glyoxals, which was used advantageously for preparing luciferins and their analogues, does not enjoy wide popularity, for unknown reasons, in the synthesis of simpler imidazopyrazines. Only few examples describing the use of this method are documented. For example, synthesis of compounds of the type **18** with

Table 3. Imidazopyrazines **21 a–v** obtained by condensation of α -halocarbonyl compounds with 2-aminopyrazines **20**.

^a Only those compounds which are considered below have been denoted by letters. ^b The substituent in the initial compound **20** is given in parentheses.

R¹ = Ph, *p*-MeOC₆H₄ and *p*-ClC₆H₄ and **R**² = H have been reported.^{88,89} Compounds **21** with **R**¹ = *p*-MeOC₆H₄, **R**² = MeO, **R**³ = **R**⁵ = H, **R**⁴ = Cl (**21w**); **R**¹ = Me, **R**² = OH, **R**³ = **R**⁴ = H, **R**⁵ = OH (**21x**) have also been prepared in this way.^{83,90}

Other methods, in which the imidazole moiety is designed based on a six-membered ring present in the molecule, have been used only in a few studies. For example, treatment of 4-acetylpi-perazin-2-one with triethyloxonium tetrafluoroborate followed by refluxing with α -amino- α -cyanoacetamide gave tetrahydroimidazopyrazine **22** (Scheme 5).^{91,92}

Another representative of the polyhydroimidazopyrazine series has been prepared in a similar way.⁹³

Successive treatment of β -enaminoacrylate **23** with phenyldiazonium tetrafluoroborate and triethylamine yields tetrahydroimidazopyrazine **24**.⁹⁴

Imidazopyrazine **21y** (**R**¹ = Me, **R**² = NH₂, **R**³ = **R**⁴ = H, **R**⁵ = PhCH₂O) has been prepared by the reaction of 2-amino-3-(benzyloxy)pyrazine with acetaldehyde and sodium cyanide.⁷⁸

Condensation of 2,3-epoxybutanal with 2-aminopyrazine in the presence of alumina gives rise to 3-(1-hydroxyethyl)imidazo[1,2-*a*]pyrazine **21z** [**R**¹ = **R**³ = **R**⁴ = **R**⁵ = H, **R**² = CH(OH)Me] in 26% yield.⁹⁵

2. Construction of a pyrazine ring based on imidazole derivatives

Condensation of substituted imidazoles is used in the synthesis of imidazopyrazines much more rarely than the strategy considered in the previous Section.^{96–104}

This approach was used for the first time by Russian researchers,⁹⁶ who synthesised 8-phenylimidazo[1,2-*a*]pyrazine **27** in 83% yield by the reaction of 2-benzoylimidazole **25**, which was used as the sodium salt, with bromoacetal **26** with subsequent refluxing of the product with ammonium acetate in acetic acid (Scheme 6).

Scheme 6

α -Halocarbonyl compounds enter into condensation with 1-alkylimidazole-2-carboxamides^{97,99} to give intermediate imidazopyrazinium salts **28**; the latter can be converted into imidazopyrazin-8-ones **29** by refluxing in imidazole (Scheme 7):

Scheme 7

$\text{R}^1 = \text{H}, \text{Alk}, \text{Ph}$; $\text{R}^2 = \text{Ph}, \text{naphthyl}, \text{pyridyl}, \text{furyl}$.

Quaternisation of imidazole-2-carboxaldehyde ethylene acetals and oximes **30** upon treatment with α -halocarbonyl compounds and their oximes followed by deoxygenation of the intermediates thus formed with phosphorus trihalides has resulted in the formation of imidazopyrazinium salts **31**.¹⁰⁰

$\text{R}^1 = \text{Me}, \text{PhCH}_2$; $\text{R}^2 = \text{H}, \text{Me}, \text{Ph}$; $\text{X} = \text{NOH}, -\text{O}(\text{CH}_2)_2\text{O}-$; $\text{Y} = \text{O}, \text{NOH}$; $\text{Hal} = \text{Cl}, \text{Br}$.

On refluxing in 1,2,4-trimethylbenzene, ylide **32** undergoes 1,6-cyclisation and simultaneous debenzoylation and is thus converted into imidazopyrazine **33**.¹⁰²

An interesting reaction of ketene *N,N*-acetals in which two isocyanide groups participate in the formation of a pyrazine ring has been reported.¹⁰³

Finally, a 5,6-dioxoimidazopyrazine derivative has been synthesised by interaction of binucleophilic 2-(arylaminomethyl)imidazolines with oxalyl chloride.¹⁰⁴

3. Simultaneous formation of imidazole and pyrazine rings from acyclic precursors

Methods for the synthesis of imidazopyrazines from acyclic precursors are used rather as rarely as those described in Section 2.

Recently, the reaction of diethylenetriamine **34** with dibenzoyl to give 1,2,3,5,6,8*a*-hexahydro-8,8*a*-diphenylimidazo[1,2-*a*]pyrazine **35** has been discovered.^{105,107}

This reaction is carried out by refluxing the reactants in methanol in the presence of mercury(II) chloride (yield 60%).¹⁰⁷

The same amine **34** condenses with diethyl oxalate to give imidazopyrazine **36**,¹⁰⁸ while its condensation with glyoxal or *N,N'*-dicyclohexylethylenediamine affords polycyclic polyamine **37** incorporating two imidazopyrazine structural fragments.¹⁰⁹

Treatment of ethyleneimine **38** with the ethyl ether of glycine or ethylenediamine gives rise to substituted imidazopyrazines.^{110,111}

A special position in this group of methods belongs to the preparation of imidazopyrazines from tripeptide (usually linear) derivatives. This approach has been developed within the chemistry of amino acids and peptides, which stands apart from the chemistry of heterocyclic compounds; therefore, terminology peculiar to peptide chemistry has taken root in this line of research.

The formation of imidazopyrazines from derivatives of linear peptides was first described by Jones *et al.*^{112, 113} It was found that the oxazolone derivative **39** of the tripeptide AIB–AIB–AIB (AIB is α -aminoisobutyric acid or α -methylalanine) readily isomerises (in ethyl acetate at room temperature) to give imidazopyrazine **41** in a high yield (95%). This reaction occurs presumably *via* the formation of monocyclic amidine **40** (Scheme 8).

Scheme 8

A conceptually similar method for the synthesis of the imidazopyrazine **41** involves treatment of AIB tri-, tetra- and penta-peptides with phosphorus pentachloride or thionyl chloride in acetyl chloride and subsequent cyclisation of the intermediate acid chlorides in pyridine.^{114–117} The yields of the compound **41** obtained in this way are much lower (11%–26%). It is of interest that when tetra- and penta-peptides are used in this reaction, bis-imidazopyrazine **42** is formed simultaneously in a yield of 4%–10%.

This method has also been used to prepare polydeuterated analogues of **41** and **42**.^{115, 116}

The reactions described above reflect the specific stereochemistry of derivatives of α, α -dialkylamino acids (in particular, AIB), namely, a certain conformational rigidity of their carbon skeleton, and are not characteristic of ordinary natural amino acids. Nevertheless, methods for the preparation of the imidazopyrazines **41**

containing Gly, Ala, Val, *etc.* as structural fragments have been developed. For example, catalytic hydrogenolysis of carbobenzoxy-derivatives of methyl esters of tripeptides¹¹⁸ makes it possible to synthesise the imidazopyrazines of the type **41** incorporating Gly, Ala, Val, Leu and Phe residues.

$\text{R} = \text{H}, \text{Me}, \text{Pr}^i, \text{Bu}^i, \text{CH}_2\text{Ph}$.

Cyclisation of activated esters of tripeptides has been studied in detail by Italian researchers.^{119–128} However, although the compounds obtained in these studies belong to the same class of imidazo[1,2-*a*]pyrazines, they possess an important feature distinguishing them from the amidines **41**: their molecules incorporate a $\text{C}(8a)\text{OH} - \text{N}(1)\text{R}^1$ fragment instead of the $\text{C}(8a) = \text{N}(1)$ fragment. Therefore, these compounds were called 'azacyclics'. As a rule, they are synthesised starting from 4-nitrophenyl esters of tripeptides **43**. According to a typical procedure, tripeptide **43** is kept in a 1 : 1 mixture of dioxane and an aqueous carbonate buffer solution (0.1 M NaHCO_3 + 0.1 M Na_2CO_3 , 1 : 1) for 1–2 h at room temperature. Characteristics for a number of imidazopyrazines **44** obtained in this way are listed in Table 4.

Undoubtedly, it is the mild conditions used in this reaction that account for the preservation of the $\text{C}(8a)\text{OH}$ group in the molecule; otherwise (at elevated temperatures) one should expect that elimination of a water molecule would occur to give the amidine analogues of **41**.

Table 4. Azacyclics **44** obtained by cyclisation of *p*-nitrophenyl esters of the tripeptides **43**.

R^1	R^2	R^3	R^4	R^5	Yield (%)	Ref.

^a As a salt with CF_3COOH . ^b In the initial tripeptide, $\text{R}^1 = \text{ClCH}_2\text{CO}$, $\text{R}^3 = \text{CH}_2\text{SSBu}^t$; the protection was removed *in situ* during the cyclisation (Bu_3P and NaHCO_3 in aqueous propanol).

Taking into account the fact that amino-acid residues are the main structural units of the molecules **41** and **44**, it would be reasonable to suggest that these imidazopyrazines could, in principle, also be obtained by intermolecular cyclisation of amino acids or their activated derivatives. However, syntheses of the imidazopyrazines **41** and **44** based on this strategy have not yet been developed. Nevertheless, in a study of the products of high-temperature (200–250 °C) condensation of vaporised amino acids (Ala, Val, Nva, and Leu) catalysed by silica gel,^{129–131} some compounds, dehydrated to a greater extent than cyclic dipeptides (piperazine-2,5-diones), have been detected. The latter are often called ‘amino acid anhydrides’, because they can be obtained directly from amino acids (although this is seldom used for practical purposes). Hydrolysis of these compounds leads to the recovery of the amino acids. Whereas the formation of piperazine-2,5-diones is accompanied by elimination of one water molecule per amino acid molecule (the same 1 : 1 ratio is retained in the case of other cyclic peptides), the products under consideration^{129–131} were found to be dehydrated to a greater extent than the corresponding piperazine-2,5-diones. The ratio of the number of amino-acid residues constituting these molecules to the number of water molecules eliminated upon dehydration is 3 : 4 and 4 : 6. Studies carried out by fast atom bombardment mass spectrometry,¹²⁹ HPLC/MS and GLC/IR/MS with computer simulation of the IR spectra^{130, 131} have permitted these compounds to be identified as imidazopyrazines and bis-imidazopyrazines.

$R^1 = \text{H}$, $R^2 = \text{Me(Ala)}$, $\text{Pr}^i(\text{Val})$, $\text{Pr}^n(\text{Nva})$, $\text{Bu}^t(\text{Leu})$.

The AIB derivatives **41** and **42** ($R^1 = R^2 = \text{Me}$) mentioned above also belong to this class of compound. According to tentative estimates, the yield of imidazopyrazines can reach 20%; however, they are strongly contaminated by products of thermal destruction that occurs immediately after their formation. Thus, the reactions in question can hardly be of any synthetic value.

Some studies, mostly directed at the modelling of the biosynthesis of the imidazopyrazine-type luciferins, have been reported.^{132, 133} The researchers suggested that modified tripeptides are biosynthetic precursors of all luminescent systems (coelenterata, crustacean, etc.). This suggestion was supported by the successful synthesis of compounds **45**¹³² and **46**¹³³ — analogues of the *Cypridina* luciferin and of coelenterazine — carried out according to Scheme 9.

Scheme 9

$R^2 = \text{Me}$; $R^3 = \text{OCH}_2\text{Ph}$, OH , H ;
 $R^2 = \text{H}$; $R^3 = \text{OH}$, H .

A typical procedure consists in heating of tripeptide-like compounds in DMF in the presence of K_2CO_3 . In the case of the compound **45**, cyclisation was carried out under an inert atmosphere (N_2 ; yield 58%).

The last case the author is aware of, where the imidazole and pyrazine rings are formed simultaneously from acyclic precursors is rather an occasional observation in the field of synthesis of polyaza-containing macrocyclic ligands. Condensation of (4-nitrobenzyl)ethylenediamine with N,N' -[*N*-(*tert*-butoxycarbonyl)iminodiacetyl]disuccinimide afforded a mixture of two isomeric imidazopyrazines instead of the expected 9-membered macrocyclic diamide.¹³⁴

4. Introduction and modification of substituents in the imidazopyrazine nucleus

Halogenation^{33, 34, 71, 86, 135, 136} of the imidazopyrazine nucleus is the most important reaction among those involving the imidazopyrazine system, since it permits not only introduction of halogen atoms into this nucleus but also their subsequent replacement by other substituents.

Treatment of unsubstituted imidazo[1,2-*a*]pyrazine (**21a**; Table 3) with bromine in glacial acetic acid results in its bromination in the 3- and 5-positions.^{71, 135, 136} The yields of 3-bromo-, 5-bromo- and 3,5-dibromo-derivatives are 5%, 81% and 5%, respectively.⁷¹

Better selectivity is achieved with *N*-bromosuccinimide. Using the imidazopyrazines **21a** and **21g** as examples, it has been shown that bromination involves the 3-position, the corresponding products being formed in 44–72% yields.^{86, 136} However, when *N*-bromosuccinimide is made to react with 8-(4-*tert*-butoxycarbonylpiperazino)imidazo[1,2-*a*]pyrazine,³⁴ substitution at C(5) predominates (the yield of the 5-bromo-derivative is 55%), and only with excess *N*-bromosuccinimide is the 3,5-disubstituted product formed (yield 59%).

Conversely, reactions of the imidazopyrazine **21b** and 8-bromo-6-chloroimidazo[1,2-*a*]pyrazine with *N*-chlorosuccinimide lead to 3-chloro-derivatives in 72% and 90% yields, respectively.³³

Exhaustive chlorination can be achieved by using phosphorus pentachloride. For example, the imidazopyrazine **21a** is converted into 2,3,5,6,8-pentachloroimidazo[1,2-*a*]pyrazine (55%),⁸⁶ and **21i** gives 3,5,6,8-tetrachloro-derivative (10%).⁷¹

When 6,8-dichloro-3-methylimidazo[1,2-*a*]pyrazine was refluxed with NaBr/HBr in butanone,³³ selective substitution of the chlorine atom at the 8-position by a bromine atom occurs (the 6-chlorine atom being retained). The yield of 8-bromo-derivative was 67%.

Finally, when 3-(2-hydroxyethyl)-8-(4-*tert*-butoxycarbonylpiperazino)imidazo[1,2-*a*]pyrazine **47** was treated with diethylaminosulfur trifluoride in the presence of magnesium oxide as a

catalyst, the hydroxy-group was replaced by a fluorine atom,³⁴ which resulted in the synthesis of fluoro-derivative **48**.

As noted above, substitution of halogen atoms is a convenient method for introducing other substituents into the imidazopyrazine nucleus. This substitution is used most frequently to introduce amino-groups.

This reaction is fairly selective; when the nucleus contains halogen atoms at the 3- and 8-positions or the 6- and 8-positions, substitution involves only the 8-halogen atom to give compounds **49a-i** (Table 5).^{33, 34, 65, 87, 135, 137}

The NH group in the piperazine ring is protected by introducing a *tert*-butoxycarbonyl group (compounds **47**, **48** and **49l, m**).³⁴

Table 5. Imidazopyrazines **49a-m** obtained by substitution of amino-groups for the bromine atom at the 8-position.

m	Me	Me	-(CH ₂) ₂ N(CO ₂ Bu ^t)(CH ₂) ₂ -		34

Substitution of the halogen atoms has also been used in the synthesis of a series of 8-(2-imidazolylmethoxy)-, 8-(2-imidazolylmethylthio)- and 8-(2-imidazolylmethylamino)imidazo[1,2-*a*]pyrazines.¹³⁸ For example, treatment of 8-chloroimidazo[1,2-*a*]pyrazine with thiourea followed by hydrolysis of the product with potassium carbonate has given a 8-sulfanyl-derivative, which has been converted into imidazopyrazine **50** by the reaction with sodium methoxide and 2-chloromethyl-2-imidazoline.

Treatment of the 8-chloroimidazopyrazines **21e** and **21s** with Grignard reagent (phenethylmagnesium bromide) and copper(I) phenylacetylide has given the corresponding substituted imidazopyrazines **51** and **52**.^{78, 82}

51: R¹ = H; R² = CH₂CH₂Ph (62%);
52: R¹ = Me; R² = C≡CPh (68%).

The ethynyl group in the compound **52** can be reduced to the vinyl group (yield 41%) by hydrogenation in the presence of the Lindlar catalyst (lead-poisoned 5% Pd/CaCO₃).⁸²

Substitution of the chlorine and bromine atoms by methoxy-groups can be accomplished by treatment with sodium methoxide.^{86, 136} In the case of polyhaloimidazopyrazines, the halogen atoms at the 5- and 8-positions are replaced predominantly. It was not specified in this study, which of these two positions is preferentially attacked. The remaining halogen atoms can be removed by hydrogenation in the presence of Pd/C (Scheme 10).^{86, 136}

Scheme 10

However, in the case of 6,8-dibromoimidazo[1,2-*a*]pyrazine, only the 8-bromine atom is substituted, whereas the 6-bromine atom remains unaffected, and the reaction yields 6-bromo-8-methoxyimidazo[1,2-*a*]pyrazine.¹³⁶

Other substituents can also be introduced in the imidazopyrazine nucleus. For example, when unsubstituted imidazo[1,2-*a*]pyrazine **21a**¹³⁹ and 6-bromo-8-methoxyimidazo[1,2-*a*]pyrazine⁸⁷ react with formaldehyde, regioselective hydroxymethylation in the 3-position occurs. Nitrosation of 8-(benzyloxy)-2-methylimidazo[1,2-*a*]pyrazine (**21o**) with sodium nitrite followed by reduction of the nitroso-derivative with metallic zinc resulted in the introduction of an amino-group in the 3-position of this compound.⁷⁸ Synthesis of 3-benzamidomethyl derivative **53** has been reported.⁸³

Alkylation of the pyrazine nitrogen atom has also been used for synthetic purposes. Thus treatment of the compound **21a** with MeI (methanol, 5 days, room temperature) affords imidazopyrazinium salt in 11% yield.¹³⁶

Nitrosation and nitration of tetrahydroimidazopyrazines **54** also involves the N(7) atom,⁷⁰ and treatment with HNO₃/H₂SO₄ leads to a mixture of 7-nitro- and 7-nitroso-derivatives.

R = Me, Et.

Similarly, a series of 7-substituted derivatives **55** have been obtained by arylation of tetrahydroimidazopyrazines **54**.^{140–142}

R¹, R² = H, Alk, Ph; R³ = Hal; R⁴ = H, Alk.

The esters **21i,k,l** can be hydrolysed to the corresponding carboxylic acids or converted into the corresponding amides by reaction with NH₄OH (or into hydrazides by reaction with N₂H₄) and then into nitriles by treatment with POCl₃.⁷¹ The latter were successively converted into amidrazones **56** and **57** according to Scheme 11.^{71, 143}

Scheme 11

R¹ = H, Me; R² = Me, Ac, Ph, *p*-O₂NC₆H₄, anisyl, furyl;
R¹ R² = -(CH₂)₅-.

Further functionalisation of the hydrazide has resulted in the synthesis of nitrofur derivative **58**.¹⁴⁴

It is possible to convert amides into the corresponding amines as has been demonstrated by the synthesis of the imidazopyrazine **21y** (Scheme 12).¹⁴⁵

Scheme 12

Substitution of the 2-chloromethyl groups in the imidazopyrazine nucleus by hydroxymethyl groups (refluxing in an aqueous solution of Na₂CO₃)⁷¹ and substitution of 2-benzoyloxymethyl groups by hydroxyethyl groups (refluxing in a solution of MeNH₂ in aqueous methanol)³⁴ have been reported. 8-Methoxy groups are replaced by methylamino-groups on refluxing in an aqueous solution of MeNH₂.⁸⁷ Imidazopyrazine **21z** [R¹ = R³ = R⁴ = R⁵ = H; R² = CH(OH)Me] is oxidised by manganese(IV) oxide to give the corresponding ketone.⁹⁵

Among the reactions involving natural imidazopyrazine luciferins and their analogues, oxidation of the luciferin **1** to luciferyls **59** is noteworthy.¹⁴⁶

R = H, Me, Prⁱ, Buⁿ.

When alcohols are used as solvents and PbO₂ is used as the oxidising agent, the reaction yields luciferyl ethers **59** (R = Alk). The corresponding alcohol **59** (R = H) can be obtained by oxidation under milder conditions: with diphenylpicrylhydrazyl as the oxidizing agent and in aprotic media (for example, DMF). In the latter case, dimeric biluciferyl **60** is formed as an intermediate product. This compound can be isolated when the luciferin **1** is oxidised with K₃[Fe(CN)₆].¹⁴⁷ Reduction of the compounds **59** (R = H) and **60** with Na₂S₂O₄ recovers the initial luciferin **1**.^{146, 147}

Introduction and/or modification of side substituents in the existing imidazopyrazine nucleus has been used in the synthesis of coelenterazine analogues. For example, radical oxidation of the *O*-methyl derivative of the compound **14a** involving the 2-position^{148,149} or the 5-position¹⁵⁰ gives rise to the following peroxide derivatives:

R = Me₃C, Me₃Si.

The 4'-methoxy-groups themselves in the *O*-methyl derivative of the compound **14a** and other compounds of this type often play only a protective role and can be subsequently removed by treatment with pyridine hydrochloride at 210 °C for 2 h under an argon atmosphere.⁴⁸ In addition, free phenolic groups can be protected by acetylation with acetic anhydride in the presence of catalytic amounts of H₂SO₄.¹⁵¹ This approach has been used in the synthesis of the β-D-glucuronopyranoside of coelenterazine **61**,²³ which exhibits bioluminescent properties (Scheme 13).

Treatment of coelenterazine with acetic anhydride in the presence of catalytic amounts of concentrated sulfuric acid at room temperature has led to its tri-*O*-acetyl derivative (yield 86%).⁶⁰ The subsequent selective hydrolysis and treatment with the Py · SO₃ complex in pyridine at room temperature resulted in the substitution of the enol residue at the imidazole ring by a sulfate group. The two remaining acetate groups were selectively eliminated. These reactions resulted in the synthesis of coelenterazine enol monosulfate.⁶⁰

IV. Reactions

The methods for the synthesis of imidazopyrazines involving introduction or modification of side groups, considered in the previous Section (III.4), give a good idea of the reactions known for imidazopyrazines, despite the fact that the studies considered have been devoted just to the development of synthetic procedures. The reactions that have received no practical use have not been studied systematically, except for the study of mechanisms of luminescence of luciferins (see below).

The reaction of the imidazopyrazine **21a** with hydrazine leads to a mixture of 2-methylimidazole and 1-ethyl-2-methylimidazole in a ratio of 5:4.⁶³ It was thus suggested that the reaction mechanism includes the attack by hydrazine either at the 5-position or at the 8-position of the imidazopyrazine molecule (Scheme 14).

Phenyllithium reacts with the compound **21a** yielding 8-phenyl-substituted derivative **27** and 5,6-dihydro-8-phenylimidazo[1,2-*a*]pyrazine in a ratio of 1:3.¹⁵² Methylolithium reacts with the imidazopyrazine **21a** in a similar way.¹⁵³

It has been found that, unlike imidazo[1,2-*a*]pyrimidine and imidazo[1,2-*c*]pyrimidine, 2- and 3-methylimidazo[1,2-*a*]pyrazines do not undergo the Dimroth rearrangement.^{61,154}

Catalytic hydrogenation of the bis-imidazopyrazine **37** leads to *N*-(2-aminoethyl)pyrazine.¹⁰⁹

The behaviour of the imidazopyrazine **41** during hydrolysis has been studied.¹¹⁵ Although the molecule of this compound incorporates amino-acid structural fragments and, hence, it resembles somewhat cyclic peptides, the compound **41** proved to be much more resistant to hydrolysis than peptides. For example, hydrolysis of **41** in alkaline aqueous methanol stops at the stage of formation of 'amidino-acid' salt **62**, which is readily converted into the initial compound **41** in acid or even in neutral solutions.

Scheme 13

Scheme 14

Scheme 15

Scheme 16

In order to determine the structure of the luciferin **1**, products of its hydrolysis as well as those of hydrolysis of its 1,2,5,6,7,8-hexahydro-analogue (6 M HCl at 100 °C) have been analysed.^{8,9} The amino acids Gly, Arg, Ile and *allo*-Ile and γ -guanidino- α -oxobutanoic acid were detected in hydrolysates obtained from the luciferin **1**, while hydrolysates obtained from its hexahydro-analogue contained Gly, Pro, Ile and *allo*-Ile. Based on these results, the researchers proposed mechanisms for the hydrolysis of these compounds (Schemes 15 and 16).

The most complex problem in the investigation of reactions of imidazopyrazines was to elucidate the mechanism of luminescence (bio- and chemiluminescence in various molecular systems) of luciferins and their analogues. Studies along these lines were started more than 30 years ago. The results of these studies have

been reported in a vast number of papers and reviews.^{2–4, 16, 17, 45, 47–49, 51–53, 58, 59, 133, 148, 155–189} However, at present, specialists admit that the molecular mechanism is ‘still unclear’, and the problem is discussed within the framework of a ‘working hypothesis’ (see, for example, Ref. 148).

Nevertheless, based on the accumulated data, it was concluded that the chemiluminescence of the luciferin **1**, coelenterazine and their synthetic analogues containing a 3,7-dihydroimidazo[1,2-*a*]pyrazin-3-one structural fragment (the compounds **14**, **16–18**, **45** and **46**) obeys identical rules, and its simplified mechanism is presented below (Scheme 17):^{47, 58 148, 158, 161, 167}

Scheme 17

Light is emitted by the excited dianion **63** of oxyluciferin **64** (or of coelenteramid in the case of luminescence of coelenterazine), and the latter can be isolated in a pure state after the completion of the reaction. Chemiluminescence is observed in aprotic solvents (1,2-dimethoxyethane, acetonitrile, dichloromethane, DMSO, etc.) in the presence of bases. For bioluminescence of the luciferin **1** and its analogues, the presence of luciferase is needed. As has already been noted, coelenterazin is a prosthetic group of the calcium-binding protein aequorin, bioluminescence of which has been induced by introduction of calcium ions.^{16, 17, 49, 148}

The efficiency of chemiluminescence has been investigated and a rate constant for the reaction of an analogue of the luciferin **1** with peroxide anion and single oxygen in various molecular systems have been determined in some other studies.^{19–20, 1}

V. Spectral and some other properties

Publications dealing with the synthesis and reaction of imidazopyrazines like many traditional studies in the organic chemistry, include characterization of compounds obtained by NMR, UV and IR spectroscopy, MS and X-ray diffraction. Therefore, the reader is interested in this topic can find the information in the original publications.

However, some papers, especially devoted to spectra and structural studies of individual imidazopyrazines, have also been published. For example, among the studies dealing with the spectra (mostly luminescent properties) of luciferin, considered in the previous Section, Refs 16 and 16 should be distinguished; in these studies, tautomerism of natural luciferin and their analogues was studied in detail by NMR and UV spectroscopy. Mass spectrometry plays a significant role in elucidating the mechanism of luminescence of these compounds.^{9, 13, 176}

Some physical methods of analysis (UV, IR and NMR spectroscopy and MS) have been invoked to confirm the unusual structure of the azacyclo **44**.^{11–9, 128} In addition, papers especially devoted to X-ray diffraction studies of these compounds have been published.^{202–203} The structure of 1,2,3,5,6, *a*-hexahydro-8, 8-diphenylimidazo[1,2-*a*]pyrazine **35** has also been characterized by X-ray diffraction data.¹⁰⁷

The use of NMR (usually ¹H NMR) spectroscopy to investigate various aspects of the structure and reactivity of imidazopyrazines has been reported.^{61, 86, 88, 89, 204–208} The structural conditions for the Dimroth rearrangement have been determined for a series of imidazopyrazines (including the compounds **21e**, **f** which do not enter into this rearrangement).⁶¹ The site of protonation and tautomeric equilibrium for a number of compounds of the type **18** and **21** have been studied by ¹H NMR,^{88, 89} ¹³C NMR,^{205, 206} and ¹⁵N NMR²⁰⁵ spectroscopy. A correlation between the position of the ring nitrogen atoms in

various azoloazines (including the imidazopyrazine **21a**) and the corresponding chemical shift has been established.²⁰⁷ Yet another application of NMR spectroscopy (¹H and ¹⁵N) has been the determination of the site of nucleophilic substitution in the molecule of the imidazopyrazines **21**.^{86, 204–208}

The site of protonation of the molecule **21a** have been determined using magnetic circular dichroism²⁰⁹ and UV spectroscopy.³⁸ The electronic structure of this compound (among other fused 5- and 6-membered aza-heterocycles) has been discussed based on the data of UV spectroscopy.^{210–211}

VI. Applications

It is not an exaggeration to say that luciferin in coelenterazin **2** and their synthetic analogue possess the most unusual properties among all known imidazo[1,2-*a*]pyrazines. Their ability to luminesce under the action of oxidants and the influence of various factors on this process permitted the development of a number of fairly specific analytical procedures.

In particular, luciferin and its synthetic analogue have been used for chemiluminescent determination of peroxide (including organic),^{212–219} oxygen,²²⁰ oxidase,²²¹ peroxidase,²²² glucosidase,²²³ galactosidase²²⁴ and ATP;²²⁵ for investigations of the reaction of amino acid and related compounds with peroxide anions²²⁶ and of the formation of peroxide anions in human blood cells;^{22–229} in other cytological studies;^{23–234} for chemiluminescent immunoassays²³⁵ and for the development of sensors based on immobilized enzymes.^{235–236}

Compounds **65** and **66** denoted by the abbreviations CLA and MCLA are analogues of luciferin. In these are used most frequently.

It has been noted (see for example, Refs 45 and 237) that MCLA is more effective than CLA for detecting oxidant formed during enzymic reactions. This is due to a higher quantum yield in the former case and also to the fact that the maximum of its luminescence is shifted to the visible region to a greater extent (for CLA, λ_{max} is 45 nm⁵⁸ and for MCLA, it is 46 nm⁴⁵).

It has been reported that the introduction of one of the analogues of Cypridin aluciferin in a tissue decreases the probability of fibrillation induced by ischemia and reperfusion.²³⁸

The main field of application of coelenterazin and its synthetic analogue is luminescent determination of calcium ions. As noted above, bioluminescent properties are inherent in the protein aequorin, in which the coelenterazin molecule acts as a prosthetic group. Bioluminescence is observed only in the presence of calcium ions,^{1, 61, 79, 50, 148, 239, 240} while in the absence of these ions the protein is very stable.

The method of investigation of the dynamics of calcium ions in living tissue is based on the formation of recombinant aequorin from coelenterazin or its analogue and the protein apoaequorin produced in the cells.^{241, 242} In a comparative study of the natural coelenterazin **2** and its synthetic analogues, it has been found that the recombination of aequorin occurs most rapidly when natural coelenterazin is used.^{243–244}

In the absence of protein, non-bound coelenterazin can be used as a luminescent probe for peroxide ions²⁴⁵ and also for investigation of translation in cell-free systems.²⁴⁶

The main field of application of synthetic imidazopyrazines having no natural analogue is pharmacology. Some compounds of this class are capable of depressing the secretion of gastric juice; therefore, they can be used as anti-ulcer drugs.^{78, 79, 82, 145, 247–252} Among the imidazopyrazines mentioned in this review, the derivative **21y**, known under the code name SCH 32651, is the most active.^{78, 145, 247–249}

Another type of pharmacological activity found for some representatives of this class of compound is the ability to relax smooth muscles.^{71, 87, 135, 253–258} For example, it has been found that^{71, 87} the imidazopyrazines **21k–m**, **49a–g** and some others possess more pronounced bronchospasmolytic properties than theophylline; as a rule, the activity of these compounds increases when bromine atoms are introduced in their molecules as substituents. 6-Bromo-8-methylaminoimidazo[1,2-*a*]pyrazine-2-carbonitrile **67** referred to as SCA 40 has been chosen for a systematic pharmacological assay.^{254–258}

Cardiotonic properties (i.e. the ability to enhance systoles) have been discovered for derivatives containing methoxyphenyl and other aromatic substituents in the 2-position of the heterocyclic nucleus,^{72–76, 77, 80, 259–261} for example, for the imidazopyrazines **21p–r**.

More complex compounds such as **55**,^{140–142} **58**¹⁴⁴ as well as peneme^{262, 263} and cepeme²⁶⁴ antibiotics with imidazopyrazine substituents have been proposed as antibacterials.

Some imidazo[1,2-*a*]pyrazine-2-carboxylic acids, imidazo[1,2-*a*]pyrazine-3-carboxylic acids^{62, 64, 73, 84, 265} and the adenosine analogue **7**³⁷ exhibit anti-inflammatory activity. Some carboxyl-containing derivatives have been found to possess analgesic properties.

Imidazopyrazine analogues of nucleosides can prove to be effective antiviral preparations and immunomodulators.^{36, 37, 266} For example, the compound **7** inhibited AIDS virus proliferation in T cells by 70%.³⁶

It has been proposed to use the piperazino-derivatives **49h–k** as appetite-suppressing agents; as antidepressants; as antihypertensive, analgesic and antiarrhythmic preparations and in the fight against smoking.^{33, 65, 267} 8-Piperazinoimidazo[1,2-*a*]pyrazine has exhibited hypoglycemic activity.^{34, 268}

Ethyl 2,3,5,6,7,8-hexahydroimidazo[1,2-*a*]pyrazine-7-carboxylate has proved to be useful in the therapy of schizophrenia.⁹³

The trifluoromethyl-substituted imidazo[1,2-*a*]pyrazines **68** have been found to be effective inhibitors of elastase and are considered as possible drugs for treatment of lung emphysema and related diseases.^{269, 270}

R = 3,4-(MeO)₂C₆H₃CH₂CH₂, 2-indanyl, cyclooctyl.

Derivatives of oxoquinoline- and oxonaphthyridinecarboxylic acids containing imidazopyrazine substituents have been patented as preparations for the treatment of acute myocardial infarction, osteoporosis and tumours.²⁷¹

There are only few examples, where synthetic imidazopyrazines have been used for other than pharmacological purposes. To the best of our knowledge, only a method for extraction of metal ions (Mo, Cr, Pb, Au, Ag, Pt, U, *etc.*) using the compound **36**¹⁰⁸ has been patented and materials for colour photography based on 5-hydroxyimidazo[1,2-*a*]pyrazines have been developed.^{272, 273}

VII. Conclusion

Our analysis of the published data indicates that considerable progress has been achieved during the four decades of studies dealing with imidazo[1,2-*a*]pyrazines.

A number of methods for the synthesis of this class of compound have been developed. These methods permit preparation of products with different degrees of saturation of the imidazopyrazine nucleus and with side substituents of various natures. The approach based on the construction of the imidazole ring when the pyrazine fragment is already present in the molecule is used most frequently. Among the reagents used for these purpose, the best results have been generally achieved when pyrazines have been involved in condensation with α -halocarbonyl compounds. Glyoxals proved to be indispensable in the synthesis of natural luciferins and model compounds.

The synthesis of 'azacyclols' presented a separate task. It was accomplished using reagents and procedures adapted from peptide chemistry. This task was even more complicated due to the presence of chiral centres in the amino-acid residues — structural fragments of 'azacyclols' — and to the lability of the C(8a)OH group.

The current views on reactions of imidazopyrazines are mostly based on the data accumulated in the synthesis of new compounds of this class by introduction of side substituents into the heterocyclic ring and their subsequent modification. Systematic studies on the reactivity of imidazopyrazines have scarcely been carried out, except for the studies dealing with the structure of luciferins and the mechanism of their luminescence.

Studies of the spectroscopic properties and characteristic features of the electronic and spatial structures of some imidazo[1,2-*a*]pyrazines are not significant by themselves; as a rule, they only supplement synthetic studies by a standard set of analytical data for new compounds. Works, in which the attention is focused on these aspects (for example, studies on the tautomerism, sites of protonation and reactivity, confirmation of an unusual structure, *etc.*), are few in number.

About a quarter of all publications (including patents) on imidazopyrazines are devoted to their use or mention their possible applications (mostly in analytical chemistry, biochemistry and pharmacology).

Analysis of the published data makes it possible to distinguish some specific features in the development of this branch of the chemistry of heterocyclic compounds. As has been mentioned in the Introduction, the studies devoted to the synthesis and studies of imidazopyrazines follow three absolutely separate lines of research:

- (1) natural luciferins and their analogues;
- (2) 'cyclols' and other derivatives of cyclic tripeptides;
- (3) imidazopyrazines having no natural analogues.

The studies along the first line were actually initiated by the discovery of *Cypridina* luciferin and coelenterazine in living organisms. Although these are only two representatives of the vast class of imidazopyrazines, their properties are so interesting that publications dealing with the synthesis of their analogues and with the conclusive determination of the mechanism of their luminescence are still appearing in the literature. These studies occupy an important place among those dealing with the chemistry of imidazopyrazines.

The fate of the second line of research is somewhat unexpected and, from the author's viewpoint, difficult to explain. The first studies on the synthesis of 'azacyclols' were published in the early 70s, while the last ones appeared in the middle 80s. Despite the fact that these compounds are extremely interesting, this line is at a deadlock. Its development stopped about ten years ago and did not result even in recommendations on practical applications of azacyclols. According to the personal viewpoint of the author, development of more general and convenient methods for the synthesis of these compounds (including, for example, fluorinated derivatives) and appropriate pharmacological assays would not

only fill the gap in the purely practical aspect but also markedly contribute to peptide chemistry. The possibility of preparing other imidazopyrazine analogues of cyclic tripeptides directly from amino acids also deserves more attention.

As regards the chemistry of synthetic imidazopyrazines having no natural analogues, its development follows the traditional route for the majority of classes of organic compounds. Since many of the compounds synthesised exhibited valuable pharmacological properties, the search for new derivatives of this type is being carried out. Although it seems that pharmacology does not encompass all the possible applications of these compounds, other practical aspects are scantily presented in the scientific literature.

Phosphorylated allenes: structure and interaction with electrophiles

I V Alabugin, V K Brel

Contents

I. Introduction	205
II. Characteristic features of the structure of phosphorylated allenes	205
III. Interaction of phosphorylated allenes with electrophiles	209
IV. Conclusion	222

Abstract. Data on the structures of phosphorylated allenes (PA) and their reactions with electrophiles are surveyed for the first time. It is shown that the influence of intramolecular interactions on the reactivity of the unsaturated centres is reflected in the selectivity of the reactions of PA with electrophiles. Depending on the nature of the reactants and the structure of the PA, various reaction mechanisms may operate. The bibliography includes 163 references.

I. Introduction

The unusual system comprising interlinked unsaturated centres, differing in properties and reactivity, in molecules of phosphorylated allenes (PA) as well as the ready availability of these compounds and the wide variety of chemical reactions based on them have long attracted the attention of chemists (see, for example, Refs 1–4). Vigorous studies on PA are also being continued at the present time. The results obtained in recent years have appreciably altered and amplified the general ideas concerning the compounds of this class. Firstly, the range of synthetic reactions based on PA has expanded significantly and it became necessary to refine the concept of their reactivity. Secondly, it was in fact in recent years that the structures of certain PA were first investigated by X-ray diffraction methods (in the case of crystalline substances) and by gas electron diffraction (in the gas phase). In addition, the quantum-chemical calculations which have been carried out (both by semiempirical and *ab initio* methods) together with photoelectron spectroscopic data made it possible to characterise fairly reliably for the first time the electronic structure of PA. In connection with the growing interest in the synthesis of promising physiologically active substances^{5–17} from PA, a systematic treatment and combined analysis of the experimental data accumulated were required. The present review surveys the new data on the structure of PA and their interaction with electrophiles.

II. Characteristic features of the structure of phosphorylated allenes

The mutual influence of three fragments — two mutually orthogonal double bonds and the phosphoryl group — in PA molecules can be exerted both *via* bonds and through space^{18–20} and can alter the properties and reactivity of these isolated fragments.

Up to the beginning of the 1990s, the structures of PA had not been investigated and studies^{21,22} on the X-ray diffraction of the allenic phosphonate **1** and the allenic 1,3,2-oxazaphospholidine **2** as well as the report²³ concerning the investigation of the dichlorides of allenylphosphonic acid **3a** and 3-methylbuta-1,2-dienylphosphonic acid **3b** by gas electron diffraction (GE) were published only a few years ago. The geometrical parameters of the principal fragments of molecules of compounds **1–3a,b** are presented in Table 1.

The allene fragment in PA molecules is linear and has an orthogonal configuration of the substituents at the C(1) and C(3) atoms. The C(1)=C(2) bond is somewhat longer than the double bond remote from the phosphorus atom. The lengths of both bonds are close to the value 1.3129(9) Å obtained²⁴ for propadiene $\text{CH}_2=\text{C}=\text{CH}_2$.

The lengths of the P–Cl bonds in the molecules of the dichlorides **3a,b** [2.011(1) and 2.024(2) Å respectively] are close to the values found for vinylphosphonic dichloride $\text{CH}_2=\text{CH}-\text{P}(\text{O})\text{Cl}_2$ [2.016(4) Å]²⁵ and methylphosphonic dichloride $\text{MeP}(\text{O})\text{Cl}_2$ (2.011–2.013 Å)²⁶ and are somewhat greater compared with the analogous bonds in the POCl_3 molecule [1.992(3) Å]. The P=O (1.453 Å) and P–O (1.566–1.574 Å) bonds in the molecule of the allene **1** have lengths almost identical with the statistical average values for the $(\text{XO})_2\text{P}(\text{O})-\text{C}$ fragments 1.457(9) Å for P=O and 1.571(13) Å for P–O.²⁷

In the molecules of the allenes **1** and **3a**, which are predominantly (100% and 72% respectively) in the *s-cis*-conformation

Table 1. The bond lengths (d) and O=P–C=C torsional angles (φ) in the molecules of the PA **1–3a,b**.

Com- pound	Met- hod	$d/\text{\AA}$				φ/deg

^a The fraction of the corresponding conformation.

(the O=P–C=C torsional angle is $\varphi = 0^\circ$), the P–C(1) bond is somewhat shorter compared with the statistical average length of the P–C(sp^2) bond, which is 1.81 Å^{26,28–30} (1.817–1.822 Å for the dichloride of vinylphosphonic acid); in the case of the allene **3b** (51.6% of the *s-cis*-conformation), this effect is weaker; in the molecule of compound **2**, where the O(1)=P–C(1)=C(6) fragment has the anticlinal conformation, the P–C(1) bond length is close to the standard value. This suggests either a comparatively lower degree of conjugation in the molecules of *s-cis*-PA or the occurrence of a different, specific to allenylphosphonates, intramolecular interaction in the case of the *s-cis*-conformation. This question will be considered below; we shall only note that the interaction through space of the 3d orbitals of the P atom with the π -system of the allyl double bond, mentioned previously, is impossible for PA because of considerations relating to the molecular geometry.³¹

The conformational composition of the PA has been investigated with the aid of vibrational spectroscopy (IR and Raman),^{32–35} the dipole moment method,^{36,37} the Kerr effect,³⁶ and electron diffraction in the gas phase.²³ The results of all the investigations show that the principal conformation relative to the C–P bond is cisoid, characterised by the coplanar disposition of the O=P–C=C fragment ($\varphi \approx 0^\circ$). The fraction of this conformation varies as follows: 72% in the gas phase²³ and 70% in solution³⁷ for the allene **3a**, 51.6% in the gas phase²³ for the phosphonic dichloride **3b**, and 100% in the crystalline state for compounds **1** and **3a,b** and a number of other allenes^{21,37} (with the exception of compound **2**).²² Our calculation of the dependence of the total energy of the allene **3a** molecule on the O=P–C(1)=C(2) angle by the PM3 method demonstrated the presence of two minima — a deeper minimum corresponding to the *cis*-conformation ($\varphi = 0^\circ$) and a shallow minimum at 180° . The rotational barrier is $< 2 \text{ kcal mol}^{-1}$. These results agree with the literature data on the conformational equilibrium in the allenecarboxylic³⁸ and vinylphosphonic acids,^{35,39–41} for which the eclipsed conformation is also the most stable.

At the same time, it is essential to note that ideas concerning the geometry of the second conformer of PA (as well as vinylphosphonates) have changed in recent years. It had been postulated earlier that the minor component is characterised by planar *s-trans*-dispositions of the atoms of the O=P–C=C fragment (by analogy with acrylic acid derivatives⁴²). However, the results of recent studies on PA by gas electron diffraction²³ support a nonplanar structure of this fragment. Thus, in the case of the allenes **3a,b**, a mixture of two rotational isomers with the following angle φ corresponds to experimental data: 0° (72.1%) and 123.3° (27.9%); 0° (51.6%) and 109.1° (48.4%). The anticlinal conformation (130°) occurs also for the allene **2** in the crystalline state.

Analysis of vibrational spectra³⁵ and *ab initio* calculations^{43–45} led to similar results as regards the conformational equilibrium in the molecules of vinyl- and *trans*-propenyl-phosphonates: the second minimum corresponds to the anticlinal

conformation (the planar *s-trans*-conformation corresponds to the transition state) for rotational barriers of $\sim 3 \text{ kcal mol}^{-1}$. For the conformers of *cis*-propenyl-phosphonates, the barriers to internal rotation are much higher. The fraction of the *s-trans*-form increases with increase in the steric hindrance induced by the interaction of the phosphoryl group and the substituent in the *cis*-position and also with increase in solvent polarity.⁴⁶ The total energy minimum at $\varphi = 0^\circ$ is due to the interaction of the nonbonded atoms, while the additional minimum is caused by intramolecular charge transfer from the vinyl fragment to the phosphorus-containing group.⁴⁷

The question of the existence and extent of conjugation in PA molecules arises in connection with the nonplanar structure of the minor conformers. Since there is virtually no information about this in the literature, we shall consider briefly data on conjugation in vinylphosphonic acid derivatives, assuming that the general rules are valid also for PA. It has been noted³⁵ that the extinction coefficients of vinylphosphonates are higher than those of the homologous allylphosphonates. This indicates the presence of π -conjugation between the vinyl and phosphorus-containing fragments, but it is much weaker than, for example, in the case of acrylic acid derivatives. The absorption by propenylphosphonates is greater than by vinylphosphonates, which may be accounted for by the hyperconjugation effect of the methyl group. The negative charge on the C(1) atom of vinylphosphonic acid is higher than on the C(2) atom (Table 2). This finding was initially regarded as an argument in support of the conjugation of the double bond and the P=O group,⁴³ but it was shown later^{44,45} that in this system conjugation is manifested weakly and that the inductive effect and hyperconjugation with participation of the PO₃ fragment must be invoked in order to account for the electronic structure of vinylphosphonates. The strong π -acceptor effect of the O=PCl₂ fragment has been attributed⁴⁸ to the group π^* orbitals made up of the σ^* orbitals of the P–Cl bonds.

The structure of the PA **3a–f** has been investigated by photoelectron (PE) spectroscopy and by means of quantum-chemical

nonempirical calculations.⁴⁹ It was shown that the 4-31 G basis set is the minimal basis set for the establishment of proportionality between the calculated molecular orbital (MO) energies and the experimental ionisation potentials (IP).

According to *ab initio* calculations, the main contribution to the highest occupied MO comes from the $p\pi(\text{O})$ and the π_1 and π_2 orbitals of PA [$\pi_1(a'')$ is the orbital of the C atom closest to the P atom and $\pi_2(a')$ is the orbital of the C atom remote from the P atom; a' and a'' correspond to the symmetry and antisymmetry of these orbitals relative to the OPCC reflection plane respectively]. The ionisation energies are similar and vary as a function of the nature of the substituents at the C atom. Fig. 1 presents the correlation diagram for the ionisation potentials of a series of PA, the dichloride of vinylphosphonic acid **4**,⁴⁹ its diethyl ester **5**,⁴⁷ and the bis(dimethylamide) **6**,⁵⁰ 3-methylbuta-1,2-diene **7**, and propadiene **8**.⁵¹ The form and intensity of the bands in the PE spectra of PA permit the interpretation, to a first approximation, of the experimental IP as the ionisation energies of individual fragments of the molecule. We shall consider how the mutual influence of these fragments affects the ionisation potentials of PA.

Figure 1. The correlation diagram for the ionisation potentials of the phosphorylated allenes **3a–f**, the alkenes **4–6**, 3-methylbuta-1,2-diene **7**, and propadiene **8**.

The replacement of two H atoms in the dichloride of vinylphosphonic acid by the methylene fragment increases the energy of the $\text{C}(1)=\text{C}(2)$ bond by 0.7 eV, compensating fully the decrease in the energy of the corresponding π orbital caused by the presence of the electron-accepting $\text{O}=\text{PCl}_2$ fragment (IP_1 for ethene is 10.51 eV⁵²), while the introduction of the $=\text{CMe}_2$ fragment increases the energy of the $\text{C}(1)=\text{C}(2)$ bond by 1 eV. On passing from ethene to allene, the energy of the π orbital increases by only 0.5 eV. Comparison of the data for PA with the analogous values for a series of other allenes⁵³ shows that the influence of the phosphorus-containing fragment on the π_1 bond is considerable and is largely determined by the inductive effect of the substituent. The transfer of electron density from the allene system to the phosphoryl group explains the decrease in the ionisation energy of the $p\pi(\text{O})$ orbital on passing from the dichloride of vinylphosphonic acid **4** (11.5 eV) to the dichloride of allenylphosphonic acid **3a** (11.25 eV); the ionisation energy of the $p\pi(\text{O})$ orbital of the allene **3b** disubstituted at the C(3) atom (11.14 eV) is lower still. We quote for comparison the known ionisation energies of the $p\pi(\text{O})$ orbitals for $(\text{EtO})_2\text{P}(\text{O})\text{H}$ (11.35 eV), $(\text{EtO})_2\text{P}(\text{O})\text{NEt}_2$ (11.41 eV),⁵⁴ and $\text{Cl}_2\text{P}(\text{O})\text{Me}$ (11.49 eV).⁵⁵ On the other hand, the ionisation energies of the $p\pi(\text{O})$ orbitals of diethyl vinylphosphonate **5** and the allenylphosphonic acid derivatives **3c,d**

were found to be similar, the IP of the allene **3d** being higher than that of the phosphonate **5** (10.7 and 10.6 eV respectively).

The replacement of two H atoms in the ethene molecule by the $\text{Cl}_2(\text{O})\text{P}-\text{C}=\text{C}=\text{C}$ fragment hardly influences the ionisation energy of the double bond (10.5 eV), while IP_2 of the allene **3b** is higher than the ionisation energy of the π orbital of isobutene (9.24 eV)⁵² by only 0.17 eV. Furthermore, the ionisation energy of the π orbitals of the phosphonate **3d** was found to be lower than that for the unsubstituted allene $\text{H}_2\text{C}=\text{C}=\text{CH}_2$ (10.04 eV). It had been shown earlier that the influence of the substituent on the bond of the allene system remote from it is best described within the framework of the long-range field effect, whereupon there is a correlation between the IP of monosubstituted allenes and the dipole moments of the corresponding alkenes.⁵³ It might have been expected that the introduction of a phosphorus-containing fragment would appreciably reduce the energy of the π_2 orbital and the corresponding IP of the allene **3a** would therefore be higher by 0.5 eV than the observed value (Fig. 2) For the allene **3d**, the difference between the real ionisation potential and the value expected on the basis of the inductive effect approaches 1 eV. The validity of the employment of this correlation for PA is based on the similar conformational behaviour of PA and vinylphosphonates and also on the existence of the above correlation for the π_1 orbitals. A similar albeit a weaker effect (Fig. 2) has been observed in the series of alkoxyallenes $(\text{RO})\text{HC}=\text{C}=\text{CH}_2$.⁵⁶ It can be explained by the orbital interaction of the nonbonded fragments through space.

Quantum-chemical calculations of the molecular orbital ener-

Figure 2. The correlation of group dipole moments (μ) of the substituents and the second ionisation potentials of allenes (**1**), PA (**2**), and alkoxyallenes (**3**).

gies of a series of PA by the AM1 and PM3 methods have indicated the possibility of orbital interactions specific to allene derivatives of phosphonic acids in the *s-cis*-conformation, namely, the interaction through space of the $\text{P}(\text{O})$ orbital of the oxygen atom of the $\text{O}=\text{P}$ group with the π_2 orbital in the allene system having a similar energy and symmetry (Fig. 3). The effectiveness of this interaction should increase with decrease in the difference between the energies of the π_2 and $p(\text{O})$ orbitals and hence should be manifested most strongly in the molecules of allenylphosphonic acid amides and allenylphosphine oxides. As a result of this, the *s-cis*-conformers of the latter should be additionally destabilised. The two mutually orthogonal π systems comprising the PA skeleton (the $\text{O}=\text{P}$ group may be regarded as a highly polarised triple bond⁵⁷) are analogous to the system of two triple bonds.¹⁹ For PA conformations other than the *s-cis*-form, account must be taken of the possibility of similar orbital interactions through space with participation of, for example, the lone pairs of the O atom in the POC fragment, *etc.*

Thus the mutual influence of the phosphorus-containing fragment and the double bond remote from the P atom is manifested by two mutually compensating effects, which determines the unique position of PA both in the series of other

Figure 3. The highest occupied MO of the allene **3** (calculation by the PM3 method; the continuous and dashed lines correspond to different signs of the wave function).

unsaturated phosphoryl compounds and in the series of substituted allenes.

We shall consider in greater detail the changes in the allene system occurring when the substituents at the P atom are varied. The presence of the $X_2P=O$ ($X = Me, OMe, Cl$) group has little effect on the relative energies of the π_1 and π_2 orbitals: the energies of the latter in the molecules of compounds **3a** and **3d** are similar, whilst for the allenes **3b**, **3e**, and **3f** the difference between them is equal to the difference between the energies of these orbitals in the molecule of 3-methylbuta-1,2-diene **7**. The absolute energies of the π_1 and π_2 orbitals in the molecules of compounds **3e,f** and **7** are similar; in the presence of the more electron-accepting $Cl_2P=O$ group, they diminish by approximately 0.5 eV. On the other hand, in the molecule of the dimethylamide **3c** the energies of the π orbitals differ appreciably and there exists qualitative evidence supporting the assignment of IP_2 (9.56 eV) to the π_1 orbital. The presence of two methyl groups at the P atom in the phosphine oxide **3f** greatly reduces the ionisation energy for the $O=P$ group.

Table 2 presents the effective charges on the atoms of the allene fragment calculated *ab initio* in terms of the 4-31 G basis set,⁴⁹ while Table 3 presents data on the energies and compositions of the π orbitals of the two model PA **9** and **10**, the acid chloride **3a**, and the dienes **7** and **8**. Similar data have been obtained^{1,58} with the aid of the semiempirical CNDO/2 method (the *spd* basis set). The degenerate frontier orbitals of the unsubstituted allene are located predominantly on the terminal atoms. The presence of the $H_2P=O$ or $Cl_2P=O$ group in the allene molecule has little effect on the relative energies of the π orbitals, but leads to a slight delocalisation of the latter and also to a change in the polarisation of the π_1 bond. The situation changes sharply in the case of the allenes **3b,e,f** in which the degeneracy of the π orbitals is removed as a consequence of hyperconjugation with the methyl groups; the polarisation of the π_2 orbital then changes and the overall electron density on the C(3) atom is appreciably reduced.

The calculated atomic charges are satisfactorily correlated with ^{13}C NMR spectroscopic data (Table 4) and illustrate the influence of the substituents on the distribution of electron density in PA molecules. The change in the polarisation of the π_1 bond on passing from 3-methylbuta-1,2-diene to PA is manifested by a downfield shift of the C(1) signal. The presence of alkyl substituents at the C(3) atom leads to a 10–15 ppm downfield shift of its signal in the ^{13}C NMR spectrum.⁵⁹ The chemical shifts in the ^{31}P and ^1H NMR spectra of PA are in the usual range for unsaturated phosphonic acid derivatives and have been discussed in fair detail.¹

The dipole moments of PA are somewhat greater compared with those of the corresponding alkenylphosphonic and alkadienylphosphonic acid derivatives³⁶ (Table 5), the experimental values exceeding the values calculated assuming additivity. This

has been attributed³⁶ to the increased polarisability of the allene system under the influence of substituents, which confirms the transfer of electron density from the allene system to the phosphorus-containing fragment. The dipole moments of PA with identical structure of the allene skeleton increase in the following sequence: esters < acid dichlorides < dimethylphosphine oxides. The dipole moments of allenes mono- and di-substituted at the C(3) atom are somewhat higher.

The molecular electrostatic potential (EP) is used widely to determine the interaction energies in the initial stage of the reaction and the direction of attack on the substrate by charged species.⁶⁰ This quantity is relatively insensitive to the accuracy of the wave functions and the results of calculations by semiempirical methods are comparable to those of *ab initio* calculations.⁶¹

Photoelectron spectroscopy makes it possible to obtain objective information about occupied molecular orbitals.⁶² There are at present no experimental data on this topic. We shall therefore henceforth make use exclusively of the results of quantum-chemical calculations (Table 2).⁴⁹ The first and second unoccupied molecular orbitals of PA are located on one of the double bonds of the allene system. According to *ab initio* calculations in terms of the 4-31 G basis set, the energy of the π_2^* orbital in molecules of the allenes **9** and **10** is lower than that of the π_1^* orbital. The introduction of two Cl atoms into the phosphorus-containing fragment decreases the energies of both lowest unoccupied orbitals in compound **3a**, the influence on the π_2^* orbital being greater. This leads to the inversion of the unoccupied orbitals, but the difference between the energies of the π_1^* and π_2^* orbitals remains small. On the other hand, the population of the $2p\pi$ atomic orbitals of the C(1)=C(2) bond exceeds by a factor of 2 the degree of localisation of the π_2^* orbital of the C(2)=C(3) bond and according to Zverev *et al.*,⁴⁹ this particular orbital actually controls the interaction of the allene **3a** with aryl azides. The AM1 method yields results qualitatively close to the values calculated by the *ab initio* method, although it leads to the inversion of the unoccupied orbitals for the allene **3a**.

According to the calculation in terms of the 4-31 G basis set, the energies of the unoccupied and occupied π and π^* orbitals in the molecules of PA vary in parallel. This made it possible to

postulate⁴⁹ that, depending on the substituents at the P atom, the above compounds may behave as electron donors or acceptors or can interact *via* a neutral mechanism, as happens for example, in the reaction with aryl azides.¹ The characteristic features of the electronic structure of PA, responsible for their increased reactivity in relation to both nucleophiles and electrophiles, have attracted attention to PA as substrates for the investigation of biphilic reagents.

On the basis of the entire set of data examined above, one may postulate that, in contrast to allenes unsubstituted at the C(3) atom, the reactions of 3,3-disubstituted PA with electrophiles occur more readily and, in the case of orbital control,⁶³ selectively with respect to the C(2) = C(3) bond (HOMO). On the other hand, in the case of charge control electrophilic attack should be directed to the C(1) = C(2) bond, where the highest negative charge density is concentrated (Table 2).

Thus, by varying the substituents at the P atom and in the allene system, one may vary the reactivity of both the O atom of the phosphoryl group and of the two double bonds and, if required, one may activate selectively a particular reaction centre.

III. Interaction of phosphorylated allenes with electrophiles

1. Reactions of phosphorylated allenes with the halogens and sulfonyl chloride

In 1977, Braverman and Reisman⁶⁴ observed that allenylphosphonic and allenylphosphinic acids **3g,h** cyclise on treatment with bromine to 1,2-oxaphosphol-3-enes **11a,b** respectively.

R = Ph (**3g**, **11a**), OH (**3h**, **11b**).

Subsequently it was shown that the bromination of PA monosubstituted at the C(3) atom is also accompanied by a similar cyclisation.⁶⁵

Scheme 1

The intermediate formation of the tertiary carbonium ion **14**, in equilibrium with a quasi-phosphonium salt (Scheme 1), the elimination of HBr from which actually leads to the oxaphospholenes **11a,b**, has been postulated.⁶⁴ However, it has been shown⁶⁵ that the bromination of the optically pure acid **3i** takes place with 41% stereoselectivity. This shows that, in the case of allenylphosphonic acids monosubstituted at the C(3) atom, the bromonium ion **12** or the nonplanar secondary carbonium ion **13** is formed as an intermediate rather than the planar carbonium ion **14**. The O atom of the phosphorus-containing group (especially in the case of the *s-cis*-conformation) is capable of trapping the onium ion **12** fairly effectively, which prevents racemisation. The quasi-phosphonium salt formed is unstable and readily eliminates an HBr molecule. It is of interest to note that the bromination of optically active allenecarboxylic acids takes place with approximately the same stereoselectivity,⁶⁶ while in the case of the corresponding allenic alcohols complete racemisation is observed.⁶⁷

The available information about the reactions of free alka-1,2-dienylphosphonic and the corresponding phosphonic acids with the halogens is limited to the two communications mentioned above. The halogenation of esters of these acids has been studied in greater detail.^{64,68–78} For substrates di- and mono-substituted at the C(3) atom, it is also as a rule accompanied by cyclisation (Scheme 2).

In this case, the reaction also proceeds *via* a stage involving the formation of insufficiently stable quasi-phosphonium salts, which rapidly split off an alkyl halide. The rate of the process depends on the nature of the halogen. On chlorination and bromination, cooling is required (the bromination reaction is weakly exothermic), while on iodination heating is needed. The reactivities of substituted allenylphosphonic esters in relation to interhalogens

Scheme 2

$R^4 = \text{Ph}$, $R^5 = \text{Alk}$; $R^4 = R^5\text{O}$, $R^5 = \text{Alk}$.

have been investigated⁷² and it has been observed that the rate of reaction with ICl is almost twice as high as that with IBr (it is an order of magnitude higher than that for the reaction with I₂).

$R^1 = R^2 = \text{H}$ (**3j**, **11d,f**), Me (**3k**, **11e,g**); $\text{Hal} = \text{Cl}$ (**11d,e**), Br (**11f,g**).

The halogenation of 2-oxo-1,3,2-dioxaphospholanes **3j,k** is accompanied by the opening of the dioxaphospholane ring and the formation of an oxaphospholene ring.⁷⁷ The oxaphospholene **11h** has been detected in a small amount on chlorination of diethyl propadienylphosphonate **3i**, although the main reaction products were found to be the 2,3-adduct **15** and diethyl propynylphosphinate **16**.⁷¹

The different ways in which 3-substituted allenylphosphonic and propadienylphosphonic acids are halogenated shows that the stability of the intermediate type **13** or **14** carbonium ion (see Scheme 1) is one of the decisive factors for the occurrence of cyclisation.

Sulfuryl chloride also reacts with the esters of di- and mono-substituted alka-1,2-dienylphosphonic acids with formation of 4-chloro-1,2-oxaphospholenes,^{79,80} while the reaction with propadienylphosphonic acid esters affords a complex mixture in which adducts formed *via* the C(2)=C(3) bond predominate.⁸⁰

The mode of the halogenation reaction of allenylphosphonic acid dichlorides depends also on the substituents at the C(3) atom of the allene system. In the case of disubstituted allenenes, tetrahalo-1,2-oxaphosphol-3-enes or quasi-phosphonium salts are formed.^{81–90} The tetrahalo-1,2-oxaphosphol-3-enes are stable in nonpolar solvents for several days. After more prolonged storage, they split off the hydrogen halide and are converted into the dichlorides of the corresponding 2-haloalka-1,3-dienylphosphonic acids.^{82,84–91} A proton is split off from the least hydrogenated carbon atom in the substituents R^2 and R^3 (Scheme 3).

$R^1 = \text{H, Alk, Ar; } R^2 = R^3 = \text{Alk; Hal} = \text{Cl, Br.}$

In polar solvents (such as nitromethane, chloroform, *etc.*), the evolution of the hydrogen halide is faster; it is accelerated on heating or removal of the solvent. The process is exothermic, *i.e.* the reaction proceeds in the direction of the thermodynamically more stable product. It is noteworthy that HBr is split off more readily than HCl and in certain cases the intermediate phosphorane cannot be detected. This may be explained by the fact that the bromo-derivatives of pentacoordinate phosphorus have a more polar structure.⁸²

The properties of phosphoranes are characteristic of P^V halides. Thus they readily interact with various nucleophiles (Scheme 4).⁸³

The alka-1,3-dienes formed from phosphoranes have the *s-cis*-configuration of the double bonds. This has been demonstrated by a study of their ^1H NMR spectra with the aid of lanthanide shift reagents⁹¹ and also by studies of the configurations of the products of the reactions of dienes with electrophiles. The halogenation of the alka-1,3-dienylphosphonates obtained by the method described above is accompanied by cyclisation with formation of six-membered heterocycles — derivatives of 5,6-dihydro-2*H*-1,2-oxaphosphorine.^{92,93} The halogenation of alka-1,3-dienylphosphonates synthesised by other methods (having the *s-trans*-conformation) leads not to oxaphosphorines but to the products of the addition of the halogen to the double bond remote from the P atom.⁹⁴ The skewed *s-cis*-conformation of the alka-1,3-diene system may impart also other unusual properties to phos-

phorus-containing alka-1,3-dienes. Thus, when the dichlorides of alka-1,3-dienylphosphonic acids **17a–e**, containing a bulky substituent in the 3-position, are heated, cyclisation takes place readily with formation of the dichlorides of cyclobutenylphosphonic acids **18a–e**.^{95,96}

$R = \text{H (3m, 17a, 18a), MeOCH}_2 \text{ (3n, 17b, 18b), ClCH}_2 \text{ (3o, 17c, 18c), Ph (3p, 17d, 18d), } p\text{-MeC}_6\text{H}_4 \text{ (3q, 17e, 18e).}$

The presence of a bulky group in the α -position relative to the P atom promotes an unusual mode of chlorination of the dichloride of 1-*tert*-butyl-4-chloro-3-methylbuta-1,2-dienylphosphonic acid **3r**: the adduct **19**, obtained by addition to the 2,3-double bond, is formed in 42% yield.^{89,90}

Evidently the presence of this compound can be accounted for by the *syn*-attack by the electrophile relative to the phosphorus atom — a process which is unfavourable in the majority of cases, but in this substrate is caused by the presence of the *tert*-butyl group. In addition, the phosphonium salt **20a** is formed in 39% yield. It is sufficiently stable to be isolated in a pure form. The salt structure of compound **20a** has been confirmed by the chemical shift of the phosphorus signal in the ^{31}P NMR spectrum: $\delta = +93$ ppm.

The *syn*-attack by the electrophile takes place to a slight extent also on halogenation of the dichloride of propadienylphosphonic acid **3a**. It is noteworthy that the cyclisation is not observed also in the case of *anti*-attack relative to the phosphorus atom: this confirms yet again the decisive influence of the alkyl substituents at the C(3) atom on the direction of the process. The halogenation of the allene **3a** takes place only when the temperature is raised to 60–65 °C. One mole of Cl_2 adds to the double bond remote from the phosphorus atom with the predominant formation of a mixture of the dichlorides of 2,3-dichloro-1-(*E*)-propenylphosphonic acid **21a** and the corresponding *Z*-isomer **21b** (with the ratio 40:41 = 5:1). By carrying out the reaction at the same temperature for 8 h, it was possible to obtain the exhaustive chlorination product **22** in 72% yield.⁷¹

The chlorination of the chloride of 3-methylbuta-1,2-dienyl(phenyl)phosphinic acid **3s** leads to the formation of the phosphonium salt **20b**, which is converted into the oxaphospholene **11i** on interaction with moist air or SO₂. The same chain of reactions occurs on treatment with sulfuryl chloride.⁹⁷

The use of sulfuryl chloride makes it possible to obtain derivatives of 1,2-oxaphosphol-3-ene from the dichlorides of alka-1,2-dienylphosphonic acids not only disubstituted but also monosubstituted at the C(3) atom.⁷⁹ The absence of alka-1,3-dienes of type **17a–e** in these reactions may be caused either by the rapid conversion of the intermediate phosphorane into an oxaphospholene with a tetracoordinate phosphorus atom as a result of the interaction with the SO₂ present in the mixture⁷⁹ or by the fact that the above phosphoranes are not formed at all as intermediates in the given instance. It has been suggested² that the reaction proceeds *via* a stage involving the formation of a carbonium ion with synchronous nucleophilic attack of the O atom of the phosphoryl group on the C(3) atom and of one of the O atoms of the sulfo-group on the P atom. This results in the elimination of the chloride ion and cyclisation (Scheme 5).

Scheme 5

Y = Cl, Ph; R¹ = R² = Alk;
R¹ = H, R² = Alk.

The attack by Cl[−] on the S atom leads to the elimination of thionyl chloride. The chloride of unsubstituted allenylphosphonic acid **3a** reacts with SO₂Cl₂ to form a complex mixture of adducts resulting from addition to the double bonds (as in chlorination by Cl₂).^{71, 79}

The modes of the reactions of PA with halogenating agents may depend not only on the substituents at the allene system but also on the nature of the groups at the P atom. Thus, in the interaction of 3-methylbuta-1,2-dienylphosphonous acid **3t** with bromine water, the cyclisation is accompanied by the oxidation of the P–H bond.⁹⁸

The halogenation of the esters of alka-1,2-dienyl(phenyl)phosphinic acid disubstituted at the C(3) atom leads to 1,2-oxaphospholenes.⁶⁴ In the reactions of allenylphosphine oxides with the halogens, cyclisation proceeds with formation of stable phosphonium salts, since in this case the stabilisation of the intermediate by the elimination of an alkyl halide is impossible. For example, the product of the reaction of the phosphine oxide **3f** with chlorine in CCl₄ is the cyclic phosphonium salt **20c**.⁹⁷

On the other hand, the diphenylphosphine oxides **3u–w** afford under the same conditions the products **23a–c**, which are 2,3-adducts. The observed differences may be explained by the fact that aromatic substituents, conjugated with the oxygen atom of the O=P group, reduce its nucleophilicity. However, according to Angelov *et al.*,⁹⁷ it is more likely that the bulky phenyl groups exert a steric influence on the geometry of the transition state, retarding cyclisation and promoting the addition reaction.

R¹ = R² = H (**3u**, **23a**), Me (**3v**, **23b**); R¹ = H, R² = Me (**3w**, **23c**).

2. Reactions of phosphorylated allenes with proton-donating electrophiles

The study of the reactions of alka-1,2-dienylphosphonic acids with Lewis acids^{99, 100} showed that only the acids disubstituted at the C(3) atom undergo protophilic cyclisation. Propadienylphosphonic acid affords exclusively decomposition products. 1,3-Di-(*tert*-butyl)allenylphosphonic acid **3x** does not interact with HClO₄ in tetrahydrofuran (THF) (18 h, 25 °C), with toluene-*p*-sulfonic acid in a CHCl₃–H₂O mixture (54 h, 25 °C),¹⁰¹ and with 2 M HCl in 80% aqueous diglyme,⁹⁹ while the reaction with trifluoroacetic acid leads unexpectedly to the ketone **25** (in 85% yield).¹⁰⁰ This has been explained¹⁰⁰ by electrophilic attack on the terminal C atom of the allene system.

On interaction with carbonyl compounds^{102, 103} and with azomethines,^{103, 104} the acid **3t** cyclises *in situ* with formation of the 1,2-oxaphosphol-3-enes **11j,k** (Scheme 6). The analogous reaction of the corresponding amide **3y** with RCHO leads to the oxaphospholene **11l** containing the O–P=N fragment.¹⁰⁵

Treatment of 3,3-disubstituted alka-1,2-dienylphosphonic acids **3t,z** with gaseous HCl results in the formation of the oxaphospholenes **11m,n**.¹⁰⁶

R = H (**3t**, **11m**), Me (**3z**, **11n**).

On treatment with HCl or hypophosphorous acids in the presence of atmospheric oxygen, hexa-1,3,4-trien-3-ylphosphonic acid **26a** cyclises, which is accompanied by the oxidation of the P–H bond.¹⁰⁷

Type **26b** phosphinic acids cyclise to oxaphospholenes above 100 °C in the presence of inorganic acids.¹⁰⁸

R¹ = H, Br; R² = Ph, CH₂Br.

The dichlorides of alka-1,2-dienylphosphonic acids react very slowly with HCl (more slowly than with other electrophiles). After 24 h in inert solvents, the interaction of the chlorides of 3-mono-substituted and 3,3-disubstituted acids with HCl has not been observed.¹⁰⁹ This reaction could be achieved by keeping the mixture in CH₂Cl₂ for 25 days. In the case of the allene **3b**, it proceeds with formation of a cyclic phosphorane,⁹⁹ which, after treatment with water, affords the corresponding acid, while its interaction with alcohols gives rise to esters of this acid (Scheme 7).

Scheme 7

The hydrochlorination of the dichlorides of alka-1,2-dienylphosphonic acids is much faster in the presence of tertiary amines or other aprotic ionising additives, for example, the oxides of tertiary phosphines, hexamethylphosphoramide, *etc.*^{76, 108} However, this reaction proceeds *via* a nucleophilic mechanism and leads to the dichlorides of 2-chloroalk-2-enylphosphonic acids. The corresponding acid difluorides react similarly (Scheme 8).¹⁰⁸ The presence of electron-accepting substituents promotes hydrochlorination. Thus HCl adds to allenes containing the CH₂F group already during their synthesis from acetylenic alcohols and PCl₃ in the presence of pyridine while in the case where the CH₂Cl group is also present the reaction is so fast that the allene itself cannot be isolated.⁷⁶

Scheme 8

R¹, R², R³ = Alk, Ar, CH₂Cl, CH₂F; X = Cl, F.

It has proved convenient to employ dichloromethylsilane for the hydrochlorination of the dichlorides of alka-1,2-dienylphosphonic acids **3a,b**. HCl then adds to the α- and β-double bonds.¹¹⁰ The reaction of the dichlorides of 1-methoxyalka-2,3-diene-2-ylphosphonic acids **26c** with dichloromethylsilane leads exclusively to the product **28a** of the allene–1,3-diene isomerisation.⁸⁶

$\text{R}^1 = \text{R}^2 = \text{H}$ (3a, 27a, 21a,b);
 $\text{R}^1 = \text{H}, \text{R}^2 = \text{Me}$ (3b, 27b, 21c,d);
 $\text{R}^1 = \text{MeOCH}_2, \text{R}^2 = \text{Me}$ (26c, 28a).

The hydrochlorination of PA having two or three P–C bonds is accompanied by cyclisation.¹¹¹ In the case of (3-methylbuta-1,2-dienyl)dimethylphosphine oxide **3f**, the quasi-phosphonium salt **20d** is formed. It is relatively stable in inert solvents, but is unstable in water and is in equilibrium with compound **29**. At pH 3, the equilibrium is fully displaced towards the open-chain compound. The ring opening may be regarded as the second stage of the Arbuzov reaction. In the given instance, the above process is reversible and the salt **20d** is reformed on raising the acidity to pH 1.

If concentrated H_2SO_4 is used for the cyclisation, it is possible to detect the formation of quasi-phosphonium salts also in the case of the esters of allenylphosphinic and allenylphosphonic acids.^{111,112} On treatment with 40%–70% H_2SO_4 in water or aqueous dioxane, the hydrolysis of the quasi-phosphonium salts is so fast that they cannot be clearly detected. In both cases, the rate-limiting stage is the protonation of the allene to a carbonium ion, after which ring closure takes place with formation of a quasi-phosphonium salt.¹¹¹

The influence of the acidity of the medium, of the isotope effect or the solvent, and of the structure of the phosphorus-containing compound on the rate and direction of the addition reaction has been investigated.¹¹³ The rate constants obtained at different H_2SO_4 concentrations confirm that the reaction is acid-promoted. This is also indicated by the magnitude of the kinetic isotope effect $k_{\text{H}}/k_{\text{D}}$, which is 1.47 for 70% H_2SO_4 and 4.23 for anhydrous trifluoroacetic acid. Thus the cyclisation represents electrophilic addition involving a proton and the substrate in its rate-determining stage. It is noteworthy that the presence of the phosphorus-containing fragment in the substrate is responsible for certain differences from the majority of other reactions involving the conversion of an alkene into a carbonium ion.^{113,114}

Depending on the nature of the substituent and the solvent polarity, the interaction of esters of 3,3-disubstituted alka-1,2-dienylphosphonic acids with HCl leads to the formation of 1,2-oxaphospholenes or 1,2-adducts (Scheme 9).^{115,116}

In polar solvents, cyclisation takes place exclusively. In non-polar solvents, the reaction proceeds in a more complex manner and 1,2-adducts are obtained together with 1,2-oxaphospholenes. The dimethyl esters of alka-1,2-dienylphosphonic acids, which

afford only oxaphospholenes regardless of solvent polarity, are an exception. The phenyl substituent in the α -position in the allene system promotes partial hydrolysis of the ester to the corresponding cyclic acid.

Unsubstituted alka-1,2-dienylphosphonates and the derivatives mono-substituted at the C(3) atom (compounds **3d**, **26d**) are not converted into oxaphospholenes even in polar solvents, giving rise to complex mixtures of products in which the adducts **27c,d** predominate.⁶⁵

$\text{R} = \text{H}$ [**3d**, **27c**, (**E**)-**21e**, (**Z**)-**21e**], Me [**26d**, **27d**, (**E**)-**21f**, (**Z**)-**21f**].

The interaction of PA with dithio-acids of phosphorus has been investigated.¹¹⁷ Possessing dual reactivity, the acids can add to alkenes *via* both electrophilic and nucleophilic mechanisms. Apart from the products of the addition to the α,β -double bond of the allene (evidently *via* a nucleophilic mechanism) and of the alkylation of the dithio-acid by the alkoxy-group of the initial PA, small amounts of the β,γ -adducts (5%–7%) (Scheme 10) and (or) derivatives of 5,5-dimethyl-1,2-oxaphospholene (5%–6%) have also been detected in the reaction mixture. It is of interest that the 1,2-adducts are formed as a result of *syn*-attack relative to the phosphorus-containing fragment, whereas 1,2-oxaphospholenes are the products of *anti*-attack.

The introduction of functional groups makes it possible to expand still further the range of possible synthetic reactions of PA. The results of the hydrochlorination of 1-methoxybuta-2,3-dien-2-ylphosphonates **26e,f** proved of interest from this point of view.^{118,119} The allene–diene rearrangement, accompanied by the elimination of an alkoxy-group, which results in the formation of 3-halobuta-1,3-dien-2-ylphosphonates **28b–e**, takes place in the course of this reaction. In order to investigate the process mechanism, a study was made of the kinetics of the hydrochlorination of the allenes **26e,f** in various solvents. The activation parameters, the isotope effect, and the influence of the solvent and nucleophilic additives agree with synchronous addition-elimination *via* a cyclic transition state involving the coordination of the acid proton to the ester oxygen and of the halogen to the central carbon atom of the allene system. It was shown that the two alternative mechanisms — the heterolytic mechanism (involving the protonation of the alkoxy-oxygen, the elimination of an alcohol molecule, and the subsequent attack by the nucleophile on the allyl carbonium ion) and the nucleophilic mechanism (*via* the attack of the halide anion on the central C atom of the allene system with subsequent elimination of an alcohol) — are unlikely. Thus the introduction of a new nucleophilic centre — the O atom of the ester group — into the allene promotes a change in the mechanism of the reaction with hydrogen halides.

R = H (**26e**, **28b,d**); Me (**26f**, **28c,e**); X = Cl (**28b,c**), Br (**28d,e**).

It has been suggested¹²⁰ that the allene–diene isomerisation of the chloroallenes **26g,h** proceeds similarly.

R = H (**26g**, **28f**); Me (**26h**, **28g**).

The hydration of the 1:1 mixture of the ethyl esters of phenylpropa-1,2-dienyl phosphinic and phenylprop-2-ynylphosphinic acids in 5% H₂SO₄ in the presence of catalytic amounts of HgSO₄ afforded ethyl acetonyl(phenyl)phosphinate in 63% yield.¹²¹ In the presence of H₂SO₄ and Hg²⁺ ions, water adds similarly to allenyl(diphenyl)phosphine with formation of β-oxo-phosphine oxide.¹²

3. Reactions of phosphorylated allenes with sulfenyl chlorides

The interaction of sulfenyl chlorides and unsaturated phosphorus-containing compounds proved extremely interesting and made it possible to observe a series of non-trivial effects. For example, the study of the kinetics of this process demonstrated that it proceeds *via* an *Ad_E3* mechanism and that two molecules of the unsaturated phosphorus-containing substrate participate in the formation of the transition state **A** of the rate-limiting stage of the reaction.¹²²

The study of the electrophilic sulfonylation of PA revealed also a series of features not characteristic of reactions of other electrophiles and determined, in the view of the majority of investigators, by the nature of the intermediate species.

The mode of interaction of sulfenyl chlorides with the dichlorides of alka-1,2-dienylphosphonic acids **3a,b** depends on the presence of substituents at the C(3) atom of the allene system.^{123–128} If the C(3) atom is primary, the reaction leads to 2,3-adducts (with the ratio *E* : *Z* = 85 : 15 in the case of MeSCl or with 100% of the *E*-isomer for PhSCl).¹²⁴ If the C(3) atom is tertiary, then the products are the dichlorides of buta-1,3-dienylphosphonic acids.

The reaction apparently proceeds *via* the formation of an episulfonium ion with its subsequent conversion into a tertiary carbonium ion (Scheme 11). According to a number of investigators,^{1, 124, 125} the reaction proceeds as a rule *via* a cyclic phosphorane intermediate and the formation of different products is determined by the different directions of attack by the chloride ion. The yields of the products of these reactions (57%–63%) are lower compared with the halogenation reaction (85%–95%),^{82–84} which suggests the occurrence of side reactions. Thus it has been shown¹²⁹ that the interaction of the dichlorides of 3,3-disubstituted allenylphosphonic acids **3a,b** and alkanesulfonyl chlorides affords the products of addition to the C(1) = C(2) bond apart from the 1,2-oxaphospholenes. The reaction is carried out in the presence of SO₂ as the fixator of the cyclic intermediate. The ratio of the 1,2-oxaphospholenes and the 1,2-adducts depends on the nature of the substituent at the S atom and on the reaction temperature. The change from R¹ = Me to R¹ = Buⁿ and the lowering of temperature promote an increase in the yield of the 1,2-adducts.

The reaction of SCl₂ with the allene **3b** at room temperature leads to the formation of the adducts **27e** involving the C(1) = C(2) bond and the product **17g** resulting from the elimination HCl in proportions of ~5:3.^{130,131} It is of interest to note that compound **17g** is the first representative of the previously unknown alkadienesulrenyl chlorides. Furthermore, the reaction mixture contains ~5% of the dichloride of 2-chloro-3-methylbuta-1,3-dienylphosphonic acid **17h**.

Scheme 11

It is believed¹²⁹ that the ratio of the 1,2-adduct and the cyclisation product reflect the stability of the episulfonium ions relative to carbonium ions. Effective cyclisation requires the formation of a free carbonium ion. In the episulfonium ion, the effective charge on the C(3) atom is reduced, which lowers the rate of cyclisation. Since the electronegative phosphoryl substituent destabilises the episulfonium ion to a lesser extent compared with the 'open-chain' α -carbonium ion, addition to the double bond adjoining the P atom also becomes possible.

In our view, the use in this instance of the concept of the 'episulfonium ion' is not altogether correct, because, firstly, episulfonium ions are fairly polar and sensitive to electronic factors¹³² and, secondly, it had been shown earlier^{132–134} that episulfonium ions are not in reality intermediates in Ad_E reactions of sulfenyl chlorides and the process proceeds *via* the formation of covalent sulfuranes or tight or solvent-separated ion pairs. It is logical to postulate that the intermediates in Ad_E reactions of sulfenyl chlorides with PA should be not sulfonium ions but much less polar structures. It is possible to account in this way for the formation of adducts involving the C(1)=C(2) bond in reactions with PA (although it is not clear why this process becomes dominant in certain cases).

The reactions of the dichlorides of 1-substituted 3-(*tert*-butyl)alka-1,2-dienylphosphonic acid with MeSCl lead exclusively to 1,3-dienes.⁷⁵

R = Ph, MeOCH₂.

Dialkylphosphorylsulfenyl chlorides react with the dichlorides of alka-1,2-dienylphosphonic acids to form derivatives of 2,4-dichloro-2-oxo-1,2-oxaphospholene (Scheme 12).^{124,125} The interaction of alka-1,2-dienylphosphonic acid esters with sulfenyl chlorides is also determined by the structures of both the allene and the electrophile.

Scheme 12

The data on the reactions of propadienylphosphonic acid esters and R²SCl (R² = Ph, Alk) are contradictory. The structure of the product of addition to the C(1)=C(2) bond in accordance with the Markovnikov rule was initially ascribed to the adduct.¹³⁵ However, subsequently the same workers^{123–125} established the *E*-configuration of the adduct formed by addition to the C(2)=C(3) bond (Scheme 13). 2,4-Dinitrobenzenesulfenyl chloride does not react with PA.¹²⁷

Scheme 13

R¹ = Alk; R² = Alk, Ph.

The interaction of alkanesulfenyl chlorides with propadienylphosphonates monosubstituted at the C(3) atom leads in all cases to a mixture of products of cyclisation and addition to the C(1)=C(2) bond (Scheme 14).¹²⁸

Scheme 14

$R^1 = \text{Me, Et, Pr; } R^2 = \text{Me, Pr.}$

However, Khusainova *et al.*¹²⁶ obtained a mixture of the cyclisation products and the 1,2- and 2,3-adducts in proportions of 1 : 1 : 4 as a result of the reaction of buta-1,2-dienylphosphonic acid esters with MeSCl.

Apart from 1,2-oxaphospholenes, the products of the reactions of the dimethyl esters of 3-methylalka-1,2-dienylphosphonic acids with MeSCl are 1,2-adducts (8%–15% for MeSCl) in the form of a mixture of the *E*- and *Z*-isomers in proportions ranging from 1.7 : 1.0 to 5 : 16.¹³⁶ Furthermore, the reaction of dimethyl 3-methylbuta-1,2-dienylphosphonate affords 4%–7% of buta-1,3-dienylphosphonic acid esters (Scheme 15). The isolation of oxaphospholenes alone (63%–82%) had been reported earlier.¹³⁷

Scheme 15

$R^1, R^2 = \text{Alk; } R^3 = \text{Cl, Me.}$

The analogous reaction with SCl_2 proceeds more selectively and leads to 4-chlorothio-1,2-oxaphospholenes in 92%–95% yields.¹³⁸ The latter readily interact with nucleophiles, which makes it possible to introduce the oxaphospholene fragment into a wide range of organic substrates.^{131, 139, 140} The study of the composition of the reaction mixture also made it possible to establish the formation of a 1,2-adduct (1%–2%) and an alkyl-1,3-diene (4%–7%).¹³¹

The principal product of the reaction of 3-methyl-1-phenylbuta-1,2-dienyl phosphonate **26i** with methanesulfonyl chloride is the adduct involving the $\text{C}(2)=\text{C}(3)$ bond.¹²⁸ On the other hand, the interaction of compound **26i** with SCl_2 leads to the formation of predominantly the adduct **27f** involving the $\text{C}(1)=\text{C}(2)$ bond, the structure of which has been confirmed unambiguously by ^{13}C NMR spectroscopic data.¹³¹

On treatment with alkane(arene)sulfonyl chlorides, allenes containing a bridged substituent in the 3-position afford spiro-linked oxaphospholenes in 71%–90% yield.¹⁴¹ For PA incorporating the 1,3,2-dioxaphospholane ring, the ratio of oxaphospholenes and 1,2-adducts in reactions with alkane-sulfonyl chlorides is 4 : 1, the content of the 1,2-adducts falling to 5% on reducing the temperature from 20 °C to –60 °C.¹⁴²

The stable quasi-phosphonium salt **20e** has been obtained by the interaction of the phosphonate **26j** with benzenesulfonyl chloride in the presence of SbCl_5 .¹⁴³

The reaction of benzenesulfonyl chloride with the PA **3f** leads to the quasi-phosphonium salt **20f** and, when the latter is heated *in vacuo*, HCl is split off and the corresponding 1,3-diene **17i** is formed.¹²⁴

Thus many reactions of PA with sulfonyl chlorides proceed in a manner different from that of the reactions with other electrophiles and a situation which is at first sight paradoxical is observed: the fraction of the adducts involving the $\text{C}(1)=\text{C}(2)$ bond increases with enhancement of the electron-accepting capacity of the substituent at this bond (transition from the dichlorides of allenylphosphonic acids to their esters). It has been postulated hitherto that the main cause of this difference is the possibility of the formation of cyclic intermediates. However, this is insufficient to account for the characteristic features of the reactions described in this section. As an example, we shall consider the interaction of PA and selenenyl chlorides — a class of electrophiles having properties close to those of sulfonyl chlorides, the addition of which to alkenes also proceeds *via* the formation of cyclic intermediates — episelenonium ions.

4. Reactions of phosphorylated allenes with selenenyl chlorides

The mode of the reactions of allenyl phosphonates with selenenyl chlorides also depends both on the structure of the electrophile and on the nature of the substituents at the $\text{C}(3)$ atom of the allene system, but in all cases electrophilic attack is directed exclusively to the $\text{C}(2)=\text{C}(3)$ bond. For example, on treatment with methane-

and benzene-selenenyl chlorides, the esters of propadienylphosphonic acid form 2,3-adducts; in the former case, the *E*- and *Z*-isomers are present in comparable amounts, while in the latter the *Z*-isomer predominates.¹⁴⁴ An interesting interpretation of the results of these reactions has been presented by Macomber *et al.*¹²⁷ On the basis of the allyl spin – spin coupling constant (1.5 Hz) and by analogy with the addition of sulfenyl chlorides, the *E*-configuration was attributed to the adduct of dimethyl propadienylphosphonate and benzeneselenenyl chloride (Scheme 16).

$\text{R}^1 = \text{Alk}; \text{R}^2 = \text{Me, Ph.}$

The interaction of the esters of 3-monosubstituted alkadienylphosphonic acids **26k** with methaneselenenyl chloride also results in the formation mainly of the adducts **21h** involving the $\text{C}(2)=\text{C}(3)$ bond [the *E*- and *Z*-isomers are in proportions of 1 : 3], although the reaction mixture contains also ~10% of the oxaphospholene **11r**.¹⁴⁴ The analogous reaction with benzeneselenenyl chloride led to the isolation of only the oxaphospholene **11s** (Scheme 17).^{127, 144}

The stereochemistry of the cyclisation of the allenylphosphonate **26l** has been investigated.¹²⁷ The reaction proceeds stereoselectively in acetonitrile [65% of (*E*)-**11t** and 35% of (*Z*)-**11t**], but selectivity is lost on passing to chloroform. This has been

explained¹²⁷ by the different degrees of solvation of the intermediate phosphonium ion.

$\text{R} = \text{Alk.}$

The interaction of esters of alka-1,2-dienylphosphinic and the corresponding phosphonic acids with methane- and benzene-selenenyl chlorides leads exclusively to phospholenes.^{127, 144–146} Thus, in contrast to the reactions of PA with sulfenyl chlorides, in this case the addition to the C(1)=C(2) bond was not observed. The different stereoselectivity of the reactions of selenenyl chlorides has been explained¹⁴⁴ by the influence of the substituents at the Se atom and at the C(3) atom of the allene system on the relative stabilities of the intermediate selenonium and carbenium ions (Scheme 18). According to Angelov and Tancheva,¹⁴⁴ the oxaphospholenes are obtained from the (*E*)-**31** ion, while the 2,3-adducts are derived from the selenonium ions **30**, the preferential formation of the *Z*-isomers¹⁴¹ being associated with the fact that the attack by the chloride ion on the selenonium ion (*Z*)-**30** proceeds more readily, for steric reasons, than the attack on the (*E*)-**30** ion.¹⁴¹

In our view, the mechanism of this reaction is more complex and, as in the case of sulfenyl chlorides, may involve the formation of tight and solvent-separated ion pairs.^{132–134}

5. Reactions of hexa-1,3,4-trienyl and hexa-1,2,4-trienyl-phosphonic acids with sulfenyl and selenenyl chlorides

The introduction into the O=P–C=C=C system of additional nucleophilic centres, which can interact with electrophiles, increases significantly the reactivity of PA. The reactions of vinyl-substituted allenylphosphonates are extremely instructive in this respect.

In the interactions with the halogens and sulfur chloride, these compounds exhibit the reactivity typical of allenyl phosphonates, forming derivatives of oxaphosphol-3-enes **11** or alka-1,3-dienylphosphonic acids **17** depending on the substituents at the P atom.^{73, 74, 80, 88}

Diethyl hexa-1,3,4-trien-3-ylphosphonate **26m** reacts similarly with selenenyl chlorides,⁸⁰ but the reaction with sulfenyl chlorides proceeds *via* an unexpected path: together with the 1,2-oxaphospholene **11u**, the thiophene derivative **32a** is formed.¹⁴⁷ The product ratio varies as a function of the reaction temperature: **11u**:**32a** = 1.00:1.33 at 0 °C and 1.25:1.00 at –40 °C.

The formation of thiophenes is probably promoted by the same factors as the formation of the 1,2-adducts. This is confirmed, firstly, by the fact that the dichloride of hexa-1,3,4-trien-3-ylphosphonic acid affords exclusively the thiophene derivative **32b** in the analogous reaction¹⁴⁸ and, secondly, by the presence of only traces of similar products in reactions with selenenyl chlorides (see below), for which addition to the C(1)=C(2) bond is uncharacteristic.¹⁴⁴

The interaction of the ester **26m** with selenenyl chlorides¹⁴⁹ leads to the formation of the 1,2-oxaphospholene **11u** as the main product. In addition, the heterocyclic compounds **32c–e** and the 1,4-adduct **28h** were obtained in an overall yield of 5%–12%.

The reactions of diethyl penta-1,2,4-trienylphosphonate **26n** with alkanesulfenyl chlorides open a path to yet another class of substituted thiophenes — 2-thienylmethyl-phosphonic acids **33a**.¹⁵⁰ The interaction of compound **26n** with MeSeCl takes place similarly and leads to 2-selenophenylmethylphosphonic acid ester **33b**.¹⁵¹

X = S (**33a**), Se (**33b**); R = Alk.

The reaction of the dichloride of hexa-1,3,4-trien-3-ylphosphonic acid **26o** with MeSeCl led to the formation of the 1,4-adduct **28i**.¹⁴⁸

The formation of phosphorylated thiophenes (selenophenes) has been explained^{145, 147–151} by the fact that the intermediate vinylselenonium (episelenonium) ions are capable of expansion to five-membered onium ions. The subsequent isomerisation and

dealkylation afford compounds **32a–c** and **33a,b**. The heterocyclic products **32d,e** are formed similarly.

The interaction of dialkyl hexa-1,3,4-trien-3-ylphosphonates with alkyldithiophosphoric acids has been described (Scheme 19).^{117, 152} The reaction proceeds as addition to the 1,3-diene system. Two alternative mechanisms, involving either a six-centre or eight-centre transition state with participation of the thiol or thione sulfur, are apparently possible.

Scheme 19

Thus electrophilic attack on the C(1)=C(2) bond is also characteristic of the reactions of the dichlorides of vinyl-substituted PA with sulphenyl chlorides. The presence of functional groups gives rise to the possibility of additional reactions. Yet another direction in which the synthetic possibilities of PA may expand involves the use of new, less traditional electrophiles.

6. Reactions of phosphorylated allenes with other electrophiles

In the course of a study of the cyclisation of the optically active allenylphosphonic acid **3i** under the influence of mercury(II) acetate, it was shown⁶⁵ that it proceeds with 86% stereoselectivity (which is almost twice as high as the selectivity in the bromination reaction).

The stereoselectivity of the cyclisation of the allenylphosphonic acid **26p** catalysed by Ag^+ ions has also been studied.¹⁵³

The reaction of the allenylphosphonic acid **3h** with percarboxylic acids has been investigated.¹⁵⁴ Compound **34**, formed initially, isomerises to the oxaphospholane **35**, which hydrolyses with ring opening and is converted into the oxophosphonate **36**. The latter may be converted into the dimethyl ester **37** by treatment with diazomethane or into the acid **38** by treatment with an excess of percarboxylic acid (Scheme 20).

Scheme 20

Hypochlorous acid reacts in an unusual manner with esters of 3,3-disubstituted alka-1,2-dienylphosphonic acids: 2,3-addition with formation of the phosphonate **21j** takes place instead of cyclisation.¹⁵⁵

The presence in the molecules of PA of two double bonds with markedly different reactivities, one of which readily interacts with electrophiles whereas the other interacts with nucleophiles, made it possible to observe a new type of reactions of potassium dichloriodate(I).¹⁵⁶ The formation of the main products of the interaction of the PA **3e** with KICl_2 corresponds to the formal addition of iodine chloride *via* the mechanism typical of reactions of electrophiles with the above substrates:

The mechanism of the formation of compound **27g** has not been fully investigated. The regioselectivity of the addition of chlorine indicates that the acyclic phosphonate **27g** is formed as a result of nucleophilic attack by the chloride ion on the α,β -double bond with subsequent protonation of the intermediate. Here it is possible to put forward two versions of the reaction (Scheme 21).

Scheme 21

The first involves the nucleophilic addition of the chloride ion, promoted by the coordination of the intermediate iodine chloride, formed from the reagent, to the O atom of the phosphoryl group (ICl is known to exhibit the properties of a Lewis acid¹⁵⁷). The alternative version is the SET mechanism which may occur in reactions of ICl with aromatic substrates.¹⁵⁸

The methoxyallene **26p** reacts with KICl_2 ¹⁵⁶ and interhalogens⁷² with formation of 4-iodo-1,2-oxaphosphol-3-ene **11z**, while its interaction with a more polar iodine-containing reagent (the complex of difluoriodobenzene with BF_3) leads to the dihydrofuran **39a** (yield 63%).¹⁵⁹ The same compound has been obtained by the reaction of the PA **29p** with iodosobenzene in the presence of an excess of BF_3 and subsequent treatment of the reaction mixture with a saturated aqueous solution of NaBF_4 . When a LiClO_4 solution was used, the corresponding perchlorate **39b** was obtained in 48% yield. The addition of the electrophilic iodonium species to the allene **26p** proceeds regioselectively with formation of the stabilised allyl cation **A**. In the concluding stage, the methoxy-group functions as a nucleophile, which is accompanied by the formation of MeF and ring closure to give the furanyliodonium salt **39** (Scheme 22).

The reaction of *N,N*-diethylbenzeneselenenylamide with the allenylphosphonates **3e** and **26p** in the presence of an activator (a sulfonate), *i.e.* under conditions where weakly polar electrophilic species are generated,^{160,161} proceeds with formation of 1,2-oxaphosphol-3-enes. As in the case of other weakly polar reagents, *anti*-attack by the electrophilic species relative to the phosphoryl residue is observed under these conditions. The subsequent cyclisation evidently takes place *via* the formation of a quasi-phosphonium salt containing the sulfamate ion as the

Scheme 22

$\text{X} = \text{BF}_4^-$ (**39a**), ClO_4^- (**39b**).

counterion. The nucleophilicity of the latter is sufficiently high for the rapid dealkylation of the quasi-phosphonium salt.

$\text{R} = \text{H}, \text{MeOCH}_2$.

The cyclopentenone derivative **40** can also be synthesised by the interaction of vinyl-substituted PA with chromyl chloride in anhydrous chloroform.¹⁶² As in the reaction with iodonium salts,¹⁵⁹ *syn*-attack by the electrophile relative to the phosphoryl fragment occurs in this case.

R = Alk.

Thus the three examples presented indicate that the stereospecificity of the attack on functionally substituted PA by electrophiles and hence the type of cyclisation are correlated with the polarity of the attacking species. This is probably associated with the fact that more ionic, harder electrophiles are initially coordinated to the O atom of the phosphoryl group. This is indicated by data on the formation of complexes with NiCl_2 ¹⁶³ and also by the results of quantum-chemical calculations (see Section II).

IV. Conclusion

Analysis of the literature data shows that there is a possibility of electrophilic attack on all three reaction centres of the PA depending on the nature of the substituents in the allene system and at the P atom, the polarity of the electrophile, its capacity for preliminary coordination to the internal nucleophilic centres of the PA, and also the stability of the intermediate carbenium, phosphonium, and bridged onium ions. This is promoted by the asymmetry of the allene system, in which the HOMO is localised on the $\text{C}(2)=\text{C}(3)$ bond, although the highest electron density is concentrated on the phosphorus-containing fragment and the $\text{C}(1)=\text{C}(2)$ bond. Whereas positively charged species are coordinated primarily to the oxygen atom of the $\text{O}=\text{P}$ group, uncharged electrophiles may attack either bond of the allene system. With certain exceptions, the electrophilic species then adds to the central carbon atom of the allene system, despite the fact that, according to the results of quantum-chemical calculations^{49, 58} and ^{13}C NMR spectroscopic data,⁵⁹ the electron density on this atom is reduced compared with both terminal carbon atoms. On the other hand, quantum-chemical calculations confirm the presence of a considerable electron density on the $\text{C}(2)$ atom for both the first and second occupied frontier orbitals of the allene [corresponding to a first approximation to the $\text{C}(2)=\text{C}(3)$ and $\text{C}(1)=\text{C}(2)$ bonds].

The molecular orbital perturbation theory may be used to explain and predict the chemoselectivity of the reactions of PA with electrophiles.⁶³ According to this theory, reactions with the early transition state may be controlled either by charge factors or by the interaction of the unoccupied MO of one reactant with the occupied MO of the other. The interaction of the frontier MO is of greatest importance; under these conditions, the greater the difference between the energies of the LUMO of the electrophile and the HOMO of the allene, the more probable is the attack on the $\text{C}(1)=\text{C}(2)$ bond of the PA.

One of the factors influencing significantly the regioselectivity of the attack on the PA by the electrophile is steric hindrance. In the case of the weakest electrophile (the proton), the terminal carbon atom remote from the phosphorus atom is also attacked in reactions with certain monosubstituted PA and PA unsubstituted at the $\text{C}(3)$ atom. The influence of steric factors also on the stereospecificity of the addition when the central atom is attacked is very appreciable. In the addition to the $\text{C}(2)=\text{C}(3)$ bond, the reacting species usually attacks the PA from the side opposite to that of the phosphorus-containing fragment. The introduction of bulky substituents in the 1-position in the allene system increases the amount of the Z-adduct involving the $\text{C}(2)=\text{C}(3)$ bond. Another factor, which probably promotes the *syn*-addition of highly polar electrophiles, is their preliminary coordination to the hard nucleophilic centre comprising the oxygen atom of the $\text{O}=\text{P}$ group. If other nucleophilic centres are present in the PA molecule, there is a possibility of the coordination of the electrophile to

them also, which promotes the operation of additional reaction mechanisms.

Thus, by virtue of the high reactivity and the unusual properties of the system of closely linked unsaturated centres, characteristic of PA, the study of the reactions of these substrates with electrophiles constitutes an extremely interesting and timely problem. The investigation of the reactivities of new electrophiles in relation to PA makes it possible to expand the synthetic possibilities of these processes and to obtain various functionally substituted unsaturated organophosphorus compounds, which are promising from the standpoint of biological activity and their employment in fine organic synthesis. It also aids understanding of the nature of electrophilic processes.

Abstracts. Methods of preparation of phosphorus ylides substituted at the carbon atom of the P=C group with atoms of various elements and their application in organic synthesis are systematised and generalised. The bibliography includes 508 references.

I. Introduction

During recent years the chemistry of phosphorus ylides substituted at the carbon atom of the P=C group with atoms of various elements has been extensively developed.^{1–14} Owing to these studies, phosphorus ylides containing elements of almost all groups of the Periodic Table have been synthesised, convenient preparative techniques of such ylides have been elaborated, and areas of their practical application in organic synthesis have been discovered. Chemical properties of C-substituted ylides are extremely diverse, which is due to the variety of the properties of the substituent elements and their different effects on the electron density distribution in ylide molecules.

The stability of C-substituted ylides has made them fascinating and convenient objects for theoretical studies, particularly, for the study of the nature of the element–carbocation bond. Depending on the nature of the element, this bond can be covalent or coordinate with various extents of negative charge transfer from the carbanion to the element.

Thus the elements of the higher periods which possess vacant orbitals (silicon, phosphorus, sulfur, arsenic, *etc.*) interact with the ylide carbanion by a $p_\pi-d_\pi$ -mechanism, which results in a decrease in the electron density on the α -carbon atom and partial element–carbon double bonding. On the other hand, the elements with σ -donor properties, *e.g.* mercury, increase the electron density on the ylide carbon, thus increasing further the already high nucleophilicity of ylides. Also certain elements, especially transition metals, can form additional coordinate bonds with the ylide carbon atom. Sometimes, the distribution of the electron density in the ylide molecule is simultaneously affected by two or

even three different factors, their relative contribution depending on the nature of the element and the surrounding ligands.

However, C-substituted phosphorus ylides attract particular interest as reagents for organic synthesis, and thus find increasing application in laboratory practice and industry. For example, C-silicon phosphorus ylides served as the basis for a series of preparative syntheses of medicinals, pheromones, and other types of phosphorus ylides. C-Phosphino phosphorus ylides are important ligands in transition-metal complexes. C-Halogeno phosphorus ylides are of interest for the preparation of halogenoalkenes. C-Nitrogen ylides are of considerable importance, especially in the synthesis of antibiotics. Active catalysts of alkene polymerisation based on C-transition metal-substituted ylides have been proposed. Complexes of phosphorus ylides with gold salts have been recommended for the treatment of certain diseases.

Unfortunately, numerous papers and patents on applications of C-substituted phosphorus ylides in various fields of organic synthesis have not hitherto been generalised. Only some topics concerning the synthesis and chemical properties of C-substituted phosphorus ylides have so far been discussed in monographs^{4, 5, 8, 13} and reviews.^{1–3, 10–12} However, the scope of the topics covered was very narrow, which is due to the specific character of these publications. Also, C-substituted phosphorus ylides are regarded there as a particular case of phosphorus ylides in general. The present review is meant to fill the gap; its aim is to demonstrate the broad synthetic potential of the C-substituted phosphorus ylides and to disclose the effect of the nature of the element at the ylide carbon atom on their reactivity. The present report summarises the data on the application in organic synthesis of phosphorus ylides substituted at the α -carbon atom by atoms of elements of Groups I–VII of the Periodic Table.

II. Phosphorus ylides substituted at the α -carbon atom by atoms of Groups I–IV elements of the Periodic Table

The influence of σ -donor inductive and π -acceptor mesomeric effects of the elements is clearly exemplified by ylides[†] containing metals and metalloids of the main subgroups of Group I–IV of the Periodic Table at the α -carbon atom. The elements with s -donor properties increase the electron density on the ylide carbon atom, thus exchanging the nucleophilicity and reactivity of the ylides, as for instance, in the case of C-lithiated ylides. On the contrary, such elements with as germanium and silicon,

[†] Hereinafter, P-ylides are considered.

Uspekhi Khimii 66 (3) 246–277 (1997); translated by M I Yanovskaya

The sodium derivatives of triphenylphosphonium cyanomethylide **18** synthesised by Bestmann and Schmidt²⁷ were used for the preparation of cyclic compounds *e.g.*, **19**.

α -Carbon metallated ylide carbanions of the type **20**, which can be obtained by direct addition of 2 equiv. of a base to a phosphonium salt or of 1 equiv. of base to a phosphorus ylide, have recently found an important synthetic application. Some ylide carbanions **20** were isolated in the form of crystalline (colourless or coloured) compounds. Highly reactive tricarbanions were obtained by reaction of trialkylphosphonium ylides with excess of butyllithium.^{14, 21–38} The structures of ylide carbanions **20** were determined by X-ray structural analysis^{39, 40} and NMR spectroscopy.⁴⁰

R = H, Ph, CN, CO₂Me;
MR' = KH, NaH, NaNH₂, LiAlk.

Ylide anions can serve as the initial compounds for the synthesis of other C-substituted phosphorus ylides, because the metal atoms in them are readily substituted for various groups in reactions with electrophiles.⁴¹ Some examples of such syntheses are given in the present review. Ylide anions react even with those electrophiles which do not react, or react with difficulty, with other phosphorus ylides. For instance, they alkenate carboxamides to give enamines **21** or acyl ylides **22** depending on the reaction conditions. Analogously, the reaction of ylide anions **20** with carboxylic esters yields vinylic ethers or acyl ylides.¹⁴

In their reactivity, ylide anions **20** are not inferior in rank to 'hyperactive' C-lithium methylides **2** synthesised by Corey and Schlosser, and they are considerably superior in availability and stability. Thus, ylide anions **20** (R = H)^{42–53} react at room temperature with sterically hindered ketones (di-*tert*-butyl ketone, fenchone), which cannot be alkenated by triphenylphosphonium methylide. The ratio of ylide anion **20** to the carbonyl compound in this reaction is 1 : 2, therefore the yields of alkenes **23** can reach 180%–200% with respect to the phosphorus ylide.⁵⁰

Reaction of ylide anions with chiral aldehydes **24** is accompanied by asymmetric induction, which results in optically active tertiary phosphine oxides **25**.¹⁴

Reactions of ylide anions with aldehydes and carbonates, thiocarbamates, isocyanates, carbodiimides, sulfonates and sulfonates are documented.^{42–53} The two latter reactions give *E*-isomers of the unsaturated sulfones and sulfoxides **26** and **27**.^{50, 52}

Free ylides containing Group II metals (beryllium, magnesium) at the α -carbon atom have not hitherto been obtained.

According to the quantum-chemical calculations for the molecule of the simplest ylide $\text{H}_3\text{P}=\text{CHBeH}$, it has planar structure.¹⁶

2. Ylides containing Group IIIA elements

Compounds of elements of Group IIIA of the Periodic Table are strong Lewis acids and readily react with phosphorus ylides.^{54–58} Reactions of triphenylphosphonium alkylides and benzylides with dialkylchloroboranes in benzene are accompanied by transylidation and result in α -dialkylboryl-substituted ylide **28**, which was isolated in the crystalline form. The NMR spectra of the ylide **28** indicate its mesomeric structure.^{58–60} Phosphorus ylides react with alkyl-dichloroboranes to give bis(ylidyl) alkylboranes.

$\text{R}^1 = \text{Alk}, \text{PhCH}_2$.

C-Boron substituted ylide **30** was isolated by Bertrand *et al.*⁶¹ by the addition of trimethyl borate to phosphinecarbene **29**:

C-Boron substituted ylides **28** are characterised by high reactivity. They readily react with polar compounds $\text{X}-\text{Y}$ to give ylides **32** and boranes *via* the intermediate onium complexes **31**.

Reaction of the ylide **28**, ($\text{R} = \text{Alk}$), with deuteriomethanol gives deuterated ylides **33**, which has been used for the preparation of deuterated olefins. In reaction with bromine, the phosphonium salts **34** were obtained; when treated with butyllithium, they yield C-bromo-substituted phosphorus ylides **35**.⁶⁰

Bestmann and coworkers^{57,62} have elaborated stereoselective methods for the synthesis of *E*-olefins, in particular pheromones, based on products of hydroboration of phosphorus ylides. The key step in the synthesis is the reaction of phosphorus ylide with borane. Betaine **36** thus formed undergoes rearrangement into the adduct of monoalkylborane with triphenylphosphine **37**. The latter is converted to *E*-olefin **39** with 99% stereochemical purity by a series of successive reactions.

The attempts to synthesise phosphorus ylides with aluminium, gallium, indium, and thallium at the α -carbon atom have failed. The corresponding ylides were unstable and were converted into dimers and oligomers with the structure of metallacycles.^{1,3,63–65}

3. Ylides containing Group IVA elements

C-Silyl-substituted phosphorus ylides are of considerable preparative importance. The interest in these compounds is due to their availability, stability, and high reactivity. C-Germanium- and C-tin-substituted phosphorus ylides are less studied.

For the synthesis of C-substituted phosphorus ylides **40**, reactions of simple phosphorus ylides containing hydrogen atoms at the α -carbon atom with silicon, germanium, and tin halides (at a 2:1 ratio of the reagents) are most often used.^{66,67} Numerous examples of the synthesis of cyclic and acyclic C-silyl-substituted phosphorus ylides by this method have been reported.^{1,66–73}

$\text{M} = \text{Si}, \text{Ge}, \text{Sn}$.

Reactions of carbanions **41** with silicon, germanium, tin, and lead halides in a 1:1 ratio lead to the formation of C-mono- or C-dimetal-substituted phosphorus ylides **42** in high yields, which allow a more economical use of the initial phosphorus ylides.^{74–77}

$\text{M} = \text{Ge}, \text{Si}, \text{Sn}, \text{Pb}$.

C-silyl-substituted ylides are often prepared by treating the corresponding phosphonium salts with organolithium compounds.^{66–78}

The reaction of trimethylphosphonium trimethylsilylmethylide with heterosiloxanes provides a simple and convenient route to germanium-, tin-, and lead-containing ylides **43**. The driving force of this reaction is the formation of disiloxane.^{74,79}

$\text{M} = \text{Ge}, \text{Sn}, \text{Pb}$.

Silicon-containing phosphorus ylides can be also prepared by the reaction of phosphorus alkylides with silacyclobutane derivatives as a result of the insertion of the ylide carbon atom into the Si–C bond.^{80–82}

The reaction of C-silyl-substituted phosphorus ylides with carboxylic acids proceeds in a similar manner. Cycloalkenones **66** containing 5–8 atoms in the ring were also prepared in high yields by reactions of C-silyl-substituted phosphorus ylides with acid anhydrides.⁷¹

$R^1 = \text{H, Alk; } X = (\text{CH}_2)_n \text{ (} n = 2-5 \text{), CH}_2\text{OCH}_2, \text{CH}_2\text{SCH}_2.$

The reaction of C-silyl-substituted phosphorus ylides with silyl carboxylates has served as the basis for the development of a method of synthesis of ceramide, leucotriene **A₄**^{111–113} and the components of the *Manica ribuda* ant pheromone.¹⁰⁵

C-Silyl-substituted phosphorus ylides are used as ligands in transition metal complexes. Stable organometallic complexes, with metal–carbon bonds are formed in reactions of C-silyl-substituted phosphorus ylides with halides of copper(I), silver, gold, and their phosphine complexes.^{114–116} Neutral complexes of iron, chromium, molybdenum, and tungsten were also synthesised.^{117–122} Examples of C-silyl-substituted complexes are discussed in the next section and in reviews.^{1–4}

III. Phosphorus ylides substituted at the α -carbon atom by transition metal atoms

Transition metal atoms at the ylide carbon atom substantially affect its negative charge, and consequently, the properties of the ylides. Three main mechanisms describing the interaction of transition metals with the ylide carbanion may be distinguished. Transition metals with s -donor properties, such as mercury, increase the electron density on the ylide carbon atom and enhance the nucleophilicity of the ylides. The electron density on the α -carbon atom decreases if the electron interaction of transition metals with the ylide carbanion, is of d_π – p_π type and the metal–carbon bond acquires partially double character. The relative contribution of these two opposite effects depends on the nature of the metal atom and the surrounding ligands. Finally transition metals can form additional coordinate bonds with the ylide carbon atoms, which may lead to dimerisation or oligomerisation of the organometallic complexes.

1. Ylides containing atoms of Group IB, IIB

The reactions of phosphorus ylides with copper, gold and silver halides are accompanied by the formation of the ylides **67**, which are easily dimerised into linear and cyclic complexes **68** due to high coordination number of the metal atoms.^{115, 116, 123–125}

$M = \text{Ag, Cu.}$

Therefore it was impossible to isolate true ylides of the type **67**. In contrast, C-mercury-substituted phosphorus ylides are mono-

mers. As has been mentioned, mercury atoms increase electron density at the ylide carbon due to their s -donor properties. Therefore, it is necessary that a second substituent at the α -carbon atom should compensate the electron-donating effect of the metal atom in order to stabilize mercurated ylides. Benzoyl, cyano- or methoxycarbonyl groups may serve as such substituents. For instance, phosphorus ylides $\text{Ph}_3\text{P}=\text{CHR}^1$ add mercuric acetate (or chloride) to form compounds **69**; their subsequent reaction with liquid ammonia or sodium methoxide leads to the C-mercurated phosphorus ylides **70**, which enter into the Wittig reaction with aldehydes.^{126, 127}

$R^1 = \text{CN, CPh, CO}_2\text{Me; } B = \text{NaOMe/MeOH, NH}_3.$

C-mercurated ylides **71** were obtained by the reaction of methylmercury chloride with an excess of C-silylated phosphorus ylide or its anion. The ylides **71** are stable liquids, which can be distilled *in vacuo*.¹²⁸

The C-mercury-substituted ylides **72**, which readily enter into the Wittig reaction to form the compounds **73**, were obtained by the reaction of phosphorus ylides $\text{Ph}_3\text{P}=\text{CHR}$ with mercury hexamethyldisilazide in inert solvents.¹²⁹

Other Group IIB metals, zinc and cadmium, give ylide complexes of the type $[\text{Ph}_3\text{PCR}_2\text{MCl}]^+\text{Cl}^-$ ($M = \text{Zn, Cd}$) (**74**). Although the latter cannot be regarded as true ylides, they readily enter into the Wittig reaction and are widely used for the preparation of alkenes,^{130–143} for instance, halogenoalkenes (see Section III.3).^{54, 141–143}

2. Ylides containing atoms of the actinide metals

The uranium complex Cp_3UCl **75** readily undergoes transylidation under the action of phosphorus ylides and their lithium derivatives to form pyrophoric, green crystalline complexes sensitive to moisture and atmospheric oxygen. On the basis of X-ray^{144–146} and electron diffraction¹⁴⁷ data, the metallocene ylide structure **76** was ascribed to these compounds. Shortening of the U–C and C–P bonds indicates the delocalization of the negative charge in the U–C–P fragment.^{145, 147}

R = Me, Ph.

The metallocene ylides exhibit nucleophilic properties in reactions with polar unsaturated compounds.¹⁴⁶ Insertion reactions into the metal–carbon bond are characteristic of the uranocene ylides.¹⁴⁸

The uranocene ylides enter into metathesis reactions with compounds containing active hydrogen atoms.^{149, 150}

3. Phosphorus ylides containing the Group IVB metal atoms

The group IVB transition metals (titanium, zirconium, and hafnium) stabilize the ylide carbanion as do the non-transition elements of this group, silicon and tin. Therefore, the preparation procedures, structures, and properties of phosphorus ylides, which contain metal atoms of Group IVA and IVB at the ylide carbon atoms, are similar. For instance, the four-membered cyclic bis-ylides **82** containing titanium or zirconium atoms at the ylide carbon atoms are obtained in the same way as cyclic silyl-substituted phosphorus ylides. The X-ray structural study of phosphorus ylides **82** has shown that they have a centrosymmetric structure.^{116, 151, 152}

M = Ti, Zr, Hf;

R¹ = Me₂N, Cl, Et; R² = Me, Et₂N, (CH₂)₂PM₂.

The titanium-containing cyclic ylides enter into the Wittig reaction with aromatic aldehydes to form the corresponding 1,3-diaryllallenes which is a promising way for their synthesis.¹⁵³

The transylidation reaction of bis(cyclopentadienyl)titanium, -zirconium, and -hafnium dihalides **83** with phosphorus ylides results in C-metallated ylides **84** containing halogen at the metal atom and exhibiting special chemical properties.^{154–160}

M = Ti, Zr, Hf;

R¹ = R² = Ph, Et₂N; R¹ = Et₂N, R² = Me.

For example, the zirconocene ylide **85** exists in a ring-chain, prototropic tautomeric equilibrium with the chelate complex **86**. The position of the tautomeric equilibrium depends on the nature of the solvent.¹⁵⁶

A zirconium hydride complex reacts with trimethylphosphonium methylide to give a four-membered cyclic ylide complex **87**, which is converted to zirconium ylide **88** on heating with methyl chloride.^{156–158}

The metallocene ylides of titanium, zirconium and hafnium **89** are formed in the reactions of triphenylphosphonium methylide **1** with the thermally generated (η²-ethene)- and (η²-aryne)metallocenes. These reactions are accompanied by the replacement of the aryne ligand by phosphorus ylide and by a proton shift from the ylide methylene to the aryne ligand.^{159, 160}

M = Ti, Zr, Hf.

When bis(cyclopentadienyl) diphenylzirconium was heated with triphenylphosphonium ethylide, the cyclic metallocene ylide **90** was formed as a result of *ortho*-metallation of the benzene ring.^{161, 162}

The nucleophilicity of the metallocene ylides **89** is lowered because of the high electron-acceptor ability of the transition metals.¹⁶¹ Nevertheless, the metallocene ylides **89** react with ketones.¹²⁵ Carbon monoxide and isocyanides readily insert into the zirconium–carbon bond of ylides **89**.^{160–165}

M = Ti, Zr, Hf.

4. Ylides containing the Group VIB–VIII metal atoms

Phosphorus ylides containing atoms of Group VI–VIII transition metals are characterised by high stability on storage and the ability to exist in a free, non-associated form. Recent detailed studies of the phosphorus-ylide complexes of Group VI–VIII transition metals allowed convenient procedures for their synthesis to be elaborated. The simplest method involves the substitution of ligands in the transition metal complexes by the phosphorus-ylide ligand.^{158, 166–174} For instance, bromopentacarbonyl complexes of manganese and rhenium undergo transylidation with phosphorus ylides to give the C-metal-substituted phosphorus ylides **91**.^{158, 166}

M = Mn, Re.

The dioxomolybdenum ylide **93** was synthesised by the reaction of the dioxomolybdenum complex **92** with tributylphosphonium methyllide.^{168, 169}

The first complex of hexavalent chromium **94**, which has high reactivity, was synthesised by the transylidation reaction of a bisalkylimide chromium complex with 2 equivalents of triphenylphosphonium methyllide.¹⁷⁰

The phosphorus ylide **95** was synthesised by addition of trimethylphosphine to a cationic rhenium complex. The bond between the rhenium atom and the ylide carbon atom in compound **95** is shortened because of the effective delocalisation of the negative charge on the ylide carbon atom by the transition metal.^{171–178}

Tertiary phosphines add to chromium, molybdenum, and tungsten carbyne complexes even at -60°C to form stable metal-substituted phosphorus ylides **97** and **98**.^{171, 172}

X = Cl, Br, I.

The phosphorus ylides containing Group VI–VIII elements at the α -carbon atom may be obtained by the salt method.^{173, 179} This method was used to prepare optically active phosphorus ylides **99** with a chiral rhenium atom, their treatment with methyl triflate in THF at -78°C produced the (*S,S,R,R*)- α -rhenium-substituted phosphonium salt **100**¹⁶⁶ as a result of asymmetric induction at the α -carbon atom.

The manganese complex **101** reacts with trimethylphosphonium methyllide to give the mesomeric, anionic manganese-substituted phosphorus ylide **102** as the adduct which is in equilibrium with the starting compound. Photolysis of the compound **102** occurs with the elimination of carbon monoxide and results in a neutral ylide **103** with a manganese atom at the α -carbon atom.^{180–183}

The phosphorus ylides react with the ligands of transition metal complexes to give C-metal-substituted phosphorus ylides.^{184–187} For instance, when chromium, molybdenum and tungsten hexacarbonyls were heated with ylides **104** at $50\text{--}60^\circ\text{C}$ in light petroleum or were subjected to UV irradiation, complexes **105** were obtained.^{188–191}

R = Ph, CH=CH₂, CH₂CH=CH₂, CH₂CMe=CH₂,
CH=CHMe, CH=CHPh; M = Mo, W.

* * *

It follows from the above material that transition metals effectively stabilise the ylide carbanion lowering its nucleophilicity. Nevertheless, in some cases such ylides exhibit a relatively high reactivity. The phosphorus ylides containing transition metals have not yet found extensive application in synthesis. Certain prerequisites allow one to anticipate considerable extension of their practical application. For instance, the metal complexes of phosphorus ylides are reported to be used as catalysts for the polymerisation of alkenes and as medicinals.^{214–216}

IV. Phosphorus ylides substituted at the α -carbon atom by atoms of elements of Groups VA – VIIA of the Periodic Table

The phosphorus ylides substituted by Group VA – VIIA elements at the α -carbon atom are of both theoretical and synthetical interest. They are widely used in the synthesis of biologically active compounds.^{9, 217–220}

1. Ylides containing the Group VA elements

The structures of the phosphorus ylides stabilised by nitrogen, phosphorus, and arsenic atoms are highly diversified due to the varying valence and different coordination states of these elements. The chemical properties of such phosphorus ylides are also characterised by considerable peculiarities. All this promoted the development of the chemistry of this class of phosphorus ylides and elaboration on their basis of new preparative methods for the synthesis of various valuable organic compounds.

Quantum-chemical *ab initio* calculations¹¹⁶ show that the trivalent nitrogen atom destabilises the ylide carbanion. Therefore, the C-amino-substituted phosphorus ylides are stable only if the second substituent at the α -carbon atom exhibits electron-accepting properties, which compensate the electron-donating effect of the amino group. For this reason, the transylidation reaction cannot be used for the synthesis of C-amino-substituted ylides. The C–N-ylides are usually synthesised by the dehydrohalogenation of the corresponding phosphonium salts. The Wittig reaction of the C–N-ylides **124** generated from the C-amino-phosphonium salts leads to the enamines **125**. Attempts to synthesise the non-stabilised C–N-ylides have failed.²²¹

The reactions developed by Woodward²²² for the synthesis of the ylides **126** containing the 4-acylthioazetidin-2-one group at the α -carbon atom, which are used for the preparation of the β -lactame antibiotics, are of considerable preparative value.

A method of generation of the phosphorus ylides based on the reaction of azetidine derivatives with an excess of a phosphite, phosphinite, or tertiary phosphine gained industrial significance.^{218, 219} The reaction is carried out at room temperature under mild conditions.²²⁰

The phosphorus ylides **127**, that are formed with high yield readily enter into the Wittig reaction.

The reaction of the compounds of two-coordinate phosphorus with lower trialkylphosphines leads to the phosphorus ylides **128**, which contain a phosphorus atom and a dialkylamino group at the α -carbon atom. This reaction is accompanied by the substitution of the fluorine atom at the sp^2 -hybridised carbon atom with the phosphonium group and substituent migration of the fluorine atom to the trivalent phosphorus atom.²²³

Cowley *et al.*²²⁴ have synthesised the C–N-phosphorus ylide **129** by adding trimethylamine to a phosphinocarbene.

Kreissl *et al.*²²⁵ have synthesised the ylide-phosphonium salt **130** by the reaction of trimethylphosphine with a carbene–chromium complex.

The Michael addition of phosphorus acyl ylides to cyclic and acyclic compounds with a multiple N=N bond activated by carbonyl groups is a convenient way for the synthesis of C–N ylides.^{226–228}

$\text{R}^1 = \text{Alk}, \text{Ph}, \text{AlkO}; \text{R}^2 = \text{Alk}.$

Triphenylphosphine and phosphorous acid amides react with C-ethoxycarbonyl- and C-acetyl-N-nitrile imines to give stable azomethylenephosphonium ylides $\text{R}_3^1\text{P}=\text{C}(\text{R}^2)\text{N}=\text{NPh}$ [$\text{R}^1 = \text{Ph}, \text{C}_5\text{H}_{10}\text{N}; \text{R}^2 = \text{CO}_2\text{Et}, \text{C}(\text{O})\text{Me}$].^{229, 230} The ylide **132** has been obtained by the reaction of the ylide **131** with diazonium salt followed by the treatment with sodium ethoxide.²³¹

The ylide $\text{Ph}_3\text{P}=\text{C}(\text{N}=\text{NPh})_2$ with the two azogroups at the α -carbon atom has been prepared by reaction of bisphenylazomethane with triphenyldichlorophosphorane in the presence of triethylamine.²³²

The 1,3-dipolar cycloaddition of triphenylphosphonium ketene ylides to toluenesulfonyl azide leads to the ylides **133** containing a triazoline ring, which may produce ylides **134** with a diazo group at the α -carbon atom.²³³

In contrast to the nitrogen atom, the atoms of trivalent phosphorus, arsenic, and antimony efficiently stabilise the ylide carbanion, thus making the transylidation reaction the main route to the synthesis of C-phosphino-, C-arsino-, and C-stibino-substituted phosphorus ylides.^{79, 80}

These ylides are obtained by the reaction of C-silyl- and C-lithium-substituted phosphorus ylides with chlorophosphines, -arsines, and -stibines.

$\text{E} = \text{P}, \text{As}, \text{Sb}.$

Trimethylsilyl arsinic acid may be used instead of chloroarsines.^{79, 80, 154}

Diaryl- and dialkyl-chlorophosphines, alkyl- and aryl-chlorophosphines, aminochlorophosphines, and phosphorus trichloride react with non-stabilised phosphorus ylides to give the compounds **135** with one, two, or three phosphorus ylide groups at the trivalent phosphorus atom.^{156, 234–238}

135

$\text{R}^1 = \text{Ph}, \text{Alk}_2\text{N}; \text{R}^2 = \text{H}, \text{Alk}; \text{R}^3 = \text{Alk}, \text{Ar}, \text{Alk}_2\text{N}, \text{Cl};$
 $n = 0-2.$

Schmidbauer *et al.*^{239, 240} have synthesised the dichlorophosphinoylide **136**, which is an interesting initial compound for preparation of phosphorus ylides of unusual structure. In the reaction with aluminium chloride, it gives the ylidylphosphonium cation **137** and with bis(trimethylsilyl)phenylphosphine it gives 1,3-bis(triphenylphosphoniumylidyl)cyclotetraphosphine **138**. X-Ray structural analysis of the compound **138** demonstrated *trans*-orientation of all the substituents of the four-membered ring.²⁴¹

$\text{R} = \text{Alk}, \text{Ar}, \text{SiMe}_3.$

Dichlorophosphinoylide **136** was used by Schmidpeter *et al.* for the synthesis of the first stable phosphorus ylides with the phosphorus sulfide and phosphorus disulfide groups at the ylide carbon atom.^{242–244}

In the last few years, considerable attention has been paid to the synthesis of phosphorus ylides substituted at the ylide carbanion with phosphorus atoms with unusual coordination.^{242–248} Phosphorus ylides, which contain two-coordinate trivalent^{242, 248} and three-coordinate pentavalent phosphorus atoms^{243, 244} at the ylide carbon atom have been synthesised. Schmidpeter^{244, 245} has shown that bisylide-substituted monochlorophosphine **139** with the phosphonium structure adds selenium with the formation of bisylide-substituted selenoxophosphonium chloride **140**. The compound **140** was the first chalcogen-phosphonium ion with a trigonal planar phosphorus atom isolated in the individual form.^{244, 245}

139

140

Diphosphoniumisophosphindol **141** containing a two-coordinate phosphorus atom at the ylide carbon atom has been synthesised by the reaction of the corresponding bisphosphorane with phosphorus trichloride and triethylamine.^{243, 245, 246} The crystal and molecular structure of the phosphorus ylide **141** was described.^{245, 249}

Grobe *et al.*²⁴⁷ have prepared phosphorus ylides substituted with the trivalent phosphorus atom at the ylide carbon atom by adding trimethylphosphine to fluorinated phosphaaalkenes. The formation of the ylides was explained by the electrophilic character of the two-coordinate phosphorus atom.

X = F, OMe, OEt.

The four-coordinate phosphorus atom efficiently stabilises the ylide carbanion, which makes the reaction of transylidation the general technique for the preparation of various C-phosphorus-substituted ylides containing phosphoryl or thiophosphoryl groups at the α -carbon atom.^{117, 209, 250} This method has also been used for the synthesis of ylides containing one, two, or three P=C groups at the four-coordinate phosphorus atom.^{154, 238, 251}

$n = 0-2$.

The salt method has also been used, although not so often, for the preparation of the C-phosphorus-substituted ylides. Thus triphenylphosphonium diphenylphosphonemethylide can be obtained by the quaternization of triphenylphosphine with diphenyl chloromethylphosphonate on heating to 175 °C.²⁵²

The bis- and tris(diorganylphosphino)methanes are alkylated by alkyl halides with the formation of the methylenephosphonium salts, which give carbodiphosphoranes²⁵³ on dehydrohalogenation. Similarly, tris(diorganylphosphino)methanes give ylide-bisphosphonium salts **142**.²⁵³⁻²⁵⁹

The ylide **143** (for the synthesis of the ylide **143** see Refs 255-264) easily undergoes recombination with trimethylphosphonium dimethylphosphinomethylide to give the bisphosphino-substituted ylide **144**.^{74, 151, 254, 255}

The phosphorus ylides stabilised by phosphorus, arsenic or antimony atoms are thermally stable. Tri- and penta-valent phosphorus atoms at the ylide carbon atom efficiently delocalise its electron density, which is confirmed by physicochemical studies.^{251, 265} Thus the effect of the phosphorus-containing groups X on the CH-acidity of the ylides $\text{Ph}_3\text{P}=\text{CHX}$ forms the following series:

X-Ray structural studies of the element-substituted phosphorus ylides reveal the shortening of the P=C bond (in Å): $\text{Ph}_3\text{P}=\text{C}(\text{R})\text{EPh}_2$: 1.720 (E = P),²⁶⁶ 1.698 (E = As),²⁶⁷ and 1.692 (E = Sb).²⁶⁸ Two or three phosphonium groups at the ylide carbon atom decrease even more the basicity of the compounds.^{269, 270} For instance, tris(triphenylphosphonium) methylide cannot be protonated even by strong acids. Bis(triphenylphosphonium) diphenylphosphinomethylide **145** (R = P^+Ph_3) is protonated at the trivalent phosphorus atom,^{215, 216} while triphenylphosphonium diphenylphosphino(e-thoxycarbonyl)methylide (R = CO_2Et) is protonated both at the α -carbon atom and at the trivalent phosphorus atom.²⁷¹ Mastryukova *et al.*²⁷² have shown by NMR the existence of a tautomeric equilibrium between the A and B forms of the compound **145**.

R = CO_2Et .

The protonation of the phenylphosphinoyl methylide **146** leads to CH- (C), or OH-protonated (D) forms depending on the properties of the substituents R. Protonation at the carbon atom takes place in the case of R = $\text{SO}_2\text{C}_6\text{H}_4\text{Me}$ -4 and PPh_3 . If R = CO_2Et the OH- and CH-protonated forms coexist in solution in a tautomeric equilibrium.²⁷³

The alkylation of the phosphine-phosphonium ylides occurs at the trivalent phosphorus atom with the formation of P-alkylated phosphonium salts, while the alkylation of the phosphoryl- or thiophosphoryl-substituted phosphorus ylides gives the C-substituted phosphonium salts.^{251, 265, 274} The reaction of triphenylphosphonium bis(diphenylphosphino)methylide with 1,4-dibromobut-2-ene is a convenient method for the preparation of the ylide-phosphonium salts **147** containing the 1,3-diphospholane ring.^{275, 276}

Some C-phosphorus-containing phosphorus ylides undergo skeletal rearrangements. Under the action of the trimethylphosphonium methylide, the phenyl group migrates from the phosphorus atom to the ylide carbon atom, and the phosphonium salt **148** is converted into the phosphorus ylide **149**.²⁷⁷

Despite the relatively low nucleophilicity of ylides stabilised by the four-coordinate phosphorus atom, they enter into the Wittig reaction with aldehydes on heating to form phosphorus-containing alkenes. The use of *C*-phosphorus-substituted ylides as alkenating agents is especially important for the synthesis of natural substances. In particular, the *C*-phosphorus-substituted ylides are used to prepare isosteric analogues of phosphates of natural origin.^{278–280}

Carbohydrates with protected hydroxy groups are easily alkenated by triphenylphosphonium diphenoxyphosphorylmethylide. The vinylphosphonates formed as a result of the alkenation are hydrogenated over platinum or palladium oxide and hydrolysed to form the phosphonic acids.²⁸¹

Using the same triphenylphosphonium diphenoxyphosphorylmethylide, the synthesis of the phosphonate analogue of fructose-1-phosphate has been performed; this manifested the properties of bioregulator of hexose-phosphate transport systems.²⁸²

Similarly, isosteric analogues of a series of phospholipids and sugar phosphates have been prepared.^{283–285} Huang *et al.*²⁸⁶ have synthesised phosphorus-containing pyrethroids using *C*-phosphorus-substituted ylides.

The phosphorus ylides **127** undergo an intramolecular Wittig reaction on heating and give penemates in high yields. They have found an important practical application in the synthesis of β -lactam antibiotics.²⁸⁷ Syntheses of a series of other β -lactam antibiotics, which are derivatives of penem and cefemic acids, have been described.^{287–295}

Japanese workers have prepared carbopeneme derivatives in high yields by refluxing the phosphorus ylide **150** in xylene. This technique has been proposed for industrial application.^{218, 219}

The thermolysis of triphenylphosphonium azomethylide gives the ylides **151** which are converted into 4-oxo-1,4-dihydroquinazolines on further heating.^{227, 296, 297}

$\text{R}^3 = \text{CO}_2\text{Me}, \text{C}(\text{O})\text{Me}, \text{SO}_2\text{Ph}, \text{SO}_2\text{C}_6\text{H}_4\text{Me-4}, \text{C}(\text{S})\text{SMe}.$

Burton *et al.* have developed a method for the synthesis of fluoroalkenes based on *C*-phosphorus-substituted ylides. The reaction presumably proceeds via a mechanism similar to that of the Wittig reaction and involves the formation of a betaine, which decomposes to give phosphine oxide and vinylphosphonium salt **A**. The phosphonium salt **A** readily decomposes with the cleavage of the C–P bond under the action of dilute alkali. The yields of fluoroalkenes do not exceed 45%–62%.^{298, 299}

Perfluoroalk-1-ynylphosphonates are obtained by pyrolysis of 2-hydroxyalkenyltriphenylphosphonium ylides, which follows the intramolecular Wittig-type reaction.³⁰⁰

C-Phosphine-substituted phosphorus ylides are used as ligands in transition metal complexes.^{226, 260–264} Thus substitution of the ligands in the chromium carbonyl complexes $\text{Cr}(\text{CO})_5\text{L}$, where $\text{L} = \text{THF}, \text{C}_7\text{H}_8, \text{Me}_2\text{S}(\text{O})\text{CH}_2$ by *C*-phosphine-substituted phosphorus ylides leads to cyclic and acyclic phosphorus ylides with a metal–phosphorus(III) bond. These complexes are diamagnetic substances stable in air and soluble in organic solvents.^{184, 301}

Carbodiphosphorane dicarbanions stabilised by two phosphonium groups provide an example of *C*-phosphorus-substituted ylides important for synthesis.³⁰² Carbodiphosphoranes are obtained by dehydrohalogenation of the ylide-phosphonium salts with sodium amide, butyllithium, potassium in dimethoxyethane, sodium hydride, triethylphosphonium ethylide.^{303–308}

The ylide-phosphonium salts formed upon the treatment of triphenylphosphine with carbon tetrachloride are dehydrochlorinated by tris-(dimethylamino)phosphine to give carbodiphosphoranes in good yields.³⁰⁵

In the last few years, carbodiphosphoranes of unusual structure with fluorine, chlorine or even hydrogen atoms at the phosphorus atom have been obtained.^{309–313}

Carbodiphosphoranes $(\text{Pr}_2^i\text{N})_2\text{HP}=\text{C}=\text{PH}(\text{NPr}_2^i)_2$ with the P–H bond are unstable and are converted into aminophosphines as a result of a prototropic shift.^{10, 271, 313}

A close chemical interrelation exists between the carbodiphosphoranes and the C-phosphorus-substituted ylides. For instance, the carbodiphosphoranes with alkyl groups at the phosphorus atom exist as prototropic tautomers.^{314, 315} The tautomeric equilibrium depends on the electronic effect of the substituents. Electron-accepting and electron-donating substituents shift the equilibrium towards the bis-ylide or the carbodiphosphorane form, respectively. It is believed that the prototropic exchange between the tautomers is intramolecular.^{308, 314–318}

The asymmetric alkyl-containing carbodiphosphoranes are converted into phosphino-substituted ylides **152** on heating to 120 °C. The reaction occurs *via* intermediate formation of the bis-ylide as a result of phenyl group migration from the phosphorus atom to the ylide carbon atom.^{222, 319}

The ylide-phosphonium salts with a dimethylmethylene group between two phosphorus atoms undergo isomerisation *via* the four-membered intermediate state into the carbodiphosphoranes **153**.³²⁰

153

The reaction of carbodiphosphoranes with electrophiles results in substitution at the central carbon atom or in the side chain. For instance, hexamethylcarbodiphosphorane reacts with chlorotrimethylsilane to give the ylide containing a trimethylsilyl group at the side carbon atom. In contrast, reaction of carbodiphosphoranes with alkyl halides, chlorophosphines, and acid chlorides usually occurs at the ylide carbon atom with the formation of the corresponding ylide-phosphonium salts.²⁵⁹ In the reaction with aromatic acid chlorides, hexaphenylcarbodiphosphorane gives C-acylated ylide-phosphonium salts **154**, which are converted on heating into (arylethynyl)phosphonium salts as a result of an intramolecular Wittig reaction.³²¹

The carbodiphosphoranes are valuable reagents in organic synthesis. They exhibit high nucleophilicity and therefore readily react with aldehydes and ketones. The allenylides thus formed enter into the Wittig reaction with aldehydes and ketones to give allenes.²⁶²

The reaction of carbodiphosphoranes with heterocumulenes (carbon dioxide, carbon disulfide, isocyanates, ketenes) yields betaines stable at room temperature, which are converted into phosphonium ketenylides, thioketenylides, keteniminylides, allenylides.^{304, 322–326}

X = O, S, NAr, CPh₂; Y = O, S.

Hexaphenylcarbodiphosphorane when treated with sulfur or selenium first yields the betaines **155**, which are stable at low temperature; at room temperature, they are converted into the triphenylphosphonium ketenylides.³²⁷

The reaction of hexaphenylcarbodiphosphorane with phthalic anhydride occurs with the substitution of the anhydride oxygen atom by the ylide function.^{321, 328}

In the reaction with salicyl aldehyde, hexaphenylcarbodiphosphorane gives a six-membered cyclic oxaphosphorane.³²⁹

Carbodiphosphoranes are used as ligands in ylide complexes of transition metals.^{135, 187, 330–335}

X-ray structural analysis and electron diffraction data proved carbodiphosphoranes to be dicarbanions. The central carbon atom of the carbodiphosphoranes has a hybridisation close to sp^2 , and the ground state of the carbodiphosphoranes may be described by the canonical structures **A**, **B**, and **C**.^{330–340}

Structural investigations of hexaphenylcarbodiphosphorane with triboluminescent properties, *i.e.* the ability to generate light on mechanical treatment, are of special interest.^{340–343} Hexaphenylcarbodiphosphorane forms several crystalline modifications: orthorhombic crystals do not have triboluminescent properties, whereas monoclinic crystals do possess such properties. The molecules in monoclinic and orthorhombic modifications have different $P=C=P$ bond angles and $Ph-P\dots P-Ph$ dihedral angles.^{344, 345} The dipole moment of hexaphenylcarbodiphosphorane in benzene is 4.69 ± 0.05 D.^{337, 338}

2. Phosphorus ylides containing Group VIA elements

The phosphorus ylides stabilised by oxygen, sulfur, selenium or tellurium atoms possess diversified structures and properties. The chemistry of these ylides is being rapidly developed. Convenient procedures for their preparation are elaborated, and chemical properties are studied. The ylides stabilised by the Group VIA elements are used in the synthesis of natural substances and biologically active compounds.

The very stable *C*-sulfonyl-substituted ylides are the most readily available phosphorus ylides of this group. They can be prepared by simple methods, such as the direct phosphorylation of sulfonylalkanes by polyhalophosphoranes in the presence of triethylamine,³⁴⁶ the salt method in the presence of organic bases, or by the reaction of diphenyldialkylaminophosphines with bis(sulfonyl)methanes and alkyl halides.^{347–349} Heating of phenyliodonium ylides with triphenylphosphine in benzene in the presence of copper acetylacetonate as a catalyst gives phosphonium ylides in high yield.^{350, 351}

$R^1 = Me, Ph, SO_2R^2$.

The sulfonyl ylides **157** can be obtained by the transylidation of phosphorus ylides **156** with sulfonyl fluorides or sulfonic anhydrides.^{348, 349} At the same time, the reaction of phosphorus ylides with arenesulfonyl chlorides results in the chloro-substituted phosphorus ylides **158** rather than the sulfonyl-substituted ylides.³⁴⁸

$X = F, R^3SO_3$;

The reactions of phosphorus ylides with alkenesulfonyl halides are also accompanied by rearrangements, which result in migration of the substituent R^1 from the ylide carbon atom to the carbon atom of the SO_2CH_2 group sulfur atom and the substituent R^2 migrates to the ylide carbon atom. The ratio of the isomers of *C*-sulfonyl-substituted phosphorus ylides **159**, and **160** thus formed depends on the nature of the substituents R^1 and R^2 .^{350, 351}

The reaction presumably proceeds *via* the formation of sulfenes $R^2CH=SO_2$, which give unstable four-membered cyclic intermediates **161** as a result of the addition to phosphoranes, and are subsequently converted into the isomers **159**, and **160**.

In order to introduce the sulfinyl group to the phosphorus atom, the reaction of the stabilised ylides with the sulfinyl chlorides in the presence of triethylamine is used. This reaction presumably proceeds *via* the intermediate formation of sulfines.^{352–354}

The reaction of diylides **20** ($R=H$) with sulfinates gives *C*-sulfinyl ylides **162**. The Wittig reaction of the latter with aldehydes proceeds with excellent stereoselectivity ($E:Z > 91:9$).

The same reaction with the chiral sulfinate yields chiral *E*-vinylsulfoxides ($E:Z > 99:1$) and is accompanied by the $>96\%$ inversion of configuration at the sulfur atom.⁵⁰

There exist convenient procedures for the preparation of the phosphorus ylides containing a bivalent sulfur atom at the α -carbon atom. The reactions of the stabilised and non-stabilised phosphorus ylides with sulfinyl chlorides in benzene or THF at $20^\circ C$ and the ratio of the reagents 2:1 or 3:1 are used most often. As a result of the transylidation reaction, the ylides containing one or two thio groups at the α -carbon atom are formed.^{354–358} Tolythio *p*-toluenesulfonate, *N*-methyl-*N*-phenylthioacetamide,¹⁶² dimethylsuccinimidiosulfonium chloride^{354, 355, 359} are used as thioaryllating reagents.

X = Cl, ArSO₂, MeC(O)NMe.

The reaction of phosphorus ylides with disulfides in benzene gives the ylides **163** in a yield of about 90%.^{354, 355, 360}

R¹ = Me, MeO; R² = R₂NC(S), EtO₂C.

The synthesis of the ylides **164** with two thioether groups at the carbon atom by the reaction of tertiary phosphines with bisalkyl(aryl)thiocarbenes has been reported.^{361, 362} Dithiocarbenes were generated by the action of sodium hydride on the corresponding tosylhydrazone³⁶¹ or by the decomposition of tris(phenylthio)methylithium.³⁶²

R¹ = Bu, Ph; R² = Et, Ph.

The most important method of synthesis of ylides containing alkylthio groups at the α-carbon atom is the dehydrohalogenation of the phosphonium salts by organolithium derivatives. The ylides synthesised by this method have been used in the Wittig reaction without isolation from the reaction solutions.^{8, 9}

The adduct of tributylphosphine with carbon disulfide **165**, which was isolated more than a hundred years ago by Hoffmann,³⁶³ has been recently intensely studied. The ability of the adduct to enter into cycloaddition reactions with the formation of phosphorus ylides containing the dithiolane ring is not the least reason for such an interest.^{364, 365}

E = CO₂Et.

Polezhayeva *et al.* have introduced the adduct **165** into reactions with various dipolarophiles to prepare C-dithio-substituted phosphorus ylides of both cyclic and acyclic structure.³⁶⁶

R = Me₃Si, PhCH₂, Ph₂P.

The ability of dithia- and tetrathiafulvenes to generate the electroconducting salts stimulated a great interest in phosphorus ylides containing thiafulvene groups.^{367–371} Thus 2-thioxo- and 2-oxo-1,3-dithiol-4-ylmethylides have been proposed as reagents for the synthesis of 1,3-dithia- and tetrathiafulvenes.³⁷²

The addition of dimethyl acetylenedicarboxylate to the adduct **165** has led to the highly reactive cyclic ylide **166a**, which enters into the Wittig reaction and yields dithiafulvenes with π-donating properties.³⁷⁰

The 1,3-dithiol-2-ylides have been generated from the corresponding phosphonium salts with the dithiolane ring even under the action of triethylamine or diisopropylamine.³⁶⁷

The ylides containing the 1,3-dithiol-2-ylide fragment have been used for the preparation of the corresponding polyformyltetrathiafulvalenes with a strong π-donating capacity.^{330, 369}

The derivatives of tetrathiafulvene **167** have been synthesised by the condensation of ylide **166** with phthalic aldehyde.³⁶⁸

By the reaction of triphenylphosphonium methoxycarbonylmethylide with thiocyanogen, triphenylphosphonium 2-oxo-1-thiocyanopropylide, $\text{Ph}_3\text{P}=\text{C}(\text{SCN})\text{C(O)Me}$, has been synthesised in 65% yield.²⁹⁵ The alkylation of the alkylthiomethyltriphenylphosphonium salt gives the phosphonium sulfonium salt, which yields the ylide-sulfonium salt **168** upon dehydrohalogenation.³⁷³

It was proposed to prepare *C*-selenium-substituted ylides by the reaction of phosphorus ylides with phenylselenenyl bromide.³⁷⁴ The *C*-selenium substituted phosphorus ylides enter into the Wittig reaction with aldehydes to yield various phenylselenoalkenes.^{374–378}

The *C*-tellurium-substituted phosphorus ylides have been synthesised similarly and used for the preparation of tellurium-substituted alkenes.³⁷⁹

$\text{R}^1, \text{R}^2 = \text{Alk}, \text{Ar}$.

The reaction of dichloroselenides with triphenylphosphonium alkoxycarbonylmethylides results in the *C*-selenium-substituted ylides **169** or phosphonium selenonium ylides **170**. If the intermediate salts **171** contain two alkyl groups, they are dehydrochlorinated by the excess of phosphorus ylide with the formation of ylide-selenonium salts **170**. If there are a phenyl and an alkyl group at the selenium atom, the ylide **169** is formed.^{380, 381}

The phosphorus ylides with alkoxy and aroxy groups at the α -carbon atom are usually obtained by the salt method.^{383, 384} Thus the treatment of a suspension of a finely-ground phosphonium salt by phenyllithium in ether gives a bright-red solution of *C*-alkoxymethylide, which readily reacts with aldehydes and ketones to give alkyl vinyl ethers.^{365, 383} Triphenylphosphonium α -methoxyethylide is prepared by the reaction of triphenylphosphine with α -chloroethyl methyl ether in benzene. The phosphonium salt is then treated with potassium *tert*-butoxide in dimethoxyethane at -40°C for a few minutes. The red solution of the highly active ylide is formed which easily alkenates aldehydes and ketones.³⁸⁵

The ylides with oxygen or bivalent sulfur atoms at the α -carbon atom are unstable. They are normally used for the further one-pot chemical transformation. *ab initio* Calculations show that although the presence of the oxygen atom at the negatively charged carbon atom should in general stabilise the carbanion, it is not the case for the phosphorus ylides. *C*-Oxygen-substituted phosphorus ylides exhibit an enhanced tendency to dissociate into carbenes and tertiary phosphine, which allows one to regard them as the carbene complexes of tertiary phosphines. The formation of carbenes at the intermediate stage of the reaction is confirmed by *ab initio* calculations by the extended Huckel method in the 6-31 basis set.¹⁶

The ylides **172** also decompose readily with the formation of carbenes, which give 1,2-diketones as a result of intramolecular rearrangement.³⁸⁶

The *C*-Sulfonyl-substituted ylides are characterised by high thermal stability due to efficient delocalisation of the negative charge of the ylide carbon atom by the hexavalent sulfur atom, which has been confirmed by physicochemical studies,^{387–392} in particular by X-ray structural analysis.^{348, 393} The IR- spectra of ylides containing sulfonyl or sulfinyl groups at the carbon atom show considerable shift of the $\text{S}=\text{O}$ and SO_2 frequencies towards the longwave region due to the efficient delocalization of the carbanion negative charge by these groups.^{349, 387–390} The triad prototropic tautomerism is typical of bis(arylsulfonyl)methylphosphine oxides, which exist in the CH -phosphine oxide form in crystals and as tautomeric mixtures of the OH -ylide and CH -phosphine oxide forms in solutions; these forms can be easily indicated by spectroscopy.³⁹¹ Diphenylbis(arylsulfonyl)methylphosphine oxides resemble in their chemical properties the OH -acids of tetracoordinated phosphorus. Thus, they are *O*-methylated by diazomethane.^{391, 392}

Hydrogen at the α -carbon atom in the *C*-sulfonyl-substituted ylides is active and can be readily substituted by various groups. The treatment of the ylides by butyllithium results in the substitution of the hydrogen atom by lithium with the formation of the dicarbanion **173**, which reacts with chlorine-containing electrophiles.³⁴⁸

The reaction of *C*-sulfonyl-substituted ylides with nitrosyl chloride in pyridine leads to the substitution of the hydrogen atom at the α -carbon atom by a nitroso group. The ylide thus formed is converted into sulfonyl cyanide in a Wittig-type intramolecular reaction.^{348, 394}

Flash-vacuum pyrolysis of the acylmethylides **174** obtained by the reaction of the C-alkylthio-substituted ylides with acid chlorides produces the alkyl(aryl) thioacetylenes **175** in good yields.^{348, 358, 394, 395}

Flash-vacuum pyrolysis of sulfinyl-stabilised ylides gives thioesters in satisfactory yield.³⁹⁷

Flash-vacuum pyrolysis of sulfonyl- and sulfinyl-stabilised phosphorus ylides is accompanied by the elimination of phosphine or phosphine oxide with the formation of thio-, sulfinyl-, or sulfonylcarbenes, which give the alkenes **176** and **177** as a result of rearrangements and insertion reactions.^{396, 397}

The substituted vinylphosphonium salts **178** are obtained by the reaction of phenylthiomethylides with iminium salts; they are used in the synthesis of cyclopentadienes.³⁹⁸

The C-sulfonyl-substituted ylides are characterised by weak basicity and nucleophilicity, which accounts for their low activity in the Wittig reaction. The monosubstituted ylides react only with aldehydes and do not react with ketones. Triphenylphosphonium bis-sulfonylmethylides also do not react with carbonyl com-

pounds. On the contrary, phosphorus ylides with alkylthio, alkoxyl, or aryloxy groups at the α -carbon atom readily enter into the Wittig reaction with various carbonyl compounds.^{399–410}

The reaction of ethoxy(ethoxycarbonyl)methylides with aldehydes and the subsequent hydrolysis of the vinyl ethers formed is a convenient way for the preparation of oxo carboxylic acids.⁴⁰³

The ylides with the alkoxyl groups at the ylide carbon atom alkenate both aldehydes and ketones with the formation of the vinyl ethers **179**, which give on hydrolysis the corresponding aldehydes ($\text{R}^1=\text{H}$) or ketones ($\text{R}^1=\text{Me}$), the latter may be again introduced into the Wittig reaction with triphenylphosphonium methoxymethylide thereby extending the carbon chain.^{399–401}

The silicon-containing α -alkoxymethylides **180** are especially convenient for this purpose. Vinyl ethers **181** that are formed in the reaction of the ylide **180** with aldehydes and ketones give aldehydes on treatment with 5% hydrogen fluoride in acetonitrile or with perchloric acid.

This method has been used for the preparation of various steroid aldehydes.^{401–410}

Danishefski *et al.* have developed a simple method for the preparation of pregnenolone **183** by the reaction of the androstenedione **182** with the C-oxygen-substituted ylide, prepared by dehydrohalogenation of the methoxymethyltriphenylphosphonium salt with sodium hydride in dimethyl sulfoxide.^{411, 412}

Triphenylphosphonium methoxymethylide enters into the Wittig reaction with sterically hindered carbonyl compounds.

For instance, it easily alkenates adamantane-1-carbaldehyde in ether at -40°C .⁴¹³

Corey *et al.*⁴¹⁵ have shown that the dehydrochlorination of the α -methoxyalkylphosphonium salts proceeds smoothly under the action of lithium diisopropylamide. The ylides thus obtained have been used for the synthesis of the 9,11-aza-analogues of prostaglandin endoperoxide PGH2 **184**.

The Wittig-type reactions of triphenylphosphonium alkoxy-methylides with chlorodifluoromethane present a synthetic route to the *gem*-difluoroolefins **185**.⁴¹⁴

$\text{R} = \text{Me}, \text{Bu}^i$.

Bis(triphenylphosphoniomethyl)oxide and -sulfide are converted under the action of lithium methoxide into bis-ylides. The latter are introduced into the Wittig reaction with dialdehydes or diketones for the synthesis of various heterocycles including macrocycles.⁴¹⁶ For instance, the reaction of the ylides **186** with β -diketones gives furan and thiophene derivatives,

$\text{X} = \text{O}, \text{S}$,

with cycloheptatriene-1,6-dicarbaldehyde and biphenyl-2,2'-dialdehyde 4,9-methanooxa[22]-annulenes⁴¹⁷ or nine-membered rings are formed, respectively.^{418, 419} [13]-Annulenes with conjugated double and triple bonds have also been synthesised.⁴²⁰

3. C-Halogen-substituted phosphorus ylides

The interest in the C-halogen-substituted phosphorus ylides is caused by the possibility of their application for the preparation of haloalkenes, which are valuable reagents for synthesis.⁴²¹

The C-halogen-substituted phosphorus ylides are usually formed in the reaction of tertiary phosphines with any source of mono- or di-halomethylene species.

One of the most common methods for the synthesis of the phosphorus ylides with one or two halogen atoms at the α -carbon

atom involves the addition of the halocarbenes and carbenoids to tertiary phosphines. They are most often prepared by the treatment of polyhalogenmethanes with strong bases in the presence of tertiary phosphine.^{422–427} This method has been used by Seyferth *et al.*⁴²⁵, and Wittig and Schlosser⁴²⁶ for the preparation of triphenylphosphonium chloromethylide **187** from dichloromethane, butyllithium, and triphenylphosphine.

Dichlorocarbene generated from chloroform under the action of potassium *tert*-butoxide reacts with triphenylphosphine to give a suspension of triphenylphosphonium dichloromethylide **188** which is used in the Wittig reaction without isolation from the reaction mixture. The ylide $\text{Ph}_3\text{P}=\text{CCl}$ (**189**) containing chlorine and fluorine atoms at the α -carbon atom has been prepared in the same way.⁴²²

Triphenylphosphonium dichloromethylide **188** has been also synthesised in a heterogeneous medium, dichlorocarbene being generated from chloroform under the action of 50% alkali in the presence of the phase transfer catalyst (TEBA) and triphenylphosphine. In this case ylide in the nascent state enters the Wittig reaction.⁴²⁸ When a benzene solution of chloroform (or dichloromethylthioether), triphenylphosphine, benzaldehyde and a catalytic amount of TEBA was vigorously stirred at room temperature for 1.5 h with 40% aqueous sodium hydroxide, β -chlorostyrenes **190** were prepared in yields of about 40%–50%. This reaction has been used for the preparation of pyrethroids.^{429, 430}

$\text{R} = \text{Cl}, \text{R}'\text{S}$.

The decarboxylation of the trihalogenacetic acid salts **191** is accompanied by the formation of dihalocarbenes, which, in the presence of tertiary phosphines, give phosphorus ylides **192**; the latter enter into the Wittig reaction with carbonyl compounds.^{431–435} An improvement of this method involves the reaction of triphenylphosphine with methyl chlorodifluoroacetate in the presence of lithium chloride, which presumably proceeds *via* the formation of difluorocarbene.^{436–439}

$\text{M} = \text{Li}, \text{Na}, \text{K}, \text{SnMe}_3, \text{R}^2 = \text{Bu}, \text{Ph}$;

Heating of triphenylphosphine with dichlorofluoromethyl(phenyl)mercury, which is the source of chlorofluorocarbene, yields triphenylphosphonium chlorofluoromethylide **189**.⁴⁴⁰

In some cases the reaction occurs without the formation of dihalocarbene. For instance, sodium dichlorofluoroacetate in a reaction with a tertiary phosphine gives a betaine, which is converted on decarboxylation into triphenylphosphonium chlorofluoromethylide **189**.^{424, 425, 432}

The C-halogen-substituted phosphorus ylides **194** have been obtained by the dehydrohalogenation of halomethyltriphenylphosphonium salts **193** by butyl- and phenyllithium, lithium diisopropylamide, and potassium *tert*-butoxide.^{399, 441–452}

R = Bu, Ph, PrⁱN, Bu^t; M = Li, K.

Butyl- and phenyllithium not only deprotonate the phosphonium salt, but can also exchange the halogen atoms at the α-carbon for lithium^{441–452} or a butyl group¹⁴² giving rise to a mixture of ylides **194** and **195**. A mixture of alkenes was formed in the subsequent reaction with carbonyl compounds. The ability of the triphenylphosphonium halomethylides to react with organolithium compounds increases in the series Cl < Br < I.^{449–452}

X = Br, Cl, I;

The substitution of butyl- or phenyllithium by a sterically hindered sodium bis(trimethylsilyl)amide allows one to eliminate the side processes.^{443, 444} The dehydrohalogenation of chloromethyltriphenylphosphonium chloride by the unstabilised phosphorus ylides, *e.g.* triphenylphosphonium methylide, occurs very smoothly without side processes and gives a pure triphenylphosphonium chloromethylide **187** in the form of orange crystals with high yields.⁴⁴³ The dehydrochlorination of dichloromethyltriphenylphosphonium chloride by hexaphenylcarbodiphosphorane in aprotic solvents gave dichloromethylide **188** exclusively.^{443, 445}

The dehydrohalogenation of trihalomethylphosphonium salts **196**,^{446, 453–467} which are obtained by the reaction of tertiary phosphines with tetrahalomethanes, is an important route for the synthesis of C-halogen-substituted phosphorus ylides.^{449–451, 453} The polyhalomethylphosphonium salts are dehalogenated by tertiary phosphines such as triphenylphosphine or tris(dimethylamino)phosphine.^{458–461}

CX₄ = CCl₄, CBr₄, CBr₂Cl₂, CCl₂F₂, CBrCl₃; R² = Ph, Me₂N.

This method has been successfully used in the synthesis of some natural and biologically active compounds, *e.g.* for the preparation of dibromovinyl dibromocyclopropanes.^{446, 461}

This method has also been used for the preparation of the phosphonium dichloromethylides immobilised on a polymer carrier.⁴⁶⁸

The reaction of triphenylphosphine with tetrahalomethanes may be accompanied by the formation of ylide-phosphonium salts **198** (X = Cl, F), which are used for preparation of halo ketones.^{462–465}

X = Cl, F.

Burton and Van Hamme have proposed to perform dehalogenation of polyhalomethylphosphonium salts by the Group II metals (zinc, cadmium, or mercury).⁴⁵⁶ This procedure gives an organometallic phosphonium salt, which dissociated to a metal chloride and the phosphorus ylide **189**; the latter readily enters into the Wittig reaction with aldehydes and ketones.⁴⁵¹ Heating of triphenylphosphine with chlorotrifluoromethane in the presence of zinc results in the formation of quasi-complex organometallic compounds, which were isolated in the individual form. Analogously, triphenylphosphine reacts with fluorodiodomethane to give a stable fluoroiodomethyltriphenylphosphonium iodide, which is converted into triphenylphosphonium fluoromethylide **194** under the action of a zinc-copper couple.^{142, 447}

NMR Studies have demonstrated that the reaction of a trihalomethylphosphonium salt with zinc gives the organozinc complex **200**, which dissociates to ZnCl₂ and the phosphorus ylide **201**.³⁸³ The equilibrium is strongly shifted towards the complex **200**. Nevertheless, the Wittig reaction occurs in the presence of a carbonyl compound, which is evidence for the formation of the ylide **201**.^{414, 446}

Collignon *et al.* have applied an electrochemical technique for the synthesis of C-halogen-substituted phosphorus ylides. The two-electron electrochemical reduction of dihalo- and trihalomethylphosphonium salts in acetonitrile led to the phosphorus ylides **202**, which enter into the Wittig reaction with aldehydes and

reactive ketones in aprotic medium (DMF or acetonitrile) to yield the corresponding haloalkenes.⁴⁶³

The C-halogen-substituted phosphorus ylides **203** have been synthesised by the halogenation of the phosphorus ylides with hydrogen atoms at the ylide carbon atom. In the case of ylides containing strong electron acceptors at the α -carbon atom (R = CO₂Alk, C(O)Alk, C(O)Ar), the dehydrochlorination of the intermediate phosphonium salt is performed in the presence of triethylamine.⁴⁶⁷ Chlorine, bromine,⁴⁶⁷ phenyliododichloride,⁴⁶⁸ and chloramine T^{469, 470} have been used as halogenating agents. The unstabilised phosphorus ylides are halogenated by perhalo-fluoroalkanes. The reaction occurs regioselectively and high yields of α -haloalkylphosphonium salts are achieved.⁴⁷¹ The fluorination of triphenylphosphonium methylide by FClO₃ followed by NaI gives the fluoromethylphosphonium salt. On its dehydroiodination, triphenylphosphonium fluoromethylide **194** has been obtained in high yield, it enters into the Wittig reaction with aldehydes to form vinylfluorides.⁴⁷²

The exchange of a hydrogen atom at the ylide carbon atom for chlorine or bromine occurs on the interaction of phosphorus ylides with carbon tetrachloride and carbon tetrabromide.^{473, 474}

X = Br, Cl.

The phosphonium-iodonium ylides **204** have been prepared by the reaction of the stabilised phosphorus ylides with derivatives of trivalent iodine.⁴⁷⁵

X = F, OAc, X₂ = O; Ar = Ph, 2-MeC₆H₄;

R = EtO, Ph, 4-MeC₆H₄.

The halogen atom at the α -carbon atom of the tertiary alkylphosphines is highly mobile, which determines its migration towards the phosphorus atom, the 1,2(C $\rightarrow$ P)-halogenotropic shift.

α -Haloalkylphosphines containing electron-accepting substituents at the α -carbon atom rearrange rather easily into phosphorus ylides, and the halogen atom in such ylides may be substituted by various substituents. Numerous examples of the preparation of phosphorus ylides by this method have been described.^{12, 476–483}

The C-halosubstituted phosphorus ylides have been studied in detail using quantum-chemical calculations and physicochemical methods. The *ab initio* quantum-chemical calculations performed by Dixon⁴⁸⁴ and Bestmann¹⁶ have shown that the C-fluorine-containing ylide H₃P=CHF has a non-planar P=CHF group with an inversion barrier of about 2.8 kcal mol⁻¹. Francl *et al.*⁴⁸⁵ have assumed, in accordance with Dixon's results, that the zwitter-ionic character of the P=C bond in the H₃P=CF₂ molecule is minimal. On the basis of the differences in electron densities it has been concluded that the introduction of a fluorine atom at the α -atom enhances the π -character of the P=C bond.

The alkoxy-carbonyl- and acylfluoromethylides exist as mixtures of two geometrical isomers. This is a result of hindered rotation about the P=C bond, caused by partial enolisation of the compounds with considerable shift of the negative charge to the carbonyl oxygen atom.⁴⁴¹

The stability of the C-halogen-containing phosphorus ylides depends on the electron-accepting properties of the second substituent at the ylide carbon atom. The C-halogenoylides stabilised by strong electron-accepting substituents can be isolated and purified, while non-stabilised ylides with one or two halogen atoms at the α -carbon atom are unstable and thus they are usually introduced in subsequent reactions without isolation and purification.^{443, 445} Only triphenylphosphonium chloromethylide⁴⁴³ and -dichloromethylide⁴⁴⁶ have been isolated in pure state. Triphenylphosphonium difluoromethylide **205**, which has been prepared by the reaction of bromodifluoromethyltriphenylphosphonium bromide with tertiary phosphines or with potassium fluoride in the presence of 18-crown-6 dissociates readily into difluorocarbene and triphenylphosphine. Difluorocarbene has been captured by tetramethylethylene. The formation of 1,1-difluoro-2,2,3,3-tetramethylcyclopropane in solution indicated the presence of difluorocarbene.⁴⁸⁶

Schlosser *et al.*⁴⁸⁷ have recently demonstrated that difluoromethylide **205** adds to mono- and disubstituted acetylenes to give difluorocyclopropenes in good yield.

The alkylation, acylation, and arylation of simple fluoromethylides leads directly to C-substituted fluoromethylides as a result of transylidation and presents a convenient synthetic route to various fluoroalkenes.⁴⁶⁷

The acylation of C-fluoro-substituted ylides **206** obtained by the reaction of tributylphosphine with trichlorofluoromethane followed by bromination is a convenient way for the preparation of haloalkyl ketones.⁴⁶⁵

The reactions of C-bromo-substituted ylides with potassium iodide or thiocyanate result in the substitution of the bromine atom at the ylide carbon atom by iodine or a thiocyanato group.^{467, 489}

X = I, SCN.

The α -haloalkylphosphines exist in a tautomeric equilibrium with ylides containing the halogen at the phosphorus atom, therefore, they manifest the chemical properties characteristic of both trivalent phosphorus and ylides. The ratio of the tautomers depends on the electron-accepting properties of the substituents at the α -carbon atom: electron-accepting substituents shift the equilibrium towards the ylides, while electron-donating substituents, on the contrary, increase the equilibrium concentration of α -haloalkylphosphines.^{489–492}

R² = Cl, Br, Alk, Ar.

The C-halogen-substituted phosphorus ylides are valuable reagents in the synthesis of haloalkenes. Electron-accepting halogen atoms at the ylide carbon atom decrease the nucleophilicity of the phosphorus ylides. Therefore, triphenylphosphonium haloalkenylides readily alkenate aldehydes and activated ketones, and do not alkenate non-activated ketones and carboxylic esters. The reactivity of haloalkenylides may be enhanced by introducing electron-donating substituents at the phosphorus atom, e.g., dimethylamino groups, which decrease the electrophilicity of the phosphonium group. Tris(dialkylamino)phosphonium ylides demonstrate definite advantages as haloalkenating reagents over the triphenylphosphonium ylides. For instance, tris(dimethylamino)phosphonium dichloromethylide converts ethyl-*cis-trans*-cinnamaldehyde into chrysanthemic acid in high yield, which could not be achieved with triphenylphosphonium ylide **187**.^{453, 457–459}

The haloalkenylsubstituted dibromocyclopropanes, the initial compounds for the synthesis of cyclopentadienes, and alkenes, have been obtained using triphenylphosphonium chloromethylide.⁴⁶¹

Schlosser has proposed a highly stereoselective method for the synthesis of haloalkenes, which involves 2-methoxymethoxyphenylphosphonium ylides **208** instead of triphenylphosphonium ylides. In this case, the ratio of *cis-trans* isomers of alkenes **209** was 98 : 2–99 : 1.⁴²⁷

The reaction of aldehydes with the ylide **210** containing a fluorine atom at the phosphorus atom yielded the four-membered cycloadducts of the Wittig reaction, **211**, which have been isolated in the individual form; their structure was studied by NMR. On heating to 60–80 °C, the adducts decomposed into 1,1-dihaloalkenes and bis(diethylamino)phosphoryl fluoride.⁴⁹³

X = Cl, Br.

The interaction of tris(dimethylamino)phosphonium chlorofluoromethylide **201** with fluoroalkylcarboxylic esters is stereoselective and occurs with the predominant formation of *Z*-isomers of alkyl polyfluoroalkenyl ethers **213**.

However, monofluoro-, fluorochloro-, and bromofluoromethylides usually react with aldehydes and asymmetrical ketones to give mixtures of *Z*- and *E*-alkenes.^{383, 384} The yields and the stereochemistry of the Wittig reaction in the case of tris(dimethylamino)phosphonium haloalkenylides depend on the method of dechlorination of the phosphonium salt. A high yield of (*Z*)-1-chloro-2-propoxyperfluoropropene is achieved in the case of dechlorination of the salt **212** with tris(dimethylamino)phosphine in the presence of isopropyl trifluoroacetate.^{446, 453–456} The zinc–copper couple dehalogenates exothermally the phosphonium salts **212** in the presence of carbonyl compounds R¹R²C=O (R¹ = Ph, C₆H₁₃, CF₃; R² = H, Ph, CF₃, Me, AlkO), with the formation of 1-chloro-1-fluoroalkenes. In the case of aldehydes and activated ketones, the yields of alkenes are almost quantitative, while with ketones of the acetophenone type the yields are about 70%.

The difluoromethylide **214**, which is generated from tris(dimethylamino)phosphine and dibromofluoromethane, is a convenient source of the difluoromethylene group; **214** enters into the Wittig reaction with cyclohexanone, acetophenone, and propiophenone.^{453, 455, 456}

Triphenylphosphonium fluoromethylide **194** alkenates aliphatic and aromatic aldehydes, and activated and non-activated ketones.^{142, 448} Triphenylphosphonium fluorochloromethylide **189** generated in the reaction of triphenylphosphine with sodium

dichlorofluoroacetate acid enters into the Wittig reaction with aldehydes and activated ketones to yield 1 : 1 mixtures of *Z*- and *E*-alkenes in 1 : 1 ratio,^{142, 448} and alkenates aromatic α -oxocarboxylic esters with formation of α -aryl chlorofluoroacrylic acids.^{423, 424, 436, 437, 494–496} Triphenylphosphonium difluoromethylide **205** converts aldehydes and activated ketones into α, α -difluoroolefins in high yields; however, it does not alkenate cyclohexanone and acetophenone because of their insufficient electrophilicity. Tributylphosphonium difluoromethylide has high reactivity owing to the electron-donating effect of the butyl groups. This ylide, generated by the haloacetate method, alkenates *in situ* such non-activated ketones as benzophenone, cyclohexanone, methylketones $\text{RC}(\text{O})\text{Me}$, where $\text{R} = \text{C}_5\text{H}_{11}$, Ph, 2-furyl, 2-thienyl, *etc.*^{436, 437} Examples of anomaly in the course of the Wittig reaction with tributylphosphonium difluoromethylide are known. For instance, in the reaction of tributylphosphonium difluoromethylide with trifluoroacetophenone, a prototropic rearrangement of the difluoromethylide into the butylide **215** yields the alkene **216**.^{431, 436}

The Wittig reaction of *C*-fluoro-substituted ylides with ketones containing perfluoroalkyl groups is sometimes accompanied by isomerisation associated with the migration of the fluorine atom from the perfluoroalkyl to difluoromethylene group.⁴³² The isomerisation of fluoroalkenes is suppressed when the reaction is performed in the absence of strong bases or dehalogenating agents.⁴³¹

The reaction of triphenylphosphonium chloromethylide with dicyclopentyl ketone gives the chloroalkene **217** in 81% yield; it is transformed into dicyclopentylacetylene, which is formed *via* a carbenoid.⁴⁹⁷

Triphenylphosphonium dichloromethylide was used for the modification of polymeric reagents, for instance, for the preparation of polymeric ynamines **218**.⁴⁹⁸

Corey has proposed a convenient method for the synthesis of haloalkenes by the reaction of triphenylphosphine with carbon tetrabromide in the presence of zinc dust.⁴⁹⁷ The dibromomethylide **219** reacts *in situ* with aldehydes to form dibromoalkenes⁴⁹⁴ that have been used in the synthesis of retinoids,⁴⁹⁴ alkynes,⁴⁹⁷ and alkynecarboxylic acids.^{359, 446}

Bestmann has prepared synthons of pheromones based on the *C*-halogen-substituted ylides.⁴⁹⁹

Methods for the preparation of α -haloalkenes on the basis of *C*-silicon-substituted ylides have been developed. The mild iodination of triphenylphosphonium trimethylsilylmethylide with 1,2-diiodoethane gives the iodoalkylphosphonium salt **220** in high yield. The dehydroiodination of the salt **220** by sodium bis(trimethylsilyl)amide results in the formation of the trimethylsilyliodo-methylide **221**, which is stereoselectively transformed into α -iodoalkenes on treatment with cesium fluoride in *tert*-butyl alcohol in the presence of carbonyl compounds.⁵⁰⁰

The successive treatment of non-stabilised phosphorus ylides by chlorotrimethylsilane and halogen yields α -haloalkyl α -trimethylsilyl-triphenylphosphonium salts **222**, their desilylation by cesium fluoride in the presence of aldehydes results in haloalkenes.⁵⁰¹

V. Conclusion

Heteroatoms at the ylide carbon atom thus considerably affect the chemical properties and the reactivity of the phosphorus ylides. Certain heteroatoms, such as the atoms of the main Group I and II, nitrogen, tin, and lead atoms increase the electron density at the carbon atom and the reactivity of ylides, while on the contrary, other heteroatoms such as silicon and germanium atoms, Group V–VII atoms and transition elements stabilise the ylide carbanion, thus lowering its nucleophilicity. As a result, C-substituted phosphorus ylides acquire new remarkable chemical properties and offer new synthetic opportunities. This determines the deep interest of chemists in the C-hetero-substituted phosphorus ylides as exceptionally promising reagents in organic synthesis.⁵⁰² Thus after the present review has been completed, new data on the chemistry of the C-element-substituted phosphorus ylides, especially ylides containing Group V main elements at the α -carbon atom appeared. Paterson *et al.*⁵⁰³ have synthesised N-methylformamido-substituted phosphorus ylide by the action of lithium bis(trimethylsilyl)amide on the phosphonium salt. This ylide was shown to be an effective reagent for the transformation of aldehydes into the corresponding N-alkenyl-N-methylformamides.

Japanese chemists have synthesised trialkoxyphosphonium ylides with a nitrogen atom at the ylide carbon atom and converted them into the α -alkylaminophosphonates.⁵⁰⁴

C-Phosphino-substituted phosphorus ylides have been also intensely studied. Schmidpeter *et al.*⁵⁰⁵ have synthesised four- and five-membered heterocycles with an exocyclic ylide group including heterocycles with a double P=P bond.

Grobe⁵⁰⁶ has performed a very interesting synthesis of a phosphorus ylide with a tetraphosphetene ring at the α -carbon atom starting from the derivatives of mono- or two-coordinate phosphorus.

Cristau *et al.*⁵⁰⁷ have studied the reactivity of ylide-anions **20** towards carbodiimides and isocyanates. The reaction is performed in two steps: at first heterocumulene is treated with the ylide-anion, and then the ylide adduct is introduced in the reaction with an aldehyde or ketone. As a result, α,β -unsaturated amides and amidines are formed in high yields and stereoselectivity.

Clausen and Becher⁵⁰⁸ have described a new synthetic route to tetrathiafulvenes from cyclic dithiosubstituted phosphorus ylides, which were generated from the corresponding phosphonium salts by the action of triethylamine.

Abstract. The mechanisms of the spectral sensitisation of silver halides by infrachromatic dyes are examined. It is concluded that the effectiveness of the spectral sensitisation is determined by secondary dark oxidation reactions of the silver atoms formed — the so called dye self-desensitisation processes in which the infrachromatic dye plays the role of a catalyst — rather than by primary steps involving electron transfer from the photoexcited dye to AgHal. It is shown that processes involving the super sensitisation of infrared photographic materials constitute the inhibition of the dye self-desensitisation reactions. Supersensitisers are classified in terms of their inhibition mechanism as supersensitisers of the first and second kind. The application of supersensitisers of the first and second kind leads to a super-additive increase in light sensitivity. The modern supersensitisation methods have made it possible to develop a new generation of infrared films with improved photographic parameters. For example, the photosensitivity of an infrared film with a sensitisation maximum at 1060 nm has been increased by a factor of 100. The possibility of spectral sensitisation up to 1500 nm is demonstrated. The bibliography includes 147 references.

I. Introduction

The spectral sensitisation of silver halide (AgHal) photographic materials is one of the few examples of a highly effective spectral sensitisation process devised by man. The discovery of the spectral sensitisation of silver halides by organic dyes (Dy) is one of the most important events in the history of photography. It was achieved in 1873 by Prof. Herman Wilhelm Vogel.¹ In the course of the 120 years history of its development, the spectral sensitisation process was raised to an extremely high level of perfection. It is sufficient to state that the relative quantum yield of the spectral sensitisation in the visible region of the spectrum is close to unity, *i.e.* the photographic effectiveness of the quanta absorbed by the dye is equal to the effectiveness of the quanta absorbed by the AgHal lattice.

Received 6 March 1996

Uspekhi Khimii 66 (3) 278–304 (1997); translated by A K Grzybowski

The expansion of the region of spectral sensitivity into the infrared emission zone is known to encounter considerable, seemingly insurmountable, difficulties. In the first place, an appreciable decrease in the sensitisation with increase in the emission wavelength is observed.² Until recently there was an empirical rule, according to which light sensitivity diminishes on moving into the IR region of the spectrum approximately by an order of magnitude for each 100 nm. A particularly marked decrease in light sensitivity occurs in the region of the spectrum at wavelengths exceeding 1000 nm. The sensitivity of a photographic material with a sensitisation maximum in the region of 1000 nm is approximately 1000 times smaller than the sensitivity of the light-sensitive layers in the visible region of the spectrum. The spectral sensitivity limit corresponds to the range 1300–1350 nm.^{3,4}

Yet another difficulty is the insufficient viability of infrachromatic photographic materials. An appreciable decrease in light sensitivity and an increase in the fogging of the light-sensitive layers is observed in the course of time, which makes them unsuitable for use a short time after their preparation. The question of the causes of the decrease in the effectiveness of their spectral sensitisation in the IR region of the spectrum has been widely discussed in the literature (see, for example, Refs 2, 5, and 6). In the dominant concept, the decrease in the light sensitivity of infrared light-sensitive layers is attributed to the energy 'deficit'. According to this concept, a light quantum absorbed by an infrared dye is significantly smaller than the quantum absorbed by AgHal and for this reason it cannot exert the same photochemical effect. Nevertheless, there are numerous experimental facts indicating the important role of secondary chemical reactions with participation of the spectral sensitiser, which determine to a large extent the effectiveness of the spectral sensitisation process.^{5,6} The aim of the present review is to compare various experimental results and to analyse the theoretical approaches to the problem of infrared sensitisation.

II. The problem of the energy 'deficit'

The main problem which arises in the spectral sensitisation of wide-band semiconductors (silver halides) by organic dyes is that of the energy 'deficit'. The theory of spectral sensitisation is invoked primarily in order to explain how a lower-energy photon, absorbed by the spectral sensitiser, exerts the same photographic effect as the higher-energy quantum absorbed by the AgHal lattice. For example, the width of the forbidden band of AgBr is

2.6 eV (~ 500 nm absorption limit). However, the spectral sensitisation by dyes is observed in the IR region of the spectrum in the vicinity of 750–1100 nm, *i.e.* the sensitisation takes place under the influence of light quanta with a significantly smaller energy (1.6–1.1 eV).

It is noteworthy that the problem of energy 'deficit' can be readily solved within the framework of the theory of the resonance transfer of excitation energy from the dye to AgHal when the local electronic levels of the photoconductor participate in the photo-process. Excitation energy transfer in spectral sensitisation was first examined in 1948 by Mott,⁷ who put forward the hypothesis that, in the sensitised photolysis of AgBr, the light energy absorbed by the dye is consumed in the liberation of an electron at a local level in the forbidden band. This scheme was developed in detail in the 1960s in the studies of Terenin, Akimov, and coworkers^{8–11} and of Kuhn, Möbius, and coworkers.¹² The possibility of spectral sensitisation *via* the excitation energy resonance transfer mechanism has been demonstrated experimentally by Akimov¹¹ and Kuhn and coworkers.¹² However, it was later concluded¹³ that the spectral sensitisation of real AgHal emulsions is determined by electron transfer from the photo-excited dye (Dy^*) to AgHal and that the contribution of the excitation energy resonance transfer does not exceed several per cent. At the present time, the electron transfer mechanism has become generally accepted.²

The electron transfer mechanism in the spectral sensitisation of AgHal by dyes was first examined by Gurney and Mott¹⁴ within the framework of the band model of silver halides in 1938. According to this mechanism, the spectral sensitisation is associated with electron transfer from the photoexcited dye Dy^* to the conduction band (CB) of silver halide. According to Gurney and Mott,¹⁴ for effective sensitisation the energy level of the photo-excited electron in Dy^* must be above the bottom of the conduction band of AgHal or at least close to it. In subsequent steps, the recombination of the electrons injected into the conduction band with the interstitial (or surface) Ag^+ ions, which takes place preferentially on the sensitivity centres (SC), results in the formation of a latent photographic image. The dye can return from the radical-cation ($\text{Dy}^{+\cdot}$) state to the initial state either *via* the injection of a hole into the valence band (VB) of silver halide or by the acceptance of an electron from defective surface sites, for example, from defective Br^- and I^- ions or the impurity centres (IC) formed during chemical sensitisation.

The determination of the positions of the electronic levels of the dyes adsorbed on AgHal in terms of the absolute potential scale is a fairly complex task. There exist both experimental methods for such determination and computational quantum-chemical methods. The lowest vacant level of the dye ϵ_{lv} , to which an electron is transferred on photoexcitation, may be characterised by the electron affinity of the dye E_{ads} . The highest occupied level ϵ_{ho} , from which an electron passes to ϵ_{lv} on photoexcitation is in its turn determined by the ionisation potential of the dye I_{ads} . Numerous attempts have been made to determine E_{ads} and I_{ads} (see James's monograph² and the communications quoted therein), but, owing to the difficulties arising in the interpretation of the experimental results, it is at present impossible to determine unambiguously the levels ϵ_{lv} and ϵ_{ho} of adsorbed dyes.

The energy levels of the dyes can be calculated by different quantum-chemical methods. The first systematic studies on these lines were carried out by Tani and Kikuchi.¹⁵ Electrochemical potentials and in the first place the polarographic half-wave reduction ($E_{1/2}^{\text{Red}}$) and oxidation ($E_{1/2}^{\text{Ox}}$) potentials of dyes have found extensive application in studies on spectral sensitisation for the determination of the energy levels of the dyes.^{2, 15–17} The potential $E_{1/2}^{\text{Red}}$ reflects the energy of the level ϵ_{lv} of Dy^* from which an electron is transferred to the conduction band of AgHal while $E_{1/2}^{\text{Ox}}$ reflects the energy of ϵ_{ho} .

The polarographic half-wave reduction and oxidation potentials of dyes are at present the principal energy criteria of the electronic levels in dyes. They are frequently resorted to instead of

the quantities ϵ_{lv} and ϵ_{ho} . The main reason for this is the ease of their determination. A definite relation between the positions of the electronic levels, characterised by the oxidation-reduction potentials of dyes, and the efficiency of the spectral sensitisation has been demonstrated in numerous studies. Mention should be made in the first place of the studies of Dähne,^{18, 19} Tani and Kikuchi,¹⁵ Gilman,¹⁶ and a number of other investigators (see the relevant reviews^{19–23}). A definite relation between the positions of the electronic levels of dyes, characterised by the potentials, and the efficiency of the spectral sensitisation was discovered in these studies. For example, it has been shown that, as the location of ϵ_{lv} becomes deeper, *i.e.* in a definite range of potentials $|E_{1/2}^{\text{Red}}|$ (as a rule, $|E_{1/2}^{\text{Red}}| < 1.0$ V relative to the saturated calomel electrode), a decrease in the effectiveness of the spectral sensitisation of negative photographic materials is observed. This is associated with the fact that, starting with a certain boundary value of $E_{1/2}^{\text{Red}}$ (Dy), the levels ϵ_{lv} are found to be deeper than the bottom of the conduction band of AgHal, which hinders the transfer of a photoelectron from Dy^* to the conduction band. The positions of the bottom of the conduction band and of the top of the valence band of AgBr have been determined⁵ in terms of the electrochemical potential scale. Relative to the normal hydrogen electrode (n.h.e.), the potential of the bottom of the conduction band of AgBr is -1.1 V, while the potential of the top of its valence band is $+1.5$ V. Relative to the saturated calomel electrode (sat. c.e.), these potentials are -1.34 and $+1.26$ V respectively. The potential of the bottom of the conduction band is close to the boundary value $E_R^* = -1.37$ V established later in a study by Tani.²⁴

The bathochromic shift of the absorption by cyanine dyes to the IR region of the spectrum is known to be attained as a rule when the length of the polymethine chain is increased. With increase in the length of the polymethine chain, the levels ϵ_{lv} become deeper and approach the levels ϵ_{ho} .¹⁵ Fig. 1 illustrates the energy level diagram for thiapolymethine dyes in terms of the electrochemical potential scale relative to the AgBr bands. The potentials were taken from Shapiro *et al.*²⁵ Starting with the carbocyanine for which $n = 1$, the levels ϵ_{lv} of the dye are found to lie below the bottom of the conduction band of AgBr and are located increasingly deeper with increase in n (*i.e.* as the absorption shifts into the IR region of the spectrum). Seemingly, the problem of the effectiveness of spectral sensitisation, namely the decrease in the effective sensitisation as the level ϵ_{lv} of the dye assumes a deeper position $|E_{1/2}^{\text{Red}}(\text{Dy})| < 1.34$ V relative to the sat. c.e., may be solved successfully within the framework of the energy approach to electron transfer. The energy gap (energy

Figure 1. Energy level diagram for thiapolycarbocyanine dyes on the electrochemical potential scale (relative to sat. c.e.).

'deficit') between ε_{IV} and the bottom of the conduction band then increases. In this case, the decrease in spectral sensitivity with increase in the energy gap (ΔE) is quite reasonable, since the sensitisation rate constant k_S which determines the quantum yield of the spectral sensitisation should vary exponentially with ΔE :

$$k_S = A \exp\left(-\alpha \frac{\Delta E}{RT}\right), \quad (1)$$

where A and α are constants. This explanation of the dependence of the spectral sensitivity on $E_{1/2}^{\text{Red}}(\text{Dy})$ can in fact be found as a rule in the literature.

Despite the agreement between the experimental results and the predictions of the theory of electron transfer from Dy^* to the AgHal conduction band noted above, a certain amount of caution must be exercised in assessing the adequacy of this model. The question of the real disposition of the dye levels relative to the AgHal electron energy bands has been discussed hitherto. The mutual assignment of the levels based on photographic experiments, electrochemical data, and quantumchemical calculations, is also not unambiguous. However, the principal disadvantage of the electron transfer model considered is the absence of a dependence of the spectral sensitivity on $E_{1/2}^{\text{Red}}(\text{Dy})$ when the light-sensitive layers are exposed *in vacuo*.

The studies by James and coworkers^{26–28} of the influence of the evacuation of photographic emulsions on the effectiveness of spectral sensitisation are undoubtedly some of the most important in the field of spectral sensitisation. It was shown in these investigations that, after the removal of oxygen and water from light-sensitive layers by evacuation and the additional reductive sensitisation by hydrogen, the dependence of the sensitisation effectiveness on $E_{1/2}^{\text{Red}}(\text{Dy})$ vanishes and many desensitising dyes, the ε_{IV} levels of which are located deep under the conduction band, become effective sensitisers. For example, spectral sensitisation has been observed for a dye with $E_{1/2}^{\text{Red}}(\text{Dy}) = -0.36$ V, for which the transfer of a photoelectron from Dy^* to the AgHal conduction band is virtually impossible ($\Delta E = 1.1$ V). This was a kind of crucial experiment, which demonstrated convincingly that the effectiveness of the spectral sensitisation is determined not so much by the disposition of the dye levels relative to the AgHal bands as by the chemical reactions with participation of oxygen and water protons, which lead to the formation of secondary products (in particular, hydrogen peroxide) and which thereby divert the photoelectrons from the formation of a latent image. A similar influence of evacuation on spectrally sensitised layers has been observed also by other investigators.^{28, 29}

In order to account for the sensitisation by dyes the ε_{IV} levels of which are located under the AgHal conduction band, James employed a two-stage electron transfer from Dy^* to AgHal,³⁰ according to which the electron is initially transferred not to the conduction band but to local surface capture levels located deeper (or near) the electronic level in Dy^* . Such levels may be surface defects and in the first place surface Ag ions (on kink sites). Electrons are next thermally excited from the surface capture levels to the AgHal conduction band. The transfer of electrons from Dy^* to local surface layers, including the silver ion levels, has also been examined by West³¹ and Mitchell.³² Gilman¹⁶ also postulates that the number and depth of the effective electron capture levels on AgHal are more important factors, controlling the sensitising effect of the dye, than the relation between the energy levels of the dye and AgHal. The spectral sensitisation processes 'under the conduction band' with participation of surface electron traps have also been examined by Gilman.³³

James's two-stage mechanism³⁰ was a logical continuation of the conclusions arising from his study³⁴ and also from that of Saunders and West³⁵ concerning the mechanism of the development process. In his earlier study,³⁴ James showed that, for microcrystals with subsurface sensitivity, the deep latent image undergoes latensification when the microcrystals come into contact with a number of developing substances (hydrazine, hydrox-

ylamine, phenidone, *etc.*), capable of effecting the transfer of one electron, while Saunders and West³⁵ observed the formation of a latent image on AgHal single crystals at a depth of several microns under the surface when they come into contact with a normal developer. The single-stage electron transfer from developers into the bulk of AgHal is unrealistic, since, for a width of the energy gap $\Delta E = 1.3$ V between the electronic level in the developers and the bottom of the conduction band, the transfer time should be approximately 100 years.

The electron transfer from the silver atom formed on surface development of AgHal into the exposed crystals constitutes the basis of the generation of a direct negative image when a fogging developer is employed³⁶ and also when light-sensitive layers initially exposed in a surface developer are subjected to uniform illumination by low-intensity light.²

Convincing evidence for electron transfer from Dy^* into the bulk of AgHal *via* the system of levels under the AgHal conduction band is provided by experiments with AgHal emulsions containing Ir^{3+} ions in microcrystals. Gilman³⁷ showed that a deep latent image is formed in such emulsions on spectral sensitisation by dyes with $E_{1/2}^{\text{Red}}(\text{Dy})$ up to -0.25 V (relative to the Ag/AgCl electrode). Thermal excitation of electrons to the conduction band has been considered.

If one takes into account the appreciable oxidation potential of the Ag^+/Ag system, then the surface silver ions can be reduced by virtually any photoexcited infrared dye.²³ It is noteworthy that, even in the presence of the excess of Br^- ions actually employed in the emulsion, the AgHal surface coated by the excess bromide ions constitutes less than 20% of the entire surface,³⁸ *i.e.* silver ions are always present on the surface.

It is well known that the effectiveness of the spectral sensitisation of AgHal by dyes with ε_{IV} levels located under the conduction band, and in the first place by infrachromatic dyes, depends greatly on the concentration of Ag^+ ions (pAg) in the emulsion. The spectral sensitivity S_λ then increases with increase in the Ag^+ concentration.² The dependence of the effectiveness of infrared dyes on pAg has been studied in detail by Collier and Gilman,³⁹ who noted an increase in the effectiveness of spectral sensitisation for dyes having a long polymethine chain with decrease in pAg. The increase in S_λ with increase in the concentration of Ag^+ ions has been attributed to the direct phototransfer of electrons from Dy^* to surface Ag^+ ions. Within the framework of the band scheme of the AgHal levels, this is equivalent to the downward bending of the bands and the approach of the bottom of the conduction band to ε_{IV} of the dye, as shown in Fig. 2. The dependence of the boundary potentials and $E_{1/2}^{\text{Red}}$ and $E_{1/2}^{\text{Ox}}$, corresponding to the injection of the dye electrons and hole into AgHal, on pAg, discovered by Berriman and Gilman,⁴⁰ is associated with this finding. Under these conditions, the injection of electrons from Dy^* into AgHal is facilitated at low pAg, while the injection of holes is facilitated at high pAg.

Figure 2. Schematic illustration of the bending of the AgHal bands with increase in the concentration of Ag^+ ions ($\text{pAg}_1 < \text{pAg}_2$) in a photographic emulsion during spectral sensitisation by a dye with a deep ε_{IV} level.

When the spectral sensitisation by infrared dyes is considered as a reaction of Dy^* with surface Ag^+ ions, the main problem becomes not the energy 'deficit' but the effectiveness of the separation of the charges formed in the primary step and hence the probability of the recombination of the charges or their irreversible binding. It is noteworthy that this is the usual problem, characteristic of all chemical oxidation-reduction reactions, which is solved mainly by the stabilisation of the final states. In the case of silver halides, such stabilisation is possible by virtue of the rapid relaxation of the generated states as a result of the electrostatic interaction with the medium and also because of the subsequent removal of electrons through space by their relay migration *via* surface (or subsurface) silver ions or *via* impurity cations. The uniqueness of silver halides in this respect may be determined by the greater probability of the formation of silver molecules (the latent image precentres), whereupon the energy of the interatomic $\text{Ag}-\text{Ag}$ bond is gained.

If it is supposed that the primary step consists in electron transfer to surface traps and in the first place to silver ions, the difference in the photographic effect of infrared dyes is determined not so much by the kinetics of the primary step as by the kinetics of the secondary reactions of the components of the photographic emulsion, involving the formation of silver atoms, and in the first place of the chemical processes involving the oxidation of the silver atoms and silver particles formed. The influence of chemical reactions, including reactions involving oxygen and protons, on the effectiveness of the photographic process is well known.¹⁸ This concerns the so called processes involving the desensitisation of AgHal by dyes.

III. Desensitisation of silver halides by dyes

The desensitisation of AgHal by dyes is understood as the decrease in the intrinsic (blue) sensitivity of the photographic emulsion following the adsorption of dyes on AgHal microcrystals. The desensitisation of AgHal was first examined by Lüppo-Cramer,⁴¹ who introduced the term desensitisation. Two principal desensitisation mechanisms are distinguished — electron acceptor and hole acceptor mechanisms. The desensitisation *via* the electron acceptor mechanism — type I desensitisation — is induced by dyes, including infrachromatic dyes, with a high electron affinity. After the exposure of AgHal to light ($h\nu$), the desensitising dyes capture photoelectrons from the conduction band in the ϵ_{lv} levels lying below the bottom of the AgHal conduction band and thereby divert them from the formation of a latent photographic image (Fig. 3). Thus the condition for the type I desensitisation is $E_{1/2}^{\text{Red}}(\text{Dy}) > E_{\text{CB}}$. This process can be represented schematically as follows:

In this scheme, stage (4) corresponds to the irreversible loss of electrons as a result of the chemical interaction of $\text{Dy}^{\cdot-}$ with the components of the photographic emulsion. Stage (5) reflects the recombination of the electrons, captured by Dy , with AgHal holes.

An appreciable intensification of the desensitisation by electron-accepting dyes in the presence of oxygen and water was already noted comparatively long ago.^{18,27} Blau and Wambacher⁴² noted that the desensitising effect of Pinakryptol Yellow and phenosafranin is manifested only in the presence of oxygen. It was postulated that the desensitiser is more likely to be an oxidation 'transferring agent' than an oxidant proper. The influence of oxygen and moisture on emulsions containing electron-accepting dyes was also pointed out by Carrol and coworkers.⁴³

Figure 3. Schematic illustration of type I desensitisation.

The influence of oxygen and moisture on the sensitivity of spectrally sensitised emulsions was later confirmed in other studies.^{26,30,40,44–51} It has been suggested⁵¹ that the influence of oxygen on infrachromatic materials is associated with the formation of the complex $[\text{Dy} \cdot \text{O}_2]$. The studies of the influence of various emulsion factors, as well as the structure of dyes, on type I desensitisation processes have been thoroughly reviewed by Dühne.¹⁸

Considerable attention has been devoted to the role of oxygen and water in type I desensitisation processes in the communications of James and coworkers,^{26,27,48} in which electron transfer from the AgHal conduction band *via* the dye to O_2 with formation of the $\text{O}_2^{\cdot-}$ radical-anion is discussed. The special role of water in the irreversible binding of photoelectrons with formation of hydrogen peroxide is emphasised.⁴⁸

The following mechanism has now been adopted for type I desensitisation (Scheme 1).^{5,6,17,27}

Scheme 1

In the first stage of the desensitisation process, an electron from the AgHal conduction band or from a surface trap (in particular from the Ag^0 precentre of the latent image) is captured by the dye in the ground state, which is then converted into the $\text{Dy}^{\cdot-}$ radical-anion. Next the excess electron is transferred from $\text{Dy}^{\cdot-}$ to O_2 with formation of the $\text{O}_2^{\cdot-}$ radical-anion. The superoxide radical-anion $\text{O}_2^{\cdot-}$ is known to be readily protonated, affording the radical $\text{HO}_2^{\cdot}$ with a much higher electron affinity than O_2 .^{5,6} The radical $\text{HO}_2^{\cdot}$ therefore readily captures a second electron. The anion HO_2^- formed thereby is subsequently protonated, giving rise to hydrogen peroxide. In addition, there is a possibility of the recombination of the radical-anions $\text{Dy}^{\cdot-}$ and $\text{O}_2^{\cdot-}$ with holes (stages 6 and 7).

According to the above mechanism, the dye in the ground state plays the role of an intermediate, transferring electrons from the silver atom to O_2 and the water protons, *i.e.* one is dealing with catalysis by the dye of oxidation processes with participation of oxygen and protons. The transformation of the single-stage oxidation reaction into a series of consecutive reactions in each of which the activation energy for the process is smaller than in the single-stage reaction then leads (as in any catalytic processes) to the acceleration of the overall process.

The intermediate participation of the dye in electron transfer (stage 1) is determined by its electron affinity or, more specifically, by the depth (ΔE) of the ϵ_{lv} level of the adsorbed dye under the AgHal conduction band (Fig. 3). Furthermore, the effectiveness of the electron capture depends on the capture cross-section, which is a function of the charge and length of the dye molecule. Thus, other conditions being equal, the deeper the ϵ_{lv} level of the dye *i.e.* the smaller the absolute magnitude of $E_{1/2}^{\text{Red}}(\text{Dy})$, the greater should be the extent of desensitisation.

The relation between the desensitising effect of dyes and the position of their lowest vacant electronic level has been pointed out independently by Bogomolov and Moshkovskii,⁵³ by Tamura and Hada,^{54,55} and also by Sheibe and Dörr.^{56,57} The dependence of the desensitisation on the polarographic potentials $E_{1/2}^{\text{Red}}(\text{Dy})$ was first noted in the study of Sheppard *et al.*⁵⁸ The authors quote a potential of -0.70 V (relative to n.h.e.) or -0.92 V (relative to the Ag/AgCl electrode) as the upper limit for desensitisation. Later these values were confirmed.⁵⁹ The same limiting potentials have been quoted by Dähne.^{18,22,60} Desensitisation potentials in the range from -0.86 to -1.05 V (relative to the Ag/AgCl electrode) have been given in a number of studies.^{17,40,61–64} Thus, on average the boundary desensitisation potential on the polarographic potential scale is -1.0 V (relative to the Ag/AgCl electrode). The limiting potential depends on emulsion factors and primarily on pAg. With increase in pAg and also with increase in the dye concentration, an intensification of the desensitisation is observed.¹⁸

In vinylogical series of polymethine dyes, the desensitising effect increases with increase in the length of the polymethine chain, which agrees with the increased depth of the ε_{IV} level.^{15,18,65} The quantitative dependence of the desensitisation on the dye ε_{IV} has been investigated by Strurmer *et al.*⁶⁶ It was shown that the desensitisation steadily increases with increase in the depth of the ε_{IV} level.

The dependence of the degree of desensitisation on $E_{1/2}^{\text{Red}}(\text{Dy})$ has been examined in detail by Mikheeva *et al.*⁶⁷ The degree of desensitisation (SD) is understood as the ratio of the intrinsic sensitivity of the AgHal emulsion without the dye (S) to the sensitivity in the presence of the dye (S'):

$$SD = \frac{S}{S'}.$$

The linear dependence of $\lg SD$ on $E_{1/2}^{\text{Red}}(\text{Dy})$ of the general type

$$\lg SD = m E_{1/2}^{\text{Red}}(\text{Dy}) + n, \quad (7)$$

has been discovered.⁶⁷ Here m and n are constants for constant pAg and the dye concentration. Figs 4 and 5 illustrate the dependence of $\lg SD$ on $E_{1/2}^{\text{Red}}(\text{Dy})$ for different dye concentrations and different pAg. It is striking that the linear relation is retained over a definite range of pAg and concentrations, the slope of the curves increasing with increase in pAg and the dye concentration. The boundary desensitisation level is -1.1 V (relative to sat. c.e.).

The linear dependence of $\lg SD$ on $E_{1/2}^{\text{Red}}(\text{Dy})$ has been explained within the framework of the kinetic model of spectral sensitisation processes⁶⁷ on the basis of the electrochemical potentials of the dyes and other components of the photographic emulsion, which was developed in the present authors studies.^{5,6,17,23} The model is based on the Marcus theory of electron transfer in polar media.⁶⁸ Since the spectral sensitisation and desensitisation of AgHal are typical oxidation-reduction reactions occurring in a polar medium, the Marcus theory is fully applicable to them. According to the Marcus theory, there is a linear relation between the free energy of formation of the transition state ($\Delta G^\ddagger$) and the thermodynamic characteristics of the elementary oxidation-reduction step:

$$\Delta G^\ddagger = -RT \ln k \approx a \Delta G^0 + b \approx an F \Delta E^0 + b, \quad (8)$$

where k is the reaction rate constant, ΔG^0 the standard free energy change in the reaction, a and b are constants for a particular class of reactions, n is the number of electrons in the reaction, F the Faraday, and ΔE^0 the difference between the standard potentials.

In this case, the rate of electron transfer between the components of the photographic emulsion — the molecules of Dy^* , Dy , AgHal^* , AgHal , and other compounds — can be expressed by kinetic equations in which the activation energy is a function of the difference between the normal oxidation-reduction potentials of the systems participating in the electron transfers. For example, the rate of passage of electrons into the conduction band or onto the AgHal surface levels, which determines the light sensitivity of

Figure 4. Dependence of $\lg SD$ on $E_{1/2}^{\text{Red}}$ at different dye concentrations $10^6 c_{\text{Dy}}$ (mol per mole of AgHal) (pAg 8.0): (1) 1; (2) 2; (3) 4; (4) 8; (5) 10.

Figure 5. Dependence of $\lg SD$ on $E_{1/2}^{\text{Red}}$ at different pAg: (1) 7.4; (2) 8.0; (3) 8.9. Dye concentration 2×10^{-6} mol per mole of AgHal.

the negative process, can be expressed as the sum of the rates of electron flow in individual channels of the electron transfer reactions:

$$\sum_i \left(\frac{dn_{i(e)}}{dt} \right) = \sum_i k_i c_i = \sum_i A_i c_i \exp \left(- \frac{\alpha_i \Delta E_i^0}{T} \right), \quad (9)$$

where $n_{i(e)}$ is the number of electrons in the conduction band or on the AgHal surface, k_i the rate constant for electron transfer, c_i the concentration (or more precisely the activity) of the electron-donating (reduced) form of the i th system, formed after photoexcitation and capable of electron exchange with the conduction band or with the surface levels, A_i and α_i are constants for a particular class of reactions, and ΔE_i^0 is the difference between the normal potential of the i th system, formed after photoexcitation, and the potential of the bottom of the conduction band E_{CB}^0 or the electron-accepting levels ($E_{\text{SL}(e)}^0$).

The kinetics of electron capture from the conduction band by the components of the photographic emulsion may be expressed

as the sum of the rates of the reactions, one of which is the formation of the latent image:

$$\sum_j -\left(\frac{dn_{j(e)}}{dt}\right) = \sum_j k_j c_j n_{(e)} = \sum_j A_j c_j n_{(e)} \exp\left(-\frac{\alpha_j \Delta E_j^0}{T}\right), \quad (10)$$

where c_j is the concentration of the electron-accepting (oxidised) form of the j th system and ΔE_j^0 is the difference between the potential of the bottom of the conduction band E_{CB}^0 (or $E_{SL(e)}^0$) and the normal potential of the j th system. The photographic sensitivity is determined by the ratio of the rates of the reactions involving the migration of electrons into AgHal and their irreversible binding.^{5,17}

We shall now consider the desensitisation process. According to Scheme 1, the primary stage of the desensitisation process is the capture of electrons from the conduction band or from the surface traps by the dye in the ground state. Stage 1 may be rate-determining for the overall desensitisation process. The rate constant for the protonation of O_2^- (stage 3) is known to be nearly diffusional, i.e. equal to $10^{10} \text{ cm}^{-1} \text{ s}^{-1}$.⁶⁹ Stage 2 can also be fairly fast, since the normal potential of the O_2^-/O_2 system is -0.284 V (relative to n.h.e.),⁶⁹ i.e. is significantly more positive than $E_{1/2}^{\text{Red}}(\text{Dy})$ for the majority of dyes. If it is assumed that stage 1 is rate-limiting, then the rate of capture of electrons from the conduction band by the dye is determined according to Eqn (10) (for $c_{Dy} = \text{const.}$ and $n_e = \text{const.}$) by the difference between the potentials of the bottom of the conduction band E_{CB}^0 and $E^0(\text{Dy}^-/\text{Dy})$. For reversible systems, the potential $E^0(\text{Dy}^-/\text{Dy})$ is virtually identical with $E_{1/2}^{\text{Red}}(\text{Dy})$. The electron capture rate constant (stage 1 in Scheme 1) can be expressed in the form

$$k_1 = A_1 \exp\left(-\alpha_1 \frac{\Delta E_1^0}{T}\right), \quad (11)$$

where $\Delta E_1^0 = E_{CB}^0 - E_{1/2}^{\text{Red}}(\text{Dy})$. The degree of desensitisation at constant pAg should be proportional to k_1 , the concentration of electrons which have emerged onto the surface of AgHal microcrystals after passing through the conduction band (c_e), and the dye concentration (c_{Dy}):

$$SD \approx k_1 c_e c_{Dy}, \quad (12)$$

For constant pAg, c_e , and c_{Dy} , we have

$$SD \sim k_1 \sim \exp\left(-\frac{\Delta E_1^0}{T}\right) \sim \exp\left(-\frac{E_{1/2}^{\text{Red}}(\text{Dy})}{T}\right). \quad (13)$$

Indeed, according to Figs 4 and 5 there is a linear dependence of $\lg SD$ on $E_{1/2}^{\text{Red}}(\text{Dy})$.⁶⁷ It is noteworthy that the form of the dependence of $\lg SD$ on $E_{1/2}^{\text{Red}}(\text{Dy})$ does not change if electrons are captured by the dye not directly from the conduction band but from the surface electron traps (e_s). In this case, only ΔE_1^0 changes. It may be that electrons are captured both from the AgHal conduction band and from the surface traps.

Naturally, with increase in the concentration of the desensitiser dye, there is an increase in the rate of electron capture. This explains the relation, noted by Dähne,⁶⁰ between $\lg SD$ and the dye concentration (more precisely $\lg c_{Dy}$ — see Fig. 4). The dependence of $\lg SD$ on pAg is determined by the competition between the silver ions and the dye for electron capture from the conduction band. Furthermore, Ag^+ ions may capture electrons from Dy^- and O_2^- , formed in stages 1 and 2 (see Scheme 1), and hence can return them to the construction of the latent image. This explains the decrease in desensitisation with decrease in pAg (Fig. 5).

The quantity $E_{CB}^0 = -1.1 \text{ V}$ (relative to n.h.e.) or approximately -1.34 V (relative to sat. c.e.) for AgBr has been determined from experimental and calculated data.⁶⁷ Fig. 6 presents a diagram illustrating the normal oxidation-reduction potentials for the components of the silver halide emulsion. The potential diagram is extremely important methodologically, since it makes

Figure 6. Oxidation-reduction potential diagram for the components of a AgHal emulsion.

it possible to compare the potentials of the electron bands of AgHal, the dyes, the photographically active silver particles, and various components of the photographic emulsion. As an example, Fig. 7 illustrates the type I desensitisation reaction path for a dye with $E_{1/2}^{\text{Red}}(\text{Dy}) = -0.6 \text{ V}$ (relative to n.h.e.).

Figure 7. Energy scheme for a type I desensitisation process.

IV. Self-desensitisation of dyes

It is natural to postulate that secondary oxidative desensitisation processes should occur not only on photoexcitation of AgHal but also on photoexcitation of the dye itself — the spectral sensitiser. One is dealing with reactions involving the self-desensitisation of dyes,^{2, 5, 6, 23} which is understood as the desensitising influence of the spectral sensitiser on the photoprocess in the region of its absorption. In the literature, this process had been previously called selective desensitisation in the region of spectral sensitisation.^{27, 32, 70}

Unfortunately it is virtually impossible to estimate quantitatively the influence of the spectral sensitisers themselves on the spectral sensitivity, since one cannot carry out a control exposure in the same spectral zone without the dye. An indirect method is

therefore used — the influence of an additionally introduced desensitiser on the spectral and intrinsic sensitivity is inferred, *i.e.* the selective desensitisation is estimated.

The difference between the desensitisation and selective desensitisation processes in the region of spectral sensitisation has been considered in a number of studies^{23, 27, 70} and the greater influence of the additionally introduced desensitisers on the spectral sensitivity compared with the intrinsic sensitivity was explained by the fact that, on photoexcitation of AgHal, desensitisation is achieved by the capture of electrons from both deep electron traps (light sensitivity centres) and from shallow surface traps. On the other hand, on photoexcitation of the dye, all the photoelectrons are initially transferred to shallow surface traps, from which the capture of electrons in vacant levels of the desensitising dye is facilitated and to a greater extent the higher the value of $E_{1/2}^{\text{Red}}(\text{Dy})$. In conformity with Scheme 1, the desensitisation increases the probability of stage 1 in this case, because the concentration of the electrons captured on the AgHal surface (e_s or Ag^0) is greater than on excitation of AgHal electrons into the conduction band, from which a large proportion of the electrons are immediately captured by the comparatively deep levels of the light-sensitivity centres.

The difference between the processes occurring on photoexcitation of AgHal and the dye has been inferred⁷¹ from the amplitude and the relaxation time of the photo-e.m.f. of AgBr(1) emulsions with sulfur sensitisation. The smaller decrease in the amplitude of the photo-e.m.f. during sulfur sensitisation in the region of spectral sensitivity compared with the region of the intrinsic absorption of AgHal was explained by the fact that the impurity centres formed on chemical sensitisation capture more effectively the electrons generated in the bulk of the microcrystals than the photoelectrons formed on photoexcitation of the dye. The latter are initially captured by centres on the AgHal surface and only then pass into the conduction band. The longer growth and relaxation times the photo-e.m.f. in the region of spectral sensitisation than in the region of the intrinsic absorption of AgHal are associated with this fact.⁷²

The influence of electron acceptors — pyrylocyanines with a variable electron affinity characterised by $E_{1/2}^{\text{Red}}(\text{Dy})$ — on the degree of desensitisation SD and the degree of desensitisation SD_λ in the region of spectral sensitivity of emulsions spectrally sensitised by thiocyanines has been studied in detail.⁶⁷ Fig. 8 presents the dependence of $\lg SD$ and $\lg SD_\lambda$ on $E_{1/2}^{\text{Red}}(\text{Dy})$ of the desensitisers for a coarse-grain AgBr(1) emulsion with S + Au sensitisation, containing thiadi- and thiatricarbocyanines as spectral sensitisers. It follows from Fig. 8 that the slope of the $\lg SD = f(E_{1/2}^{\text{Red}})$ relations is significantly greater than that of the $\lg SD = f(E_{1/2}^{\text{Red}})$ relations, *i.e.* the influence of desensitisers on the additional sensitivity is more marked.

On desensitisation, the fate of the n_0 electrons formed in the conduction band ($n_{e,\text{CB}}$) on photoexcitation of AgHal can be represented by the following scheme:⁶⁷

Some of the electrons (f_1) migrate to the sensitivity centres and form the latent image (n_{LI}) others (f_2) are captured directly by the dye (n_{Dy^-}) and are lost in accordance with Scheme 1, while a third part of the electrons (f_3) initially migrate to other surface traps ($n_{e,s}$), a proportion of which (f_4) are captured by the dye while another fraction (f_5) may be thermally excited into the conduction band and can be used in the construction of the latent image. Thus $n_0(f_2 + f_3f_4)$ electrons are diverted from the construction of the latent image. In this case,

$$SD = \frac{n_0}{n_0 - n_0(f_2 + f_3f_4)} = \frac{1}{1 - f_2 - f_3f_4} = \frac{1}{f_1 + f_3f_5}. \quad (15)$$

Figure 8. Dependence of $\lg SD$ (1, 2) and $\lg SD_\lambda$ (3, 4) on $E_{1/2}^{\text{Red}}$ for emulsions sensitised by 3,3'-diethylthiadicarbocyanine iodide (1, 3) and 3,3'-diethylthiatricarbocyanine iodide (2, 4). Dye concentration 2×10^{-6} mol per mole of AgHal (pAg 8.0).

When the quantities f_2 and f_3 are small compared with f_1 , $SD = 1$ and $\lg SD = 0$.

If it is postulated that, on structural sensitisation, all n_0 electrons initially migrate to surface traps, then the scheme according to which electrons are distributed becomes different:

In this case,

$$SD_\lambda = \frac{1}{1 - f_4} = \frac{1}{f_5}. \quad (17)$$

It follows from Eqns (15) and (17) that

$$\frac{SD_\lambda}{SD} = \frac{1 - f_2 - f_3f_4}{1 - f_4} = \frac{f_1 + f_3f_5}{f_5}. \quad (18)$$

Since usually $f_1 > f_5$ in the presence of a desensitiser, we have $SD_\lambda/SD > 1$. On the other hand, the contributions of f_2 and f_4 diminish exponentially with decrease in $E_{1/2}^{\text{Red}}$ of the dye:

$$f_2(f_4) \sim \exp\left(\frac{E_{1/2}^{\text{Red}}}{RT}\right),$$

Therefore, at a certain limiting potential $E_{1/2}^{\text{Red}}$ where f_2 and f_4 tend to zero, we have $SD_\lambda/SD = 1$. This corresponds to the observed critical potential $E_{1/2}^{\text{Red}} = -1.1$ V at which the $\lg SD = f[E_{1/2}^{\text{Red}}(\text{Dy})]$ and $\lg SD_\lambda = f[E_{1/2}^{\text{Red}}(\text{Dy})]$ curves intersect (Fig. 8).

$$\Delta \lg SD = (\lg SD_\lambda - \lg SD) \sim [E_{1/2}^{\text{Red}}(\text{Dy}) - 1.1]. \quad (19)$$

Thus the difference between SD and SD_λ can be explained within the framework of the above scheme governing the transition of electrons from Dy^* to surface levels by the difficulty of the direct electron transfer to sensitivity centres on spectral sensitisation. Such transfer requires an additional energy for the excitation of electrons into the conduction band. In the absence of such energy, the probability of the capture of electrons from surface traps by the dye increases. According to Eqn (19), the difference between SD and SD_λ increases with increase in $E_{1/2}^{\text{Red}}(\text{Dy})$.

The same type of dependence of SD and SD_λ on $E_{1/2}^{\text{Red}}(\text{Dy})$ (Figs 4, 5, and 8) suggests that the self-desensitisation by the spectral sensitisers themselves, possessing an electron affinity, is fully realistic and may at the same time significantly exceed the desensitisation, particularly at elevated concentrations of dyes. The marked dependence of the spectral sensitivity of infrared emulsions on the concentration of the sensitiser compared with the intrinsic sensitivity is well known. It follows from Fig. 9 that the decrease in spectral sensitivity observed at certain dye concentrations is more abrupt than the decrease in the 'blue' sensitivity of AgHal. The effective self-desensitisation then requires, like desensitisation, the presence of oxygen and moisture in the light-sensitive layer. This has been confirmed by the observation⁷³ of an increase in the spectral sensitivity of infrachromatic layers *in vacuo* and in a moist atmosphere without oxygen whereas the simultaneous presence of oxygen and water suppressed sharply the sensitivity. The influence of water on the sensitivity of infrachromatic ultrafine-grain AgBr emulsions has been investigated.⁷⁴ It was shown that the increase in the spectral sensitivity

Figure 9. Dependence of the intrinsic light sensitivity S_i (1) and additional light sensitivity S_λ (2) of an emulsion sensitised by 3,3'-diethylthiadicarbocyanine iodide on the dye concentration (pAg 8.0).

of the emulsions after their drying is greater the higher the values of $E_{1/2}^{\text{Red}}(\text{Dy})$ and pAg. The influence of an electron-accepting dye on the lifetime of the silver precentres of the latent image in the presence of oxygen and moisture has been convincingly demonstrated in a study⁷⁵ where a sharp decrease in the lifetime of the precentres under the influence of a desensitising dye (phenosafranin) was observed. The regression of the latent image on an emulsion with sulfur sensitisation under the influence of a series of infrared dyes has been investigated.^{6, 76} According to the results presented in Fig. 10, electron-accepting dyes accelerate significantly the regression of the latent image in conformity with Scheme 1.

The contribution of the dye self-desensitisation processes depends to a significant extent on the type of the AgHal emulsion. The decrease in self-desensitisation on emulsions of the 'core-shell' type and on an emulsion with Ir^{3+} ions in the bulk of the microcrystals may be a consequence of the lower probability of the oxidation of the latent image precentres as a result of the rapid electron transfer from these centres into the bulk of the microcrystals — onto the subsurface electron acceptance centres. This is equivalent to a decrease in the fraction of the electrons f_5 in Eqn (17). This property of the 'core-shell' emulsions and emulsions

Figure 10. Variation of the intrinsic sensitivity S_i of photographic emulsions sensitised by thiapentacarbocyanine (1) and thiatetracarbocyanine (2) and in the absence of dyes (3) at 35 °C and 100% humidity. Dye concentration 1.8×10^{-4} mol per mole of AgHal.

with Ir^{3+} has in fact made it possible to increase significantly the concentration of spectral sensitisers and the efficiency of the spectral sensitisation itself.^{37, 77–81} The decrease in the desensitisation of dyes in the region of their spectral sensitisation on a 'core-shell' emulsion has been demonstrated.⁶⁷

As a result of the examination of the role of dye self-desensitisation processes in the establishment of spectral sensitivity, it was concluded²³ that the self-desensitisation of dyes can in essence determine the effectiveness of the spectral sensitisation itself. From this it follows that the main problem in raising the effectiveness of spectral sensitisation is that of the inhibition of the secondary dye self-desensitisation reactions.

V. Supersensitisation processes as inhibition of the self-desensitisation of dyes

There are methods for increasing the spectral sensitivity of photographic emulsions sensitised by dyes with a low level of the photoexcited electron [$E_{1/2}^{\text{Red}}(\text{Dy}) > -1.0$ V], including infrachromatic dyes.^{2, 5, 82, 83} These methods known under the general term of supersensitisation, can be considered from a single standpoint of dye self-desensitisation processes within the framework of Scheme 1.^{5, 6}

For the inhibition of stage 1 (Scheme 1), the dye molecules must be separated from the AgHal surface on the defects of which electrons from Dy^* may be captured. One is dealing with a kind of insulation of dye molecules from AgHal, which, however, must not prevent the electron transfer from Dy^* , i.e. a 'spacer' sufficiently permeable to photoexcited electrons and impermeable to electrons captured by traps on the AgHal surface must be created between the dye and AgHal. One can postulate *a priori* that organic substances readily adsorbed on AgHal are needed for the creation of spacers between AgHal and the dye. Such insulation is important also from the standpoint of the elimination of reactions involving the recombination of electrons with the dye radical-cations formed in the spectral sensitisation step. It may be that the separation of the dye not from the entire AgHal surface but only from the photographically active centres, where photoelectrons are located, plays an important role. In this case, the role of the organic spacers is the same as that of the AgHal shells in emulsions of the 'core-shell' type or in emulsions with deep electron capture centres created by Ir^{3+} ions.

It is essential to note that the problem of the effective charge separation in a photochemical reaction, including separation owing to the decrease in the reverse recombination of charges with the aid of the so called membranes, is general and constitutes one of the principal problems of sensitised photolysis, in particular the sensitised photolysis of water.^{84, 85}

The inhibition of stages 2–5 (Scheme 1) by the insulation of the dye molecules from oxygen and water with the aid of hydrophobic organic compounds, introduced in the stage involving the preparation of photographic emulsions, is also extremely promising.^{5,23,86} Such compounds should not be adsorbed on AgHal, but, on introduction into a water–gelatin emulsion, they should be deposited on the AgHal microcrystals owing to their hydrophobic nature and create a kind of shell protecting the dye from oxygen and water.

The use of substances adsorbable on AgHal as supersensitisers for photographic materials is well known. Riester^{87,88} showed that, when a series of sulfomercapto-derivatives of heterocyclic bases are introduced, certain dyes, including azomethine dyes, which are relatively ineffective and even desensitising under the usual conditions, become effective spectral sensitisers. According to Riester's 'glue' model, the supersensitisers (potentiators) are attached with the aid of the mercapto-group to the Ag⁺ ions on the surface of microcrystals, while the sulfo-groups interact with the positively charged dye chromophores with formation of salt-like products, retaining thereby the dye molecules at a certain distance from AgHal (vaulted structure). The formation of this type of structure of the adsorbed dye promotes, according to Riester, a more effective excitation energy or electron transfer from Dy* to AgHal and also a decrease in desensitisation as a result of the capture of photoelectrons by the dye. This agrees with the conclusions reached by O'Brien,⁸⁹ who believes that the sensitisation efficiency is greater when the dye is fixed at a distance of 10–20 Å above the AgBr surface.

Carrol and Johnson⁹⁰ and also Vompe and coworkers^{91,92} described the supersensitising effect of bistriazinylamino-derivatives of stilbene-*o,o'*-disulfonic acid on infrachromatic dyes. The alkyl derivatives of 4-hydroxy-6-methyl-1,3,3a,7-tetraazaindene (for example, the 2-heptyl derivative)^{93,94} and various triaryl-phosphines^{95–98} also exert supersensitising and antifogging effects.

It is essential to note that Gilman's supersensitisation mechanism,⁸² adopted in the literature, the operation of which requires that the supersensitiser should be oxidised more readily than the dye, is inapplicable in this instance, since supersensitisers of the above type are as a rule more difficult to oxidise than the dyes.⁸³ Thus the mechanism of the action of supersensitisers of this type on infrachromatic emulsions is obscure and the search for the latter is purely empirical. However, it is striking that the above compounds are adsorbed on AgHal^{99,100} and may therefore play the role of 'insulators' between the dye and AgHal.

As an illustration of the action of supersensitisers of different structures, we shall present data obtained on an ultrafine-grain ($d = 0.05 \mu\text{m}$) transparent AgBr(I) emulsion.^{101,102} The use of a transparent emulsion makes it possible to measure the absorption spectra of light-sensitive layers in the IR region. The emulsion was sensitised by penta-, tetra-, and tri-carbocyanine dyes with structures **1**, **2**, and **3**.

Di-(*p*-anisyl)phenylphosphine **4**, 2-heptyl-4-hydroxy-6-methyl-1,3,3a,7-tetraazaindene **5**, the disodium salt of *p,p'*-bis(4,6-diphenoxo-1,3,5-triazin-2-yl-amino)stilbene-*o,o'*-disulfonic acid **6**, and *C,N*-diphenylnitron **7** were used for supersensitisation. The supersensitisers **4–6** are compounds adsorbable on AgHal, while the nitron **7** is weakly adsorbable.

In the first place, it was shown in experiments without supersensitisers that the intensity of the principal bands of the dyes depends on pAg: with decrease in pAg, the absorption and the stability of the adsorbed dye increase.^{5,102} This is manifested particularly clearly on the pentacarbocyanine **1**. It follows from Fig. 11a that an appreciable increase in absorption by the dye occurs when pAg changes from 7.6 to 5.6, whereupon the absorption band maximum undergoes a hypsochromic shift. The increase in absorption and in the stability of the dye when a fused emulsion is allowed to stand may be attributed to the formation of complexes of the type $[\text{Dy} \cdot \text{Ag}_2^+]$ on the AgHal surface.^{23,83,103} This may be the cause of the hypsochromic shift of the absorption band, since the polymethine structure of the dye should be disturbed with a consequent hypsochromic shift of the absorption on formation of a bond between a methine carbon atom of the chain and Ag_2^+ . The stabilisation of the dye is also induced by the Ti^+ , Cd^{2+} , Pb^{2+} , Bi^{3+} , Al^{3+} , and Th^{4+} cations. It is striking that, with increase in the charge on the cation, the concentration of the compound which leads to an increment in the absorption by Dy and in the stabilisation of the latter diminishes steadily.¹⁰⁴ The stabilising effect of inorganic cations is associated with the formation of the complexes $[\text{Dy} \rightarrow \text{M}^{n+}/\text{AgHal}]$ on the AgHal surface, as a result of which there is a decrease in the probability of the donor–acceptor interaction of the adsorbed dye with the components of the dispersion medium (water, gelatin, etc.), resulting in the decolorisation of the dye.¹⁰³

With decrease in pAg, the spectral sensitivity S_λ increases (Fig. 11b) and, with increase in the wavelength of the absorbed light, the increase in spectral sensitivity becomes more marked (the 'fan' effect). Owing to experimental limitations, measurements at the sensitisation maximum have not been made. The increment in the long-wavelength sensitivity exceeds, even after correction for the increase in the intrinsic sensitivity of the emulsion, the increment in adsorption. A similar picture has been observed for the tetra- and tri-carbocyanines **2** and **3**.¹⁰²

The introduction of compounds **4** and **7** and their mixture into an emulsion with the pentacarbocyanine **1** also induces an increase

Figure 11. Absorption spectra (*a*) and spectral sensitivity curves (*b*) for emulsions sensitised by dye **1** at different pAg: (1) 7.6; (2) 5.6; (3) 4.6. Dye concentration — 2×10^{-4} mol per mole of AgHal.

in absorption and in the spectral sensitivity of the light-sensitive layers (Fig. 12). It is striking that di(*p*-anisyl)phenylphosphine causes a bathochromic shift of the dye absorption band (Fig. 12*a*). The increase in spectral sensitivity is illustrated in Fig. 12*b*. An analogous picture of the growth of absorption and sensitivity following the introduction of supersensitisers has been observed for emulsions sensitised by tetra- (Fig. 13) and tri-carbocyanines (Fig. 14). Like compound **4**, compounds **5** and **6** induce a bathochromic shift of the principal absorption band of the dye. The results of the supersensitising effects of the additives **4**–**7** are summarised in Table 1.

The observed increment in the additional sensitivity under the influence of supersensitisers in most cases exceeds the increment in absorption. Thus the action of these compounds is to some extent analogous to the action of silver ions (pAg) noted above. It is noteworthy that the addition of supersensitisers induces an increase in the intrinsic sensitivity (for dyes **1** and **2**, owing to the decrease in the desensitisation of the dyes). After correction for the intrinsic sensitivity, the supersensitising effect of the additives **4**–**6** is manifested in all the cases listed in Table 1, while compound **7** has an effect only in a certain range of pAg (see experiments 2, 5, 9, and 14 in Table 1).

The increase in absorption and partly also the increase in sensitivity in the presence of supersensitisers are apparently associated with the increase in the adsorption and stability of the adsorbed dye. This can be accounted for by the decrease in the donor–acceptor interaction of the adsorbed dye with the components of the dispersion medium (water, gelatin, etc.) and by the insulation of the reaction centres of the dyes by organic (including hydrophobic) compounds.¹⁰³ This question will be examined below.

^a Ratio of the optical densities of photographic emulsions with a dye and a supersensitiser and with the dye alone. ^b Ratio of the spectral sensitivities of photographic emulsions with a dye and a supersensitiser and with the dye alone. ^c Correction introduced to take into account the intrinsic sensitivity of AgHal (S_{420}); $n = S_{420}(\text{Dy})/S_{420}(\text{Dy} + \text{S})$. ^d For experiments 1–3, the values of *D* are not quoted because they are very low.

It is necessary to deal in greater detail with the effect of supersensitiser compositions. The compositions are responsible for a greater increase in absorption than the individual supersensitisers. This increase is in a number of instances close to the additive value or less than that (Table 1). On the other hand, the increment in additional sensitivity, even after correction for ΔS_{420} is in many instances superadditive, *i.e.* exceeds (sometimes considerably) the sum of the effects due to the individual supersensitisers. Superadditivity is manifested particularly clearly at high values of pAg (pAg 9.0 for dye **2** and pAg 7.6 for dye **1**). Thus the increase in the additional sensitivity greatly exceeds the increment in the absorption by the emulsions. It is striking that the use of compositions consisting of supersensitisers **4–6** does not induce a superadditive effect. Such an effect is observed only when these supersensitisers are employed together with the nitron **7**.

Since the supersensitisers alter only slightly the position of the absorption maximum due to the adsorbed dyes, one may conclude that these compounds hardly affect the positions of the energy levels of the dyes. The existence of a superadditive effect for compositions comprising supersensitisers of two types — adsorbed (compounds **4–6**) and weakly adsorbed (compound **7**) on AgHal⁹⁹ — constitutes definite evidence for the different mechanisms of the action of these compounds.

Special mention should be made of the fact that the relative quantum yield of the spectral sensitisation (ϕ_r^{420}) for light-sensitive layers containing the pentacarbocyanine **1** and the **4** + **7** composition (pAg 5.6) in the region of $\lambda = 1000$ nm is 0.14.⁵ This value is only a few times smaller than the yields ϕ_r^{420} for fine-grain photographic materials sensitised towards visible light despite the twofold decrease in the active light quantum.

The superadditive effect of the **4** + **7** and **5** + **7** supersensitiser compositions has been investigated in greater detail on a coarse-grain ($d = 1 \mu\text{m}$) highly sensitive AgBr(1) emulsion sensitised by the pentacarbocyanine **1** at pAg 7.2 and 7.8.¹⁰⁵ The supersensitisation was investigated over a wide range of light-sensitive layer exposure times — 10^2 – 10^{-11} s. For times of the order of 10^{-5} – 10^{-11} s, a YAG : Nd laser with $\lambda = 1060$ nm was used for the exposure, while for times of 5×10^{-2} – 1.6×10^2 s the emulsions were exposed in a FSR-41 sensitometer behind an interference light filter with $\lambda = 1050$ nm. The supersensitisation coefficient (*K*) was characterised by the ratio of the spectral sensitivity of the emulsion with the given supersensitiser (or with a supersensitiser composition) to the light sensitivity of the emulsion without supersensitisers. The results of these studies are presented in Table 2.

It follows from Table 2 that the introduction of supersensitisers into spectrally sensitised light-sensitive layers leads to an

Table 2. Dependence of the infrared emulsion supersensitisation effect on the supersensitisers employed and on the duration of exposure.

No. of experiment	Exposure time / s	pAg 7.2

appreciable increase in sensitivity, but the degree of supersensitisation is different under these conditions: the greatest supersensitisation effect is observed for di-(*p*-anisyl)phenylphosphine **4**. A superadditive effect is characteristic of supersensitiser compositions, especially at pAg 7.8. The highest degree of supersensitisation has been determined for the **4** + **7** composition. It is striking that the coefficient K changes comparatively little (not more than by a factor of 2–3) over a wide range of exposure times, covering 13 orders of magnitude. This is possible if the supersensitisers have little effect on the primary step of the photochemical reaction and their action is manifested on slower secondary stages of the process involving the formation of the latent photographic image.

The results obtained for mixtures of supersensitisers are of special interest. The coefficients of supersensitisation by compositions greatly exceed the sum of the coefficients for the individual compounds and in certain cases are almost equal to or even exceed the product of the parameters for the individual substances (Table 2). Similar results have been obtained for a monodisperse AgBr(l) emulsion with cubic microcrystals ($l = 0.25 \text{ m}$).⁷⁶

As already mentioned, the superadditive effect of compositions may be a consequence of the different mechanisms of the action of the compounds constituting the composition and the fact that in most cases the coefficients are closer to the product than to the sum of the individual parameters can be regarded as a result of the supersensitising effect of the substances in the consecutive stages of the self-desensitisation process presented in Scheme 1. Since compound **7** does not possess a specific affinity for AgHal and is poorly adsorbed on the latter,⁹⁹ microcrystals and it most probably inhibits the self-desensitisation in stages 2–4 and 7 by insulating the dye molecules from oxygen and water. Thus its effect is similar to that of evacuation.^{23,83} The nitron is a hydrophobic compound, so that, after its introduction into a water–gelatin emulsion, it can be deposited on the AgHal may generate a kind of shell around them, promoting thereby the removal of oxygen and water from the surface of the crystal. The supersensitising effect of compounds **4**, **5**, and **6** may be associated with the inhibition of stage *I*, i.e. when adsorbed on AgHal,^{99,100} these compounds may separate the dye from AgHal and hence prevent the capture of electrons. One cannot rule out also a decreased probability of the direct electron transfer from Dy* to the dye in the ground state under the influence of these compounds.¹⁰⁶

The different effects of supersensitisers are schematically illustrated in Fig. 15, where it is shown that one supersensitiser (S-1) separates the dye from AgHal and the impurity centres formed in the course of chemical sensitisation, whilst the other (S-2) creates a shell insulating the dye from the medium.^{5,6}

We shall now consider the result of the effect of the supersensitiser composition assuming that the supersensitisers inhibit the electron loss reactions in two consecutive stages (for example, in stages 1 and 2 of Scheme 1) of the dye self-desensitisation process. The transfer of electrons from AgHal to the desensitiser D (for example to O₂) mediated by the dye is shown schematically in the same Fig. 15. Here f_1 is the designation of the fraction of electrons lost in the presence of the dye, $f_1 f_2$ represents the fraction of electrons lost in the presence of the dye and the supersensitiser S-1 separating the dye from AgHal, $f_1 f_3$ is the fraction of electrons in the presence of the dye and the supersensitiser S-2 separating the dye from the desensitiser D, and $f_1 f_2 f_3$ designates the fraction of electrons in the presence of the dye and the two supersensitisers S-1 + S-2 subject to the condition that the supersensitisers inhibit the loss of electrons in two consecutive stages.

If the light sensitivity of the photographic emulsion (S) is proportional to the number of electrons remaining on AgHal and forming the latent photographic image, then the supersensitisation coefficients can be formulated as follows:

Figure 15. Schematic illustration of the processes involving the supersensitisation of photographic emulsions spectrally sensitised by a dye (a), by individual organic supersensitisers S-1 (b) and S-2 (c), and by the S-1 + S-2 composition (d).

$$K_1 = \frac{S_1}{S_0} = \frac{1 - f_1 f_2}{1 - f_1}, \quad (20)$$

$$K_2 = \frac{S_2}{S_0} = \frac{1 - f_1 f_3}{1 - f_1},$$

$$K_3 = \frac{S_3}{S_0} = \frac{1 - f_1 f_2 f_3}{1 - f_1}.$$

We shall consider several limiting cases:

1. $K_3 = K_1 K_2$.

We find from Eqns (20)

$$K_1 K_2 = \frac{(1 - f_1 f_2)(1 - f_1 f_3)}{(1 - f_1)(1 - f_1)} = \frac{1 - f_1 f_3 - f_1 f_2 + f_1^2 f_2 f_3}{(1 - f_1)^2}. \quad (21)$$

We adjust the quantities $K_1 K_2$ and K_3 to a common denominator:

$$K_3 = \frac{1 - f_1 f_2 f_3 - f_1 + f_1^2 f_2 f_3}{(1 - f_1)^2}. \quad (22)$$

Hence it follows that $K_3 = K_1 K_2$ if $f_2 + f_3 - f_2 f_3 = 1$. This is possible if the coefficients f_2 and f_3 or one of them are close to 1. In the latter case, one of the supersensitisers is appreciably less effective than the other.

2. $K_3 < K_1 K_2$

This case holds if $f_2 + f_3 - f_2 f_3 < 1$ or f_2 and $f_3 < 1$. This is a real case if both supersensitisers are active.

In the most general case where several (i) photosensitisers operate consecutively, we have

$$K_{i(i \rightarrow \infty)} = K_{\max} = \frac{1 - f_1 f_2 \cdots f_i}{1 - f_1} = \frac{1}{1 - f_1}, \quad (23)$$

i.e. the limiting value of the supersensitisation coefficient is determined by f_1 . If $f_1 = 0.9$ then $K_{\max} = 10$ and, if $f_1 = 0.99$, we have $K_{\max} = 100$. The last value is close to those obtained for the **4** + **7** supersensitiser composition at pAg 7.2 (Table 2).

3. $K_3 > K_1 K_2$

This case occurs for $f_2 + f_3 - f_2 f_3 > 1$ or for f_2 and $f_3 > 1$. It is unrealistic, because the number of electrons lost exceeds the number present initially.

If it is assumed that the light sensitivity of emulsions with the 4 + 7 supersensitisers is close to the limiting value and that the supersensitisation coefficient is close to $K_{\max}$, we arrive at the conclusion that, in emulsions without supersensitisers, only one photoelectron out of the 100 formed ($f_1 = 0.99$) is used to form the latent image. The fact that in a number of instances the coefficient of supersensitisation by compositions exceeds the product of the coefficients for the individual substances may be associated with the change in the absorption of light by the dye under the influence of the supersensitisers. Thus phenomenological examination of the processes involving supersensitisation by mixtures of substances confirms the possibility of their acting in two consecutive stages of the self-desensitisation of dyes.

1. Supersensitisers of the first kind

We shall deal in greater detail with the effect of supersensitisers of the first kind, *i.e.* those adsorbable on AgHal. The adsorption of triarylphosphines on AgHal is undoubtedly associated with the ability of these compounds to form complexes with silver ions *via* the lone pair of $3s^2$ electrons on the phosphorus atom.¹⁰⁷ Thus the adsorption of phosphines in the presence of silver ions on the AgHal surface is apparently associated with the formation of a complex with these ions. On the other hand, in the presence of an excess of Hal^- ions on the AgHal surface, there is a possibility of either the desorption of these ions under the influence of the phosphines or of the adsorption of the phosphine with formation of a complex with the subsurface silver ions (another adsorption model).^{100, 109}

In the presence of an excess of halide ions, the surface of microcrystals in AgHal emulsions is known to be negatively charged and at a certain depth under the surface there is a region of a positive space charge generated by the interstitial silver ions.² There is a dynamic equilibrium between the surface silver ions and the subsurface interstitial ions. It may be that, when phosphines are introduced into the emulsion, the silver ions are 'drawn' from the region of the subsurface charge to the surface and complexes are formed with these ions.⁵

The interaction of triaryl derivatives of Group V elements having the general formula XAr_3 , where $\text{X} = \text{P}, \text{As}, \text{or Sb}$, with the surface of AgHal microcrystals has been investigated by IR spectroscopy and by measuring the ionic conductivity.¹¹⁰ According to IR and Raman spectra, vibrations ($\nu = 158 \text{ cm}^{-1}$) having the same frequency as the vibrations of the $\text{P} \rightarrow \text{Ag}^+$ bond in the complex $\text{AgBr} \cdot \text{PPh}_3$ are observed when PPh_3 is adsorbed on AgBr. Spectroscopic data led to the conclusion that the adsorption of the phosphine on AgBr results in the formation of a chemical bond between a surface Ag ion and the phosphorus atom of the PPh_3 molecule. This leads in its turn to a shift of the vibrational frequencies of the $\text{C}-\text{P}$ bond sensitive to the nature of the complex-forming agent. Similar changes in the IR spectra have been observed also for AsPh_3 and SbPh_3 . The compounds XAr_3 decrease the longitudinal ionic conductivity of sputtered AgBr layers, whereupon a definite relation is observed between the conductivity and stability constants of the silver complexes $\text{AgBr} \cdot \text{XAr}_3$.¹¹⁰ Measurements of the ionic conductivity of AgBr(I) emulsion layers by the dielectric loss method have shown that the adsorption of PPh_3 shifts the frequency maximum ($f_{\max}$) on the dielectric loss curve to lower frequencies. Since the conductivity of AgHal is proportional to $f_{\max}$ according to Sillars,¹¹¹ the observed shift of $f_{\max}$ indicates a decrease, following the addition of the phosphine, of the ionic conductivity generated by interstitial silver ions.

When silver complexes are formed on the surface of AgHal microcrystals, the surface charge changes. The interaction of the supersensitiser 4 with AgHal has been investigated by the luminescence method.¹⁰⁸ The adsorption of organic substances on

AgHal alters the surface charge, which influences in its turn the mechanism of the luminescence of paired iodine centres. Thus, if the surface charge of the AgBr(I) microcrystals is negative or the surface is uncharged, then, by irradiating an excited specimen with long-wavelength light at 77 K, it is possible to achieve a luminescence flash at the wavelength corresponding to the green luminescence band of the paired iodine centres. On the other hand, if the surface charge is positive by virtue of the excess of silver ions, a flash is not observed. It has been shown¹⁰⁰ that, when di-(*p*-anisyl)phenylphosphine 4 is introduced into a AgBr(I) emulsion prepared using poly(vinyl alcohol) as the binder, the green-band luminescence flash diminishes.

Additional evidence for the influence of the compounds XAr_3 on the surface charge of AgHal microcrystals has been obtained in experiments on a primitive coarse-grain AgBr(I) emulsion without chemical sensitisation.¹¹² In such emulsions, the subsurface sensitivity exceeds the surface sensitivity as a result of the positive space charge generated by the interstitial silver ions. The introduction of triphenylstibine into the emulsion leads to a sharp increase in the surface sensitivity owing to a redistribution of the surface charge, which is illustrated in Fig. 16. The subsurface sensitivity was determined after the successive etching of layers in a 1% $\text{Na}_2\text{S}_2\text{O}_3$ solution and on developing the specimens (after etching) in a glycine surface developer.

Figure 16. Dependence of the surface and subsurface sensitivity of light-sensitive layers based on a primitive AgBr(I) emulsion without additives (1) and containing triphenylstibine (2) on the etching time in 1% $\text{Na}_2\text{S}_2\text{O}_3$ solution. Triphenylstibine concentration 5×10^{-4} mol per mole of AgHal. Development — 8 min in a surface glycine developer.

The influence of adsorbed organic compounds on the surface charge has been considered in a number of studies. Thus the change in the sign of the AgHal photo-e.m.f. under the influence of gelatin has been explained¹¹³ by the redistribution of charges on the surface of microcrystals. It has been shown¹¹⁴ that, under certain conditions, the binding of the interstitial silver ions by the adsorbed gelatin leads to the appearance of a positive charge on the AgBr(I) surface. Tani¹¹⁵ explained the decrease in the bending of the electron bands of AgHal on the surface by the decrease in the subsurface positive charge under the influence of a series of stabilisers and antifogging substances — derivatives of tetraazaindenes and benzotriazole.

The appearance of a positive charge on the surface of AgHal microcrystals when triarylphosphines are adsorbed promotes the adsorption of infrachromatic dyes, which leads to an increase in the absorption and in the stability of the adsorbed dye, as happens with increase in the concentration of silver ions in the emulsion. This has been demonstrated in relation to the pentacarbocyanine 1 (cf. curves 2 and 4 in Fig. 12a). The stability of dye 1 in aqueous gelatin solutions and in the adsorbed state on the AgBr(I) emulsion at different pAg as well as the influence of di-(*p*-anisyl)phenylphosphine 4 on the stability of the adsorbed dye

Figure 17. Absorption spectra of the pentacarbocyanine dye **1** in ultrafine-grain AgBr(I) emulsion at pAg 7.6 (1–3) and in the presence of supersensitiser **4** (4–6) as a function of the period during which the emulsion is allowed to stand at 40 °C: (1) and (4) after 5 min; (2) and (5) after 18 min; (3) and (6) after 30 min. Concentration of dye **1** 2.5×10^{-4} mol per mole of AgHal; concentration of supersensitiser **4** 1×10^{-2} mol per mole of AgHal.

have been investigated in detail.¹⁰³ Fig. 17 illustrates the increase in the absorption (cf. curves 1 and 4) and in the stability of the adsorbed dye **1** (cf. curves 1–3 and 4–6) under the influence of the phosphine **4**.

The observed bathochromic shift of the absorption of infrachromatic dyes under the influence of phosphines and the increase in the stability of the infrared dye can be accounted for by the formation of a ternary complex between the silver ions, the supersensitiser, and the dye $[\text{Ag}^+ \cdot \text{S} \cdot \text{Dy}]$.⁵

It has been shown¹¹⁰ that, when PAr_3 is adsorbed on AgBr, a new variable-composition organosilver bromide phase of the type $\text{AgBr} \cdot \text{PAr}_3$ may be formed in addition to the local chemical bond $\text{Ag}^+ - \text{P}$. Thus the dye may be adsorbed not on AgBr but on the organosilver bromide phase. In any case, both under conditions involving the participation of the ternary complex and on adsorption of the dye on the organosilver bromide phase, a spacer consisting of organosilver complexes is created between AgHal and the dye.

It is noteworthy that the action of phosphines differs from that of Riester's potentiators,^{87,88} which bind the surface silver ions *via* their mercapto-groups in the form of salts and thereby compensate their positive charge. Neutral (from the standpoint of the electrical charge) phosphines only partially compensate the charge of the silver ions in the complex, increasing the overall surface concentration of the silver ions and hence promoting the adsorption of the dye and the interaction of the photoexcited infrared dye with silver ions. The spacer should not prevent electron transfer from Dy^* *via* the silver ions to AgHal, but it may inhibit significantly the secondary reactions involving the oxidation of the generated silver atoms by dye molecules in the ground state. Indeed, in the presence of di-(*p*-anisyl)phenylphosphine, the desensitisation of silver halides by infrared dyes diminishes.¹⁰² Such insulation of the strongly fogging infrared dyes from AgHal leads to a sharp diminution in the fogging of infrared emulsions in the presence of triarylphosphine.

It may be expected that the effect of uncharged complex-forming agents examined above is definitely associated with the

complex-forming capacity of the silver ions. To test this hypothesis, a study was made of a series of triphenyl derivatives having the general formula XPh_3 , where X = N, P, As, Sb, or Bi. The photographic effect of this series of compounds had not been investigated previously on coarse-grain AgBr(I) emulsions sensitised by tricarbo-cyanine.¹¹⁶ It has been shown that the maximum supersensitisation effect is attained in the case of triphenylphosphine, which is followed by triphenylarsine and triphenylstibine; triphenylamine and triphenylbismuthine hardly influence the photographic properties of emulsions.

The effect of compounds of the above series has been investigated on an ultrafine-grain AgBr(I) emulsion ($d = 0.05 \mu\text{m}$) sensitised by the pentacarbocyanine **1**.¹⁰⁹ The introduction of these compounds as well as di-(*p*-anisyl)phenylphosphine **4** leads to an increase in the absorption by the adsorbed dye. In terms of their effect, the test compounds can be arranged in the sequence $\text{N} < \text{Bi} < \text{P} < \text{As} \approx \text{Sb}$. The absorption curves for the emulsions are presented in Fig. 18. In conformity with the data of Akhmedzyanov *et al.*,¹¹⁶ it was established that NPh_3 and BiPh_3 do not have a positive photographic effect, whereas PPh_3 , AsPh_3 , and SbPh_3 induce an increase in the spectral sensitivity in the long-wavelength band. At pAg 8.6, the supersensitisation coefficients for compounds in the series PPh_3 , AsPh_3 , and SbPh_3 are 2.1, 2.9, and 5.8 respectively.

In order to estimate the complex-forming capacities of the

Figure 18. Absorption spectra of ultrafine-grain AgBr(I) emulsion sensitised by dye **1** at pAg 7.6: (1) without additives; (2) NPh_3 ; (3) additional amount of AgNO_3 ; (4) BiPh_3 ; (5) PPh_3 ; (6) $\text{P}(\text{CH}_3\text{OC}_6\text{H}_4)_2\text{Ph}$; (7) SbPh_3 ; (8) AsPh_3 . Concentration of dye **1** 3×10^{-4} mol per mole of AgHal; concentration of additives 1×10^{-2} mol per mole of AgHal.

compounds, the changes in the pAg of the emulsions were measured after the introduction into the latter of equal molecular amounts of the above substances (10^{-2} mol per mole of AgHal). The initial pAg 7.6 changed to 7.8, 7.8, 8.5, 8.6 and 8.65 after the addition of NPh_3 , BiPh_3 , PPh_3 , AsPh_3 , and SbPh_3 respectively, while the initial pAg 6.6 changed to 6.95, 6.95, 7.9, 7.9, and 8.2. Thus the absence of a photographic effect by NPh_3 and BiPh_3 is associated with their weak complex-forming capacity. The compounds AsPh_3 and SbPh_3 have approximately the same complex-forming capacities in relation to silver ions in solution, but PPh_3 is a stronger complex-forming agent.¹¹⁷ The observed increase in the supersensitising activity in the series $\text{PPh}_3 < \text{AsPh}_3 < \text{SbPh}_3$ is apparently associated with the different adsorbabilities of these

compounds on AgHal, which are determined by the molecular geometry. Hence it follows that these two properties must be considered jointly.

The specificity of the action of the compounds XPh_3 ($X = N, P, As, Sb$) as well as $(PhC \equiv C)_n PPh_3 - n$ has been attributed¹¹⁰ to the structure of the surface organosilver bromide complexes. The structure of the complex formed — the stoichiometric composition, the phase state, the type of crystal lattice, and the structure of the electron bands — should determine the effectiveness of the interaction with it of the spectral sensitiser in the ground and photoexcited states. For example, when PPh_3 is adsorbed on a AgBr emulsion with cubic microcrystals at pAg 7.5 and on a coarse-grain AgBr(I) emulsion with cubooctahedral microcrystals at pAg 8.5, two different surface complexes, differing in their IR spectra, are formed. The vibrational frequencies of the ν -modes in these spectra are close to those of the bond vibrations in the complexes $Ag_2Br_2 \cdot PPh_3$ and $AgBr \cdot PPh_3$ (1099 and 1095 cm^{-1} respectively). On spectral sensitisation at the wavelength corresponding to the absorption band of the infrared dye, a decrease in the intensity of the band with $\nu = 1099\text{ cm}^{-1}$ is observed, while the band with $\nu = 1095\text{ cm}^{-1}$ changes little under these conditions.¹¹⁸ This indicates different photochemical reactivities of the surface complexes.

A similar picture has been observed for supersensitiser **4**. On the basis of Ahrlund's data,¹¹⁷ it was concluded that organosilver complexes may participate in the primary step of the spectral sensitisation by the infrared dye, undergoing photochemical decomposition with formation of a silver atom. Furthermore, the photographic activity of the complexes is manifested in secondary dark stages as a result of the inhibition of the recombination and oxidation reactions of silver atoms.

We shall now consider the activity of another supersensitiser of practical importance — the disodium salt of bistriazinylaminostilbene-*o,o'*-disulfonic acid **6**. The increase in the adsorbability of dyes under the influence of supersensitiser **6** has been demonstrated^{99, 100} and is illustrated in Fig. 19, which presents the isotherms for the adsorption of penta- and tetra-carbocyanines on AgBr powder without a supersensitiser and in the presence of

compound **6**. The interaction of a series of derivatives of aromatic diamino-compounds having the general formula $RHN-Ar-NHR$ with cyanine dyes in solutions and on the AgHal surface has been investigated in detail.^{119, 120} In order to establish the nature of the interaction of the supersensitisers and spectral sensitisers in adsorption on AgHal, the principal types of interaction were examined in the above studies stage by stage: (1) dye — supersensitiser, (2) supersensitiser — substrate, and (3) dye — supersensitiser — substrate. The following supersensitisers were investigated:

**8****9****10****11**

The peripheral groups R were 1,3,5-triazinyl and acyl substituents. The studies were carried out on quino-4,4'-cyanines with different lengths of the polymethine chain and also on thiapoly-carbocyanine dyes.¹²¹

Figure 19. Isotherms for the adsorption of penta- and tetra-carbocyanines on a AgBr preparation from alcoholic solutions (*1*) and after preliminary adsorption of supersensitiser **6** (*2*) at 25 °C; dye: (a) 3,3'-diethylthiatetracarboyanine iodide; (b) 3,3'-diethyl-9,11-(β,β -dimethyltrimethylene)thiatetracarboyanine iodide; (c) 3,3'-diethylthiapentacarboyanine iodide; (d) 3,3'-diethyl-9,11,9',11'-bis(β,β -dimethyltri-methylene)thiapenta-carboyanine iodide; c_{ads} = amount of adsorbed dye; c_{eq} = equilibrium concentration of dye.

It has been shown¹²⁰ that in solutions the interaction in the dye–supersensitiser system is in the nature of the π – π interaction of the two planar systems of the dye and the supersensitiser. A condition for the effective interaction of the π -system of the dye with the π -system of the compound RHN–Ar–NHR is both the presence in the supersensitiser structure of a central π -conjugated Ar skeleton and of auxochromic fragments R capable of π -conjugation with the central skeleton *via* the nitrogen atoms of the amino-groups. A bathochromic shift of the stretching vibrations of the NH groups and also a change in the profile of the absorption bands due to the SO₃[–] groups¹²⁰ were observed in the IR spectra of supersensitisers adsorbed on AgBr microcrystals. This led to the conclusion that the nature of the adsorption centres is the same: NH and SO₃[–] groups. The IR spectra of *p,p'*-bis(4,6-diaminophenyl-1,3,5-triazin-2-yl-amino)stilbene-*o,o'*-disulfonic acid **6a**, adsorbed on AgBr microcrystals had been obtained earlier¹²² in the frequency range 700–1700 cm^{–1}.

It was concluded that the test compounds do not form a strong chemical bond with the silver ions. This conclusion was confined by the small influence of supersensitisers of the above type on the ionic conductivity of sputtered AgBr layers.¹²⁰

It has been concluded¹²⁰ that the SO₃[–] and NH groups participate in the interaction of compounds **8–11** with AgHal, the main π -system of the molecules being hardly involved. The interaction *via* the SO₃[–] groups should be most probably regarded as the substitution of halide ions on the AgHal surface by ArSO₃[–] ions and not as the binding of interstitial or surface silver ions by analogy with the adsorption of compounds of the type of triarylphosphines. One may imagine that, in the adsorption of compound **6**, and similar derivatives, the molecule assumes an orientation such that its aromatic component is separated from AgHal by SO₃[–] groups. In the case of compound **6**, the planar π -conjugated part of the molecule is arranged parallel to the AgHal surface and is at a definite distance from the latter. Conventionally this constitutes the ‘table on two SO₃[–] legs’ model. The NH groups can also serve as ‘supports’. It is noteworthy that this model resembles the Riester potentiators model.^{87, 88}

The observation of the interaction of the nonplanar supersensitiser **12** with the dye on the AgHal surface should be regarded as the most important result of the above study.¹²⁰

12

Like supersensitisers with π -conjugated aromatic fragments Ar, compound **12** induced a bathochromic shift of the absorption maximum of the adsorbed infrared dyes, an increase in the absorption intensity, and a supersensitisation effect comparable other in magnitude to that of compound **6**. On the other hand, it has been found that compound **12** does not interact with the dye in solution.

In order to account for the photographic activity of this sensitiser and the bathochromic shift of the absorption maximum of the dye, it is necessary to postulate a flattening of the molecule of compound **12** following adsorption on AgHal. Consequently, the situation on AgHal changes significantly compared with that in solution, *i.e.* the π – π interaction between the supersensitiser and the dye becomes possible in the dye–supersensitiser–AgHal ternary system. In this case, a decisive factor for the dye–supersensitiser interaction may be not only (and perhaps not so much) the planarity of the entire molecule of compound **12** but also the geometrical correspondence between certain parts of the two interacting systems. Such a part in the molecule of compound **12** may be the phenylaminotriazinyl fragment (PATF), which interacts with AgHal *via* the SO₃[–] and NH groups according to IR spectra.¹²⁰

It has been postulated¹²⁰ that, in more general terms, a molecule having the following structure should be photographically active:

Y = –(CH=CH)_n–, –(C≡C)_n–, –(CH₂–CH₂)_n–, where n = 1, 2, 3.

in which the two phenylaminotriazinyl fragments are disposed at a certain distance specified by the bridging group Y. This distance between the two π -systems is apparently in fact the principal factor determining the photographic activity of the supersensitisers. The geometrical requirements which must be met by the supersensitiser may be determined both by the AgHal lattice constant and by the structure of the supersensitising dye. It is probably quite unnecessary that PATF should be the anionic π -fragment. Other compounds can also assume the role of such π -fragments.⁵ In a general form, the structure of the supersensitiser can be represented as follows:

where A[–] is the acid group, π the conjugated system, Y the bridging group, and M⁺ the cation. Thus one is dealing with bisanionic structures of supersensitisers consisting of two π -systems with negative charges localised on the acid groups and linked to one another *via* the bridging Y group.

A certain analogy between the supersensitisers of the class under consideration and the bridged bisquaternary salts of heterocyclic bases used for the supersensitisation of orthochromatic and panchromatic dyes, as a rule in the *J*-aggregated state, is striking.^{123–125} Therefore, continuing the generalisation, one may put forward the hypothesis that there is a single principle underlying the supersensitising activity of bridged compounds containing at least two cationic or anionic fragments:

where X[±] is a group with a localised positive or negative charge. The specificity of the activity of particular supersensitisers having structure **15** may be associated with the following structural features of the dyes: (1) the overall charge on the spectral sensitiser (cationic, betaine, anionic), (2) the distribution of the π -charge density in the molecule, (3) the polarisability of the molecule, (4) the electron-donating or electron-accepting capacity of the π -system, *etc.*¹²⁰ Since infrared dyes are as a rule used in the form of cations, the suitability of the bisanionic compounds **14** as supersensitisers may be associated with purely electrostatic factors.

The question naturally arises what is the mechanism of the supersensitising activity of the test compounds. The photographic activity of compounds of the given class can apparently be usefully considered within the framework of the insulation model, according to which the supersensitiser creates a ‘spacer’ of molecular dimensions between the dye and AgHal.^{5, 6} This is illustrated conventionally in Fig. 20. The insulation model is in essence similar to Riester’s model,⁸⁸ but there are also significant differences associated with the mechanism of the interaction in the dye–supersensitiser–AgHal system. The insulating spacer prob-

Figure 20. A model of the adsorption of a supersensitizer and dye on AgHal.

ably does not prevent electron transfer from the excited Dy^* molecule to AgHal (apparently *via* a tunnelling mechanism), but it does prevent the reverse capture of photoelectrons by the dye radical-cations formed or by neighbouring electron-accepting Dy molecules in the ground state in accordance with Scheme 1.

The activity of the supersensitizer 2-heptyl-4-hydroxy-6-methyl-1,3,3a,7-tetraazaindene **5**, which induces an increase in the absorption by the dye adsorbed on AgHal (Fig. 13, Table 1), is caused not only by the presence of the tetraazaindene ring but also to a large extent by the presence of the long (C_7H_{15}) alkyl group. It has been shown^{94, 126} that the supersensitising activity of alkyl derivatives of tetraazaindene and 1,2,4-triazole increases with increase in the length of the alkyl group from C_1 to C_7 , *i.e.* with increase in the hydrophobicity of the compounds. The supersensitising activity of 2-alkyl (compound **16**) and 5-alkyl (compound **17**) derivatives of tetraazaindene on emulsions sensitised by thiapenta- and thiatetra-carbocyanines **1** and **2** has been investigated.¹²⁷

$n = 1-11$.

In the series of compounds investigated, the hydrophobicity increased steadily on passing from C_1 to C_{11} alkyl substituents. The 2-alkyl derivatives **16** showed the greatest photographic activity, especially on emulsions sensitised by the pentacarbocyanine **1**. The results obtained are presented in Fig. 21. The supersensitisation effect increases the spectral sensitivity by a factor of 11. It is striking that an abrupt jump in the effectiveness of the sensitisation is observed on passing from $n = 4$ to $n = 6$. On further increase in the length of alkyl group from $n = 6$ to $n = 11$, the effectiveness changes little.

Figure 21. Dependence of the spectral sensitivity of photographic emulsions sensitised by the thiapentacarbocyanine **1** on the number of carbon atoms in the alkyl groups of compound **16** (1) and **17** (2).

The effectiveness of 5-alkylated derivatives **17** is appreciably smaller than that of compound **16** (cf. curves 2 and 1 in Fig. 21). The increase in the spectral sensitivity of emulsions with the tetracarbocyanine **2** is smaller than for emulsions with the pentacarbocyanine **1**, but the nature of the activity of the supersensitisers remains the same.¹²⁷ The supersensitisation by compounds **16** and **17** can be partly due to the increase in the adsorbability of the supersensitisers with increase in the length of the alkyl substituent, which has been observed, for example, for a series of *N*-alkyl derivatives of cations.² Comparison of the results obtained for 2- and 5-alkyl derivatives of tetraazaindene permits the conclusion that the photographic activity of supersensitisers is determined not only by their hydrophobicity but also by the disposition of the hydrophobic groups in the molecule. It is also possible that the higher photographic activity of the 2-alkyl derivative **16** is associated with the location of the alkyl substituents at the photographically active fragment of the molecule.¹²⁷

The mechanism of the action of supersensitisers of the first kind, *i.e.* those absorbable on AgHal, has been investigated in model electrochemical experiments. The inhibition of electron transfer to oxygen and protons by supersensitisers has been demonstrated extremely clearly in experiments designed to investigate the influence of these compounds on the polarographic oxygen reduction waves in aqueous alcoholic media.¹²⁸ In this case, the mercury dropping electrode and not photoexcited silver halide served as the source of electrons for oxygen. Under the usual conditions, in aqueous media, oxygen is reduced at the mercury electrode to hydrogen peroxide in accordance with Scheme 2.¹²⁹

Scheme 2

Under these conditions, the reversibility of stages 1–3 depends on the pH of the medium. It was shown that the introduction of di-(*p*-anisyl)phenylphosphine **4** into the solution shifts the half-wave oxygen reduction potential towards more negative values and diminishes the height of the wave (cf. curves 1 and 3 in Fig. 22). The shift of the wave is caused by the inhibition of electron transfer in stage 1 (Scheme 2) owing to the formation on the electrode of an insulating film preventing electron transfer to oxygen. Calculation of the electron transfer rate constant showed that, in the presence of the phosphine **4**, the rate of transfer diminishes by a factor of 3000. Compound **5** induces a smaller effect. In its presence, the rate falls by a factor of 400 (cf. curves 2 and 3 in Fig. 22).

Figure 22. Polarographic curves for the reduction of oxygen in an air-saturated aqueous propanol solution at pH 13.0: (1) without supersensitizer; (2) with supersensitizer **5**; (3) with supersensitizer **4**. Concentration of supersensitisers 6.2×10^{-4} mol per mole of AgHal.

The decrease in wave height in the presence of the phosphine **4** down to virtually the one-electron value is associated with the inhibition of stage 2 by the insulating film. Oxygen is then reduced to O_2^- and not to hydrogen peroxide. The effect of the phosphine **5** is smaller in this stage than that of the phosphine **4**. In terms of their inhibiting effect on electron transfer and the inhibition of the protonation of O_2^- , the supersensitisers XPh_3 ($X = P, As, Sb$) may be arranged in the sequence¹²⁸ $SbPh_3 > AsPh_3 > PPh_3$. The average ratio of the pore area in a film comprising the compounds XPh_3 on the electrode to the area occupied by one molecule is 0.30, 0.32, and 0.42 for $SbPh_3$, $AsPh_3$, and PPh_3 respectively, *i.e.* the density of the insulating film diminishes in the sequence $SbPh_3 > AsPh_3 > PPh_3$. Thus the functions of certain supersensitisers of the first kind involve not only the creation of an 'insulating spacer' but also the formation of a hydrophobic spacer inhibiting secondary processes involving water protons.

2. Supersensitisers of the second kind

We shall now proceed to the consideration of supersensitisers of the second kind, *i.e.* compounds which are poorly adsorbable on AgHal and the activity of which is apparently associated mainly with their hydrophobic nature. The secondary oxidation reactions with participation of oxygen and water in stages 2–4 and 7 (Scheme 1) are in fact inhibited precisely because of the hydrophobic nature of the supersensitisers. The activity of *C,N*-diphenylnitrone **7**, which supersensitises infrared light-sensitive layers both individually and in compositions with supersensitisers of the first kind, has already been considered above. The supersensitising effect of nitrones was discovered in 1975 at the State Research and Design Institute of the Chemical-Photographic Industry (GOS-*NIKhIMFOTOProekt*). *C,N*-Diphenylnitrone is weakly adsorbed on AgBr.⁹⁹ According to IR spectroscopic data (in the frequency range 400–4000 cm^{-1}), no changes are observed in the vibrational spectrum of the nitrone **7** after its adsorption on AgBr.⁷⁶ The weak interaction of nitrones with AgHal is also indicated by their small influence on the ionic conductivity of AgBr emulsions.⁷⁶

In order to test experimentally whether organic hydrophobic compounds do really inhibit reactions involving electron loss by silver halide, a study was made of the influence of a series of substances (*C,N*-diphenylnitrone, azobenzene, azoxybenzene) on the luminescence of spectrally sensitised AgBr microcrystals.¹³⁰ If such compounds are able to insulate the surface of the emulsion microcrystals from interaction with oxygen and water, then one may expect an increase in the concentration of electrons in the conduction band and on the surface capture levels and hence an increase in the intensity of the low-temperature luminescence of microcrystals and dyes, arising on recombination of electrons with the holes of AgHal and the dyes respectively.

Measurements of the low-temperature (77 K) luminescence of a fine-grain AgBr emulsion have been carried out with excitation by light corresponding to the region of the intrinsic absorption by AgBr ($\lambda = 365$ nm). Fig. 23*a* presents the luminescence spectra of the emulsion before and after the introduction of solutions of the nitrone **7**. It follows from the results presented in the figure that the nitrone **7** increases the intensity of the orange luminescence of the AgBr microcrystals. Furthermore, the intensity of the optical luminescence flash, stimulated by infrared light, increases. Similar results have been obtained for azobenzene and azoxybenzene.

It is striking that the increment in the luminescence intensity under the influence of the supersensitisers investigated corresponds to an increase in the photographic activity of the compounds. Thus the facts described agree with the hypothesis that hydrophobic substances on the surface of emulsion microcrystals prevent the liberation of photoelectrons into the medium and hence increase the intensity of the recombination luminescence and the light sum localised in deep traps.

The fluorescence and phosphorescence bands of the dyes are observed in the luminescence spectra of silver bromide emulsions sensitised by thiacyanines and thiadicyanines: with

Figure 23. Luminescence spectra of a AgBr emulsion: (a) before (1) and after (2–4) introduction of compound **7** at different concentrations (10^{-3} mol per mole of AgHal) (2) 1; (3) 5; (4) 10; (b) before (1) and after the introduction of azobenzene (2) and azoxybenzene (3) at a concentration of 10^{-3} mol per mole of AgHal.

$\lambda_{max} = 615$ and 740 nm in the former case and with $\lambda_{max} = 770$ and 900 nm in the latter. The luminescence appears as a result of the recombination of free electrons with holes localised by dye molecules. As was to be expected, the addition of the nitrone **7** to spectrally sensitised emulsions leads to an increase in the intensity of the low-temperature recombination luminescence, which is due to a sharp decrease in the probability of the capture of photoelectrons by molecular oxygen and moisture.¹³⁰

Akhmerov *et al.*¹³¹ investigated in detail by luminescence and photographic methods the activity of nitrones having the general formula

$R^1 = H, R^2 = H$ (**7**); $R^1 = o\text{-Cl}, R^2 = H$ (**18**); $R^1 = H, R^2 = p\text{-Me}$ (**19**); $R^1 = p\text{-OMe}, R^2 = p\text{-Me}$ (**20**); $R^1 = o\text{-Cl}, R^2 = p\text{-Me}$ (**21**).

The studies were performed on a fine-grain AgBr emulsion spectrally sensitised by thiapolycyanines **22** with different lengths (n) of the polymethine chain.

The activity of the nitrones was compared with their hydrophobicity estimated from the partition coefficients (K_{part}) of the substances in the 1-octanol–water two-phase system.¹²⁷ A correlation between the hydrophobicity of the nitrones and their ability to increase the intensity of the low-temperature luminescence of AgBr and the dyes was demonstrated. Fig. 24 presents the dependence of the intensity (μ_1) of the orange luminescence of AgBr on the hydrophobicity of the nitrones. The luminescence intensity increases with increase in hydrophobicity. Fig. 25 illustrates the dependence of the effectiveness of the activity of nitrones on the length of the polymethine chain of the thiapolycarbocya-

Figure 24. Dependence of the intensity of the orange luminescence of a AgBr emulsion on the hydrophobicity of the nitrones **7**, **18**, **19**, and **21**. Concentration of nitrones — 3×10^{-3} mol per mole of AgHal. $\mu_1 = (I - I_0)/I_0$ (I_0 and I are the intensities of the AgBr luminescence in the absence and presence of the nitrone respectively).

Figure 25. Dependence of the intensity of the luminescence of dyes (**1**–**4**) and of the increase in spectral sensitivity (**5**) for a AgBr emulsion sensitised by thiapolycarbocyanines **22** after the introduction of the nitrones **18**–**21** [(**1**) **18**; (**2**) **19**; (**3**) **20**; (**4**) **21**] on the length (n) of the polymethine chain of the dyes. Concentration of dyes — 5×10^{-5} mol per mole of AgHal; concentration of nitrones — 3×10^{-3} mol per mole of AgHal. $\mu_2 = (I - I_0)/I_0$ (I_0 and I are the intensities of the fluorescence of the dyes at the maximum in the absence and presence of a nitrone respectively); $\Delta \lg S_\lambda = \lg(S_\lambda/S_\lambda^0)$ (S_λ^0 and S_λ are the spectral sensitivities in the absence and presence of a nitrone respectively).

nines **22**. For all the nitrones, an increase in the intensity of the luminescence of the dyes (μ_2) with increase in chain length is observed, the effectiveness of the nitrones being greater the greater their hydrophobicity (cf. curves **1**–**4** in Fig. 25). The figure also illustrates the effect of the supersensitisation ($\Delta \lg S_\lambda$) of the light-sensitive layers with thiapolycarbocyanines by the nitrone **21** (curve **5** in Fig. 25). The results can be accounted for within the framework of Scheme 1 by the self-desensitisation of the dyes. Indeed, with increase in the length of the polymethine chain of the dyes, their vacant level under the AgBr conduction band becomes deeper and hence there is an increase in the probability of electron capture in stage **1** of Scheme 1. The effectiveness of the insulating spacer, which prevents electron transfer from $\text{Dy}^{\cdot-}$ to oxygen and the water protons, should therefore increase with increase in the length of the polymethine chain, which agrees with experimental results. The increase in effectiveness with increasing hydrophobicity of the compounds can also be explained within the framework of the supersensitisation scheme examined above.

The hydrophobic properties of nitrones are manifested by a shift of the polarographic half-wave reduction potential of oxygen and also by a decrease in wave height (Fig. 26).¹²⁸ The increase in the hydrophobicity of the nitrones, associated with the introduction of chlorine atoms into the benzene ring, is accompanied by the inhibition of electron transfer to the oxygen and the protonation of $\text{O}_2^{\cdot-}$. In terms of its influence on the inhibition of the electron transfer from the electrode to the oxygen, the nitrone **21** is close to di-(*p*-anisyl)phenylphosphine **4**, while in terms of the inhibition of the protonation of $\text{O}_2^{\cdot-}$ it is 2.5 times more effective than the latter.¹²⁸

Figure 26. Polarographic curves for the reduction of oxygen in an air-saturated 10% aqueous propanol solution at pH 11.0; (**1**) without supersensitiser; (**2**) with the nitrone **7**; (**3**) with the nitrone **21**. Concentration of supersensitisers — 6.2×10^{-4} mol per mole of AgHal.

According to Scheme 1, the probability of the dye self-desensitisation processes increases with increase in the concentration of the electron-accepting dye and in its electron affinity. The effectiveness of the supersensitisation by nitrones inhibiting the loss of photoelectrons should therefore also increase with increasing concentration of the dye and of its affinity. Fig. 27 presents the dependence of the supersensitisation coefficients (K_s) on the dye concentration for photographic emulsion6 sensitised by the thiapentacarbocyanine **1** and containing the supersensitiser **4** of the first kind and its compositions with supersensitisers of the second kind — the nitrones **7** and **21**.⁷⁶ According to Fig. 27, with increase in the concentration of the dye **1** the supersensitisation effect produced by the phosphine **4** diminishes (straight line **1**),

Figure 27. Dependence of the coefficient of the supersensitisation of photographic emulsions sensitised by the thiapentacarbocyanine **1** and containing supersensitisers **4** (1), **4** + **7** (2, 3), and **4** + **21** (4) on the dye concentration. Concentrations of supersensitisers (mol per mole of AgHal): 9×10^{-4} of compound **4**, 5×10^{-3} (2) and 1×10^{-2} (3) of compound **7**, and 2.5×10^{-3} of compound **21**.

while that by the additionally introduced nitrone **7** (or **21**) actually increases (straight lines 2–4). This clearly demonstrates the difference between the mechanisms of the supersensitisation by the two types of substances.

The photographic activity of nitrones has been attributed¹³² to a certain combination in its molecule of the hydrophobic aryl rings and the polar oxyazamethine group. Calculations showed¹³³ that the length of the N–O bond (1.406 Å) is close to that of the C–C bond in the polymethine chain of cyanines; this makes possible quadrupole interactions of the type

with the alternating charges of the chain. As a result of such interaction, part of the polymethine chain of the dye may be insulated by the nitrone from oxygen and water.

The acceleration of the regression of the latent image centres by the molecules of infrared dyes in the ground state in conformity with Scheme 1 (Fig. 10) was already examined above. It is essential to emphasise that stable latent image centres (LIC), consisting of at least four (or more) silver atoms and formed in the course of the exposure of the light-sensitive layers, are oxidised in model investigations whereas in a real spectral sensitisation process mainly silver atoms with a low stability (precentres of the latent image) are oxidised in the course of the desensitisation. Nevertheless, model studies are useful for discovering the general rules governing the oxidation of silver particles.

The influence of supersensitisers on the regression of LIC has been investigated on a monodisperse AgBr(I) emulsion with sulfur sensitisation.^{76, 132} The activity of supersensitisers of the first kind (compounds **4** and **6**) and second kind (compound **7**) and of their compositions has been investigated. Fig. 28 presents curves for the regression of LIC, characterising the variation of the intrinsic (S_i) and spectral (S_λ) sensitivity of photographic emulsions at 35 °C and 100% humidity. According to the results, the phosphine **4** retards somewhat the decrease in S_i and S_λ for the light-sensitive layers (curves 1 and 2 in Figs 28a and 28b). A similar

picture is observed in the presence of supersensitiser **6** (cf. curves 1 and 3). It is striking that the hydrophobic compound (the nitrone **7**) inhibits the regression of LIC to a greater extent than compounds **4** and **6**. Special mention should be made of the considerable decrease in the degree of regression (by a factor of 7–10) in the presence of a composition comprising supersensitisers of the first kind (compound **4**) and second kind (compound **7**) (cf. curves 1–4 and 5 in Figs 28a and 28b). Thus model studies on the regression of LIC agree with the hypothesis that oxidation reactions involving dyes in the ground state are inhibited by supersensitisers of the first and second kind.

Figure 28. Variation of the intrinsic (S_i) (a) and spectral (S_λ) (b) sensitivities of photographic emulsions sensitised by the thiapentacarbocyanine **1** individually and in the presence of supersensitisers at 35 °C and 100% humidity: (1) dye **1**; (2) **4** + **1**; (3) **6** + **1**; (4) **1** + **7**; (5) **4** + **1** + **7**; (6) without a dye. Dye concentration 18×10^{-6} mol per mole of AgHal; concentrations of supersensitisers (mol per mole of AgHal): 3×10^{-4} of compound **4**, 5×10^{-3} of compound **6**, and 1×10^{-2} of compound **7**.

The method involving the evacuation of photographic emulsions before exposure¹³⁴ has been used⁷⁶ to obtain additional experimental proof of the role of oxygen and moisture in dye self-desensitisation processes and also of the inhibiting influence of supersensitisers on these secondary processes. As was to be expected, on exposure *in vacuo* of a photographic emulsion sensitised by the thiapentacarbocyanine **1**, the spectral sensitivity of the emulsion increased by a factor of 2.7 (Table 3), while after the admission of air it fell again and virtually reached the initial value.

A supersensitiser of the first kind (compound **4**) increased the spectral sensitivity of an emulsion of this type by a factor of 4. On

Table 3. The influence of evacuation on the photographic sensitivity of infrared emulsions (pAg 7.6).

Exposure conditions	$S_\lambda(1)$	$D_0(1)$	$S_\lambda(4+1)$	$D_0(4+1)$	$S_\lambda(1+7)$	$D_0(1+7)$	$S_\lambda(4+1+7)$	$D_0(4+1+7)$
Before evacuation	1.0	0.35	4.0	0.25	5.0	0.48	11.0	0.35
<i>In vacuo</i>	2.7	0.25	6.0	0.30	7.5	0.60	11.0	0.35
After admission of air	1.2	0.38	4.5	0.25	6.0	0.60	11.5	0.50

Note. The values of S_λ behind a KS-14 light filter are quoted in relative units based on the criterion of density $D = D_0 + 0.85$.

evacuation of emulsions, S_λ increased by a further factor of 1.5 and on subsequent admission of air it fell and virtually attained the initial value. The nitrone **7** also induced an increase in spectral sensitivity (by a factor of 5). It is striking that the joint activity of supersensitisers **4** and **7** exceeded the influence of evacuation. Thus their activity is not restricted solely to the inhibition of the reactions with oxygen and water. However, on exposure of evacuated light-sensitive layers containing the nitrone, their sensitivity nevertheless increased by a further factor of 1.5. This result as well as the decrease in S_λ for light-sensitive layers with supersensitiser **7** after the admission of air apparently indicate the incomplete inhibition of secondary reactions with participation of oxygen and water by the nitrone **7**.

Attention should be drawn to the fact that neither evacuation nor the introduction of individual supersensitisers ensured the maximum increment in the light sensitivity of photographic emulsions. A superadditive increase in the spectral sensitivity of an emulsion was attained only when supersensitisers **4** and **7** were employed jointly. There was then no evacuation effect. Thus the experimental data presented confirmed the hypothesis that oxygen and moisture influence the self-desensitisation reactions of electron-accepting dyes and indicate the ability of supersensitisers to inhibit secondary reactions involving oxygen and water protons.

Whereas the greater influence on S_λ compared with evacuation, in the case of the supersensitiser of the first kind **4** can be accounted for by the formation of a 'spacer' between the dye and AgHal, which effectively inhibits the self-desensitisation reactions in stage 1 of Scheme 1, another explanation is possible for nitrones.

In experiments on the regression of the latent image during the storage of exposed specimens with *C,N*-diphenylnitron at an elevated temperature and humidity, the appearance of a sensitometric wedge on the undeveloped emulsions has been observed.^{76, 132} The formation of visual densities is definite evidence for the occurrence of processes involving the intensification of the latent image. Thus the nitrone has a reducing function. The nitrone **7** belongs itself to the class of compounds which are difficult to oxidise, but its hydrolysis product — phenylhydroxylamine — has reducing properties. A 'reductive' mechanism, involving the latensification of the latent image, can therefore be considered as a variant of the supersensitising activity of nitrones. This results in a decrease in the probability of stage 1 (Scheme 1). The supersensitisation of infrared photographic materials by reductants has been discussed.^{135, 136} According to the authors of these publications, the infrared dye is oxidised on the surface of AgHal to radical-cations, which intensify the desensitisation processes by electron capture. The reductant (for example, ascorbic acid) reduces the radical-cations to the dye, promoting a decrease in desensitisation.

When secondary chemical dye self-desensitisation chemical processes are considered, attention is concentrated on the inhibition of stages 1–5 (Scheme 1). The recombination reactions of the electrons captured by the dye and oxygen with the dye holes (stages 6 and 7) have been examined to a significantly lesser extent. On the other hand, the recombination processes can also contribute to the self-desensitisation of dyes. It may be that the role of supersensitisers of the first and second kind consists also in

the inhibition of the recombination processes. In particular the reducing function of nitrones may involve the acceptance of a dye hole and hence the inhibition of stages 6 and 7 (Scheme 1), *i.e.* nitrones or their hydrolysis products can function in accordance with Gilman's hole capture mechanism.⁸² The difference between the approaches of the present author and Lenhard *et al.*¹³⁵ to the 'reductive' mechanism of supersensitisation concerns only the question of the origin of the infrared dye radical-cations; thus Muentert¹³⁵ believes that the radical-cations are formed in a dark process during the oxidation of the dye on the AgHal surface, whereas the present author believes that it occurs during the spectral sensitisation photochemical reaction.

VI. Self-supersensitisation of infrared dyes

Infrachromatic dyes with saturated cyclic groups in the polymethine chains belong^{137, 138} to the class of highly effective spectral sensitisers. The photographic effectiveness of such dyes has been attributed in a number of studies^{139–141} to hydrophobic protection by the saturated cyclic groups of the polymethine chain of the dyes against oxygen and water protons. The increase in the photographic activity of the infrachromatic dyes as hydrophobic alkyl groups accumulate in the chain has been demonstrated in relation to the thiatetracarbocyanines **23–26**.^{139, 141}

Table 4 presents results obtained on a monodisperse AgBr(I) emulsion with cubic microcrystals ($l = 0.27 \mu\text{m}$). The photographic activity of cyanines has been studied both individually and in the presence of supersensitisers of the first (the phosphine **4**) and second (the nitrone **7**) kind. The spectral (S_λ) and intrinsic (S_i) sensitivities of the photographic emulsions are quoted in relative units. The sensitivity of the emulsion without a dye has been adopted as unit S_i , whilst the sensitivity of photographic emulsions sensitised by dye **23** unsubstituted in the chain adopted as unit S_λ .

Table 4. The influence of the cyclic groups in the polymethine chain of thiatetracarbocyanines on the effectiveness of spectral sensitisation.

No. of experiment	Supersensitiser + dye	S_λ (KS-14)	S_i (S3S-22)
1	Unsensitised emulsion	—	1.0
2	23	1.0	0.3
3	4 + 23	2.0	0.4
4	4 + 23 + 7	3.5	0.5
5	24	2.0	0.4
6	4 + 24	5.0	0.45
7	4 + 24 + 7	7.0	0.55
8	25	4.0	0.5
9	4 + 25	10.5	0.55
10	4 + 25 + 7	20	0.6
11	26	6.0	0.5
12	4 + 26	18	0.6
13	4 + 26 + 7	40	0.6

Note. The values of S_λ and S_i have been obtained at pAg 7.4 from the criterion of density $D = D_0 + 0.85$ at a colour temperature of the light source of 2850 K.

It follows from Table 4 that, with increase in the number of cyclic groups in the polymethine chain of the dyes from one (dye **24**) to two (dye **25**) and three (dye **26**), the spectral sensitivity due to the individual dye increases relative to the unsubstituted thiatetracarbocyanine **23** by factors of 2, 4, and 6 respectively (cf. experiments 2, 5, 8, and 11 in Table 4). The desensitising activity of the dyes diminishes in the same series of compounds (by a factor of 1.1–2.0) (cf. the values of S_i obtained in experiments 2, 5, 8, and 11). It is striking that the influence of cyclic groups on S_λ is significantly greater than on S_i .

The introduction of the supersensitiser of the first kind **4** promotes an increase in the spectral sensitivity of emulsions, which becomes more marked as cyclic groups accumulate in the chain (cf. the values of S_λ obtained in experiments 3, 6, 9, and 12 in Table 4), as a result of which the sensitivity of the emulsions with the **26** + **4** composition exceeds by a factor of 18 the sensitivity of those with the thiatetracarbocyanine **23** alone. Under the same conditions, the intrinsic sensitivity increases only by a factor of 2. The supersensitising activity of the nitron **7** is also determined by the number of hydrogenated bridges in the polymethine chain and reaches a maximum for dye **26** with three rings. Similar results have been obtained also on emulsions with the supersensitiser of the first kind **6**.¹⁴¹ The regular features of the influence of cyclic groups in the chain are retained in the series of

substituted thiapentacarbocyanines.^{132, 141} The greater influence of supersensitisers and cyclic groups on S_λ than on S_i confirms the difference, already discussed, between the dye desensitisation and self-desensitisation processes. According to the data presented, the supersensitising activity of cyclic groups in the dye chains is retained also in emulsions containing the supersensitisers of the first kind **4** and **6**, which themselves reduce the self-desensitisation of dyes as a consequence of the insulation of the latter from AgHal and promote thereby a more effective manifestation of the inhibiting activity of the hydrophobic saturated rings. The additional increase in spectral sensitivity in the presence of the hydrophobic supersensitiser of the second kind **7** can also be accounted for by the increase in the protective functions of the hydrophobic bridging groups in the presence of *C,N*-diphenylnitron. The hydrophobic nitron probably insulates additionally from oxygen and water the part of the dye chain which is not protected by the cyclic groups. This can explain the increase in the effectiveness of the nitron as rings accumulate in the chain, because the hydrophobic protective effects are then, as it were, added together. A contribution by the 'reductive' mechanism is possible.

It has been suggested^{132, 141} that the photographic activity of dyes with bridging groups should be manifested when the groups are in those positions in the polymethine chain where there is an excess π -electron density of the dye molecule which has captured an electron (in $\text{Dy}^{\cdot-}$). The probability of electron transfer to oxygen is a maximum at precisely these sites. When these sites are shielded by saturated groups, which hinder the approach of oxygen and especially water molecules, the probability of the dye self-desensitisation reactions should diminish. According to the molecular diagram (Fig. 29) of the distribution of π -electron density, constructed on the basis of LCAO MO quantum-chemical calculations in the Hückel approximation, the excess electron density in $\text{Dy}^{\cdot-}$ is concentrated in the 9-, 11-, 13-, and 15-positions in the polymethine chain of the thiatetracarbocyanine. Indeed, the introduction of two or three hydrogenated bridges at sites with the highest π -electron density (the 9-, 11-, and 13-positions for dye **25** and the 9-, 11-, 13-, and 15-positions for dye **26**) leads to a significant increase in the spectral sensitivity of the photographic emulsions. The value of S_λ for photographic emulsions with dye **24**, containing a saturated excess group in other positions in the chain (10, 12), where there is no excess electron density, is greater by a factor of 2 than for emulsions with the unsubstituted dye **23**. Presumably in this case the hydrophobic protection by the cyclic group extends not only to the sites to which it is attached but also to the neighbouring 11-position.

The distribution of π -electron density in the thiapentacarbocyanine molecule is also illustrated in Fig. 29. The highest π -electron density in $\text{Dy}^{\cdot-}$ is concentrated in the 9-, 11-, 13-, 15-, and 17-positions in the outer polymethine chain. According to experimental data,^{132, 141} the introduction of the β, β -dimethyltri-

**Figure 29.** Molecular diagrams for the distribution of π -electron density in the polymethine chain of thiatetracarbocyanine (a) and thiapentacarbocyanine (b).

methylene hydrophobic bridges in the 9- and 11-positions and in the 9-, 11-, 15-, and 17-positions (dye **1**) also increases the photographic activity of these dyes in the presence of supersensitisers compared with the thiapentacarbocyanine unsubstituted in the chain.

It is striking that cyclic bridging groups in the chains of thiatetra- and thiapentacarbocyanines decrease the catalytic effect of the dyes on the oxidation of latent image centres, *i.e.* the regression of LIC at elevated temperatures and humidities. Fig. 30 presents data taken from Mikheeva¹³² for the thiatetracarbocyanines **23**–**26**. The decrease in catalytic activity with increase in the number of rings in the chain is associated with the hydrophobic protection of the chain, already discussed, and hence with the inhibition of the reactions presented in Scheme 1. Thus, if it is assumed on the basis of the results that cyclic groups do indeed play the role of the hydrophobic protectors of the chain, one may speak of a new phenomenon — the self-supersensitisation of infrared dyes under the influence of saturated bridging groups.¹⁴¹ It is essential to note that one is dealing with the self-supersensitisation of dyes different from that considered by Collier,¹⁴² according to which the self-supersensitisation of *J*-aggregates of dyes is effected by dyes in the molecular form *via* the hole-acceptance mechanism.

Figure 30. Variation of the intrinsic (S_e) (a) and spectral (S_λ) (b) sensitivities of photographic emulsions sensitised by the thiatetracarbocyanines **23** (1), **24** (2), **25** (3), and **26** (4) and of photographic emulsions without a dye (5) (28 °C, 78% humidity).

VII. Conclusion

The data examined indicate convincingly that the secondary chemical oxidation processes, or, in photographic terminology, the desensitisation processes play a very important role in the establishment of the sensitivity of infrared photographic materials. The desensitisation in the region of absorption by the dye (self-

desensitisation) then exceeds the desensitisation in the region of absorption by the silver halide. The self-desensitisation can actually determine the effectiveness of the spectral sensitisation itself. The oxidative mechanisms and the kinetics of the self-desensitisation processes are determined by the positions of the energy levels of the dyes relative to the energy bands of AgHal and also relative to the local surface levels.

It is striking that the infrared dye may play the role of an oxidation catalyst in the secondary processes. In a general sense, the vacant molecular orbitals of π -conjugated systems such as the molecules of polymethine dyes can therefore participate in the catalysis of the oxidation reactions of photographically active species. The role of oxygen and water protons is very important in these processes. To use a picturesque expression, one may say that the infrared photographic material, as it were, 'breathes' after photoexcitation. The silver atoms (the latent image precentres) are burnt up in the oxidative flame blown up by the infrared dye itself.

The supersensitisation processes reduce to a large extent to the inhibition of the secondary self-desensitisation reactions, *i.e.* the inhibition of the oxidation reactions of the products of the primary photochemical reaction. The ways in which oxidative processes are inhibited can be extremely diverse. They are determined both by the properties of the spectral sensitisers and by the type of the emulsion, so that the supersensitisers may be compounds with significantly different properties. There is a possibility of the self-supersensitisation of dyes as a result of the introduction into their molecular structure of self-desensitisation inhibitors. For example, dyes with the polymethine chain 'protected' to the maximum extent are promising. This can be achieved either by introducing hydrophobic substituents into the chain or by the 'truncation' of the outer polymethine chain when part of the chromophore chain is incorporated in heterocyclic rings. The use of various supersensitisers and their mixtures makes it possible, in principle, to eliminate fully the secondary oxidative processes and to approach thereby the limiting relative quantum yield of the spectral sensitisation. The greatest increment in spectral photosensitivity should then be expected for infrared photographic materials with a sensitisation zone longer than 1000 nm. Indeed, the effectiveness of the spectral sensitisation in the IR region with $\lambda \approx 1000$ nm has been increased by a factor of 100 and made to approach the values for the visible region of the spectrum^{5, 102} despite the fact that the level of the photoexcited electron in the thiapentacarbocyanine, used as the spectral sensitiser, is located approximately 0.7 eV deeper than the bottom of the AgBr conduction band.

One should note that the problem of the effectiveness of the spectral sensitisation of the direct positive process, based on the oxidation of pregenerated silver centres, is diametrically opposite to the problem of the effectiveness of the negative process already considered. Whereas in negative emulsions one is dealing with the inhibition of secondary oxidation reactions, in direct positive emulsions the supersensitisation is actually associated with the acceleration (promotion) of secondary oxidation reactions. In order to accelerate the oxidation of silver by dye holes, it is necessary either to introduce additional hole-transferring agents or to create conditions for the preferential adsorption of dyes on the centres containing silver particles which catalyse the development. Oxidative hole processes may intensify when the infrared dyes form extended *J*-aggregates. The formation of infrared dye *J*-aggregates on AgHal has been observed.^{143, 144} The promotion of electron capture reactions requires catalysis of electron transfer to oxygen and the water protons with the aid of additionally introduced electron-accepting compounds. Questions concerning the supersensitisation of direct positive emulsions have been examined, for example, by Belous *et al.*¹⁴⁵ and Steiger and Reber.¹⁴⁶

In conclusion, attention must be drawn to the following factor. In previous studies on spectral sensitisation, attention was concentrated on the primary spectral sensitisation step, on the effectiveness of which the effectiveness of the entire spectral

sensitisation process was assumed to depend. On the other hand, the effectiveness of the primary step was considered from physical standpoints, namely from the standpoint of the relation between the electronic levels of the photoexcited dyes and the electron bands of AgHal. Although secondary reactions were also taken into account in this approach, a secondary role was nevertheless attributed to them, *i.e.* their influence depended significantly on the probability of the primary process. On the other hand, in the chemical approach discussed here, the most important role in the establishment of the photographic parameters of the process is assigned to the secondary reactions. The primary spectral sensitisation step is treated as a surface oxidation-reduction reaction of the photoexcited dye with the silver ions,¹⁴⁷ which is virtually equally probable for the majority of the adsorbed dyes. Thus the problem of spectral sensitisation may be transferred from the class of 'purely physical' problems to the class of chemical problems, reducing to the search for effective ways of the inhibition, or, conversely, the promotion of the secondary oxidation reactions. The new chemical approaches have made it possible to expand the region of spectral sensitisation approximately to 1500 nm.¹⁴⁷

VII. Conclusion	297

Abstract. The results of quantum-chemical calculations of electronic structures of complexes of non-transition elements are surveyed. Their X-ray emission and X-ray photoelectron spectra are analysed. General principles of the electronic structure of these complexes are established. It is shown that the effective participation of partially or completely occupied valence np^m orbitals of the central atom A of AL_k complexes in the formation of delocalised MOs, the negligibly small contribution of vacant nd orbitals to the bonds with ligands, the valence inertness or rather low contribution of occupied Ans^2 orbitals (except for $2s^2$ AO) to the valence MOs, and the initiation of multiple bonds (in the electronic structure of complexes) due to covalent or hypervalent π -interactions involving only $2p$ (but not $3p$, $4p$, etc.) atomic orbitals are the most significant factors influencing the electronic structure of non-transition element compounds. The concept of d orbitals and hypervalent bonds is criticised. The bibliography includes 130 references.

I. Introduction

The essence of the problem of the electronic structure of non-transition element compounds is quite simple. The main task is to find out what valence orbitals of central atoms (A) in the complexes AL_k ($k \geq 1$) of non-transition elements participate in the formation of bonds with ligands (L) described by delocalised molecular orbitals (MO).

In ionic compounds of alkali and alkaline earth metals, the leading part is played by the ns^1 and ns^2 orbitals; in other complexes of these metals, the contributions of the np orbitals should also be taken into account (especially in complexes formed by A^{II}). The physicochemical nature of the majority of compounds of Group I and II metal is too specific, and its analysis is beyond the scope of our review.

The electronic structures of complexes of Group III and IV non-transition elements can be described fairly adequately in

terms of the Ans and Anp orbitals and usually correspond to the traditional concept of sp^m -hybridisation of the basis AOs, especially in the case of boron and carbon complexes. The electronic structures of complexes of aluminium, silicon and their analogues with coordination numbers above 4 are more complicated.

The problem of describing the electronic structures of complexes of Group V–VIII non-transition elements is even more complicated, because the ground states of atoms of these elements contain one or more electron pairs localised in the valence ns and np AOs (in this case, the total number of valence electrons in an atom is greater than the number of valence orbitals, which is equal to four). At this point, the problem branches. The structures of the valence shells of the simpler molecules such as HF, HCl, H_2O , H_2S , NH_3 or PH_3 , in which the chemical bonds are mostly formed by unpaired Anp -electrons, are relatively simple; problems arise in determining the contributions of the occupied Ans^2 orbitals to the valence MOs and in solving the problem of hybridisation of the basis ns and np orbitals of the central atom.

The problem of describing an electronic structure is the most complicated in the case of higher compounds of Group V–VIII non-transition elements. The term 'higher compounds' is used in relation to molecular systems in which the oxidation state of a non-transition element A exceeds the number of unpaired np -electrons in the ground state of the atom, while the number of the unpaired Anp -electrons alone is insufficient to ensure that all the A–L bonds in the complex AL_k are two-electron two-centre interactions. The term 'higher compounds' cannot be regarded as appropriate, and its use can be justified only in striving for short presentation. According to this terminology, not only compounds of elements in the maximum oxidation states (Cl^{7+} , S^{6+} , etc.) are referred to as higher compounds, but also those in which the A atom is in a lower oxidation state (for example, complexes of formally trivalent chlorine ClO_2^{1-} or tetravalent sulfur, SO_3^{2-}).

Undoubtedly, the key role in the formation of bonds with ligands in the higher complexes of non-transition elements belongs to the valence np^m orbitals of the central atom. Therefore, the main point in studying the electronic structures of these compounds is to elucidate the degree to which the vacant nd orbitals and ns^2 orbitals occupied in the ground state of the central atom participate in the delocalised valence MO.

The problem of the description of electronic structures of complexes of non-transition elements has a long-standing history. Three stages, not separated from one another (in time or in the essence of the problems solved), can be distinguished, namely, empirical, semiempirical and non-empirical periods. The name of

G P Kostikova, D V Korol'kov, Yu P Kostikov St. Petersburg State University, Universitetskii prosp. 2, 198904 St. Petersburg, Peterhof, Russian Federation. Fax (7-812) 428 69 39. Tel. (7-812) 428 67 33 (G P Kostikova)

Received 15 April, 1996

the last stage is conventional; this stage combines theoretical *ab initio* calculations of the electronic structures of non-transition element complexes carried out by the SCF and MO LCAO methods, by the methods of scattered waves and by X_α -discrete variation; experimental studies of these complexes by X-ray emission and X-ray photoelectron spectroscopy; coordinated studies of electronic structures using both X-ray spectroscopy and the MO theory and general theoretical approaches to the problem.

II. Empirical concepts

In our review, attention is concentrated on the electronic structures of higher compounds of Group V–VIII non-transition elements. A considerable part is occupied by the discussion of the nature of, and the reasons for the differences between, the electronic structures of complexes formed by elements of the Second Period and by elements of the Third and higher Periods.

To describe the electronic structures of higher compounds of Group V–VIII non-transition elements of the Third and subsequent Periods, two alternative concepts were developed as early as the 1950s. According to one of them (the concept of *d* orbitals), it is assumed that both the ns^2 and np^m orbitals of the central atom A occupied in the ground state and its vacant *nd* orbitals are involved in the binding with ligands.^{1,2} The bonds between the atom A and the ligand were described by multi-centre MOs formed according to the requirements of group theory with efficient participation of the *ns*, *np* and *nd* orbitals of atom A (strictly specified for each type of molecular symmetry) and the corresponding group orbitals of the ligands. This concept was based on the idea of $sp^m d^n$ hybridisation of valence orbitals of the central atom and made it possible to pass from the canonical delocalised MOs to equivalent localised MOs, *i.e.* to describe the electronic structure of an AL_k complex by a certain set of two-electron two-centre covalent A–L σ - and π -bonds. A fairly important role has been allocated to the allowance for the symmetry of the complex. The vacant *nd* orbitals of the central atom able to participate in the σ - or π -interactions with the ligand orbitals were strictly specified in conformity with the symmetry point group. The concept of *d* orbitals (sometimes referred to as the theory of complete hybridisation) has been presented clearly and systematically in monographs.^{3,4}

The second concept is the concept of hypervalent bonds. It is based on the idea of three-centre four-electron interactions proposed by Pimentel and Rundle^{5–7} and assumes that the bonds of atom A with ligands are mostly formed through the valence np^m orbitals of the central atom. The ns^2 -electrons are used only in some cases, whereas the vacant *nd* orbitals remain valence-inactive and do not participate in the A–L bonds. The electronic structure of an AL_k complex is described as a set of two-electron two-centre covalent A–L bonds involving the unpaired electrons of the A atom and three-centre four-electron (hypervalent) $L_{(1)}-A-L_{(2)}$ bonds involving the paired np^2 -electrons or, more rarely, the ns^2 -electrons of the A atom.^{8,9} In the case of complexes with central atoms in the highest oxidation states (SF_6 , PF_5 , *etc.*), the Ans^2 orbitals are assumed to participate necessarily in the valence MOs. The concept of hypervalent bonds (or the theory of three-electron bonds), the history of its development and its numerous consequences have been considered in monographs.^{3,4,10}

In the 1950s and 1960s, the concept of *d* orbitals occupied a leading position in the theory of electronic structure of compounds AL_k of non-transition elements. This can be explained retrospectively as follows. In those years, theoretical studies were mainly concerned with complexes of transition metals. Their electronic structures have been modelled using the crystal field theory, the ligand field theory and the MO theory including various versions of calculation procedures. The theory of the electronic structures of compounds of non-transition elements has remained the Cinderella of quantum chemistry and has been ‘fascinated’ by the successes in the rapidly progressing theory of electronic structure of transition metal complexes. Researchers

believed that the electronic structure of AL_k cannot present anything conceptually new, interesting or significant compared to that of complexes ML_k of transition metals M; the electronic structures of the latter have usually been described using all the valence AOs [*ns*, (*n*–1)*d*, *np*] with allowance for the symmetry requirements. Therefore, views on the electronic structures of AL_k have largely resulted from the groundless transfer of the general ideas of the theory of the electronic structure of ML_k to coordination compounds of non-transition elements and from the wide use of the statement that the principles of the electronic structure of two types of complexes — AL_k and ML_k — are close and even identical. Moreover, the concept of *d* orbitals has been supported by many experimenters, who have searched and seemingly ‘found’ evidence supporting participation of the *And* orbitals in the electronic structures of AL_k and in the A–L bonds.

However, at that time, some arguments in favour of the concept of hypervalent bonds were found. Syrkin and Linnet^{11–13} noted that *d* AO make fairly low contributions to the electronic structures of non-transition element complexes. They stressed that the characteristics of those vacant *d* orbitals of non-transition element atoms that should be included in the basis set of atom A cannot be theoretically estimated with a sufficient accuracy. Furthermore, since the *And* orbitals in AL_k can be delocalised near the ligands, the problem of *d* AOs is generally less significant than it had seemed initially. The requirement that the number of hybrid orbitals of the central atom in an AL_k complex should coincide with the number of two-centre bonds and the *a priori* judgment of the multiplicity of the A–L bonds cast special doubt upon the concept of *d* orbitals. Therefore, the setback of these ideas observed in the last few years is surprising.¹⁴

In the 1960s, it was believed that the problem in question could be solved by systematic quantum-chemical calculation of the electronic structures of non-transition element complexes. Both concepts are ‘one bone and one flesh’ in MO theory. Within the framework of these concepts, the electronic structures of AL_k complexes can be described using both delocalised MOs and localised two- and three-centre MOs. Therefore, since the middle 1960s, quantum-chemical calculations have been used systematically to model the electronic structures of various AL_k complexes in various approximations of the MO theory.

III. Semiempirical calculations of molecular orbitals

The greatest number of calculations for AL_k complexes have been carried out by semiempirical MO LCAO methods. Owing to computational difficulties only few *ab initio* calculations for complex multi-electron and multi-centre AL_k compounds, based on the Hartree–Fock–Roothaan (SCF MO LCAO) method with fairly complete and balanced atomic basis sets, were performed at that time.

The MO LCAO calculations have provided extensive information; these results have been presented fully and comprehensively and in a clear and systematic form in the review by Dyatkina and Klimenko.^{15 †}

The review begins with comments on the calculations of spatial and energy characteristics of vacant *nd* orbitals of isolated atoms and atoms in a ligand field. These calculations did not give an answer to the direct question, whether the *nd* AOs can participate in bonds, but indicated that the spatial characteristics of *d* orbitals (unlike those of *s* and *p* AOs) can vary over wide limits, from very diffuse to contracted orbitals, depending on the valence state of the atom. The calculations for excited states of atoms also have not clarified the situation, although they have provided useful information on the energies of excitation from the

† We advise those who are interested in the problem of vacant AO, to read this brilliant review, which was published in 1973 and marks the completion of a stage in the development of the quantum-chemical views about electronic structure of non-transition element compounds.

ground states of atoms to their valence states in which the nd orbitals are occupied by electrons and on the orbital energies of these electrons.¹⁶

Based on the results of semiempirical MO LCAO calculations for various AL_k complexes, the authors of the review made some conclusions that seemed the most reliable and significant at that time. These conclusions can be outlined as follows.

The populations of d AOs are substantial but not more than 0.5–1 electron. According to the theory of localised bonds, the populations of d orbitals are postulated to be large integer values, and thus the contributions of these orbitals are overestimated twice or even more. The contributions of d orbitals are greater in compounds with high valences of the central atom (such as SO_2 , SO_4^{2-} , SF_6) and increase with an increase in its formal valence. In addition, the contributions of d AOs increase with the decrease in the degree of ionicity of bonds (in oxygen compounds they are greater than in fluorine compounds, the number of ligands being the same). No considerable donor-acceptor $Lp_\pi \rightarrow Ad_\pi$ interactions can be detected even in those cases where these interactions are allowed from the symmetry viewpoint. The allowance for d orbitals influences the calculated properties of molecules in different ways. For example, it should be noted that the calculation of dipole moments and inversion barriers requires that d orbitals be necessarily included in the basis set of AOs even for elements of the Second Period (although in this case, the contributions of d AOs are lower than those for atoms of the Third Period elements). However, the MO energies are less sensitive to the expansion of the basis set due to d AOs. Therefore, it would be hasty to judge the role of d AOs based only on the analysis of one or several molecular properties, the more so as an increase in the influence of d AO on a particular characteristic is not always proportional to the increase in the electron population of d AO. It is necessary to analyse a variety of properties that respond in different ways to the inclusion of d orbitals in the atomic basis set. The results of calculations do not identify any correlations between the contributions of d AOs to the MOs and electronic characteristics of the atom and, hence, they do not make it possible to discuss the variation of the nd AO populations as a function of the position of the non-transition element in the Periodic Table.

In addition to the MO LCAO semiempirical calculations, the maximum overlap method has also been used to study the role of d orbitals and the extent to which they participate in the hybrid orbitals of tetrahedral oxo-anions. The tetrahedral hybrid orbitals

$$\varphi = \alpha\chi_s + \beta\chi_p + \gamma\chi_d,$$

were calculated with allowance for the contributions of both d_σ and g_p components. The $s^1p^3d^n$ electronic configurations of the central atoms were estimated from the relations $l:m:n = \alpha^2:\beta^2:\gamma^2$. The results of the calculations showed that the relative d -contribution to the electron population of atom A varies over wide limits (from 0.02 for BrO_4^- to 0.3 and 0.4 for ClO_4^- and AsO_4^{3-}), but it is always several times smaller than the d -contribution to the electron population of central atoms M in analogous tetrahedral oxo-anions formed by transition metals (for example, VO_4^{3-} , CrO_4^{2-} , MnO_4^-).

In other studies,^{18–21} the problem of vacant d orbitals of non-transition element atoms has been discussed in terms of the results of semiempirical calculations of valence electron density distribution in two- and multi-atomic fluorides, chlorides, oxides and complexes of the $AX_{k-n}Y_n$ type with coordination numbers of 3, 4 and 6. The calculations were carried out by the MO method in the zero differential overlap (ZDO) approximation. It was found that d orbitals play an insignificant role in the formation of chemical bonds between central atoms and ligands. In particular, it was shown that the fact that the energies of dissociation of the Si, P, S and Cl monofluorides are larger than those of the C, N, O and F monofluorides is not associated with the role of d orbitals of the atoms of Third Period non-transition elements but is due to the specificity of their s and p AO, i.e. to specific spatial and energy characteristics of $A3s$ and $A3p$ orbitals.

The statistical theory of Thomas–Fermi atoms²² has also been invoked to the solution of the problem of vacant $3d$ orbitals of the atoms of non-transition elements of the Third Period. It was shown that these atoms, unlike those of elements of the Second Period, have no states occupied by electrons and characterised by the orbital quantum number $l = 2$; the states with $l = 2$ can be occupied only in the case of cations. The electron populations of the states with $l = 2$ is determined by the degree of ionisation of the atom; both lower and upper limits to the degree of ionisation exist. Depending on its effective positive charge, the same central atom can have, or not have, occupied $3d$ states. A particular degree of ionisation of the atom is necessary but insufficient for the $3d$ AO to be occupied, because the extent of this occupation is also determined by the nature of the donor of valence electrons. Thus the population of the $3d$ AO of chlorine in ClF_2^+ is close to zero (0.05 a.u.), despite the considerable degree of formal ionisation of the chlorine atom ($q_{Cl} = +1.18$ a.u.), which is favourable for the population of its $3d$ AO. Apparently, this is due to the low electron-donating ability of fluorine atoms ($q_F = +0.09$ a.u.).

In recent years, semiempirical calculations have been seldom used to solve the problem of vacant d orbitals; sometimes, the results of these calculations are compared with the photoelectron spectroscopy data for the corresponding complexes.^{23,24} The results of the latter indicate that d orbitals contribute significantly to the valence electron structures of higher sulfur fluorides, silicon oxo-complexes, etc.

Nevertheless, the conclusion that the problem of d orbitals cannot be solved adequately within the framework of the semiempirical approach is beyond any doubt.¹⁵ The semiempirical MO LCAO calculations exaggerate the role of d orbitals and give a wrong picture of the electron density distribution; they are of little use for the description of the qualitative variation of d -contributions in various series of molecules, do not prove in any way the real participation of the And AOs in the A–L bonds and give so great a scatter of the calculated values of d -populations that attempts to extract unambiguous information from them are hopeless. These calculations confuse rather than clarify the problem of outer d orbitals.

In the early 70s, it seemed that the final solution of the nd AO problem would become possible as a result of systematic non-empirical calculations for a great number of complexes; generalisation of experimental values for a broad range of molecular properties; thorough analysis of the regularities in the variation of these properties and establishing correlations between the molecular properties and calculated characteristics of the contributions of d orbitals to the valence molecular orbitals in the electronic structures of complexes. However, the first studies along these lines have already shown that counting on the non-empirical approach to the estimation of the role of d AOs in the valence electronic structures of complexes of non-transition elements also has no prospects.

IV. Non-empirical MO calculations and X-ray spectra of complexes

The need to determine reliably the populations of the outer (vacant) atomic orbitals in an explicit form and their contributions to various molecular properties imposes stringent requirements upon the MO method used for the calculations. The non-empirical SCF MO LCAO method and X_σ -methods meet these requirements best of all. However, even fairly legitimate calculations carried out for AL_k complexes in terms of these methods have not resulted in the solution of the nd AO problem.

The following approach is normally used to solve the nd -AO problem in terms of *ab initio* and X_σ -methods. The participation of And orbitals in $\sigma(d_\sigma-s, p_\sigma)$ or $\pi(d_\pi-p_\pi)$ bonds with ligands is set depending on whether or not the inclusion of the nd_σ and nd_π orbitals into the atomic basis set results in the calculated energies of single-electron MO approaching the corresponding experimental values and/or in a decrease in the total energy of the molecular

system. The electron population of the *And* orbitals in the complex is estimated from the same viewpoint.

Unfortunately, no unambiguous conclusions have been drawn from the results of calculations for complexes of non-transition elements accumulated over the past two decades.

The results of some of the *ab initio* SCF MO LCAO and SCF SW X_α -calculations attest to an appreciable electron population of the *And* orbitals in the complexes studied,^{15,25–29} whereas according to other calculations, this population is equal to zero.^{30–32} In addition, the results published for the same compounds are sometimes at variance with one another. For example, the population of the atomic *And* orbitals in SF₆ has been found²⁹ to be 1.2e[–], whereas according to another study,³² the electron structure of SF₆ is hypervalent and is described without participation of the 3*d* orbitals of the central atom. X_α -calculations for SF₆ has led Condlii and Johnson³¹ to the conclusion that the S3*d* orbitals remain virtually unoccupied.

In a typical case, the inclusion of *nd* AOs into the atomic basis set leads to a slight decrease in the energy of those MOs which can contain *nd* AOs [for example, $e_g(\sigma)$ and $t_{2g}(\pi)$ MO in an octahedral complex]. However, this decrease in the MO energies does not occur for all *nd* exponents, and, besides, the energies of the rest of the single-electron MOs can increase when the *nd* AOs are taken into account. Therefore, despite the fact that allowance for the *And* orbitals is believed to result (according to the variational principle) in a decrease in the total energy of the molecule, this is due to the change in the energies of the Coulomb and exchange interelectron interactions rather than to stabilisation of single-electron energy levels.³³ This paradoxical result is reproduced in the *ab initio* and SCF SW X_α -calculations for SF₆, SeF₆, TeF₆ and PF₅ complexes and for the isoelectronic series PO₄^{3–}, SO₄^{2–}, ClO₄[–].

The results of SCF DV X_α -calculations^{34–38} of the electron structures of many halides and halo-anions of non-transition elements AL₄^{*p*–} (*p* = 0–3) including SF₆, SF₅Cl, SF₅O[–], etc. in the basis of numerical Hartree–Fock functions indicate that the chemical bonds and many properties of AL₄^{*p*–} complexes (reactivity, geometrical structure, stability and its dependence on the charge for series of isoelectronic complexes) are due to the formation of multi-centre MOs. The latter consist of all the valence *s* and *p* orbitals of the central atom and the ligands, which are transformed in terms of the corresponding irreducible representations for the symmetry groups of the complexes under study.^{34–38} Most of the calculations do not confirm the participation of the vacant *And* orbitals in the bonds with ligands. In particular, when the electronic structure of SF₆ has been calculated in the *s,p* basis, good agreement between the calculated single-electron energy levels and the experimental ionisation potentials has been observed.^{34,37} The addition of the S3*d* orbitals to the Hartree–Fock basis did not change the order of the levels and did not result in significant improvement of the calculated single-electron MO energies with respect to the experimental values for the *d* exponent varied over a fairly broad range. However, it should be noted that in the case of TeF₆, good agreement between the calculated and experimental MO ionisation potentials is observed when the calculation is carried out with the *s, p, d* basis set of the central atom;³⁷ thus, a more adequate description of the sequence of MO energies in TeF₆ is achieved when the atomic basis is supplemented by the Te5*d* orbitals. Based on the results obtained by DVM X_α -calculations of the molecular orbitals of the SF₅O[–] anion, isoelectronic to SF₆, the increase in the multiplicity of the S–O bond has been explained by the fact that all the valence AOs of oxygen participate in binding with the AOs of sulfur to a greater degree than those of fluorine, without assuming the occurrence of the S3*d* _{π} –O2*p* _{π} interactions.³⁸ Perhaps, the higher multiplicity of the bonds in the SO₄^{2–} tetraoxo-anion is also not associated with the S3*d* _{π} –O2*p* _{π} interaction.

In the non-empirical calculations, the agreement between the calculated and experimental geometric parameters of a complex (type of the polyhedron, bond lengths, bond angles) are often used as a criterion for elucidating the role of *nd* AOs. In this case, one

must take care whether the addition of *nd* functions of the central atom to the atomic basis set improves the geometry (*i.e.* the agreement with experiment). Again, some *ab initio* results imply that *And* orbitals exert only insignificant influence on the optimum geometrical parameters of sulfur halides and show their low electron population.³⁹ Conversely, some other calculations attest that *d* functions need to be taken into account in order to describe adequately the geometric structures of molecules of this type and, in these cases, the populations of *And* orbitals are found to be high.^{40–43} However, in this case, too, some interesting peculiarities have been found. Firstly, the large population of *nd* AOs has a substantial influence on the energies of Coulomb and steric repulsions and does not lead to enhancement of the d_π – p_π interaction. Moreover, in addition to the *d*-contribution, the second-order Jahn–Teller effect, caused by the presence of low-lying excited states with appropriate symmetries, can also be a crucial factor influencing the geometric (and electronic) structures.⁴¹ Secondly, the addition of *d* functions results in almost identical effects for complexes of elements of the Third Period (SF₄, SOF₂, SO₂F₂)⁴² and of the Second Period (NO₂⁺, NO₂[–], NO₃[–], NO, etc.).⁴³ In both cases the addition of 3*d* orbitals to the basis set improves the geometry and reduces the total energy of the molecule, which correlates well with the population of *d* AOs. The higher the formal valence of the central atom, S or N, the larger the effect of stabilisation due to *d* AOs. Similarly, non-empirical calculations for homonuclear polyhedral molecules P₄, As₄, P₈ and As₈ using a pseudopotential and a two-exponent basis set indicate that the expansion of the basis set due to vacant *nd* AOs makes it possible to explain the fact that the P₄ and As₄ clusters are more stable than the 2P₂ and 2As₂ systems, respectively.⁴⁴ It was noted⁴⁴ that the crucial factor determining the higher stability of P₄ with respect to 2P₂ is the increase in the electron population of *d* AOs from 0.06 to 0.10. However, very close values have been found⁴⁵ not only for the As₂ and As₄ clusters but also for N₂ and N₄, although the hypothetical N₄ molecule is known to possess much higher energy than 2N₂.

Here we encounter a quite typical situation, which has been analysed in detail in the review by Bochvar *et al.*⁴⁶ Up to now, while we discussed the problem of *d* orbitals, we proceeded from the assumption of real atomic *d* orbitals in the sense in which the valence *s* and *p* orbitals in a molecule are real. Then we assumed that non-zero electron populations of *d* AOs can serve as an actual criterion and a measure for their participation in the A–L bonds. Note in this connection that Coulson⁴⁷ has suggested that two cases should be distinguished: (1) the contribution of *d* AOs is large (about 0.5–1 electron or more), then one can speak of their real participation in bonds; (2) the contribution of *d* AOs is small, then they act as polarising functions, and the discussion of their populations makes no particular sense. The second case represents a different aspect of the problem of *d* orbitals, based on the fact that the radial parts of *d* functions obtained in MO calculations by minimising the total energy of the molecule (with allowance for the variation of the AO exponents) differ markedly from the radial parts of *d* orbitals of isolated atoms (they are more contracted) and approach the radial parts of the corresponding valence *s* and *p* AOs; for example, 3*d* → 3*s*, 3*p*.^{48,49} This strong contraction is observed in all cases and is independent of the *d*-population and of the effective charge on the atom in a molecule. These altered *d* orbitals are no longer related directly to vacant valence orbitals of the atom. Now they have a different meaning: they should be regarded as certain corrections in *ab initio* calculations that take into account polarisation of valence *s* and *p* AOs upon the formation of bonds and make the total molecular wave function more precise. Mulliken has suggested that the populations of these outer $d_{\sigma,\pi}$ AOs should be regarded as the populations of those valence σ,π AOs, which they polarise.⁵⁰

If we assume that the role of *d* orbitals reduces to corrections for calculations, then we should find out what the relative significance of these corrections is in the calculations of the electronic structures of compounds of Second and Third Period

elements. The inclusion of $3d$ functions into the central atom basis sets in the calculations for compounds of elements of the Second Period is always accompanied¹⁵ by their strong compaction ($3d \rightarrow 2s, 2p$), non-zero electron populations, and by a decrease in the total energy of the molecular system.^{15, 46} Thus, in the case of *ab initio* calculations for compounds of elements of the Second Period, the atoms of which have no valence d orbitals at all, the $3d$ functions also act as effective corrections. Using numerous nitrogen and phosphorus compounds as examples, Bochvar *et al.*⁴⁶ demonstrated convincingly that the role of d -type corrections in the calculations for compounds of Second and Third Period elements is approximately the same; in these two cases, d -populations are close and the effects of d AOs on various molecular properties are quite comparable in magnitude. For quantum-chemical reasons, the participation of d orbitals in the electronic structures of compounds of Second Period elements has never been considered to be necessary; therefore, the second ('correction') aspect of the allowance for d orbitals seems to be more and more preferable. It can be assumed that in *ab initio* calculations for compounds of Third Period elements, the role of d -type orbitals is to counterbalance the defects caused by an inadequate sp basis set.⁵¹

Expansion of a basis set increases the number of variational parameters; consequently, the test function becomes more flexible and, hence, the total energy of a molecular system always decreases (owing to the variational principle). Basis set expansion is typical of quantum-chemical calculations. The expansion of the basis set in terms of the Roothaan method makes it possible to obtain (within the specified accuracy) the wave functions corresponding to the Hartree–Fock limit. However, the total energy of a molecular system is less sensitive to the basis set expansion than other electronic characteristics and, therefore, it cannot be a reliable criterion for establishing the Hartree–Fock limit in calculations by the Roothaan method (the virial theorem and the Gelman–Feynman theorem are used as additional criteria).⁵² In addition, the stability of a molecular system cannot be fully explained in the Hartree–Fock terms; for this purpose, the correlation energy and core effects should also be taken into account.^{53, 54}

It is clear from the above that it is impossible to determine correctly the populations of d AOs and, hence, to solve the problem of vacant d orbitals in terms of merely quantum-chemical Hartree–Fock–Roothaan (HFR) calculations (even the most accurate) with a multi-exponential expanded and balanced basis set, without allowance for configuration interactions (CI) (which is typical of most of *ab initio* calculations). Apparently, only in terms of the multi-configuration approximation for a self-consistent field (MC SCF), will an adequate estimation of d -contributions to various properties of the systems under consideration be possible. (All the above is also true for the little-studied problem of occupied *Ans*² orbitals.) Within the scope of the MO LCAO method, the problem of outer d AOs is additionally complicated because, as noted above, the term d AO is used with two meanings, and there is no clear criterion to distinguish between the 'real d AOs' and 'polarising d functions'.¹⁵ It should also be borne in mind that the question of outer d AOs arises only in the MO LCAO approximation, which is most extensively used now but is not the only one existing.

Since the early 70s, ultrasoft X-ray spectroscopy has been used actively in studies dealing with the problem of vacant d orbitals. X-Ray emission spectra provide vital information on the electronic structures of complexes; relative energies of all valence MOs and the contributions of the majority of atomic orbitals to them can be found in this way. According to the dipole selection rules, those MOs that contain contributions of the $3s$ and $3d$ orbitals of atoms of the element under investigation ($3s \rightarrow 2p$ and $3d \rightarrow 2p$ transitions) can be manifested in the L -spectra of elements of the Third Period (Cl, S, P, Si, *etc.*).^{55–57} The complete sets of X-ray fluorescence spectra for a large number of chlorine and sulfur compounds have been studied most extensively in this

respect.^{58–63} In the opinions of the researchers cited, these spectra unambiguously indicate that $3d$ orbitals of chlorine and sulfur atoms do contribute to chemical bonds. These and other similar data on ultrasoft X-ray spectroscopy covering a wide range of non-transition element compounds are believed to be indisputable experimental evidence for effective participation of $A3d$ -electrons in chemical bonds.

However, another viewpoint also exists. Analysis of X-ray emission L -spectra of sulfur and chlorine compounds⁶⁴ permits one to distinguish several reasons for the complicated and inconsistent structure of emission CL - and SL -spectra. One of them is decomposition of a substance during recording of the spectrum with both the primary excitation of the spectra by electrons and the secondary excitation by photons. Experimental (emission CL -spectra of ClO_4^-) and theoretical (SCF SW X_α -calculations of ClO_4^-) data confirm that a large fraction of the intensity of the low-energy band in the X-ray emission L -spectrum is due to products of decomposition of ClO_4^- .⁶⁵ It should also be taken into account that under the conditions of recording X-ray emission spectra, interaction of a compound studied with the copper anode surface is possible. Finally, one more reason lies in the fact that in the assignment of spectral bands, the superimposition of short-wave radiation with higher-order reflection on the recorded spectrum (for instance, the sixth order reflection of $L_{\alpha_{1,2}}$ - and L_{β_1} -lines of copper) is not monitored (and, hence, is not taken into account).

The theory of X-ray emission spectra is largely based on the single-electron orbital model. The X-ray lines in a multi-electron system are assumed to be due to a transition between two states having particular electron configurations and described by the Hartree–Fock method. In the one-particle approximation (in the approximation of 'frozen' orbitals) in which the relaxation effects are ignored, the Hartree–Fock orbitals of the ground state of the molecular system under study are used in calculations of excited states. The results of SCF *ab initio* calculations of the fine structures of X-ray emission spectra for SO_2 , CS_2 , SCO and Cl_2 molecules have been reported,⁶⁶ and it has been found that the orbital model has only limited utility for the interpretation of the spectra due to the presence of significant correlation effects. In the $CK\beta$ -spectra of CS_2 and SCO , high-intensity transitions from the lower antibonding molecular orbitals (which are vacant in the ground state) have been detected. To explain the presence of short-wave satellites, the X-ray re-emission mechanism (inelastic non-shifted scattering) has been invoked. Previously, high-intensity short-wave satellites have been found in K - and L -spectra of boron, carbon and sulfur and interpreted as re-emission transitions from excited levels.^{61, 67–69}

Thus, the data of ultrasoft X-ray spectroscopy cannot be regarded as indisputable evidence for the participation of d orbitals of the central atoms in the chemical bonds in complexes of non-transition elements, since experimental results often disagree with one another and their traditional interpretation is incorrect and unambiguous. It is significant that stricter investigations carried out more recently have a different character. The energies and intensities of the X-ray L -emission of the central atom for PO_4^{3-} and ClO_4^- have been measured experimentally and calculated theoretically by the SCF SW X_α method.⁷⁰ The inclusion of $A3d$ orbitals in the basis set improves the agreement between the calculated and measured intensities of lines and energies of X-ray spectral transitions (the transition energies were calculated using the transition state approximation) but has almost no influence on the orbital energies of the PO_4^{3-} and ClO_4^- ground states. This implies that $A3d$ orbitals participate only slightly in their electronic structures. A study of the electronic structure of $POCl_3$ carried out by X-ray and X-ray photoelectron spectroscopy and by SCF MO LCAO, MINDO/3 and SCF SW X_α *ab initio* calculations⁷¹ has shown that the contribution of d orbitals of the phosphorus and chlorine atoms to the occupied valence molecular orbitals of $POCl_3$ is relatively small.

The results of studies on the effect of the chemical shifts of the emission X-ray lines for compounds of non-transition elements do not lead to unambiguous conclusions on the role of *d* orbitals either. The chemical shifts of the emission K_{α_1} - and K_{β_1} -lines of xenon in the X-ray spectra of XeF_2 , XeF_4 , Li_4XeO_6 , NaHXeO_4 and Na_4XeO_6 with respect to similar xenon lines in a hydroquinone clathrate have been measured.⁷² These chemical shifts were compared with the Mössbauer isomer shifts of xenon for the same compounds.¹²⁹ The results were interpreted in terms of the model of valence electron configuration of a free effective ion. X-Ray transition energies and the electron density on the nucleus in this ion were calculated by the Dirac–Slater method. The question of whether the $\text{Xe}5d$ orbitals participate in the bonds with ligands remained open; however, the workers⁷² pointed to the possibility of this participation in the electronic structures of high-valence oxygen compounds of xenon. Analogous results have been obtained somewhat earlier for a number of iodine compounds.^{73, 74}

Based on the most general statements of the MO theory and the perturbation theory, Shustorovich has justified theoretically the fact that *And* orbitals do not make a significant contribution to the valence MOs of complexes of non-transition elements.^{33, 75, 76} An indispensable condition for effective electron interaction between the valence orbitals of the central atom and the ligands is proximity of their orbital energies. In the second order of perturbation theory (for non-degenerate levels), the energy of stabilisation for a bonding MO

$$\varphi = C_A \chi_A + C_L \chi_L,$$

(where C is a variational parameter) is determined by the formula

$$\Delta E_{\text{AL}} \sim \frac{\beta_{\text{AL}}^2}{|\alpha_A - \alpha_L|}, \quad (1)$$

where α_A and α_L are the Coulomb integrals characterising ‘self-consistent’ energies of χ_A and χ_L orbitals (in those approximations of the MO theory in which an effective single-electron Hamiltonian is used), β_{AL} is the resonance integral determining the energy of interaction between the χ_A and χ_L AOs and proportional to the overlap integral S_{AL} . In the atoms of Group IV–VIII non-transition elements, the energies of *nd* orbitals are 10–15 eV higher and the energies of *ns* orbitals are 10–20 eV lower than those of *np* orbitals. This indicates that the contributions of *ns*, *np* and *nd* orbitals of atom A to the bonds with ligands are necessarily inequivalent. In typical cases, the energies of the valence orbitals of ligands are somewhat lower than the energies of the *Anp* orbitals. Therefore, the vacant *And* orbitals prove to be too high-lying for them to interact efficiently with the occupied valence orbitals of ligands. For the same reason, the occupied *Ans*² orbitals are not always able to participate in the bonds with ligands: their energy is often too low compared to those of the valence orbitals of the ligands. Generally, the high *ns*–*np* and *np*–*nd* separation energies for atom A attest to a crucial role of the *Anp* orbitals in the formation of the electronic structure of AL_k complexes and to much smaller contributions of the *Ans*² and, especially, *And* orbitals to the valence MOs. Characteristic properties of coordination compounds of non-transition elements can be calculated without using the *nd* orbitals of the central atom, which act as polarisation corrections for the orbital basis set.^{26, 77–80} As a whole, the general theoretical ideas prove unambiguously that the vacant *And* orbitals make no significant contribution to the valence MOs in the electronic structures of non-transition element complexes; the role of the occupied *Ans*² orbitals is less clear.

While researchers discuss the problem of *d* orbitals (more precisely, when a large contribution of *d* AOs to the electronic structure of a complex is stated *a priori*), they often refer to the symmetry criteria and stress that for any point group of symmetry of an AL_k complex, there are always some orbitals among the *And* AOs that belong to the same irreducible representations as the

valence orbitals of the ligands. Therefore, σ or π interaction of the *And* orbitals with the ligand orbitals is always possible to one or another extent.

Later, this thesis has been made more precise in the following way:⁸¹ the *d* AOs make a real contribution to the electronic structures of complexes in the case where these orbitals, being included in the basis set, form, in conformity with the symmetry properties, new bonding MOs upon interaction with the AOs of the ligands (for example, *e* orbitals in MX_4 or *t*_{2g} and *e*_g in MX_6); otherwise, they should be regarded as polarising corrections. However, firstly, non-empirical calculations show that *d* AOs are by no means always involved in bonds, even when it is possible from the symmetry viewpoint. Secondly, the results of a comparative study of the influence of *d* functions in various calculation versions[‡] imply⁸² that *d* orbitals with appropriate symmetry are not more important than the rest of *d* AOs. Besides, in calculating the electronic structure of the excited state of a molecule, the criterion of symmetry is less significant for the selection of *d* AOs than the optimisation of an additional diffuse *d* AO needed to describe MO of the Rydberg type. Finally, what is the most essential, the allowance for *d* AOs is not necessary for the construction of the appropriate number of MOs in the electronic structure of an AL_k complex of a certain symmetry. For example, when only one *ns* and three *np* orbitals of the central atom are available, one can construct, resorting to the AOs of ligands, six equivalent MOs corresponding to the canonical orbitals (*a*_{1g}, *t*_{1u}, *e*_g) of an octahedral complex; having only three *np* orbitals of the central atom at disposal, one can construct four equivalent MOs corresponding to the canonical orbitals (*a*₁, *t*₂) of a tetrahedral complex.³³ In the former case, the *e*_g MO is a non-bonding ligand orbital, while in the latter case, this refers to the *a*₁ MO.

Thus, since the results of nonempirical calculations of the electronic structures of non-transition element complexes are ambiguous and the interpretation of the ultrasoft X-ray spectroscopy data is by no means irrefragable, it is still an urgent task to describe the general principles of the electronic structures of non-transition element complexes and to answer the basic theoretical question: what valence orbitals of central atoms do participate in the formation of delocalised MOs?

V. X-Ray photoelectron spectra of compounds of non-transition elements

The most significant studies accomplished in recent years reveal the inconsistency of the concept of *d* orbitals. However, the existing theory of the electronic structure of non-transition element complexes is still contradictory in some aspects and lacks inherent unity. Besides, there exists not only the problem of vacant *nd* AOs, but also the problem of occupied *ns*² AOs, and the latter has been quite little investigated until recently. Further development of the theory requires precise experimental studies on the electronic structures of these compounds.

Below we discuss the results of systematic studies of typical complexes of non-transition elements carried out by photo- and X-ray photoelectron spectroscopy, which are now the basic physical methods used to study occupied electron levels in free molecules and crystals.^{83–85} In appropriate points of the discussion, we present data from X-ray emission and Mössbauer spectroscopy, Auger electron spectroscopy and spectroscopy of internal conversion electrons. We include only those experimental results that have been obtained repeatably by various authors and virtually agree with one another, *i.e.* results that can be regarded as final. The discussion material covers compounds of Group IVA–VIIIA elements. The discussion is based in many respects on our own studies in which the parameters of the X-ray photoelectron

[‡] Using *d* functions of the central atom, appropriate from the symmetry viewpoint; with a basis set of the central atom incorporating *d* functions not corresponding to the criterion of symmetry; taking into account the full set of *d* functions in a balanced basis set.

spectra (XPS) of the valence band and inner levels of the central atoms were interpreted for the first time independently of the results of theoretical calculations on the electronic structures of the corresponding complexes. The analysis of line intensities was performed using photoionisation cross-sections and included systematic comparison of relative intensities. In the analysis of the energy positions of the lines, we used the energies of the valence orbitals and the core levels of the corresponding free atoms. As a result of these studies, X-ray electron criteria have been established that make it possible to estimate the degree of participation of vacant nd and occupied ns^2 orbitals of the central atom in the molecular orbitals of the A–L bonds.

1. Vacant And orbitals

To determine the degree to which nd orbitals of the central atom A participate in the valence MOs of non-transition element complexes from the parameters of their X-ray photoelectron spectra, two approaches have been used: analysis of the relative intensities of the XPS valence lines and of the energies of the inner levels of the A atom in these complexes.^{85,86}

At present, there are only a few reviews devoted to the analysis of the XPS of non-transition element compounds.^{85,87} In the majority of cases, the analysis of XPS and the interpretation of the electronic structure of complexes based on it are carried out resorting to the results of the corresponding non-empirical calculations. Most of these coordinated investigations seem to support the view on the considerable contribution of And orbitals to the electronic structure of complexes. This relates, first of all, to the most studied series of isoelectronic tetraoxo-anions,^{85,87,88} ClO_4^- , SO_4^{2-} , PO_4^{3-} and even to xenon fluorides.^{89,90}

However, apparently, the conclusions about the large contributions of d AOs based on the analysis of XPS are not quite correct. This is indicated not only by the fact that the results of some SCF calculations are in excellent agreement with XPS even without allowance for d AOs.

In fact, the valence XPS of tetrahedral oxo-anions ClO_4^- , SO_4^{2-} and PO_4^{3-} and many other oxo-anions^{85,87,91,92} contain identical numbers of bands and are quite similar to one another in the positions of bands and in their relative intensities. A typical example is provided by the X-ray photoelectron spectrum of the ClO_4^- , which is shown in Fig. 1a. In this spectrum, the two upper bands corresponding to the $1t_1$ and $3t_2$ MOs with the same electron population ($6e^-$) are close in energy and have almost

identical intensities. This means that these MOs consist of only $2p_\pi$ orbitals of the oxygen atoms, and there is scarcely any significant contribution of the And orbitals to the $3t_2$ MO (the contribution of And AOs to the $1t_1$ MO is forbidden from the symmetry viewpoint). Otherwise, the relative intensities of the two bands under consideration would have been markedly dissimilar owing to the different photoionisation cross-section of the nd levels of the atom A and the $2p$ levels of the oxygen atoms.

Analysis of the intensities of the two next bands corresponding to the $1e$ ($4e^-$) and $2t_2$ ($6e^-$) molecular orbitals does not permit one to distinguish unambiguously between the absence or the presence of a contribution from the And orbitals to these valence MOs, because this contribution is, in principle, allowed from the symmetry viewpoint for both $1e$ and $2t_2$ MOs composed of the $\text{Cl}3p$ and $\text{O}2p$ orbitals. However, the high intensity of these bands suggests that the And orbitals do not make any significant contribution with low ionisation cross-sections to them. In addition, the $1e$ and $2t_2$ MOs lie lower in energy than the $1t_1$ and $3t_2$ molecular orbitals and, therefore, a contribution of the fairly high-lying And orbitals to the $1e$ and $2t_2$ MOs is even less likely than their contribution to the $1t_1$ - and $3t_2$ MO, which contain no And AOs.

Further evidence for the absence of a contribution of the And orbitals to the valence MOs of the AO_4^{n-} oxo-anion is the fact that the structure of the upper energy bands in the valence XPS of tetrahedral oxo-complexes of transition metals MO_4^{n-} is absolutely different. The latter are isostructural and isoelectronic with AO_4^{n-} .^{85,87,91,92} The electronic structures of the M–L bonds in the oxo-complexes are described with allowance for the valence ns^2 and $(n-1)d$ orbitals of the central atoms M (Fig. 1b,c).

Similar conclusions can be drawn from the results of X-ray photoelectron studies of some other complexes of non-transition elements.^{93–97} A specific place in this series of studies is occupied by the study of Siegbahn,⁹⁷ who carried out a detailed analysis of the intensities of lines in the valence photoelectron spectra of SF_6 recorded with various types of ionising radiation (He-I, He-II) and concluded that the spectral parameters would have been different if the $3d$ orbitals of the sulfur atoms had played a significant role.

Thus, the intensities of XPS valence bands indicate that there is no $And_{\sigma,\pi} \leftarrow Lnp_{\sigma,\pi}$ donor-acceptor interactions involving vacant And orbitals in the electronic structures of non-transition element complexes. This was shown, for example, in the studies of SO_4^{2-} (without $\text{S}3d_\pi \leftarrow \text{O}2p_\pi$) or SF_6 (without $\text{S}3d_\sigma \leftarrow \text{F}2p_\sigma$), although from the viewpoint of the d orbital concept, the XPS studies should have revealed the participation of the nd orbitals of the central atom in the formation of delocalised valence MOs of the complexes.

Another X-ray electron confirmation of the fact that vacant And orbitals do not participate in the A–L bonds is the character of dependence of the energies of inner levels of the central atom A on its oxidation state (formal valence) in the complexes.

Based on the results of a systematic study of the X-ray photoelectron spectra of the inner levels of central atoms in many complexes of non-transition elements, it has been shown⁸⁶ for the first time that the variation of the energy and of the chemical shift of some inner level of atom A in a series of compounds formed by this element follow a linear dependence on its formal valence. For series including numerous compounds of a non-transition element, starting from the Third Period, for example, $\text{NaCl} - \text{NaClO}_4$ ($\text{Cl}2p_{3/2}$), $\text{KBr} - \text{NaBrO}_4$ ($\text{Br}3d_{5/2}$), $\text{KI} - \text{KIO}_4$ ($\text{I}4d_{5/2}$), $\text{CdS} - \text{Na}_2\text{SO}_4$ ($\text{S}2p_{3/2}$), $\text{CdSe} - \text{Na}_2\text{SeO}_4$ ($\text{Se}3d_{5/2}$), $\text{CdTe} - \text{H}_6\text{TeO}_6$ ($\text{Te}4d_{5/2}$, $\text{Te}3d_{5/2}$), no substantial deviations from linearity for the correlations: ‘energy of an inner level of A – the oxidation number of A’ have been found (Fig. 2). When the chemical shifts were calculated from the experimental E_b values, the binding energy of the inner level of the central atom in its compound with the lowest oxidation state is taken as the zero point. The results obtained for all the systems studied are alike: the binding energy and the chemical shift of the inner level of atom A increase linearly with increase in its oxidation number. Moreover,

Figure 1. Valence band X-ray photoelectron spectra of tetrahedral tetraoxo-anions ClO_4^- (a), AO_4^{n-} (b), MO_4^{n-} (c). For numbers I–VI, see the text.

Figure 2. Chemical shifts for inner levels of atoms A as functions of their oxidation numbers.

a: N1s_{1/2} (1); Cl2p_{3/2} (2); Xe3d_{5/2} (3); b: S2p_{3/2} (1); Te3d_{5/2}; Te4d_{5/2} (3)

this 'linear effect' does not depend on the type of the inner level of the atom A (for example, Te3d_{5/2} and Te4d_{5/2}, Fig. 2).

This linearity was explained⁸⁶ as resulting from the low contribution of vacant *And* orbitals to the valence MOs of A–L bonds. Indeed, participation of vacant *nd* orbitals of the atom A in bonds with ligands (for example, with the 2*p* AO of oxygen in oxo-complexes) is possible only through a donor-acceptor mechanism with transfer of the valence electron charge from the occupied orbitals of ligands to the vacant *nd* orbitals of the atom A (*And* ← *Lnp*, 0:2), and this should have led to a relative increase in the electron charge on the atom A, to the corresponding decrease in the binding energy of its inner level, and to a deviation from the linear dependence described above up to its disappearance. This is why the 'linear effect' implies that the virtual *nd* orbitals of the central atom almost do not participate in the bonds with ligands in compounds of phosphorus, arsenic, antimony, sulfur, selenium, tellurium, chlorine, bromine, and iodine, *i.e.* of typical non-transition element of the Third Period and subsequent Periods. This conclusion is also strongly supported by the following facts. Firstly, the linear correlation between the binding energy and the chemical shift of the inner energy level of anion A holds for those compounds of a non-transition element, the electronic structures of which are known to contain no contribution of the *And* orbitals (Na₂S, CdS, S, see Fig. 2) and is extended in the same form to its compounds with high oxidation states (Na₂SO₃, Na₂SO₄) in which the concept of *d* orbitals suggests effective participation of *And* orbitals in the A–L bonds. Secondly, a similar linear dependence is also observed for nitrides and nitrogen oxo-complexes as well as for xenon

fluorides (see Fig. 2)^{98,99} in which the absence of any contribution of *nd* orbitals of the central atom to the bonds with ligands is beyond any doubt. Thirdly, in the series of coordination compounds of transition metals in which all the valence orbitals of the central atom including *M*(*n*–1)*d* AOs can participate in M–L bonds, the dependences of the inner level energies of the atom M on its oxidation state are complicated and non-linear; in this case, there is no linear correlation (or any other correlation, up to the 'star sky'), owing to the differences in the relative roles of the covalent M–L, donor-acceptor M ← L and dative M → L bonds in each particular ML_k compound.

2. Occupied *Ans*² orbitals with *n* ≥ 3

The problem of participation of *Ans*² AOs in A–L bonds in non-transition element complexes can be solved by studying their valence X-ray photoelectron spectra. For this purpose, one should find out whether the band of the quasiatomic *Ans*² level is retained in the spectrum or is missing due to the involvement of the *Ans*² orbitals in valence delocalised MOs of the complex.

Fig. 1 shows the typical valence X-ray photoelectron spectra for tetraoxo-complexes of non-transition elements AO₄^{m–} and transition metals MO₄^{m–} obtained for A = Cl, Br, I, S, Se, Te, As and M = V, Cr, Mn, Mo, W, Re.^{87,91,92} The traditional interpretation^{87,91} of the valence XPS of an AO₄^{m–} or MO₄^{m–} complex (*i.e.* the assignment of the bands to particular MO of the complex) is based on the results of semiempirical and non-empirical quantum-chemical calculations for the electronic structures of tetrahedral oxo-anions. In the spectrum of AO₄^{m–} (see Fig. 1b), high-energy bands I and II were assigned to the atomic O2s² levels (the 1a₁ and 1t₂ MO), bands III and IV were attributed to the 2a₁, 2t₂, and 1e molecular orbitals of the A–O σ-bonds formed upon interaction of the valence *Ans*, *Anp*, *And*, and O2*p* orbitals; finally, bands V and VI were assigned to the non-bonding O2*p*_π levels (the 3t₂ and 1e MOs, poorly resolved in energy). This assignment provokes serious objections for a number of reasons.⁹²

Firstly, the valence spectra of isoelectronic and isostructural (*T_d*) AO₄^{m–} and MO₄^{m–} tetraoxo-anions are absolutely different, and this is natural, because the valence electronic configurations of the central atoms A and M are different. However, within the region of O2s² levels, one should expect (from the viewpoint of the above interpretation) that the forms and energies of the X-ray photoelectron bands would be fairly similar if not completely alike. However, there is no similarity (Tables 1 and 2). The O2s-lines in the spectra of MO₄^{m–} are highly symmetrical (the asymmetry index is close to unity) and have virtually identical energies irrespective of the nature of the central atom. This means that in the MO₄^{m–} tetrahedral anions, the O2s² levels and the corresponding 1a₁ and 1t₂ MOs are very close in energy (the splitting energy Δ = 1–2 eV), which is in full agreement with the results of *ab initio* calculations¹⁰⁰ for the electronic structure of MO₄^{m–}. According to these calculations, the O2s²-electrons are quasiatomic and are not involved in the formation of bonds with the central atom. At the same time, in the spectra of AO₄^{m–}, the two bands with higher

Note. The following designations are used: I is the energy of a line /eV; II is the line width at the basis /eV; III is the width at the half-height /eV; IV is the asymmetry index.

energies, which are assigned traditionally to the quasiautomic O2s² levels, have much more complex shapes. In conformity with the generally accepted views, the splitting energies for the 1a₁ and 1t₂ MOs calculated from the XPS parameters are relatively large ($\Delta = 5\text{--}6\text{ eV}$; in the case of ClO₄⁻, $\Delta = 7.4\text{ eV}$) and this is at variance with the low energy of splitting of the O2s² levels in MO₄^{m-}.

Secondly, if bands *I* and *II* (see Fig. 1b) were actually due to the O2s² levels in conformity with the generally accepted interpretation, the ratio of their intensities would be 1 : 3, since the ionisation cross-sections for the 1a₁ (2e⁻) and 1t₂ (6e⁻) O2s² levels are virtually identical (because their energies are close) and the ratio of their intensities is determined only by their electron populations, *i.e.* it is 1 : 3. However, in all valence XPS of the AO₄^{m-} complexes without exception, the ratio of the intensities of lines *I* and *II* is markedly larger and ranges from 0.5 to 0.7 (instead of the expected 0.33).

Thirdly, the energies of the O2s² levels in the MO₄^{m-} complexes are close to those of the O2s² level in the free oxygen atom (the vertical line at 28.5 eV in Fig. 1). If band *I* in the spectrum of AO₄^{m-} is attributed to the O2s² level, it is impossible to explain its substantial stabilisation, taking into account the negative effective charge on the oxygen atoms in AO₄^{m-} (as well as in MO₄^{m-}). The situation can hardly be saved by referring to the stabilisation by the crystal field of the positively charged cations (K) in the crystal structure of K_mAO₄ (in this case, this stabilisation would be also manifested in K_mMO₄).

The detailed analysis of the intensities and energies of the two bands with the highest energies (*I* and *II*) in valence XPS of AO₄^{m-} shows⁹² that the former band corresponds to the quasiautomic ns² level of the central atom A, which is not involved in the valence delocalised MOs and hardly participates in the bonds of the atom A with ligands; the latter band, like the corresponding band in the spectra of transition metal tetraoxo-anions, is due to the quasiautomic 2s² levels of the oxygen atoms (2a₁ and 1t₂ MOs). This interpretation (see Fig. 1a) eliminates simultaneously all the contradictions mentioned above and makes it possible to understand the characteristic features of the X-ray photoelectron spectra and the essential difference between these spectra of isostructural and isoelectronic tetraoxo-anions of non-transition elements and transition metals.

In fact, since the electronegativity of oxygen is higher than that of the central atom in the AO₄^{m-} complex (as well as in other oxo-complexes of non-transition elements and transition metals), a positive effective charge appears on the central atom and a negative charge appears on oxygen (it is also necessary to take into account the negative charges of the AO₄^{m-} and MO₄^{m-} anions themselves). This results in stabilisation of quasiautomic An_s² orbitals with respect to those in the free atom A and in destabilisation (to a markedly lesser degree) of the quasiautomic O2s² levels with respect to those in free oxygen atoms (Fig. 3a). This is why the highest-energy (~35 eV) band *I* in the valence XPS of AO₄^{m-} cannot belong to the O2s² levels but represents the quasiautomic ns² orbital of the central atom A, which is markedly stabilised (by 7–

**Figure 3.** Changes in the energy of quasiautomic orbitals upon the formation of oxo-complexes of a non-transition element (*a*) and a transition metal (*b*).

10 eV) with respect to the ns² orbitals of the free atom A. The same energy of stabilisation (up to 10 eV) of both the core and quasiautomic valence orbitals of the central atom A upon the formation of higher complexes has been pointed out by Siegbahn,^{83,84,97} based on the analysis of the parameters of numerous X-ray photoelectron spectra.

The energy separating bands *I* and *II* in the valence spectrum of AO₄^{m-}, which has earlier been regarded as the energy of splitting of the 1a₁ and 1t₂ O2s² levels, is actually the difference between the energies of the quasiautomic An_s² orbital and the O2s² levels and can vary over wide limits depending on the individual nature of the atom A (on the energy of the ns² orbitals in the free atom A) and on its formal valence.

Now we make an important comment. Whereas in the oxo-complexes of non-transition elements AO₄^{m-}, the quasiautomic ns² orbital possesses the greatest binding energy in the valence band, in the case of fluorides AF_k^{m-}, it is the F2s² levels that are characterised by the greatest binding energy in the valence band. This is due to the fact that the energy of the 2s² orbital of F is much greater (37.8 eV) than that of the 2s² orbital of O (28.5 eV); therefore, the quasiautomic An_s² orbital, which is highly stabilised in the electronic structure of the fluorides AF_k^{m-}, cannot 'outrun' in energy the F2s² levels, which are somewhat destabilised. Therefore, in the valence XPS of both MF_k^{m-} and AF_k^{m-}, the lines with the highest energies correspond to the F2s² levels.

The valence ns² orbitals of the central atom in the electronic structure of MO₄^{m-} (unlike those in AO₄^{m-}) are incorporated in the valence MOs (their energies being markedly higher than those of the O2s states) and thus participate efficiently in the M–L bonds. Therefore, the quasiautomic 2s² levels of oxygen have the greatest binding energies (Fig. 3b) in the valence band and, hence, the valence XPS of a MO₄^{m-} complex does not and cannot contain a band similar to band *I* in the spectrum of AO₄^{m-}.

The degree of ionicity of bonds and consequently the effective negative charge on the ligands in MO₄^{m-} are higher than those in isoelectronic AO₄^{m-} complexes, since the electronegativities of atoms M are markedly lower than those of A. Therefore, one can expect that the O2s-line in the valence XPS of MO₄^{m-} should be destabilised (with respect to 28.5 eV) to a greater extent than that in the case of AO₄^{m-}. Experimental studies (Fig. 1) have completely confirmed this assumption.

The ratio of intensities of lines *I* and *II* (see Fig. 1b) in the valence spectrum (if the former is assigned to the An_s² state) should not be equal to 0.33, but should vary, as is actually observed in experiments, depending on the nature of the central atom A (Cl, Br, I, S, Se, P, or As), on the corresponding changes in the ionisation cross-sections¹⁰¹ of the valence ns² levels of these atoms and on the integral intensity of band *I*, if the ionisation cross-section of the O2s² level and the integral intensity of band *II* corresponding to it are constant.

The energies of the ns^2 orbitals of the central atoms A in the series $\text{ClO}_4^- - \text{BrO}_4^- - \text{IO}_4^-$, $\text{ClO}_4^- - \text{SO}_4^{2-} - \text{PO}_4^{3-}$, *etc.* depend on the electron populations (effective charges) of atoms A; the latter, in turn, are determined by the chemical individuality of the particular atom A, *i.e.* by the energy of ns^2 AOs in the free atom and by the orbital electronegativity. The energy of an ns^2 AO is also influenced by the total electrostatic charge of the complex, by the difference between the orbital electronegativities of the central atom and the ligands and by some other factors. In addition, according to the interpretation being developed, the energies of the $\text{O}2s^2$ levels vary in the same series. In particular, in the series $\text{ClO}_4^- - \text{SO}_4^{2-} - \text{PO}_4^{3-}$ and $\text{BrO}_4^- - \text{SeO}_4^{2-} - \text{AsO}_4^{3-}$, the energy of stabilisation of the Ans^2 level increases with respect to the ns^2 energy in the free atom A; this corresponds to a decrease in the total charge on atoms A in these series due to the decrease in the ns and np orbital ionisation potentials of A. The destabilisation of the quasiatomic $\text{O}2s^2$ and $\text{O}2p^2$ levels in relation to their energies in a free oxygen atom increases in the same series; this is due to the increase in the valence electron density on the oxygen atoms in AO_4^{m-} . Similar regularities caused by the same reasons are observed in the series $\text{ClO}_4^- - \text{BrO}_4^- - \text{IO}_4^-$ and in analogous series of tetraoxo-anions of sulfur, selenium, phosphorus, arsenic, *etc.*

This new interpretation of valence XPS of oxo-complexes of non-transition elements is versatile and covers not only AO_4^{m-} tetraoxo-anions but also the rest of known oxo-complexes with different numbers of coordinated oxygen atoms, with another symmetry, *etc.* In this case, additional arguments supporting this interpretation appear.

Firstly, the quasiatomic nature of Ans^2 AOs is confirmed by the fact that the intensity of a particular line in valence XPS of compounds of the same non-transition element is almost the same; this is also true for those compounds in which the Ans^2 orbitals are known not to participate in A–L bonds, for example in the $\text{ClO}_4^- - \text{ClO}_3^- - \text{ClO}_2^- - \text{ClO}^- - \text{Cl}$ series. If an Ans^2 orbital did participate in A–L bonds, the intensity of the Ans^2 -line (normalised with respect to a certain core level) would not remain constant irrespective of the structure of the oxo-complexes, owing to different degrees of mixing of Ans^2 and $\text{O}2p$ orbitals in the valence MOs.

Secondly, as the number of coordinated oxygen atoms in an oxo-complex decreases, the ratio of the intensities of Ans^2 - and $\text{O}2s^2$ -lines in its valence spectrum increases proportionately. This type of behaviour is characteristic only of quasiatomic electron levels.

Thirdly, if the line with the highest binding energy in valence X-ray photoelectron spectra of oxo-anions and other complexes of a non-transition element actually corresponds to a quasiatomic Ans^2 state, then the energy of this level, like that of any inner level, should increase linearly following an increase in the oxidation state of the atom A. Besides, the 'sensitivity' of the binding energy of a quasiatomic Ans^2 level to the number of ligands with a higher electronegativity (oxygen atoms in this particular case) coordinated to it should be higher than that of other inner levels of the atom A with the same symmetry. In other words, it should be expected that the rate of increase in the ns level binding energy will be higher than those for $(n-1)s$, $(n-2)s$, *etc.* levels in the series of compounds with increasing oxidation state of the central atom, because the ns level is the most outer level among those considered. In the valence XPS of chromium, sulfur, selenium, and arsenic compounds with various oxidation states, the binding energies for ns^2 levels of atoms A have been determined. This is illustrated by Fig. 4, which shows, as an example, the dependence of the chemical shift of the $\text{Cl}3s^2$ level on the oxidation state of chlorine. Moreover, this Figure contains analogous relationships for the chemical shifts of the $K(1s)$ and $L(2s)$ levels of chlorine based on the data of Siegbahn.⁸⁴ It can be seen that the binding energy of the $\text{Cl}3s^2$ level actually increases linearly with an increase in the oxidation number of chlorine atoms, the rate of its growth being much greater than those for the energies of core levels.

The fact that the energies of the valence ns^2 levels of central atoms A behave in the same way as the core $1s^2$ and $2s^2$ levels (as

Figure 4. Dependence of the chemical shifts of $\text{Cl}ns^2$ levels on the oxidation number of the chlorine atom.

(1) $\text{Cl}3s$, (2) $\text{Cl}1s$, (3) $\text{Cl}2s$.

regards a nearly linear variation of their energies as functions of the formal valence of the atom A) seems very important for the solution of the problem of participation of Ans^2 orbitals in the formation of the electronic structure of a non-transition element complex. According to the generally accepted views, only valence-inactive quasiatomic electron levels behave in this manner.

Thus, the analysis of the parameters (energies and line intensities) of valence band X-ray photoelectron spectra of oxo-complexes of non-transition elements of the Third and subsequent Periods (especially, comparison of these parameters with those for oxo-complexes of transition metals) leads to the following conclusion: the occupied ns^2 orbitals of the central atom in AO_k^{m-} , unlike those in MO_k^{m-} , are involved in bonds with ligands to only a small extent. The Ans^2 -electrons remain quasiatomic and are markedly stabilised compared to the corresponding electrons in free atoms.

Further X-ray-electron evidence for the valence inactivity of the occupied Ans^2 orbitals is the linear dependence of the inner level energy of the central atom on its formal valence, which has been considered above.⁸⁶ In fact, the occupied ns^2 orbitals of the central atom A could participate in two-centre two-electron (covalent) bonds with ligands by the dative mechanism, $\text{Ans}^2 \rightarrow \text{L}np$ (2:0) due to the vacant valence orbitals of the ligands or by forming three-centre four-electron (hypervalent) $\text{L}_{(1)}np \leftarrow \text{Ans}^2 \rightarrow \text{L}_{(2)}np$ bonds due to the valence orbitals of the ligands with unpaired electrons. In both cases, this would be accompanied by the transfer of electronic charge from the central atom to the ligands, a decrease in the electronic charge on atom A, a corresponding increase in the binding energy of its inner level and by the disturbance of the linearity discussed above. This is due to the fact that, since the penetration ability of the ns orbitals in atom A is higher than that of the np orbitals, their participation in the bonds with ligands should 'uncover' the nucleus of the atom A to a greater extent and, in conformity with the effect of internal shielding, this should stabilise more efficiently the core levels of the atom A. The linear variation mentioned above of the binding energy of the $\text{Xe}5d_{5/2}$ level in the series of xenon fluorides is spectacular in this respect. It is almost obvious that not only the $\text{Xe}5d$ AOs do not participate in the electronic structure of xenon fluoride, but the occupied $\text{Xe}5s^2$ orbitals [$\sigma_g(\text{XeF}_2, D_{\infty h}$ symmetry), $a_{1g}(\text{XeF}_4, D_{4h}$ symmetry), $a_{1g}(\text{XeF}_6, O_h$ symmetry)] also remain quasiatomic^{89,90} and refer to fully symmetrical irreducible representations; the hypervalent bonds $\text{F}-\text{Xe}-\text{F}$ involve only the valence $5p$ orbitals of the xenon atom.

In general, the 'linear effect' indicates that the vacant And and occupied Ans^2 orbitals of the central atom A do not make any significant contribution to the A–L bonds and that these bonds are formed via consecutive involvement of valence orbitals of the atom A of only one type, namely, the np AOs. The linear increase in the energy of the inner level is due to the variation in the quantitative characteristics of the participation of np -electrons in the bonds with ligands following the change in the oxidation state of the central atom A. In the electronic structures of AL_k complexes,

the *And* orbitals remain virtual, while the occupied *Ans*² orbitals prove, as a rule, to be valence-inactive and remain quasiatomic.

Thus, taking into account the differences in the shielding effects, in the penetration ability, in single-electron energies, and in the electronegativities of valence *ns*, *np*, and *nd* orbitals of the atom A, one can conclude that if the *And* and (or) *Ans*² orbitals did really participate in the A–L bonds, the linear dependence of binding energy (*E*_b) of the inner level of the atom A on its oxidation state would be necessarily violated. Experimental evidence for the fact that the dependence of *E*_b of the inner levels always deviates from linearity when *Ans*² orbitals are effectively involved in the valence MOs will be presented below. Analogous facts concerning *And* orbitals have not yet been found, but SCF MO LCAO *ab initio* calculations of the electronic structures of the ClO₄[−], SO₄^{2−}, and PO₄^{3−} oxo-anions²⁶ indicate that when the A3*d* functions are included in the atomic basis set, the effective charge on the central atom A sharply decreases compared to that obtained for a purely *sp* basis set (for example, from +2.4 to +0.8 for Cl in ClO₄[−]). Therefore, the electron density on the atom A increases, and this should markedly diminish the binding energy of its inner levels, *i.e.* should result in abnormal values of *E*_b, deviating from the linear dependence.

The present concept of small contribution of the valence *Ans*² orbitals to the MOs of A–L bonds has also been supported in other experimental and theoretical studies, which are yet few in number. The results of HFR non-empirical calculations^{26,88} show that in the electronic structures of ClO₄[−], SO₄^{2−}, PO₄^{3−} and ClO₃[−] oxo-complexes, the A3*s*² orbitals make the major contribution to the lowest valence MO (thus, it is not a pure O2*s*² level) rather than to those MOs, which are located above the O2*s*² energy levels and are responsible for the A–L bonds. In the X-ray emission SL-spectra of sulfur compounds, the parameters of the high-intensity long-wavelength band reflecting the transition from the lowest valence MO of the complex imply that this MO is mostly S3*s*² rather than O2*s*². The data of Mössbauer spectroscopy are more difficult to interpret. The results of examination of the Mössbauer spectra (and the chemical shifts therein) of numerous compounds of antimony, tellurium, iodine, xenon do not permit unambiguous conclusions to be made on the participation of valence *Ans*² orbitals in the A–L bonds.¹⁰²

The views about a minor role of valence *Ans*² AO in the bonds with ligands are applicable to many compounds of non-transition elements of the Third and subsequent Periods but certainly, not to all of them.

Let us first consider complexes of non-transition elements of the second halves of the rows, *i.e.* Group V–VII elements: P, S, Cl, Ar (the so called late *p*-elements), and their analogues. Experimental results and general theoretical considerations based on the *ns* and *np* orbital energies and on the energies of (*np*–*ns*)-separation for free atoms A¹⁰ make it possible to draw the following significant conclusion: the valence activity of A3*s*², A4*s*², and, especially, A6*s*² orbitals is low (the inert pair effect¹⁰). For atoms of Group VII and VI non-transition elements, both the energies of (*np*–*ns*)-separation (~10–15 eV) and the ionisation potentials of *ns* and *np* orbitals are high; this rules out the donor capacity of these atoms and thus predetermines the valence inactivity of their *ns*² orbitals. In the case of the phosphorus atom and its analogues (Group V), the energies of (*np*–*ns*)-separation are no longer large (3–7 eV), but the *ns*- and *np*-orbital ionisation potentials are still high. The latter factor proves to be the crucial factor that restricts the participation of the *Ans*² orbitals in bonds with ligands.

The valence 5*s*² orbitals of antimony, tellurium, iodine and xenon atoms participate most likely in bonds with ligands. The (*np*–*ns*)-separation energies in their subgroups are the lowest.¹⁰ First of all, precise studies are needed for the electronic structures of their complexes with large coordination numbers such as [Sb(OH)₆][−], TeF₆, H₆TeO₆, IF₇, H₅IO₆, XeF₆^{2−}, [H₂XeO₆]^{2−}, *etc.* Some data on this topic have been already reported. Both the internal conversion electron spectra and XPS of Ag₆TeO₆

attest¹⁰³ to the direct participation of the Te5*s*²-electrons in the formation of bonds (whereas in TeO₂, the bonds are formed only through the 5*p*-electrons of Te). The valence XPS of Ag₆TeO₆ contains no Te5*s*²-line, which is present in the XPS of TeO₂. However, in the interpretation of the valence XPS of complexes of the Ag₆TeO₆ type, there is a risk of taking the absence of the *Ans*²-band as direct evidence for the participation of the *Ans*² orbital in the bonds with ligands, whereas this AO can be destabilised (due to changes in the valence electron density distribution or in the internal shielding) and thus, it can be masked by normal valence MOs having close energies, even though it remains a non-valence quasiatomic orbital.

Nevertheless, the actual participation of *Ans*² orbitals in the valence MOs forming the A–L bonds in some complexes seems more likely. In this case, the formation of dative (2:0) *Ans*² → L bonds or three-centre four-electron L₍₁₎ ← *Ans*² → L₍₂₎ hypervalent bonds is possible. In any case, the effective participation of valence *Ans*² orbitals in binding with ligands seems to be feasible only when a number of conditions are fulfilled. The main conditions are sufficient electron-donating capacity of the central atom A (which can be increased, for example, by the formation of primary A–L bonds involving the valence *Anp*-electrons) and large electron-accepting capacity of the ligands, up to the presence in their valence structures of vacant orbitals with low energies capable of participating in dative two-electron *Ans*² → L interactions. It is evident that high oxidation numbers and high coordination numbers of atom A are favourable for the involvement of its *Ans*² orbitals in the valence MOs.

In the case of complexes of early non-transition elements (Na, Mg, Al, Si, and their analogues), the traditional statement that their valence *Ans*¹ and *Ans*² orbitals are completely (in the majority of cases) involved in covalent bonds with ligands is beyond any doubt. These atoms are characterised by fairly low energies of the (*np*–*ns*)-separation¹⁰ and by relatively low excitation energies of valence states¹⁶

3. Occupied A2*s*² orbitals

A special position in the theory of the electronic structure of complexes of non-transition elements is occupied by elements of the Second Period. This is due to the specific spatial and energy characteristics of the valence 2*s* and 2*p* orbitals of their atoms. ‘The valence behaviour’ of the 2*s*² orbitals of atoms of the Second Period elements requires special investigation. To solve the problem of the contribution of the occupied valence 2*s*² orbitals of atoms of these elements to delocalised MOs, the X-ray photoelectron spectra of the inner atomic levels and the valence bands of nitrogen compounds with various formal valences of the nitrogen atom have been studied. Based on the results obtained, conditions of effective participation of the valence 2*s*² orbitals of the central atoms in bonds with ligands have been identified.^{104,105} The energies of the N1*s* and N2*s* levels in nitrogen compounds needed for further discussion are listed in Table 3.

Study of the effects of chemical shift of the inner 1*s* level in X-ray photoelectron spectra of nitrogen compounds demonstrates, first of all, that, in a number of its compounds, the dependence of the binding energy of the N1*s* level on the nitrogen oxidation state is nearly linear (Fig. 5). When the oxidation number of nitrogen increases by unity, the binding energy of the N1*s* level increases by ~1 eV, as has also been noticed in other studies.^{106–108} The fact that this dependence is linear implies that in these compounds, the valence 2*s*² orbitals of nitrogen atoms barely participate in the bonds with ligands (in the formation of delocalised MOs) and that the N2*s*²-electrons remain quasiatomic.⁹² The chemical bonds in nitrates, nitrites, cyanides, thiocyanates and nitrides are mainly formed from the valence 2*p*-electrons of the nitrogen atoms, the 2*s*²-electrons being inactive.

At the same time, for some lower compounds of nitrogen (NH₄⁺, N₂H₆²⁺, NH₃OH⁺), the plots for *E*_{N1*s*} deviate markedly from linearity (see Fig. 5). These deviations exceed the error in the determination of the N1*s*-energy by a factor of ten. In particular,

Table 3. Energies of inner N1s levels and valence N2s levels in nitrogen compounds.

^a The N1s-level energies were taken from Refs 106 and 107 and scaled to the binding energy of the Cls-level, equal to 284.5 eV. ^b The N2s-level energy was not measured.

the average energy of the N1s level in the ammonium cation (401.5 eV) is much greater than that in solid ammonia (398.3 eV) or in other compounds of nitrogen with the same (−3) oxidation number. The energy of the N1s level in NH₃ is determined by the effective charge on the nitrogen atom, which appears owing to the

**Figure 5.** Energy of the N1s level as a function of the oxidation number of the nitrogen atom.

non-zero degree of ionicity of the three covalent (1:1) N–H bonds involving the unpaired 2p-electrons of the nitrogen atom and the 1s-electrons of the hydrogen atoms. The formation of an NH₄⁺ tetrahedral cation via protonation of an NH₃ molecule is possible only when the fourth N–H bond is formed by a dative mechanism (2:0), due to the transfer of electron density from the quasiatomic 2s² orbital of the nitrogen atom to the vacant 1s orbital of H⁺. Thus, the valence electron density on the nitrogen atom decreases, and its effective charge becomes positive; as a result, the inner N1s level (in NH₄⁺) is stabilised. This fact can be detected experimentally: on passing from solid ammonia (398.3 eV) to the ammonium cation (401.5 eV), the binding energy of the N1s level increases by 3.2 eV.

It is this participation of the 2s²-electrons of nitrogen in the formation of the N–H bonds in NH₄⁺ that accounts for the fact that the *E*_{N1s} value for the NH₄⁺ ion is abnormally high, taking into account the clear-cut decrease in the binding energy of the N1s level following the decrease in the oxidation number of nitrogen (from nitrates and nitrites to NH₃, nitrides, cyanides and thiocyanates), and does not fit the linear dependence. It is obvious that the same fact leads to the abnormally large chemical shifts and to the deviations from the linear dependence of the N1s binding energy on the oxidation state of nitrogen in the case of hydrazinium (N₂H₆²⁺) and hydroxylammonium (NH₃OH⁺) compounds and for the central bridging nitrogen atom in the azide anion N₃[−]. The deviation from linearity can be different in each particular case, since it depends on the type and the number of ligands bound to nitrogen, on the nature of partners of the nitrogen-containing complex in a crystal, *etc.*

Certainly, in solid ammonia, too, some participation of the 2s²-electrons of the nitrogen atom in the formation of hydrogen bonds cannot be ruled out completely; therefore, the binding energy of the N1s level in solid NH₃ exceeds somewhat the corresponding value for nitrides, thiocyanates and cyanides. The coordination of NH₃ molecules to transition metal atoms M, *i.e.* the formation of dative M ← NH₃ (2:0) σ-bonds through the 2s²-electrons of nitrogen atoms and vacant orbitals of M atoms in ammine complexes, stabilises the inner N1s levels in these complexes with respect to those in free NH₃ molecules (or in the molecules, weakly associated in the solid state). Therefore, the binding energy of the N1s level in ammine complexes is greater than that in solid NH₃; it increases as the M ← NH₃ bonds strengthens, approaching the value characteristic of the ammonium cation.

The dissimilar roles of the N2s²-electrons in the structures of N₂H₄–N₂H₅⁺, N₂H₆²⁺ and NH₂OH–[NH₃OH]⁺ can be explained by analogy with the NH₃–NH₄⁺ pair.

The deviations from linearity of the dependence of the *E*_{N1s} binding energy on the oxidation state of the nitrogen atom for some of its compounds not only indicate that the valence 2s² orbitals of nitrogen atoms participate in delocalised MOs. Besides, it can serve as additional evidence for the fact that the linearity itself in the change of the energy of the inner level of the central atom actually shows the absence of a significant contribution of the valence *ns*² AOs of atoms of non-transition elements to the chemical bonds in the corresponding complexes⁹² and the participation of only valence *np*-electrons of the central atom in the bonds with ligands. The involvement in the A–L bonds of orbitals with a different symmetry (*ns*) and with a qualitatively different spatial distribution results in sharp deviations from linearity; this is actually observed for the *E*_{N1s} binding energy in the series of nitrogen-containing compounds.

The second X-ray photoelectron criterion for the participation (or non-participation) of the 2s²-electrons of the central atom in the A–L bonds is the presence or the absence of the N2s-line in the valence XPS of nitrogen compounds and the appropriate shifting effects. In fact, the XPS of those compounds, the *Ans*-electrons of which knowingly participate in A–L bonds, contain no *Ans*-lines in the valence band (compounds of Na, Mg, *etc.*). Fig. 6 shows the valence band of the X-ray photoelectron spectra of typical nitro-

gen-containing compounds: nitrates, nitrites, ammonium cations and some others. Of course, the $\text{N}2s$ -line is present in the spectra of all those compounds of nitrogen in which its valence $2s^2$ -electrons do not participate in bonds with ligands and remain quasiatomic (the binding energies of the $\text{N}1s$ level in these compounds depend linearly on the oxidation state of nitrogen, see Fig. 5). In this case, the line due to the $\text{N}2s$ level shifts regularly to lower energies as the electronegativity of the atoms bound to nitrogen decreases, *i.e.* from NO_3^- , NO_2^- to Si_3N_4 and AlN . In the NO_3^- anion, the $\text{N}2s$ level is observed at 35.4 eV, the intensity of this line in the appropriately normalised spectra of particular nitrates (LiNO_3 , KNO_3 , NH_4NO_3) being constant to within the error of determination. For these compounds, the ratio of the integrated intensities of the lines due to the $\text{N}2s$ and $\text{O}2s$ levels also remains constant. In the NO_2^- anion, the $\text{N}2s$ -level energy diminishes to 32.8 eV, and the ratio of the intensities of $\text{N}2s$ - and $\text{O}2s$ -lines increases; this is caused by the increase in the nitrogen-to-oxygen stoichiometric ratio on passing from NO_3^- (1 : 3) to

NO_2^- (1 : 2). In the spectra of silicon and aluminium nitrides and silicon oxynitride, the $\text{N}2s$ level shifts to lower binding energies to an even greater degree approaching the ionisation potential of the $2s$ orbital in the free nitrogen atom.

The main effect that is found in analysis of the valence X-ray photoelectron spectra of nitrogen-containing compounds is that the $\text{N}2s$ -line is not observed in the spectra of ammonium compounds (see Fig. 6). This fact indicates unambiguously that the $2s^2$ -electrons of the nitrogen atom are completely involved in the formation of the N-H bonds in the NH_4^+ cation. The effective participation of the nitrogen $2s$ orbitals in the valence MOs of this cation is supported by one more fact. The valence X-ray photoelectron spectra of NH_4Cl , NH_4Br and KCl , KBr , in which the positions of the $\text{Cl}3s$ - and $\text{Br}4s$ -lines remain constant, possess the following significant feature. If the spectra of NH_4Cl and KCl are normalised with respect to the $\text{Cl}3s$ -line, and the spectra of NH_4Br and KBr are normalised with respect to the $\text{Br}4s$ -line, it can be seen that the integrated intensities of the most outer bands in the spectra of ammonium compounds are markedly higher (by $\sim 30\% - 40\%$) than those for potassium compounds. This could be possible only in the case where the intensities of the outer bands in the spectra of NH_4Cl and NH_4Br contain some contribution from the molecular orbitals forming the N-H bonds and formed with participation of not only the $\text{N}2p$ - and $\text{H}1s$ -electrons with small ionisation cross-sections (91.1 and 2.7 barns, respectively), but also the $\text{N}2s^2$ -electrons with much larger ionisation cross-sections (1179 barns).¹⁰⁹

It is evident that the same reasons (the $2s^2$ -electrons of the nitrogen atom participate in the bonds in NH_4^+ and do not noticeably contribute to the bonds in NO_3^- , NO_2^- , CN^- , N_2 and NH_3) account for the difference in the forms of KVV-Auger lines of nitrogen (Fig. 7). (It should be borne in mind that here we speak about the coordinated CN^- anion, the electron structure of which differs appreciably from that of the 'free' anion; regarding the N_2 molecule, we speak mainly about the virtually non-bonding $2\sigma_u$ MO consisting mostly of the $\text{N}2s$ AO.). The valence bands in the KVV-Auger spectra of NO_3^- , NO_2^- , CN^- , N_2 and NH_3 contain two complex lines and are quite similar to one another. However, the spectrum of NH_4^+ contains only one line.¹¹⁰ Probably, these differences in the KVV-Auger spectra of nitrogen are due to the fact that its $2s^2$ orbitals participate in the bonds with ligands in NH_4^+ and are quasiatomic in NO_3^- , NO_2^- , CN^- , N_2 and NH_3 . This analogy in the

Figure 7. KVV-Auger spectra of nitrogen.

shapes of the valence X-ray photoelectron and Auger spectra of the nitrogen compounds in question is a significant argument in favour of the ideas about the electronic structures of nitrogen-containing complexes developed in this review.

We can see that the X-ray photoelectron spectra of the inner $N1s$ -electrons (the linearity in the variation of the E_{N1s} value or disturbance of the linearity) and of the valence electrons (the presence or the absence of the $N2s$ -line and shifting effects) and the KVV-Auger spectra (the presence of one or two complex bands) all indicate that the $2s^2$ orbitals of nitrogen either participate efficiently in the valence MOs, or, conversely, remain quasiautomatic in the electronic structure of nitrogen compounds. The valence XPS of those compounds for which the linear dependence of the E_{N1s} binding energy on the oxidation state of nitrogen holds, exhibit a line for the $N2s$ -electrons, and the KVV-Auger spectra of these compounds contain an additional band. The same spectra of those compounds for which the E_{N1s} values deviate markedly from the linear dependence do not exhibit the spectral bands mentioned above. The valence $2s^2$ orbitals of nitrogen in the former type of compound are scarcely involved in the A–L bonds and remain quasiautomatic, whereas those in the latter type of compound contribute considerably to the corresponding delocalised MOs.

Thus, analysis of X-ray photoelectron spectra of complexes of the Second Period elements carried out in relation to nitrogen compounds (containing nitrogen in various oxidation states) shows that the valence $2s^2$ orbitals of these atoms can both participate efficiently in the bonds with ligands and remain quasiautomatic. This depends not only on the spatial and energy parameters of the $2s^2$ AO but also on some 'indirect' parameters such as the charge of the complex ($NH_4^+ - CH_4 - BH_4^-$), the $\varepsilon_{2p} - \varepsilon_{2s}$ energy difference of the central atom, etc.

However, it is possible that the $2s^2$ AOs always participate in the formation of MOs in the complexes under consideration but the extent of this participation can be very low; therefore, it may not manifest itself in the physical properties of compounds, in particular, in the parameters of the X-ray photoelectron spectra of the valence band and inner levels. The scope of publications devoted to the results of experimental and quantum-chemical studies of the electronic structures of complexes of typical elements is immense. Therefore, it is expedient to identify the criteria for participation or non-participation of the $A2s^2$ orbitals in the A–L bonds in a general form; it is clear that these criteria will be approximate and will claim only to serve as more or less general rules.

In the majority of compounds of early typical elements (Li, Be, B, C) including diatomic homo- and heteronuclear molecules, the $A2s^1$ and $A2s^2$ orbitals, together with the $A2p^m$ orbitals, participate efficiently in typical covalent bonds with ligands, irrespective of the oxidation state of atom A, the nature of ligands L and the geometry of the complex. Both the spatial and energy factors are favourable for this participation. The main maxima of the radial density of $A2s$ orbitals are located at a larger distance from the atomic nucleus than the maxima of $A2p$ orbitals; the magnitudes of the energy of $A2s$ and $A2p$ orbitals are relatively small and are close to each other (the separation energies do not exceed 5–6 eV); the energies of excitation of valence states are also relatively low.

The electronic structures of compounds of late typical elements (N, O, F) including their diatomic molecules are much more diverse. The spatial factors are again favourable for the $A2s^2$ orbitals to be involved in the valence MOs of the A–L bonds. However, the energy factor impedes the valence activity of the $A2s^2$ AOs, since these AOs have very low energies; the fairly large energies of the $2p-2s$ separation should be taken into account (they amount to 15–20 eV, and only for nitrogen, this energy is as low as 6 eV).

In the case of atoms of late typical elements with occupied $2s^2$ orbitals, there exists, as a matter of fact, only one way for these orbitals to participate in bonds with ligands, namely, the formation of dative A–L ($2:0$) bonds. In fact, the formation of hyper-

valent $L_{(1)} \leftarrow A2s^2 \rightarrow L_{(2)}$ bonds is unlikely, due to the fairly low energies of the $A2s^2$ orbitals of nitrogen, oxygen and fluorine. Therefore, in this case, the criteria for participation of $A2s^2$ AOs in the A–L bonds go beyond the spatial and energy characteristics of $A2s^2$ AOs. For this participation, a number of conditions should be fulfilled, which are determined by the individual nature of the A and L atoms and their state in the molecule (the difference between their electronegativities, the energies of their valence orbitals, the electron populations of their AOs, etc.) An important condition for the involvement of $A2s^2$ AO in the A–L bonds is, as in the case of ns^2 AO with $n \geq 3$,⁹² the presence of a vacant acceptor orbital with a low energy in the valence structure of the ligand. In this case, the formation of a dative $A \rightarrow L$ ($2:0$) bond becomes possible even though the donor $A2s^2$ orbital itself has a low energy. A significant role is played by the electron rearrangements following the formation of the 'primary' A–L bonds involving the valence orbitals of the atom A, which leads to redistribution of the electron density in the complex. A new (with respect to the free atoms) electron density distribution gives rise to a change in the spatial and energy characteristics of the AO. These changes can be taken into account, for example, by varying the AO exponents. For $A2s$ AOs, these changes can promote an increase in the overlap with the valence orbitals of L and an approach to them in energy, i.e. they enhance the interaction of $A2s$ AOs with the ligand orbitals; however, they can also act in the opposite direction. One must bear in mind that relaxation effects (changes in the length and energy) are more pronounced for the $A2s$ AOs, which possess high penetration abilities, than for the $A2p$ AOs. Therefore, the relaxation effects caused by the formation of the 'primary' A–L bonds can result in inverted lengths of the $2s$ and $2p$ orbitals of the atom A (the $2s$ AO can become less extended than the $2p$ AO) and in increased separation energies of these AOs (i.e. substantial stabilisation of the $2s^2$ AO); consequently, the contribution of the $A2s^2$ AO to the delocalised MOs of the complex would diminish.

Apparently, for $A2s^2$ orbitals to participate efficiently in the A–L bonds, all (or most) of the above conditions need to be satisfied; each of these conditions can be regarded as necessary but not sufficient. Apparently, this accounts for the fact that in many complexes of late Second Period elements, the $A2s^2$ orbitals scarcely participate in the bonds and remain quasiautomatic.

The $A2s^2$ orbitals in the electronic structures of the molecules of hydrides FH, OH₂ and NH₃ are quasiautomatic and, according to the data of photoelectron spectra,¹¹¹ they are stabilised by 2, 4 and 7 eV, respectively, in relation to their energies in the corresponding free atoms. The role of $A2s^2$ orbitals in the valence structures of the FH_2^+ and OH_3^+ molecular cations is less obvious. The electronic structures of CH₄ and NH₄⁺ must be discussed specially; this is necessary to generalise the views about the electronic structures of tetrahedral molecules and ions, CH₄, CF₄, NH₄⁺, BH₄⁻, BF₄⁻, NR₄⁺, etc.

An important feature of the electronic structure of the NH₄⁺ cation lies in the fact that the difference between the energies of its valence molecular orbitals a_1 and t_2 is very small; according to the XPS data, this difference does not exceed 1.5–2 eV, whereas the generally accepted estimate of this value is ~10 eV (by analogy with the isoelectronic CH₄ molecule). It follows from the valence XPS of the NH₄⁺ cation (see Fig. 6) that both the a_1 and t_2 orbitals are located within the same (outer) band including also F2p, Cl3p or Br4p levels. Whereas the structure of the valence band XPS of NH₄Cl and NH₄Br, in which the Cl3s and Br4s levels are separated by 8–10 eV from the outer line, gives rise to the illusion of a large difference between the energies of the a_1 and t_2 MO in the NH₄⁺ cation, the interpretation of the valence spectrum of NH₄F does not involve any ambiguity and, therefore, it is especially representative. In this spectrum nothing is added to the outer (in energy) band (the energy of the F2s level closest to it is higher by 25 eV); both ($a_1 + t_2$) valence MOs of the NH₄⁺ cation are obviously included in this band, and this leaves no doubt in the fact that their energies are close to each other.

The energies of the a_1 and t_2 MOs of the NH_4^+ cation in the halides lie in the range of 8–12 eV and thus they are markedly higher than the energies of the $2p$ (15 eV) and, especially, the $2s$ AO (20 eV) in the free nitrogen atom. Attention is drawn to the fact that the system of 8 valence electrons is markedly destabilised on passing from NH_3 (MO: $2a_1$ — 11 eV, $1e$ — 16 eV and, especially, $\text{N}2s^2$: $1a_1$ — 28 eV) to NH_4^+ . Of course, one should bear in mind that this is a transition from a free molecule to a molecular cation in the crystal, but, nevertheless, the strong destabilisation of the $\text{N}2s^2$ -electrons on passing from the quasiatomic state (NH_3) to a delocalised multi-centre MO (NH_4^+) deserves attention.

The minor difference between the energies of the a_1 and t_2 MOs in NH_4^+ is consistent with the relatively small difference (3 eV) between the same MOs in CF_4 and differs appreciably from the corresponding value (9 eV) for the isoelectronic CH_4 molecule.¹¹² Unlike the $2s^2$ orbitals of the central atom in NH_4^+ and CF_4 participating efficiently in the valence MOs, the valence $2s^2$ -electrons of the C atom in the electronic structure of CH_4 are apparently involved only partly in the bonds with ligands and largely retain their quasiatomic character;² this predetermines the higher energy of separation of the a_1 and t_2 MOs in this case. This means that even in the ‘classical case’ of the CH_4 molecule with sp^3 -hybridisation, the problem under consideration is not simple. The $\text{C}2s^2$ -electron pair remains significantly unshared (*i.e.* the a_1 MO is non-bonding), and the C–H bonds are formed mainly due to the $\text{C}2p_\sigma$ –H1s interactions (owing to the occupation of the bonding t_2 MO); hence, the C–H bonds are orbital-deficient hypervalent bonds ($6e^-$) rather than normal covalent bonds ($8e^-$) described by equivalent MOs in terms of the sp^3 -hybridisation of AOs as in CF_4 . The above differences between the electron structures of CH_4 and CF_4 are confirmed by the fact that on passing from CH_4 to CF_4 , the average (and total) MO bonding energy increases. Undoubtedly, this relation would be the opposite if the electron structures of CF_4 and CH_4 were identical (covalent 8-electron bonds).¹⁰

Thus, in tetrahedral AL_4 molecules, the difference between the energies of valence a_1 and t_2 MOs is small in the case where the $2s^2$ -electrons of the central atom participate in A–L bonds; conversely, in the case of ‘valence inertness’ of the $2s^2$ AOs this difference proves to be fairly large. In turn, the effective interaction of the $2s^2$ AO of the central atom with the valence orbitals of ligands is largely determined by close energies of the interacting orbitals of A and L (for example, the $\text{C}2s$ and $\text{F}2p_\sigma$ orbitals in CF_4 are closer to each other than the $\text{C}2s$ and H1s orbitals in CH_4). The relationship between the energies of valence a_1 and t_2 MOs follows a complex dependence on the difference between the orbital electronegativities, on the distribution of valence electron density in AL_4 induced by the formation of the A–L bonds consisting of the $2p$ -electrons of the central atom, on the initial and optimised orbital energies of the A and L atoms depending on the effective charges on them and on some other factors. A small difference between the a_1 and t_2 MO energies may appear in both neutral molecules (CF_4 but not CH_4) and in cations (NH_4^+) and, probably, in anions as well. It can be foreseen that in the BF_4^- tetrahedral anion, the valence a_1 and t_2 MOs are characterised by a low separation energy. Indeed, the valence band XPS of BF_4^- make it possible to reliably determine this difference as being equal to ~2 eV (Fig. 8). To interpret the valence bands in the spectra of LiBF_4 and NaBF_4 , the valence band spectra of LiF and MgF_2 are also presented. The value of 2 eV is also reproduced in the DVM X_α -calculations for the electronic structure of BF_4^- .¹¹³

In the compounds of late Second Period elements, $2s^2$ orbitals of the nitrogen atoms are virtually always involved in the bonds with ligands. In this case, unlike the O and F atoms, the difference between $2p$ and $2s$ orbital energies is relatively small and close to the corresponding values for C and B. The valence activity of the $\text{N}2s^2$ orbitals depends on many factors. It is promoted by low oxidation state of nitrogen, low electronegativities of ligands, and relatively low effective charge on the N atom. These conditions are satisfied, for example, for NH_4^+ , N_2H_5^+ , $\text{N}_2\text{H}_6^{2+}$ and NH_3OH^+

Figure 8. Valence band X-ray photoelectron spectra of the BF_4^- anion (the $\text{Na}2p$ and $\text{Mg}2p$ levels are omitted for the sake of simplicity; the $\text{Li}1s$ level lies beyond the energy range presented). (1) LiBF_4 , (2) NaBF_4 , (3) LiF , (4) MgF_2 .

cations and their substituted derivatives like NR_4^+ as well as for N_3^- and HN_3 . When some of the above conditions are not fulfilled, (for example, for NO_3^- , NO_2^- , *etc.*), the $\text{N}2s$ orbitals remain quasiatomic and markedly stabilised with respect to those in the free nitrogen atom, if they are bound to ligands with a high electronegativity. This stabilisation, observed when the unpaired $\text{N}2p$ -electrons are involved in the bonds with highly electronegative ligands, results from the decrease in the internal shielding of the $\text{N}2s^2$ orbitals, which possess a higher penetration ability than $\text{N}2p$ AOs.

In some cases, this simple picture becomes more complicated. For example, this is the case with NH_3 and NO_2^+ . In the former case, the valence inactivity of the $\text{N}2s^2$ orbital is dictated by the lack of vacancies in the valence structures of the ligands (H atoms), while in the latter case, the degree of participation of the $\text{N}2s^2$ orbital in the valence MOs is identical to the behaviour of the $\text{C}2s$ AO in the isoelectronic CO_2 molecule, which is also linear.

The very low energy of the $\text{F}2s^2$ orbital and the extremely large difference between the $2p$ - and $2s$ -energies virtually preclude the involvement of the $\text{F}2s^2$ AO in the bonds with ligands. These energy limitations diminish somewhat in the case of oxygen atoms and, therefore, participation of the $\text{O}2s^2$ orbital in bonds with ligands seems to be seldom possible. The only well-studied example illustrating this possibility is the $[\text{Ru}_2\text{OCl}_{10}]^{4-}$ and $[\text{Os}_2\text{OCl}_{10}]^{4-}$ complexes incorporating linear triatomic $\text{M} \equiv \text{O} \Rightarrow \text{M}$ groups that include ($\sigma + \pi$) two-centre double bonds and a tetravalent oxygen atom. This unusual electronic structure can easily be understood by taking into account the relaxation effects and the energetic modification of the valence AOs in these complexes following the formation of the ‘primary’ σ -bonds of the central oxygen atom with both ligands (here, a unique role is played by the two metal atoms). The formation of σ -bonds (as well as the specific environment of the M atoms in $[\text{M}_2\text{OCl}_{10}]^{4-}$) causes stabilisation of the vacant orbitals of the acceptor atoms (M) and, simultaneously, destabilisation of the two electron pairs in the valence orbitals of the donor (O); this predetermines the subsequent formation of two dative $\text{O} \rightarrow \text{M}$ π -bonds. On the whole, all the four valence orbitals of the oxygen atom including the $2s^2$ AO are involved completely in the delocalised MOs of the complex. It is possible that the $2s^2$ AO of oxygen is partially admixed with the $2p_\sigma$ AO in the electronic

structures of oxo-complexes with multiple bonds like $[\text{Ti} \equiv \text{O}]$ and $[\text{O} \equiv \text{U} \equiv \text{O}]$.

Quantum-chemical calculations for compounds of non-transition elements show¹¹⁴ that as the A–L interatomic distance increases, the contribution of the $2s^2$ AO to the MOs of the A–L bonds diminishes (probably, due to the fact that on moving away from the nucleus, the $2s$ -electron density decreases faster than the $2p$ -electron density). This has several consequences. For example, in free diatomic molecules and ions, CO , CN^- , NO^+ and some others, the $\text{A}2s^2$ AOs are often incorporated in valence MOs; when these diatomic groups are coordinated to M atoms in transition metal complexes, the multiplicity of the two-centre bonds decreases, because the electron density moves from valence d_π AO of the M atom to the antibonding π^* MO of the diatomic group; the interatomic distance in this group thus increases, and the contribution of the $\text{A}2s^2$ AO to the valence MOs probably diminishes. The same effects account for the change in the $\text{A}2s^2$ -contribution and the energy inversion of the 1π and $3(5)\sigma$ MOs in diatomic species on passing from N_2 , CO , CN^- and NO^+ with short interatomic distances to O_2 , F_2 and some other molecules with longer bond lengths.

To solve the problem of valence $2s^2$ AOs in AL_k complexes, one should take into account that the geometry of these molecules with bond angles of 104.5° need not be associated with a tetrahedral distribution of the electron density. The results of calculations carried out for H_2O not including the $2s^2$ orbital of the oxygen atom lead to a geometry similar to the experimental one, namely, the minimum total energy is achieved for a bond angle of $101-102^\circ$, without any sp^3 -hybridisation but simply due to interelectron repulsion.

To complete this section, we shall pay attention to the diversity of the electronic structures of compounds of typical elements, which defies simple systematisation (from the viewpoint of participation of the $\text{A}2s^2$ orbitals in the bonds with ligands). All the factors involved must be taken into account: the geometry of the complex, the number of atoms in it, the spatial and energy characteristics of $\text{A}2s$ and $\text{A}2p$ orbitals, the differences in the electronic characteristics of atoms A and L, etc. A representative example is the isoelectronic ($16e^-$) series of linear triatomic molecules and molecular ions: CO_2 – FCN – NO_2^+ – OCN^- – ONC^- – CN_2^- – N_3^- – N_2O . To interpret the differences between the electronic structures of these species one should take into account not only the above parameters but also some specific features characterising the properties of atoms in these systems (whether it is a central atom with a greater role of $2s^2$ orbitals or a ligand with a smaller role of $2s^2$ AOs), the total charge of the complex and some others.

The effective participation of $\text{A}2s$ AOs in the valence MOs in compounds of the Second Period elements accounts for many characteristic features of these compounds and determines the pronounced difference between the typical elements and the rest of non-transition elements, main manifestations of the Periodic Law in the chemistry of Group A elements and the biogenic character of C, N, O, etc.

VI. Principles of electronic structures of complexes of non-transition elements

Numerous results of experimental and quantum-chemical studies on complexes of non-transition elements make it possible to formulate the general principles of their electronic structure. Theoretical generalisations will always be revised, refined and improved. Therefore, we note specially that it is the X-ray photoelectron spectra (XPS) of compounds of non-transition elements that act as the paramount physical basis of our review. The studies of the intensities, energies and chemical shifts of lines in the inner-level and valence band XPS for a great number of complexes of non-transition elements with acido-ligands made it possible to observe regular repetition of consistent effects. Based on these effects, X-ray-electron criteria for the degree of participation and

the role of the valence orbitals of central atoms in the formation of the bonds with ligands were established. By analysing all the available XPS in the context of these criteria, the results of the analysis being necessarily consistent with quantum-chemical results and with the data obtained by other types of high-energy spectroscopy, the main principles of electronic structure of non-transition element complexes have been elucidated.^{104,105}

The vacant nd orbitals of the central atom A scarcely participate in the A–L bonds in the compounds under consideration, including those containing elements in the highest oxidation states, and remain virtual. Apparently, the And orbitals can contribute to the structures of the electronically excited states of complexes. It cannot be ruled out that in rare cases the And orbitals also do contribute to the ground states of complexes; this occurs when the ground state contains a considerable proportion of excited configurations.

In the electronic structures of the majority of complexes of atoms of all early (Group I–IV) non-transition elements of the Second and subsequent Periods, the Ans orbitals occupied by one or two electrons ($n \geq 2$) are involved in the valence MOs and participate in the formation of the A–L covalent bonds, together with the Anp orbitals. The electronic structures of these complexes can be described in terms of multicentre delocalised (canonical) MOs or by two-centre localised (equivalent) MOs that reflect the valence electron density distribution near the two-centre bond using the concept of hybridisation of the basis AOs. The usual views on AO hybridisation can be preserved only for coordination numbers of A atoms of no more than 4 and only for the sp^m type of hybridisation; and even in this case, this should be done with a certain caution (cf. CH_4 and CF_4).

The occupied Ans^2 orbitals ($n \geq 3$) of the atoms of late (Group V–VIII) non-transition elements of the Third and subsequent Periods make a fairly small contribution to the valence MOs of most of the complexes. In the case of ligands with high electronegativities, the valence Ans^2 orbitals remain quasiatomic and markedly stabilised (with respect to those in the corresponding free atoms A). The contributions of Ans^2 orbitals to delocalised MOs are appreciable in some complexes with large coordination numbers (for instance, $\text{Te}5s^2$ in Ag_6TeO_6).

The A–L bonds in most complexes of late non-transition elements of the Third and subsequent Periods, unlike those in the analogous compounds of transition metals, are formed with participation of only valence np orbitals of central atoms (in contrast to the traditional views stating that the ns , np and nd AOs participate in bonds irrespective of their electron populations in the free non-excited atoms A). Here, the concept of hybridisation of the basis AOs is irrelevant. It is expedient to describe the electronic structures of these acido-complexes in terms of MOs containing no contribution of the And and Ans^2 orbitals and consisting of only the Anp^m (and, in some rare circumstances, Ans^2) orbitals and in terms of covalent and hypervalent A–L bonds. To describe these complexes within the framework of the general MO LCAO theory, the hypervalent structure is the best approximation. Generally, the chemistry of phosphorus, sulfur, chlorine, argon and their analogs can be regarded as the chemistry of compounds, the electronic structures of which are built mainly from valence np^m orbitals of the central atom and hardly contain any contribution of the Ans^2 and And orbitals to the valence delocalised MOs.

In the complexes of late elements of the Second Period (N, O, F), the main and sometimes the only contribution to the MOs is made by the valence $\text{A}2p^m$ orbitals. In some complexes, the occupied $\text{A}2s^2$ orbitals prove to be valence inactive and remain quasiatomic, while in some other complexes, they participate efficiently in the formation of delocalised MOs. The involvement of the $2s^2$ -electrons of central atoms (and sometimes, the ns^2 -electrons with $n \geq 3$) in the bonds with ligands is possible only when a number of conditions are satisfied; the most important condition is the presence of a low-energy vacant orbital (i.e. a strong acceptor AO) in the valence structure of the ligand. The

two-centre A–L bonds consisting of the $A2p^m$ -electrons are formed both by the covalent (1 : 1) and the dative (2 : 0) mechanisms, and those consisting of the $A2s^2$ -electrons are formed, as a rule, by the dative mechanism.

In the electronic structures of complexes of the Second Period elements, covalent and hypervalent π -bonds are often formed, due to the $A2p_\pi$ -electrons.^{115–117} The simultaneous participation of $A2s$ AO (together with $A2p$ AO) in the A–L σ -bonds leads to the formation of high-multiplicity homo- and hetero-atomic two-centre bonds ($N\equiv N$, $[C\equiv N^-]$, $C\equiv O$, etc.). For $n \geq 3$, the possibility of the formation of covalent and, especially, hypervalent π -bonds upon the interaction of Anp_π orbitals is sharply decreased; therefore, the electronic structures of complexes of non-transition elements of the Third and later Periods seldom contain multiple two-centre bonds.^{3,45}

In conclusion, let us discuss the theoretical substantiation of the principles formulated above. The primary attention will be focused on two factors, viz. the energy and spatial factors.¹⁰⁴

The theoretical justification of the valence inactivity of vacant nd and occupied ns^2 orbitals ($n \geq 3$) of the central atoms in the electronic structure of complexes of non-transition elements of the Third and subsequent Periods is based on the fact that the energy difference between these AOs, on the one hand, and the valence orbitals of the ligands, on the other hand, is great. The energies of the vacant nd orbitals are too high and those of the occupied ns^2 orbitals are too low compared to the energies of the valence orbitals of the acido-ligands, which have higher electronegativities than atom A (the energies of Anp orbitals are close to the energies of σ, π orbitals of the ligands). The large difference between the orbital energies is reinforced by the fact that the And orbitals are fairly diffuse and the Ans^2 AOs are strongly contracted; this also hampers their effective interaction with ligand orbitals (the length of the Anp AO is the optimum in this respect). Hence, the participation of vacant And and occupied Ans^2 orbitals in the MOs of bonds with typical ligands is hampered by both the energy and spatial factors.

The theoretical substantiation of the participation of the occupied valence $A2s^2$ orbitals of the Second Period atoms in the molecular orbitals of complexes with acido-ligands is mainly based on the fact that their $A2s$ AOs are more extended in space than the $A2p$ AOs (the main maxima of the radial density of the $A2s$ AOs are located farther from the nucleus than those of the $A2p$ orbitals). For the rest of the valence AOs with $n \geq 3$, the situation is known to be the opposite, and this accounts for the fact that $A2s^2$ AOs participate in A–L bonds far more efficiently than any other ns AO. Thus, in this case, the crucial role belongs to the spatial factor, which ensures a high value of the numerator (via the overlap integral) in the expression for the energy of stabilisation of a bonding MO [see formula (1)]. It is owing to their specific spatial characteristics that the $2s$ AOs of atoms A, unlike ns AOs with $n \geq 3$, often participate efficiently in the formation of delocalised MOs. The crucial role of the spatial factor,¹⁰⁴ which ensures that the magnitudes of the overlap integral for the interaction of the $2s$ orbitals of atom A with the valence orbitals of ligands are larger than those for all the other ns orbitals, is stressed by the fact that the contribution of the occupied $A2s^2$ orbitals to the valence MOs diminishes with increase in the A–L interatomic distances,¹¹⁴ and also by the fact that the energy factor exerts a restraining influence on the participation of occupied $A2s^2$ AO in the A–L bonds (in fact, the $2s$ AO energies are much smaller than the energies of valence orbitals of the ligands; therefore, the denominator in the equation mentioned above is always large). However, the energies of $A2s$ (generally, Ans) orbitals may come closer to those of the valence orbitals of ligands, as a result of redistribution of the valence electron density in the complex, caused by the formation of ‘primary’ A–L bonds from the valence $A2p$ (or Anp) orbitals, i.e. due to electron rearrangements controlled by the differences in the atomic characteristics of A and L. However, the same electron rearrangements

can also cause the opposite effect, namely, a decrease in the spatial dimensions of ns AOs and in their energies, i.e. their energy discrepancy with the valence orbitals of ligands can thus be aggravated.

VII. Conclusion

To avoid unfavourable criticism of theorists engaged in the theory of electronic structures of complexes of non-transition elements or of those going to work in this field in the future, we should like to emphasise that our review deals with the main principles of the electronic structures of complexes of non-transition elements.

Certainly, the quantum nature of electrons gives rise to the tendency for their delocalisation. Therefore within the framework of the MO LCAO formalism, which is a part of the wave mechanics of atoms and molecules, it is always possible and even likely that non-zero contributions to the electron density in the electronic structure of a molecular system are made by those states which remain vacant in free unexcited atoms. This refers, in particular, to the And orbitals in non-transition element complexes. However, while describing the electronic structure of these systems, one must not lose the sense of proportion required in any situation (the speculations on the problem of d orbitals in many papers, reviews and monographs in which too much attention is paid to details, while the main meaning is lost, suffer from the lack of this sense). The more so, because views on the atomic s , p and d orbitals in a molecule are not rigorous. The angular momentum of electrons is not conserved in molecules, and the classification of states as s -, p -, and d -types loses its meaning. Only near the atomic nucleus, is there a region where the influence of the molecular environment is fairly minor compared to the nuclear field, so that the concept of s , p and d orbitals is roughly retained. Therefore, by the participation of And orbitals in the A–L bonds, we mean the presence of occupied single-electron states that have the form of d orbitals near the nucleus of the central atom A and are modified away from the nucleus, in conformity with the influence of the molecular environment.¹¹⁸

It is precisely and solely in this sense that we proclaim the general idea on the valence inactivity of And orbitals in the electronic structure of non-transition element complexes and on the valence activity of Ans^2 orbitals being markedly lower than is usually assumed.

In this review we express our opinion: the role of And orbitals in the majority of cases is negligibly small. These orbitals are so unfavourable in energy and so diffuse that they are incapable of any substantial interaction with the valence orbitals of the ligands. In *ab initio* calculations, d orbitals are important as polarisation functions but their population is much smaller than has been assumed in the $sp^m d^n$ -hybridisation model.

Some recent publications devoted to the electronic structures of non-transition element complexes present the results of theoretical studies of several complexes of this type carried out using empirical methods,^{119–120} density functional¹²¹ and other high-level quantum-chemical calculations.^{122–125} The results of these studies are not inconsistent with the main (conceptual) conclusions made in our review.

However, the foregoing refers to the ground states of complexes. In the excited states, the participation of d AO in bonds and their influence on the molecular properties can be markedly higher than those in the ground state. However, up to now, no reliable calculations on the excited states of complexes as applied to the problem of d AOs have been reported. It has been shown¹²⁶ that the participation of the d orbitals of the central atom in MOs can result from the interaction of a non-excited configuration containing no d -contribution with electron-excited configurations having fairly occupied d orbitals.

In this connection, it seems necessary to consider briefly the X-ray diffraction studies dealing with the electron density distribution in crystals. Precision calculations based on these experi-

ments provide reliable data, convenient for further processing, on the differential and deformation electron densities, the ease of dealing with these results has withstood the test of time better than many complicated constructs and refined approaches. The theoretical interpretation of the results obtained recently along this line point to the substantial electron population of *And* orbitals. At present, there are only few results of this type, but they are attracting considerable attention and require a clear and strict explanation.

The direct proof for the population of the $Si3d$ orbitals in the SiO_4^{4-} anion is among the first examples of this sort.^{127,128} The distribution of the differential ($\Delta\rho$) and total (observed experimentally, ρ^0) electron density in the crystal of γ - Ni_2SiO_4 has been studied quantitatively based on the set of measured structural amplitudes;¹²⁷ in this study, a substantial electron population of the $Si3d$ orbitals in the tetrahedral SiO_4^{4-} anion and their strong compression were found (the experimental effective charge on the Si atom amounts to +2.5). We believe that if the electron density in the $Si3d$ orbitals of γ - Ni_2SiO_4 is actually fairly high, this can apparently be explained in the following way. A large contribution to the real state of SiO_4^{4-} in the γ - Ni_2SiO_4 crystal is made, in addition to the non-excited configuration of the free hypothetical SiO_4^{4-} anion, by its electronically excited configurations, which can contain a considerable proportion of the $Si3d$ orbitals. The large contribution of the electronically excited configurations can be due to the 'extreme' environment of the SiO_4^{4-} anion in the crystal of γ - Ni_2SiO_4 consisting of several Ni atoms with high positive charges (+1.3). It is significant that the electronic structure of the SiO_4 -group in the SiO_2 crystal rules out the participation of the $Si3d$ functions in the valence orbitals. This has been found¹²⁹ in a study of photoionisation, X-ray emission ($SiK\beta$, $SiL_{2,3}$, $OK\alpha$) and ultraviolet excitation of SiO_2 ¹²⁹ and in SCF SW X_α -calculations of the electronic structure of the SiO_4 -group in SiO_2 . The environment of the SiO_4 -groups in crystalline quartz has nothing in common with that in γ - Ni_2SiO_4 ; in SiO_2 , they can be isolated only as $SiO_{4/2}$, which assumes that the SiO_4 -group is surrounded by Si atoms with fairly small charges. There are no indications of any substantial contribution of the $Si3d$ orbitals to the electronic structure of Na_2SiO_3 . It has been noted¹²⁸ that on the cross-sections of deformation densities of $AlPO_4$ and $CaSO_4$ crystals, some peaks can be observed that correspond to the partly occupied $3d$ orbitals of phosphorus and sulfur atoms in the PO_4^{3-} and SO_4^{2-} anions, isoelectronic with SiO_4^{4-} .

One of the complications in solving the problem of *And* orbitals lies in the multielectron character of the wave function of the molecule. Therefore, it is necessary to distinguish between the influence of *And* AOs on the properties of a molecular system and manifestation of *And* AOs in a direct study of the electron density or in calculations of the electronic structure of a molecule by multiconfiguration methods of quantum chemistry.

Thus, there are grounds to believe that, under certain conditions, appreciable electron population of *And* orbitals in non-transition element complexes is quite possible and is largely promoted, among other factors, by a great contribution of electronically excited configurations to the wave function of a complex. It can be assumed that substantial *And*-electron populations are typical of many short-lived electronically excited states of the complexes under discussion (the contribution of electronically excited configurations to these states is great by definition) as well as some (apparently, relatively rare) stable states of complexes in which, due to certain reasons, the contribution of electronically excited configurations is large.

So, both empirical concepts — the concept of *d* orbitals and hypervalent bonds — although they seem attractive due to their simplicity and apparent versatility, cannot serve any longer for the strict description of the electronic structures of complexes of non-transition elements; in principle, the latter concept is certainly a better approximation. In both concepts, an important role, although non-equivalent, in the formation of bonds with ligands

is attributed to the valence ns^2 orbitals of the central atom A, and this point is their common flaw (recall that even in the concept of hypervalent bonds, which is the best approximation for the description of the electronic structures of the complexes in question, the participation of valence ns^2 -electrons of central atom A in binding with ligands is assumed for higher compounds in which the oxidation state of A is maximum). The ideas about hybridisation of valence orbitals of the central atom, including isovalent hybridisation, (not increasing the valence), are applicable only to complexes of elements of the Second Period. In this case, they are fairly effective (with the exception of molecular compounds of fluorine and oxygen), because the energy and spatial characteristics of valence $2s$ and $2p$ orbitals give the best fit to each other.^{45,104}

The theory of the electronic structure of non-transition element complexes has not yet been completed. Some of its points require refinement and reasoned modification. There are also blank spots in it, which account for the necessity for the formation and development of conceptually new ideas: for example, in connection with the electronic structure of so-called double bonds: S—O in H_2SO_4 , P—O in H_3PO_4 , the multiplicity of which is actually much less than two.⁴⁵ Of course, the main point is the problem of valence of central atoms and the adjoining problem of the instability of PH_5 , SH_4 , SH_6 , etc. The existing views stating that SO_3 , H_2SO_4 and SF_6 contain hexavalent sulfur and P_2O_5 , H_3PO_4 and PF_5 contain pentavalent phosphorus seem to be no more than a myth, which is simple and convenient for a non-theorist chemist but, in many respects, delays the progress of the theory.

The fact (more precisely, the paramount sign) that in the majority of non-transition element complexes, only *p* AO of the central atom participate in the 'central atom—ligand' orbital interactions accounts for the sharp differences between the electronic structures of complexes of non-transition elements and transition metal complexes. In the electronic structure of the latter, both spatial and energy factors are often favourable for efficient participation of all types of valence orbitals of the M atom [ns , $(n-1)d$, np] in delocalised MOs, in conformity with the symmetry of the complex. This, in turn, explains easily and simply, why transition metal complexes are characterised by more diverse bond multiplicities and also by greater valencies of central atoms M than the corresponding non-transition element complexes, and also why the former are generally more stable.

However, apparently, the electronic structure of transition metal complexes is also far from this ideal scheme; this is indicated by the results of recent investigations on the roles of various valence orbitals in the chemical bonding in ML_k complexes. Based on the calculated¹³⁰ wave functions for $Ni(CO)_4$ and $Cr(NO)_4$, the structure of the 'central atom—ligand' bonds has been analysed within the framework of a new method, free from the artifacts of the traditional analysis of electron populations. It was shown that it is the $3d$ orbitals of atoms M ($3d$ -Ni, $3d$ -Cr) that make the predominant contribution (apart from the ligand orbitals) to the covalent M—L interactions, whereas the contribution of $4s$ and $4p$ AOs is negligibly small.

Although the above results are not general (only two complexes were studied), the main conclusion can be regarded as the beginning of a concept assuming a crucial role of valence $(n-1)d$ orbitals of atoms M in M—L bonds and, simultaneously, valence inactivity (more precisely, low valence activity) of their ns and, especially, np orbitals in the electronic structure of transition metal complexes ML_k . Together with the general conclusion about the crucial role of valence np orbitals of central atoms A in A—L bonds in complexes of non-transition elements and about the valence inactivity of their ns and, especially, nd orbitals, this can lead to a nontrivial and a very simple view on the most general principles governing the electronic structure of the two 'polar' types of complex, AL_k and ML_k , namely: transition metal complexes are mostly formed due to the valence *d*-electrons of central

atoms, whereas complexes of non-transition elements are formed from the valence *p*-electrons of central atoms.

The authors are grateful to I B Bersuker and B S Tsukerblat for benevolent criticism and discussion and to V S Strykanov and M I Raitsina for assistance during the investigation.

VIII. Conclusion	319

Abstract. Modern concepts of the self-assembly of amphiphiles are considered on the example of self-organising structures of the natural lecithin. Binary, ternary and multicomponent systems are discussed. A considerable part of the review is devoted to the peculiarities of self-organisation of this phospholipid in non-aqueous media and to the role of polar organic solvents. Virtually all of the structures formed by lecithin are examined: micelles, swollen micelles, microemulsions, emulsions, organogels, vesicles (liposomes), and lyotropic liquid crystals. In each specific case, attention is drawn to the dependence of self-assembly at the macroscopic level on interactions at the molecular level, shape of molecules, and their solvation and packing at the interface. The self-organising lecithin structures formed in the interfacial area of immiscible liquids in the course of unrestricted adsorption from the bulk of non-aqueous solution are considered. The bibliography includes 282 references.

I. Introduction

The term 'self-organising structures' has appeared in physical and colloid chemistry rather recently. It was borrowed from molecular biology where it serves to describe the mode of cellular structure assembly from constituent molecules. Nowadays, much attention is being given to the elucidation of principles and mechanisms underlying the aggregation of substances and their association into supramolecular systems.

Lecithin is the best known of all natural surfactants. It is widely distributed in living nature, being a basic structural component of the lipid matrix of biological membranes and membranous organelles, and finds uses in food industries, cosmetics, pharmacology, and biotechnology as an effective dispersive and emulsifying agent. All this explains the keen interest of investigators from different fields of science in studies of lecithin properties, its self-organisation, the structures formed, and their transformation.

Received 29 May 1996

Uspekhi Khimii 66 (4) 328–352 (1997); translated by V D Gorokhov

Lecithin forms monomolecular layers, bimolecular films, liposomes and vesicles, liquid crystals, emulsions and microemulsions, and organogels. The systematic studies, which are underway in many laboratories virtually through all this century, have provided a tremendous body of experimental material on its structural organisation in various media. Numerous monographs and reviews devoted to phospholipids and surfactants describe the specific properties and phase behaviour of lecithin; however, no generalising consideration and analysis of its self-organisation have been done until now. The present review is an attempt to fill in this gap.

II. Composition of the lecithin molecule

Lecithin belongs to the class of phospholipids. The content of phospholipids in living cells varies from 15 mass % to 50 mass % (dry mass), whereas in the nerve tissue its level is as high as 60 mass %–80 mass %.^{1–4} Lecithin dominates over other phospholipids in marine invertebrates, plants, and animals.^{1–5} In animal organs and tissues, lecithin is mostly contained in the nerve tissue, liver, heart, lungs and blood.^{2,4} The content of lecithin often exceeds that of any individual phospholipid.^{1–5}

The principal natural sources of lecithin are egg yolk and soybeans. The yolk accounts for 30%–35% of the egg mass of which ~1/3 is lecithin.⁴ The content of phospholipids in the soybean oil is much lower ranging from 1.5% to 2.5%. Nonetheless, soybeans are the major industrial source of lecithin. The soybean lecithin accounts for as much as ~90% of the annual world lecithin production of 145 000 tons.⁶ This is explained by the large scale of soybean oil production. For example, 16 m tons of this oil was produced in 1989–1990.⁴ Accordingly, the phospholipids, which are obtained as by-products in the soybean oil purification, accounted for about 300 000 tons of which 40% was lecithin.⁴

Lecithin is an ester of glycerol in which two hydroxy groups at positions 1 and 2 are esterified by higher fatty acids, whereas the third hydroxyl is esterified by phosphoric acid to which a choline residue is attached (Fig. 1). Owing to the presence of phosphate residue, phospholipids are sometimes called 'phosphatides', while lecithin is widely known as 'phosphatidylcholine'.

The fatty acid composition of the egg yolk and soybean lecithins is presented in Table 1. It is seen that the latter is more unsaturated. Usually, a saturated fatty acid residue is at the position 1, while the residue of an unsaturated acid occupies the position 2.⁸ In its physicochemical properties, the egg yolk lecithin is close to 1-palmitoyl-2-oleyl-*sn*-glycero-3-phosphatidylcholine⁹

Figure 1. The structural formula of 1-palmitoyl-2-*sn*-glycero-3-phosphatidylcholine, an analogue of egg-yolk lecithin. (I) fatty acid residues; (II) glycerol residue; (III) phosphate group; (IV) choline.

(Fig. 1). No close synthetic analogues of the soybean lecithin have been suggested to date.

Table 1. Fatty acid composition of natural lecithins.

Fatty acid composition						Molecular mass	Ref.
C _{16:0}	C _{16:1}	C _{18:0}	C _{18:1}	C _{18:2}	C _{18:3}		
Soybean lecithin							
12.2	0.4	2.7	10.7	67.2	6.0	773	10
Egg lecithin							
35.8	1.5	18.3	37.4	6.8	—	766	11

One should pay attention to the following important fact. The fatty acid composition of natural phospholipids is heterogeneous (Table 1); however, it does not exhibit any substantial variation from sample to sample and is little dependent on the lecithin source. An important consequence is that all investigators deal with natural phospholipids, which are sufficiently close by their composition. This allows an adequate comparison of the results obtained at different times and in different laboratories.

III. The factors determining self-organisation

The lecithin molecule carries two non-polar hydrocarbon chains and a voluminous polar region composed of residues of three molecules (Fig. 1). The lecithin molecule is neutral in the pH range of 3–12.⁷ The combination of two large moieties of opposite polarities occurs definite effects on all the physicochemical properties of lecithin. For instance, it cannot exist in the molecular form in media of any polarity.^{12, 13} Lecithin is either concentrated at the interface or self-assembled into micelles or liquid crystals in the bulk solution.

1. Hydrophobic effects

The existence of two hydrocarbon chains drives the lecithin molecule out of the water towards the interface or stimulates its association with other molecules. In aqueous solution, these chains are surrounded by water molecules which, owing to additional hydrogen bonds, are less mobile and more structured than the bulk-distributed solvent molecules. Therefore, the dissolution of non-polar compounds leads to an entropy (*S*) decrease, which proves to be rather significant. Being of entropic nature, this effect is known as ‘hydrophobic’.¹⁴ The resulting change in the free energy may be expressed as

$$\Delta G = \Delta H - T \Delta S, \quad (1)$$

where *H* is the enthalpy, and *T* is the temperature. Changes in the standard free energy upon transition from aqueous solution to oil may be estimated using the equation, proposed^{15–17} for the calculation of the hydrophobic effects in the adsorption of surfactants

$$\Delta G_a^\circ = -C_a(38.3n_{\text{CH}_3} + 31.9n_{\text{CH}_2} + 18.6n_{\text{CH}} + 1.9n_{\text{C}}), \quad (2)$$

where *C_a* is the adsorption coefficient equal to 106 J mol^{−1} Å^{−2}, *n* is the number of the respective hydrocarbon groups, the factors involving *n* are the areas of the cavity surface (in Å²) formed around the group indicated by the subscript. According to Eqn (2), the absolute value of ΔG_a° for the lecithin molecule containing the hydrocarbon chains of 15–17 carbon atoms can be higher than 100 kJ mol^{−1}.

2. Thermodynamic description of self-organisation

The contact of hydrocarbon chains with water can also be excluded by the aggregation of amphiphilic molecules. This may result in the formation of various structures. Their common feature is that the surface is covered by polar groups shielding the inner volume filled with non-polar groups. Micelles are the best known example. As a matter of fact, the thermodynamic description of the self-organisation is based on the approach[†] proposed for micelle formation by Tanford¹⁹ and supplemented with molecular geometry by Israelachvili *et al.*^{20, 21} that permitted its application for any self-organising structures.

Let us represent the process of aggregation of one type non-ionogenic surfactant in the form of a reversible chemical reaction

where *B* and *M* stand for the surfactant molecule and micelle, respectively; *N* is the aggregation number. The condition of aggregative equilibrium in a micellar system coincides with the condition of equilibrium of a reversible chemical reaction that was first deduced by Gibbs^{18, 22}

$$N\mu_1 = \mu_N, \quad (3)$$

where μ_1 and μ_N are the chemical potentials of a compound in the monomeric and aggregated states, respectively. Taking into account the expression for the chemical potential

$$\mu = \mu^\circ + RT \ln X,$$

one may transform Eqn (3) into

$$N\mu_1^\circ + NRT \ln X_1 = \mu_N^\circ + RT \ln X_N, \quad (4)$$

where μ_1° and μ_N° are the standard chemical potentials of a compound in the monomeric and aggregated states, respectively; *X*₁ and *X_N* are the mole fractions of this compound in each state, *R* is the gas constant, and *T* is temperature. The equation does not include the activity coefficients, since the interactions between non-aggregated molecules and between aggregates were not considered.

In this case Eqn (4) at *N* → ∞ gives an approximated equation

$$\Delta G_N^\circ = -A_N^\circ \simeq RT \ln X_{\text{CMC}}, \quad (5)$$

where ΔG_N° is the change of the standard free energy during the aggregation of surfactant, *A_N*[°] is the standard affinity for micellisation,[‡] *X_{CMC}* is the critical concentration of micelle formation.

In colloidal chemistry, Eqn (5) is often used to calculate the standard free energy of micelle formation.^{14, 18, 23} The critical micelle concentration is easily found from the experimental property — composition dependence of surfactant solutions. In the scale of molar fractions, the standard substance concentration is assumed to be unity.¹⁸

One can estimate the magnitude of ΔG_N° for dipalmitoyllecithin. For this phospholipid, the critical micelle concentration in water is 4.6×10^{-10} M.²⁴ Substitution of this value into Eqn (11)

[†] It should be noted that the approach to the description of micelle formation is not uniform. To this end, various models were proposed in the literature. They are exhaustively discussed in the substantial monograph by Rusanov.¹⁸ The present review provides a schematic account of the basic concepts of the thermodynamics of micellisation.

[‡] The affinity for micellisation corresponds to the chemical affinity for reaction in thermodynamics (for details, see Ref. 18).

gives the standard free energy of micelle formation of 53 kJ mol^{-1} (at 25°C). In order of magnitude, this value is comparable with the standard free energy of adsorption.^{16, 17}

If the dependence of ΔG_N° on temperature and pressure (p) has been established (for which purpose experimental values of CMC under different conditions are required), it is possible to calculate the volume-related (V_N°) effects accompanying micellisation and the standard thermodynamic functions of aggregation, *i.e.* entropy (S_N°) and enthalpy (H_N°).

Analysis of the standard thermodynamic functions alone does not permit the estimation of the aggregate size or the prediction of the type of the structures formed. Therefore, the description of the processes underlying the self-organisation of amphiphiles usually includes the consideration of intermolecular interactions.^{14, 18, 20, 21, 25–28} In the standard free energy of aggregation, two groups of components are distinguished: standard energies of attractive and repulsive interactions. A balance of these interactions determines the optimal packing of amphiphilic molecules, which in turn defines the type of self-organising structures.

3. The dimensionless packing parameter

It has been proposed^{20, 21, 25} to characterise the packing of amphiphilic molecules in aggregates by three parameters: the optimal area A_0 occupied by one molecule at the interface, the volume V of hydrocarbon chains, and the maximal length $L_{\max}$ to which the chains are extended in the *trans*–*trans*-conformation. Criteria of such packing are derived from the following consideration.

The aggregation number, *e.g.* spherical, of micelles with radius r may be expressed as

$$N = 4\pi \frac{r^3}{3V}. \quad (6)$$

It is assumed^{18, 20, 21, 25} that the molecules are incompressible, and that the radius of spherical aggregates cannot be larger than $L_{\max}$. In this case,

$$r = 3 \frac{V}{A_0} \leq L_{\max}. \quad (7)$$

This allows transformation of Eqn (7) into

$$N = 4\pi \frac{r^2}{A_0}. \quad (8)$$

The criterion of amphiphile micellisation is derived from Eqn (8). Provided that the above-stated conditions are met, the molecules whose size satisfies the requirement

$$S_p = \frac{V}{A_0 L_{\max}} \leq \frac{1}{3}, \quad (9)$$

will organise themselves into spherical aggregates.

The criteria of all other types of structures (Fig. 2) are established in a similar way.

The criterion S_p is commonly called ‘the dimensionless packing parameter’, since the $V/(A_0 L_{\max})$ ratio is dimensionless. This term will be used further in this review.

Numerous studies^{20, 21, 25–30} showed that the consideration of molecular geometry alone makes it possible to predict the character of the structural organisation of amphiphiles. In a number of instances, the theoretical aggregation number and micelle size are in good quantitative agreement with the experimental values. Nonetheless, the estimation of the magnitude of the dimensionless packing parameter is far from being simple. The major difficulties are related to the determination of real A_0 and $L_{\max}$ values. Calculations based on molecular models give an S_p parameter which differs markedly from its real value.³¹ This discrepancy is due to the fact that the amphiphile structures are not in the molecular form but in the solvated state. The solvation shell imposes definite steric constraints on the packing of molecules.

Figure 2. Types of structures formed by amphiphiles and the corresponding values of the dimensionless packing parameter S_p : (1) $1/3$ (micelles); (2) $1/2$ (hexagonal structures); (3) 1 (lamellar structures); (4) 2 (inverted hexagonal structures); (5) 3 (reverse micelles).

Accordingly, these should be accounted for in the parameters V , A_0 , and $L_{\max}$. In order to make realistic estimates, one should know the number of solvent molecules in the solvation shell as well as its structure.^{31–33}

Nowadays, the parameter S_p is used basically for qualitative estimates. Based on simple geometric concepts, the use of the dimensionless packing parameter permits prediction of the type of self-organising structures and the direction of phase transformations. The effects of compounds on the structure of amphiphiles are interpreted with due account for their additivity.^{29, 30, 34} In other words, the use of S_p makes it possible to approach the development of a system with the required structural organisation without resort to complex, arduous, and time-consuming studies (see, for example, Ref. 35).

IV. Binary systems

1. Lecithin–water

Natural lecithins in their molecular form are virtually insoluble in water (the solubility is of the order of 10^{-10} M).¹² Nevertheless, they are hygroscopic. Sometimes, even azeotropic distillation with benzene lasting many days fails to remove water completely. Therefore, lecithins, even after thorough drying, usually contain ~ 1 molecule H_2O per phospholipid molecule.¹⁰ Lecithin is insoluble in aqueous solutions, but rather swells. Depending on the magnitude of water/lecithin ratio, various liquid-crystalline structures are formed. This property has been given the name of ‘lyotropic mesomorphism’.

a. Liquid crystals

Binary phase diagrams of egg lecithin–water and soybean lecithin–water systems are presented in Fig. 3. Their superposition shows that the diagrams are not fully analogous, which is due to the difference in the fatty acid composition of two lecithins.

The lamellar liquid-crystalline mesophase L_α [§] is predominant in lecithin–water mixtures. It is formed by numerous parallel lamellae arranged into a bimolecular layer (Fig. 3). The polar groups of phospholipid molecules are localised on the bilayer surface, while their hydrocarbon chains fill the inner volume. Water molecules form a hydration shell around the polar groups and an aqueous interlayer between lamellae.

At room temperature, a homogenous lamellar liquid-crystalline mesophase L_α exists when the water content is in the range from 9 mass %–10 mass % to 43 mass %–45 mass % for egg lecithin and from 7 mass % to 35 mass % for soybean lecithin. In sealed tubes, the mesophase L_α is preserved up to 220 – 240°C . At higher temperatures, it melts to form an isotropic liquid composed apparently of reversed micelles (L_2 phase). When the water content exceeds the indicated limits, the lamellar mesophase L_α separates into the mesophase L_α and aqueous solution. This is the region of liposome and vesicle formation.

At low water levels (< 10 mass %), the formation of other liquid-crystalline mesophases is observed: lamellar L_β , hexagonal H_{II} , and cubic Q_x (Fig. 3). Note that the non-bilayer mesophases

[§] Liquid-crystalline mesophases are designated according to Luzzati.³⁶

Figure 3. Binary phase diagrams of egg (1) and soybean (2) lecithins.^{10, 13, 58} The basic types of liquid-crystalline structures are shown as schematic insets. For comments, see the text.

H_{II} and Q_{α} occur solely at higher temperatures ($> 90^{\circ}\text{C}$). The phase transition $L_{\alpha} \rightarrow Q_{\alpha} \rightarrow H_{II}$ is induced by the different bilayer expansion in the polar and non-polar regions. Its expansion is larger in the region of hydrocarbon chains due to the thermal activation of *cis-trans*-transitions of C—C bonds.^{25, 27, 28} As a result, the molecule acquires the shape of inverted cone, *i.e.* the magnitude of the dimensionless packing parameter S_p becomes > 1 , and phase transition occurs. The transition $H_{II} \rightarrow L_2$ takes place in sealed tubes at temperatures above 220°C .

When a dry phospholipid is left in air, it absorbs water vapour and adopts the lamellar liquid-crystalline mesophase L_{α} . The quantity of absorbed water is dependent on the air humidity (partial pressure of water vapour). The maximum absorption is 20–21 H_2O molecules per molecule of egg phospholipid.^{37, 38} According to different estimates,^{13, 39–41} the full hydration shell contains from 33 to 39 water molecules, though it is formed only when lecithin is in a direct contact with water.

Hydration is a multistage process. The first solvent molecules are absorbed fairly rapidly. The absorption time constant is below one minute.⁴² The rate of this process considerably decreases as the hydration shell is filled, and in the final stage the absorption time constant is as high as ~ 40 min.⁴²

The water of hydration is believed to consist of three or four types. The first one or two H_2O molecules linked to a lecithin molecule are regarded as the 'inner' or 'strongly bound' water.^{43–45} The use of molecular models⁴⁶ has shown that the energy of their interaction with phosphorylcholine is as high as $30\text{--}40\text{ kJ mol}^{-1}$, while that of the interaction of H_2O molecules with each other in bulk water is only 25 kJ mol^{-1} . Further addition of water induces formation of the basic hydration shell around the polar region of the lecithin molecule. This water type is called 'bound' water because of a markedly lower mobility of H_2O molecules in comparison with liquid water. According to the reported estimates,^{45, 47–50} the quantity of 'bound' water varies from 5 to 11 molecules. The next type is the 'included' or 'trapped' water comprising 4–11 H_2O molecules.^{41, 43, 45, 49, 50} In the final stage, water molecules form mostly an aqueous interlayer between the bimolecular layers. As regards its physicochemical properties, this water virtually does not differ from that in the bulk of aqueous solutions, and this was the reason for calling it 'free' water.

The first 4–5 water molecules are attached to the phosphate group by means of hydrogen bonds and are localised in the region of phosphorylcholine (Fig. 1). The subsequent molecules of the polar solvent penetrate deep enough to reach the hydrocarbon chains and form hydration shells around their carbonyl groups.^{51–53}

The changes in the parameters of the bimolecular layer in the lamellar mesophase L_{α} of egg and soybean lecithins induced by the variation of the water level are shown in Fig. 4. It is seen that under the same conditions, for the lamellar mesophase the period in egg lecithin determined by electron diffraction (curve 1) is somewhat larger than that in soybean lecithin (curve 4). This difference is explained by the higher unsaturation of the latter (Table 1). A detailed picture of osmotic swelling is offered by the example of egg lecithin. The absorption of water leads to the thickening of the layer comprising the bimolecular layer and an aqueous interlayer (curve 1), as well as to the increase in the area A_0 per lecithin molecule in the bilayer (curve 3). At the same time, a decrease is observed in the thickness of the layer formed by the hydrocarbon chains L_{max} (curve 2). The observed thickening of lamellae is achieved through hydration of the polar region of lecithin and the formation of the water interlayer between lamellae.

The area A_0 and the layer thickness L_{max} have been reported⁵⁶ to vary in the opposite ways. This results in a virtual independence of the dimensionless packing parameter S_p of the water content. This finding explains the stability of the bilayer structure and the persistence of the lamellar mesophase (L_{α}) over a wide range of water concentrations.⁵⁶

In conclusion, it should be noted that the presence of 1 mass %–3 mass % of admixtures of ionogenic substances is conducive to a dramatic increase in the extent of lecithin swelling in aqueous solutions (Fig. 4, points 5).^{12, 55, 57, 58} In the presence of ionogenic compounds the thickness of water interlayers may be 4–6 times larger than of lamellae. In this situation, the interval of the lamellar mesophase (L_{α}) occurrence may be considerably extended due to the shift of the right-hand boundary in the binary phase diagram (Fig. 3) towards higher H_2O concentrations (sometimes, up to 85 mass %).⁵⁵ This effect is explained by the electrostatic repulsion of lamellae from each other. This is

Figure 4. The lamellar mesophase (L) period determined from the results of X-ray diffraction (1, 4, 5), thickness of the hydrocarbon portion of lamellae (h) (2), and the area occupied by a lecithin molecule in the bimolecular layer (A) (3).^{10, 13, 54, 55} Egg lecithin (1–3), soybean lecithin (4, 5), mixture containing 1.5 mass % of cetyltrimethylammonium bromide (5).

confirmed by the absence of the extremal swelling of lecithins in solutions of inorganic salts.⁵⁵

b. Liposomes and vesicles

In the phase diagram region corresponding to the binary system phase L_α –water (Fig. 3), the lecithins placed into water are swelling to form characteristic structures known as ‘myelin figures’ (Fig. 5). They were first described by Virchow⁵⁹ in 1854. The appearance of myelin figures indicates that an amphiphile adopts the form of a lamellar mesophase L_α .⁶⁰

The formation of myelin figures is associated with the expulsion of lamellae from the bulk of a substance as a result of their swelling (for more details, see Refs 61–63). The coaxially arranged bimolecular layers form cylinders which possess high optical anisotropy. The process of swelling is illustrated by a series of photographs shown in Fig. 5. The final stage appears to be highly significant for the problem under discussion. It comprises disintegration of myelin figures into spherical and oval particles (Fig. 5c), whereas the substance bulk is transformed into a sort of paste as a result of swelling. Microscopic examination in the light transmitted through crossed polaroids reveals that the pasty mass formed has a pseudoisotropic texture with oily streaks (Fig. 5d). This type of texture is characteristic of the lamellar mesophase L_α .

Under mechanical impacts (even weak ones), *e.g.*, shaking, the swollen mass is dispersed in the excess of the aqueous solution. Electron microscopy showed⁶⁴ that such dispersions, known nowadays as ‘liposomes’ or ‘vesicles’,[¶] were formed (like an onion bulb) by numerous closed lamellae.

Papahadjopoulos⁶⁵ proposed the following classification of vesicles by size (μm): 0.1–100 — multilamellar vesicles (MLV); 0.02–0.1 — small unilamellar vesicles (SUV); 0.1–1.0 — large unilamellar vesicles (LUV); up to 50 — giant vesicles (GV);

0.02–0.1 — small oligolamellar[†] vesicles (SOV); 0.1–1 — large oligolamellar vesicles (LOV).

The vesicle size is determined by subsequent mechanical impact, its intensity and duration. The diameter of vesicles produced under standard conditions is usually within the limits of 1–4 μm .

Spontaneous formation is observed only in the case of MLV. All other vesicle types can be produced through external impact. The largest energy is required for the production of SUV. This is due to the increase in the free energy during dispersion (Fig. 6).

The increase in the free energy as the vesicle size decreases is caused by an abrupt increase in the interface surface. Consequently, the unilamellar vesicles SUV and LUV turn out to be thermodynamically unstable systems, though they prove to be stable kinetically. With time, the unilamellar vesicles are fused to form multilamellar structures, *i.e.* the system recovers to its initial state. The transitions occurring may be schematically represented as follows:

The result is the separation of a homogeneous dispersion into an aqueous solution and a sediment composed of a mixture of multilamellar liposomes and lamellar mesophase L_α .

Most of the basic techniques for producing vesicles were developed in the 1970s. Their description may be found in a number of surveys (see, *e.g.*, reviews^{66–70}). In the subsequent years, diverse modifications of these techniques were proposed. Information on the basic methods of vesicle preparation, as well as their advantages and drawbacks are listed in Table 2, which also gives values of the inner water volume, accounted for when

¶ The term ‘liposome’ is mostly used in the technical literature. In the scientific literature, dispersions of phospholipids are commonly called ‘vesicles’.

† The term ‘oligolamellar’ means that the vesicular envelope is composed of one to several bimolecular layers. This vesicle type is intermediate between the unilamellar and multilamellar vesicles.

Figure 5. Different stages of egg lecithin swelling in a water–glycerol mixture (glycerol content, 75 vol. %) at 20 °C. (a) Simple rod-shaped myelin figure (initial formation stage); (b) advanced stage of lecithin swelling: complex double-helical figures are available along with simple rod-shaped myelin figures; (c) beginning of the breakdown and partially degraded myelin figures; (d) domains of spherulites (vesicles), final stage of myelin figures breakdown; (e) pseudoisotropic texture of an ‘oily streak’ observed after the solvent penetration into the sample.

incorporating drugs, proteins, DNA, *etc.* into vesicles. The techniques employed for the preparation of unilamellar vesicles are illustrated in Fig. 7.

The mechanism underlying the vesicle formation is not as yet fully understood. Numerous questions remain still unanswered.⁷¹ The most universal model was designed by Lasic.^{66, 72} It relies on the aggregation of the preformed bimolecular 'blocks' into vesicular structures.

Soon after their discovery, vesicles became very popular as models of biological membranes, and they remain active performers of this role until now. Vesicles allow the investigation of the

transport of various compounds across membranes, membrane fusion, as well as the reconstitution of lipoprotein complexes.^{67, 73–76} The vesicles have acquired wide use in medicine, pharmacology, genetic engineering, cosmetics, and food industries. Today, there are bright prospects for their application in the development of highly specific systems for the targeted transport of drugs and genetic material.^{76–79}

2. Lecithin — organic solvent

Owing to its amphiphilic nature, lecithin is soluble in virtually all organic solvents, except for acetone.^{4, 12, 13} The type of self-organising lecithin structures in solutions is determined by the nature of the solvents. The latter may be divided into two large groups. The first group includes for the most part non-polar solvents in which lecithin forms reverse micelles; the second group comprises polar solvents whose molecules (like water) form numerous hydrogen bonds generating three-dimensional arrays. In these media, the lecithin molecules self-organise to form liquid crystals and display lyotropic mesomorphism.

a. Reverse micelles

The phenomenon of micellisation was studied mostly for egg lecithin.^{94, 95} The critical micelle concentrations have been determined for its solutions in *n*-heptane and benzene. In both cases, the formation of micelles is initiated at a lecithin content of 0.01 μM .^{11, 95, 96} Table 3 lists the aggregation numbers *N* in different solvents, dielectric constants (ϵ) of solvents, as well as conditions of their determination and relevant methods.

Elworthy and McIntosh⁹⁷ have attempted to relate the micelle formation to the dielectric constant of a medium. The magnitude of ϵ was varied by the addition of water or benzene to ethanol. It was found that no aggregates were present in 93% ethanol ($\epsilon = 29.0$). The absence of micellisation was explained by the balance of the solvent interactions with the polar and non-polar lecithin regions. These authors have assumed a medium with $\epsilon = 29.0$ to be the dividing line. The increase in the solvent polarity must initiate the formation of direct micelles, whereas its decrease must stimulate the reverse micelles.

Analysis of the data presented in Table 3 does not reveal any direct correlation between *N* and ϵ . In studies of micellisation, more justified seems to be the approach, according to which the solvent influences the molecular form of lecithin in its aggregates. Certain evidence for this effect may be found in Ref. 95.

In their mixtures with lecithin, non-polar solvents accumulate in the region of hydrocarbon tails that is conducive to a higher effective volume and eventually to the magnitude of the dimensionless packing parameter S_p exceeding unity. For example, the addition of alkanes to the lamellar mesophase L_α (Fig. 3) results in its transition to the inverted hexagonal mesophase H_{II} .^{98, 99} No formation of micelles is observed when the solvent molecules are localised not only near a certain individual group, but occupy the space along the entire lecithin molecule. For instance, under definite conditions such a situation was observed in benzene. Cooling of concentrated solutions led to their thickening. Relevant studies^{100, 101} showed that in this case the reverse micelles are replaced by structures similar in their composition to the lamellar mesophase L_α . In such structures, the benzene molecules are localised in the regions of both the hydrocarbon tails and the polar groups of lecithin and also fill the interlamellar layers. According to the reported results,^{100–103} the localisation of benzene in the polar region is explained by the interaction of benzene with the functional groups of the phospholipid.

b. Non-aqueous liquid crystals

The formation of the lamellar mesophase L_α by lecithin in a water-containing glycerol was first described by Rinne,¹¹⁴ though this report remained mostly unnoticed. The first systematic studies of non-aqueous liquid crystals in ethylene glycol, as well as in alkanediols and low-molecular-mass polyethylene glycols were carried out by Friberg *et al.*^{115–119}

Table 3. Micellisation of egg lecithin in organic solvents.

The interest in mixtures of phospholipids with organic solvents was related, on the one hand, to the problem of perturbation of the intact lipid matrix under the influence of toxic solvents, *e.g.* ethanol. On the other hand, the investigation of lecithin proved to be in the wake of the studies aimed at elucidating the nature of the self-assembly of surfactants in media of different polarity. Nowadays, there are sufficiently settled views on the nature and mechanisms underlying the self-assembly of amphiphiles in organic media.

In organic media, like in water, lecithin can form different types of liquid crystals,^{120, 121} depending on its concentration and temperature. The lamellar mesophase L_{α} is the most characteristic of this phospholipid at room temperature. Excess quantities of glycerol and ethylene glycol cause swelling of lecithin with the formation of myelin figures that further disintegrate into multi-lamellar vesicles.^{60, 63, 122}

The physicochemical properties of solvents, in which the formation of liquid crystals is observed, are listed in Table 4. It also carries characteristics of some solvents, that makes it possible to reveal distinctive features determining the aggregation of amphiphiles.

Analysis of these tabulated data shows that the liquid-crystalline state of lecithin occurs in high-polarity media with a considerable cohesion between the solvent molecules. The latter is characterised by the dipolar angular correlation index and the cohesion parameter.^{113, 123, 124} The ability of solvents to form hydrogen bonds is determined by their donor and acceptor numbers.^{113, 123} The cohesion is seen to be the strongest in the case of water, formamide, glycerol, and ethylene glycol. It is caused by the intermolecular hydrogen bonding. Of note are the maximum values of acceptor numbers of solvents in which liquid-crystalline structures are formed. This may mean that the donor properties are significant for the self-assembly of lecithin.

The above peculiarities of polar organic solvents provided the grounds for suggesting that the necessary condition of the amphiphile self-organisation is the occurrence of hydrogen bondings in the medium.^{120, 121, 125, 126} This suggestion was convincingly confirmed in the experiments with formamide, methylformamide, and dimethylformamide.¹²⁰ Successive methylation of the amino group in these solvents results in the total

Table 4. Viscosity (10^{-1} / Pa s), surface tension (σ / mN m⁻¹), dielectric constant (ε), dipolar angular correlation parameter (g), cohesion parameter ($\sigma / V^{1/3}$ / mN m⁻²), donor number (DN) and acceptor number (E_t) of solvents.

DMF	0.796	35.2	36.7	1.00	—	26.6	43.8

Note. Abbreviations: DMSO, dimethyl sulfoxide; DMF, dimethyl-formamide. The solvents in which liquid crystals are formed are characterised by the formation of three-dimensional networks of H-bonds; ethanol favours linear chains; in other solvents formation of networks of H-bonds is not characteristic.

^a The dipolar angular correlation parameter indicates the deviation of the electric permittivity from the magnitude that the liquids would have at the same values of polarisability and dipolar moment in the absence of their association. Another meaning: g is the inverse energy of reactive interaction of dipolar molecules; therefore, this parameter is the index of hindrance to their free rotation induced by dipole-dipole interactions. For non-associated solvents, $g \approx 1$. When the liquids are strongly structured and the dipoles are parallel one to another, $g > 2$.^{113, 123} ^b The cohesion parameter proposed by Gordon;¹²⁴ V is the molar volume. For solvents with high cohesion, $\sigma / V^{1/3} > 12.5$ mN m⁻². ^c The donor number of Gutman serves for the quantitative estimation of the basicity of individual solvents.^{113, 123} ^d The acceptor number proposed by Dimrot and Reihardt¹¹³ for the quantitative estimation of the acidity of individual solvents.^{113, 124}

closing of the H-donor centre. It was found that upon transition from formamide to methylformamide, the interval of the lamellar mesophase L_α occurrence is sharply reduced, whereas in dimethylformamide, in which no hydrogen bonds are available, the liquid-crystalline structures are not formed.

It should be noted that the self-organisation of lecithin into the liquid-crystalline state can occur in not all media with intermolecular hydrogen bonds. In this case, an important role is played by the character of hydrogen bonding. A good example are the aliphatic alcohols in which micellisation was found to occur (Table 3), but no liquid crystals were revealed (Table 4). The peculiarity of the aliphatic alcohols is that they form linear hydrogen bonds, which link molecules into chains.^{113, 123} The formation of liquid crystals is observed in solvents (water, formamide, glycerol, and ethylene glycol) with three-dimensional networks consolidated by H-bonds.

Studies of non-aqueous liquid crystals by the NMR and X-ray methods have provided conclusive data on the diminished structural ordering of lecithin molecules upon substitution of organic solvents for water.^{126–128} This is ascribed to the decrease in the solvophobic effect in the series water > formamide, glycerol >> ethylene glycol.¹²⁹ This inference is also confirmed by the fact that micellisation of the same surfactants is initiated in polar solvents at concentrations ~100 times larger than those in aqueous solutions.^{23, 126} As a result, the standard free energy of aggregation calculated by Eqn (5) proves to be smaller by 11–12 kJ mol⁻¹. Interestingly, the increment per methylene group remains unchanged.²³

In the lamellar mesophase L_α , polar solvents form a solvation shell around the polar lecithin region and an interlamellar layer, but they do not penetrate as far as the region of hydrocarbon tails. Investigation of ethylene glycol-containing systems by NMR revealed the existence of three types of its molecules.^{116, 118, 128} The first type is realised when a single diol molecule is attached to the phosphate group of the phospholipid via hydrogen bonds and turns out to be the least mobile. The second type includes up to seven diol molecules. They form the basic solvation shell on the polar portion of the lecithin molecule. Further addition of ethylene glycol induces the third type whose characteristics do not differ from those of the pure solvent. Apparently, the third solvent type comprises free diol molecules localised in the interlamellar layers. The above division of the ethylene glycol molecules into three types in the lamellar mesophase L_α is consistent with what has been proposed for water (see above).

The role of specific solvent in the non-aqueous liquid crystals may be performed by esters of fatty acids and polyethylene glycol. Friberg *et al.*¹³⁰ observed the formation of the lamellar mesophase L_α after mixing lecithin with tetra- or heptaethylene glycol laurate in the absence of any other additives. The period of lamellar structure determined by the method of small-angle electron diffraction diminished with the increase in the content of synthetic surfactant. The same effect took place when the temperature was increased. It has been assumed that the alkyl group of polyethylene glycol laurate is incorporated into lamellae between the phospholipid molecules, while the polyethylene residue acts as a solvent by forming a sort of solvation shell around the polar lecithin region.

The ability of phospholipids to exist in the form of lamellar mesophase L_α in the presence of a variety of organic solvents is of high biological significance.¹³¹ Plant seeds, yeast cells, fungal spores, as well as some microorganisms undergo dehydration during drying. Addition of water causes osmotic swelling and leads to the recovery of their vital functions. A similar cycle is observed in plants preserved in the dehydrated state during the winter season. The removal of water and lower temperatures induce the phase transitions $L_\alpha \rightarrow L_{\beta'} \rightarrow$ crystalline phase (Fig. 3). Hydration causes the reversal to the lamellar mesophase L_α . This reverse transition is the usual cause of perturbations in intact biological membranes.¹³¹ To prevent negative consequences of drying, the living systems have devised a mechanism of stabilisation

of the biomolecular structure of the lipid matrix consisting in the replacement of water by polyols (ethylene glycol, glycerol), disaccharides (trehalose and sucrose), or an amino acid (proline).¹³¹

In this respect, the best studied is the phase behaviour of trehalose-containing systems.^{132–134} The stabilisation seems to consist in the substitution of water and the binding of trehalose hydroxyls to the phosphate group of phospholipids through hydrogen bonds. In this case, the range of the lamellar mesophase L_α occurrence is extended towards smaller solvent concentrations and lower temperatures. The latter circumstance allows polyols, disaccharides, and proline to act as cryoprotectors.¹³¹

V. Ternary systems

In a ternary system containing lecithin, water, and oil, the lecithin molecules are localised at the oil–water interface. Their interaction with two solvents from different phases rather than with one offers additional possibilities for varying the parameters A_0 , $L_{\max}$, V , and S_p .

1. Water-containing systems

a. Swollen micelles

In the case of natural lecithins, the formation of micelles takes place only in organic solvents. Therefore, the further discussion is devoted to the reverse micelles.

Lecithin retains its hygroscopy in the dissolved state, which determines the absorption of water from air by its non-aqueous solutions.^{135, 136} This leads to the dissolution of relatively small quantities of H₂O, from 15 to 30 molecules per phospholipid molecule.^{12, 47, 94, 95, 136–138} The addition of water induces changes in the form of reverse micelles. The spherical shape of aggregates is preserved in aromatic (benzene, toluene) and chlorinated (chloroform, tetrachloromethane) solvents. On the other hand, there is a large group of organic solvents in which the spherical micelles are transformed into cylindrical ones under the influence of traces of aqueous solution (see below).

The first molecules of absorbed water are used to form a hydration shell around the polar head of the lecithin molecule. The hydration pattern has much in common with that described in Section IV.1.a. The differences reside in the number of water molecules: the hydration shell of lecithin in the reverse micelles includes somewhat smaller solvent quantities than, *e.g.*, that in the lamellar mesophase L_α .^{95, 138} The ‘free’ water forms an aqueous core of the aggregates. As the amount of water increases, the radius of the aggregates increases, which provided the ground for calling such micelles ‘swollen’.

The swollen micelles are water droplets surrounded by a monomolecular lecithin layer. Their radius can vary from 10 to 100 Å.⁹⁴ In benzene, for example, the diameter of the water core at the maximum level of the solubilised H₂O is 50±15 Å, whereas in carbon tetrachloride it is 30±5 Å.¹³⁷

The existence of the water core makes it possible to solubilise inorganic and water-soluble organic substances in the non-polar systems with swollen micelles. It is also possible to introduce proteins and to carry out enzymatic reactions in such systems, and this seems to be promising for biotechnological applications.^{94, 139}

b. Organogel

Addition of small quantities of water to non-aqueous lecithin solutions induces their thickening and formation of a gel phase (organogel). The list of organic solvents, in which this phenomenon takes place, includes over 50 names. The presence of organogel in organic solvents was first observed by Scartazzini and Luisi¹⁴⁰ in 1988. An analogous phenomenon was simultaneously and independently observed in a system of immiscible liquids. It was induced by the transfer of water into a non-aqueous solution of lecithin upon application of an electric field.¹⁴¹

The formation of lecithin organogel begins at the level of egg and soybean lecithins of 4–7 g litre⁻¹ (≥ 550 μM).^{140, 142} After the complete dissolution of water, the organogel is outwardly

indistinguishable from the initial solution; it is homogeneous, transparent, and optically isotropic. Differences are revealed upon mechanical impact. The lecithin organogel forms a jelly-like mass. Its viscosity is strongly temperature-dependent. On heating, the organogel is transformed into a non-viscous solution, though it regains its gel-like state on cooling. In other words, jellification is a thermally reversible phenomenon.

An organogel stabilised with lecithin appears to be a thermodynamically stable system. This view is supported by its spontaneous formation. Such a stability is time-limited; the appearance of oxidation products induces degradation of an organogel; their presence also prevents the gel phase formation.¹⁴⁰

The occurring phase and pseudophase transitions, as well as the dependence of static viscosity (η_0) on the number of water molecules (n) per lecithin molecule are shown in Fig. 8 on the example of soybean lecithin solution in n-decane.¹⁴² The initial

Figure 8. Dependence of the static viscosity of soybean lecithin solution in n-decane (10 mg ml^{-1}) on the number of added water molecules per lecithin molecule (n). The dashed lines indicate the boundaries between different phase and pseudophase states in solution: (I) Newtonian fluid; (II) organogel; (III) non-viscous solution + sedimented organogel; (IV) non-viscous solution + solid sediment. The graph was plotted from the data reported in Ref. 143.

water-free solution containing spherical reverse phospholipid micelles displays properties of a Newtonian fluid.¹⁴³ Upon addition of water, the static viscosity increases proportionally to the quantity of introduced solvent according to the equation

$$\eta_0 = \eta_s(1 + f), \quad (10)$$

where η_s is the viscosity of the initial solution, C is the constant, and f is the solvent volume fraction. The range of linear dependence is not large. Deviation from the linearity is observed when the quantity of added water exceeds $0.5 \text{ H}_2\text{O}$ molecules per lecithin molecule. Within the range from one to two water molecules, η_0 increases more than 10^4 times (Fig. 8). Other rheological parameters (loss modulus G' and storage modulus G'') also abruptly increase.^{143, 144} When the magnitude of η_0 reaches its maximum, the separation of the gel phase into a non-viscous non-aqueous solution and a dense gel begins. In other words, until a certain level, the water acts as a thickener, and then it plays the role of coagulant. It was proposed to characterise this critical concentration by the parameter n_{cr} ^{140, 143} indicating the number of water molecules per lecithin molecule, which corresponds to the maximal water quantity at which the most viscous organogel is formed. The n_{cr} values of non-polar solvents, in which the soybean lecithin forms organogel, are the following: n-hexane, 3; n-octane, 2; n-decane, 2; n-dodecane, 1; 2,3-dimethylbutane, 4; oct-1-ene, 4; octa-1,7-diene, 7; isooctane, 3; cyclohexane, 6; cyclododecane, 12; ethyl laurate, 4; dibutyl ether, 6; tripropylamine, 4; and tributylamine, 2.

The lecithin organogel does not belong to the class of Newtonian fluids. It displays the properties of a viscoelastic (Maxwell-

lian) body.^{143, 144} The rheological behaviour of such bodies is simulated by a spring-piston model, whereas the dependence of dynamic moduli on the frequency of harmonic oscillations is described by the equations¹⁴³

$$G'(\omega) = \frac{G_0 \omega^2 \tau^2}{1 + \omega^2 \tau^2}, \quad (11)$$

$$G''(\omega) = \frac{G_0 \omega \tau}{1 + \omega^2 \tau^2}, \quad (12)$$

where ω is the angular frequency equal to $2\pi\nu$ (ν is the harmonic oscillation frequency), τ is the structural relaxation time, and G_0 is the static modulus. At fast deformations, the lecithin organogel displays properties characteristic of elastic bodies, whereas at slow deformations its properties resemble those of fluids. These states are characterised, respectively, by the static modulus (the high-frequency storage modulus) G_0 and the zero shear viscosity (Newtonian viscosity limit) η_0 (Fig. 8).

Investigations of the lecithin organogel by the methods of light scattering, small-angle neutron scattering, dielectrometry, rheology, electron microscopy, and IR and NMR spectroscopy carried out primarily by Schurtenberger *et al.*^{144–149} and by other researchers^{137, 150, 151} have ascertained changes occurring in the reverse micelles upon addition of water.

Water causes one-dimensional growth rather than swelling of spherical aggregates, which leads to the appearance of giant rod-like micelles (Fig. 8). The size of aggregates increases from 30 to 400–700 Å and may eventually be as high as thousands of angstroms.¹⁴⁹ The transformation of micelles occurs within a narrow range of water concentrations. Addition of 1–3 water molecules per lecithin molecule often proves to be sufficient (Fig. 8). The giant rod-like micelles entangle and form three-dimensional networks.

By its structural organisation and rheological properties, the lecithin organogel resembles semi-dilute solutions of polymers.^{152, 153} A number of other surfactants were found to form gels in aqueous^{152–162} and organic^{158, 163–168} solutions in the absence of polymeric compounds. This provided the ground for segregating micellar gels into a special group. Cates^{169–171} proposed to consider the flexible rod-like micelles as the regular components of the gel phases of amphiphiles. They play the role of polymeric (long-chain) molecules. That is why the giant rod-like micelles are known in the literature as ‘polymer-like’ or ‘worm-like’ micelles. Formation of a three-dimensional network of entangled aggregates in the bulk of solutions determines the visco-elastic properties of the gel-like phases of amphiphiles.

The dynamics of polymer-like micelles was considered by Cates^{169–171} from two different standpoints. On the one hand, aggregates may be regarded as stable flexible rod-like particles, for which a reptation mechanism is applicable. The latter has been proposed for the description of the diffusion of chain molecules in a structured medium.^{172, 173} The migration occurs in an imaginary tubular cavity the dimensions of which are determined by the interactions with the neighbouring molecules. A close analogy may be the movement of individual snakes in their ball. Diffusion in the gels is quantitatively characterised by the relaxation time τ_{rep} required for the particle to migrate at the distance equal to its length.

On the other hand, micelles cannot be regarded as stable formations. They are dynamic structures that are in the process of continuous reversible dissociation and recombination. The amphiphilic molecules pass into solution, reform associations or become involved in exchanges between aggregates;^{14, 23} the aggregates themselves dissociate reversibly into smaller associations. The stability of micelles is characterised by their lifetime τ_b , which is the mean time span between an aggregate formation and its breaking into two parts.

Naturally, the dynamics of polymer-like micelles is determined by the ratio of times τ_{rep} and τ_b . It was proposed to distinguish between the two extreme cases.^{169–171}

1. $\tau_b \gg \tau_{rep}$. The processes of dissociation and recombination are inhibited to such an extent that the micelles may be considered as stable particles whose movement in gel systems follows the reptation mechanism. Such systems may be described within the framework of net theories of polymers.

2. $\tau_b \ll \tau_{rep}$. The dynamics of the processes depends on both the reversible dissociation/recombination of micelles and their diffusion via the reptation mechanism. In this case, the time of structural relaxation is determined by the dependence $\tau \simeq (\tau_b \tau_{rep})^{1/2}$.

The nature of dynamic processes may be clarified by the analysis of concentration dependences of the rheological parameters.^{169–171} The theoretical values of the exponents of lecithin concentrations corresponding to the reptation mechanism and those of polymer-like micelles in the case of G_0 and η_0 are listed in Table 5 along with some experimental values.^{143,144} The variations of G_0 and η_0 are considered as functions of lecithin and water concentrations since the formation and properties of organogels are determined by both components. The best correlation between the experimental and theoretical data is achieved for the dependence of the rheological parameters on lecithin concentration. However, in this case too, a substantial discrepancy is observed. A better fit to experimental data is achieved by employing a more complex model of dissociation/recombination of micelles, though noticeable differences are still found.^{144,170} The participation of water in the self-assembly of lecithin is believed¹⁴³ to be a possible cause of the deviation of parameters from the values calculated on the basis of theory of polymer-like micelles. Usually, the role of solvent in the formation of amphiphilic gels is passive. In a number of cases, the addition of water leads to shortening of cylindrical reverse micelles¹⁷⁴ or to the degradation of organogels.¹⁶⁷ The structure-forming function of H₂O is manifested only in non-aqueous solutions of lecithin. This is the principal difference of lecithin organogels from the gel phases of other amphiphiles. A molecular mechanism of the lecithin self-assembly into polymer-like micelles has been developed and substantiated.^{142,175,176} It is considered below in the discussion of the role of polar solvents.

Table 5. Exponents of concentrational dependences.

Theoretical values		Experimental values	
Reptation mechanism	Polymer-like micelles	Data from Ref. 144	Data from Ref. 143
Concentrational dependence of G_0			
2.25	2.25	2.0±0.1	11
Concentrational dependence of η_0			
3.75	3.5	1.9±0.1	18

In conclusion, it is noteworthy that lecithin organogels have good perspectives for the practical use in cosmetics and pharmacology. Preliminary studies have demonstrated the possibility of incorporation of biologically active compounds, medicinal preparations, and enzymes into lecithin organogels. High viscosity of lecithin organogels makes their use particularly promising as the basic components of creams and ointments for cosmetic purposes, and in the therapy of skin diseases and burns. A number of successful applications of such organogels have been reported.^{177–179}

c. Emulsion

Emulsions are not ranked among thermodynamically stable systems, though they possess the so-called ‘kinetic stability’.^{180–183} In the absence of surfactants, dispersions are extremely unstable and rapidly separate into layers of initial liquids. The coalescence (fusion) of droplets can be prevented, first of all, by a shell formed by amphiphilic molecules adsorbed at the interface of

two immiscible liquids. The scope of this review does not go as far as surveying all the factors determining the stability of emulsions; it is confined to the consideration of peculiarities inherent in lecithin.

Lecithin belongs to the group of effective emulsifiers, *i.e.* emulsions are preserved for an extended time period after dispersion. Since this phospholipid is more soluble in non-aqueous media, one could expect formation of an emulsion of the ‘water-in-oil’ type in accordance with the empirical rule of Bancroft.¹⁸⁴ Nonetheless, in the presence of lecithin, the usual case is dispersion of oil in water.¹⁸⁵ Furthermore, in some instances, spontaneous emulsification takes place.¹⁸⁶

Fairly stable emulsions are formed at an oil–water ratio of 0.4–0.6 and a lecithin concentration above 0.5 mass %.¹⁸⁵ The size of droplets is dependent on the lecithin concentration¹⁸⁷ and varies from 5 to 15 μm .^{185,187}

Lecithin emulsions are characterised by high viscosity levels close to that of gel-like systems. The dramatic growth of viscosity (η) is frequently related to the formation of the lamellar mesophase L_α .^{160,188} This is fully justified in the case of lecithin. Numerous studies^{12,17,58,95,185–187,189–198} have shown that the shell of emulsion droplets is made of a number of bimolecular layers. When present at high concentrations, multilamellar structures can be observed in a polarisation microscope even at a small magnification, owing to anisotropy of the lamellar mesophase L_α . The appearance of the L_α -phase induces a sharp increase in the emulsion stability (see, *e.g.* the papers^{17,95,185–187}). Groves *et al.*¹⁹⁸ believe however that the shell of emulsion droplets does consist of the monomolecular lecithin layer, while the stability is attributed to the formation of multilayer vesicles separating oil droplets.

It should be noted that the multilamellar shell effectively prevents the coalescence of emulsion drops, though it does not prevent flocculation (agglutination).^{185,187} In the course of time, emulsions are observed to separate into a layer of aqueous solution and a concentrated emulsion phase. The multilamellar shell may be regarded as an effective structural-mechanical barrier.¹⁹⁹ Surfactants form usually a monomolecular film around emulsion drops. The more complex structural organisation of lecithin is associated with its proneness to self-assembly into liquid-crystalline structures at the interface of immiscible liquids. The preferential formation of the lamellar mesophase L_α is due to the cylindrical shape of molecules. The insufficient resistance to flocculation is explained by the electroneutrality of the lecithin molecule. This resistance is enhanced by the addition of ionogenic surfactants. Furthermore, the addition of phospholipids carrying other polar groups modifies the dimensionless packing parameter S_p . This enables one to change the emulsion type and enhance its stability, which is widely used for practical purposes.

d. Liquid-crystalline structures

There are numerous studies on ternary systems (see, *e.g.*, Ref. 200); however, no whole phase diagram for the lecithin–water–oil system has been constructed until now. This circumstance does not allow discussion of the general pattern of phase transitions as a function of concentration, although certain features of the phase behaviour of lecithin may be considered.

Most of the studies centred on the transformation of the lamellar mesophase L_α into the inverted hexagonal mesophase H_{II} . The increased interest in this problem was initiated by the hypothesis of the important role of non-bilayer structures in processes occurring in living cells, such as their fusion, endo- and exocytosis, as well as transport of proteins and nucleic acids across biological membranes.^{25,27,201–205} It was presumed that the elucidation of the basic factors determining the phase transition $L_\alpha \rightleftharpoons H_{II}$ would allow a better understanding of the mechanisms for the certain cell processes.

As can be seen in the binary phase diagram (Fig. 3), lecithin occurs mostly in the form of lamellar mesophase L_α . Its transition to the non-bilayer state (the cubic or the inverted hexagonal mesophase H_{II}) takes place on heating. Non-polar solvents induce

this phase transformation at room temperature. For example, the molecules of n-alkanes, the effects of which were most extensively studied by numerous investigators, penetrate between the hydrocarbon chains of phospholipids organised into bimolecular lamellae. This penetration is accompanied by increased lateral pressure in the region of hydrocarbon chains, which results in higher values of the dimensionless packing parameter S_p (Fig. 2) and in the occurrence of the phase transition $L_\alpha \rightarrow H_{II}$.

A thermodynamic approach to the description of phase transition has been developed by Gruner *et al.*^{206–208} According to this approach, the free energy of a system is the sum of three components: the elastic component including all intermolecular interactions, the hydration component, and a component accounting for the packing of the hydrocarbon chains of amphiphilic molecules. Their theoretical estimation proves to be highly problematic because of the complexity of such systems; therefore, phase transitions are considered phenomenologically in terms of the ‘spontaneous’, known also as ‘equilibrium’ or ‘inner’, curvature radius R_0 of the monomolecular layer of amphiphiles. When $R_0 \rightarrow \infty$, the amphiphile molecules aggregate spontaneously into the lamellar mesophase L_α ; when R_0 has a finite value, the monolayer is curved, which leads to the formation of spherical (cubic mesophase) or cylindrical (hexagonal mesophase) aggregates. Specifically, solubilisation of alkanes in the lamellar mesophase L_α induces the decrease of R_0 . In this case, the deformation progresses towards the aqueous solution, which corresponds to the transition to the mesophase H_{II} .^{27, 28, 209}

The lamellar mesophase (L_α) of lecithin solubilises about 8 mass % of n-alkanes.^{99, 210–212} The critical alkane concentration, which induces the phase transition $L_\alpha \rightarrow H_{II}$, is determined by the size of alkane molecule, the degree of phospholipid unsaturation, the lecithin–water ratio, and temperature. The ability of hydrocarbons to induce phase transitions diminishes as the molecular mass increases.^{28, 99, 211, 212} This effect correlates with the decrease in the adsorption and the penetration of n-alkanes into bimolecular layers.^{213–215} In addition, at low water content, non-polar solvents are known to reduce the temperature of the phase transition $L_\alpha \rightarrow H_{II}$ (Fig. 3).²⁰⁹ Unsaturation of lecithin favours phase transformations.^{99, 211, 212} For example, a smaller quantity of hydrocarbon is required for the phase transition $L_\alpha \rightarrow H_{II}$.²⁰⁹

All of the above-discussed effects of non-polar solvents may be explained in the framework of the model of Gruner *et al.*^{206–208} on the one hand, and by the transformation of the cylindrical form of the phospholipid molecule into a conical one, on the other. Clearly, the polar solvents will act in the opposite manner. By forming the solvation shell of functional groups, they increase the effective cross-sectional area of the lecithin polar region. This leads to a decrease in the magnitude of the dimensionless packing parameter S_p , which in turn induces the reversal of phase transitions (Fig. 2). For example, the dissolution of water in a non-aqueous solution of lecithin with inverted spherical micelles (L_2 -phase) initiates the transformation of aggregates into the lamellar mesophase L_α . Lindman *et al.*²¹⁰ observed a more complex phase behaviour. Successive addition of water to the mesophase H_{II} obtained at a definite lecithin–n-alkane ratio induced the following transitions: $H_{II} \rightarrow L_\alpha \rightarrow H_{II}$. The phase transition $L_2 \rightarrow L_\alpha$ usually proceeds with concomitant precipitation.^{4, 13, 15, 17, 94, 135, 136} This effect has found its practical application in the technology of lecithin isolation from soybean oil.⁴

2. Non-aqueous systems

In the discussion of the binary systems, it was shown that the ability of lecithin to self-assemble is preserved upon substitution of water by polar organic solvents. This property of lecithin is observed also in the ternary system lecithin–polar organic solvent–oil, though such systems have been studied to a lesser extent. For example, no reports devoted to liquid crystals are available, although some mention of their existence can be found in the relevant literature. Systematic studies were carried out solely on

lecithin organogels. It should be noted that the formation of microemulsion was observed in non-aqueous ternary systems, whereas in the presence of water only emulsions could be prepared.

a. Organogels: a molecular model of self-assembly

Solubilisation of trace quantities of polar organic solvents in a non-aqueous solution of natural lecithin leads, as in the case of water, to its thickening.^{142, 175, 176} Being a Newtonian fluid, the initial solution is transformed into a viscous-elastic gel-like mass displaying properties of a Maxwellian body. The gel-forming solvents and their critical concentrations n_{cr} , at which the maximal level of viscosity is achieved, are listed in Table 6. Comparison of parameters n_{cr} shows that the gel-inducing efficiency decreases in the series glycerol > water > formamide > ethylene glycol. In some of its properties, the diol occupies an intermediate position between the gel-forming and gel-non-forming additives.¹⁴²

Similarly to water, polar organic solvents induce one-dimensional growth of the reverse spherical micelles. These are trans-

Table 6. Formation of lecithin organogels and physicochemical properties of solvents.^{142, 175}

Solvent	n_{cr}	$10^3 \eta$ /Pa s	σ /mN m ⁻¹	ε	Solubility ^a (%)
Lecithin organogel is formed					
Water	3.6–3.8	0.894	72	78.3	0.01
Formamide	4.6–4.8	3.30	58.2	111.0	0.01
Glycerol	1.7–1.9	945	63	42.5	–
Ethylene glycol	> 5	16.9	47.7	37.7	–

1,3-Propanediol	–	39.2	49.2	35.0	0.02
Ethanol	–	1.078	21.9	24.55	0.2
DMF	–	0.796	35.2	36.7	0.08

Note. The organogel-forming solvents and 1,3-propanediol are characterised by the formation of three-dimensional networks of H-bonds; ethanol favours linear chains, while DMF is not characterised by formation of H-bonds. ^a Solubility in squalene; data from Ref. 221.

formed into giant flexible cylindrical aggregates. The molecular mechanism of the lecithin self-assembly into polymer-like micelles has been proposed and substantiated in a number of reports^{142, 175, 176} from IR and NMR spectroscopic studies of the interactions of different polar organic solvents with the phospholipid.

Jellification takes place upon the addition of glycerol, formamide, and ethylene glycol, which form three-dimensional networks through hydrogen bonds. In this case, non-aqueous liquid crystals are also formed. Nonetheless, if the self-assembly of lecithin into liquid-crystalline structures is induced by the solvophobic effects, the roles of polar organic solvents and water in the formation of polymer-like micelles turn out to be different.

This inference is implied by the fact that the addition of 1–3 solvent molecules per phospholipid molecule (parameter n_{cr}) is sufficient for inducing the gel formation. The totally filled hydration shell of lecithin comprises up to 30 water molecules. In other words, the quantity of polar solvent in polymer-like micelles is insufficient even for the total filling of their solvation shells. Consequently, the polar solvent plays a different role in jellification, which should be regarded as structure-forming.

Comparison of structurally close polar organic solvents may provide a better understanding of the mechanism for the self-organisation of lecithin. The full list of the additives studied to date may be found in Refs 142, 175. We shall confine ourselves to

considering the effects of 1,3-propanediol, ethanol, and dimethylformamide (Table 6).

These solvents are structurally close to ethylene glycol, glycerol, and formamide. However, they cannot induce jellification in non-aqueous solutions of lecithin. The IR and NMR studies have shown that the water molecules,^{142, 175, 176, 216, 217} like those of gel-forming organic solvents,^{142, 175, 176} concentrate in the region of the phospholipid polar group by linking to it via hydrogen bonds. 1,3-Propanediol, ethanol, and dimethylformamide also bind with the phosphate residue, though this binding is substantially weaker. The essence of distinctions between the effects produced by the additives that can and cannot induce gel formation may be readily demonstrated by comparing dimethylformamide and formamide.

The molecule of the former carries an acceptor centre (C=O group) and hence can form H-bonds with the donor phosphate group (P—OH). Formamide has larger possibilities since its molecule contains both acceptor (C=O group) and donor (NH₂ group) centres. This allows its linking to the P—OH and P=O groups of phosphate via hydrogen bonding. The polymer-like micelles have been assumed^{142, 175} to form when the molecules of solvents interact simultaneously with the neighbouring lecithin molecules. A possible variant of the structure with formamide is presented in Scheme 1.

The basic distinction between formamide and dimethylformamide, which prevents simultaneous binding of the latter with two lecithin molecules, is that the methyl groups exclude the formation of hydrogen bonds (Scheme 2).

By forming hydrogen bonds with the adjacent phospholipid molecules, formamide acts as a bridging agent. An important aspect is that the phosphate carrying both acceptor and donor groups can also take part in the establishment of several H-bonds.^{113, 123} It has been assumed^{142, 175} that the self-assembly of lecithin into polymer-like micelles is possible because of the formation of extended chains made up of solvent molecules and phospholipid phosphate residues.

Linear networks of hydrogen bonds exert a stabilising effect. This inference was prompted by the comparison of lecithin with didodecyldimethylammonium bromide. This ammonium salt forms, like lecithin, reverse cylindrical micelles, but without participation of H-bonds. The entanglement of micelles produces in the bulk of solutions a similar three-dimensional network, though such micelles do not possess any viscoelastic properties.^{218, 219} Hoffmann¹⁶⁰ has found that the time of structural relaxation (τ) is 10–20 μ s in solutions of didodecyldimethylammonium bromide. After addition of polar solvents to lecithin organogels, *i.e.* after the

appearance of hydrogen bonds, the τ value increases abruptly and amounts to several seconds in the vicinity of n_{cr} .^{142, 143}

The formation of a bridged structure is dependent on the disposition and orientation of solvent molecules relative to the lecithin phosphate group. A possible reason for the lack of jellification after the addition of 1,3-propanediol and ethanol, which can form multiple H-bonds, is thought^{141, 175} to be their insufficiently high polarity (Table 6). It determines both the distribution character of substances in systems of immiscible liquids and their localisation in the interface area.^{161, 180, 220, 221} The lecithin molecule has different polarity regions (Fig. 1). The variation of the dielectric constant [from ϵ (H₂O) to ϵ (oil)] in the monolayer of lecithin occurs not by jumps but rather in a stepwise mode.^{222–224} The molecules of penetrated compounds are localised in different regions along the lecithin molecule according to their polarity.²²⁵ The highest polarity is characteristic of the phosphate group. The probability of a solvent molecule being located near the phosphate group increases with higher solvent polarity. In the series glycerol–ethylene glycol–1,3-propanediol–ethanol, the dielectric constant diminishes, whereas the solubility in the non-aqueous phase increases (Table 6).^{221, 224} The use of the ³¹P NMR method has shown that upon transition from the gel-forming to gel-non-forming additives, the hydrogen bond with the lecithin phosphate group is considerably weakened. This is usually favoured by its curving.²²⁶

b. Non-aqueous microemulsion

Lecithin is known not to form microemulsions in aqueous ternary systems. Microemulsification was found to occur in mixtures with water replaced by ethylene glycol. It is unknown whether or not microemulsions are formed with other polar solvents, since the system soybean lecithin–ethylene glycol–*n*-decane is the only one that has been described to date.^{228, 229} Microemulsions are characterised in greater detail below. Now, we shall consider the picture of non-aqueous microemulsion formation, as reported by Friberg *et al.*^{227, 228}

The area of microemulsion existence in the system lecithin–ethylene glycol–*n*-decane is shown in Fig. 9.²²⁷ At soybean lecithin concentrations of 6 mass %–10 mass %, microemulsification was observed in mixtures where the diol level increased from 30 mass % to 80 mass %. The size of droplets immediately after their preparation was 100–150 nm. Such a water-free microemulsion displayed a limited stability: the separation into immiscible layers began after 10–28 days. Its stability was enhanced with the increasing content of phospholipid and ethylene glycol.

A distinctive feature of microemulsions is their stability during indefinitely long time periods, since they belong to the thermody-

Figure 9. Position of the microemulsion region in the triangular phase diagram of the system *n*-decane–ethylene glycol–lecithin.^{227, 228}

namically stable systems. The separation of a three-component system with time into immiscible layers casts some doubts on the validity of its reference to the microemulsion systems.

Friberg and Podzimek²²⁷ have pointed out the absence of common boundaries between the microemulsional and micellar regions in the phase diagram. This also differentiates the non-aqueous emulsion of lecithin from the known microemulsion systems. The reason for such differences still cannot be identified, since the lecithin microemulsions with ethylene glycol have not as yet been studied to the extent usually required for such purposes. It is hoped that studies of non-aqueous systems along these lines will be reported soon.

VI. Multicomponent mixtures

Mixtures of one or two solvents and different amphiphiles with lecithin are acquiring diverse practical applications. These are already so numerous that merely their listing would require considerable space. The present section is devoted to the basic criteria used for the selection of appropriate components of practically important systems, such as microemulsions and emulsions possessing enhanced stability. In this approach, much attention is given to mixtures of lecithin with other phospholipids and a number of surfactants having important practical and physiological significance.

1. Microemulsions

The term ‘microemulsion’ is used for a dispersion of microdroplets of one liquid in another.²²⁹ This does not, however, necessarily reflect the essence of given dispersive systems and is far from providing their adequate characterisation. The definition proposed by Danielsson and Lindman²³⁰ is gaining popularity over recent years. They refer to microemulsions the water–oil–amphiphile systems that form homogeneous, optically isotropic, and thermodynamically stable liquid solutions. Generally, microemulsions are prepared by adding a third solvent (co-solvent) or a low-molecular surfactant (co-surfactant). It should be noted that the number of ternary systems in which microemulsification can occur is limited. Lecithin belongs to the group of amphiphiles incapable of stabilising the microemulsion phase in the absence of co-solvents or co-surfactants.

The principal difference of emulsion from microemulsion resides in the higher stability of the latter. To understand the reason for different stability, let us express the variation of free energy during dispersion of one liquid in another as

$$\Delta G = \gamma \Delta A - T \Delta S,$$

where γ is the interfacial tension at the oil–water interface, A is the interfacial area between immiscible liquids, and S is the entropy of dispersion. Microemulsification is accompanied by a dramatic increase in the A area. The system is thermodynamically stable when $\Delta G < 0$. In other words, the increase in A must be totally compensated. It has been shown^{231–233} that in some cases this may be done at the expense of the increase in entropy in the course of dispersion. Apparently, the increment ΔA is compensated by the decrease in the interfacial tension. So, in microemulsions containing alkanes, the magnitude of γ diminishes sometimes from $\sim 50 \text{ mN m}^{-1}$ down to $10^{-4} \text{ mN m}^{-1}$,^{23,139} whereas in emulsions it does not drop below 1 mN m^{-1} .

The distribution of microemulsion phases in a three-component phase diagram plotted in the triangular coordinates is presented schematically in Fig. 10 along with the insets showing different dispersive systems. The phase state in the system is determined by the ratio of its components. The single-phase microemulsion is usually localised near the central part of the diagram. The decrease in the amphiphile concentration induces the separation into bi- or tri-phase mixtures. These were first described and classified by Winsor²³⁴, and ever since are referred to by his name.

All the multiphase systems are divided into three types (Fig. 10). Winsor I (WI): microemulsion is in contact with the

Figure 10. Microemulsion phases in the ternary phase diagram and schematic drawings of dispersive systems. For comments, see the text.

organic phase. Winsor II (WII): microemulsion is in contact with the aqueous solution. Winsor III (WIII) microemulsion separates the organic and water phases. Transitions between states are induced by changes in the system composition or temperature. The most common are the transitions $WI \rightleftharpoons WIII \rightleftharpoons WII$. When the amphiphile quantity proves to be sufficient for the total filling of the interface between immiscible liquids, a one-phase microemulsion is formed instead of WIII. In this case, the ‘phase behaviour’ is often complicated by the appearance of lamellar mesophase L_α .^{23,228,235} In the phase diagram, its region is in contact with the region of one-phase microemulsion (Fig. 10).

A reversible transition from WI to WII is accompanied by the reversal of the sign of curvature $C' = 1/r$ (r is the droplet radius) of the amphiphile monolayer localised at the interface separating two immiscible liquids. For the oil-in-water dispersions, the curvature C' is assumed to be positive, i.e. the monolayer is curved relative to the water. In this case, in the WII system, $C' < 0$. The transition from WI to WII must proceed via an intermediate state with $C' \approx 0$ at $r \rightarrow \infty$. Though the structures formed in this process occur less frequently than the microdrop dispersions, they nonetheless attract the attention of investigators owing to a number of their specific properties. For example, at $C' \approx 0$, one-phase, homogeneous mixtures are produced with the largest content of immiscible liquids, which is highly important for practical purposes. The structures formed at $r \rightarrow \infty$ have come to be known as sponge-like or bicontinuous. They are characterised by the interpenetration of the aqueous and non-aqueous phases with a constant dynamic inversion of ‘water-in-oil’ into ‘oil-in-water’ structures and *vice versa*. This is explained by the proximity of value of the elasticity modulus (K) for an amphiphile monolayer to kT ,²³ which makes the structures sensitive to thermal oscillations. For comparison, the magnitude of K for the condensed monolayers of amphiphiles on the water surface is close to $100 kT$,²³⁶ while in the bimolecular films of egg lecithin it amounts to $10 kT$.²³⁷ Interestingly, the introduction of a bipolar amphiphile (an amphiphile with two functional groups separated by an extended hydrocarbon chain) into lecithin vesicles was observed to reduce the value of K down to $(1.0-0.1)kT$ with the concomitant fast and large-amplitude fluctuations of the bimolecular layer resulting in the appearance of diverse vesicle shapes.^{237,238} A similar pattern of dynamic rearrangements seems to take place in the bicontinuously organised microemulsions.

Figure 11. The interfacial tension between aqueous solution and alkane in the system soybean lecithin–water solution of propanol–n-hexane as a function of the propanol content in water (30 °C) (a), and the phase diagrams of the ternary system soybean lecithin–aqueous solution of propanol–n-alkane (25 °C) (b, c). The ordinate, propanol content in water; the abscissa, lecithin concentration in n-alkane. The water : n-alkane ratio = 1 : 1. The region of lamellar L_α phase is hatched; the regions of one-phase microemulsion are marked with grey colour. The system contains n-hexadecane (1–3), n-tetradecane (4), and n-dodecane (5). The diagrams were plotted from the data of Refs 241 (2, 3) and 245 (1, 4, 5).

The role of an amphiphile in the microemulsion systems appears to be crucial. It forms a monomolecular film that separates two immiscible liquids and thereby creates conditions for mixing and simultaneous solubilisation of solvents and compounds with opposite polarities. The resultant balance of molecular interactions turns out to be very sensitive to experimental conditions and the composition of mixtures. Even a slight variation of the latter factors may induce the transitions $\text{WI} \rightleftharpoons \text{WIII} \rightleftharpoons \text{WII}$. On the other hand, phase transitions may also be initiated by changing the form of amphiphile molecules from the inverted to the normal conical shape. In this case, the magnitude of the dimensionless packing parameter must vary successively from 1/3 to 3 (Fig. 2). The shape of molecules cannot change so strongly spontaneously; this may be done only under the action of a number of factors. These include temperature, electrostatic interaction between charged groups, hydration, and the penetration of solvents and co-surfactants into the monomolecular layer of amphiphiles. The magnitude of the dimensionless packing parameter may be regulated by one or all of these factors. They shift the equilibrium in the required direction and induce formation of any of the possible microemulsions or initiate their successive transformations (Fig. 10). Natural lecithin is well-suited for the consideration of the basic regularities of such transitions.

The lecithin molecule preserves its cylindrical form at different water–non-polar solvent ratios, as well as over a wide temperature range.⁵⁶ Besides, lecithin does not reduce the oil–water interfacial tension below 1 mN m^{-1} .^{11, 17, 95} As a result, no formation of microemulsion is observed in the ternary lecithin–water–oil systems. In this case, the only possibility is to prepare emulsions.

First systematic studies of the conditions of microemulsification in the multicomponent systems containing lecithin were carried out by Shinoda *et al.*^{239–243} It was shown that microemulsions are formed upon addition of low-molecular-mass aliphatic alcohols to the ternary system soybean lecithin–water–hexadecane. The addition of co-surfactants induced a sharp decrease in the interfacial tension (Fig. 11). The process of microemulsification was markedly dependent on the alcohol polarity. For example, the addition of butanol led to the formation of reverse swollen micelles. The preparation of Winsor mixtures and one-phase microemulsions was found to require the presence of

ethanol or propanol. The latter was more effective, as microemulsification occurred at its lower concentration. The phase states in the ternary systems with propanol at two levels of soybean lecithin are shown in Fig. 12. It is noteworthy that the area of one-phase microemulsion with bicontinuous organisation is considerably extended with higher phospholipid content.

Thorough investigation of the dependence of microemulsification on the length of lecithin hydrocarbon chains, molecular mass of n-alkanes, and hydrophilicity of aliphatic alcohols has enabled Kahlweit *et al.*²⁴⁴ to reveal a number of regularities making it possible to determine *a priori* the composition of microemulsions intended for different purposes. It was shown that the shorter hydrocarbon chains in lecithin, the more hydrophobic co-surfactants should be used. This is achieved, for example, by substituting butanol for propanol. In the case of didecyllecithin, a further increase in the hydrophobicity of alcohols is required. To this end, the addition of equal amounts of butanol and pentanol was proposed. The increase in the molecular

Figure 12. Phase diagram of the system soybean lecithin–water solution–n-hexadecane at 25 °C. The ordinate, propanol content in water. Lecithin concentration in n-alkane: 1 mass % (1) and 3 mass % (2); the arrows indicate the expansion of the microemulsion region with higher lecithin levels. mass of n-alkanes favours microemulsification in the presence of natural lecithins. This is illustrated by Fig. 11 *b, c*.^{241, 242, 245} On going from n-dodecane to n-hexadecane, the microemulsification is seen to occur at a lower propanol content. Furthermore, a one-phase microemulsion is obtained at a smaller lecithin concentration. The reduction of the molecular mass of n-alkanes and the replacement by aromatic hydrocarbons require a higher hydrophilicity of the aliphatic alcohol. For example, upon transition to n-hexane, propanol proves to be ineffective as co-surfactant because of higher solubility. Preparation of microemulsions requires its replacement by ethanol.

Kahlweit *et al.*²⁴⁴ have proposed to use mixtures of alcohols for the fine regulation of phase equilibria. One should bear in mind that aliphatic alcohols exert toxic effects on living systems. This fact restricts essentially the practical use of microemulsions stabilised by natural lecithins. Non-toxic mixtures containing 1,2-alkanediols as co-surfactants were proposed.²⁴⁶ Besides, n-alkanes were replaced by the non-toxic ethyl oleate. Comparative studies of 1,2-alkanediols have revealed that the optimal conditions for microemulsification in mixtures containing soybean lecithin are created in the case of 1,2-pentanediol whose efficiency is comparable with that of propanol.

In conclusion, it should be said that today the relevant literature carries rather definite concepts of the structure and mechanisms of microemulsion formation. As indicated in a number of recent reviews,^{139, 160, 247–251} the period of intensive studies is giving way to wide and diverse practical applications of microemulsions. The spectrum of their uses proves to be tremendously broad, ranging from chemical and biochemical technologies to functional technologically important fluids, food, cosmetic and medicinal preparations. In this context, it seems appropriate to mention basic advantages that make microemulsions attractive for most varied fields.

1. Universal solvents. As microemulsion systems comprise aqueous and non-aqueous phases, they allow simultaneous solubilisation of both polar and non-polar substances. Consequently, it becomes possible to prepare mixtures of compounds that otherwise cannot exist in direct contact as solutes.

2. Microreactors. In bicontinuous structures, each droplet or domain contains all of the reagents included in a given mixture, which makes it possible to consider them as individual reaction systems. Owing to the size of such microreactors, microemulsions are promising for the synthesis of nanomaterials.

3. Highly effective extraction and reaction systems. High dispersiveness ensures a tremendous interfacial area between immiscible liquids. This intensifies the processes whose rates are limited by migration across the interface or are determined by contacts of substances belonging to different phases.

2. Mixtures with phospholipids and surfactants

In the discussion of emulsions, it was noted that although lecithin is an effective emulsifier, its effect still proves to be insufficiently great. Numerous extensive studies of mixtures of this phospholipid with different substances were, therefore, aimed at enhancing the stability of the emulsions finding most varied practical applications. The present review does not centre on the consideration of numerous experimental data reported to date. Instead, it focuses on the basic principles of the selection of co-emulsifiers illustrated by a number of concrete examples.

The stabilising effect of lecithin is associated with the formation of a multilamellar shell around each emulsion droplet which acts as an effective structural-mechanical barrier preventing coalescence. Despite this, the resistance of droplets to flocculation is not sufficiently high. To eliminate this drawback, methods should be employed that would prevent contacts between the emulsion droplets.

The distance between the bimolecular layers of lamellar mesophase L_α is enlarged by electrostatic repulsive forces (see Fig. 4). Consequently, in order to avert the flocculation of an emulsion stabilised by neutral lecithin, it is necessary to introduce

ionogenic additives. This is achieved through the employment of natural phospholipids, which introduce no toxic properties and do not perturb the biocompatibility with living systems, and by the addition of different ionogenic surfactants.

The set of phospholipids that can acquire an electrical charge via dissociation is rather limited. It includes phosphatidylserine, phosphatidylinositol, and phosphatidic acid. Their addition is conducive to a substantial increase in the resistance of lecithin-stabilised emulsions to flocculation.^{58, 185, 194} These phospholipids have been found to possess different efficiency. This is illustrated by a diagram in Fig. 13. This diagram presents the half-lifetimes of oil droplets from the moment of their contact to fusion measured in model experiments. Accordingly, as regards their efficiency, the anionic phospholipids may be arranged in the following series: phosphatidylinositol < phosphatidylserine < phosphatidic acid. The addition of the latter to lecithin produces the strongest stabilising effect.

Ionogenic surfactants exert analogous effects. A good example are the salts of bile acids, which play an important physio-

Figure 13. Resistance of oil droplets in water to coalescence.

The non-aqueous phase contains soybean lecithin (PC, 0.1 mM), mixture of lecithin with phosphatidylinositol (PI, 30 mg ml⁻¹), phosphatidylserine (PS, 25 mg ml⁻¹), phosphatidic acid (PA, 15 mg ml⁻¹), and lyso-phosphatidylcholine (LPC, 20 mg ml⁻¹). The ordinate, the half-lifetime of droplets from the moment of their contact to fusion. The graph was plotted according to the data of Ref. 194.

logical role in the processes of fat digestion in the human and animal intestine.²⁵² The major bile ingredients are lecithin and bile acid conjugates, *e.g.*, of cholic acid with taurine and glycine. Their simultaneous presence provides for the emulsification of lipids coming with food. In order to achieve an effective functioning of lipases and subsequent uptake of fatty acids by the intestine walls, the emulsion must be composed of as small droplets as possible and be maintained in the non-flocculated state for a few hours.

The highly significant physiological role of the lecithin mixtures with salts of bile acids stimulated a keen interest shown by different groups of researchers.^{187, 253–256} Studies of the emulsification process *in vitro* revealed that nature had devised a highly effective system. For instance, model experiments¹⁸⁷ showed that the addition of sodium taurocholate to the egg lecithin-stabilised emulsions led to the further increase in their stability. Electrophoretic measurements confirmed that this effect was induced by the appearance of charges on the droplet surface. In addition, sodium taurocholate promoted the formation of a finer dispersion. After its addition, the size of emulsion droplets decreased three to four times.¹⁸⁷ The relevant literature carries indications²⁵⁷ that the presence of sodium cholate can stabilise even microemulsions, although the pertinent processes and the phase behaviour of systems have been little studied.

Another possibility for enhancing the stability of emulsions and modifying their type is offered by the regulation of the dimensionless packing parameter S_p . Lecithin, having an S_p

parameter close to unity, does not possess a molecular geometry optimal for the formation of curved surfaces. This explains wide practical use of additives modifying the dimensionless packing parameter S_p . The surfactants with a large polar region and single hydrocarbon chains diminish S_p , which favours the formation of 'oil-in-water' emulsions, while those with small functional groups and two hydrocarbon radicals induce the formation of 'water-in-oil' emulsions. Let us consider how this is realised in practice.

Lysolecithin, *i.e.* a lecithin derivative in which one of the two fatty acid residues is missing, often serves as an amphiphilic additive with a large polar head. As can be seen from the diagram in Fig. 13, the neutral lysolecithin induces a sharp increase in the stability of lecithin-stabilised emulsions. Its efficiency proves to be substantially higher even than that of ionogenic phospholipids.

As a stabilising additive, lysolecithin has the advantage of being a lecithin derivative. It seems more convenient to perform partial hydrolysis of this phospholipid instead of adding other co-emulsifiers. It has been proposed to use group A phospholipases for this purpose. The enzymatic treatment of lecithin has been shown to result in a substantial increase in the stability of emulsion systems.^{258–260}

The type of emulsion may be changed by the addition of phosphatidylethanolamine. This phospholipid is a lecithin analogue whose molecule includes a quaternary nitrogen carrying three hydrogen atoms instead of three methyl groups. This determines a smaller cross-sectional area of the polar region. As a consequence, the molecule has a conical shape, and $S_p > 1$. Contrary to lecithin, phosphatidylethanolamine forms mostly non-bilayer liquid-crystalline structures, in particular an inverted hexagonal mesophase H_{II} .^{13, 28, 58, 73} Its mixing with lecithin increases the S_p parameter. This leads to the eventual transformation of direct emulsions into their reverse type.^{58, 261}

The efficiency of co-emulsifiers increases when both factors are brought into play, *i.e.* when the droplet surface is charged and the variation of the dimensionless parameter is directional. Sometimes, it is problematic to differentiate them since the molecules of different substances are always different in their shape, while electrostatic interactions affect the magnitude of S_p . The interrelation of these factors may be analysed on the example of lecithin mixtures with sodium taurocholate.

In the study of emulsification, Fillery-Travis *et al.*¹⁸⁷ analysed only the effects associated with electrical charges of droplets. As a matter of fact, the hydrophobic taurocholate anion cannot penetrate inside the bimolecular layer and is most likely localised in the region of the lecithin polar groups. With this distribution, the polar region is expanded, which leads to lower values of the S_p parameter. The decrease in the magnitude of S_p is also favoured by the mutual electrostatic repulsion of molecules in the lateral plane. The mixing of lecithin with taurocholate in the monolayer makes the average molecule acquire the reversed cone shape, which favours the surface curvature and explains the experimentally observed formation of smaller dispersion droplets.¹⁸⁷

It should be noted that the quantitative estimation of the S_p parameter variation in mixtures is a complex, if at all realistic, task. We can predict a general character of changes in the molecular form. The variation of surfactant concentration in mixtures with lecithin induces a series of successive structural rearrangements,^{253–256, 262} which are indicative of a gradual variation of S_p . It seems impossible to establish *a priori* the concentration limits of the existence of different structures. Therefore, appropriate compositions for specific practical purposes are selected on an empirical basis. For example, the German company 'Lucas Meyer', a major producer of soybean lecithin, offers various lecithin-based compositions²⁶³ including lysolecithin, charged phospholipids, and phosphatidylethanolamine as ingredients. Tests of lecithin-based mixtures in technological processes and as components of various systems made it possible to determine their composition ranges for the optimal use in food industry, cosmetics, pharmacology, and paint and varnish production.

VII. Self-organisation of lecithin at the interface of immiscible liquids in the course of adsorption

The investigation of three- and multi-component systems comprising immiscible liquids has shown that their properties and phase behaviour are determined by the state of the amphiphile layer at the water–oil interface. Despite the important role of interfacial films, the problem of lecithin self-assembly in the interfacial regions has not received due attention. Most of the studies were devoted to the monomolecular layer,^{264–271} though even those were not numerous because the priority was always given to the air–water interface.

However, it should be noted that the specifics of experiments with monolayers, such as a limited amount of amphiphile that is added directly at the oil–water interface and the mechanical compression–expansion cycles brought about with the help of a mobile barrier, rule out the occurrence of spontaneous processes. A more suitable approach to the study of the self-organisation phenomena is offered by the method based on the investigation of the course of adsorption, which is not limited by any external factors, after bringing a non-aqueous lecithin solution and water into direct contact, and on the analysis of structures formed in the process of equilibrium onset. Such studies were mostly carried out at the Institute of Chemistry (the Far-Eastern Branch of the Russian Academy of Sciences). The basic results pertinent to the topic of this review are discussed in this section.

Numerous studies were devoted to egg lecithin adsorption from the bulk of n-alkanes at the alkane–water interface.^{11, 17, 95, 272–274} These papers report values of basic thermodynamic and kinetic parameters of egg lecithin adsorption, such as the standard free energy of adsorption (G_{ad}°), diffusion coefficient (D), and the rate constant of lecithin adsorption (β) from the non-aqueous phase at the n-alkane–water interface: $G_{ad}^\circ = -47.6 \text{ kJ mol}^{-1}$, $D = (2.0 \pm 0.5) \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$, $\beta = 5 \times 10^{-7} \text{ m s}^{-1}$. The diffusion coefficient is calculated from the equation

$$\Pi = RTC \left(\frac{Dt}{\pi} \right)^{1/2},$$

where Π is the interfacial pressure equal to the difference of interfacial tensions at the oil–water interface in the presence and the absence of lecithin, C is the phospholipid concentration in the non-aqueous solution, t is the time of contact between two immiscible liquids. The diffusional kinetics is characteristic of the initial stages of the adsorption layer formation. As the interface is filled, the diffusional kinetics gives way to adsorptional events. In other words, the entry of the substance into the interfacial film becomes the limiting stage of the process.⁹⁵

The character of the interface filling may be estimated from the dependence of the area per lecithin molecule at the n-alkane–water interface on the concentration of lecithin in the non-aqueous solution (Fig. 14).

Analysis of the peculiarities of the interfacial processes allowed differentiation of at least three concentration ranges in which different types of the adsorption layer are formed.

Dilute solutions (10^{-7} – 10^{-6} M). Lecithin possesses a high surface activity. The change in the interfacial tension begins from the lecithin concentration of about 10^{-7} M. Such a high activity is explained by the large polar region of lecithin (Fig. 1), which does not allow its molecules to remain in the monomeric state in non-polar media, and by the high hydration energy determining the preferential localisation of the phospholipid molecules at the oil–water interface. Thus the standard free energy of lecithin adsorption proves to be of the same order as the hydration energy.^{17, 93}

Relevant studies have shown that within the framework of the classical thermodynamic theory of Gibbs, lecithin adsorption may be described only for strongly dilute solutions. The basic equation used for this purpose is

Figure 14. Dependence of the area per egg lecithin molecule at the n-decane – water interface on the concentration in the non-aqueous phase. The dashed line indicates an approximate boundary of the transition from the two-dimensional to three-dimensional filling of the interface. The A values were calculated by the Gibbs equation (3). The interfacial tension was determined using the droplet profile technique which allows measurements after the equilibrium onset in the system (15–17 h).

$$d\Pi = \frac{RT}{AN_A} d\ln C, \quad (13)$$

where N_A is the Avogadro number. The Gibbs equation (13) makes it possible to estimate the area per lecithin molecule in the adsorption layer and to establish thereby the character of the filling of the interface separating immiscible liquids (Fig. 14). At the egg lecithin concentrations ranging from 10^{-7} to 10^{-6} M, the characteristics of its adsorption layer have been found to be close to those of the monolayer.^{17, 95, 272–274}

Intermediate solutions ($> 10^{-6} - 10^{-2}$ M). At the lecithin concentrations above 10^{-6} M, its quantity at the oil – water interface exceeds the level required for the monomolecular filling.^{17, 95, 273, 274} Two-dimensional interfacial films are giving way to the formation of three-dimensional ones. In concentrated solutions, they become distinguishable even at small magnification.^{95, 273} Until now, no special physicochemical techniques have been employed to study the structure of the interfacial layer. This problem is addressed only in rare accounts of experimental observations.

The interfacial structures have been found to display optical anisotropy,^{95, 275} which is indicative of their possible liquid-crystalline organisation. This is consistent with the results from studies of the emulsion droplet shell. More definite ideas of the interfacial layer structure may be derived from experiments on the thinning of non-aqueous films separating two aqueous solutions. It has been shown^{95, 214, 276, 277} that the structure of the adsorption layer resembles the lamellar mesophase L_α . Such a structural organisation is implied by a discrete thinning similar to the successive ‘removal’ of layers with a thickness approximately equal to that of the bimolecular layer.^{214, 277}

It is noteworthy that the formation of three-dimensional structures at the interface of immiscible liquids is not characteristic of surfactants. Generally, the multilayer filling of the interfacial surface takes place, as confirmed by numerous checks of the validity of the Gibbs equation (13). In the case of lecithin, self-assembly of its molecules into more complex structures has been revealed. Hydration of this phospholipid is believed^{95, 273, 274} to be the driving force of this process. Kinetic studies^{95, 273, 274} of the absorption from the bulk of non-aqueous solutions have shown that on reaching the oil-water interface, a lecithin molecule is retained there because of its high hydrophilicity resulting from its hydration with up to 30 water molecules, which considerably

reduces its solubility in the non-polar phase. Lecithin gradually accumulates near the oil – water interface, and when its level becomes higher than that required for monolayer filling, the formation of more complex structures begins.

Concentrated solutions ($\geq 10^{-2}$ M). The interfacial processes spread inside the non-aqueous phase and modify their character. Figure 15 is a photograph illustrating the liquid phase separation near the oil – water interface.^{274, 278} Its appearance in the form of a thin interfacial film is revealed a few minutes after the contact of non-aqueous lecithin solution with water. The film grows thicker, though irregularly. Its surface reveals protrusions directed towards the non-aqueous phase. At a certain moment the film is disrupted allowing a liquid influx to the surface.

Studies of the interfacial processes have led to the conclusion^{274, 278} that it was not a separate liquid phase that was isolated, but rather a dilute non-aqueous solution with a reduced lecithin content. The phospholipid is concentrated in a different, gel-like film in which it is later transformed into a floccular sediment. The gel and the sediment are localised directly on the surface of the water support.

The experimental findings have been used as a basis for developing a mechanism of the interfacial processes^{274, 278} that

Figure 15. A photograph of the segregated liquid phase in a non-aqueous solution of lecithin near the alkane-water interface at the moment when the liquid is jetting to the alkane surface (a) and a schematic representation of the cell used for experiments (b).

The photograph was taken after a 5.4 min contact of immiscible liquids. Illumination was done with a halogen lamp. For distinct revelation of the segregated liquid phase, the photograph was taken through partially crossed polaroids. Soybean lecithin concentration in n-decane, $10 \text{ mg mlitre}^{-1}$.

relies on the transformation of reverse spherical lecithin micelles into polymer-like aggregates after addition of trace amounts of water. This transformation involves a number of phase and pseudophase transitions: the formation of organogel and its subsequent separation into a compact gel and a dilute non-aqueous solution, and transformation of the gel bulk into a solid sediment (Fig. 8).

In a system of immiscible liquids, the above-mentioned phase and pseudophase transitions are recognised by the appearance of the corresponding phases near the oil–water interface. The respective processes are induced and develop with time owing to the water supply from the adjacent aqueous solution. Since H₂O is insoluble in the non-polar phase, the role of carrier seems to be performed by the lecithin itself. The possible mechanism of such processes may be as follows.

A lecithin molecule attaches water molecules by virtue of hydration at the interface with subsequent desorption of the hydrated molecule and its migration into the bulk of non-aqueous solution, where H₂O is redistributed among non-hydrated lecithin molecules, which induces the transformation of spherical micelles into the polymer-like ones.

It is remarkable that the phase transitions take place not in the adsorption layer but spread considerable distances to occur inside the non-polar phase (Fig. 15). Similar situations are created artificially by bringing into contact two immiscible liquids with one containing a substance that is also well soluble in the second liquid. Its migration may be caused by solubilisation. This may lead to successive phase transitions determined by the phase behaviour of individual amphiphiles.^{180, 279} In the lecithin-containing systems, the migration of water to the non-polar phase is due to different causes, the principal being the hydration of the phospholipid.

The self-organising structures of lecithin modify the interface of immiscible liquids and endow it with new properties. This is especially clearly manifested under external impacts. The application of electric fields has been shown^{17, 95, 274, 280, 281} to lead to the decreased interfacial tension and the emergence of electrodynamic instability at a field strength nearly 100 times as low as that inducing analogous phenomena in the absence of lecithin. Furthermore, the application of a voltage has been found to induce some phenomena that did not occur beforehand: dispersion of a planar interface, the formation of inverted emulsion, and jellification of the non-polar phase. The latter is of interest for practical uses. The substantial decrease in the electric field strength, inducing dispersion of water in oil, allows realisation of processes under mild conditions without high-voltage equipment. Another advantage is that the dispersions formed are preserved only in external electric fields. This makes possible regulation of the processes of the formation and degradation of dispersions.

VIII. Conclusion

The above consideration of the lecithin self-assembly in different media has shown that today it is possible to present a sufficiently full picture of its structures and their phase transformations. One could hardly expect it to be otherwise, since a tremendous number of studies have been devoted to this phospholipid. The investigation of specific aspects of the self-organisation of natural lecithin often gave impetus to the development of new research directions. Liposomes are a good example.

The development of preparative techniques and the use of dispersions as models of cell membranes *in vitro* were for the most part based on lecithin-containing systems. When *in vivo* applications of liposomes were brought onto the agenda, they revealed a number of drawbacks of lecithin among which the principal disadvantage was fast degradation of liposomal structures by cell systems and their insufficient specificity towards the cells selected as targets for biologically active compounds. The efforts aimed at enhancing the stability and targeting the liposomes that involved chemical modification of the lecithin molecule and its complex-

ation with different compounds have resulted in the development of a new generation of liposomal transport systems for biologically active compounds and drugs that has laid the foundation for one of the most rapidly developing directions in biochemistry and biomedicine.^{69, 70, 76–79} Nowadays, further ways for the application of the principles of lecithin self-organisation for devising novel structures are being actively debated in the literature. Specifically, there is a view⁷⁶ that the next stage in the perfection of liposomes will be the development of virus-like systems that would allow a deep insight into the problem of genetic information transfer that is indispensable for the therapy of hereditary diseases or targeted transformations of cell structures for the needs of biotechnology.

The investigation of the self-organising lecithin structures has resulted in the development of a novel type of hemocompatible polymeric material. The basic stages of this work and the application of the principles of lecithin self-assembly have been described in the recent review by Chapman.²⁸² An impetus to the development of this scientific field has been given by the discovery of blood non-coagulation in the lecithin-containing systems. Much work was done to study self-organising structures, such as monomolecular films, liposomes, and liquid crystals that are extensively used as cell membrane models. At the first stage, polymers were produced by polymerisation of the lecithins containing diacetylene bonds in its hydrocarbon chains. It has been found that the incorporation of choline alone proves to be sufficient for making the polymeric materials hemocompatible.

The above-cited examples provide evidence that the potential of the investigation of self-organising lecithin structures has not been exhausted, despite the many-year record of systematic studies. On the contrary, new perspectives seem to appear in this field. They are for the most part related to the study of the lecithin self-assembly in mixtures with biologically active substances, *i.e.* to the investigation of structures that are still closer to the living cell systems.

This work was in part financially supported by the Volkswagen Stiftung (Federal Republic of Germany), grant I/71 486.

Fullerene hydrides: synthesis, properties, and structure

N F Gol'dshleger, A P Moravskii

Contents

I. Introduction	323
II. Methods of synthesis of fullerene hydrides	323
III. Properties of fullerene hydrides	333
IV. Conclusion	339

Abstract. The results of studies on the methods of synthesis of exohedral fullerene hydrides, including the reduction of fullerenes by hydrocarbons, the catalytic hydrogenation of fullerenes, *etc.*, are surveyed. Much attention is devoted to the state of hydrogen in solid fullerene hydrides, the structure of fullerene hydrides, and their reactivity. The bibliography includes 148 references.

I. Introduction

Fullerenes are unique molecules, the reactivity of which has been the object of numerous studies (see, for example, Refs 1–4). Early studies revealed that C_{60} exhibits a high reactivity in relation to nucleophiles,^{1,5–9} free radicals,^{4,10} and the halogens¹¹ and it participates in cycloaddition reactions, including the photocycloaddition of anthracene.¹² These reactions usually result in the formation of a set of products which are difficult to separate and which retain the spherical C_{60} structure. The selective reactions include the osmylation reactions¹³ and the synthesis of fullerene epoxides^{14–16} and fulleroids containing the diphenylmethylene fragment.¹⁷ The reactions involving the addition of metal complexes to C_{60} and C_{70} are controlled by the stoichiometry of the process and the steric loading of the complex.^{18–20} The formation of complexes between fullerenes and low-valence electron-donating metal centres, such as $(Ph_3P)_2Pt(\eta^2-C_{60})$, $[(Et_3P)_2M]_6(\eta^2-C_{60})$ ($M = Pt, Ni$) $(\eta^2-C_{60})IrCl(CO)(PPh_3)_2 \cdot 5C_6H_6$, $(\eta^2-C_{60})RhH \cdot (CO)(PP_3)_2$, $(\eta^2-C_{60})Ru(CO)_4$, *etc.*, in which fullerene acts as a η^2 -ligand, indicates that the double bonds of the fullerene skeleton are electron-deficient. Thus the degree of electron transfer from the metal in the adduct $(\eta^2-C_{60})Ir(CO)Cl(PPh_3)_2$ is similar to that observed in the dioxygen complex $O_2Ir(CO)Cl(PPh_3)_2$.²¹ Calculations of the electronic structure of C_{60} ^{23,24} confirmed that the π -system of the molecule is electron-deficient and that fullerene behaves like a polyolefin rather than an aromatic compound.

The C_{60} structure (I_h symmetry) contains C–C bonds of two types: the shorter double bonds forming common sides of two hexagons (henceforth referred to as the 6–6 bonds)[†] and the longer single bonds, constituting the common side of a hexagon and a pentagon (the 6–5 bonds).^{25,26} In the C_{70} structure (D_{5h}

symmetry), there are five types of carbon atoms and correspondingly eight distinct types of C–C bonds. Four of these constitute the common sides of hexagons, while the other four are formed when five- and six-membered rings fuse.²⁰ Fig. 1 presents the lengths of the 6–6 and 6–5 bonds in the C_{60} molecule, while Fig. 2 presents schematic Schlegel diagrams for C_{60} and C_{70} .²⁷ In the C_{60} and C_{70} fullerenes, the 6–6 bonds are the most reactive and addition to these bonds occurs when fullerenes interact with transition metal complexes (see, for example, Refs 18–22).

Figure 1. The lengths of the 6–5 and 6–6 bonds and their positions in the C_{60} molecule.

The simplest method for the chemical modification of fullerenes is the hydrogenation of double bonds. The reduction of fullerenes is of great interest because they can serve as an effective medium for the storage of hydrogen.²⁸ Theory predicts that hydrogen atoms may be located both within (endohedrally) and outside (exohedrally) the fullerene spherical surface and that a stable $C_{60}H_{60}$ isomer can be obtained only if ten hydrogen atoms are bound endohedrally in the molecule. Traditional methods of organic chemistry are used in the chemistry of fullerenes for the synthesis of a wide variety of compounds, including hydrogenated derivatives.

The aim of the present review is a survey of the available literature data on the methods of synthesis and studies on the structures and reactivities of exohedral fullerene hydrides. There exist several reviews and monographs in which the problem of the hydrogenation of new carbon clusters is dealt with (see, for example, Taylor and Walton² and Hirsch³), but the rapid development of research in this field requires its special consideration and systematic treatment.

II. Methods of synthesis of fullerene hydrides

1. Birch reduction of fullerenes

The C_{60} fullerene can be reduced by the Birch–Hückel method. According to thin-layer chromatographic data, the reduction produces a single compound (TLC, CH_2Cl_2 :hexane = 1:3, R_f = 0.37).²⁹ On heating, the substance obtained (white or cream coloured) began to darken at 170 °C but did not melt up to 305 °C.

[†] For the numbering of the atoms, see Taylor.²⁷

Table 1. Reduction of the C₆₀ and C₇₀ fullerenes.

^a Designations adopted for the reagents: DHA = dihydroanthracene, K = [7H]benzanthrene catalyst. ^b Designations adopted for the methods: EI-MS = mass spectrometry with sample ionisation by electron impact, L²TOF-MS = laser desorption-laser ionisation time-of-flight mass spectrometry, ICR-MS = ion-cyclotron resonance mass spectrometry, SIMS = secondary ion mass spectrometry, FAB-MS = fast atoms bombardment mass spectrometry, FD-MS = mass spectrometry with field desorption. ^c The ratios of the reaction products are given in brackets. ^d Does not dissolve in the majority of organic solvents.

Figure 2. The Schlegel diagram for the C_{60} (a) and C_{70} (b) fullerenes with the numbering of the carbon atoms.²⁷

Mass-spectrometric analysis with ionisation of the sample by electron impact (EI-MS) revealed the presence of two components with m/z 756 (M^+) and 378 (M^{2+}), as well as 738 (M^+) and 369 (M^{2+}), which agrees with the formulae $C_{60}H_{36}$ and $C_{60}H_{18}$ respectively (Table 1). $C_{60}H_{18}$ may be both the product of the direct reduction of C_{60} and the product of the pyrolysis of $C_{60}H_{36}$ formed in the course of the mass-spectrometric analysis. Thorough investigation of the initial reduction product using 'milder' mass-spectrometric methods showed that the Birch reduction leads to the formation of a mixture of polyhydrofullerenes $C_{60}H_{18}$ – $C_{60}H_{36}$, the main product being $C_{60}H_{32}$.³⁰ This experimental distribution of C_{60} hydrides agrees well with the distribution of the products calculated by approximate methods on the assumption that the Birch reduction does indeed involve 1,4-hydrogen addition to the cyclohexadiene fragments of C_{60} (Table 2).³⁰

Treatment of a toluene solution of the fullerene reduction product with a strong oxidant — 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) — leads to C_{60} on refluxing. Thus the reduction of C_{60} is fully reversible and the C_{60} skeleton does not break down in the course of the reaction.²⁹

Under the conditions of the Birch reduction, the C_{70} fullerene affords $C_{70}H_{30}$ as the main product. It has been suggested that the most stable fullerene hydride is obtained as a result of the 1,4-addition of hydrogen to the double bonds on the C_{70} surface.³¹

Benzene may serve as the source of hydrogen in the reduction of fullerene by metallic potassium in the presence of crown-ethers (18-C-6).³²

Table 2. Experimental and calculated (numerical modelling of 1,4-addition by the Monte Carlo method) distributions of the products of the Birch reduction of C_{60} .³⁰

Composition	Distribution of polyhydrofullerenes produced (% of main peak)	
	experiment ^a	calculation ^b
$C_{60}H_{24}$	39(24)	0.2
$C_{60}H_{26}$	53(35)	3
$C_{60}H_{28}$	72(57)	19
$C_{60}H_{30}$	96(89)	53
$C_{60}H_{32}$	100(100)	100
$C_{60}H_{34}$	71(62)	98
$C_{60}H_{36}$	11(10)	55
$C_{60}H_{38}$		14
$C_{60}H_{40}$		0.3

^aThe results of SIMS are quoted. The results of ICR-MS with laser desorption are given in brackets. ^bThe calculation is based on the reduction of 20 000 C_{60} molecules.

2. Reduction of fullerenes by hydrides

The number of thermodynamically and kinetically stable isomers of the simplest fullerene hydrides ($C_{60}H_2$ and $C_{70}H_2$) is small.

Thus the reduction of C_{60} to $C_{60}H_2$ can lead to the formation of 23 isomeric dihydrides, two of which are the products of the 1,2- or 1,4-addition to the 6–6 bonds and have the lowest heats of formation, the latter isomer being less stable to the extent of 3.8 kcal mol^{−1}.³³ A two-stage process (the hydrometallation of C_{60} and C_{70} with subsequent hydrolysis), occurring with high regioselectivity, is a convenient method of synthesis of the lowest fullerene hydrides, which has been demonstrated in relation to the synthesis of $C_{60}H_2$ and $C_{70}H_2$ by hydroboration³³ or hydrozirconation³⁴ (Scheme 1).

The interaction of C_{60} with $BH_3 \cdot THF$ in toluene at 5 °C (Table 1) with subsequent hydrolysis leads to a 10%–30% yield of $C_{60}H_2$ — the simplest fullerene hydride,³³ which was isolated with the aid of high performance liquid chromatography (HPLC). The formation of the stable $C_{60}H_2$ isomer is consistent with calculations.^{35,37} The ^1H NMR spectra of $C_{60}H_2$ as well as $C_{60}HD$, prepared by the reaction of the intermediate $C_{60}HBH_2$ (Scheme 1) with CH_3COOD or D_2O , agree with the spectra of the products of the hydroalkylation of fullerene.³⁶ The regioisomer obtained is the product of 1,2-addition to the 6–6 bond. As in the case of 1-organo-1,2-dihydrofullerene,³⁶ the protons of the dihydrofullerene $C_{60}H_2$ give rise to a signal in the ^1H NMR spectrum at $\delta = 5.9$ ppm (toluene- d_8).³³ The second stable isomer ($\delta = 6.13$ ppm) was detected in this system in a significantly smaller amount.³⁸ The presence of a band at 430 nm in the electronic absorption spectrum of the brown solution of $C_{60}H_2$ is a characteristic property of C_{60} 1,2-adducts.³⁹ The interaction of C_{60} with an excess of $BH_3 \cdot THF$ and subsequent hydrolysis of the

resulting complex with either glacial CH_3COOH , $\text{NaOH} - \text{H}_2\text{O}_2$, or NaOH leads in the presence of atmospheric oxygen to the water-soluble fullerols $\text{C}_{60}(\text{OH})_x$. When the IR spectra of the reaction products obtained under an inert atmosphere and in the presence of atmospheric oxygen were compared, it was found that the reaction proceeds via the oxidation of the C–H bonds in the hydrofullerene formed initially.⁴⁰ A similar process has been observed also in the reduction of C_{60} by tetrabutylammonium tetrahydroborate in benzene at room temperature.⁴¹

The hydroboration of the dihydride C_{60}H_2 (Scheme 2) leads to the formation of a mixture of six isomeric compounds C_{60}H_4 in ~10% yield, among which 1,2,3,4- C_{60}H_4 with all four hydrogen atoms added to neighbouring 6–6 bonds, is, according to ^1H NMR data, the main (~50%) reaction product.⁴² It is also the thermodynamically most stable isomer.

The interaction of C_{70} with $\text{BH}_3 \cdot \text{THF}$ (Table 1, Scheme 3) takes place, in contrast to C_{60} , at room temperature and leads to a ~20% yield of a mixture of 1,9- and 7,8- C_{70}H_2 in the ratio of 2 : 1, for which the difference between the free energies is $\Delta G_{295} = 1.4 \pm 0.2 \text{ kcal mol}^{-1}$.⁴³

According to calculations,³⁷ the products of the 1,2-addition of H_2 to the 6–6 bond of the C_{60} and C_{70} fullerenes and the products of addition in the *para*-position in the six-membered ring have the lowest energy. Both C_{70}H_2 isomers isolated are the products of 1,2-addition. The 7,8- and 1,9- C_{70}H_2 isomers are not interconverted either on standing at room temperature for several weeks or on heating up to 100 °C for 1 h. However, in the presence of Pt/SiO_2 at room temperature, 7,8- C_{70}H_2 in solution in toluene is converted into a mixture consisting of the 7,8- C_{70}H_2 , 1,9- C_{70}H_2 formed as a result of isomerisation, and C_{70} obtained on decomposition.⁴³ The 7,8- C_{70}H_2 isomer is less stable than the 1,9-isomer, but both are stable for a long time at –20 °C in toluene or hexane. Both substances are more sensitive to the action of light and air than C_{60}H_2 .

The structures of the C_{70}H_2 isomers obtained have been confirmed by ^1H NMR spectra: the 7,8- C_{70}H_2 protons give rise to a singlet with $\delta = 3.91 \text{ ppm}$, while the 1,9- C_{70}H_2 protons generate a quartet with the centre at 4.0 ppm. The electronic spectra of the C_{70}H_2 isomers differ appreciably from the absorption spectrum of C_{70} and may be useful for the identification of the C_{70} adducts.⁴³

The interaction of organometallic compounds with fullerenes proceeds exclusively at the 6–6 bond.^{18–22} Thus hydrozirconation opens a path to the selective synthesis of functional derivatives of fullerene. The product of the hydrozirconation of C_{60} is a zirconium(IV) complex, namely $[(\eta^5\text{-C}_5\text{H}_5)_2\text{ZrCl}]_n\text{C}_{60}\text{H}_n$, where $n = 1, 2$, or 3. Hydrolysis of this intermediate leads to a mixture of fullerene hydrides, among which the main product is C_{60}H_2 (Scheme 1).³⁴ The dihydride C_{60}H_2 obtained in this way has been characterised with the aid of ^1H NMR, IR and UV spectroscopy, and mass spectrometry.[‡]

‡ C_{60}H_2 : M^+ , m/z 722; IR (KBr), $\nu/\text{cm}^{-1} = 2956, 1427, 1327, 1259, 1184, 1042, 791, 728, 725, 599, 590, 574, 565, 550, 527, 478$; UV and visible spectra, $\lambda/\text{nm} = 486, 457, 431, 404, 322, 308, 256$, and 212.

Other methods for the reduction of C_{60} and C_{70} fullerenes have also been described, for example reduction by hydrogen in the presence of 5% Pt/C , by $\text{Cr}(\text{II})$ acetate, and by diimide.³⁸ A change in the spectroscopic characteristics of the reaction mixtures in the visible region was noted in all cases. Peaks with $\delta = 5.9$ and 6.1 ppm were observed in the ^1H NMR spectra of C_{60} fullerenes. They refer to reduced C_{60} derivatives.^{33, 38} The fullerene derivatives obtained on treatment with $\text{Cr}(\text{II})$ acetate or with hydrogen in the presence of 5% Pt/C are unstable in the light; in the presence of atmospheric oxygen, they are converted into fullerols. On the other hand, the products of the reduction of C_{60} and C_{70} by diimide are formed in a high yield; the reaction is distinguished by its simplicity. This method is convenient for the synthesis of the di- and tetra-hydride derivatives of fullerenes.

The main product of the reduction of C_{60} by diimide is the 1,2,3,4-tetrahydrofullerene C_{60}H_4 ; apart from this compound, other C_{60}H_4 isomers and more highly hydrogenated compounds are also formed. When C_{70} was reduced with diimide, eight products were obtained: two of these were characterised as the tetrahydrides 1,5,6,9- C_{70}H_4 and 1,7,8,9- C_{70}H_4 and a further two were characterised as the dihydrides 1,9- C_{70}H_2 and 7,8- C_{70}H_2 identical to the compounds obtained previously by reduction with diborane.⁴³ It has been noted that the hydrogenated fullerene derivatives dissolve more effectively in CS_2 than in benzene or toluene. The chemical shifts of the ^1H NMR signals strongly depend on the solvent: in CS_2 , they undergo a downfield shift (by 1 ppm) compared with benzene.

3. Reduction of fullerenes by hydrocarbons

At elevated temperatures, fullerenes serve as dehydrogenating agents in relation to hydrocarbons. Thus treatment of C_{60} in a sealed glass tube at 350 °C under an inert atmosphere with a melt of 9,10-dihydroanthracene (C_{60} :9,10-DHA = 1 : 120), which serves as a source of hydrogen, leads to rapid (30 min) decolorisation of the melt.

It has been found that the reduction of the C_{60} fullerene under the conditions of the noncatalytic transfer of hydrogen atoms from the donor to the acceptor (transfer hydrogenation)⁴⁴ leads to the hydrides $\text{C}_{60}\text{H}_{36}$ and $\text{C}_{60}\text{H}_{18}$.⁴⁵ In this reaction, fullerene can function as a radical trap.⁴⁶

After the sublimation of the excess DHA and of the anthracene produced, a white (or slightly yellowish) solid product $\text{C}_{60}\text{H}_{36}$ was isolated and was characterised by mass spectrometry. A peak at m/z 756 corresponds to it. The increase in reaction time to 24 h leads to the formation of a coloured product with m/z 738, which corresponds to the compound $\text{C}_{60}\text{H}_{18}$. The presence of a hydride having this composition has also been confirmed by thin-layer chromatography.⁸ At the same time the free C_{60} fullerene was detected in the melt. EPR study of this reaction showed that the 9-hydroanthryl radical is formed as an intermediate. $\text{C}_{60}\text{D}_{36}$ and $\text{C}_{60}\text{D}_{18}$ are formed similarly when dihydroanthracene-*d*₄, deuterated in the 9- and 10-positions, is used for the reduction of fullerene. Cyclohexa-1,4-diene has been used in the hydrogenation of C_{60} by the method of transfer hydrogenation.⁴⁵

Solutions of $\text{C}_{60}\text{H}_{36}$ in a series of organic solvents are unstable even under an inert gas atmosphere. After a time, they become turbid and the signals in the ^1H NMR spectrum become broadened. Heating of the hydrides $\text{C}_{60}\text{H}_{36}$ and $\text{C}_{60}\text{H}_{18}$ in an inert gas (550 °C, 15 min) leads to their quantitative dehydrogenation to C_{60} . Anthracene and α -methylstyrene may serve as chemical dehydrogenating agents for the hydride $\text{C}_{60}\text{H}_{36}$ (the reduction of

§ SiO_2 , CH_2Cl_2 :hexane = 1 : 3; $R_f(\text{C}_{60}\text{H}_{36}) = 0.37$ ^{29, 45} and $R_f(\text{C}_{60}\text{H}_{18}) = 0.15$.⁴⁵

anthracene affords 1,2,3,4-tetrahydroanthracene, which is inert under these conditions).⁴⁵

The conclusion about the structure of $C_{60}H_{36}$ obtained by the method described by Rüchardt *et al.*⁴⁵ was reached on the basis of the inability of the latter to be reduced to the corresponding radical-anion[¶] on treatment with metallic potassium in dimethoxyethane. According to the authors,⁴⁵ this indicates the presence of isolated C=C bonds in the $C_{60}H_{36}$ molecule, as has been postulated for the product of the Birch reduction.

[7H]Benzanthrene plays the role of a catalyst in the hydrogenation of C_{60} and C_{70} by the method of Rüchardt *et al.*⁴⁵ using dihydroanthracene as the reducing agent (fullerene:catalyst:DHA = 1:5:100).⁴⁷

The use of a catalyst made it possible to reduce the reaction temperature from 350 °C (for the noncatalytic reaction) to 250 °C, but the selectivity of the reaction became lower under these conditions. The C_{70} fullerene reacted more slowly than C_{60} . Deuterio-derivatives of C_{60} and C_{70} have also been obtained by this method. The mass spectra of the reaction products formed in the presence of the catalyst are characterised by a wide mass distribution (Table 1). According to a mass-spectrometric study with ionisation of the sample by electron impact, in the case of C_{60} a hydride with a higher hydrogen content, namely $C_{60}H_{44}$, may be obtained under the conditions of the catalytic reaction. On the other hand, the mass spectra of the products of the reaction with ionisation of the sample by laser desorption (LD-MS) were identical with the spectra of the products obtained in the noncatalytic reaction, which indicates the same degree of reduction of C_{60} and C_{70} in both cases, namely to $C_{60}H_{36}$ and $C_{70}H_{36}$. This feature of the LD-MS method has also been noted by other researchers and has been explained by the possibility of the elimination of hydrogen from the unstable hydrides on laser desorption.

It is of interest that the main peak in the EI-MS of $C_{70}H_{36}$ (at m/z 876) indicates an increased stability of the hydride with 36 hydrogen atoms. The enthalpy of formation of $C_{70}H_{36}$ has been calculated: $\Delta H_f^\circ(\text{gas}) = 490.2 \text{ kcal mol}^{-1}$.⁴⁷ Further reduction of C_{70} to $C_{70}H_{40}$ leads to an increase in $\Delta H_f^\circ(\text{gas})$ to 535.7 kcal mol⁻¹. Consequently the formation of $C_{70}H_{36}$ is the thermodynamically preferred process.

When C_{60} and mesitylene were refluxed (163 °C) under an inert atmosphere for 24 h, both the products of the dimerisation of mesitylene and the product of its addition to C_{60} were detected in the reaction mixture (C_{60} adducts with one, two, and three mesitylene residues), the yield of the products of the oligomerisation of mesitylene (dimers and trimers) exceeding by a factor of 7 the initial C_{60} concentration. One may therefore speak in this case of the catalytic activity of the C_{60} fullerene.⁴⁸

The influence of C_{60} on the dehydrogenation of hydroaromatic compounds on heating has also been mentioned by Malhotra *et al.*⁴⁸ For example, in the dehydrogenation of 9,10-dihydrophenanthrene in the presence of C_{60} , the phenanthrene: -dihydrophenanthrene ratio is 33, while in its absence, other conditions being equal, it is 1.3.⁴⁸ The C_{60} fullerene is then converted into reduced derivatives with different hydrogen contents. After prolonged heating, the hydrogenated fullerene derivatives are dehydrogenated, as in the case of $C_{60}H_{36}$.⁴⁵ Thus C_{60} behaves as a catalyst in this reaction.

The effect of C_{60} on the cleavage of the carbon-carbon bond in 1,2'-dinaphthylmethane has been investigated in the presence of hydrogen donors such as dihydroanthracene, dihydrophenanthrene, *etc.* (Scheme 4).⁴⁸ It was found that, when C_{60} is added to anthracene system, the rate constant of the reaction increases

appreciably and the selectivity (the 2-methylnaphthalene: 1-methylnaphthalene ratio) changes. On hydrogenolysis of 1,2'-dinaphthylmethane in the absence of fullerene, the ratio is ~1.5, whilst in the presence of fullerene-containing systems it reaches ~4.4–5.4. The results indicate the involvement of C_{60} in the acceptance of hydrogen atoms from the hydroaromatic compounds or the corresponding hydroaryl radicals and in the subsequent hydrogen transfer to 1,2'-dinaphthylmethane.

Scheme 4

Ar/ArH₂ = anthracene/9,10-dihydroanthracene, pyrene/4,5-dihdropyrene, or phenanthrene/9,10-dihydrophenanthrene.

The hydroalkylation of fullerene by unsaturated compounds, such as hept-1-ene and 4-allylanisole, with formation of fullerene alkyl hydrides, has been reported.⁴⁹

It has been observed that, when various hydrocarbons, including alkanes, are come into contact with fullerenes (fullerene cocoons)[†] at high temperatures (500–700 °C), large amounts of molecular hydrogen and of the products of the dehydrogenation of the hydrocarbons are evolved into the gas phase.⁵⁰ The reactions were carried out at a very low pressure of the hydrocarbons (1 Torr),⁵⁰ which indicates a high activity of fullerenes in the activation of C-H bonds, including the bonds in alkanes. In contrast to industrial pyrolytic processes, lower olefins predominate in the reaction products in this instance. For example, ethene, propene, and hydrogen have been obtained from hexane in the complete absence of ethane, propane, and C₄ hydrocarbons.⁵⁰ Thus, apart from the dissociation of the C-H bonds, the cracking of strong C-C bonds in alkanes also takes place effectively on the fullerene cocoons. The pyrolysis of toluene is also accompanied by the dissociation of the CH₃-C₆H₅ bond, which is indicated by the presence of methane and benzene in the reaction products.⁵⁰

The activation of methane also becomes possible in the above temperature range (the C-H bond energy is 105 kcal mol⁻¹).^{51–53} The threshold temperature of the onset of pyrolysis of methane on fullerene black[‡] as the catalyst is 600 °C, which is lower by 250 °C than the reaction threshold in the absence of a catalyst and lower by 100–200 °C than the threshold temperatures for graphite, activated charcoal, and other carbon catalysts.^{51–53} High degrees of conversion, of methane (dozens of %) are attained under the conditions of a flow reactor at temperatures above 900 °C. The dehydrogenating activity of the initial fullerene black is then so high that at the beginning of the reaction hydrogen is virtually the only gaseous product.⁵³ Only after the accumulation of a certain amount of pyrolytic carbon and the concomitant decrease in the dehydrogenating activity of the catalytic system do gaseous hydrocarbons, among which ethene predominates, appear in the products. Further accumulation of pyrolytic carbon leads to a decrease in both the degree of conversion of methane and in the selectivity with respect to ethene.⁵³ This undesirable phenomenon was overcome by diluting the initial stream of methane with hydrogen.⁵³

[†] Fullerene cocoons are polymeric structures, which are nonsublimable (in contrast to fullerenes) at high temperatures and in which the fullerene molecules are linked to one another by oxygen bridges, the number of which is approximately equal to the number of fullerene molecules.⁵⁰

[‡] Fullerene black is the finely dispersed carbon material remaining after the extraction of fullerenes with a suitable solvent from the fullerene-containing soot obtained on electric arc vaporisation of graphite under an inert gas atmosphere.

[¶] All attempts to observe the EPR spectrum of the radical-anions of the hydrogenated and deuterated fullerenes were unsuccessful.⁴⁵

It has been observed⁵³ that the addition of hydrogen to methane can alter drastically the process selectivity. At a sufficiently high dilution, the reaction begins immediately, without the induction period mentioned above, whereupon virtually pure ethene is formed (the selectivity with respect to ethene is 90%–94%) while the amount of propene does not exceed 6%–10% and there are only traces of other products.⁵³ The degree of conversion of methane is comparatively low ($\sim 4\%$), but remains stable for many hours at 1000 °C. The accumulation of pyrolytic carbon is not observed under these conditions.

Such influence of dilution on the process is fully reversible, which suggests that the mechanism of this interesting phenomenon involves the dynamic blocking by hydrogen of the most active dehydrogenation centres on the surface of fullerene black. Fullerene black consists mainly of three–five layer stacks of markedly curved graphene sheets with a local radius of curvature of the order of the dimensions of the usual fullerenes.⁵⁴ The curvature caused by the presence of five- and seven-membered rings in the structure of the sheet arises under the highly non-equilibrium conditions in the electric arc, characterised by high temperature and carbon species concentration gradients. This distinguishes fullerene black from all industrial blacks, activated charcoals, and graphite, the only basic structural element of which is absolutely planar graphene sheets, *i.e.* planar two-dimensional macromolecules consisting of carbon atoms, forming adjacent hexagons. The curvature of the carbon surface in fullerenes and in fullerene black may be the cause of their higher reactivity towards dihydrogen and C–H bonds.

The mechanism of the activation of hydrocarbons RH in the presence of fullerenes is as follows. The C–H bond is activated by the strained $C^*=C^*$ double bond of the curved carbon surface in the primary step of the interaction of the hydrocarbon with fullerene, which results in the formation of the $R-C^*-C^*-H$ fragment. The subsequent migration of hydrogen atoms and the radicals R on the surface, multiple reversible addition of the RH molecules and hydrogen, reactions of the two-centre and β -elimination types, and also the dissociation of the free radicals R and other processes possible at sufficiently high temperatures are responsible for the formation of the set of products in the liquid-phase and gas-phase reactions investigated. Thus methylated derivatives of fullerenes, namely $C_{60}(CH_3)_n$, were detected in the mass-spectrometric analysis of the fullerene-containing soot, carried out after the high-temperature dehydrogenation of methane.⁵¹ Modification of the catalyst, for example doping of the fullerene-containing soot with potassium, increases the selectivity in the formation of higher hydrocarbons from methane.⁵²

4. Reduction of fullerenes in a metal–acid system

The reduction of C_{60} in metal (M)–acid systems, where $M = Sn[E^{Ox/Red}(Sn^{2+}/Sn) = -0.75\text{ V}]$, $Fe[E^{Ox/Red}(Fe^{2+}/Fe) = -1.05\text{ V}]$, and $Zn[E^{Ox/Red}(Zn^{2+}/Zn) = -1.37\text{ V}]$, has been investigated. The potentials were measured relative to Fe^+/Fe ($Fe = \text{ferrocene}$).⁵⁵ In principle, these results make it possible to obtain the anions C_{60}^- and C_{60}^{2-} since the potentials for C_{60}^0/C_{60}^- and C_{60}^-/C_{60}^{2-} are -0.98 and -1.37 V relative to Fe^+/Fe . However, the Sn–acid and Fe–acid systems proved to be ineffective for the reduction of C_{60} and only the Zn–acid system was found to be suitable for such purposes. The acids employed are 6 M or 12 M HCl, glacial CH_3COOH , and concentrated H_2SO_4 . When a toluene solution of C_{60} is refluxed under an inert atmosphere, a mixture consisting of 7% of $C_{60}H_2$, 3% of $C_{60}H_4$, and 1% of $C_{60}H_6$ is formed. It was separated by means of HPLC. It contains also small amounts of fullerenes with a higher hydrogen content ($C_{60}H_6$ – $C_{60}H_{22}$), but these were not isolated.⁵⁵ The mass spectra of the fullerene hydrides obtained by this method demonstrate a strong tendency of the products for fragmentation back to the parent C_{60} on ionisation. It has been demonstrated that the substance with a mass of 722, present in the reaction mixture in the largest amount, has the same spectroscopic and chromatographic characteristics as 1,2- $C_{60}H_2$.³³ Thus, under the conditions indi-

cated, mainly the most stable dihydrofullerene isomer (1,2- $C_{60}H_2$) is formed in the C_{60} –Zn–acid system. Treatment of the reaction mixture obtained as a result of the interaction of C_{60} with zinc in hydrochloric acid with DDQ leads to C_{60} , which confirms the formation of hydrogenated C_{60} derivatives.

The reduction of C_{60} and C_{70} in the Zn–conc. HCl–toluene (benzene) system under an inert atmosphere takes place rapidly even at room temperature and leads to the preferential formation of $C_{60}H_{36}$, $C_{70}H_{36}$, and $C_{70}H_{38}$ in the absence of light.⁵⁶ In the case of C_{60} , appreciable amounts of more highly hydrogenated derivatives are also formed in this case: $C_{60}H_{38}$ (15%) and $C_{60}H_{40}$ (3%).⁵⁶ The C_{70} fullerene is reduced at a lower rate than C_{60} . Furthermore, the compound $C_{70}H_{36}$ is thermally less stable than $C_{60}H_{36}$.

The sensitivity of fullerene hydrides synthesised by this method to oxygen increases appreciably in solution in the presence of light. The peaks due to the initial fullerenes and their lower hydrides are therefore absent from the mass spectra of $C_{60}H_{36}$, $C_{70}H_{36}$, and $C_{70}H_{38}$, obtained with the aid of ionisation by electron impact, only in the case where the spectra have been run immediately after work up. Otherwise, peaks corresponding to completely dehydrogenated products (C_{60} and C_{70}) and the lower hydrides ($C_{60}H_{18}$ in the case of $C_{60}H_{36}$), as well as fullerols appear in the mass spectra. The formation of highly hydrogenated fullerenes, including $C_{60}D_{44}$ and $C_{70}D_{48}$ on treatment with Zn in concentrated DCl, is associated with the greater stability of the C–D bonds compared with the C–H bonds, as a result of which the loss of the resonance energy of the initial fullerene is partly compensated. The hydrogen atoms in fullerene hydrides do not undergo H/D exchange in the absence of light either with D_2O , or with $D_2O/NaHCO_3$, or with $D_2O/NaOH$, which indicates a decrease in the acidity of the C–H bond in $C_{60}H_{36}$ compared with, for example, the acidity of this bond in the adduct of C_{60} with morpholine $[NH(CH_2)_4O]$ having the composition $HC_{60}N(CH_2)_4O$ since in the latter case hydrogen rapidly exchanges with CH_3OD .^{5,57}

The hydrides $C_{60}H_{36}$ and $C_{70}H_{36}$ are resistant to further reduction by hydrogen in the presence of the Rh/ Al_2O_3 catalyst (toluene is used as the solvent), but they tend to form trimethylene adducts (this is indicated by the appearance in the mass spectrum of peaks with m/z 798, 840, and 882 in the case of $C_{60}H_{36}$) via an unknown mechanism.⁵⁶ When the reaction was carried out in benzene- d_6 (as a solvent), H/D exchange between the fullerene hydride and the deuterium of the solvent was observed.⁵⁶

Figure 3. Absorption spectra of $C_{60}H_{36}$ (a) and $C_{70}H_{36}$ (b) (higher hydrides are present as impurities).⁵⁶

The UV spectrum of $C_{70}H_{36}$ has a broad band with a maximum at 275 nm and a shoulder at 223.5 nm (Fig. 3), which are close to the wavelengths λ for naphthalene (221 and 258–280 nm).⁵⁶ According to the authors,⁵⁶ this is consistent with the aromatic structure proposed for $C_{70}H_{36}$.⁵⁸

5. Reduction of fullerenes by hydrogen

The direct reduction of C_{60} and C_{70} has been carried out in the solid phase at a hydrogen pressure of 50–80 MPa and a temperature of 573–623 K without using a catalyst.⁵⁹ Fullerene hydrides having the composition $C_{60}H_x$ ($x = 2–18$) and $C_{70}H_y$ ($y = 4–30$), identified with the aid of mass spectrometry, are then formed. The authors⁵⁹ also attempted to answer the question whether hydrogen atoms or molecules can be added at a high pressure and an elevated temperature to endohedral positions in the fullerene molecule. In order to avoid losses of fullerene, the reaction was carried out in a sealed capsule. The material of the capsule (25% Ag–75% Pd alloy, Au, or glass), in which the hydrogenation is carried out, does not affect the yield of the products and the rate of hydrogenation. This provided grounds for the assumption that the hydrogenation proceeds only under the influence of hydrogen and is initiated by small amounts of atomic hydrogen, which is generated in the reaction medium at these temperatures and pressures.

Heating of the C_{60} fullerene in a sealed AgPd capsule in a H_2 atmosphere at a temperature ≥ 950 K leads to the complete disappearance of the specimen. Since neither C_{60} nor its hydrides can diffuse from the capsule, under the given experimental conditions fullerene apparently decomposes to low-molecular-mass fragments, which react with the material of the capsule and the presence of hydrogen then plays an important role.

The study of the products of the direct hydrogenation of fullerene showed that hydrogen usually if not always adds exohedrally to the fullerene skeleton. In order to demonstrate this fact, use was made of the proton transfer reaction

Pyridine (Py, proton affinity 220.4 kcal mol⁻¹) is a stronger base than C_{60} (proton affinity 205 kcal mol⁻¹), so that the interaction can occur only when all or some of the hydrogen atoms in the fullerene hydride are bound exohedrally, although the possibility of the endohedral binding of hydrogen is also not ruled out. Hydrogenation lowers somewhat the ionisation potential of fullerene: $I(C_{60}H_x = 2–18) \leq 7.53$ eV, while $I(C_{60}) = 7.6$ eV. It has been noted that the hydride $C_{60}H_x$, obtained by direct solid-phase hydrogenation is distinguished by a greater stability than the specimens obtained by other methods.^{29, 60}

Fullerite⁸ (a mixture of C_{60} and C_{70}) was hydrogenated (~ 1 h) by hydrogen at 400 °C and a H_2 pressure of 6.9 MPa using ethyl iodide as the promoter of the formation of atomic hydrogen in the system.⁶¹ In the absence of C_2H_5I , hydrogenation does not occur. An increase in temperature and pressure leads to a decrease in the degree of hydrogenation. Mass-spectrometric analysis of the reduced fullerite by FAB-MS technique showed that a mixture of hydrides $C_{60}H_{36}$ and $C_{70}H_{36}$ is mainly formed in the reaction. The use of 'harder' mass-spectrometric methods, such as EI and LD, proved impossible owing to the thermal decomposition of the product to compounds with lower molecular masses ($C_{60}H_{18}$, $C_{60}H_8$, etc. in the case of $C_{60}H_{36}$). No spectroscopic evidence for the ethylation or iodination of fullerene under these conditions was found. The reaction product is insoluble in the majority of organic solvents and is only slightly soluble in nitrobenzene, which distinguishes it from the hydride obtained by Birch reduction²⁹ or by the transfer hydrogenation.⁴⁵

§ The solid crystalline material consisting of pure fullerenes or their mixtures is called fullerite.

The solid-phase ^{13}C NMR spectrum of polyhydrogenated fullerene $C_{60}H_{36}$, obtained by radical hydrogenation, indicates the presence of a single highly symmetrical compound, possibly of D_{3d} or C_{3i} symmetry.⁶¹ On the other hand, Buhl *et al.*⁶² see no agreement between the experimental ^{13}C NMR spectrum of $C_{60}H_{36}$ ⁶¹ and the D_{3d} structure.

The reaction of C_{60} (up to 90% in the mixture) with an ultrasonic molecular beam of H_2 or D_2 has been investigated at 540–750 °C and a pressure of 100–500 Torr.⁶³ It was found that the interaction of H_2 with C_{60} under these conditions leads to both the hydrogenation of fullerene (up to eight hydrogen atoms may add to C_{60}) and to the formation of low-molecular-mass hydrocarbon species as a consequence of the disruption of the C_{60} skeleton. When H_2 is replaced by D_2 , a large isotope effect is observed. The main product is $C_{60}H_2$, the yield of which depends both on the H_2 pressure and on the temperature.

Solid C_{60} has been hydrogenated by atomic hydrogen at 77 K (in a cyclohexane matrix).⁶⁴ The $C_{60}H$ ($g = 2.00218 \pm 0.0004$), $C_{60}H_{2n+1}$, and $C_{60}H_{2n}$ species were identified by EPR and IR spectroscopy and FAB-MS technique.

The hydrogenation of thin C_{60} films by atomic hydrogen has been investigated with the aid of the plasma desorption method.⁶⁵ The approach proposed⁶⁵ makes it possible to determine the degree of hydrogenation of C_{60} molecules. It was found that hydrogen is bound covalently to the fullerene molecule with formation of the hydride $C_{60}H_n$ ($n = 2–24$). The authors rule out the possibility of the formation of fullerene hydrides by the interaction of C_{60} with the residual toluene in the film under the conditions of the mass-spectrometric analysis.

An attempt to implant a hydrogen atom inside the C_{60} molecule has been reported [plasma, 10–25 eV, 550–600 °C, $(5–10) \times 10^{-4}$ Torr]. It has been shown with the aid of HPLC, ^1H NMR, and mass spectrometry that hydrogen adds exohedrally with formation of the compounds $C_{60}H_2$ and $C_{60}H_4$. No evidence has been obtained for the formation of complexes with endohedrally bound hydrogen under these conditions.⁶⁶

We may note that the addition of a H atom to C_{60}^+ in the gas phase takes place very effectively, the bimolecular reaction rate constant being $k \approx 6 \times 10^{13}$ cm³ mol⁻¹ s⁻¹ at 294 K and a helium pressure of 0.4 Torr.⁶⁷ Under the same conditions, the reaction of C_{60}^+ with molecular hydrogen does not occur,⁶⁸ but a C_{60} ion accelerated up to an energy of 5–6 keV is apparently capable of incorporating a H_2 molecule into the carbon framework with formation of the endohedral complex $H_2@C_{60}^+$.⁶⁹

The hydrogenation of the molecules of fullerenes and other neutral C_n carbon clusters in the gas phase at a high temperature has been investigated by the TOF-MS technique with LD evaporation of the test substance for the wide range $n = 6–75$.⁷⁰ The clusters were obtained by the laser pulse evaporation of graphite and were mixed with D_2 in a flow reactor. The kinetics of the variation of the C_n concentrations and of the formation of the C_nD_m products ($m = 1–4$) have been investigated. Deuterated clusters are formed as a result of the successive addition of D atoms via the reaction involving direct abstraction from the D_2 molecule ($k \approx 10^{11}$ cm³ mol⁻¹ s⁻¹ at 2800 K).

In certain cases, excited C_nD^* species undergo unimolecular decomposition with the preferential formation of the compound $C_3(p = 3)$:

In the case of 'even' C_{2n} clusters with $n < 20$, the reaction product $C_{2n}D_2$ is a linear polyyne (a carbyne), which is inert in relation to more extensive hydrogenation. An attempt may be

made to use this fact in order to obtain the crystalline form of the carbyne by depositing on a cold support the products of the reaction of graphite vaporised in a hydrogen atmosphere. The possibility of the existence of such a form of the carbyne stable at room temperature is indicated by experiments on the condensation of the products of the electric spark disintegration of graphite on a copper plate under an argon atmosphere (0.5 Torr)⁷¹ and also by the presence of linear carbon molecules in the fullerene black obtained by the electric arc⁷² or laser⁷³ vaporisation of graphite.

The 'odd' C_{2n+1} clusters react with D_2 at a higher rate than the 'even' clusters.⁷⁰ This difference increases progressively with increase in n in the fullerene mass range ($n > 36$), where the reactivity of even clusters (fullerenes) diminishes and that of the odd clusters (structures with open carbon shells of a radical character with a larger geometrical collision cross-section) increases.⁷⁰

The high-temperature hydrogenation reactions of fullerenes and their precursors influence the yield of fullerenes in hydrocarbon flames and in a carbon arc. Even several per cent of hydrogen in helium fully blocks the formation of C_{60} in the electric arc vaporisation of graphite.⁷⁴ The possibility of the formation of the hydrides $C_{60}H_x$ in this process for a low hydrogen content in the gaseous medium has not been specially investigated. On the other hand, under a hydrogen atmosphere, open carbon nanotubes appear in the cathodic deposit formed in a d.c. carbon arc.^{75,76} Under these conditions, the inner channel of the open nanotubes is free of the amorphous carbon deposits characteristic of tubes opened by treatment with strong oxidants. In addition, the number of spherical carbon nanoparticles in the deposit decreases sharply under a hydrogen atmosphere.^{75–77} Thus the use of hydrogen is extremely promising for the solution of the problem of the preparation of open and pure nanotubes. The effect of hydrogen consists in this instance of the hydrogenation of the end-face of the growing open nanotube with formation of relatively stable C–H bonds, which prevent the formation of five-membered rings and hence the closure of the tube when the temperature is reduced.^{75,76}

6. Reduction of fullerenes by organic compounds under irradiation

In the study by the EPR method of the products formed in the photolysis (high-pressure Hg/Xe lamp) of a benzene solution of C_{60} containing thiophenol, cyclohexa-1,4-diene, or Bu_3SnH , it was found that the EPR spectrum consists of two lines with a splitting of 33 G.⁷⁸ The authors assigned this spectrum to the radical $C_{60}H^\bullet$ — the initial product of the reaction of the photogenerated hydrogen atom with C_{60} (the hydrogen atoms are formed on photolysis of thiols, tin hydrides, and cyclohexa-1,4-diene).

On heating (100 °C, toluene) or flash photolysis (Nd^{3+} : YAG-laser, $\lambda = 532$ nm, benzonitrile) of the C_{60} fullerene–diethyl 2,6-dimethyl-1,4-dihydropyridine-3,5-dicarboxylate (**1**) reaction mixture, appreciable changes are observed in the absorption spectrum of C_{60} in the visible region: bands at 434 and 708 nm, characteristic of dihydrofullerene, appear in it, while the bands characteristic of free C_{60} vanish. It has been shown by ^1H NMR that the solution contains the diethyl ester of 2,6-dimethylpyridine-3,5-dicarboxylic acid — the product of the dehydrogenation of compound **1**. The formation of the hydrides $C_{60}H_x$ ($x = 2, 4, 6$) has been demonstrated mass-spectrometrically.⁷⁹

Scheme 5

7. Catalytic hydrogenation of fullerenes

The possibility of the catalytic hydrogenation of C_{60} in the presence of transition metals has been investigated.^{80–85} It was found that, in the presence of Ru/C, Pt/C, and Pd/C, fullerene is

hydrogenated (H_2 pressure 100 atm, 180 °C), affording a low yield of $C_{60}H_{36}$ (a mixture of $C_{60}H_{36}$ and $C_{60}H_{18}$ is formed depending on the hydrogen pressure). The activity of the catalysts varies in the sequence $Pt < Ni < Pd < Ru$. The low yield of the hydrogenated products is due to a number of causes, including the high adsorption capacity of the activated charcoal, which leads to losses of fullerene and its hydrides, and also to the hydrogenation of the solvent (toluene) on certain catalysts (Ru/C, Ni/diatomite). The formation of C_{60} complexes with palladium, stable up to 120 °C (their dissociation begins above this temperature), has been reported.⁸⁶ This is in fact the temperature of the onset of the hydrogenation of C_{60} in the presence of Pd/C.^{80,81} The fullerene hydrides formed are unstable even under an inert atmosphere.

The hydrogenation of C_{60} has been investigated in C_6D_6 in the presence of Rh/ Al_2O_3 .⁸⁷ Comparison of the ^1H and ^{13}C NMR spectra of the product and of $C_{60}H_2$ synthesised by the method described by Henderson and Cahill³³ demonstrated their complete identity. It was found that the yield of $C_{60}H_2$ in the hydrogenation of C_{60} in the presence of Rh/ Al_2O_3 initially rose, reaching ~14%, and then diminished, the yield of the more highly hydrogenated fullerenes increasing under these conditions (HPLC data). The reaction product was fairly stable in the reaction medium, but it decomposed in the light on treatment with O_2 and was partly converted into C_{60} .

The reactivity of the coordinated C_{60} fullerene has been demonstrated in relation to the hydrogenation in the solid phase of the palladium fulleride $C_{60}Pd_{4.9}$ by molecular deuterium (473–673 K, D_2 pressure 20 atm).⁸⁸ In the course of the reaction under relatively mild conditions, a set of deuterofullerenes $C_{60}D_x$ ($x = 2–26$) are formed, the main products being those with $x = 2, 4, 18$, and 26. Deuterofullerenes containing an odd number of deuterium atoms have also been detected by means of field desorption (FD-MS) mass spectrometry. The IR spectrum of the fullerene deuteride obtained at 473 K contains a broad band with the centre at 2150 cm^{-1} [$\nu(C-D)$], the intensity of which increases with increase in the reaction temperature. The spectrum of a solution of the fullerene deuteration product in the visible range contains bands at 407(C_{60}), 435, and 715 nm.

The direct solid-phase synthesis of $C_{60}H_2$ from C_{60} and the stoichiometrically controlled amount of hydrogen has been achieved (reaction temperature 400–500 °C, reaction time 12 h).⁸⁹ Palladium hydride was used as the source of activated hydrogen. The main product is 1,2- $C_{60}H_2$ (~15%). $C_{60}H_4$ is also formed in a small amount (3%–5%) in the form of the thermodynamically most stable 1,2,3,4- $C_{60}H_4$. The isomerisation of the fullerene hydrides $C_{70}H_2$ and $C_{60}H_4$ to the most stable 1,2- and 1,2,3,4-isomers had already been observed.^{42,43} With increase in the hydrogen pressure, the yield of $C_{60}H_4$ rises, while the amount of dihydrofullerene remains unchanged.

The catalytic hydrogenation of C_{60} in boiling toluene in the presence of Ru/C leads to highly hydrogenated compounds (up to $C_{60}H_{50}$).⁸³ The degree of hydrogenation increases with increase in the hydrogen pressure and reaction temperature. The signal, corresponding to the ion with m/z 780, which belongs according to the authors,⁸³ to the hydride $C_{60}H_{60}$, has been detected in the mass spectrum (FD-MS) of the C_{60} hydrogenation products obtained at 280 °C and a H_2 pressure of ~130 atm.

In boiling toluene, the fullerene hydrides $C_{60}H_{18}$, $C_{60}H_{36}$, $C_{60}H_{40}$ are dehydrogenated by DDQ, the yields of C_{60} being 51%, 48%, and 45% respectively.⁸² The hydrogenation of C_{70} under similar conditions (Ru/C catalyst) leads to $C_{70}H_{36}$.⁸⁴ The dehydrogenation of the latter with the aid of DDQ also proceeds almost quantitatively.

The dehydrogenation of the hydrofullerenes $C_{60}H_{2n}$ and $C_{70}H_{2n}$ on treatment with DDQ in the presence of catalysts (Ru/C) or on heating has also been investigated.⁸⁵ High yields of fullerenes are obtained only in the presence of DDQ as the dehydrogenating

agent, whereas refluxing of $C_{60}H_{36}$ in toluene in the presence of Ru/C leads to the appearance of only 1% of C_{60} (FD-MS).

It has been found that the temperatures corresponding to the loss of 1% of mass for $C_{60}H_{18}$ and $C_{60}H_{36}$ are 164 and 175 °C (in a nitrogen atmosphere) and 348 and 247 °C (in air) respectively. The degrees of conversion of $C_{60}H_{18}$ and $C_{60}H_{36}$ in nitrogen at 600 °C are 30.5% and 26.8%, whereas at 400 °C in air the corresponding values are 56.6% and 40.1%.⁸⁵

8. Interaction of fullerenes with transition metal hydride complexes

Treatment of solutions of C_{60} (C_{70}) in toluene, benzene, or CH_2Cl_2 with metal (Ir, Rh, *etc.*) hydride complexes at room temperature leads to an instantaneous change of the colour of the solution. Three bands then appear in the electronic spectra of the solutions at $\lambda = 435, 604(600),$ and $640(630)$ nm. Their intensity is significantly higher than the intensity of the absorption of fullerenes in this region, which indicates the quantitative formation of metal complexes with fullerene (Scheme 6). The latter were characterised by a spectroscopic method.^{90–93} The molecular and crystal structures of the complex $\eta^2-C_{60}Rh(CO)H(PPh_3)_2$ have been determined.⁹³ The composition of the complexes $(\eta^2-C_n)IrH.(CO)(PPh_3)_2$ ($n = 60, 70$), their configuration, and the position in the fullerene nucleus of the $C=C$ double bond coordinated to the metal were established from the IR spectra (by comparative analysis relative to the spectra of the corresponding deuterated analogues) and ^1H and ^{31}P NMR spectroscopic data.⁹¹

The complexes $(\eta^2-C_{60})TaCp_2H$ and $(\eta^2-C_{60})MoCp_2$ are formed on interaction of the hydride complexes Cp_2TaH_3 and Cp_2MoH_2 with fullerene. Molecular hydrogen is apparently evolved as a result of the reaction, but its presence in the gas phase has not been demonstrated.⁹⁰ The interaction of the 16-electron square planar complex $PtHCl(PPh_3)_2$ and of the 18-electron octahedral complex $Ir(H)_2Cl(CO)(PPh_3)_2$ with the C_{60} fullerene on refluxing an alkaline (NaOH) solution of the reactants in a 1 : 2 ethanol–benzene mixture leads to the formation of $(\eta^2-C_{60})Pt(PPh_3)_2$ and $(\eta^2-C_{60})IrH(CO)(PPh_3)_2$ respectively.⁹⁴

9. Hydrogenation of mechanical mixtures of powdered fullerite and hydrogen-sorbing metals and intermetallic compounds

The study of the hydrogenation and dehydrogenation reactions of fullerenes is of interest both from the standpoint of the development of systems for the accumulation and storage of hydrogen and from the standpoint of other practical applications.^{3, 28, 95, 96} Such systems are constructed nowadays on the basis of intermetallic compounds or metals capable of absorbing considerable amounts of hydrogen selectively and reversibly.⁹⁷ In this respect, fullerene hydrides which have a low density and are capable of containing up to 8 mass% of hydrogen (as in the $C_{60}H_{60}$ hydride), are of special interest. However, direct noncatalytic hydrogenation of the C_{60} fullerene proceeds effectively only at high pressures (50–85 MPa) and temperatures (573–623 K).⁵⁹ The other methods of synthesis of fullerene hydrides listed above considered as systems for the reversible storage of hydrogen have also proved to be relatively unattractive owing to the difficulty of achieving multiple repetition of the ‘hydrogenation–dehydrogenation’ cycle in the presence of solvents in the system. This difficulty can be overcome by developing processes for the solid-phase catalytic hydrogenation of fullerenes. The choice of hydrogen-sorbing intermetallic compounds and metals as potential catalysts of such processes is natural because hydrogen possesses a high chemical reactivity at the instant of its evolution from metal hydrides.⁹⁸

The reactions involving the hydrogenation of fullerenes by molecular hydrogen in the solid phase in the presence of intermetallic compounds and metals effectively sorbing hydrogen have been achieved in relation to the compounds $LaNi_5$, $LaNi_{4.65}Mn_{0.35}$, $CeCo_3$, metallic palladium and vanadium, and also the hydrides of the above compounds.^{99–101} The use of hydrides as the initial components of mechanical mixtures with fullerenes is preferable, because, owing to the high brittleness of the hydrides, the preparation of smaller particles is ensured when mixtures are treated in a vibromill compared with powdered metals and intermetallic compounds. When hydrides are used, it is possible to avoid the undesirable oxidation of the surface of the particles in the course of the mechanical milling of their mixture with fullerite powder (such milling is necessary to ensure the homogeneity of the mixture and to increase the surface of contact of the two initial components).^{99–101}

The hydrogenation of fullerenes in such mechanical mixtures proceeds quite effectively already at a hydrogen pressure of 1–2.5 MPa and temperatures in the range 573–673 K, which is indicated, for example, by the appearance in the IR spectra of the product (after the treatment of the mixtures with deuterium under these conditions)^{99–103} of an intense absorption band at 2120 cm^{-1} (stretching vibrations of the $C-D$ bonds).⁸⁸ According to the results of chemical analysis, the deuterium content in the mixture specimens increases monotonically with increase in the deuteration temperature to 673 K, with increase in the D_2 pressure, and with increase in the number of ‘ D_2 sorption-desorption’ cycles. The product with the highest deuterium content (24–26 deuterium atoms per C_{60} fullerene molecule) has been obtained in the interaction of D_2 with mixtures of fullerite and intermetallic compounds or metals at a gas pressure of 2.5 MPa and for a sevenfold repetition of the ‘heating to 673 K (1 h)–cooling to 293 K (1 h)’ cycle.^{99–101} Hydrides of similar composition are formed also when the usual hydrogen is employed.

It has been found with the aid of differential thermal analysis (DTA) and thermogravimetry of the hydrogenated mechanical mixtures that the endothermic decomposition of the fullerene hydride takes place in all cases at 800 K with evolution of 1 mass %–3 mass % of gaseous hydrogen. The constancy of the decomposition temperature (800 K) means that the presence of metals and intermetallic compounds does not affect the dehydrogenation of fullerene hydrides, in contrast to the hydrogenation process, which is appreciably facilitated in the presence of these mechanical mixtures (a decrease in hydrogen pressure from 50–80 to 1–2.5 MPa). This may be induced by the irreversible transfer of activated hydrogen from the metal to the $C=C$ bonds of the fullerene component of the mixture. It is known that the effective action of the composite system requires, apart from fine mechanical milling of the mixture in a vibromill ensuring a high area contact of the components, also several ‘hydrogenation–dehydrogenation’ cycles, during which the molecular structure of the contact apparently changes with removal of surface oxygen and the probable formation of $M-C$ bonds. The irreversible hydrogen transfer from the metal to the $C-C$ bond apparently actually occurs with participation of $M-C$ bridges. At 800 K fullerenes are effectively dehydrogenated, the $M-C$ bonds are to a large extent dissociated, preventing the reverse hydrogen transfer to the metal, whereupon the organic subsystem must evolve the excess hydrogen spontaneously without the participation of the metals.

The hydrogenated specimens of the mechanical mixtures contain, apart from fullerene hydrides, also the hydride phases of the corresponding intermetallic compounds or metals,^{99–101} which is indicated by clearly distinguishable endothermic effects in the range 350–600 K. The decomposition of the corresponding hydrides of palladium (360 K)⁹⁹ and vanadium (450 and 550 K) and of the hydride phases of the intermetallic compounds $LaNi_{4.65}Mn_{0.35}H_x$ and $CeCo_3H$ (500–600 K), accompanied by the evolution of hydrogen, takes place at these temperatures.^{100, 101} The amount of evolved hydrogen is correlated with the content of the metal or the intermetallic compound in the

composite mixture and is usually 70%–90% of the amount of hydrogen in the fully saturated stoichiometric hydrides.

Intense exothermic peaks unaccompanied by a change in the mass of the specimen have been observed on the DTA curves in the temperature range 950–1000 K for all the hydrogenated compositions (except the palladium ones) investigated.^{99–101} Their appearance is associated with the irreversible chemical interaction of fullerenes with intermetallic compounds or metals, leading to the formation of metal carbides. In the hydrogenation in the presence of vanadium, the endothermic effect observed at 900 K is due to the decomposition of fullerenes and the formation of the vanadium carbide $\text{VC}_{0.8}$ with a NaCl type lattice.¹⁰¹ In the case of compositions based on fullerite and the intermetallic compounds LaNi_5 , $\text{LaNi}_{4.65}\text{Mn}_{0.35}$, and CeCo_3 , the products of the high-temperature heating of the hydrogenated specimens are the hydrides of the lanthanide and the metallic phases of the corresponding transition metal.¹⁰⁰

In the case of palladium, the high-temperature exothermic effect is not observed and the initial phase state of the metal does not change.⁹⁹ Bands characteristic of fullerenes are retained in the IR spectra of specimens of the mixed palladium compositions heated to 1200 K, in contrast to the compositions based on vanadium, for which analogous heat treatment leads to the complete disappearance of the fullerene bands. The palladium compositions partly dissolve in toluene, in contrast to the insoluble vanadium compositions.

The absorption bands due to fullerenes are absent from the IR spectra of specimens based on intermetallic compounds heated to 1200 K, while peaks due to the metallic nickel, manganese, or cobalt phase respectively can be seen on the X-ray diffractograms. Magnetic measurements have shown that the content of ferromagnetic nickel and cobalt particles in the products of the heat treatment at 1200 K is approximately equal to the amount of Ni and Co in the initial intermetallic compounds, which indicates the almost complete decomposition of the latter. This finding and the decomposition of the fullerenes mentioned above suggest that the lanthanide metal remains in the specimen in the form of the X-ray-amorphous carbide. The chemical interaction of intermetallic compounds and fullerenes proceeds after the completion of the decomposition of the fullerene hydrides, which apparently facilitates the formation of carbides as a result of the removal of the impurity oxygen (there is also a possibility of the preliminary formation of a small number of metal–carbon bonds).

Thus the presence of carbide-forming metals (including those in the intermetallic compounds) in the compositions leads to the degradation of the fullerene structures even when the temperature corresponding to the complete evolution of hydrogen from the hydrogenated composites (800 K) is only slightly exceeded. The formation of metal carbides and metallic phases observed under these conditions lowers the capacity of the composites with respect to hydrogen and the sorption–desorption reversibility. The elimination of this effect, which is undesirable for hydrogen storage systems, may involve the determination of the upper permissible limiting temperature to which the composite material may be heated and also the search for materials for which the formation of carbides is difficult or impossible.¹⁰¹

One of the most significant obstacles on the way to the technical realisation of fullerene-based hydrogen accumulators is the evolution of a large amount of heat in the adsorption of hydrogen by compacted fullerite,²⁸ which, when combined with the low thermal conductivity of the latter, leads to its mechanical disintegration and also to the retardation of the saturation by hydrogen and failure of the latter to reach completion. The use of compacted mixed compositions of hydrogen-sorbing metals or intermetallic compounds with fullerites makes it possible to deal with this problem. Other advantages of mixed compositions is significant softening of the conditions governing the hydrogenation of the double bonds of the fullerene molecules, the possibility of the multiple repetition of the ‘hydrogenation–dehydrogenation’ cycle, and the ability of the hydrogenation catalyst to

absorb hydrogen. All these factors make the mixtures examined above promising for practical applications.

III. Properties of fullerene hydrides

1. The stability of fullerene hydrides

From the very beginning of the studies on fullerenes, chemists endeavoured to obtain the fully hydrogenated $\text{C}_{60}\text{H}_{60}$ molecule, but this has not been achieved hitherto.^{29, 45, 56, 80–85} As a rule, mixtures of fullerene hydrides are obtained in all the experiments and the main products are usually $\text{C}_{60}\text{H}_{36}$ and $\text{C}_{70}\text{H}_{36}$. These polyhydrofullerenes are the most stable also according to theoretical calculations.^{47, 58, 102–106} However, even these decompose slowly in solution, which hinders their detailed investigation by spectroscopic methods.^{45, 56, 107} Even solid specimens of fullerene hydrides having the same empirical formula but synthesised by different methods exhibit markedly different solubilities, resistances to the action of light and air, capacities for prolonged storage, and other properties,^{29, 45, 59, 61, 80–85} which is apparently induced both by the structural differences between the polyhydrofullerenes themselves and by the presence in the composition of the solid fullerene hydride specimens of different amounts of crystallisation solvents and impurities comprising the components of the catalytic hydrogenation systems, as well as the presence of inhomogeneities and defects in the molecular structure. TGA and emission IR spectroscopy have shown that the fullerene hydrides obtained under the conditions of radical hydrogenation begin to decompose at 350 °C,⁶¹ while the $\text{C}_{60}\text{H}_{36}$ specimen obtained by Birch reduction²⁹ began to darken already at 170 °C.

The causes leading to instability of the hydrofullerenes^{38, 40, 45, 56} may also be the strain in the newly formed ring as a result of the breakdown of the sp^3 hybridisation of the carbon atoms, the appearance of 5–6 double bonds (Fig. 4), and the steric influence of the hydrogen atoms on one another when their number is large.

Figure 4. The 1,2- (a) and 1,4-addition (b) of XY to fullerene.

The instability of $\text{C}_{60}\text{H}_{60}$ should be associated principally with the deviation of the configuration of the bonds between the carbon atoms from the regular tetrahedral configuration. In this molecule, there are 20 sterically strained cyclohexane fragments on the surface of the sphere. According to the results of molecular-mechanical calculations, the strain may be reduced if at least ten hydrogen atoms in the $\text{C}_{60}\text{H}_{60}$ molecule are attached exohedrally. This is the most stable conformation for $\text{C}_{60}\text{H}_{60}$.¹⁰⁸ The difference between the energies of this conformer and the compound in which all the hydrogen atoms are attached exohedrally is 400 kcal mol^{−1}.

The preferred paths in the fullerene halogenation and hydrogenation reactions have been analysed theoretically.¹⁰⁹ Electronic effects are more significant in the interaction of fullerene with fluorine; fluorine adds preferentially in the *ortho*-positions in the 5–6 or 6–6 bonds, although according to theoretical analysis 1,4-addition (Fig. 4) is also possible. On the other hand, in the interaction of C_{60} with bromine the most stable isomer is formed as a result of 1,4-addition and the direction of the fullerene hydrogenation reaction is intermediate between the directions of the reactions with fluorine and bromine.

2. The state of hydrogen in solid fullerene hydrides

In the direct synthesis of solid fullerene hydrides under a high pressure of hydrogen in the absence of solvents and catalysts, the

formation of the most stable specimens is ensured.^{59,110} Such specimens are most suitable for the study of the nature of the binding of hydrogen by fullerenes in the solid phase. The interest in this problem has been stimulated by the possibility of encapsulating hydrogen molecules either in the intermolecular cavities of the crystal structure of fullerene hydrides or inside the polyhydride carbon framework. These hypotheses are confirmed by the experimental observations made by the investigators of the MER Corporation (USA). The electrochemical cathodic saturation of the C₆₀ fullerite with hydrogen results in the formation of compounds containing between 24 and 56 hydrogen atoms per C₆₀ molecule and part of this hydrogen is not bound covalently and is readily removed. The conjugation of the double bonds in the fullerene molecule is then retained even for the empirical composition C₆₀H₅₆.²⁸ The synthesis of compounds having the superstoichiometric composition C₆₀H_{60+x} (x reaches 24) by the hydrogenation of fullerite in the region of moderately high temperatures and hydrogen pressures has been reported (without experimental details), the integrity of the carbon framework of the fullerene molecule being retained in these compounds.¹¹¹ This intriguing result may imply that under the reaction conditions hydrogen molecules may permeate through the cyclohexane fragments of the shell of the perhydrogenated C₆₀H₆₀ fullerene into its inner cavity and may accumulate in the latter. This possibility merits detailed study.

Treatment of C₆₀ fullerite with hydrogen (PH = 14 MPa) at room temperature leads only to the formation of an interstitial solid solution of molecular hydrogen, *i.e.* a compound in which the type of packing of the fullerene molecules in the crystal remains unchanged on slight alteration of the lattice parameters.¹¹² The formation of C–H bonds or new interstitial phases with an altered (compared with the initial fullerite) type of packing of the C₆₀ molecules is not observed under these conditions.

In the analogous direct noncatalytic solid-phase synthesis at 600 K, hydrogen actively interacts with C₆₀, giving rise to the hydrides C₆₀H _{x} = 50–8 MPa)⁵⁹ and $x \approx 23$ (at P_{H_2} = 0.6 GPa).¹¹⁰ The hydrides obtained in this way can be stored for a long time without a significant change in composition and properties. The pressures employed in the above studies^{59,110} did not exceed the threshold value of 0.7 GPa at which the bulk–phase polymerisation of C₆₀ fullerene begins at 600 K with formation of C–C bonds between neighbouring fullerene molecules.¹¹³ The temperature of the synthesis was also lower than the initial 950–1000 K level of the temperature range corresponding to the irreversible degradation of fullerene hydrides obtained by different methods.^{59,110} The integrity of the fullerene molecules in the hydrogenated specimens was achieved thereby.¹¹⁰ The hydrogen content in such specimens is relatively low,^{59,110} but the possibilities for its increase whilst retaining the integrity of the carbon framework of C₆₀ have not been fully exhausted.

An attempt has been made¹¹⁰ to establish the state of hydrogen in fullerene hydride. For this purpose, the chamber with the specimen was cooled after the high-temperature treatment at a high hydrogen pressure¹¹⁰ and the specimen was extracted directly into liquid nitrogen. The ‘quenched’ specimen was then heated in a calibrated evacuated space up to 300 K, whereupon the evolution of 2.8 hydrogen atoms per C₆₀ molecule was observed. The ‘annealed’ specimen obtained in this way contained about 23 atoms of covalently bound hydrogen per C₆₀ molecule.

Crystallographic data indicate the same type of packing (a body-centred cubic lattice) of the C₆₀ molecules in the quenched and annealed specimens. The volume per C₆₀H _{x} molecule in the annealed specimen is then smaller by 61 Å³ than in the quenched specimen. Thus the specific volume of the hydrogen evolved on annealing was 61/2.8 $\approx$ 22 Å³ per H atom, which is close to the specific volume of solid molecular hydrogen at 4.5 K (19.022 Å³ per H atom). This fact shows that the hydrogen evolved was present in the quenched specimen in the form of hydrogen molecules occupying the interstitial cavities in the C₆₀H _{x} lattice. There is evidence that these are not octahedral but tetrahedral interstices in the body-centred cubic lattice.¹¹⁰

The state of hydrogen in fullerene hydrides has also been investigated by nonelastic neutron scattering spectroscopic methods.¹¹⁰ The rotational spectrum of the hydrogen molecules inserted in the interstices obtained at 85 K¹¹⁰ contains distinct absorption bands corresponding to transitions with the 0 $\rightarrow$ 1, 1 $\rightarrow$ 2, and 0 $\rightarrow$ 2 changes in the rotational quantum number. Thus the inserted hydrogen molecules exist as both para-hydrogen and ortho-hydrogen (at 85 K, their equilibrium ratio is 85:15). The rotational spectra of the interstitial hydrogen differ somewhat from those of the free molecules, which is a consequence of the interaction of the hydrogen rotator with the C₆₀H _{x} ($x \approx 23$) molecules surrounding the cavity. There are similar differences in the rotational spectrum of the molecular hydrogen trapped in amorphous carbon.^{114,115} However, in the latter case, the rotational bands are broader, which apparently indicates the presence of a set of sites where hydrogen molecules are located with different potentials of the interaction with the rotator. On the other hand, in the solid fullerene hydride C₆₀H _{x} (H₂)_{1.4} ($x \approx 23$) there is apparently one such site.

The vibrations in the low-frequency part of the spectrum (from 0 to 65 cm^{−1}) correspond to the intermolecular interaction in C₆₀H _{x} ($x \approx 23$).¹¹⁰ Certain differences in the intermolecular vibrational spectra in solid C₆₀H _{x} ($x \approx 23$) and C₆₀ have been noted. They are due to the anisotropy of the moment of inertia of the C₆₀H _{x} molecules, leading to the splitting of the libration bands, and also to the much higher dispersion of the libration modes of the hydrogenated C₆₀ compared with pure C₆₀. However, despite these slight differences, the C₆₀ and C₆₀ and C₆₀H _{x} spectra are extremely similar in this range, which is somewhat surprising bearing in mind the differences between the molecular structures and the types of crystal lattices [simple cubic for C₆₀ (77 K) and body-centred cubic for C₆₀H _{x} ($x \approx 23$)].¹¹⁰

3. The structure and isomers of fullerene hydrides

The hydride C₆₀H₃₆ was first obtained by an extremely nontraditional method, namely by the Birch reduction of the C=C double bonds. It was therefore postulated that the hydride C₆₀H₃₆ contains 12 isolated double bonds in the molecule, one in each five-membered ring.²⁹ However, subsequently the compounds C₆₀H₃₆ were obtained also under other conditions.^{45,56,61,80–84} Furthermore, the structure with isolated double bonds for the fullerene hydride C₆₀H₃₆ does not explain the inhibition of the reduction after the addition of 36 hydrogen atoms to C₆₀.

The most symmetrical C₆₀H₃₆ isomer has 12 double bonds, which are disposed in each five-membered ring and belongs to the T_h symmetry group.^{29,116} The introduction of double bonds into the six-membered rings leads to a structure with a lower point group symmetry T in which there are four benzenoid fragments on the surface of the C₆₀H₃₆ molecule located at the corners of the tetrahedron.^{102–104} The less symmetrical structures with the D_{3d} and S_6 symmetries,^{61,116} in each of which there are two six-membered rings comprising hydrogen-free carbon atoms located at the poles of the molecule along the threefold axis, are intermediate between these extreme structures. The remaining six double bonds are isolated and disposed along the meridians and parallels of the D_{3d} and S_6 spheres respectively (Fig. 5).

The structures and stabilities of 63 C₆₀H₃₆ isomers have been analysed (the total number of C₆₀H₃₆ isomers is 6.1×10^{14} , but after the introduction of a series of restrictions, including threefold axes, their number diminishes to 63); one of them has the tetragonal T symmetry, four have the D_{3d} symmetry, three have the S_6 symmetry, nine have the C_{3v} symmetry, and four isomers have the C_3 symmetry.¹¹⁷ Detailed theoretical analysis of the C₆₀H₃₆ structures confirmed that the isomers with the D_{3d} and T molecular symmetries were the most stable.

The relative energies, the electronic structures, and the geometries of four isomers of the C₆₀H₃₆ molecule have been calculated by the semi-empirical local density functional (LDF) method (Fig. 5): the symmetries are T , T_h , S_6 , and D_{3d} .¹⁰⁵ It was found that the isomer with the T symmetry is energetically the

Figure 5. The structural isomers of $C_{60}H_{36}$.¹⁰⁵

most stable, which agrees with the semi-empirical AM1 calculations,¹⁰⁴ according to which this isomer is more stable than the isomer with the T_h symmetry by 0.7 eV. It may be that the stability of the isomer with the T symmetry, associated with the presence of aromatic rings, is the cause of the inhibition of the more extensive reduction of fullerene.⁵⁸ The smallest disruption of the initial fullerene skeleton and the greatest gain of the electron delocalisation energy are characteristic of the structure of the $C_{60}H_{36}$ molecule with the T symmetry. Furthermore, this structure agrees best with the available experimental data.¹⁰³ The remaining unsaturated bonds in the isomer with the T symmetry are of the 6–6 type. The ionisation potentials of all the $C_{60}H_{36}$ isomers lie within the range 6.47 ± 0.05 eV and the electron affinity is -0.24 ± 0.03 eV (Table 3).

Theoretical calculations have shown^{102–106} that the conjugated structure should be the most stable. It is significant that some of the eight $C_{60}H_4$ isomers, which exist and have been isolated,^{38,42} may be built up to the $C_{60}H_{36}$ T isomer on further reduction without any rearrangement of those double bonds of the molecule which are not involved in the reaction. The hydride $C_{60}H_{36}$ may be obtained also by the reduction of the octahedral $C_{60}H_{12}$, which is present among the hydrogenation products.

Since, like $C_{60}H_{36}$, the hydride $C_{70}H_{36}$ is distinguished by a high resistance to further reduction, there may apparently exist common causes which would explain this feature. In particular, steric causes (the mutual repulsion of the hydrogen atoms) should not be decisive in view of the fact that, since 36 hydrogen atoms ensure the maximum stability of the exohedral hydride of the C_{60} fullerene, in the case of C_{70} the maximum number of hydrogen atoms which may be added to the hydrocarbon skeleton without a significant increase in the overall energy should be greater.

In order to account for the characteristic features of the $C_{70}H_{36}$ molecule, structures A–C have been subjected to a theoretical analysis (Fig. 6).⁵⁸

(1) Structures A and C have the C_s symmetry, while structure B has the C_2 symmetry. The last structure is most uniformly hydro-

Table 3. Energy characteristics of the $C_{60}H_{36}$ isomers.¹⁰⁵

Symmetry	Relative energy/eV	Ionisation potential/eV	Electron affinity/eV	HOMO	LUMO
T_h	2.10	6.49	−0.27	$27t_u$	$7a_u$
T	0.00	6.52	−0.21	$17e$	$50t$
D_{3d}	2.35	6.48	−0.23	$33e_u$	$34e_g$
S_6	0.43	6.40	−0.23	$33e_u$	$34e_u$

genated and has 18 hydrogen atoms in each hemisphere of the molecule. (2) The calculated resonance energies suggest that the hydride $C_{70}H_{36}$ exists as a mixture of three isomers and that the compound with structure B should predominate, in conformity with its high symmetry. (3) Just as addition to the 9,10-bond in phenanthrene leads to a small change in resonance energy, addition to the analogous bonds of the phenanthrene-like formations in structures A–C leads to a slight loss of conjugation (80 kJ mol^{−1} for each C^{16} – C^{17} and C^{28} – C^{29} double bond in A and C^{16} – C^{17} and C^{61} – C^{62} in B; there is a similar loss of 94 kJ mol^{−1} for the C^{65} – C^{66} bond in isomer C). The model predicts the formation of $C_{70}H_{38}$ and to a lesser extent of $C_{70}H_{40}$ on further hydrogenation, which has been confirmed experimentally.^{56,80,84} (4) Structures A–C may be obtained by reducing the $C_{70}H_4$ isomers, which really exist.^{38,42}

Further reduction of the stable $C_{60}H_{36}$ and $C_{70}H_{36}$ becomes possible only by overcoming the high energy barrier, which presumably corresponds to the hydrogenation of the six-membered fragments.⁵⁸ In this case, the reduction of $C_{60}H_{36}$ should proceed via stepwise hydrogenation with formation of the hydrides $C_{60}H_{36} + n$ ($n = 6, 12, 18, 24$) and there is experimental evidence for the existence of the compounds $C_{60}H_{42}$ and $C_{60}H_{48}$.^{47,83} The reduction of structures A and B for the composition $C_{70}H_{36}$ should take place via multistage hydrogenation with formation of the hydrides $C_{70}H_{36} + n$, namely $C_{70}H_{46} \rightarrow C_{70}H_{52} \rightarrow C_{70}H_{58} \rightarrow C_{70}H_{64} \rightarrow C_{70}H_{70}$, whereas the reduction of structure C should proceed as $C_{70}H_{42} \rightarrow C_{70}H_{46} \rightarrow C_{70}H_{52} \rightarrow C_{70}H_{58} \rightarrow C_{70}H_{64} \rightarrow C_{70}H_{70}$. Since there is a greater loss of resonance energy on formation of $C_{70}H_{70}$ from $C_{70}H_{36}$ (~ 1060 or ~ 31 kJ mol^{−1} for each C=C bond) than on formation of $C_{60}H_{60}$ from $C_{60}H_{36}$ (~ 602 or ~ 25 kJ mol^{−1} respectively), the synthesis of perhydrofullerene $C_{70}H_{70}$ appears even more difficult.⁵⁸

It follows from the foregoing that in principle there may exist three stable $C_{70}H_{36}$ isomers, namely two isomers with two phenanthrene-like and one benzenoid rings and one isomer with one phenanthrene-like and one naphthenoid rings. The increased stability of such structures, associated with the presence of aromatic fragments, prevents their further reduction.

Another study¹⁰⁶ has also been devoted to the question of the stability of various structures of the fullerene hydrides $C_{60}H_{36}$ and $C_{70}H_{36}$. The results of the calculations showed that the formation

Figure 6. The structural isomers of $C_{70}H_{36}$.⁵⁸

energy of the $C_{60}H_{36}$ isomers with the T symmetry is lower by $97.4 \text{ kcal mol}^{-1}$ than the formation energy of the T_h isomer, which confirms the general conclusion reached in other investigations (for example that of Taylor¹⁰²) that the real $C_{60}H_{36}$ structure has the T symmetry. For $C_{70}H_{36}$, structures in which the hydrogen atoms are located at the poles of the molecule in the 1,2,3-positions in the 12 five-membered rings have been considered. Since in this case a graphite-like region with a high degree of conjugation is formed in the equatorial region of the fullerene skeleton, the isomers corresponding to this model should have low formation energies.

The structure of $C_{70}H_{36}$ has also been calculated by methods of molecular mechanics⁴⁷ on the assumption that after reduction the reaction product contains only nonconjugated double bonds or double bonds resembling aromatic bonds which are unreactive in relation to hydrogen transfer.⁴⁴ In each of the 12 five-membered rings of the carbon cluster, there is one double bond; there is one double bond also at each pole of the $C_{70}H_{36}$ molecule, whilst the remaining ten cyclopentene rings are joined together in such a way that a pentaphenylene strip is formed in the equatorial region. The enthalpy of formation of the hydride $C_{70}H_{36}$ (corresponding to the proposed model) has been calculated as $\Delta H_f^\circ(g) = 490.2 \text{ kcal mol}^{-1}$. Further reduction of $C_{70}H_{36}$ with formation of $C_{70}H_{40}$ leads to an increase in $\Delta H_f^\circ(g)$ to $535.7 \text{ kcal mol}^{-1}$.

4. Electronic and IR spectra of fullerene hydrides

The lower fullerene hydrides, for example $C_{60}H_2$, retain the C_{60} structure, which is reflected in their UV and visible spectra.³³ A characteristic feature of the formation of the 1,2-addition product is the appearance in the electronic spectrum of bands at ~ 430 and $\sim 700 \text{ nm}$ ³⁹ (436 and 702 nm for $C_{60}H_2$). The formation of $C_{60}H_4$ (the addition of H_2 to the second double bond) is accompanied by the disappearance of the band at 700 nm. The absorption at 220 (230) nm is characteristic of $C_{60}H_{36}$.^{29,45} The most detailed spectra of $C_{60}H_{36}$ and $C_{70}H_{36}$, obtained by the reduction of the corresponding fullerenes in a saturated solution in hexane (inert atmosphere) in the Zn/conc. HCl system, have been published by Darwish *et al.*⁵⁶ (Fig. 3).

The absorption in the range 255–280 nm has been regarded as evidence for the presence of aromatic fragments of the benzene type in $C_{60}H_{36}$ and of phenanthrene-like fragments in $C_{70}H_{36}$.⁵⁸ The presence of these fragments in the fullerene hydride molecule has been demonstrated by the appearance of a charge-transfer band in the spectra of compounds of the type $C_{60}H_{36} \cdot TCNE$ ($TCNE = \text{tetracyanoethene}$).¹⁰⁷

The IR spectra of the hydrogenated derivatives of fullerenes agree with the presence of C–H and C=C bonds. Thus bands in the region of C–H stretching vibrations are present in the IR spectra of fullerene hydrides (Table 1) — they are weak in the case of the lower hydrides and intense for $C_{60}H_{36}$ and $C_{70}H_{36}$, the number of bands in the case of $C_{60}H_{36}$ depending on the method of synthesis of the hydride. For example, the IR spectrum of the hydride $C_{60}H_{36}$ obtained by radical hydrogenation consists of three intense C–H stretching vibration bands and a weak band at 1490 cm^{-1} band (together with other weaker bands).⁶¹ The bands at 1490, 1511, and 1606 cm^{-1} for $C_{60}H_{36}$ obtained by the transfer hydrogenation⁴⁵ lie in the region of the stretching vibrations of the C=C bonds.⁶¹ It has been noted that the intensity of the C=C bond vibration in the region of 1650 cm^{-1} diminishes on reduction under more severe conditions.⁸³

For the $C_{60}H_{36}$ molecule with the T_h symmetry, only one active C–H vibration should be observed in the IR spectrum, while for the molecules with the D_{3d} and C_{3i} symmetries one may expect at least 5 and 17 vibrations respectively. ¹³C NMR data as well as comparison of the experimental and calculated IR spectra for $C_{60}H_{36}$ enabled Attalla *et al.*⁶¹ to reach the preliminary conclusion that the $C_{60}H_{36}$ hydride which they obtained corresponds to the D_{3d} and not the T_h symmetry. At the same time, for a more exact assignment of the IR and NMR bands, the studies should probably be performed on individual specimens of the

hydrides of C_{60} and C_{70} fullerenes synthesised by the radical hydrogenation method.

The IR spectrum of the fullerene hydride $C_{60}H_{36}$ obtained by Birch reduction contains bands characteristic of both aliphatic C–H and aromatic C=C bonds.¹⁰⁷ Comparison of the experimental IR spectra with the spectra calculated for the T and T_h structures showed that they are in better agreement with the structure having the T symmetry.¹⁰⁷

Bands due to the stretching vibrations of the hydrocarbon skeleton in the polyhydride $C_{60}H_x$ containing ~ 23 H atoms have been identified at 242, 306(s), 453(s), 524, 783, and 912 cm^{-1} . Compared with the vibrations of pure C_{60} , these vibrations have appreciably lower frequencies and differ significantly in the distribution of intensities, which confirms the expected weakening of the C–C bonds and the decrease in molecular symmetry as a result of the hydrogenation of the double bonds. The deformation vibrations of the C–H bonds in the hydride $C_{60}H_{23}$ are characterised by an intense broad ($\Delta\nu_{1/2} = 280 \text{ cm}^{-1}$) absorption band at 1250 cm^{-1} with a shoulder in the region of 1090 cm^{-1} .¹¹⁰ A similar peak is characteristic of hydrogenated amorphous carbon,^{114,115} which indicates the similarity of the C–H bonds in the two structures.

5. Mass spectrometry in the study of fullerene hydrides

Mass-spectrometric analysis plays a decisive role in the identification of the products of the hydrogenation of fullerenes. The MS analytical methods, differing in the method of vaporisation of the sample and the procedure used for its ionisation, may influence the result, therefore it is necessary to treat mass-spectrometric data with caution. The influence of differences in the analytical method on the results of the analysis has been most fully elucidated in the identification of the products of the Birch reduction of C_{60} .^{29,30} The composition of $C_{60}H_{36}$ was first determined from EI-MS data.²⁹ When the molecules are ionised by fairly soft electron impact in the gas phase, radical-cations are produced with a low internal energy — 2–8 eV (200–775 kJ), which is insufficient for the effective fragmentation of the excited species. This ionisation method is therefore fully suitable for the solution of a series of problems associated with the determination of the molecular structure of the hydride. However, the EI-MS method suffers from a number of disadvantages: in combination with the most readily available method involving vaporisation from a Knudsen cell, it is applicable only to the analysis of thermally stable volatile organic compounds; furthermore, in certain cases the fragmentation of ions with an odd number of electrons, formed on electron impact, proceeds so effectively that the mass spectra contain no molecular ions. The use of the EI-MS and LD-MS methods for the study of $C_{60}H_{36}$ obtained by the radical hydrogenation method proved impossible owing to the thermal decomposition of $C_{60}H_{36}$ to lower-molecular-mass compounds: $C_{60}H_{18}$, $C_{60}H_8$, *etc.*⁶¹ The elimination of hydrogen from the unstable fullerene hydrides ($C_{60}H_n$, $n > 36$) on laser desorption has also been noted by Gerst *et al.*⁴⁷

One of the most important 'mild' and selective ionisation methods is chemical ionisation (CI), which is usually achieved as a result of ion–molecule reactions between neutral molecules of the substances analysed and the ions derived from the reagent gas (methane, isobutane, and ammonia are the most frequently used). The reagent gas ions are as a rule obtained by bombardment with electrons having energies of 100–500 eV at a pressure of 10^{-10} – 10^{-2} Pa in the ion source. The collisions of the ions formed with the molecules of the reagent gas result in the formation of reagent ions with an even number of electrons (CH_3^+ and CH_5^+ from methane), which then react with the molecules of the substances analysed. They protonate the molecules of these substances or form adduct ions with them, for example:

The ions with an even number of electrons generated on chemical ionisation are more stable than the ions with an odd

number of electrons formed on electron impact, so that the mass spectra of the ions generated as a result of chemical ionisation contain the intense peaks due to the adduct ions (or cluster ions) or protonated ions, while the peaks of the fragment ions have low intensities or are absent altogether.

Ionisation methods such as field desorption, secondary ion mass spectrometry, bombardment by fast atoms, laser desorption, *etc.* are also used for the analysis of involatile and thermally unstable compounds.¹¹⁸ When FD-MS is used, there is no need to vaporise the sample. The sample of solution or suspension is deposited on an activated emitter and the temperature of the latter is chosen to ensure sufficient intensity of the molecular ion peak in the spectrum accompanied by minimal fragmentation (usually 300–600 K). Indirect heating of the emitter with the aid of a laser has sometimes proved more effective as regards the formation of molecular ions.

Fullerene hydrides have been studied⁴⁵ mass spectrometrically with the aid of various methods, including electron impact, bombardment by fast atoms, and field desorption. M^+ and sometimes M^{2+} peaks are usually present in the $C_{60}H_{36}$, $C_{60}D_{36}$, $C_{60}H_{18}$, and $C_{60}D_{18}$. It has been noted that in the analysis of the above hydrides by the electron impact method, partial fragmentation, accompanied by loss of hydrogen and the appearance of free C_{60} , is observed. The field desorption method gives rise to only the M^+ peak. The FAB method yielded satisfactory results in the analysis of the fullerene dihydride prepared by the reduction of C_{60} with diborane, but its application to other hydride specimens proved difficult (see, for example, Avent *et al.*³⁸ and Becker *et al.*⁸⁷).

It has been found with the aid of 'mild', mutually complementing mass-spectrometric methods, such as time-of-flight mass spectrometry with vaporisation of the test substance by laser desorption and subsequent laser photoionisation, ion-cyclotron mass-spectrometry with laser desorption, and secondary ion-spectrometry, that a mixture of polyhydrofullerenes with compositions ranging from $C_{60}H_{18}$ to $C_{60}H_{36}$ is indeed formed in the course of the Birch reduction of C_{60} , the main product being $C_{60}H_{32}$.³⁰ When the L^2 TOF-MS method was used to analyse fullerene hydrides in the mass range 740–760 a.m.u., the resolution of the instrument proved insufficient for the determination of the mass distribution of the hydrides. Nevertheless, the mass spectrum obtained with the aid of L^2 TOF-MS yields no evidence for the formation of $C_{60}H_{36}$ as the main product. The ICR-MS method made it possible to obtain a spectrum with a well resolved series of peaks grouped around the main peak with a mass number of 753 ($752 + H^+$), corresponding to the distribution of the reaction products. The appearance of weak peaks in the range m/z 720–730 has been attributed to the fragmentation of the products to low-molecular-mass hydrofullerenes. Finally, the mixture was characterised with the aid of the SIMS method, which yielded a very well resolved spectrum, from which the exact distribution of the hydrogenation products was obtained (Fig. 7).³⁰

Thus the difference between the compositions of fullerene hydrides^{29,30} is frequently associated with the difference between

Figure 7. Mass spectrum of the products of the Birch reduction of C_{60} obtained by means of SIMS (matrix — 3-nitrobenzyl alcohol).³⁰

the methods used for mass-spectrometric analysis and can be accounted for by the thermal lability of the mixture of hydrogenated fullerenes on prolonged exposure to the high ($> 250^\circ C$) temperature necessary for the mass-spectrometric study by the method involving the direct introduction of the heated sample.

6. ^1H and ^{13}C NMR spectroscopy

The ^1H NMR spectrum of the hydride $1,2-C_{60}H_2$ contains a singlet at $\delta = 5.93$ ppm (toluene- d_8), which does not change in the range from -80 to $100^\circ C$. On the other hand, there are no well resolved and stable, in terms of time, ^1H NMR spectra of either $C_{60}H_{36}$ or $C_{70}H_{36}$. The broad bands with δ in the region from 2.5 to 4.2 ppm and a maximum at 3.80 ppm (for comparison, we may note that δ for dodecahedrane protons is 3.38 ppm), which refer to $C_{60}H_{36}$,^{29,45} agree poorly with the symmetrical structure for which the ^1H NMR spectrum should consist of narrow lines.⁵⁶ The spectra presented refer as a rule to either mixtures of hydrofullerenes or, if one is dealing with an individual compound, to a mixture of isomers. Finally, the broadening of the bands may be a result of the oxidation of fullerene hydrides by atmospheric oxygen in the presence of light. The attempts to obtain NMR spectra in more concentrated solutions, for example in CS_2 (the $CS_2-C_6D_6$ solvent mixture has been used in the case of lower fullerene hydrides of the type $C_{60}H_4$ ³⁸) proved unsuccessful owing to the interaction of CS_2 with $C_{60}H_{36}$ ⁵⁶ observed for the first time in this way. The observation of satisfactory spectra at a low concentration of the test substance requires a long time, which leads to the decomposition of the specimen in the presence of oxygen.

Even in the case of individual C_{60} hydrides, the physicochemical properties of specimens of the same composition but prepared by different methods are different, which may be associated with structural differences.

A complex multiplet with $\delta = 2.1-4.25$ ppm is manifested in the ^1H NMR spectrum of the catalytic hydrogenation products.⁸³ A spectrum with $\delta = 2.5-4.5$ ppm has been published for $C_{60}H_{36}$ obtained by the Birch method.²⁹ The appearance of additional signals in the range 2.1–2.5 ppm may be associated with the products of the more far reaching hydrogenation of fullerene.⁸³

At least four types of sp^3 -hybridised carbon atoms with $\delta = 31, 38, 44$, and 49 ppm and three types of sp^2 -hybridised carbon atoms with $\delta = 128, 134$, and 138 ppm are manifested in the solid-state ^{13}C NMR spectra of a reduced mixture of C_{60} and C_{70} .⁶¹ Integration yields the ratio $sp^2:sp^3 \approx 22:38$. When account is taken of the integration error, this ratio corresponds satisfactorily to the presence of a hydride with 36 hydrogen atoms. Analysis of the ^{13}C NMR spectrum led the authors⁶¹ to the conclusion that a structure with the D_{3d} symmetry may be assigned to the compound $C_{60}H_{36}$.

The structure of the hydride $C_{60}H_{36}$ formed on Birch reduction of C_{60} has also been investigated by Govindaraj.¹⁰⁷ The results agree with the data of Haufler *et al.*²⁹ but their interpretation is different. Thus the ^{13}C NMR spectrum of the hydride $C_{60}H_{36}$ obtained by the Birch method contains signals with $\delta = 140$ and 40 ppm, which Govindaraj¹⁰⁷ assigns to aromatic and saturated carbon atoms respectively. The signals of the carbon atoms in the aromatic ring proved weaker than might have been expected (apparently owing to the quaternary nature of these atoms). According to Govindaraj,¹⁰⁷ these spectra confirm a structure with the T symmetry for $C_{60}H_{36}$. The UV spectrum of this compound contains bands at 218 and 275 nm. Govindaraj¹⁰⁷ believes that the band at 275 nm indicates the presence of an isolated aromatic fragment in the $C_{60}H_{36}$ molecule (see also Darwish *et al.*⁵⁶). The presence of such an isolated benzene ring is demonstrated by the appearance of a charge-transfer band (305 nm) when $C_{60}H_{36}$ interacts with tetracyanoethene¹⁰⁷ (in the benzene-TCNE system, the charge-transfer band is at ~ 300 nm¹¹⁹). It has been suggested that the hydride $C_{60}H_{36}$ with the T symmetry and having isolated double bonds is formed initially during the hydrogenation reaction and is then transformed via sigmatropic shifts into a thermodynamically more stable molecule

with the T symmetry and isolated benzene rings. This hypothesis has been confirmed by the synthesis by the method of Rüchardt *et al.*⁴⁵ of a $C_{60}H_{36}$ specimen stable in the solid state.

The ^3He chemical shifts in the ^3He NMR spectra of the possible isomers of the endohedral complexes $\text{He}@C_{60}H_{36}$ have been calculated.⁶² The calculated shifts for different isomers (the type of symmetry is indicated in brackets) of $\text{He}@C_{60}H_{36}$ are $-10.8(T)$, $-7.4(D'_{3d})$, $-6.1(S_6)$, $-3.4(T_h)$, and -5.6 ppm (D_{3d}).⁶² The calculation also confirmed that the chiral structure with the T symmetry is the most stable among the possible $C_{60}H_{36}$ isomers (the T structure is more stable than the T_h structure by 59 kcal mol^{-1}). The authors⁶² suggest that the experimental investigation of compounds of the type $\text{He}@C_{60}H_{36}$ will yield new information about the composition of the C_{60} hydrogenation products.

7. Photophysical properties of fullerene hydrides

The photophysical properties of three hydrofullerenes have been investigated at room temperature in solution in toluene: $C_{60}H_2$, $C_{60}H_4$, and 2,3-[1-(3-carboxypropionyloxymethyl)-4-methylbut-2-enol]buckminsterfullerene **2** (the last compound has a hydrophilic substituent linked to the hydrophobic C_{60} skeleton).¹²⁰ The visible absorption spectra of these compounds in the ground state were compared with the spectra of methanofullerenes and methanofulleroids.[†] The changes observed in the spectra of methano- and hydro- fullerenes compared with the spectra of C_{60} and methanofulleroids are associated with the differences between the electronic structures of these molecules (58 and 60 π -type electrons respectively). The absorption spectra of $C_{60}H_2$, $C_{60}H_4$, and compound **2** in the triplet state are similar ($\lambda_{\text{max}} \approx 700 \text{ nm}$ for $C_{60}H_2$ and compound **2** and $\lambda_{\text{max}} \approx 710 \text{ nm}$ for $C_{60}H_4$). The quantum yield in the formation of the photosensitised $^1\text{O}_2(^1\Delta_g)$ in the presence of $C_{60}H_2$, $C_{60}H_4$, and compound **2** is close to unity, as in the case of C_{60} . The high effectiveness of the generation of singlet oxygen is probably the cause of the frequently observed degradative changes in the structures of fullerene hydrides in solution.^{33,45,56} The molar absorption coefficients of $C_{60}H_2$, $C_{60}H_4$, and compound **2** in the excited triplet state have been calculated as $\sim 10\,500$ (at 700 nm), ~ 4800 (at 710 nm) and $\sim 11\,000 \text{ mol litre}^{-1} \text{ cm}^{-1}$ (at 700 nm) respectively.

8. The acidity and strength of the C–H bonds in fullerene hydrides

The voltammetric method has been used to investigate the acid–base reactions of hydrogenated fullerenes in solution in dimethyl sulfoxide (DMSO).¹²¹ According to Guarr *et al.*¹²² and Boulas *et al.*,¹²³ dihydrofullerene $C_{60}H_2$ gives rise to three reversible reduction peaks (the radical-anion, dianion, and trianion) with potentials approximately 0.1 V more negative than the corresponding potentials of C_{60} in the 67:33 (by volume) DMSO–toluene mixture. It was noted that $C_{60}H_2$ decomposes slowly in this medium to C_{60} . A series of bases were used to deprotonate $C_{60}H_2$ and to determine the acidity.

$$K_1 = \frac{[C_{60}H^-][BH]}{[C_{60}H_2][B^-]}.$$

(B^- represents the sodium salts of dichloroacetic acid, saccharin, and trifluoroacetic acid; the pK_a for these acids in DMSO are 6.4, 4.0, and 3.45 respectively).

The values of pK_a (1) and pK_a (2) (for the first and second dissociation constants) found for $C_{60}H_2$ are 4.7 and 16 respectively (DMSO, 298 K). The acid dissociation constant of the C–H bond in $\text{Bu}^tC_{60}H$ is 5.7.¹²⁴ The replacement of the *tert*-butyl group

by hydrogen leads to an increase in acidity by virtue of the stronger electron-donating character of the *tert*-butyl group compared with hydrogen.

By employing the sensitivity of the absorption band of the complex of the $C_{60}^{\bullet-}$ radical-anion and γ -cyclodextrin (γ -CD) at 1080 nm in the near IR, the pK_a of the conjugate acid ($C_{60}H$)[•] was determined in the 9:1 H_2O – Pr^iOH mixture and was found to be $4.5 (\pm 0.5)$.¹²⁵

A pK_a of the same order of magnitude has been quoted for $\text{HC}_{60}^{\bullet}$ in dichlorobenzene.¹²⁶ On the other hand, in DMSO the value $pK_a = 9$, was obtained for $\text{HC}_{60}^{\bullet}$ by Niyazymbetov *et al.*¹²¹ The high acidity of $\text{HC}_{60}^{\bullet}$ is combined with a low strength of the C–H bond (71 kcal mol^{-1} for $\text{Bu}^tC_{60}H$).¹²⁴ We may note that quantum-chemical calculations yield C–H bond energies in $C_{60}H_{12}$ (73 kcal mol^{-1}) and $C_{60}H_{18}$ – $C_{60}H_{36}$ (70 – 71 kcal mol^{-1})¹⁰⁴ which are close to the experimental C–H bond strengths in fullerene monohydride.¹²⁴ The calculated average C–H bond energy in $C_{60}H_{60}$ is $\sim 62 \text{ kcal mol}^{-1}$. Such a decrease is caused by the significant structural strain in the fully saturated hydrocarbon framework.¹⁰⁴

Electrolysis of C_{60} to give C_{60}^{2-} with subsequent protonation constitutes an alternative free-radical method of synthesis of $C_{60}H_2$.¹²⁶ The stepwise protonation of the dianion showed that the first proton adds more readily than the second.

An attempt has been made to create a pK_a scale for the hydrofullerene series.¹²⁷ The calculated acidities confirm the hypothesis² that the acidity of fullerene hydrides diminishes with increase in the degree of hydrogenation. In this sense, fullerene monohydride $C_{60}H$ should have the most acidic aliphatic C–H bond.

9. X-ray photoelectron spectroscopy in the study of fullerene hydrides

The fullerene hydride $C_{60}H_{36}$ synthesised by reducing C_{60} with dihydroanthracene in the melt⁴⁵ has been investigated by electron energy loss spectroscopy (EELS).¹²⁸ Fig. 8 presents the loss functions for $C_{60}H_{36}$ and C_{60} . Both functions have a similar form, but the maximum due to the oscillations of all the valence electrons [the $(\sigma + \pi)$ -plasmon] is located at a lower position as regards energy in the case of the hydride (23.8 eV) than in the case of solid C_{60} (25.0 eV). This means that the valence electron density, determined by the magnitude of this energy, diminishes on passing from C_{60} to $C_{60}H_{36}$. The relative intensity of the peak associated with the excitation of the π -plasmon also decreases appreciably in this transition. Under these conditions, the π -plasmon peak loss energy hardly changes. With increase in the irradiation time, the form of the loss function for $C_{60}H_{36}$ becomes similar to that of the function for C_{60} , which is apparently associated with the evolution of hydrogen from the hydride.

Figure 8. The loss functions for the hydride $C_{60}H_{36}$ (continuous line) and fullerene (dashed line) in the EELS spectra.¹²⁸

10. Electrochemistry of fullerene hydrides

In many respects, the electrochemical behaviour of $C_{60}H_2$ is similar to the behaviour of C_{60} fullerene, but $C_{60}H_2$ is reduced

[†] Methanofullerenes and methanofulleroids differ in the way that the ligand is attached to the double bonds of fullerene: addition to the 6–6 bonds with retention of the fullerene framework and the formation of a cyclopropane ring in the former case and the opening of the 6–5 bond in the case of methanofulleroids.

with somewhat greater difficulty.¹²² The potentials $E_{1/2}$ for the reduction of $C_{60}H_2$ in various solvents are presented in Table 4.¹²²

Table 4. Electrochemical reduction of $C_{60}H_2$.¹²²

Solvent ^a	$E_{1/2} (C_{60}H_2^{2-}/C_{60}H_2^{(z+1)-}) / V$ rel. to Fc^+/Fc			
	0/1—	1—/2—	2—/3—	3—/4—
PhMe—CH ₃ CN	−1.05	−1.44	−1.99	−2.36
PhCN	−1.04	−1.43	−2.01	
CH ₂ Cl ₂	−1.11	−1.48	−1.99	

^a 0.1 M (C₄H₉)₄NPF₆ was used as the electrolyte.

The electrochemical properties of $C_{60}H_2$ and 1.9- and 7.8- $C_{70}H_2$ in the DMF–toluene mixture have been investigated.¹²³ $E_{1/2} = -1.02, -1.46, -2.07$, and -2.58 V (relative to Fc/Fc^+) have been obtained for $C_{60}H_2$. Owing to the lower solubility of the reduced $C_{70}H_2$ isomers in the DMF–toluene mixture, it is possible to observe only three consecutive electron transfers for these substances. Thus $E_{1/2} = -1.04, -1.48$, and -1.96 V (relative to Fc/Fc^+) have been obtained for 7.8- $C_{70}H_2$, while the corresponding values for 1.9- $C_{70}H_2$ are $-1.03, -1.52$, and -1.93 V. The electronic effects in these isomers, having different stabilities, are not reflected in their electrochemical behaviour. The stability of the reduced hydride derivatives decreases with increase in the charge, temperature, and (or) the content of DMF in the DMF–toluene mixture. The singly charged radical-anion $C_{60}H_2^-$ proved to be the most stable among the reduced compounds (the EPR spectrum of $C_{60}H_2^-$ is characterised by $g = 2.000$ and $\Delta H = 3$ G at 160 K, whereas the EPR spectrum of C_{60}^- has $g = 1.997$ and $\Delta H = 5.8$ G).¹²³

The electrochemical oxidation of $C_{60}H_2$ has been investigated in PhCN. It is irreversible and takes place in two stages. In the first stage, C_{60} is formed from $C_{60}H_2$ as a result of the loss of two protons and two electrons, and then oxidised in the second stage at more positive potential ($E_p = 1.13$ and 1.35 V relative to Fc/Fc^+).

11. Reactions of fullerene hydrides

The anion $C_{60}H^-$ exhibits fairly strong nucleophilic properties. It is formed when stoichiometric amounts of C_{60} and $LiEt_3H$ are mixed in toluene.¹²⁹ Methyl iodide does not alkylate this compound,¹²⁹ whereas $Et_3O^+BF_4^-$ in dichloromethane reacts with $C_{60}H^-$ to form 1,2- $C_{60}(H)(Et)$ in a quantitative yield. The ¹H NMR spectrum of the product of the reaction of $C_{60}H^-$ with $Et_3O^+BF_4^-$ in CS_2-CDCl_3 [$\delta = 6.42$ (s, 1 H, $C_{60}H$), 3.50 (q, 2 H, CH_2), 2.09 (t, 3 H, CH_3)]¹³⁰ agrees with that described by Hirsch *et al.*¹³¹ The anion $C_{60}H^-$ is protonated by HBf_4 in ether with formation of 1,2- $C_{60}H_2$, giving rise to a singlet at $\delta = 5.93$ in toluene- d_8 .¹³⁰

The addition of nucleophiles to unsaturated ligands in cationic metal complexes, well known in organometallic chemistry, proceeds smoothly also in the reaction with $C_{60}H^-$, the unsaturated ligands serving as a bridge between fullerene and the metal.¹³⁰

The ¹H NMR spectra of these complexes exhibit a signal in the range $\delta = 5.9-6.5$ ppm, characteristic of the compounds 1,2- $C_{60}(H)(R)$.^{3,132} The mass spectra of the products indicate that the molecular ions 1,2- $C_{60}(H)(RML_x)^{+*}$ decompose mainly via the β -elimination mechanism with formation of C_{60}^+ . The com-

pound 1,2- $C_{60}(H)[CH_2CH_2Re(CO)_5]$ decomposes as a result of double β -elimination to C_{60}^+ , $H_3CCH_2Re(CO)_5^+$ and $HRe(CO)_5^+$. Thus a convenient method has been proposed¹³⁰ for the synthesis of metal complexes in which fullerene is linked to the metal atom not directly but via a carbon bridge.

IV. Conclusion

The history of the study of fullerene hydrides covers only a few years, but, despite the preliminary nature of many investigations and the controversial character of certain conclusions, it is already clear that a long life in science and technology lies ahead of this field. The report concerning the study of the structure of the individual hydride $C_{60}H_{18}$ by the ¹H NMR method may be regarded as a consecutive advance in this direction.¹³³ The hydride $C_{60}H_{18}$, obtained by the solid-phase hydrogenation method, has the C_{3v} symmetry according to ¹H NMR data. The study by the differential scanning calorimetry (DSC) of the thermal stability of the highly pure $C_{60}H_{36}$ showed that, together with the dehydrogenation of $C_{60}H_{36}$ to C_{60} , processes involving the degradation of the carbon skeleton of the fullerene take place.¹³⁴

The great potential possibilities for the practical employment of systems based on fullerene hydrides have also promoted the rapid development of the relevant research. One may postulate the possibility of creating electrochemical cells employing intermetallic compounds — fullerene hydride compositions as cathodic materials, as well as the creation of reversible hydrogen accumulators.

The possibility of employing a wide temperature range and of the chemical modification of fullerenes makes it possible to regulate their reactivity in relation to hydrogen. This is of fundamental importance for the creation of active catalysts of the reactions of hydrocarbons. For example, the crystalline adducts of fullerenes with alkali metals, certain representatives of which (M_3C_{60}) exhibit superconducting properties, are capable of catalysing effectively even at -100 °C the homonuclear isotope exchange of hydrogen.¹³⁵ At 300 K and a pressure of the $H_2 + D_2$ mixture of 100 Torr, the reaction rate constant for the Cs_6C_{70} catalyst is 10 min^{-1} . It is 60 times greater than for the caesium compound of graphite having the same composition. The activation energy for the reaction is 11.1 kJ mol^{-1} . In the presence of the Cs_6C_{70} catalyst, ethene is hydrogenated by hydrogen already at 373 K and the rate constant at a pressure of the $C_2H_4 + H_2$ mixture of 200 Torr is 0.5 min^{-1} . The proposed process mechanism involves the dissociative adsorption of the H_2 molecule on the hydrocarbon framework with formation of fullerene hydrides (H_2 is activated similarly on the noble metals platinum and palladium).¹³⁵

The dehydrogenating activity of fullerene catalysts in relation to alkanes,⁵⁰ including methane,^{52,53} exhibited in the range of high temperatures, as well as the influence of hydrogen on the dehydrogenation process similar to that of catalysts based on noble metals,⁵³ makes it possible to regard fullerene catalysts as functional analogues of noble metals. The possibility of a wide variation of the composition of fullerene-containing catalysts and of the temperatures at which they are used makes fullerene structures promising catalysts for a wide variety of reactions of saturated hydrocarbons such as reforming, hydrocracking, dehydrogenation, and others of great industrial importance.

Catalysis with participation of fullerene hydrides may contribute to the recombination of hydrogen atoms with formation of H_2 occurring in interstellar space.¹³⁶ This fundamental hypothesis may be tested with the aid of laboratory studies of the absorption and emission spectra of fullerenes in the UV and IR ranges and by comparison with the spectroscopic characteristics of interstellar space. Another stage in testing the hypothesis may be the laboratory study of the possibility of achieving the bimolecular reaction involving the addition fullerene skeleton with radiation cooling of the excited adduct. Only the readily occurring termolecular addition of a hydrogen atom has now been demonstrated experimentally.¹³⁶

The problem of the reduction of fullerenes continues to interest investigators. The electrochemical hydrogenation of C_{60} in 30% aqueous KOH solution has been achieved.¹³⁷ The cathodic C_{60} reduction potential has been found to be -1.4 V (relative to Ag/AgCl). It has been shown that $C_{60}H_2$ is formed under these conditions, although the yield of the dihydride is low. The hydrogenation of C_{60} and the dehydrogenation of $C_{60}H_x$ during electrolysis are reversible.

Thus the possibility of using C_{60} as the electrode material for the creation of batteries in aqueous KOH has been demonstrated.

Preliminary results of the study of the reduction of higher (C_{76} , C_{78} , and C_{84}) fullerenes in the Zn–conc. HCl–toluene system in the dark and in the absence of oxygen have been reported.¹³⁸ The reduction of C_{76} leads to $C_{76}H_{46}$ – $C_{76}H_{56}$, while the reduction of C_{78} (according to the isomeric composition of the initial fullerene) affords a wide range of hydrogenation products, $C_{78}H_{48}$ being the main component. Products having the compositions $C_{84}H_{48}$ – $C_{84}H_{52}$ have been obtained as a result of the reduction of C_{84} . In each case, the reduction of higher fullerenes is accompanied by the degradation of the specimen and the appearance of the hydrides $C_{60}H_{36}$ and $C_{70}H_{36}$ and $C_{70}H_{40}$ (HPLC), which confirms yet again that the stability of these hydrides is a maximum and that the reduced C_{84} derivatives are least stable.

The photochemical reaction ($\lambda = 350$ nm, N_2 , 12 h) of C_{60} with tertiary amines $RNMe_2$ ($R = Ph, Me$) leads to products of the addition of the amine to the 6–6 bond of the fullerene.¹³⁹ On further irradiation of the reaction mixture in the presence of an excess of C_{60} , the adduct is converted into a pyrrolidine derivative of C_{60} and 1,2- $C_{60}H_2$, confirming thereby the possibility of reducing the fullerene when mixtures of fullerenes with organic compounds are irradiated.

The theoretical analysis of fullerene hydrides has been continued.^{140, 141} Structures with a skewed pentagonal-pyramidal disposition of hydrogen atoms have been considered. The addition of hydrogen to $C_{60}H_6$, $C_{60}H_{12}$, or $C_{60}H_{18}$ takes place mainly in the *ortho*-position, whereas the addition of bromine occurs preferentially in the *para*-position. Hydrogen and bromine are eliminated respectively from the *para*- and *ortho*-positions in one of the skewed pyramidal structures. The pentagonal-pyramidal $C_{60}H_6$, the doubly pentagonal-pyramidal $C_{60}H_{12}$, the triply pentagonal-pyramidal $C_{60}H_{18}$ and also $C_{60}H_{26}$, $C_{60}H_{28}$, and $C_{60}H_{36}$ do not disproportionate to higher and lower hydrides.

It has been shown with the aid of IR and ^1H NMR spectroscopy that, in the interaction of C_{60} with $HIr(C_8H_{12})(PPh_3)_2$ the transition metal atom is coordinated to the C_{60} molecule via the $C1$ – $C2$ bond.¹⁴²

It has been shown¹⁴³ that in the absence of oxygen in the dark and on irradiation, the interaction of C_{60} with $H_3Ir(PPh_3)_3$ leads to different products: to the complexes of iridium with η^2 -coordinated C_{60} on heating in toluene ($100^\circ C$) and to the oxidation of iridium by the triplet-excited C_{60} (Nd^{3+} : YAG laser, $\lambda = 532$ nm) on irradiation in benzonitrile. The photochemical reaction in benzonitrile leads to the appearance of an absorption band in the near IR and of an EPR signal for the C_{60} radical-anion ($\lambda = 1078$ nm, $g = 2.0001$). The triplet-excited C_{60} is quenched by the complex $H_3Ir(PPh_3)_3$ via a reductive mechanism, the quenching constant being $k_q = 1.1 \times 10^9$ mol $^{-1}$ s $^{-1}$.

It has been noted¹⁴⁴ that the appearance of a signal with m/z 780 (see, for example, Shigematsu *et al.*⁸³) in the mass spectrum of the C_{60} hydrogenation products when toluene is used as the solvent is probably associated with the formation of the trimethylene adduct of the fullerene hydride $C_{60}H_{18}$ and not with the formation of $C_{60}H_{60}$.

The optimum structures and the relative stabilities of the $C_{70}H_{36}$ molecule (the heats of formation of the isomers) have been calculated, which showed that the presence of aromatic fragments on the surface of the molecule is not the dominant factor determining the stability. The energy of the deformation of

the molecule owing to steric strain, induced by the fact that aromatic fragments must be planar, exceeds the resonance energy gained. A series of structures have already been proposed for $C_{70}H_{36}$ with partly isolated double bonds,¹⁴⁵ their calculated heat of formation being significantly lower than for the 'aromatic' isomers. The search for the optimum combination of aromaticity and steric strain in $C_{70}H_{36}$ isomers is being continued.¹⁴⁶

The photophysical properties of the hydrides $C_{60}H_{18}$ and $C_{60}H_{36}$, obtained with a purity of 90%–98% by the transfer hydrogenation⁴⁵ with subsequent purification by sublimation, differ significantly.¹⁴⁷ The absorption spectrum for the ground state of $C_{60}H_{36}$, measured in solution and in methylene chloride, indicates the presence of isolated benzenoid fragments in the structure of the hydride. They are present in the isomers with the T , S_6 , or D_{3d} point symmetry group and are absent from the most symmetrical T_h isomer. Furthermore, the energy calculated for the molecule with the T_h symmetry is higher by more than 2 eV than the energy of the most stable-isomer.¹⁰⁵ Additional information about the symmetry of $C_{60}H_{36}$ is provided by the group-theoretical study of the IR and Raman spectra of the specimens obtained and also by the solid-phase ^{13}C NMR spectrum, which contains signals due to several different sp^3 -hybridised carbon atoms instead of the single signal expected for the T_h structure.¹⁴⁷ Analysis of the entire set of data enabled the authors¹⁴⁷ to reject the T_h structure for $C_{60}H_{36}$ and to identify the structure with the S_6 symmetry as the most probable. This conclusion differs from the conclusion by the authors of earlier studies^{61, 112} that the $C_{60}H_{36}$ specimens obtained by direct hydrogenation at a high pressure have the D_{3d} symmetry. These were investigated by electron and X-ray diffraction and also with the aid of NMR and IR spectroscopy, the spectroscopic characteristics of the specimens differing significantly from those obtained by Bensasson *et al.*¹⁴⁷ These differences have been interpreted¹⁴⁷ as evidence that different synthetic methods afford $C_{60}H_{36}$ isomers having different symmetries.

However, within the limits of one method products with different isomeric compositions can apparently be formed. Thus the hydrogenation of C_{60} by 9,10-dihydroanthracene,¹⁴⁸ analogous to that described by Bensasson *et al.*¹⁴⁷ leads to a product containing as the main component the $C_{60}H_{36}$ isomer with the T symmetry. Its solid-state ^{13}C NMR spectrum contains three signals due to sp^3 -hybridised carbon atoms at 31.1, 37.2, and 44.1 ppm and three signals due to sp^2 -hybridised carbon atoms at 124.9, 134.7, and 137.3 ppm with an integral intensity ratio of 36:24.¹⁴⁸

The electronic absorption spectrum of $C_{60}H_{18}$ in the ground state differs greatly from the spectrum of $C_{60}H_{36}$ ¹⁴⁷ and its structure is very close to that of the spectrum of C_{60} , which suggests the presence in the $C_{60}H_{18}$ molecule of an analogous conjugation system of sp^2 -hybridised carbon atoms, but with the difference that they do not cover the entire surface of the sphere.¹⁴⁷ This agrees with the results of the analysis of the ^1H NMR spectra of $C_{60}H_{18}$ specimens obtained by the solid-phase hydrogenation method.¹³³ The absorption spectrum of the lowest $C_{60}H_{18}$ triplet, obtained by flash photolysis in benzene,¹⁴⁷ is also structurally very similar to the spectrum of the triplet–triplet absorption of C_{60} in benzene and is located in the identical wavelength range, which confirms the postulate that the type of conjugation present in the initial C_{60} is retained to a significant extent in $C_{60}H_{18}$. An additional argument in support of this claim is the similarity of the lifetimes of the lowest $C_{60}H_{18}$ triplet (210 μs)¹⁴⁷ and C_{60} (47 μs) in benzene. The quantum yield in the formation of the triplet $\phi_t(C_{60}H_{18}) < 0.12$, estimated from the results of the flash photolysis of solutions in benzene, is appreciably lower than $\phi_t \approx 1$ for C_{60} and the lowest hydrides $C_{60}H_2$ and $C_{60}H_4$.^{120, 147} This fact agrees with the very weak fluorescence of C_{60} , $C_{60}H_2$, and $C_{60}H_4$ (the quantum yield of the C_{60} fluorescence is $\approx 10^{-4}$) compared with the fairly intense fluorescence of $C_{60}H_{18}$.¹⁴⁷ Such modification of the photophysical properties as a result of the increasing hydrogenation of the carbon framework of C_{60} may be of interest for medicine, biology, and photonics. Unfortunately, the photophysical characteristics of the triplet state of $C_{60}H_{36}$ could not

be measured: the triplet–triplet absorption spectrum of this compound in the wavelength range accessible to measurements ($\lambda > 300$ nm) is lacking.

This review has been written with the financial support by the Russian Fundamental Research Fund (project Nos. 95–03–08932 and 96–03–34102) and by the State Scientific–Technical ‘Fullerenes and Atomic Clusters’ program.

II. Intramolecular reactions	343
III. Intermolecular reactions	351
IV. Conclusion	361

Abstract. Published studies on the reactivity of terpenes and their analogues in an ‘organised medium’, viz. upon adsorption on solid catalysts and upon complex formation with cyclodextrins (photochemical processes), are analysed. It is shown that the use of an ‘organised medium’ not only improves the environmental characteristics of the known processes involving natural terpene derivatives. In addition, due to the specific features of the latter (conformational mobility, polyfunctionality), it opens broad opportunities for discovering unusual transformations, and this extends the prospects of using the ‘renewable raw materials’ for fine organic synthesis. The bibliography includes 92 references.

I. Introduction

‘Fixing’ of substrates through their adsorption on solid catalysts or due to complex formation with cyclodextrins are among the methods for influencing the reactivity of chemical compounds in thermal or photochemical processes that have been vigorously developing in recent years. This approach makes it possible to change sharply the selectivity of a process by creating steric hindrance in certain parts of the molecule or by imparting conformational rigidity to the molecule. In addition, adsorption of organic substrates on solid catalysts often changes the activation barriers to many transformations; in the case of molecules with multivariant reactivity, this makes it possible to direct the reaction along a previously unknown route.

Whereas reactions of aromatic compounds in the ‘fixed state’ have been intensely studied for a fairly long period,^{1,2} studies on the reactivity of terpenoids under these conditions are still at their early stage. However, it can be said with confidence that the number of works devoted to this topic will sharply increase, firstly, because researchers will attempt to extend the range of substrates that can be involved in these reactions and, secondly, because terpenoids are promising compounds, which can undergo new unusual transformations due to their polyfunctionality and conformational flexibility.

This review appears to be the first attempt to summarise the accumulated experimental results in this interesting field of organic chemistry.

II. Intramolecular reactions

1. Isomerisation of terpenoids on solid catalysts

Acid-catalysed rearrangements of terpenoids in various homogeneous media (from weakly acid to superacid) have been studied fairly comprehensively (see, for example, Ref. 3). In this Section, we consider the rearrangements of terpenoids on solid catalysts, which have been used with increasing frequency in recent years, in place of Lewis and Brønsted acids, for isomerisation of organic compounds.

Tanaka *et al.*⁴ have studied the transformations of limonene **1** in the presence of various metal oxides and phosphates at 60 °C under normal pressure.

Basic (MgO), acid-base (ZrO₂, Al₂O₃, and TiO₂–ZrO₂) and weakly acidic (AlPO₄, Nb₂O₅) catalysts proved to be inactive in this reaction. The other catalysts used in this study (including 96% H₂SO₄) led to the formation of mixtures of products containing terpinolene **2** (the main product) and **3–5** in various ratios.⁴ The SiO₂–Al₂O₃ and SO₄^{2–}/ZrO₂ systems proved to be the most active catalysts; the use of the latter results in fairly selective (up to 84%) formation of the compound **2**. The researchers believe that both Lewis and Brønsted acid sites are active in this reaction; however, better selectivity with respect to terpinolene is achieved in the case of catalysts having strong Lewis sites. At the same time, the strong solid Lewis acid SO₄^{2–}/Fe₂O₃ does not exhibit catalytic activity in this reaction, and this prompts the thought that the dependence of the degree of conversion of the compound **1** on the characteristics of the catalyst used is more complex.

A number of patents^{5–10} have been devoted to isomerisation of α -pinene **6**, β -pinene **7** and turpentine containing these terpenes in the presence of X-type zeolites. This process leads to a mixture of products, which contains limonene **1** as the major component.

When this transformation is carried out at 150–175 °C, the yield of limonene amounts to 50%–65%; the reaction mixture also contains camphene **8** (15%–20%) and terpinolene **2**

(~10%). It has been found¹¹ that the use of KX zeolite leads to better results than the use of the NaX, CaX and NH₄X zeolites.

The isomerisation of optically active longifolene **9** on the wide-pore β -zeolite giving optically active isolongifolene **10** has been studied.¹²

Polovinka *et al.*¹³ who have compared isomerisation on zeolites with transformations of the compound **9** in a superacid medium, have found that in the latter case, the degenerate rearrangement with 1,2-shift of the C(8)–C(11) bridge occurs more rapidly than the non-degenerate 6,1-hydride shift, and this gives the racemic compound **10**. Evidently, in the case where zeolite is used, the opposite relationship between the rates of these processes is observed, which results in the retention of the optical activity.

α -Humulene **11** also isomerises in the presence of β -zeolite: at 20 °C it is converted into bicyclohumulene **12** in 60% yield over a period of 1.5 h.¹⁴

When (+)-aromadendrene **13** is kept at room temperature over alumina with deposited potassium, it is converted quantitatively into (–)-isolekene **15**. If this reaction is carried out at 100 °C, (+)-ledene **14** is formed in addition to the compound **15**. The alkene **15** is thermally unstable and is converted into (+)- γ -gurjunene **16** on heating to 450 °C.¹⁵

Isomerisation of the alkene **14** in the presence of the solid superacid SO₄^{2–}/TiO₂ (10 min, 20 °C) has led to 7-isopropyl-2,10-dimethylspiro[4,5]deca-1,6-diene **17** and its isomer, 7-isopropyl-2,10-dimethylspiro[4,5]deca-2,6-diene **18**.¹⁶ It was suggested that these compounds are formed intermediately during the more extensive isomerisation of ledene **14** in formic acid.

The same products were obtained in the isomerisation of (1*S*,4*R*,5*R*,6*S*,10*R*)-7-isopropyl-4,10-dimethyltricyclo[4.4.0.0^{1..5}]deca-7-ene **19**. It was found¹⁶ that the alkene **16** adsorbed on SO₄^{2–}/ZrO₂ isomerises at room temperature into (6*R*,10*R*)-3-isopropyl-6,10-dimethylbicyclo[5.3.0]deca-1(7),2-diene **20**.

The transformations of caryophyllene **21** and isocaryophyllene **22** on acid alumina lead mostly to clovene **23** and α -neoclovene **24**, respectively.¹⁷ Caryophyllene **21** not only isomerises to clovene **23** but is also hydrated to give alcohols, caryolan-1-ol **25** and isocaryolan-8-ol **26**.

Considerable attention of researchers is paid to isomerisation of terpenoids containing functional groups, *i.e.* aldehydes, ketones, alcohols or epoxides of the terpene series. Cyclisation of citronellal **27** to isopulegol **28** in the presence of acidic zeolites such as clinoptilolite, mordenite and fojazit in various solvents at 61–84 °C has been studied.¹⁸ A possible mechanism of this process includes the protonation of the carbonyl group, the interaction of the carbocation centre with the 6,7-double bond and abstraction of a proton yielding the alcohol **28**.

The reaction mixture contains also a small amount of di(2-isopropenyl-5-methylcyclohexyl) ether **29** resulting from bimolecular dehydration of the alcohol **28**.

Salakhutdinov *et al.*¹⁹ have studied the behaviour of some dienones — analogues of terpene derivatives — on the NH₄Y- and β -zeolites in order to elucidate the dependence of the reaction route on the structure of the initial ketone and the reaction conditions.

The transformation of ketones **30a–c** in the presence of NH₄Y zeolite (60–80 °C) gives rise to mixtures of compounds **31a–c** and **32a–c**, respectively.

R = Me (a), CH=C(Me)₂ (b), Buⁱ (c).

In the case of trienone **30b**, 3-isopropylidene-1,1-dimethyl-2-(1-oxo-3-methylbut-2-enyl)-cyclopentane **33** is formed, in addition to the compounds **31b** and **32b**. When the wide-pore β -zeolite is used as the catalyst and the substrate is adsorbed on the catalyst by a different method, the ketones **30a** and **30b** are converted into compounds **34a** and **34b**, respectively.

A possible mechanism of the transformations of the ketones **30a–c** is presented in Scheme 1.

The use of the CaY zeolite made it possible to solve a problem of practical importance, namely, to carry out selective cyclisation of pseudoionone **35** to α -ionone **36**.

Cyclisation of 2,6-dimethyl-1,5-heptadienecarbonitrile has been reported.²¹ When this compound is applied on the β -zeolite at room temperature, it is converted almost immediately into cyclic nitriles **38** and **39**.

Prolonged keeping of nitrile **40** under the same conditions does not lead to any cyclic products; instead, the arising carbocation reacts with a nucleophile from the reaction medium to give alcohol **41**.

A study devoted to the transformations of labdane alcohols on the HY zeolite has been reported.²²

When epimanol **42** was kept on a zeolite (40 °C, 4.5 h), $\Delta^{8,9}$ -pimaradiene **43** and $\Delta^{8,9}$ -isopimaradiene **44** were isolated from the reaction mixture.

The transformations of 6-oxolarixol **45** on a zeolite gave bicyclic products **51** and **52**, in addition to tricyclic compounds

47–50. The bicyclic compounds could have formed *via* the migration of the 8,17-double bond to the position conjugated with the oxo-group, which makes cyclisation impossible.

Keeping compound **46**, the $\Delta^{7,8}$ -isomer of the oxalcohol **45**, on a zeolite leads to a mixture of products containing isomeric bicyclic ketones **53** and **54** and tricyclic ketone **55** in a ratio of 2:1:2.

Analysis of experimental data permitted the researchers cited²² to conclude that the transformations of the alcohols **42**, **45** and **46** on HY zeolite follow different pathways depending on the position of the double bond in ring *B*. In the case of the compounds **42** and **45** containing *exo*-methylene double bonds, acid-catalysed cyclisation yielding isomeric tricyclic diterpenoids occurs predominantly, whereas in the case of the compound **46** containing no highly reactive exocyclic double bond, the dehydration and polymerisation processes predominate.

A large number of works have been devoted to heterophase isomerisation of epoxides of the terpene series, which are fairly reactive compounds capable of being functionalised to alcohols, aldehydes and ketones.

Analysis of the data presented in Table 1 leads to the following conclusions. Firstly, in the presence of solid catalysts, apart from the cleavage of the epoxide ring and functionalisation of the substrate (for example, the transformations **60**→**61**; **62**→**63**+**64**; **87**→**88**), isomerisation of the carbon skeleton occurs (for example, **62**→**66**; **67**→**68**+**72**; **84**→**85**). Secondly, the use of various types of solid catalysts permits selective preparation from the same epoxide of products belonging to various classes. For example, limonene epoxide **62** can be converted either into ketone **61** or into aldehyde **66**, and α -pinene epoxide **67** affords either campholenic aldehyde **68**, or alcohol **70**, or the ketone **63**. Thus by varying the character of the catalyst used, one can control the reaction route. Thirdly, comparison of the products obtained from the epoxides under heterogeneous conditions (Table 1) with those formed in homogeneous acid media implies that isomerisation can follow

Table 1. Isomerisation of epoxides on solid catalysts.

different pathways under homogeneous and heterogeneous conditions. For example, the transformation of humulene 6,7-epoxide **87** in a homogeneous acid medium follows a concerted mechanism with the consecutive participation of the 9,10- and 2,3-double bonds and with fixation of the most stable *cis-trans*-conformation,⁴⁵ whereas on solid catalysts, the isomerisation apparently occurs by a non-concerted mechanism, and a conformation other than the most stable is fixed. Depending on the nature of the catalyst, cleavage of the epoxide ring is followed either by 1,2-hydride shift to give ketone **89** (the askanite–bentonite clay) or by abstraction of a proton yielding alcohol **88** (SO₄²⁻/Al₂O₃).¹⁴

2. Photochemical isomerisation of terpenoids and their complexes with cyclodextrins

Besides thermal isomerisation of terpenoids in the presence of solid catalysts, considerable interest is aroused by photochemical transformations of these compounds; this is due to their natural origin and to the important role of solar light for the biogenetic processes.

Owing to polyfunctionality and conformational flexibility of terpenoids and to the high energy of UV radiation, exposure of solutions of terpenoids to radiation usually leads to non-selective transformations yielding numerous products. To increase the selectivity of the process, complex formation is employed. The formation of complexes with cyclodextrins (CD) makes the substrates conformationally rigid by fixing a particular arrangement of the reactive sites of the molecules. Consequently, photochemical processes either occur more selectively or follow a different pathway.

Cyclodextrins are natural cyclic oligosaccharides consisting of 6 (α -CD), 7 (β -CD) or 8 (γ -CD) D-(+)-glucopyranose units linked by α -1,4-glycosidic bonds. They are capable of acting as 'hosts' in complexes of the 'host–guest' type.² Cyclodextrins bind a guest molecule through hydrophobic interactions, *i.e.* by forming complexes with low-polarity molecules or parts of molecules. This complex formation closely resembles binding of substrates by

enzymes, which is especially valuable for the investigation of natural terpenoids. For example, complex formation with CD has been used^{2,46} to change the photochemical reactivity of organic molecules. However, these studies referred only to aromatic substrates.

In a study of photochemical reactions of compounds **30a–c** and **112** (the latter is a homologue of the dienone **30a**), it was found⁴⁷ that on exposure to radiation, the compounds **30a**, **30c** and **112** undergo *cis-trans* isomerisation, while the ketone **30b** is converted into cyclopentane derivative **113**.

The situation changes when complexes of the ketones **30a–c** and **112** with β -CD are irradiated. In all the cases, the allylic hydrogen atom undergoes a 1,4-shift to the carbon atom, located in the α -position with respect to the carbonyl carbon atom, and the 1,3-biradical undergoes ring closure to give substituted cyclopropanes **114a–d**.

R = Me (**a**), Buⁱ (**b**), CH₂CMe=CH₂ (**c**), Et (**d**) (**114**).

The results of the photolysis of the ketones **30a**, **30c** and **112** indicate that the size of the alkyl group **R** at the carbonyl carbon atom does not influence the direction of the process but does influence the yield of **114**: as the bulk of the alkyl substituent increases, the product yield decreases. Apparently, this is due to the fact that the complex formation between the substrates and β -CD becomes difficult.

Comparison of the photochemical reactions of the complexes of **30b** and **30c** with β -CD indicates that the presence of the rigid conjugated dienone system prevents the cyclisation with 1,4-shift of hydrogen yielding cyclopropanes (compound **30c**). The partial destruction of the dienone system due to allylic rearrangement facilitates transition to a conformation favourable for the cyclisation giving a cyclopropane ring.

Analysis of the products resulting from the photochemical transformations of the ketone **30b** as such and as the complex with β -CD allowed Luzina *et al.*⁴⁷ to assume that the isopropylidene group of the ketone drops into the cavity of β -CD. This assumption is consistent with the fact that the allylic rearrangement occurring on irradiation of free **30b** involves the isolated double bond, whereas irradiation of the complex results in the violation of the conjugated system of π -bonds, which is substantially less favourable energetically. The assumption that the non-conjugated double bond is shielded is also in agreement with the fact that photochemical reactions of the complexes of **30a–c** and **112** with β -CD are always accompanied by *trans–cis*-isomerisation of the double bond.

The behaviour under the same conditions of a number of compounds containing a 2,6-dimethylhepta-1,5-dienyl fragment has been studied.²¹

This seemingly insignificant modification of the structural unit results in substantial changes in the photochemical reactivity. In fact, when 4,8-dimethylnona-3,7-dien-2-one **115** is exposed to radiation, *trans–cis*-isomerisation of the double bond occurs. Irradiation of the complex of **115** with β -CD gives rise to cyclopentanone **117** and dienone **118** (*cf.* Refs 48 and 49).

The influence of functional groups on the photochemical processes was studied²¹ in relation to alcohol **119**, aldehyde **120** and nitriles **37**, **40** and **121**.

Neither the alcohol **119** nor its complex with β -CD exhibit photochemical activity indicating that the conjugated carbonyl group plays a significant role in this process. When citral **120** in methanol is exposed to radiation in the absence of β -CD, acetal **122** is formed, while this compound bound in the complex with β -CD is converted into cyclopentanone derivative **123** (*cf.* Ref. 49).

During irradiation of the nitriles **37**, **40** and **121**, cyclodextrin acts as a sensitizer. The reactions yield nitriles **124–126**, respectively.

Let us consider a possible mechanism of the formation of these products using the nitrile **37** as an example.

The 1,3-hydride shift gives biradical **127**, which undergoes ring closure yielding nitrile **128** containing a cyclobutane ring. The subsequent rupture of the C–C σ -bond in the four-membered ring of the nitrile **128**, hydride shift and formation of a double bond give rise to the compound **124**.

The irradiation of methanol solutions of the ketones: pseudoionone **129**, ϕ -ionone **130** and ϕ -methylionone **131**, the structures of which are similar to that of the ketone **115** and the carbonyl group is conjugated with two double bonds, results in *trans–cis* isomerisations of both double bonds. When solutions of complexes of the ketones **129** and **131** with β -CD are exposed to radiation, bicyclic ketones **132** and **134**, respectively, are formed as virtually the only products.

$R = R' = H$ (**129**, **132**); $R = Me$, $R' = H$ (**130**, **133**);

$R = H$, $R' = Me$ (**131**, **134**).

Photolysis of the complex of the ketone **130** with β -CD in solution follows a different pathway: bicyclic ketone **133** and ketone **135** ($\sim 1:1$, according to GLC) are formed as the main products.

Photolysis of cyclic ionones — α -ionone **136**²¹ and β -ionone **137** and products of its crotonic condensation with acetaldehyde (**138**), acetonitrile (**139**), and ethyl acetate (**140**), has been studied.⁵⁰

The irradiation of a methanol solution of the ketone **136** and benzene solutions of the ketone **137** and the aldehyde **138** leads to

trans–*cis* isomerisation of the double bond. When the complex of **136** with β -CD is exposed to radiation, rearrangement products **141** and **142** are formed ($\sim 2:1$, according to GLC), while in the case of complexes derived from **137** and **138**, retro- γ -ionone **143** and retro- γ -ionylidenacetaldehyde **144**, respectively, are formed as the major products.

When β -ionylideneacetonitrile **139** and ethyl β -ionylideneacetate **140** are bound in complexes with β -CD, their reactivity does not change. Both these compounds themselves and their complexes with β -CD react to give compounds **145** and **146** as the main products.

If the ketone **136** is bound in a complex with α -CD, this reaction yields retro- α -ionones **147**, instead of the compounds **141** and **142**.²¹

III. Intermolecular reactions

Intermolecular reactions of terpenoids in 'organised media' are of interest for both theoretical and applied organic chemistry. Multi-site adsorption of reactants and substrates on solid catalysts sharply decreases the activation barriers to a number of transformations, and hence, some practically valuable processes can be conducted at low temperatures and under atmospheric pressure. The fact that the adsorbed substrate and reagent molecules can approach each other and the presence of channels and pores in the catalyst not only decrease the activation energies of the possible processes but also provide the possibility of making a reaction follow selectively a particular pathway. This pathway is often unusual and unknown in the chemistry of homogeneous reactions. The use of solid catalysts (mostly aluminosilicates) in the chemistry of terpenoids leads sometimes to results that can change our views on the role of homology, isomerism and similarity of molecules.

1. Cycloaddition reactions
