Among cycloaddition reactions involving terpenoids, a special place belongs to the Diels–Alder reaction, because the adducts that are formed are used as perfumes or intermediates for their production. To carry out reactions of this type without a catalyst, high temperatures and elevated pressures are needed. Consequently, the reaction mixtures can contain substantial amounts of resins.⁵¹ The use of zeolite catalysts⁵² or chromatographic sorbents⁵³ in the reactions of a natural terpene, myrcene **148**, with methyl vinyl ketone and acrolein results in the formation of Diels–Alder adducts **149**–**151** in good yields under mild conditions.

The Cu²⁺NaY, NiNaX and dealuminised NiNaY' zeolites and natural clinoptilolite were used as catalysts in this reaction.⁵² It was found that the process is best performed without a solvent, at 50 °C using 1.5 moles of methyl vinyl ketone per mole of the triene **148** and 100% (by mass) of the NiNaX zeolite with respect to the organic components introduced in the reaction. Under these conditions, the degree of conversion of the compound **148** was 80% over a period of 5 h, and the overall yield of the products **149** and **150** was 45% (the **149**:**150** ratio was 9:1). In the presence of the CuNaY zeolite, the yield of the adducts **149** and **150** did not exceed 40%, their ratio being the same. The activity of natural clinoptilolite was the same as that of the NiNaX zeolite. When the reactions of the triene **148** with methyl vinyl ketone and with acrolein were carried out on the surface of a chromatographic adsorbent without a solvent, the reaction temperature could be decreased by 50–100 °C, and the adducts **149** and **151** were formed in good yields (73% and 66%, respectively).⁵³ The best effect was achieved when various kinds of silica gel for chromatography were used as the 'dry media'. Magnesium silicate was less active, and alumina was ineffective in this reaction. The catalytic effect of the sorbents was explained by the fact that the reactants, being adsorbed on them, lose their solvation shells, and this markedly facilitates the formation of pre-reaction complexes due to weak van der Waals interactions of the substrates.

The possibility of stereoselective diene condensation of alloocimene **152** with α -methylacrolein in the presence of wide-pore β -zeolite has been demonstrated.⁵⁴

One of the four possible diastereomers, aldehyde **153**, is formed predominantly. Furthermore, it was found that other diastereomers do not isomerise into the compound **153** under the reaction conditions.

The results of the reactions of the trienes **148** and **152** with acrolein, methyl vinyl ketone, α -methylacrolein and crotonaldehyde on β -zeolite are presented in Table 2.

When the methyl ester of abietic ester **164** has been made to react with α -methylacrolein in the presence of wide-pore β -zeolite or askanite–bentonite clay (boiling benzene, 7 h), epimeric products of the Diels–Alder condensation **165a,b** have been isolated.⁵⁵

The reaction of the ester **164** with maleic anhydride on the same catalysts results in the formation of adduct **166**. In the absence of catalysts, the yield of the product **166** is five times lower, while the compounds **165a,b** are not formed at all.

The reaction of the triene **148** with crotonaldehyde carried out with the askanite–bentonite clay as the catalyst unexpectedly yielded 2,2,6-trimethyl-4-(prop-1-enyl)-3-oxabicyclo[3.3.1]non-6-ene **167** as the main product.⁵⁴

Table 2. Diels–Alder adducts obtained from the trienes **148** and **152** on a β type zeolite.⁵⁴

Diene	Dienophile	Adducts	Diene	Dienophile	Adducts
152	Acrolein	4,5 β -Dimethyl-2 β -(2-methylprop-1-enyl)-cyclohex-3-ene-1 β -carbaldehyde 154	148	α -Methyl-acrolein	Myrcenal 159
		4,5 β -Dimethyl-2 β -(2-methylprop-1-enyl)-cyclohex-3-ene-1 α -carbaldehyde 155		Methyl vinyl ketone	Isolone 160
	Methyl vinyl ketone	4,5 β -Dimethyl-2 β -(2-methylprop-1-enyl)-1 β -acetylcyclohex-3-ene 156		Croton-aldehyde	5 α -Methyl-1-(4-methyl-pent-3-enyl)cyclohex-1-ene-4 β -carbaldehyde 161
		4,5 β -Dimethyl-2 β -(2-methylprop-1-enyl)-1 α -acetylcyclohex-3-ene 157			5 β -Methyl-1-(4-methyl-pent-3-enyl)cyclohex-1-ene-4 β -carbaldehyde 162
148	Acrolein	Cyclonal 158			4 α -Methyl-1-(4-methyl-pent-3-enyl)cyclohex-1-ene-5 β -carbaldehyde 163

The formation of ether **167** is accompanied by transformation of three π -bonds into three σ -bonds and by the appearance of two new rings, *i.e.* this reaction conforms formally to the definition of the ‘Diels–Alder homo-reaction’. This type of transformation is unusual, because, despite the presence of conjugated double bonds in the molecule of **148**, it involves two non-conjugated double bonds, and because α,β -unsaturated aldehyde reacts at the carbonyl group rather than at the double bond, which would be the usual pathway.

Let us dwell on the possible mechanisms of this unusual transformation. The researchers⁵⁴ proposed two mechanisms — homolytic (*a*) and heterolytic (*b*) mechanisms.

Both proposed mechanisms include the intermediate formation of compounds **168** and **170** with the *p*-menthane skeleton.

The same bicyclic ether **167** is formed in the reaction of diene **171** with crotonaldehyde. However, this reaction does not conform to the definition of Diels–Alder synthesis, because the diene **171** contains no conjugated double bonds, or to the definition of the Diels–Alder homo-reaction, since in this case only two double bonds disappear.

Since the formation of bicyclic ethers is of interest by itself, its mechanism has been studied in relation to the reaction of the diene **171** with various aldehydes. If the reaction of dipentene with crotonaldehyde occurs by the homolytic mechanism, one must assume that it involves the cleavage of the C(7)=C(8) double bond followed by hydride shifts to give the intermediate species **172**.

If the reaction follows the heterolytic mechanism, there is no need for the hydride shifts.

To make the choice in favour of a particular mechanism, a model compound, 4-isopropenyl-1,2,4-trimethylcyclohex-1-ene **173**, was introduced in the reaction with crotonaldehyde. The methyl group in the 4-position of this compound precludes the 1,2-hydride shifts leading to an intermediate structure like **172**. The reaction of the diene **173** with crotonaldehyde in the presence of the askanite–bentonite clay gave ether **174**; the positions of the methyl groups in this compound differ from those in compound **175**, which would have formed by the homolytic reaction route.

These facts count in favour of the heterolytic mechanism. The latter can be accomplished by two pathways.

According to the first variant (pathway *c*), the protonated diene acts as the attacking species and the aldehyde acts as a nucleophile, whereas in the second variant (pathway *d*), the protonated aldehyde is an electrophilic species and the diene acts as a nucleophile. In our opinion, the fact that the reaction of 1-methylcyclohexene with crotonaldehyde, which models the first

step of pathway *d*, does not occur is evidence supporting the former pathway.

The reaction under consideration is general. Acrolein, α -methylacrolein, butyraldehyde, benzaldehyde, perfluorobenzaldehyde, and *p*-hydroxybenzaldehyde react with the diene **1** to give bicyclic ethers **176–181**, respectively.

The formation of optically active ester **181** ($[\alpha]_{580}^{20} = +171.4^\circ$, c 5.49, CHCl_3) in the reaction of the diene **1** with *p*-hydroxybenzaldehyde also supports the heterolytic mechanism for this process.⁵⁶ At the same time, the reactions of the dienes **1** and **173** with salicylaldehyde, isomeric to *p*-hydroxybenzaldehyde, on the askanite–bentonite clay at room temperature do not stop at the stage of the formation of bicyclic ethers but proceed further to give compounds with the xanthene skeleton. Thus the interaction of the cationic centre in the intermediates **182** and **183** with the *o*-OH group gives rise to 2,2,8-trimethyl-3,7-dioxo-5,6-benzotricyclo[6.2.2.0^{4,12}]dodecane **184** and 1,2,2,8,12-pentamethyl-3,7-dioxo-5,6-benzotricyclo[6.2.2.0^{4,12}]dodecane **185**, respectively.⁵⁶

$R = \text{H}$ (**1**, **182**, **184**); Me (**173**, **183**, **185**).

When salicylaldehyde was made to react with hydroxyalkenes of the carane and menthane series: valtherol **186**, *trans*-4-(1-hydroxyethyl)-2-carene **187** and (1*S*,4*R*,6*R*)-6-hydroxymethyl-*p*-mentha-2,8(9)-diene **188**

on the askanite–bentonite clay, products with the xanthene skeleton were also obtained, but in this case, this skeleton was fused to a tetrahydrofuran ring rather than to a tetrahydropyran ring as in **184** and **185**, and the arrangement of alkyl substituents was also different.

It is clear that in this case the process follows a different pathway.⁵⁷ A possible mechanism for this reaction is shown below in relation to valtherol.

In the first step, protonated salicylaldehyde attacks the double bond of valtherol to give cation **189**. Intramolecular heterocyclisation in this cation accompanied by cleavage of the three-membered ring yields cation **190**. This can be followed by 1,2-hydride shift and deprotonation affording intermediates **191** and **192** and by heterocyclisation leading to the final product, 10-isopropyl-12-methyl-2,6-dioxo-3,4-benzotricyclo[6.3.1.0^{5,12}]-dodec-10-ene (**193**). The reactions of unsaturated alcohols **187** and **188** with salicylaldehyde apparently occur in a similar way.

A study of the behaviour of the unsaturated alcohols **186**–**188** in superacid media has shown⁵⁸ that under these conditions, the alcohols undergo intramolecular cyclisation yielding ethers with the oxabicyclo[3.2.1]octane skeleton.

The researchers⁵⁸ suggested that the intramolecular cyclisation occurs upon the interaction of the carbocation centre with the hydroxyl group acting as an inherent nucleophile. When the reaction is carried out in the presence of the askanite–bentonite clay, the intramolecular cyclisation product of this type is formed only in the case of **187**, despite the fact that the entropy factor is favourable for this process. Apart from compound **194**, 1-isopropyl-4,6-dimethyl-7-oxabicyclo[3.2.1]oct-3-ene was isolated from the reaction mixture.⁵⁷ In other cases where the askanite–bentonite clay has been used, bimolecular reactions predominate.

Comparison of the reactions of salicylaldehyde with the dienes **1** and **173** and with the unsaturated alcohols **186**–**188** shows that, although both processes afford xanthene derivatives, in the former case the protonated diene acts as an electrophile and the aldehyde is a nucleophile, while in the latter case, the protonated aldehyde reacts as an electrophile and the unsaturated alcohol is a nucleophile.

Interesting results have been obtained when alkenes have been made to react with compounds containing a vinyl or vinylidene group. An unusual reaction of the triene **152** with α -methylacrolein on the wide-pore β -zeolite has been reported.⁵⁴ The reaction occurs stereoselectively and yields substituted cyclopentanone **195**.

It is noteworthy that this reaction, which can formally be regarded as [3 + 2]-carbocyclisation with a 1,2-shift of the aldehyde proton, involves only one of the three double bonds of the triene **152**, while the two other bonds are incorporated unchanged in the ketone **195**. This fact stimulated Tatarova *et al.*⁵⁹ to search for monoalkenes that would enter into the same unusual reaction with α -methylacrolein. They found that of a broad range of alkenes including terpenes and model compounds, only styrene reacted with α -methylacrolein (β -zeolite, 20 °C). This reaction yields a mixture of diastereomers of 5-methyl-2-phenylcyclopentanone **196**.

This process, like the reaction of α -methylacrolein with the triene **152**, occurs as [3 + 2]-carbocyclisation accompanied by a 1,2-shift of the aldehyde hydrogen atom. The reactions of styrene with methyl vinyl ketone and acrolein in the presence of the wide-pore β -zeolite result unexpectedly in the formation of cyclobutane derivatives **197**–**200**.⁵⁹

R = Me (**197**, **199**), H (**198**, **200**).

These reactions are among the best studied processes in the chemistry of photochemical transformations of unsaturated compounds and are referred to as 'cyclobutane reactions'. It is noteworthy that the formation of [2 + 2]-cycloaddition products from non-activated (or weakly activated) alkenes at room temperature is quite unusual. Thermal [2 + 2]-cycloaddition also occurs fairly rarely and is observed, as a rule, on prolonged heating of acetylene derivatives⁶⁰ or perhalogenated ethene derivatives.⁶¹

When α -methylacrolein reacts with camphene **8** which, like styrene, contains a terminal double bond but attached to the bicyclic framework, a cyclopentane fragment does form; however, the reaction pathway differs from that in the case of the triene **152**.⁵⁹ This reaction is accompanied by the rearrangement of the bicyclic skeleton and gives 4,10,10-trimethyltricyclo-[5.2.1.0^{1,5}]decane-4-carbaldehyde **201**.

In this case, intermediate **202** is formed initially. Intramolecular stabilisation of the cationic centre results in a new carbocycle with an aldehyde group in the side chain.

The common feature of the reactions of α -methylacrolein with the compounds **152** and **8** is that [3 + 2]-carbocyclisation does occur in both cases. However, in the former case, it results from the transfer of a hydrogen atom, while in the latter case, it is due to the charge transfer. In the former case, the alkene acts as a dienophile and the aldehyde acts as a '1,3-dipole', while in the latter case, the aldehyde is a dienophile and the alkene is the '1,3-dipole' precursor.

Now we consider the reaction of camphene **8** with formaldehyde on the wide-pore β -zeolite. The condensation of these compounds in the presence of acid catalysts (the Prins reaction)⁶² or in the presence of the KU-2 cation-exchange resin⁶³ yields mostly products with the non-rearranged camphene skeleton, namely 8-hydroxymethylcamphene **203** (or its ethers) and 1,3-dioxane **204**.

When this process is carried out on the β -zeolite, the formation of unusual products — tricyclic ethers **205** and **206** — becomes the main reaction pathway.⁵⁹ In the first stage, a protonated formaldehyde molecule attacks the C = C double bond in the compound **8**, and then the reaction follows two pathways: (1) Wagner–Meerwein rearrangement in which the positive charge is stabilised via binding to the oxygen atom (ether **205**); (2) 1,2-shift of the *exo*-methyl group followed by stabilisation of the arising cation (ether **206**).

A different variant of the Prins reaction, which is also unusual, is accomplished when methyl isopimarate **207** reacts with para-formaldehyde on the askanite–bentonite clay.⁶⁴

It was assumed that the products **208**–**210** are formed via successive addition of two equivalents of protonated formalde-

hyde to the initial ester **207**. The researchers noted that the reaction of the second formaldehyde molecule with the intermediate formed does not yield 1,3-dioxanes as would be the case in the classical variant of the Prins reaction or in the presence of other aluminosilicate catalysts.¹ Instead, it occurs again by the 'ene' mechanism giving rise to tetracyclic compounds with tetrahydropyran or tetrahydrofuran rings. During the reaction, 1,2-shift of the methyl group occurs, accompanied by the transformation of compounds of the pimarane series into rosane type compounds.

2. Addition reactions

In this Section, we consider the addition reactions in which at least the main reaction pathway is not associated with cycloaddition.

The use of other carbonyl compounds, for example, acrolein or methyl vinyl ketone in place of formaldehyde, in the reaction with the alkene **8** results in the formation of only slight amounts of carbocyclisation products **213a,b**. Compounds **211** and **212** formed as mixtures of geometrical isomers are the major products in this case. These compounds can formally be regarded as resulting from replacement of the vinylic hydrogen atom in compound **8**.

R = H (a), Me (b).

Judging from the structures of the main products, the reaction under consideration resembles most closely two well known processes: the 'ene' reaction and the Prins reaction; however, it differs from these reactions in some significant points. According to the definition proposed by Snider,⁶⁵ an 'ene' reaction is the interaction of an alkene having an allylic hydrogen atom (the 'ene') with a compound containing a double or a triple bond (the 'enophile') with the formation of a new bond accompanied by the migration of the double bond in the 'ene' and by the 1,5-hydrogen shift. In the reaction under consideration, alkene **8** acts as the 'ene' having an allylic hydrogen, while acrolein or methyl vinyl ketone acts as the 'enophile'. The interaction yields two σ -bonds (C–C and C–H); no double bond migration or 1,5-shift of the allylic hydrogen occurs. Thus, the reaction in question does not conform to the definition of the 'ene' reaction. Now we compare this transformation of the alkene **8** with the Prins reaction.

The Prins reaction (pathway *a*) consists in the interaction of a protonated aldehyde (which is $\text{H}_2\text{C}^+\text{OH}$ virtually in all cases) with a double bond resulting in the transformation of the carbonyl group into an alcohol group or into the corresponding ether. If the reaction of an alkene with formaldehyde is carried out thermally without a catalyst, it affords products of 'ene' synthesis, for example

When carbonyl compounds are made to react with the alkene **8** in the presence of a zeolite, the β -olefinic atom attacks initially

the polarised double bond, and the carbonyl group remains intact. Thus, this process cannot be classified as the Prins reaction. This type of reaction could be referred to as 'pseudo-ene synthesis'.

Now we consider a possible mechanism of the 'pseudo-ene synthesis'. For example, the process can occur as a sequence of transformations with the intermediate formation of tricyclic derivative **214**.

R = H, Me.

Reactions of this type have been reported previously;⁶⁶ however, the tricyclic product described in this study was converted into a bicyclic compound only on refluxing in AcOH.

Thus if we assume that the reaction occurs via the intermediate **214**, we should expect the formation of tricyclic products. However, this is not the case.

Probably, the reaction under consideration occurs via the intermediate formation of non-classical ion **216**:

R = R' = H (a), R = Me, R' = H (b).

R = H, R' = Me.

This ion can be represented as the set of resonance structures **216a**–**216c**, which can undergo either carbocyclisation (**216c**→**213**) or formation of a double bond (**216b**→**211, 212**). The relationship between these routes is governed by the nature of the substituent R'.

When aluminosilicate catalysts are used in reactions of enophiles with alkenes in which the allylic hydrogen atom is more mobile than that in **8**, typical products of the 'ene' reaction are

formed. For example, it has been reported⁵⁹ that the reaction of alkene **7** with methyl vinyl ketone on the β -zeolite gives rise to 6,6-dimethyl-2-(4-oxopentyl)bicyclo[3.1.1]hept-2-ene **217**.

The reaction of the compound **164** with acrolein or α -methylacrolein in the presence of the β -zeolite gives compounds **218** and **219**, which result from isomerisation of the products of the ene synthesis **220** and **221**.⁵⁵

R = H (**218, 220**), Me (**219, 221**).

Methyl isopimarate **207** containing one endocyclic C = C bond and two allylic hydrogen atoms in the 9- and 14-positions reacts with acrolein or α -methylacrolein in the presence of the β -zeolite or askanite–bentonite clay according to two competing pathways: $\Delta^{8,9}$ - and $\Delta^{8,14}$ -ene condensation,⁶⁷ the latter being the predominant pathway. Under the reaction conditions, the product of $\Delta^{8,14}$ -condensation **222** undergoes further transformations, namely, intramolecular reaction of the aldehyde group with the double bond followed by cyclisation of the resulting alcohol to ether **223** with a new type of skeleton. The product of $\Delta^{8,9}$ -condensation **224** is more stable under the reaction conditions and undergoes no secondary transformations, although it is formed in substantially smaller amounts.

R = H, Me.

Interesting results have been obtained when styrene has been involved in the reaction with the terpenes **171** and **5**, containing no carbonyl group, on the askanite–bentonite clay. The reaction of the diene **171** with styrene at room temperature leads to a mixture of products **226**, **227** and **228** in a ratio of 1.5 : 1 : 3 (Scheme 2a).

The bicyclic compound **226** is probably formed via dehydrogenation of the intermediate **225**, which can be formally regarded as resulting from [3C+2C]-cycloaddition. The compounds **227** and **228** can be regarded as the products of alkylation and hydrogenation of **171** to give the intermediate **224** which then

undergoes allylic rearrangements. The workers⁵⁹ have noted that in the presence of clay, the diene **171** does not react with styrene derivatives containing electron-withdrawing (*p*-nitrostyrene, *p*-bromostyrene, 2,3,4,5,6-pentafluorostyrene) or electron-donating (*p*-methylstyrene) substituents. Apparently, the influence of substituents is mostly due to the steric restrictions to the adsorption of the substrate on a catalyst created by them rather than by their electronic effects.

The interaction of styrene with the diene **5** also affords a mixture of products: alkene **228**, bicyclic compound **229** and *p*-cymene (Scheme 2b). It is noteworthy that the mode of coupling of the molecules of styrene and **5** giving rise to compound **229** differs from that leading to the product **226**.

It is also noteworthy that the processes of hydrogenation and dehydrogenation of the alkenes **171** and **5** occur at room temperature. In fact, hydrogenation of alkenes is usually carried out in the presence of zeolite catalysts doped with metals such as Pt, Pd or Ru at 100–200 °C, while dehydrogenation is performed with the same catalysts at 400–600 °C.¹

Considerable attention of researchers has been paid to the hydration of terpenoids with various hydroxyl-containing reagents on aluminosilicate catalysts. The catalysts used for this purpose and the products thus obtained are listed in Table 3. Analysis of the results of these reactions indicates that hydration of terpenoids is accompanied by rearrangements, by oxidation of the alcohols formed initially and by the formation of ethers from these alcohols.

Replacement of the aluminium alkoxide in the Meerwein–Ponndorf–Verley reaction by zeolites leads to reduction of the

aldehyde **27** either to the cyclic alcohol **28** or to acyclic citronellol **255**, depending on the catalyst used.⁷⁷

However, in the presence of zeolites, **27** cyclises to **28** (see Ref. 18) and, in all probability, it is more correct to regard this reaction, carried under the conditions described,⁷⁷ as carbocationic cyclisation rather than as the Meerwein–Ponndorf–Verley reaction.

The nitration of camphene **8** with N_2O_4 or with 69% HNO_3 in the presence of various zeolite catalysts has been studied.⁷⁸

It was shown⁷⁸ that when N_2O_4 is used, depending on whether or not a catalyst is present and on the type of the solvent, the reaction occurs either as nitration to give ω -nitrocamphene and 2-hydroxy-3,3-dimethyl-2-nitromethylnorbornane **257** or as nitrosation followed by rearrangement of the camphene skeleton and by intramolecular cyclisation yielding 10,10-dimethyl-3-aza-4-oxatricyclo[5.2.1.0^{1,5}]dec-2-ene **258**. Variation of the nature of the zeolite basically does not change the reaction outcome. When camphene **8** reacts with 69% HNO_3 , isobornyl nitrate **259** is formed as the major product; the addition of a zeolite has virtually no influence on the composition of the reaction mixture.

The nitration of dehydroabietic acid **260** in the presence of acidic montmorillonite impregnated with copper nitrate affords 12,14-dinitrodehydroabietic acid **261** in a good yield.⁷⁹

Now we consider arylation and alkoxylation of terpenoids on aluminosilicate catalysts. This group of reactions is very significant, because many of the products obtained in this way are used as intermediates for the production of perfumes.⁸⁰

When camphene **8** is arylated with phenols using the askanite clay as the catalyst, the composition of the reaction mixture depends on the reaction temperature.⁸¹ At 160–180 °C, the mixture consists only of terphenols **262**–**264**.

$\text{R} = \text{R}' = \text{H}$ (a); $\text{R} = \text{Me}$, $\text{R}' = \text{OH}$ (b).

When the temperature is decreased to 100 °C, the reaction mixture contains up to 60% of terpenophenyl ethers. The terpenophenol fraction consists mostly of *o*-terpenophenols, the terpene residues of which have the isocamphyl structure (**262a**, 74%) or isobornyl structure (**263a**, 26%). In some studies,^{81–84} in addition to the traditional acid catalysts (Lewis and Brønsted acids), the askanite clay was also used for arylation of various terpenes. In each case, a broad range of compounds have been obtained. This was explained by secondary rearrangements of labile terpene skeletons, by dearylation, and by possible attack at various positions of the aromatic ring by the arising bicyclic carbocations. For example, when the alkene **8** condenses with guaiacol, the reaction mixture contains products **264** with the isofenchyl skeleton, together with the compounds **262b** and **263b**.

Arylation of terpenes and model compounds has been carried out on zeolite catalysts. For example, phenylation of norbornadiene **230** on wide-pore and medium-pore zeolites has been described.⁸⁵

In the presence of wide-pore zeolites, 5-phenyl-2-norbornene **265** and 3-phenylnortricyclene **266** were obtained; medium-pore catalysts proved to be inactive in this reaction. Arylation of 1- and 2-methylnorbornenes with aromatic hydrocarbons in the presence of the TsEOKAR-2 zeolite-containing catalyst has been reported.⁸⁶ This reaction gave a mixture of hydrocarbons of unknown structures.

Arylation of camphene **8** with benzene and its mono- and disubstituted derivatives in the presence of the wide-pore β -zeolite has been investigated.⁸⁷

The reaction of benzene with optically active camphene yields racemic products **267** and **268**, the former compound predominating. Attention is attracted by the unusual structure of the terpene skeleton in the compound **268** with the methyl groups at the 1-, 4-, and 7-positions. For this skeleton to be formed, at least a five-stage rearrangement of the arising camphenyl cation must occur; therefore, the researchers⁸⁷ put forward the hypothesis that the carbocations generated from camphene on zeolites possess relatively long lifetimes.

R = Me (a), Et (b), Prⁿ (c), Bu^t (d).

Analysis of the reaction mixtures obtained by the reaction of the alkene **8** with monoalkyl-substituted benzene derivatives indicates that as the size of the alkyl substituent increases, the overall yield of products diminishes from 60% (**269a–271a**) to 20% (**269d–271d**). The proportion of the meta-isomer **270a–d** in the mixture increases with an increase in the bulk of the alkyl group. Monosubstituted benzene derivatives containing electron-donating groups other than methyl (phenol, anisole) or electron-withdrawing groups (nitrobenzene, benzaldehyde, chlorobenzene) do not enter into the reaction with camphene **8** on the β -zeolite.

Isomeric xylenes give rise to products **272–274**, the overall yield of the reaction products increasing on passing from *p*-xylene to *m*-xylene and then to *o*-xylene.

Ar = 2,5-Me₂C₆H₃ (**272a**), 2,4-Me₂C₆H₃ (**272b**), 3,4-Me₂C₆H₃ (**272c**);
 Ar' = 2,5-Me₂C₆H₃ (**273a**), 2,6-Me₂C₆H₃ (**273b**), 2,3-Me₂C₆H₃ (**273c**);
 Ar'' = 2,5-Me₂C₆H₃ (**274a**), 2,4-Me₂C₆H₃ (**274b**), 3,4-Me₂C₆H₃ (**274c**).

Mesitylene does not react with camphene. Naphthalene and biphenyl also do not enter into this reaction, although their successful alkylation with lower alkenes in the presence of zeolites has been reported in a vast number of studies (see, for example, Ref. 88).

When benzyl alcohol reacts with the alkene **8** on the β -zeolite, alkoxylation occurs instead of arylation, and the ethers **275a–277a** are formed.

R = CH₂Ph (a), CH₂CH₂Ph (b), CH₂C₆H₄Me-*m* (c), Me (d).

Phenethyl alcohol reacts with the alkene **8** in the presence of the β -zeolite to give the ethers **275b–277b**. The introduction of strong electron-donating (*p*-methoxy) or strong electron-withdrawing (*p*-nitro) substituents into the aromatic nucleus of benzyl alcohol retards alkoxylation. However, *m*-methylbenzyl alcohol is readily converted into the ethers **275c–277c**. The reaction involving *p*-methylbenzyl alcohol **278** requires much more rigorous conditions and follows another route yielding hydrocarbon **279**.

The study of the reactions of camphene with *p*- and *m*-methylbenzyl alcohols showed that minor changes in the structure of the reactant result in an absolutely different reaction pattern. This fact cannot be explained by merely the different thermal effects of formation of *p*- and *m*-methylbenzyl cations from the corresponding alcohols and of the camphenyl cation from the alkene **8**, because the difference between the energies of formation of the methylbenzyl cations is relatively small.

It may be expected that the transition from benzyl alcohol to benzhydrol would lead to *C*-alkylation instead of *O*-alkylation. In fact, the reaction of benzhydrol **281** with the alkene **8** yields hydrocarbons **282** and **283**.⁸⁹

Apparently, in the reaction of the alkene **8** with the alcohol **281**, it is the benzyl cation **284** arising from the alcohol **281** upon protonation and dehydration that acts as the electrophilic species, and not the camphenyl cation, as in the reaction of **8** with benzyl alcohol or aromatic hydrocarbons. Evidently, the cation **284** is more stable than the cation **280** and, hence, the reaction of the alkene **8** with the alcohol **281** occurs under markedly milder conditions than that with the alcohol **278**. The dissimilar reaction pathways observed in the case of benzyl alcohol and benzhydrol may be due to the differences between the enthalpies of formation of the camphenyl cation, the ion **284** and the benzyl cation from the corresponding precursors; this assumption was confirmed by AM1 and PM3 calculations.⁸⁹

α,α -Dimethylbenzyl alcohol **285**, which is also capable of forming a stable benzyl cation, apparently does form it. This cation (**286**) is then converted into α -methylstyrene **287**; the latter is more nucleophilic than the alkene **8** present in the reaction mixture and, therefore, it reacts with the cation **286** to give 1,3,3-trimethyl-1-phenylindane (**288**).

Thus, aliphatic-aromatic alcohols, depending on their structure, can react with camphene on zeolites according to two pathways: (1) to give ethers — *O*-alkylation; (2) to give hydrocarbons with the formation of a new ring or a new linear chain — *C*-alkylation. The process yielding indane derivatives does not involve the alkene **8**.

The reaction of **8** with aliphatic alcohols, for example, with methanol, on the β -zeolite also leads to ethers (**275d–277d**). The preparation of the ether **276d** from **8** and methanol in the presence of the HSZ-330HUA zeolite has also been reported.⁹⁰

This zeolite was also used to obtain ethers **289** and **290** from tricyclene **237** and butanol and from 2- and 3-carenes and alkanols, respectively.⁹⁰

The reaction of α -terpinene **4** with propanol on the HSZ-600HOA zeolite gives rise to a mixture of compounds **291** and **292**.

When α -phellandrene reacts with C_1 – C_4 alcohols under the same conditions, compounds of type **293** are formed.⁹¹ At the same time, alkoxylation of γ -terpinene **5** on zeolites of the 300 series affords ethers **294**.⁹²

Some terpenoids undergo skeletal rearrangements during alkoxylation with C_1 – C_4 alcohols. For example, dihydromyrcene **246** is converted into ether **295** with a terminal double bond, β -caryophyllene **21** yields tricyclic product **296**, and longifolene **9** gives products **297** and **298**.⁹²

IV. Conclusion

Analysis of the data considered in this review leads to interesting conclusions. The main of them is that many concepts and regularities of the chemistry of homogeneous reactions customary for organic chemists, such as homology, isomerism, vinylogy, *etc.*, cannot be transferred directly to the reactions of polyfunctional compounds occurring on the surface of heterogeneous catalysts (mostly aluminosilicates). In fact, even the closest homologues (acrolein and α -methylacrolein), vinylogues (formaldehyde and acrolein) and isomers (α -methylacrolein and crotonaldehyde) react in different ways in this case. The functional group in the reactant also does not play a crucial role: acrolein and α -methylacrolein react with camphene to give quite different products, whereas the products obtained from acrolein and methyl vinyl ketone are similar. The reaction route is determined not only by the structure of the reagent, but also by the structure of the

substrate. For example, despite the fact that the bicyclic fragment in camphene and the benzene ring in styrene do not formally participate in the reaction with acrolein, which involves only the double bonds of these compounds, the reaction outcomes are totally dissimilar.

These speculations prompt the thought that the role of a heterogeneous catalyst does not always reduce to mere acid catalysis, although it is owing to the acid properties of the catalysts that some reactions can be conducted under milder conditions and their selectivities and the yields of products can be increased. However, the main role of a heterogeneous catalyst is to ensure a certain orientation of the molecule with simultaneous decrease in the energy barriers to many transformations, and this often sets the process on an unusual pathway.

The lack of understanding of the regularities of adsorption of even simple organic substrates on the surface of a catalyst hampers the prediction of the behaviour of complex polyfunctional compounds, such as terpenoids, under these conditions. The currently available experimental data permit only some empirical conclusions to be drawn. However, accumulation of knowledge in this interesting field of organic chemistry will certainly make it possible to generalise and classify the information and, hence, to predict with confidence the reactivities of various substrates. Finally, it should also be mentioned that, although the research in the field of reactions of terpenoids on heterogeneous catalysts is still being carried out by the 'trial and error' method, important and interesting results have already been obtained, owing to the polyfunctionality and conformational flexibility of the substrates under consideration and also owing to abnormal orientations, compared to those in homogeneous reactions, of reacting molecules on the surface of catalysts.

Abstract. The chemical approaches to the study of systems for template biosynthesis are examined. The general problems of template biosynthesis solved with the aid of these approaches and the principal results obtained as regards transcription are described. Attention is concentrated on the results obtained in the study of the interaction of RNA polymerase and its subunits with DNA and the RNA product. The approaches to the study of the active centre in RNA polymerases by the affinity modification method as well as the interaction of eukaryotic transcription factors with DNA are described. The bibliography includes 64 references.

I. Introduction

The enormous role of chemical methods in the study of proteins, nucleic acids, and their complexes, which perform the most refined functions in living organisms, including template biosynthesis systems, is well known and unquestionable. Chemical methods constitute the basis of many most important stages in the determination of the primary structures of proteins and nucleic acids. It is sufficient to mention the Edman procedure for the stepwise cleavage of peptides, the basically chemical method of Maxam–Gilbert which revolutionised the determination of the DNA nucleotide sequences, and the Sanger sequencing method based initially on the employment of chemically synthesised dideoxynucleoside-5'-triphosphates and subsequently automated by the introduction of fluorescent dyes either into terminators or primers. The development of convenient and effective methods for the chemical synthesis of polypeptides and oligonucleotides has played an inestimable role in the study of biopolymers and their functions. We shall not consider these two groups of chemical approaches, but it is understood that the primary structure of any protein and of any nucleic acid can be established and polypeptides or oligonucleotides of sufficient length (tens or several

hundreds of monomer units) may be synthesised chemically when this is needed or when it is of interest to do so.

In the present review, attention is concentrated on the use of the chemical reactions of proteins and nucleic acids to study systems of template biosynthesis. Three groups of chemical methods will be dealt with.

The first group includes methods for the chemical cleavage of polymer chains under mild conditions. Naturally, any biopolymer can be disintegrated into fragments on sufficiently severe treatment. For example, RNA may be hydrolysed to mononucleotides in an alkaline medium. However, under conditions necessary for alkaline hydrolysis the tertiary structure of RNA is disrupted. Furthermore, in the review attention is concentrated on the application of chemical approaches to the study of functionally active biopolymers, and for this purpose one has to deal with a native biopolymer whose tertiary structure is disrupted to a minimum extent. Methods of cleavage under mild conditions, which do not distort the steric organisation of biopolymers and their complexes, will therefore be described and considered. Up to now these approaches have found extensive application only in the study of nucleic acids.

The second and third groups include methods for the chemical modification of biopolymers. Chemical modification is understood as chemical reactions which do not lead to the degradation of the main polymer chain. Two principal types of chemical modification are distinguished: the group-specific and affinity modification. In the first case, use is made of a reagent capable of modifying particular types of biopolymer residues, usually amino-acid side groups or the heterocyclic bases of nucleic acids.

In the second case, a ligand capable of specific interaction with the biopolymer, for example the substrate of any kind of enzyme, is provided with a reactive group. As a result of the affinity for a particular site of the native biopolymer, the reagent is fixed on this site and the chemical reaction takes place in the vicinity of the latter.^{1,2}

Much has been hoped for of the chemical modification methods as regards the study of the structures and reactivities of biopolymers.

Thus, by studying with the aid of a group-specific reagent which of the biopolymer residues potentially capable of modification should actually be modified, it may be inferred which of them are in a position accessible to the reagent, *i.e.* which are concealed within the protein globule and which participate in the hydrogen bonding forming the secondary or tertiary structure of the nucleic acid. Furthermore, by comparing the degree of

biopolymer modification by such a reagent with the degree of loss of biological activity, the involvement of the modified residues in the functioning of the biopolymer may be inferred.

By employing affinity reagents, the modified residue may be identified. It was assumed that this is one of the residues forming the active centre of the biopolymer or is at least in the vicinity of the active centre.

In order to investigate systems consisting of several biopolymer molecules (subunits), bifunctional chemical reagents, capable of reacting with the two functional groups of the biopolymers, may be used. This led to the possibility of obtaining information concerning the subunit areas which are at a sufficiently close distance from one another, permitting one molecule of the reagent to react with both polymeric components (to cross-link them into a single structure).

However, during the last decade, many changes have occurred in physicochemical biology which have made it necessary to correct our view on the possibilities and principal tasks of the chemical modification methods. Thus the tertiary structures of many enzymes, including those participating in template biosynthesis, have been established by X-ray diffraction. In certain cases, the structures of complexes of proteins with specific ligands or their analogues were determined, *i.e.* data were obtained concerning the disposition of the ligand (substrate) on the protein. The importance of individual aminoacid residues in the functioning of the protein can be readily established with the aid of site-specific mutagenesis — the specific replacement by genetic engineering methods of a particular aminoacid residue by any other out of the 20 residues constituting proteins. Therefore, in applying chemical approaches to the study of systems of template biosynthesis, it is necessary to take into account the current possibilities of both direct physical methods and genetic engineering.

Together with the exposition of the main data obtained with the aid of chemical methods for the study of RNA and DNA polymerases, an attempt will therefore be made to examine which principal possibilities and advantages are provided by chemical approaches in the study and practical employment of systems of template biosynthesis. However, we shall deal initially with the general problems faced by investigators in the field of template biocatalysis.

II. Certain general problems of the template biosynthesis of nucleic acids[†]

Nucleic acid polymerases possess a set of features of many other enzymes. Like any other enzymes, they act on specific substrates, which are in this case the growing polynucleotide chain and nucleoside 5'-triphosphates (henceforth abbreviated in the general case and for ribonucleotides as NTP and for deoxyribonucleotides as dNTP).

Polymerases have an active centre which catalyses the transferase reaction, the transfer of the nucleotide residue of the NTP from the pyrophosphate to the 3'-OH group of the growing polynucleotide chain. In terms of the single-letter nucleotide nomenclature, this reaction can be formulated as follows:

where X is the nucleoside, *i* the index designating the position of the nucleoside in the polynucleotide chain, and p the phosphoric acid residue.

However, there are many specific aspects characteristic either solely or predominantly of enzymes of template biosynthesis. These aspects are apparently characteristic also of the biosynthesis of proteins on ribosomes.

Firstly, the normal function of polymerases of nucleic acid requires the presence of a template with the aid of which one out of the four NTPs present in the system is selected at each step of chain lengthening. Four types of nucleic acid polymerases, differing in

the chemical nature of the template and in the substrates, are known. DNA polymerases catalyse the template biosynthesis of polydeoxyribonucleotide chains, using either DNA (DNA-dependent DNA polymerases, usually called simply DNA polymerases) or RNA (RNA-dependent DNA polymerases or reverse transcriptases) as the template. RNA polymerases synthesise polyribonucleotides using either DNA (DNA-dependent RNA polymerases or simply RNA polymerases) or RNA (RNA-dependent RNA polymerases or RNA replicases) as the template. The processes catalysed by these enzymes are referred to simply as replication, reverse transcription, transcription, and RNA replication. DNA and RNA polymerases are characteristic of all living organisms without exception, and these enzymes have already been the subject of intensive investigations, by procedures including chemical methods, in the course of many years. Vigorous studies on the reverse transcriptases present as the obligatory component of retroviruses, which include the HIV-1 virus responsible for AIDS, have been initiated in recent years.

The selection of the required monomer at each stage of the lengthening of the polynucleotide chain via reaction (1) must serve as the signal for the switching on of the catalytic centre effecting the transfer of the α -phosphate of the nucleotide residue to the 3'-OH group of the growing chain. This may be associated with the more refined adjustment of the structures of the substrates to the groups of the catalytic centre of the enzyme in response to the recognition of the correct substrate.

Secondly, at each chain lengthening stage one nucleotide base of the template, working as an information element, is involved in the selection process. The active centre of the enzyme consists of three main subsites (Fig. 1): the site accommodating the information unit of the template, ensuring the selection of the monomer (A) required at the given stage, the site in which the substrate is bound in its prereaction form (B), and the site accommodating the 3'-terminal unit of the growing chain to which the new nucleotide residue (C) is attached. In this scheme, the selection step takes place at the junction between sites A and B. If it is assumed that a certain time after the addition of the nucleotide unit the participants in the process remain in their places, the following situation is created: site C is occupied by the penultimate nucleotide residue of the lengthened chain; site A is occupied by the information element already employed; site B is occupied by the 3'-terminal

Figure 1. Processes occurring in the active centre of a template enzyme on elongation: Y is information elements of the template, X is monomer units of the growing chain; pppX_i is free monomer; A is binding section for the information element of the template, B is monomer binding section, C is binding section for the end of the growing chain. (1) Selection of the monomer; (2) formation of a chemical bond; (3) translocation.

[†] The general problems of the template biosynthesis of nucleic acids have been examined by Knorre and Myzina.³

unit of the lengthened chain. It is reasonable to assume that all three domains of the enzyme are unique. In this case, the continuation of the synthesis requires the specific displacement of the template–growing chain system relative to the enzyme by one unit — translocation. The process can occur either synchronously with the chemical reaction or can follow it.

Thirdly, the initiation of the synthesis of new polynucleotide chains begins from a definite start point. The method of specifying this start point is different for polymerases of various types. In the case of transcription, the RNA polymerase must be located, before initiation, on a particular section of the DNA template, usually outside the region where transcription should occur. This section is referred to as the promoter if it is not too far (within the limits of tens of nucleotide pairs from the start point) or as the enhancer, as is the case for eukaryotes. There is, in addition to the promoter, a centre significant for the initiation of transcription located several hundreds or even thousands of nucleotide pairs from the start point. A random collision of the enzyme with the promoter appears to be a very improbable event. There is therefore the problem of the search for the promoter (or enhancer) by the enzyme or a special auxiliary protein — the transcription factor, which subsequently assists in the correct placing of the RNA polymerase near the start point.

It is noteworthy that in all the cases investigated initiation occurs only with the aid of RNA polymerases. Not one instance of initiation with the aid of DNA polymerase is known hitherto. These enzymes are capable only of lengthening an already existing chain. The synthesis of new DNA molecules in the cells therefore begins with the synthesis by a special enzyme of a short ribooligonucleotide, which is subsequently lengthened by the DNA polymerase, apparently this time with the aid of a second active centre. In the experiment, this can be achieved by introducing into the system a short deoxyribooligonucleotide complementary to the template. This oligomer can be subsequently lengthened with the aid of DNA polymerase. Such oligonucleotides have been called primers and the RNA polymerase generating the RNA primer for the subsequent synthesis of DNA is referred to as the primase. After the synthesis of the short RNA fragment by the primase, the growing end of the chain is switched to work with the DNA polymerase. This refers to cell enzymes. For enzymes the synthesis of which is programmed by viral nucleic acids, there are alternative paths. The initiation of the synthesis of DNA with the aid of the reverse transcriptase of retroviruses is being most intensively investigated. In this case, the genome viral RNA captures the primer from the cell, the role of the primer being assumed by one of the tRNA of the host cell, the 3'-end of which is complementary to a definite section of the genome RNA (the primer binding section), whereupon the reverse transcription begins with the attachment of the dNTP residue to the 3'-terminal ribonucleotide of the primer.

All the aspects of the functioning of polymerases enumerated — the adjustment of the selected substrate with the aid of the information element to the catalytic centre, translocation, the search for start points, and the directed switching of the template — product complex from one active centre to another — are dynamic events. Although dynamic elements are present also in the functioning of other types of enzymes, one can claim confidently that the role of dynamics in the functioning of template enzymes is especially important.

The second specific feature of template biosynthesis (especially characteristic of processes in eukaryotes) is that transcription and replication occur in a highly organised multicomponent system. In the case of eukaryotes, such a system is chromatin. In both transcription and replication, several components participate directly in the biosynthesis of nucleic acids. These must be combined in a single complex to effect the process. For example, transcription precedes the formation of a complex between the template and a set of transcription factors. The processivity of replication (the occurrence of a large number of elongation stages without the dissociation of the enzyme–substrate complex) is

ensured by the presence of special clamping proteins which prevent dissociation. The knowledge of the structure of these complexes and of the dynamics of their changes during the functioning of the template system is extremely important for the understanding of the mechanism of the functioning of nucleic acid polymerases under the conditions in the living organism.

Yet another characteristic feature of template processes is that template systems must involve a template having an arbitrary primary structure. RNA polymerase must interact with an arbitrary transcribable sequence, which moves along the enzyme in the course of transcription. There are grounds for the assumption that the RNA synthesised remains for some time in contact with the enzyme. If this is so, then a certain 'exit corridor' for the transcription product should exist on the enzyme (Fig. 2, section *f*). DNA polymerase interacts with any template susceptible to replication, moving along it in such a way that only the information residue of the template and the 3'-end of the product are located in the active centre. It may be expected that a segment of the as yet nonreplicated template as well as a section of the duplex produced are in contact with the enzyme over a certain distance. The region of contact with the latter can also be referred to as the exit corridor. The problem of the determination of the region of the nonspecific contact between the enzyme, on the one hand, and the template and the polymeric product, on the other, therefore exists for template systems.

Figure 2. Schematic illustration of the interaction of the chains of the template and the product during transcription: (*a*) RNA polymerase; (*b*) nontranscribed DNA strand; (*c*) transcribed DNA strand; (*d*) temporarily unwound segment of DNA (bulge); (*e*) product RNA (transcript); (*f*) product RNA exit corridor.

By virtue of the length of nucleic acids and the presence as a rule of 'singular points' on the molecules of nucleic acids with the aid of which a definite catalytic step (initiation of transcription, onset of the repair process) should take place, the problem of the search for these singular points arises — for example, the search for the promoter by RNA polymerase, the search for the damaged point by repair enzymes, *etc.* In this connection, yet another problem of template biosynthesis is the determination of the mechanism of the search for such singular points.

III. Specific chemical approaches used in the study of nucleic acid polymerases

The majority of the problems arising in the study of template biosynthesis required the knowledge of the region of contact between nucleic acid and other components of the system, in the first place proteins. The region of contact is to a large extent protected against the influence of external factors, in particular enzymes and chemical reagents. When any kind of agent acts on the free biopolymer and on the polymer involved in a specific complex, it is in principle always possible to compare regions modified in the presence or absence of other components of the system and hence to determine which region is covered by these components. However, in the current state of experimental methods such a problem can be readily solved only for nucleic acids. The nucleic acid may be labelled at one of its ends. If it is treated by an endonuclease or a reagent cleaving the polynucleo-

tide chain at the modification point and the process is carried out to an extent such that on average there is one break for each chain, then the mixture obtained after separation by gel electrophoresis gives rise to a series of bands corresponding to cleavage products of different lengths (counting from the labelled end). When highly radioactive phosphorus or an intense fluorescent label is used, only fragments which have retained the labelled end are determined on the gel. If the nucleic acid has no tertiary structure, a series of bands corresponding to all the imaginable break points within the limits of the resolution of the electrophoresis are obtained. On the other hand, if during treatment the nucleic acid forms a complex with a protein or several proteins, then, within the limits of the region of contact, no cleavage occurs or at least it is not very pronounced. In this case, a 'white' spot, *i.e.* a region without radioactivity or a nonfluorescent region, appears on a series of bands. This spot is the imprint of the segment bound to the nucleic acid and is referred to as the footprint. Naturally, the effects of reagents used should not influence the stability of the complex investigated.

In footprinting, it is desirable that the specificity of the cleavage reaction in relation to heterocycles should be low. It is noteworthy that, together with chemical reagents, enzymes hydrolysing nucleic acids are frequently employed for footprinting. For this purpose, use is most often made of DNase I, which catalyses the cleavage of the inner phosphodiester bonds, including those in double-stranded DNA, leading ultimately to the formation of a set of relatively short oligonucleotides, as well as exonuclease III from *E. coli*, which catalyses the stepwise splitting off of the 5'-nucleotides from the 3'-ends of both strands of the double-stranded DNA. However, the resolution of the methods based on enzymic cleavage is restricted by the size of the enzyme (the larger the enzyme, the smaller the resolution), which in the case of DNA polymerase I is ~ 4 nm in diameter.⁴

A significantly better resolution is achieved when chemical reagents of small size are employed. The free radical $\text{HO}^\bullet$, generated in the $\text{Fe}(\text{EDTA})^{2-}/\text{H}_2\text{O}_2$ system, has recently come to be widely used for the cleavage of DNA.⁵ A specific feature of this method is that the reactions proceed via deoxyribose, which makes the method more specific in relation to the sequence of nucleotides. Footprinting with the aid of KMnO_4 is also used to investigate polymerases.⁶

In principle, it is possible to obtain a similar footprint of the protein molecule interacting with nucleic acid. Until recently, such studies were held back by the lack of effective methods for the determination of the points of modification of the protein, which made this problem extremely difficult. Very recently, a study has been published⁷ in which a highly radioactive label was introduced into the transcription factor TFIIB by attachment to the C-end of the pentapeptide 'tail' — arginylarginylalanylserylvaline, which is the target for phosphorylation with the aid of heart muscle protein kinase. This made it possible to introduce the [^{32}P] phosphate residue at the OH group of serine and then to carry out single-impact hydrolysis of the protein with the aid of weakly specific proteases with subsequent electrophoretic separation of the set of peptides obtained. As in the footprinting of nucleic acids, only peptides containing the C-terminal fragment and differing in their lengths appeared on the radioautograph. Comparison of the set of peptides obtained from the initial transcription factor and its complex with yet another factor TAF made it possible to identify the region protected by this factor against proteolytic cleavage by TFIIB.⁷

The existence of the elongation stage leads to interesting possibilities both in the methods whereby affinity modification can be carried out and in the design of reagents for affinity modification. Among the modification procedures, the method which has been called highly specific or competent labelling is especially interesting.⁸ Nucleotides and their derivatives are in many cases capable of interacting not only with the active centre of the enzyme but also with a set of other regions on the surface of the protein. Cases are known where a large number of molecules

of a reactive nucleotide derivative are bound to the enzyme molecule and such interaction is not always accompanied by the loss of enzyme activity. For example, the photoaffinity modification of phenylalanyl-tRNA synthetase from *E. coli* by ATP γ -*p*-azidoanilide can lead to the addition of 20 molecules of the ATP analogue without loss of enzyme activity.⁹ In template biosynthesis, there is a possibility of the situation where the addition of a nucleotide to a protein does not prevent its participation in the elongation process. In this case by carrying out in the first stage of the experiment the modification by a nonlabelled reagent, designed as an affinity reagent, and then adding the next NTP carrying a radioactive label, for example α - ^{32}P , it is possible to discriminate the modification point in the region of the active centre, because only the residue of the reagent attached covalently in this region undergoes elongation and contains the radioactive label. It must be emphasised that not all the residues of the affinity reagent attached to the enzyme in the region of the active centre are detected by this method because, if the modification involved the residue participating in the catalytic step, elongation cannot occur owing to the loss of catalytic activity. However, it is clear that no residues bound outside the active centre of the enzyme, even at functionally significant points, can be detected.

In the template biosynthesis of nucleic acids, the participants in the process are the template nucleic acid, the newly synthesised nucleic acid chain, and the corresponding NTP. The first two participants are polymeric molecules. The corresponding affinity reagents may be generated by synthesising the corresponding oligonucleotide fragments modelling these polymers, or by the modification of the polymers themselves. However, it is possible to introduce chemically reactive groups also during the elongation process. Derivatives of nucleoside 5'-triphosphates carrying reactive groups are used as substrates for such purposes. An example of a substrate of this kind for RNA polymerases is 5-(4-azidophenacylthio)-CTP.¹⁰ In this case, the elongation product contains a reactive group template and is already an affinity reagent in relation to the template enzyme which was used in its synthesis. The substrate which participates in the elongation step but, being incorporated in the 3'-end of the chain, cannot combine with the next nucleotide unit is optimal. It is also possible to use reactive derivatives of terminators, for example dideoxynucleoside 5'-triphosphate in the biosynthesis of DNA. In this case, the reactive group is automatically fixed in the region of the active centre of the enzyme.

As already noted, it has been hoped that affinity modification is a method which will make it possible to determine the amino-acid residues in the active centre of the enzyme and in its vicinity. However, for this purpose it was necessary to know how to locate the modified residue on the polypeptide chain. The most direct approach consists in the cleavage of the modified protein at specific points, the identification in the set of peptides obtained that which contains the modified residue, and the analysis of this peptide by stepwise cleavage with the aid of the Edman method. The appearance in the course of this procedure of an unusual derivative or the arrest of cleavage at a particular unit indicates that this is the point where modification has occurred. The nature of the modification may be inferred provided that the product of the interaction of the modified residue with the reagent employed is known (from independent experiments).

In a number of instances, it is possible to apply indirect procedures whereby one can deduce the modification point with a particular degree of reliability. Such an approach has been proposed and widely developed in the studies of Grachev and coworkers⁸ in relation to the location of the modified lysine and histidine residues in RNA polymerase by phosphorylating reagents. The properties of the phosphoramides formed on phosphorylation of the aliphatic ϵ -amino-group of lysine and of the imidazole ring of histidine differ quite sharply. Both phosphoramides are labile in an acid medium, but the kinetic characteristics of the hydrolysis are different. By measuring the rate of elimination of the attached label (demodification), it is possible to

compare the kinetic constants obtained with those measured for model compounds.[‡] ATP γ -*N*-methylamide and ATP γ -imidazolidine have been used as such compounds. The rate constants for their cleavage at pH 4.9 are 0.014 min^{-1} at 50°C for the amide and 0.016 min^{-1} at 20°C for the imidazolidine, *i.e.* they differ quite sharply. After the determination of the peptide in which the modified residue is located, it is possible to determine from the primary structure of this peptide how many aminoacid residues are present in it and at what positions. If a residue of this kind, for example a histidine residue, is the only one in this peptide, then the location of the modification point is unambiguous. When the modified protein is cleaved into fragments and when particular procedures are used to separate the mixture of peptides, one must naturally bear in mind the stability of the modification product. For example, it is clear that in the case examined one cannot use proteases acting in an acid medium for the cleavage of the protein.

The use of photoaffinity modification by bromodeoxyuridine (brdU) residues may be quoted as yet another approach. Bromouracil is known to react photochemically with cysteine, tyrosine, phenylalanine, and histidine residues.¹¹ By employing this property, Skiba *et al.*¹² investigated the modification of the *E. coli* RNA polymerase by the decanucleotide $T_3\text{brdUT}_4$ labelled with ^{32}P . Analysis of the peptides obtained by successive cleavage by bromocyanogen at the methionine residue and by trypsin hydrolysis at the lysine and arginine residues showed that the label is contained in the 721–731 peptide of the β -subunit and in the 984–990 peptide of the β' -subunit. Since each contains one aromatic aminoacid residue, the authors believe that the modification points are Tyr-726 and Phe-988 respectively.¹²

The above example demonstrates how important it is to have information about the chemical nature of the products of the modification of the aminoacid residues. Unfortunately, the modification products have been at present quite inadequately investigated for the most promising approach on the photoinduced modification, in particular for the widely employed method based on direct photocross-links between nucleic acids or nucleotides and the protein.

IV. Principal stages of transcription. The subunit structure of RNA polymerases §

So far, the main object of the detailed study of the mechanism of the functioning of RNA polymerases has remained the enzyme isolated from *E. coli*. From this example, it is easier to elucidate what can be obtained and what may be expected in the future from chemical approaches to the study of transcription. A few words must therefore be said about the enzyme itself and about the phenomenology of its functioning.

The main enzyme (core) consists of three types of subunits — α , β , and β' . The first of these is present in the form of two copies, so that the subunit structure of the enzyme is formulated as $\alpha_2\beta\beta'$. In the transcription initiation stage, the regulatory σ -subunit also enters into the composition of the enzyme, as a result of which the whole enzyme (the holoenzyme) $\alpha_2\beta\beta'\sigma$ functions. Only then is the correct complex between the enzyme and DNA formed in the region of the promoter, which in fact determines the point of the onset of transcription.

It is appropriate to mention that the numerals assigned to DNA nucleotide pairs in transcription are arranged in an increasing sequence on moving downwards, *i.e.* in the direction of motion of the enzyme during transcription, the numeral +1 being assigned to the pair coding for the first nucleotide of the transcript. In the nontranscribable section, located above the transcribable section, including the arrangement in the promoter, the numbers

are negative and the numeral 0 is absent. According to the views of Yager and Hippel,¹⁴ the transcription in prokaryotes takes place in six stages:

(1) The interaction of the enzyme with DNA is initially as a rule nonspecific but terminates with formation of an enzyme–promoter complex.

(2) Fusion of the template DNA in the region of contact between the promoter and the enzyme with formation of a locally unwound region (bulge) on the double-stranded DNA, which makes possible retranscription with the aid of the active centre of the enzyme located on the transcribable information strand (in the form of a ribonucleotide sequence).

(3) Abortive initiation, which begins with the reaction of two ribonucleoside 5'-triphosphates (NTP) selected by the DNA template,

and continues in accordance with Eqn (1) until ~ 10 elongation steps have been completed, after which the σ -subunit is split off from the complex and the latter is markedly stabilised [up to this moment, the possibility of the dissociation of the complex with ejection of a short (abortive) product, an oligonucleotide, remains].

(4) Elongation occurring in the stable complex with migration of the enzyme and the bulge along the DNA; within the limits of the bulge the 3'-terminal fragment of the newly synthesised DNA forms a duplex with the transcribable DNA strand (see Fig. 2).

(5) Encounter between the enzyme and the nucleotide sequence in the transcribable DNA, which is potentially capable of promoting termination.

(6) Decomposition of the transcription complex with liberation of the transcription product.

Naturally the active centre moves along the strand being transcribed and a hybrid duplex comprising the fragment of the strand being transcribed and the RNA product is formed on the region between the start of the bulge and the active centre. At a certain instant, the RNA product begins to separate from the template, whereupon the latter is rejoined to the nontranscribed strand. On the other hand, the DNA strands continue to move apart ahead of the active centre migrating along the strand being transcribed.

In recent years, studies by chemical methods of eukaryotic RNA polymerases have begun to be published. These enzymes have a significantly more complex structure than the enzyme from *E. coli*. They consist of approximately ten different subunits. Furthermore, three different RNA polymerases, usually designated as RNA polymerases I, II, and III, function within the cores. For yeast the corresponding enzymes are designated by the Latin letters A, B, and C. These enzymes are respectively responsible for the transcription of the genes of the ribosomal RNA, the genes of information RNA, and the genes coding for various small RNA, including transport and ribosomal 5S RNA. The subunit composition of certain, most intensively investigated enzymes is presented in Table 1. An important distinctive feature of eukaryotic enzymes is the need for the involvement of special transcription factors in the transcription initiation process. According to the available data, the functionally significant interaction of all three RNA polymerases with DNA begins with the formation of a complex between DNA and the set of transcription factors specific to each of the three polymerases.

Thus the following problems are solved (or can be solved) with the aid of chemical methods. The first is the establishment of the nature of the subunits interacting with DNA and the study of the dynamics of the primary interaction of the enzyme with DNA. These problems can be solved by the direct photocross-linking method. The second is the establishment of the region of DNA interacting with the enzyme at different transcription stages, which may be achieved with the aid of footprinting. The third is the determination of the size and position relative to the enzyme of the 'bulge' migrating along DNA, which can be achieved by identifying the DNA residues not involved in the Watson–Crick

‡ If the phosphorylation occurred at serine, threonine, or tyrosine residues, the modification product would be stable in the pH range used for demodification. Thus the knowledge of the chemical nature of the modified residue makes it significantly easier to locate it.

§ For the principal concepts, see Alberts *et al.*¹³

interactions. The fourth is the identification of the subunits participating in the interaction with the DNA strands in the region of the bulge, with the newly synthesised RNA before and after its separation from the template DNA (establishment of the exit corridor), and with the substrates (NTP). The last range of problems may be solved with the aid of the affinity labelling of the components by the corresponding reactive analogues, including the use of competent labelling, or by direct photocross-linking on UV irradiation. For adequately stable products, it becomes possible to establish the positions of the interacting aminoacid residues by identifying the modified aminoacids. In this case, one obtains information about the individual elements of the active centre of the enzyme. For eukaryotic enzymes, the study of the region of DNA interacting with the transcription factors and also the interaction of the latter with the enzyme itself are added to these tasks. We shall examine consecutively the principal results obtained by applying chemical approaches to the solution of these problems.

V. Interaction of RNA polymerase and its subunits with DNA

The first experiments designed to investigate the interaction of RNA polymerase with DNA were carried out by means of the chemical method easiest to use — the method of direct photocross-links. A mixture of DNA and the enzyme irradiated with UV light (usually at $\lambda = 254$ nm) is treated with the corresponding nucleases, after which only small fragments of the attached DNA are retained in the form bound to the enzyme. The enzyme subunits are separated by gel electrophoresis and the subunits bound covalently to DNA on irradiation are found from the positions of the radioactively labelled bands. It is also possible to treat the irradiated mixture with restriction enzymes, which cleave DNA at strictly defined sections, to precipitate with the aid of antibodies to RNA polymerase the fragments which contain the covalently bound enzyme, to remove the enzyme from the precipitated fragments by treatment with the corresponding proteinase, and, having separated them by gel electrophoresis, to find from the positions of the bands which of the fragments and in what amount were cross-linked with RNA polymerase on irradiation.

The results of the first study of this kind are presented in the paper of Hillel and Wu.¹⁵ It was noted that, when an excess of the enzyme is mixed with ³H-labelled DNA of T7 phage and on subsequent UV irradiation of the mixture, the main part of the enzyme is bound outside the promoters, *i.e.* nonspecifically. If an excess of unlabelled DNA is added to the mixture before irradiation, then the complexes between labelled DNA and the pro-

moters are retained for a fairly long time and the labelled DNA in the nonspecific complexes is replaced by the unlabelled DNA, so that on UV irradiation the radioactivity is retained only in the specific complexes. It was established in this way that three subunits (β , β' , and σ) participate in the nonspecific interaction, while only β and σ are involved in the formation of specific complexes. In both cases, there is no interaction with the subunit α .

It has been shown using DNA in which thymine had been substituted by bromouracil, affording more stable cross-linking products,¹⁶ that the third heterocycle in the upward direction from the start point (the -3 pair) participates in one of the cross-links in the σ -subunit, while the $+3$ pair participates in one of the cross-links in the β -subunit.

Similar results, which agree in principle with those presented on the basis of photocross-links, have been obtained on cross-linking the enzyme with DNA by means of formaldehyde.¹⁷ The procedure developed by Mirzabekov¹⁷ for the study of the interaction of DNA with histones in chromatin was used for these purposes. It is based on the elimination of purines from DNA to a slight extent (the purine heterocycles are split off from certain nucleotide residues with formation of the open-chain form of deoxyribose). The aldehyde groups of such DNA can interact with the ϵ -amino-groups of the lysine residues in close proximity with formation of Schiff bases, which are readily converted into stable alkylamines by treatment with sodium tetrahydroborate. The most detailed picture of the cross-linking of RNA polymerase with the promoter section of lac UV5 has been obtained¹⁸ by this method.

The results of the modification of *E. coli* RNA polymerase by the alkylating derivative of the oligonucleotide carrying at the 5'-terminal phosphate the 4-[*N*-methyl-*N*-(2-chloroethyl)amino] benzylamine residue and having a sequence corresponding to the fragment from -13 to -2 of the nontranscribed DNA strand containing the *spc* promoter have also been described. It has been established that the oligonucleotide itself has a high affinity for the enzyme, which may be evidence in support of the mechanism involving the unwinding of the double-stranded DNA in the region of the promoter as a result of the preferential binding of the nontranscribed strand and hence the liberation of the strand being transcribed. The alkylating derivative of this oligonucleotide modifies the σ -subunit. The phenomenon involving the effective binding of the octaribonucleotide, complementary to the section from -13 to -6 of the nontranscribed strand, to the enzyme, which has not so far found a satisfactory explanation, is also described in the above study; the alkylating derivative of the octaribonucleotide then modifies the β, β' -subunits.¹⁹

The dynamics of the cross-linking of the enzyme with DNA has been investigated by means of a special apparatus for rapid mixing and subsequent irradiation after a specific time interval by a powerful short (10 μ s) UV light pulse.²⁰ The distribution of the attached enzyme between eight different sections of DNA, obtained as a result of the highly specific fragmentation of DNA with the aid of the Kpn I and Mbo I restriction enzymes, was analysed for this purpose. It was found that in such cleavage the three main promoters of the T7 phage DNA are located in one fragment. During the first tens of milliseconds, the distribution was close to statistical, *i.e.* the amount of the RNA polymerase bound to the fragment was correlated satisfactorily with the size of the fragment. The redistribution of the enzyme between the fragments with its gradual accumulation in the fragment containing the promoter then took place gradually. This made it possible to determine the rate constant for the formation of primary nonspecific complexes and the rate constant for the migration of DNA in the direction of the promoter. The nature of this migration agrees with the mechanism of migration by means of one-dimensional diffusion along DNA.

The region of contact between the *E. coli* RNA polymerase and DNA has been repeatedly investigated with the aid of footprinting. Complexes formed with the promoter in the absence of transcription and in the course of the latter were investigated. In the first case, it was possible to detect and characterise three states

of the complex — closed, intermediate, and open. The best results were obtained when OH radicals were used.²¹ In the closed complex, formed at 4 °C, the region protected by the enzyme against the action of radicals is that between -4 and -53 and the transcribed and nontranscribed strands are alternately protected with the periodicity corresponding to the helical structure of the DNA. This fact shows that only one side of DNA comes into contact with the enzyme in this region. On formation of the intermediate complex (20 °C), the turns of the DNA helix are fully protected and full protection of the nontranscribed strand along the section from -10 to +21 and of the transcribed strand along the section from -13 to +18 is observed. It had been proposed earlier²² that this section be referred to as the fusion domain, whereas the region of the incomplete contact located above it should be called the recognition domain. It must be emphasised that the fusion domain does not coincide with the fused region of DNA, namely with the size of the bulge which enters into the composition of the domain, *i.e.* is significantly smaller. The part of DNA in the fusion domain, adjoining the bulge, is still (to the right) or already (to the left) in the double-stranded form. Finally, at 37 °C, whereupon the open transcription-active complex is formed, the region of contact with the nontranscribed strand is retained while a section from -7 to +2 accessible to modification arises on the strand being transcribed.

VI. Investigation of the segment of DNA unwound in the complex with RNA polymerase (the bulge)

In the study of transcription with the aid of footprinting, it is possible to detect the migration of the edges of the bulge. Thus, in the transcription the promoter lac UV5 (the first transcribed nucleotides of which form the sequence TTAACA...) in the complex with the enzyme or with the enzyme and the primer ApA simulating the first two transcription steps, the residue C in the +5 position is not alkylated by dimethyl sulfate, whereas after the addition of dTTP, which elongates the substrate by a further two units, the same residue C becomes accessible to alkylation.²³

Further investigations required the formation of a series of transcription complexes with different lengths of the transcripts. This was achieved by employing nucleotide sequences in the transcribed part of DNA favourable for this purpose. For example, the transcription has been carried out²² from the fragment of T7 DNA with the sequence (3')T(+1)AGCTCTCC...CTGTGCCGCTTA...(5') on the strand being transcribed. When the transcription is performed using the trinucleotide AUC as the primer and ATP and GTP as the substrates, the synthesis proceeds as far as the eleventh unit, since, owing to the absence of CTP from the mixture, the next step cannot be carried out. Similarly, by carrying out the transcription in the presence of CTP, ATP, and GTP, it is possible to obtain a transcription complex in which the length of the transcript is 20, because in the absence of UTP the 21st step of the synthesis cannot occur. By altering the nucleotide sequences in DNA as a result of the introduction of mutations, it is possible to obtain transcription complexes with most diverse lengths of the newly synthesised RNA. It has been established²² with the aid of footprinting by OH radicals that, when the transcript reaches a length of 11 units, the disruption of the contact between the enzyme and the recognition domain without change in the size of the fusion domain is observed. However, a further increase in the length of the transcript leads to a decrease in the fusion domain from ~30 units to 23 units. The disruption of the contacts between the enzyme and the recognition domain after the attainment of a length of 11 units by the transcript has also been recorded by means of footprinting with the aid of the Cu²⁺ - 1,10-phenanthroline system.²⁴

A more universal procedure is based on the immobilisation of RNA polymerase on a carrier.²⁵ By employing stepwise elongation (by omitting at each stage one of the four substrates), it was possible to obtain transcription complexes with different lengths of the transcript. The length of the transcript for each such

complex yields the position of the catalytic centre of the enzyme and footprinting (in the above study, exonuclease III was employed) yields the lower point of the contact between DNA and the enzyme. Systematic measurements of the distance between these two points showed that the transcription proceeds mainly continuously, *i.e.*, for each step of the migration of the enzyme active centre, the boundary of the region of the DNA - enzyme interaction undergoes unit migration. However, in certain cases it was found that the migration of the active centre of the enzyme itself does not lead to the migration of the enzyme relative to the template and after several such steps the enzyme, as it were, executes a jump over several pairs of template nucleotides.

The migration of the enzyme in jumps has been detected also in a study²⁶ involving the application of a more refined chemical technique. In this investigation, a series of transcription complexes were obtained with the length of the transcript from 11 to 20 nucleotides. These complexes were obtained by transcription on a DNA fragment containing the promoter and the sequence of the first 20 transcribed nucleotides (3')d(TAGCTCTCCCTGTG...CCGCTT...)(5'). In order to obtain the set of complexes, the transcription was initiated with the aid of the ribonucleotide pAUC using GTP and ATP as the substrates. This system yielded a complex with a transcript length of 11 units (complex 11). After its isolation by means of gel filtration and by adding CTP, complex 12 was obtained, while the addition of CTP and ATP afforded complex 14. Complex 14 was converted into complex 16 in the presence of GTP, into complex 18 in the presence of CTP + GTP, and into complex 20 in the presence of CTP + GTP + ATP. The position of the uncoiled section of DNA (the bulge) was determined by means of three reagents, each of which was specific to one type of heterocycle: thymine, adenine, and cytosine were determined with the aid of OsO₄, diethyl pyrocarbonate, and dimethyl sulfate followed by treatment with hydrazine respectively. In combination with footprinting by OH radicals, these investigations showed that, up to and including complex 18, the double helix is uncoiled ahead of the RNA polymerase and the position of the upper contact between DNA and the enzyme does not change. After the attainment of a length of 20 units by the transcript, a jump occurs and the helix is closed, passing to the double-stranded state.

The change in the size of the region of contact between the template and RNA has been recorded for transcription complexes with RNA polymerase II from calf thymus with transcripts having lengths corresponding to 135, 138, and 143 nucleotides. Footprinting with the aid of DNase I showed that the dimensions of the sections protected against hydrolysis correspond respectively to 48, 55, and 51 pairs of nucleotides.²⁷

VII. The study of the RNA exit corridor

In order to trace the migration path of the 5'-end of the transcript formed, two principal approaches were employed. One of them is based on the introduction of a reactive group into the initiating substrate or primer. The first experiments of this kind were described in studies^{28, 29} where ATP γ -*p*-azidoanilide was used as one of the substrates. The latter may serve for both initiation and elongation. Naturally the photoreactive section of γ -*p*-azidoanilide is retained only at the 5'-end of the transcript. Photomodification was detected only in the β - and σ -subunits. A more detailed study of the transcript by means of this procedure has been carried out in a study³⁰ where transcription by the *E. coli* RNA polymerase was carried out on a poly[d(A-T)] template using labelled [α -³²P] ATP and a primer containing the photoreactive label *p*-N₃C₆H₄C(O)CH₂SP(O)(O⁻)AdoPUrd. After the transcription, the transcription complex was irradiated, the labelled subunits were separated from one another, were separated by dialysis from the substrates, and were treated with PheHgOAc in order to split off the label from the transcript. The transcripts were separated by electrophoresis and were radioautographed. This made it possible to determine the amount of transcript of a

particular length bound to each subunit. It was found that transcripts with lengths of 6–8 units modify DNA preferentially, those with a length of 9–12 units modify the σ -subunit, and those with a length of 13–19 units modify the β/β' -subunit.³¹

The second procedure is based on the hypothesis that the newly synthesised template RNA within the limits of the template DNA bulge is in the form of a duplex with the DNA strand being transcribed. In this case, it can be modelled by an oligonucleotide complementary to several residues of the open part of the strand being transcribed and carrying a reactive group at the 5'-end. This was done on the A2 section of the T7 phage DNA promoter which, forming part of a complex with *E. coli* RNA polymerase, forms the open section (3')d(ATGTTAGCGA) on the strand being transcribed, the first seven residues referring to the non-transcribed region (i.e. corresponding to numbers from –7 to –1), while the dC residue is the first transcribed nucleotide.

A series of derivatives of oligonucleotides complementary to the open section and having the general structure R(pdN)_npTprC with a 3'-terminal dinucleotide complementary to the fragment A(–2)G(–1) (the first group of reagents) and R(pdN)_npdGprC with the terminal dinucleotide complementary to the fragment C(+1)G(+2) (the second group of reagent), where R is the reactive group, were prepared. The group R contained either a benzaldehyde residue (see below) or a fragment of an aromatic 2-chloroethylamine derivative capable of alkylating the nucleophilic centres of proteins and nucleic acids, or a phosphate activating group, for example *N*-methylimidazole. After the affinity modification with the aid of the first group of reagents, [α -³²P]GTP was added to the reaction mixture and competent labelling was carried out, i.e. the label was introduced into the oligonucleotide bound covalently to the enzyme. In the case of the second group of reagents, [α -³²P]UTP was added in order to carry out the competent labelling. Next a study was made of the distribution of the radioactivity among the subunits and the presence of the histidine and lysine residue modification was detected (with the aid of the criteria described above, based on the kinetics of the demodification of the phosphorylation products). In the case of alkylating reagents, the modification of DNA was also observed. The distribution and nature of the labelled aminoacid residues differed significantly for reagents with different lengths of the oligonucleotide component, i.e. with different distances between the chemically reactive group and the G·C(+1) pair. Fig. 3 presents the results of the determination of the 'exit corridor' obtained with the aid of the first group of reagents.³² The data obtained using the second group of reagents³³ agree qualitatively with those presented in Fig. 4 for reagents of the first group. However, there are also distinct differences. For example, the σ -subunit is modified by reagents of the first group at both lysine and histidine residues and the group R cannot be attached closer than to the residue forming the –7 pair. On the other hand, when reagents of the second group were employed, the modification of the histidine residues in the σ -subunit was already observed in the modification by the hexanucleotide ($n = 4$).

The determination of the RNA exit corridor for human RNA polymerase II (HeLa cells), based on the photoaffinity modification of the enzyme with the aid of the transcript into which 4-thiouridine monophosphate (s⁴UMP) residues were introduced during transcription, has also been described. The length of the transcripts was regulated by introducing 3'-CH₃O-GTP as the terminator. Mainly large subunits with masses of 240 and 140 kDa were modified.³⁴ It was found that the length of the transcript must correspond to at least 16 nucleotide residues for sufficiently effective modification. This makes it possible to infer the distances between the active centre and the start of the exit of the transcript from the duplex formed by the transcribed DNA strand and the transcription product.

This procedure has also been used to identify the subunits in contact with the transcript, formed in the isolated nucleoli, in which ribosomal RNA genes are transcribed with the aid of RNA polymerase. For this purpose, s⁴UTP and labelled CTP were

Figure 3. Topography of the product RNA exit corridor obtained by labelling the transcription complex of the *E. coli* RNA polymerase by reagents containing aldehyde and alkylating groups, and by phosphorylating derivatives of oligoribonucleotides. The arrows indicate the interactions of the reactive groups of the reagents with the aminoacid residues of the protein — Lys, His, and X (X is an aminoacid residue other than lysine and histidine).

Figure 4. Schematic illustration of the highly selective affinity labelling of RNA polymerase. (1) Phosphorylating residue; (2) site of addition of the phosphorylating residue to the protein.

introduced into the nucleoli of the HeLa cells and UV-irradiation was carried out for a time. Analysis of the radioactivity associated with the RNA polymerase I isolated from the irradiated nucleoli showed that subunits with masses of 200 and 120 kDa are modified in the first place. With increase in the size of the transcript, the fraction of the transcript bound covalently to the subunit with a mass of 52 kDa also increases.³⁵

The same system has been used to locate RNA polymerase II in the nucleus. It was established that, after the irradiation of the nuclei in which transcription with participation of s⁴UTP and labelled CTP took place, the enzyme molecules are not bound to the nuclear template but move along loops formed by chromosomal DNA.³⁶

VIII. Approaches to the study of the active centres of RNA polymerases by the affinity modification method

Most of the information about the aminoacid residues of the enzyme participating in the formation of the active centre or adjoining it has been obtained by the highly selective labelling method described above. The initiating region of RNA polymerases from various sources such as the enzyme produced by the T7

phage,³⁷ three yeast RNA polymerases,³⁸ and the RNA polymerase II from human placenta³⁹ and from wheat seedlings⁴⁰ has been investigated by this method. Derivatives of the initiating purine nucleotide containing benzaldehyde at the 5'-end and forming a Schiff base with the ϵ -aminogroup of lysine were used as the affinity reagent in the above investigations. The Schiff base was reduced with tetrahydroborate to an alkylamine, after which elongation was carried out with the aid of the labelled [α -³²P]NTP. Adenosine 5'-trimetaphosphate was used to modify the region of the initiation of transcription. In the case of eukaryotic enzymes, the second subunit in terms of size was labelled. In the case of the T7 RNA polymerase, the 631 lysine residue was modified.⁴¹ In the *E. coli* RNA polymerase, the modification points were the 1065 lysine residue and the 1237 histidine residue of the β -subunit.⁴² In the yeast RNA polymerase II, the 979 and 987 lysine residues were modified.⁴³

By virtue of its high selectivity, the competent labelling method may be applied also in cell extracts. Although this has been done on RNA replicase (which we do not consider because of the scantiness of the available data),⁴⁴ we thought it useful to present an example of the determination of the functions of two nonstructural proteins of the tick encephalitis virus, because it demonstrates the possibilities of the use of the above approach in complex supermolecular systems. The UUC(3') sequence is present at the 3'-end of the plus-chain of the viral RNA, from which replication should begin in order to form the double-stranded replicated RNA. The reactive analogue from which replication may begin should be a derivative of GMP. In competent labelling, elongation should be achieved with the aid of [α -³²P]ATP. When these components were introduced into the cell extract from pig embryo kidneys infected with the virus, the radioactive label was detected in a protein with a molecular mass of 69 kDa 8 h after infection, which, judging from the spectra of the viral RNA, corresponds to the nonstructural (*i.e.* not entering into the composition of the mature virus) NS3 protein. In the extract obtained from the cells isolated 45 h after the start of infection and subjected to the same treatment, the label was present in another nonstructural protein (NS5) with a molecular mass of ~ 100 kDa. In conformity with the logic of the events characteristic of RNA-containing viruses, one may assume that the NS3 protein participates in the replication of double-stranded RNA, required for the conversion of the viral RNA into the double-stranded form while NS5 participates in the replication of the double-stranded RNA needed for the accumulation of new plus-chains entering into the composition of new viral particles.

5-Azido-UTP⁴⁵ and 8-azido-ATP have also been proposed for the direct modification of NTP-binding centres.⁴⁶ The first proved to be the substrate of the enzyme from *E. coli* with $K_m \sim 80$ μ M. Photoirradiation of the enzyme in the presence of this reagent leads to approximately the same incorporation of the label into the β -, β' -, and σ -subunits, the presence of DNA not influencing the distribution of the label between the subunits. 8-Azido-ATP is a poor substrate for this enzyme, but it inhibits the enzyme competitively (in relation to ATP). Photoaffinity modification leads mainly to the modification of the β' - and σ -subunits. When the analogue is incorporated in the 3'-terminal position in the transcript and on subsequent irradiation, the β' -subunit is modified within the limits of the 932–1020 peptide.⁴⁷ 8-Azido-ATP has also been used for the photoaffinity modification of the RNA polymerase coded for by the T7 phage⁴⁸ and of the RNA polymerase II from calf thymus.⁴⁸ Peptides containing the attached photolabel were isolated in these two investigations.

Affinity modification makes it possible to detect the migration of the substrate within the limits of one enzyme molecule or between subunits. As an example, one may quote a study⁵⁰ in which the transformation of the transcription-active complex formed by the enzyme from *E. coli* into an inactive complex was observed when transcription ceased as a result of the lack of substrate for the next elongation step. This transformation occurs when the system is incubated for several tens of minutes at 37 °C and is irreversible, *i.e.* the addition of substrate no longer leads to

continuation of transcription. The complex was obtained by stepwise elongation on the immobilised enzyme²⁵ and it contained the photoreactive 4-thio-UMP residue at the 3'-end. The complex was irradiated at 360 nm. Analysis of the modification of the subunits showed that in the transcription active complex the β -subunit is modified within the limits of the 515–660 and 1091–1107 peptides and the β' -subunit is modified within the limits of the 400–465 peptide; in the inactive complex, only the β' -subunit is modified within the limits of the 1091–1107 peptide.

Other less traditional approaches to the study of the active centres of RNA polymerase have been developed recently. Thus it has been proposed⁵¹ that the chemical and genetic approaches be combined in order to establish the region where the Mg^{2+} ion is bound in the active centre of the enzyme with replacement of the Mg^{2+} ion by Fe^{2+} . It was found that oxidative degradation of both the template and the enzyme takes place in this instance. The degradation proved to involve mainly the β' -subunit, cleavage occurring within the limits of the peptide located between the 466 and 400 methionine residues. Since the conservative sequence (*i.e.* a sequence characteristic of a wide variety of nucleic acid polymerases) NADFDGD (in terms of single-letter designations, N = asparagine, A = alanine, D = aspartate, F = phenylalanine, and G = glycine) is located on this section, it was concluded that the above fragment participates in the binding of the magnesium ion. A mutant variant of RNA polymerase, in which the β' -subunit contained in the same place the NAAFAGA sequence (the aspartate residues were replaced by alanine residues) was obtained by the protein engineering method for additional confirmation of the cleavage site. After the replacement of Mg^{2+} by Fe^{2+} , the enzyme was not cleaved in the presence of this fragment. The cleavage of template DNA at rigorously defined sections in the –1 and –2 positions relative to the transcription start point was observed in the same experiment.

The use of a chimeric reagent, consisting of the conjugate of the initiating substrate (ATP) with an antibiotic (rifampicin), for affinity modification has been described.⁵² This antibiotic is a powerful inhibitor of prokaryotic RNA polymerases and it is therefore an effective antitubercular preparation. A series of conjugates with different lengths of the $-NH-(CH_2)_n-NH-$ spacer, connecting the carboxy-group of the antibiotic with the ATP γ -phosphate, were prepared. It was found that, when the length of the linker is $n > 3$, the conjugate serves as the initiating transcription substrate, whereupon the optimum length of the spacer corresponds to $n = 5$. Rifampicin is known to be bound strongly to the enzyme. This means that the distance between the centres binding the antibiotic and initiating the substrate is ~ 1.5 nm.

A conjugate of the spacer of which included the alkylating group $-NH(CH_2)_2N[C(O)CH_2Br](CH_2)_6$ has also been synthesised. In this case, the modification of the transcribed DNA strand in the C(–3) and C(–2) positions was detected.

The authors also employed a procedure which they called a pseudoenzymic reaction. For this purpose, the alkylating fragment $-NH(CH_2)_nNHC(O)CH_2Br$ was attached to the carboxy-group of rifampicin and an ATP analogue, containing a sulfur atom instead of one of the oxygen atoms in the γ -phosphate, was introduced into the reaction mixture containing the enzyme and the rifampicin derivative. When these compounds were disposed favourably in the corresponding active centres, the alkylation of the thio-analogue of ATP was observed. The most effective alkylation was noted for $n = 4$, which corresponds to the size of the spacer with six carbon atoms.

Nucleoside triphosphates can function in the transcription process in ways other than as substrates of the polymerisation process. In the study of the photoaffinity modification of RNA polymerase II from calf thymus with the aid of 8-azido(naphthalene-1'-sulfonyl) [α -³²P]ATP, it was established that, when one residue of the reagent is attached covalently, modification accompanied by the complete inactivation of the enzyme takes place. The inactivation occurs competitively in relation to ATP. However, other substrates — CTP and GTP — are not competitive

inhibitors in relation to the reagent and hence the modified section is not a substrate binding site. Since for the initiation of the transcription by RNA polymerase II the hydrolysis of one ATP group is required, it has been suggested that the modification takes place at a specific ATP binding site in which the hydrolysis required for the initiation occurs.⁵³ Using the 2'-*O*-dansyl-ATP fluorophor, which according to the authors forms a complex with the modified enzyme at the substrate binding site, it was possible to determine the distance between the ATP and the other substrate binding site, by measuring the resonance energy transfer. It was found to be ~2.5 nm.

All the methods described above lead to the labelling of the enzyme in the NTP binding region. There have been individual studies in which an attempt was made to bind the enzyme to the 3'-end of the growing RNA chain. The syntheses of several short transcripts into the 3'-ends of which the s⁴UMP residue had been introduced have been described.⁵⁴ Short single-stranded templates with the general structure (3')d(CCCCCGCTTGTGGTG – X), where X = A, TA, TTA, or TTTA, were used for this purpose. They were transcribed with the aid of yeast RNA polymerase I in the presence of the GpCpG primer and three substrates: ATP, [α -³²P]CTP, and s⁴UTP (the transcribed part of the template is underlined). It is not difficult to note that the transcription began with the site where the 3'-end of the primer is located and, since there is a single dA residue on the transcribed strand, located at the 5'-end of the template, a single s⁴UMP residue, coded for by this dA, was incorporated in the 3'-end of the transcript. After the completion of the process, the transcripts obtained, with a length equivalent to 12–15 nucleotide residues, were found to be part of the composition of the transcription complexes containing the enzyme, the template, and the transcript with a photoreactive residue located in the region of the active centre. Irradiation led to the attachment of the radioactive label to two subunits with molecular masses of 190 and 135 kDa. The ratio of the levels of radioactivity of the two subunits changed as a function of the length of the transcript, although it would seem that in all the systems investigated the photoreactive residue has always been in the same position on the enzyme, corresponding to the 3'-end of the transcript. This is unexpected and has not found a convincing explanation.

The same approach with the same set of template and transcripts labelled at the 3'-end has been used for the affinity modification of RNA polymerase II from yeast and wheat seedlings. In both cases, the affinity modification led to the incorporation of radioactivity solely in the largest subunit (220 kDa for the yeast enzyme and 180 kDa for the enzyme from wheat seedlings).⁵⁵

IX. The study of the interaction of eukaryotic transcription factors with DNA

For each of the three eukaryotic RNA polymerases, there is an intrinsic set of transcription factors participating in the transcription initiation stage. In accordance with the number of the polymerase, they are designated as TFI, TFII, and TFIII. Within the limits of each set, they are additionally designated by Latin letters. The majority of the factors consist of several subunits. In the transcription of the genes of information RNA, the set of principal factors necessary for the transcription of any genes participates in the initiation, while additional highly specialised factors are needed to trigger a whole series of genes. The principal factors include TFIIA, TFIIC, and TFIID, which form a primary complex in the immediate vicinity of the section of DNA containing the d(TATA) sequence at a short distance upward from the start point of the transcription, as well as the factors TFIIIE, TFIIF, TFIIB, and TFIIH. One of the subunits of the last factor is a protein kinase and catalyses the phosphorylation of the large subunit of the RNA polymerase, which is necessary for the manifestation of enzyme activity.

Figure 5 presents a schematic illustration of the disposition of the subunits of the factors TFIIB and TFIIC on genes.

Figure 5. Schematic illustration of the interaction of the transcription factors III with the genes of 5S rRNA (a) and the 4th suppressor tRNA^{Tyr} (b). The masses of TFIIA, TFIIB, and TFIIC are indicated in kDa. The arrows indicate the position in the DNA sequence which have been photocross-linked with a particular subunit of the transcription factors.

A detailed arrangement of the subunits on two DNA specimens coding respectively one of the tRNAs and ribosomal 5S RNA has been established for the factors TFIIC with the aid of photoaffinity modification. The disposition of part of the promoter region within the limits of the coding section is characteristic of RNA polymerase III. A large series of double-stranded DNA have been obtained by genetic engineering techniques.^{56,57} One of the strands was elongated by several units with the aid of DNA polymerase with incorporation into the mixture of the elongating substrates of a photoreactive dNTP — 5-(3-*p*-azido-benzoylaminoallyl)dUTP. The photoreactive label was introduced in this way into various positions in DNA, after which a complex with the corresponding factors was formed, the photoaffinity modification of the factors was carried out, and it was established to which genes the covalent binding had taken place.

X. Conclusion

The methods based on chemical modification began to be applied to template biosynthesis systems primarily on ribosomes. The first studies of the modification of the tRNA binding region with the aid of an alkylating derivative of tRNA and of the mRNA binding region with the aid of an alkylating derivative of an oligonucleotide were published at the beginning of the 1970s.^{58,59} These were followed by systematic investigations of the structural-functional topography of the *E. coli* ribosomes with the aid of photoreactive derivatives of tRNA and reactive derivatives of ribooligonucleotides (the main results of these investigations are presented in a review⁶⁰). In recent years, similar studies have been initiated on ribosomes from human placenta. Information has been obtained about the protein environment and the sections of ribosomal RNA in the region where genetic information is decoded.^{61,62} Bifunctional cross-linking methods have found extensive application in the determination of the steric organisation of ribosomes. They make it possible to determine the mutual disposition of the ribosomal proteins and their disposition relative to particular sections of ribosomal RNA. In combination with data on the mutual disposition of proteins found by the neutron scattering method, this made it possible to construct a detailed three-dimensional model of the disposition of the 16S ribosomal RNA in the small subunit of the *E. coli* ribosome.⁶³

From the data presented in the review, it is seen that the systematic application of chemical methods to the study of transcription has only just begun.

With the exception of the investigation of ribosomes, the bifunctional cross-linking method has not so far found extensive application in the study of transcription. As an individual example, mention may be made of the study⁶⁴ whose authors used a bifunctional reagent (*N*-hydroxysuccinimidyl-4-azidobenzoate) — to elucidate the interaction of the subunits of the *E. coli* RNA polymerase with the protein ω , which is present in a highly purified enzyme preparation in a stoichiometric amount but is not an essential component for transcription. Bifunctional cross-linking data have shown that the protein is bound to the β' -subunit of the whole enzyme. The bifunctional cross-linking method is particularly effective in the study of systems with a large number of proteins and nucleic acids and one may therefore expect that its importance will increase as one proceeds to the study of transcription in more complex systems, for example in complexes of chromosomal DNA with eukaryotic RNA polymerases and with a set of transcription factors, including those forming part of the composition of chromatin.

It is seen from the examples quoted that chemical approaches lead to new unique possibilities for the study of template biosynthesis. The possibility of investigating the mechanism of the search by the enzyme for points at which the functionally significant process begins,²⁰ the determination of the positions and dimensions of the unwound section of DNA on RNA polymerase and its migration in the course of transcription,²⁶ and the determination of the RNA exit corridor, *i.e.* of the actual 'track' of the migration of the product on the enzyme as it moves away from the catalytic centre where biosynthesis takes place, are the most impressive features at the present time.^{29–34} It is at present difficult to even imagine experiments not based on chemical approaches which would make it possible to look quite so deeply into the dynamic aspects of template biosynthesis. Some of the procedures described may be and are already employed for the study of the transcription process in cell organelles.^{35,36}

Abstract. The application of the methods of low-frequency vibrational spectroscopy to studies of amides and urethanes including polyamides, polypeptides, and proteins is critically analysed. Special attention is concentrated on the spectroscopic studies of intermolecular interactions and in particular on spectral features of the intrinsic vibrations of hydrogen bonds. The methods are considered that allow one to identify experimentally the bands in the region of $90\text{--}130\text{ cm}^{-1}$ associated with the vibrations of the hydrogen bridge. The potential and limitations of the methods of low-frequency spectroscopy for the investigation of these classes of compounds are discussed. The bibliography includes 131 references.

I. Introduction

Compounds containing amide and urethane groups constitute an important class of substances that are widely used in the processing and production of polymeric materials (polyamides and polyurethanes), and are of special importance in molecular biology (polypeptides and proteins). Among the structural methods used for the investigation of the structure of these compounds, vibrational spectroscopy occupies a prominent position contributing to the solution of many problems in the physical chemistry and chemistry of polymers.¹

The so-called middle spectral region of vibrational frequencies, which is normally used, falls in the range of wavenumbers from $400\text{ to }4000\text{ cm}^{-1}$. The low-frequency spectral region, which lies below 400 cm^{-1} , is much less studied. Nevertheless, this interval, usually called the low-frequency region, allows one to gain information that is unavailable by other methods. Low-frequency spectroscopy is used in both the physics of solids, in the study of radiation absorption by magnetic, ferromagnetic semiconducting, and other materials,² and in physical chemistry, in the study of barriers to internal rotation, charge transfer

compounds, inorganic complexes, intermolecular interactions, vibrations of crystal lattices, *etc.*³

The low-frequency spectral region is of interest for the studies of amides and urethanes because first of all bending and torsional vibrations of the molecular skeleton manifest themselves in this region. These vibrations are especially sensitive to the spatial structure of molecules and to intermolecular interactions. It is in this region that the intrinsic vibrations of the hydrogen bond and intermolecular vibrations of crystal lattices are observed.

Three major experimental methods are used for the investigation of the low-frequency region of vibrational spectra, namely, far infrared spectroscopy (FIR),³ low-frequency Raman spectroscopy (Raman),⁴ and inelastic neutron scattering (INS).⁵ It is well known that IR and Raman spectroscopy are complementary to each other because the selection rules for symmetric molecular systems for the IR and Raman usually differ. However, even in the absence of symmetry, the combined use of these methods is very helpful, for there is no direct relationship between intensities in these two types of spectra. If, for example, in the IR spectrum a band of some vibration is weak and overlaps another band, it can manifest itself distinctly in the Raman spectrum, and *vice versa*. The INS method is less accessible to researchers, but it is attractive since there are no selection rules for these spectra, and in many cases the INS spectrum contains therefore more bands than the IR or Raman spectra. Recently FIR spectroscopy has gained wide usage for a number of experimental reasons. This is determined by the fact that since the 60s serial diffractive spectrometers for this region are being manufactured and, especially, in the context of the development of Fourier spectroscopy, which covers the low-frequency region of the spectrum, too.

There is no difference in principle in the approaches to the interpretation of the spectra in the middle and far regions: normal coordinate analysis, the method of group frequencies (though in the low-frequency region this method has a limited application because organic compounds seldom have group bands in this region), the method of examination of isotopically-substituted compounds, and some other methods are used in both cases. However, there are specific features in the low-frequency region consisting, first of all, in the fact that intermolecular vibrations manifest themselves in this region (as has already been mentioned), which is primarily typical of crystalline compounds and some associated liquids. Therefore, for normal coordinate analysis of crystals in both middle and far frequency regions, strictly speaking, the structure and symmetry of the crystal lattice should

be considered. A numerical calculation of frequencies is substantially complicated due to the large number of atoms that are to be taken into account. These calculations are possible and are being conducted⁶ for crystals of low-molecular-weight compounds, whereas in the case of polymeric molecules, they can be performed only for the polymers with simple structure such as polyethylene⁷ and polypropylene.⁸

The following approach is used as a rule for the interpretation of the spectra of crystalline polymers. A normal coordinate analysis is run for an isolated chain; sometimes, for polypeptides and proteins with the helical structures, the hydrogen bonds stabilising these structures are taken into consideration. Then, the symmetry of the crystal lattice is analysed, and the number and activity of the expected intermolecular vibrations is determined from the group theory. The assignment of these vibrations in the spectrum is usually made empirically on the basis of selection rules, polarisation, *etc.*, though the methods of approximate calculations of the frequencies have been developed for intermolecular vibrations.⁶

A fairly complete bibliography (up to 1969) covering all the problems of FIR spectroscopy has been compiled by Bloor.⁹ Unfortunately, more recent publications,^{10–13} in which FIR spectroscopy of organic and in particular polymeric compounds have been considered, are incompatible with the above-mentioned review⁹ in the scope of problems and coverage of references. To our knowledge, there are no reviews devoted especially to low-frequency Raman spectroscopy.

The purpose of the present review is the consideration and systematisation of the principal results accumulated to date of investigations concerning the application of low-frequency spectroscopy to the studies of amides and urethanes. The range of problems associated with the band assignment in this region is defined.

In most cases, the interpretation of low-frequency spectra is a rather complicated task. Vibrations of the bonds between heavy atoms, skeletal, bending, and torsional vibrations sensitive to the spatial structure and intermolecular association, vibrations of crystal lattices and polymeric chains, and the intrinsic vibration of the hydrogen bond are located in this frequency region. In each specific case, the band assignment most often requires special investigations. As intermolecular interactions are of special interest for the studies of amides and urethanes, let us dwell on the methods of identification of the bands originating from the vibrations of hydrogen bonds.

II. Methods for the assignment of bands in the low-frequency region of vibrational spectra to the hydrogen bond modes

The absorption bands sensitive to the presence of hydrogen bonds can be identified if the hydrogen bond is fully or partially broken or somehow changed. Dilution is one of the methods used to this end. Thus the analysis of the vibrational spectra of solutions, in which the hydrogen bond in the compound under study is broken upon dilution in the middle IR region of vibrational frequencies allows one to make a definite conclusion on the presence or the absence of H-bonds. However, the application of the dilution method in the low-frequency region is markedly complicated for it is impossible to measure FIR spectra at low concentrations. If thick layers are used, weak bands corresponding to H-bonds are obscured by the bands associated with strong absorption by the solvent.

Hydrogen bonds are more often studied by the method of dissolution in polyethylene matrices.¹⁴ This method has been developed specially for the FIR region as polyethylene is practically transparent in the low-frequency region. The spectra of compounds measured in the polyethylene matrix at room temperature and at the temperature of liquid nitrogen correspond to the 'normal' spectra of these compounds in solutions of different

concentrations. This phenomenon has been used by Jakobsen and Brasch¹⁵ in the investigation of hydrogen bonds in phenol derivatives. It was found that when phenol adsorbed as a polymer with hydrogen bonds was slowly heated, it was transformed into a monomeric form as a result of H-bond cleavage and, on the contrary, cooling restores the system of hydrogen bonds. Thus, 'dilution' can be achieved by changing the temperature.

The method of matrix isolation¹⁶ is rather efficient. The principle of this method is to hold the molecule in a solid inert medium at temperatures that are sufficiently low to prevent translational motions of the molecules. Knozinger and Schrems¹⁷ have reviewed the data on the studies of hydrogen bonding obtained by FIR spectroscopy.

The phenomenon of a change in the H-bond strength with temperature and pressure is also used for studies of hydrogen bonding. High sensitivity of the hydrogen bonds to temperature results from an equilibrium shift of the process of H-bond formation, which leads to a change in the proportion of the groups taking part in the intermolecular interaction. This causes substantial changes in the spectra in the frequency region corresponding to vibrations of the groups involved in the hydrogen bond formation, which is normally used as the key criterion for the presence of the hydrogen bond.¹⁸ The application of the technique of high pressures in spectral studies also provides a possibility to reveal changes in the bands sensitive to the hydrogen bond, since high pressure (up to 160 000 atm) affects intermolecular interactions and hence their vibrational characteristics.³

The deuteration method is widely used for the assignment of bands in the middle IR region to the modes involving the hydrogen atom. In the spectra of deuterated analogues, the frequencies associated with the vibrations of the hydrogen atom are always shifted. However, in the low-frequency region of the spectrum, deuteration is not so efficient and does not always lead to the desired result, since the frequency shift for the bands of the hydrogen bond is 1–5 cm⁻¹ (see Ref. 19) and sometimes is not observed at all. This originates from the fact that this is not the vibration of the hydrogen atom relative to the proton acceptor but that of the proton donor relative to the proton acceptor. However, if this small frequency shift does take place, the FIR method registers it quite reliably.

Comparative analysis of the spectra of a series of related compounds is often applied to interpret the spectra. For example, comparison of the FIR spectra of a series of carboxylic acids allowed one to distinguish the bands belonging to the hydrogen bond from those associated with intramolecular modes.²⁰ The application of this method along with other methods to polymeric systems also gives positive results.²¹

Reliable data on the assignment of a band to the vibration of the hydrogen bridge can be obtained by replacing the hydrogen atom by a group that does not form a hydrogen bond. This method was used in studies of the inherent modes of the hydrogen bond in the simplest amides.²²

In the case of anisotropic systems such as oriented polymers, monocrystals, definite information can be gained from the polarised spectra. In the majority of cases, the direction of the hydrogen bond is close to that of the A–H valency bond. The knowledge of the structure of the anisotropic system and the dichroic ratio of the bands allows the proposed assignment to be proved or demolished. This method is widely used in studies of oriented polymeric systems in the middle IR region²³ and sometimes in the low-frequency region.¹²

As for low-frequency Raman spectra of liquid systems, the difficulties in their measurement is associated with the large half-width of the band due to Rayleigh scattering. Nielsen²⁴ has developed the technique of the *R*(*v*) representation for the low-frequency Raman spectrum, which permits subtraction of the background of the Rayleigh scattering so that a rather distinct low-frequency spectrum can be obtained, which can be successfully compared with the FIR spectrum. According to this technique, the spectrometer is connected with a computer and

processing of the spectra is carried out automatically. Nielsen and co-workers have performed a series of investigations by means of the $R(\nu)$ representation; in particular, low-frequency Raman spectra for compounds containing the amide group have been studied. This method is especially valuable because it allows the investigation of biological systems in aqueous solution.

Naturally, it is desirable to use a complex of the methods described to obtain reliable results.

Definite progress can be achieved in the studies of intra- and intermolecular vibrations if experimental results are supplemented with theoretical calculations. The number, type, character, and optical activity of the intermolecular modes can be predicted from theoretical calculations for crystalline systems.^{6,25} At present, methods for calculation of these frequencies have been developed. Service programmes are available for these calculations on big and personal computers.^{26,27}

III. Low-molecular-weight amides

The simplest secondary amide, *N*-methylacetamide (*N*-MAA), is often considered as a model of an amide unit in polyamides, polypeptides and proteins. This is the reason for an interest in the investigation of its structure. Numerous papers are devoted to the study of the vibrational spectra of *N*-MAA. These investigations were started in the 50s and are still in progress.

It is well known that *N*-MAA is liquid at temperatures above 28 °C; in the solid state it can exist in two crystalline forms:²⁸ as a disordered crystal in the temperature interval from 28 to 10 °C, and as an ordered crystal at temperatures below 10 °C. The skeleton of the molecule has a planar structure with a *trans*-arrangement of the carbon atoms of the two methyl groups.²⁸ However, the presence of the *cis*-form is also suggested, which allows the fine structure of vibrational bands to be explained.²⁹

The vibrational spectra of *N*-MAA have been well studied both experimentally and theoretically. The characteristic bands of the modes of the amide group have special names from 'Amide I' to 'Amide VII'.¹

Since *N*-MAA is convenient as a model compound, recently a normal coordinate analysis has been performed in detail for this compound^{30–32} in order to obtain the force field that can be applied to calculations of the spectra of polypeptides and proteins.

The FIR spectra of *N*-MAA and related compounds were first studied by Itoh and Shimanouchi.³³ Two bands at 201 and 102 cm^{−1} are observed in the FIR spectrum of liquid *N*-MAA (Fig. 1). The authors assign the band at 201 cm^{−1}, which is shifted to 185 cm^{−1} upon deuteration of the methyl groups, to the torsional mode about the C–N bond. The absorption at 102 cm^{−1} is associated with the intrinsic mode of the hydrogen bond. This assignment is based on the fact that this band, which is typical also of other simple amides,²² is shifted by *ca.* 3–4 cm^{−1} upon deuteration of the NH-group and disappears upon replacement of the hydrogen atom at the nitrogen by another group (Fig. 1). The deuteration of the methyl groups does not affect the frequency of this mode.

The data obtained from the FIR spectra are confirmed by investigations of the low-frequency Raman spectra of *N*-MAA,^{34,35} which, in particular, show that the band in the region of 100 cm^{−1} is shifted to the low-frequency region as the temperature increases (Fig. 2). The authors^{22,34} believe that the *N*-MAA molecules in the liquid state form linear chains *via* hydrogen bonds and have a structure close to that of the disordered crystal phase.

The problems of association of the *N*-MAA molecules in the liquid state and in CCl₄ solution have been discussed in more detail.^{36–38} A detailed analysis of frequencies and intensities of the amide associates formed *via* the hydrogen bonds has been performed on the basis of normal coordinate analysis and an experimental study of the IR spectra of *N*-MAA in solution.³⁶ A force field and a set of electrooptical parameters were proposed for H-bonded associates of *N*-MAA molecules. The complex

Figure 1. The FIR spectra of model amides and related compounds.³³ (a) HCONHCH₃, (b) CH₃CONHCH₃, (c) CD₃CONHCH₃, (d) CD₃CONHCD₃, (e) EtCONHCH₃, (f) CH₃CONHEt, (g) HCON(CH₃)₂, (h) CH₃COOCH₃.

contour of some bands 'Amide I', 'Amide II' in solution might be rationalised by the existence of associates of various length.

Figure 2. The smoothed $R(\nu)$ spectrum of liquid *N*-MAA at different temperatures (°C): (1) 165, (2) 150, (3) 120, (4) 90, (5) 60, (6) 30.

The comparison of absorption bands in the middle IR region in the spectra of tetramer, pentamer, and hexamer shows that a specific saturation of the frequency shifts takes place as the degree of association increases, then only the band contour changes.³⁷ On the contrary, in the FIR region where the bands of the hydrogen bond modes are located, a systematic shift to the low-frequency region occurs with an increase in the number of molecules in the complex. According to calculations of the frequencies for the final chains, the dependence of the frequency on the number of the *N*-MAA molecules in the associate manifests itself well in the range of the NH stretch (3348, 3338, 3334, and 3330 cm⁻¹ for *n* = 2, 3, 4, and 6, respectively) and in the FIR region, where the intrinsic vibration of the H-bond manifests itself (121, 105, 101, and 98 cm⁻¹ for *n* = 2, 3, 4, and 6, respectively). The comparison of the calculated frequency for the hydrogen bond vibration with that in the experimental spectra makes it possible to estimate the size of associates in liquid *N*-MAA (*n* = 2–6).

The complex structure of the amide bands can alternatively be explained by assuming that *cis*- and *trans*-isomers coexist in solutions of *N*-MAA,³⁸ which is based on examination of the spectra of solutions at various temperatures and concentrations. The 'Amide I' band was separated into four Gaussian components, which the authors relate to the *cis*- and *trans*-isomers of *N*-MAA. However, from our viewpoint these results do not contradict the explanation of the complex contours of the bands by the existence of associates of different length.^{36,37} Moreover, the dependence of the enthalpy of the hydrogen bond formation on the chain length of associates is proposed,³⁸ which cannot but influence the frequencies of the 'Amide I' and 'Amide II' bands.

ab initio Calculations performed by Nielsen²² as well as normal coordinate analysis for the *N*-MAA molecules³³ indicate that the band at 100 cm⁻¹ is the bending vibration of the hydrogen bond of the type

The crystalline *N*-MAA was studied by FIR,³³ Raman,³⁹ and INS⁴⁰ spectroscopy in the low-frequency region. On going from liquid to disordered crystal, the frequency of the hydrogen bond mode in the IR spectrum³³ shifts from 102 to 125 cm⁻¹ (Table 1). The passage to the ordered crystal results in its further shift to 130 cm⁻¹ and a new band appears at 90 cm⁻¹, the intensity of the latter increasing with a decrease in temperature. Simultaneously, the band at 201 cm⁻¹ shifts to higher frequencies and splits into two components at 221 and 243 cm⁻¹. The crystal existing at temperatures below 10 °C exhibits two torsional vibrations (*A*₂ and *B*₂) about the C–N bond. For structures of *C*_{2v} symmetry, the *A*₂ mode is inactive in the IR, and the appearance of two torsional modes about the C–N bond means that the structure of the crystal unit of *N*-MAA deviates from this group symmetry.

Normal coordinate analysis³³ for the crystal lattice of *N*-MAA with consideration of the hydrogen bond confirms the presence of two torsional modes in the crystal: 205 (*A*₂) and 227 (*B*₂) cm⁻¹. In addition, it is shown that the band in the region of 130 cm⁻¹ is associated with librational lattice modes and that in the range of 90 cm⁻¹ belongs to translational lattice vibrations. Hence, according to the data from Ref. 33, temperature changes

Table 1. The frequencies (ν/cm⁻¹) of H-bond bands in the spectra of *N*-MAA in the region of 30–300 cm⁻¹.

Phase state of <i>N</i> -MAA	Method	Temperature / °C	ν in the region		Ref.
			100 cm ⁻¹	200 cm ⁻¹	
Liquid	Raman	30	102	201	35
Disordered crystal	IR	15	125	201	33
Ordered crystal	IR	10	130	210	33
			90		
	IR	–80	132	221	
			90	243	

in the crystal affect the frequency shift for the torsional vibration much more significantly than the frequency of the hydrogen bond vibrations (see Table 1).

The Raman³⁹ and INS⁴⁰ spectra of crystalline *N*-MAA and its isotopomers supplement information from the IR spectra. The frequencies observed in the IR, Raman, and INS spectra of crystalline *N*-MAA³⁹ are presented in Table 2. About 10 lines are recorded in the region below 200 cm⁻¹ in the Raman spectrum. The authors³⁹ believe that the lattice modes (external vibrations) are in the region below 110 cm⁻¹ because isotopic substitution has little influence on the frequencies of these bands; the torsional vibrations about the C–N bonds manifest themselves in the region of 120–170 cm⁻¹. Calculation of the potential function for this torsional vibration revealed two symmetric energy minima separated by a small potential barrier, which suggests that the skeleton of the molecule is non-planar. Provided this result is applied to the peptide group, this can be important for understanding the physicochemical properties of polypeptides and proteins.

Formamide and its derivatives have been studied in the liquid by the method of the *R*(ν) representation (Raman) in the low-frequency region.^{34,41,42} The conclusions on the structure of H-bonded chains of formamide are analogous to the results obtained for *N*-MAA. The bands in the region of 150–200 and 110 cm⁻¹ observed for formamide are interpreted as librational modes of the molecules associated *via* the hydrogen bonds, which is in accordance with the data on degrees of the line depolarisation, temperature measurements, and the spectra of solutions.

IV. Polyamides

A large body of publications is devoted to investigations of polyamides by IR spectroscopy in the middle frequency region (see, for example, Refs 1, 43, and references cited therein) in which the problems of the structure and orientation of molecules, the hydrogen bond formation, *etc.* have been discussed. However, there are relatively few publications on the FIR spectra of polyamides. The emphasis is on revealing the correlation between the FIR spectra of polyamides and the conformations of the molecular backbone, because a number of skeletal and torsional bands sensitive to conformations are located below 700 cm⁻¹.

Nylons are known to exist in three crystalline modifications. In the α- and β-forms, planar extended chains have the *trans*-

Table 2. The comparison of frequencies and intensities of the bands in the IR, Raman, and INS spectra for *N*-MAA.

Method	T/K	ν/cm^{-1} ^a								Ref.	
IR	93	130 s								90 s	33
Raman	35	164 s		127 s	105 vs	98 sh	91 m	73 w	65 w	39	
INS	5	164 s	153 s	126 w	104 w		87 w		62 vw	40	

^a Accepted notations for band intensities: vs is very strong, s is strong, m is medium, w is weak, vw is very weak, sh is shoulder.

Figure 3. The IR spectra of the α - (a) and γ -forms (b) of nylon-6.⁴⁵ Hereinafter gaps in the spectra are connected with the special features of the equipment used: with changing of diffraction gratings, filters, changes in the thickness of the samples, etc.

conformation, in the γ -modification chains are turned about ordinary bonds neighbouring the amide groups.

A series of various kinds of nylons has been studied by the FIR^{44,45} and INS⁴⁶ methods. The IR spectra of nylon-6 in the α - and γ -modifications⁴⁵ are presented in Fig. 3. It is seen that the spectra in the low-frequency region differ substantially. Analysis of the spectra of 18 polyamides (nylons- n,m and nylons- n) made it possible to reveal the common bands typical of the planar and non-planar conformations and to give an empirical assignment for a number of bands (Table 3).⁴⁴ The difference in chain conformations is responsible for the different frequencies of such bands as 'Amide V', 'Amide VI', and 'Amide VII', which manifest themselves in the regions 700, 600, and 230–300 cm^{-1} , respectively. The bands associated with bending and torsional modes of the amide and methylene fragments of the chains appeared to be sensitive to chain rotation.²¹ The examination of the 'Amide VII' bands sensitive to conformation and bending vibrations in the range of 300 cm^{-1} allowed one to investigate chain conformations in polyamide fibres and fabrics, in particular, for nylon-6 depending on the method of sample preparation.⁴⁷ The 'Amide VII' mode for the pseudo-hexagonal crystal structure has a frequency of 205 cm^{-1} . It is noted that the X-ray diffraction method cannot distinguish satisfactorily the crystalline forms of nylon-6, in this case FIR spectroscopy appears to be very useful.

Table 3. The low-frequency absorption bands (cm^{-1}) of the amide groups for polyamides in various crystalline forms.

α -Form	γ -Form	Assignment ^a
690	715	'Amide V' (γ , NH)
580	630	'Amide VI' (γ , C=O)
360	—	Deformation of the skeleton —CH ₂ —CONH—CH ₂ —
230	300	'Amide VII' (τ , CONH)

^a γ is out-of-plane modes, τ is torsional modes.

Jakes and Krimm⁴⁸ have performed normal coordinate analysis for a series of amides and polyamides. They calculated the valence-force field for this class of compounds. The calculations performed for a series of molecules containing the amide groups fit well the experimental spectra in the middle region of frequencies. No detailed analysis of the low-frequency region has been carried out, the authors only mentioned that skeletal and torsional vibrations of the chain manifest themselves in the region below 500 cm^{-1} .

Tadokoro *et al.*²¹ calculated the frequencies in the far region for nylon-6 having the planar conformation of the chain (α -form). Besides nylon-6, these authors studied a series of polyesters [$-(\text{CH}_2)_m-\text{CO}-\text{O}-$]_{*n*} ($m = 1, 2, 4, 5$) having the planar zigzag structure in the crystalline state. The absorption bands in the spectra of the polyesters studied and nylon-6 appeared to be related to similar modes. Comparative interpretation of the spectra of these compounds was made on the basis of band calculations²¹ (Table 4). It was shown that bending and torsional modes of the chain backbone and the amide group are located in the region below 700 cm^{-1} .

Table 4. The assignment of group bands in the spectra of aliphatic polyesters and nylon-6.²¹

Frequency / cm^{-1}	Band assignment ^a	
	aliphatic polyesters	nylon-6 (α -form)
730–630	$\delta(\text{C}=\text{O})$, $\nu(\text{CH})$, $\delta(\text{skeletal})$	—
690	—	'Amide V'
590–580	$\gamma(\text{C}=\text{O})$	'Amide VI'
523 ^b	$\delta(\text{CH}_2-\text{CO}-\text{O})$, $\delta(\text{skeletal})$	$\delta(\text{CH}_2-\text{CO}-\text{N})$, $\delta(\text{skeletal})$
450–430	$\delta(\text{OCH}_2-\text{CH}_2)$, $\delta(\text{CH}_2-\text{chain})$	$\delta(\text{NCH}_2\text{CH}_2)$, $\delta(\text{CH}_2-\text{chain})$
370–295	$\delta(\text{CHCOOCH})$, $\delta(\text{CH}_2-\text{chain})$	$\delta(\text{CHCONHCH})$, $\delta(\text{CH}_2-\text{chain})$
233–195	$\tau(-\text{CO}-\text{O}-)$, $\tau(\text{CH}_2-\text{chain})$	$\tau(\text{CH}_2-\text{chain})$
150–90	$\tau(\text{CH}_2-\text{chain})$, $\tau(-\text{CO}-\text{O}-)$	$\tau(\text{CH}_2-\text{chain})$

^a Accepted notation (here and in Tables 5 and 6): ν is stretching, γ is out-of-plane, δ is bending, τ is torsional vibrations. ^b This band appears when the number of the CH₂ groups exceeds 5.

A normal coordinate analysis has been performed for isolated chains.²¹ The spectra measured at the temperature of liquid nitrogen appeared to be similar to those taken at room temperature, and the intermolecular modes did not manifest themselves in the experimental IR spectrum.

The band observed in the region of 100 cm^{-1} is believed to be associated with the coupled torsional vibrations of the methylene chains and the amide group. This band has a complex contour, its frequency shifts somewhat upon deuteration of the NH group and becomes more intense when the samples underwent annealing and thermal treatment. From these facts, the data from the studies of low-molecular-weight amides, and the fact that the paper cited reports the spectra of films,²¹ which doubtless contain the bands of the hydrogen bond, it was reasonable to assign the band in the region of 100 cm^{-1} (or, probably, one of its components) to a mode of the hydrogen bond.

It was this interpretation that was given by Frank and Fiedler⁴⁹ who considered the IR spectra of nylons in the region of 20–400 cm^{-1} . They assigned the absorption band in the region of ca. 100 cm^{-1} in all the spectra examined to the translational motion of the bonded amide groups of neighbouring chains, which they represented by the model of coupled oscillators. The frequency of this band is practically the same in the spectra of α - and γ -nylons despite the difference in conformations of the macromolecules. It can only be noticed that the half-width of the band is somewhat smaller for α -nylons.

An attempt to study moments of inertia for a repeating unit of the polymeric chain has been made on the basis of the data on the frequencies of the absorption bands assigned to the torsional modes about the C–N bond.⁴⁹ The bands at 630 cm^{-1} (nylon-2),

374 cm^{-1} (nylon-4) and 291 cm^{-1} (nylon-6) were assigned to the torsional modes about the C—N bond, the decrease in the frequency with the chain length increase was explained by the dependence of the absorption frequency on the moment of inertia of a repeating unit of the polymer. However, on going to nylons with a longer repeating unit, further decrease in the frequency was not observed. In this case, the determination of the moments of inertia for repeating units can hardly be considered correct because the band assignment is not justified, and the frequencies 630 cm^{-1} and 374 cm^{-1} are too high to be assigned to the torsional modes about the C—N bond.

Fibres of poly-*p*-phenyleneterephthalamide (Kevlar-49), the representative of aromatic polyamides, have been studied by FIR spectroscopy.^{47, 50} The FIR spectra of oriented samples in polarised light are reported without any band assignment,⁴⁷ and an attempt to interpret the spectra is made.⁵⁰ The bands were assigned (Table 5) taking into consideration data on the band dichroism and comparing the spectra obtained with those for the model low-molecular-weight substance, benzanilide, in the condensed state and in solution. The assignment of the bands associated with the intramolecular modes of the amide group in the low-frequency region is, in general, in accordance with the data on nylons. However, the assignment of the bands associated with the intermolecular vibrations raises some difficulties. For example, the bands at 253, 287, and 305 cm^{-1} assigned to external vibrations have too high frequencies for a repeating unit of such a large mass.

Table 5. The absorption bands in the IR spectra of benzanilide and poly-*p*-phenyleneterephthalamide (fibre 'Kevlar-49')⁵⁰ in the region of 30–400 cm^{-1} .

Benzanilide	Kevlar-49	Dichroism	Assignment ^a
solu- tion	condensed state	fibre	
Intramolecular modes			
109	108	112	$\pi + \sigma$ $\tau(\text{C}_p\text{—NH}) + \delta(\text{CONH})$
180	184	198	$\pi > \sigma$ $T'(A') + \delta(\text{C}_p\text{—CONH—C}_p)$
209	202	216	$\sigma > \pi$ $\tau(\text{C—N})$
295	307	331	$\pi + \sigma$ $\delta(\text{CONH})$
356	370	348	$\pi > \sigma$ $\delta(\text{C}_p\text{—CONH—C}_p)$
Intermolecular modes			
—	61	67	$\pi + \sigma$ $T'(A'')$
—	90	83	$\pi + \sigma$
—	138	138	$\sigma > \pi$ $R'(A')$
—	160	160	$\sigma > \pi$ $R'(A'')$
—	240	253	$\pi > \sigma$ $R'(A' + A'')$
—	263	287	$\pi + \sigma$ with the participation of H-bond
—	305	305	$\pi + \sigma$

^a Mode: *T* — translational, *R* — librational.

Hence, the investigation of the FIR spectra and normal coordinate analysis for polyamides allowed the interpretation of these spectra. The features of the hydrogen bond in the low-frequency region are considered, and the bands sensitive to chain conformations are revealed. This provided a possibility to apply the low-frequency region of the spectra for analytical purposes.

V. Polypeptides and amino acids

The interest in the structure of amino acids and polypeptides stems from the rapid development of molecular biology. The knowledge of the structure of amino acids gives the key to understanding the structure of proteins. The application of molecular spectroscopy

to the studies of biological systems started in the 60s. Since that time, a number of monographs^{51–53} and reviews^{54, 55} has appeared reflecting the situation in this field. The problems of molecular spectroscopy of amino acids in the middle frequency region are discussed in the monograph by Parker.⁵⁶

The examination of the low-frequency region of the spectrum is of interest, first of all, from the viewpoint of investigation of intermolecular modes including the intrinsic modes of the hydrogen bond. Series of amino acids such as glycine, D,L-alanine, D,L-leucine, and others have been studied.⁵⁷ The authors have clearly demonstrated the advantages of low-temperature spectral investigations by showing distinct shifts of the bands belonging to intermolecular modes with a decrease in temperature (Fig. 4). Assuming that the frequencies of torsional vibrations depend on temperature, the bands in the region of 500 and 200 cm^{-1} , which are 10–20 cm^{-1} shifted upon cooling to 113 K, were assigned to the torsional modes of the NH and C—C groups, respectively. The bands in the region of 100–130 cm^{-1} , which are less shifted (by 5–7 cm^{-1}), were assigned to the stretch of the NH...O hydrogen bridge.

Figure 4. The FIR spectrum of α -glycine at 298 K (1) and 113 K (2).⁵⁷

The FIR spectra of crystalline L-alanine have been comprehensively studied.^{58, 59} Using the method of deuteration, temperature measurements, and normal coordinate analysis for crystalline L-alanine, Bandekar *et al.*⁵⁹ reported a detailed assignment of the bands observed in the IR and Raman spectra of crystalline L-alanine in the region of 40–500 cm^{-1} . The calculations showed that the vibration of the hydrogen bond manifests itself at a frequency of 146 cm^{-1} , it contributes, however, to other vibrational modes with frequencies of 110–150 cm^{-1} . The correctness of the assignment of the bands associated with the vibrational modes of the hydrogen bonds is proved by their small shift (3 cm^{-1}) upon deuteration of L-alanine, which, as was mentioned above, is typical of amides. The plot of the dependence of the position of the peak at 146 cm^{-1} on temperature is depicted in Fig. 5. On the basis of these data, the authors

Figure 5. Temperature change in the position of the peak at 146 cm^{-1} in the IR spectrum of crystalline L-alanine at 300 K.⁵⁹

have performed the calculation of vibrational frequencies in the spectrum of L-alanine at 6 K. In this way the authors could follow the change in the potential energy of the crystal as the temperature decreases.

The comprehensive investigation of the spectra of low-molecular-weight amides and polyamides permitted a relatively simple progression to the interpretation of the spectra of polypeptides with the aim of establishing their structure. The bands of the amide modes such as 'Amide I' and 'Amide II' in the IR spectra and 'Amide I' and 'Amide III' in the Raman spectra (the 'Amide II' line is weak in the Raman spectra) are the main tool in this case. Although these bands reflect the structure of polypeptides, the molecules of which can exist in the helical and planar extended forms, the spectral features of different conformations can be substantially supplemented by the data on the low-frequency spectra as the low-frequency modes are especially sensitive to chain conformations. In addition, in a number of cases, low-frequency modes make it possible to quantify the content of different conformers because the bands in the low-frequency region associated with different chain conformations do not overlap neighbouring bands whereas the amide bands in the middle region, as a rule, overlap one another.

Polyglycine $(-\text{NH}-\text{CH}_2-\text{CO}-)_n$ is a polypeptide of the simplest structure, which can also be considered as a polyamide. Polyglycine exists in two crystalline modifications differing in the chain structure: polyglycine-1 (PG-1) with the planar chain conformation and polyglycine-2 (PG-2) with the helical structure. This polypeptide has been well studied by the methods of vibrational spectroscopy.¹ Thus the existence of two rotameric structures was first predicted from the data of IR spectroscopy.⁶⁰

The FIR spectrum of polyglycine was first studied by Miyazawa,⁶¹ who found that the spectra of PG-1 and PG-2 differ substantially. The INS spectra of polyglycine in the low-frequency region are reported.^{62,63} The availability of the IR, Raman, and INS spectral data has stimulated calculations of frequencies that have been carried out for both isolated chains⁶³ and crystals.^{64,65} Fanconi^{66,67} has performed an experimental and theoretical investigation of the low-frequency spectra of polyglycine in various forms and presented the most complete interpretation of the bands observed in the spectra.

Table 6 contains the assignment of the low-frequency modes for PG-1, which demonstrates the participation of the hydrogen bonds in vibrational modes in this region. As can be seen from Table 6, the band at 133 cm^{-1} observed in the FIR spectra of polyglycine is assigned to the nearly pure stretching vibration of the hydrogen bond as it accumulates 92% of the potential energy. An intense band at 82 cm^{-1} in the Raman spectrum results from the non-planar bending vibrations of this bond. Comparison of the band frequencies for polyglycine and *N*-MAA in the low-frequency region shows that the vibrations of the hydrogen bond give the bands of the same frequencies. These are the bands at 130 and 90 cm^{-1} for crystalline *N*-MAA³³ and 133 and 82 cm^{-1} for solid polyglycine. This gives reason to suppose that the hydrogen bond in the amide structures is characterised by the same vibrational frequencies regardless of the size of the molecule.

There is a discrepancy in the interpretation of the bands observed in this spectral region proposed by different authors. Itoh³³ and Nielsen²² assign the bands at 130 and 90 cm^{-1} observed for *N*-MAA to the bending and stretching modes of the hydrogen bridge, respectively, whereas Fanconi⁶⁷ interprets the band at 133 cm^{-1} for polyglycine as a stretching and that at 82 cm^{-1} as a bending vibration. These conclusions were made on the basis of theoretical calculations and seem to call for further consideration.

A number of publications^{68–74} are devoted to the studies of low-frequency spectra of the simplest chiral polypeptide, poly-L-alanine, the molecules of which also exist in two forms, *viz.* as the α -helix and the planar form. Normal coordinate analysis has been performed for both forms over all the spectral intervals (including

Table 6. Experimental and calculated frequencies for polyglycine-1 $(-\text{NH}-\text{C}^1\text{H}_2-\text{C}^2\text{O}-)_n$.⁶⁷

the low-frequency region).^{75–77} On the whole, the theoretical and experimental data were in satisfactory agreement.

Itoh *et al.*^{78–80} studied the FIR spectra for a series of poly-(α -amino acids) having helical and planar conformations of the chain and showed that each conformation has its own set of frequencies in the low-frequency region. In particular, it was shown^{69,70} for a series of polypeptides that the 'Amide V' band has a frequency about 610 cm^{-1} for compounds in the α -form, that for compounds in the β -form is in the region of 700 cm^{-1} , and a diffused band at 650 cm^{-1} corresponds to the disordered form. Itoh *et al.*^{78–80} examined the low-frequency spectra of a series of poly-(α -amino acids) and showed that the FIR region allows one to analyse the chemical and conformational composition of these homopolymers and copolymers of different amino acids.

It should be noted that Krimm and coworkers made a significant contribution to theoretical analysis of vibrational spectra of polypeptides. They have published a great number of papers including a series of papers having the common title 'Vibrational analysis of peptides, polypeptides and proteins' (*ca.* 40 publications). Thus the first publication of this series dates back to 1976,⁸¹ and one of the recent papers dates back to 1988.⁸² Krimm *et al.* have shown that normal coordinate analysis provides a rather full understanding of vibrational spectra of polypeptides and of a series of proteins having secondary structures such as α -helix, and β -layers. Normal coordinate analysis has been performed over the whole frequency interval up to lowest frequencies and in various approximations: for isolated molecules, with and without regard to hydrogen bonds, and for crystals. The value of this work is also in the fact that the force field established allowed one to perform calculations of the spectra of various conformations for both polypeptides and simplest proteins.

Recently low-frequency modes of polypeptides and proteins have attracted attention of researchers. The authors of

Figure 6. The low-frequency phonon-dispersion curves for the seven-masses model (a), one-mass model (b), and two-masses model (c) of poly-L-alanine in the form of the α -helix calculated for three values of the force constants: $F(\text{NH}\cdots\text{O}) = 0$ (1), $F(\text{NH}\cdots\text{O}) = 0.15 \times 10^{-3}$ (2), and $F(\text{NH}\cdots\text{O}) = 0.3 \times 10^{-3}$ dyne $\text{\AA}^{-1}$ (3).⁹⁰

Refs 83–85 believe that these modes play a definite role in biological processes. In particular, vibrations of the α -helix belong to these modes. ‘Breathing’ and acoustic longitudinal (of the type of ‘stretching accordion’) and transverse vibrations are the most interesting among them.

Itoh *et al.*⁷² and Fanconi *et al.*⁸⁶ were the first to calculate the frequencies of vibration of the α -helix for poly-L-alanine. The former authors considered a simplified model of the helix, in which the CH_3 group was considered as a single mass and the presence of the stabilising hydrogen bonds was taken into account. Normal coordinate analysis showed that the frequencies of 690, 370, and 260 cm^{-1} and in the region of 40–140 cm^{-1} correspond to helix deformations. The band in the range of 260 cm^{-1} was assigned to the ‘breathing’ mode, which was later confirmed by the Raman spectra.⁸⁷ The force was developed that allowed one to interpret the optically active modes of the α -helix, to calculate the frequencies of the modes with various phase difference and to obtain dispersion curves. Using these curves, which reflect the density of vibrational states, the INS spectra of poly-L-alanine were interpreted.⁸⁶ The vibrational frequencies appear to depend on the phase difference in the region below 1000 cm^{-1} , this dependence being especially pronounced in the region below 200 cm^{-1} where two acoustic modes are observed. These modes are strongly affected by hydrogen bonds.

The calculations show that in the case of the α -helix with a finite number of elementary units, the bands reflecting the helix length appear in the spectrum. Thus the frequency of the mode of the type ‘stretching of the accordion’ is inversely proportional to the helix length (n is the number of repeating units).

n	10	15	20	25	30	40	50	75	100
ν / cm^{-1}	67	50	40	32	28	24	20	15	11

Hence, the helix length can be estimated from longitudinal acoustic modes that manifest themselves in the Raman spectra. This method has found wide application in the studies of simple synthetic polymers such as polyethylene, polyoxymethylene, *etc.*^{88,89} In particular, the method permits the determination of the thickness of lamellas formed in polymers under various conditions. Using experimental data on longitudinal acoustic modes observed, the Young’s modulus of the helix can be easily calculated, which, for instance, is $E = 2.31 \times 10^{11}$ dyne cm^{-2} for poly-L-alanine.⁷²

The calculation of low-frequency modes for helices of more complex polypeptides becomes cumbersome due to the great number of atoms. In this case, simplified models can be used. Fanconi and Peticolas^{90,91} considered three simplified models of α -helix with poly-L-alanine as an example in order to calculate the

lowest-frequency modes. The first model is a seven-masses model including all the atoms of the elementary unit in which only the CH_3 group is considered as a single mass. This model is the closest to the structure of the real molecule. The second model is a one-mass model in which a repeating unit is considered as a single point mass. The third model is a two-masses model in which a chemical repeating unit devoid of the mass of the amide oxygen, is taken for one mass (this mass is located at the place of the oxygen atom in the α -helix), and the mass of the hydrogen atom located in its real position is taken for the other mass. In all the three models, the hydrogen bond is considered as a bond between the amide hydrogen and the third nearest oxygen atom thus allowing the helix structure to be reproduced.

Dispersion curves were calculated for three values of force constants of the hydrogen bond, namely, 0.3×10^{-3} dyne $\text{\AA}^{-1}$ (this force constant was taken from the force field for formic acid), 0.15×10^{-3} dyne $\text{\AA}^{-1}$ (the force constant was taken from the force field for *N*-MAA), and 0 dyne $\text{\AA}^{-1}$. The comparison of two dispersion curves obtained on the basis of these models and corresponding to the lowest-frequency modes shows (Fig. 6) that they are in good agreement with one another, the seven-masses model fits the two-masses model the best. Therefore, the lowest-frequency modes for helical structures can be calculated on the basis of a simple model that takes into account only intramolecular hydrogen bond. There is reason to suppose that this approach can be useful for the analysis of low-frequency modes of proteins.

VI. Proteins

Investigation of proteins by means of IR spectroscopy is a difficult task, for proteins have much more complex structures than synthetic polymers and polypeptides. Investigation of proteins is usually based on the analysis of the amide bands that provide information on the conformation of the backbone and side chains, on hydrogen bonding, *etc.*^{92,93} As a rule, the low-frequency region remains beyond the authors’ attention.

Buontempo *et al.*^{94,95} were among the first to study the FIR spectra of proteins. They have analysed the possibility of gaining structural information from the low-frequency modes. The authors found the presence of a wide intense absorption band centred near 150 cm^{-1} in all the FIR spectra for a series of globular proteins. Changes in the protein conformations and denaturation influence insignificantly the spectral pattern. No fine structure of the spectra in this region could be detected neither by increasing the resolution of the instrument nor by lowering the temperature of the sample. The authors supposed that the band broadening observed in the spectra of proteins originated from a

superposition of many bands corresponding to individual oscillators that have different force constants and effective masses. Since the proteins that differ significantly in the structure have practically the same spectra, the authors^{94,95} believe that the nature of this broad absorption can be rationalised by the anharmonic interaction between weak vibrations *via*, in the first turn, the H-bonded groups.

Chirgadze and Ovsepjan^{96,97} have performed more detailed investigations and have found that FIR spectroscopy can be useful for studies of conformational changes in, and denaturation of, proteins. The spectra of myoglobin reported in these papers and in Ref. 95 exhibit a broad absorption but with a rather pronounced fine structure (Fig. 7). It is seen from Fig. 7 that the bands at 376, 417, 422, and 470 cm^{-1} for natural myoglobin disappear upon denaturation of the protein in the alkaline medium, and the spectral pattern in the region below 300 cm^{-1} changes. Using the data on polypeptides with the structure of the α -helix and bearing in mind that 77% of the amino acidic residues are included in such a helix in the myoglobin under study, the authors associate the bands disappearing upon denaturation with the helical fragments of the protein molecule and propose the assignment for these bands. The changes in the bands at 324, 422, and 470 cm^{-1} reflect the changes in conformations of both the backbone and side chains. The authors obtained sufficiently good differential spectra by subtracting the spectrum of the natural protein from that of the denatured myoglobin. These spectra, however, should be regarded with due caution because false bands may result from subtraction, which have no physical meaning. These investigations⁹⁶ have led to the conclusion that FIR

Figure 7. The IR spectrum of myoglobin in the natural (continuous line) and denatured states (dotted line). Arrows point to the changes in the spectra after denaturation.⁹⁷

spectroscopy provides definite information even for such complex molecules as globular proteins.

Other authors make the same conclusion (see, for example,^{98,99}). Ataka *et al.*⁹⁹ showed that the quality of the FIR spectrum depends significantly on the method of sample preparation. He proposed to study proteins in the form of monocrystals, which made possible a decrease in the surface scattering and to obtain the material with a dense packing. In this case, the spectrum consisted of a number of pronounced absorption bands that were absent in the spectrum of the sample prepared as a powder.

The interpretation of some bands in the low-frequency region in the IR and Raman spectra for crystalline lysozyme has been carried out empirically⁷² by comparing the spectra with the data on homopolypeptides and the above-considered myoglobin. The band assignment for lysozyme is, on the whole, close to that for myoglobin.⁹⁷ The authors supposed on the basis of the data of Ref. 72 that the bands at 56 and 25 cm^{-1} are associated with

longitudinal acoustic modes of the finite chains in the α -helix having five and fifteen amino acid residues, respectively.

There is a quite definite regularity observed in the FIR region when passing from low-molecular-weight biological compounds to complex high-molecular structures. If the spectra of the former (for example, of amino acids) have a distinct structure, the spectra of the latter (for example, of proteins) contain a broad diffuse band having some fine structure (note that this picture is not observed on going from amino acids to polypeptides). The same trend is noticed for nucleic acid compounds.¹⁰⁰ The spectra of nucleosides in the low-frequency region are clear-cut, they contain well-resolved, rather intense bands, whereas the spectra of nucleotides, polynucleotides, and nucleic acids are composed of broad bands with indistinct peaks, as in the case of proteins.

The nature of broad background absorption observed in the FIR spectra of various proteins has been discussed in the papers mentioned above. Buontempo⁹⁵ believes that this absorption can be related to anharmonic interactions between low-frequency modes. According to Chirgadze,⁹⁷ at least a part of this absorption results from a wing of the broad 'Amide V' band. However, Ataka *et al.*⁹⁹ believe that the broad background in the low-frequency region originates from the absorption of water molecules present in proteins, which seems to be the closest to the truth. This follows from the comparison of the shape of absorption bands in the spectra of ice and normal water with that of crystalline lysozyme at liquid nitrogen temperature and at room temperature, respectively. In general, it should be noticed that the existence of the broad background absorption in the spectra of proteins makes it difficult to investigate their FIR spectra.

Direct normal coordinate analysis becomes difficult, if at all possible. It is connected with the fact that the secular equation for molecules containing a large number of atoms and devoid therefore of symmetry, has a very high order and its solution becomes problematic even for modern computers. However, in some cases calculations can be successfully used. Thus frequencies have been calculated¹⁰¹ for β -coils that are difficult to identify in models, but occur in globular proteins together with the α -helices and planar β -structures.

The above-mentioned simplified methods for normal coordinate analysis of the α -helix developed for polypeptides⁹⁰ have been applied to the interpretation of low-frequency modes for one of the fragments of the α -helix in the pig insulin molecule.¹⁰² The authors regarded various peptide residues as single masses. In this case, they dealt with a secular equation of the 60th order.

Raman spectroscopy is an efficient experimental tool for the studies of proteins in the region below 100 cm^{-1} . The examination of Raman spectra provides information on vibrations at very low frequencies, up to 20 cm^{-1} , *i.e.* in the region that is difficult to study by FIR spectroscopy. As was already mentioned, the water molecules present in proteins give undesirable anisotropic scattering in the frequency region of 50 cm^{-1} and below. Nevertheless, the necessary signal can be detected by both experimental expedients¹⁰³ and computer processing of the spectra.¹⁰⁴ In this way it became possible to approach the excitation line. Thus bands were observed^{103–108} in the region of 20–40 cm^{-1} in the Raman spectra of a series of crystalline proteins, bands that disappear on dissolution of the protein in water. This behaviour of the bands can be explained either by their intermolecular nature or by the fact that these bands belong to the internal vibrations, which are rapidly damped out in the presence of water molecules.

An active interest in vibrations at these frequencies is observed. These modes are believed to be potentially sensitive to the order and to play a key role in the biological functions of macromolecules. Thus the vibrations of subunits, or molecules as a whole, is supposed to determine the activity of immunoglobulin.

There are a number of approaches to the description of these vibrations. Several models have been developed in order to estimate their frequencies. A model has been proposed¹⁰⁹ in which two parts of the protein globule move relative to one

another, the presence of water damping these vibrations. The model proposed by Go¹¹⁰ considers the protein molecule as a homogeneous elastic conglomerate, which is physically justified since in the case of low-frequency modes, the wavelength is large relative to the size of side pendants in the protein molecule. To estimate the frequencies of vibrational modes, the sample of protein was considered as a system of cubes arranged in space in a regular manner. This permitted the usage of boundary conditions and the consideration of an aggregate of elastic waves in this model system. Estimations have shown that the region of vibrational frequencies in this case is limited to an interval of 18–200 cm⁻¹.

Chou^{111–114} has developed a theory of vibrations in a quasi-continuous model that allows one to calculate the so-called 'dominating low-frequency modes' for various biomacromolecules. These modes, usually termed 'breathing', correspond, in the author's opinion, to the line observed in the Raman spectra at the lowest frequency. They seem to have the maximum amplitudes and, from the biological point of view, can be considered as 'activating low-frequency modes', the existence of which will activate the biological function of the macromolecule. According to Chou's theory,¹¹³ the frequency of these modes depends on the masses of the chains under consideration, the number of their coils, the number of hydrogen bonds, and the force constants of the latter. The low-frequency modes have been studied¹¹⁴ for the immunoglobulin molecule, which is known to consist of 12 domains of light and heavy types. Considering the domains to be of three types, Chou assigned the bands at 28 and 36 cm⁻¹ observed in the Raman spectrum¹¹⁵ to the 'breathing' modes of different types of domain.

It should be noticed that in the studies of nucleic acids, the low-frequency modes of the types considered also attract interest, because these vibrations are associated with the destruction of helices and changes in hydrogen bonding in them. A series of investigations in this direction has been carried out.^{116–122} Hence, the investigation of the low-frequency modes for complex biological systems may now be spoken of as a new field in molecular biophysics.

VII. Urethanes

Polyurethanes are very important for industry, that is why they are being widely investigated by a variety of methods including IR spectroscopy.¹²³ The appearance of a great number of publications devoted to compounds of this class has been stimulated by the creation of segmented polyurethanes exhibiting a number of valuable physicochemical properties. The application of spectral methods to the investigation of hydrogen bonding, orientational behaviour of rigid and flexible segments in the deformation appeared to be rather fruitful. However, a somewhat paradoxical situation exists in the spectroscopy of polyurethanes. There is a large body of publications devoted to the IR spectra of polyurethanes in the middle spectral region, whereas the data on Raman (excluding Refs 124 and 125) and FIR spectra for polyurethanes are practically lacking in literature. Only recently, the FIR spectra of polyurethanes have been reported.^{126–128}

Partially crystalline polyurethane synthesised from diphenylmethyl diisocyanate and 2,4-toluylene diisocyanate has been studied.¹²⁶ The absorption bands at 101 cm⁻¹ for the amorphous sample and at 107 cm⁻¹ for the highly oriented sample were assigned to vibrations of the hydrogen bond. These bands are temperature-sensitive (Fig. 8), and the spectra of oriented samples exhibit perpendicular dichroism. As is seen in Fig. 8, in the spectrum of the highly oriented sample, the band at 107 cm⁻¹ shifts to 115 cm⁻¹ on cooling from room temperature to -75 °C. In the melt, this band has a frequency of 88 cm⁻¹. A large band width in the region of 100 cm⁻¹ in the spectrum of polyurethane is related to the existence of different hydrogen bonds.

In the spectrum of a solution of the polyurethane in DMF, bands at 98 and 87 cm⁻¹ are observed. The authors assign the

Figure 8. FIR (a) and polarised (b) spectra of partially crystalline polyurethane.¹²⁶

(a) The IR spectra of amorphous (1) and oriented (2) samples measured at room temperature. Curves 3 and 4 represent the spectra of the oriented sample measured at -75 and 180 °C, respectively; (b) polarised spectra of polyurethane extended by 300%: (1) the axis of polarisation is orthogonal to the axis of extension, (2) the axis of polarisation is parallel to the axis of extension.

former band to the inter-urethane hydrogen bonds and the latter to the bond between the urethane NH group and the carbonyl group in DMF. This choice of the solvent and concentration (30 mass %), is explained, probably, by the solubility of this polyurethane only in this solvent. However, DMF can form different types of hydrogen bonds with this compound and various self-associates. All this makes the band assignment rather ambiguous.

Analysis of the bands in the region of 270–400 cm⁻¹ was based on polarisation measurements for oriented samples. It is shown that the band at 320 cm⁻¹ exhibits the parallel dichroism and is sensitive to the packing of the molecules, which is seen from the changes in its intensity and half-width. This band almost disappears in the amorphous sample. By analogy with the data on polyesters,²¹ it is assigned to the coupled bending modes of the methyl and -O-CO-NH-C- groups, the main contribution to this mode being made by the bending vibrations of the methyl groups.

The bands exhibiting perpendicular dichroism are assigned to the torsional modes about the C-N bond (350 cm⁻¹) and to torsional vibrations of the CH₂ units (280 cm⁻¹) bound to the OCONH group. It might be expected that the frequency of the torsional vibration about the C-N bond should be affected by intermolecular interactions existing in the system, however, this band has the same frequency and intensity within a wide temperature interval for samples having different degrees of crystallinity, whereas the band at 100 cm⁻¹ undergoes significant changes. Unfortunately, the region of 200–270 cm⁻¹ in which, according to the literature data,^{21,45,46} these torsional modes are expected, is not covered by the interferometer used in Ref. 126.

Normal coordinate analyses for polyurethane molecules, which could be useful for a reliable assignment of the bands in the low-frequency region, are not yet available, which is why the interpretation of the bands presented in Ref. 126 has an empirical character.

Normal coordinate analysis has been performed for low-molecular-weight urethanes,^{124, 125} in particular, for urethane of the simplest structure, methyl *N*-methylcarbamate.¹²⁹ Vibrational analysis for 2,6- and 4,6-polyurethanes based on 1,6-hexamethylene diisocyanate and for a model urethane, dimethyl-1,6-hexamethylenedicarbamate, allowed only planar modes to be assigned.¹²⁵ Hence, there is no full assignment of the bands in the low-frequency region for the polyurethanes.

The absence of reliable data on normal coordinate analysis for compounds containing the urethane group and on the low-frequency region of vibrational spectra has stimulated thorough experimental studies of urethanes by FIR spectroscopy.

A series of low-molecular-weight model urethanes has been experimentally studied¹²⁷ in the FIR region. The comparison of a series of spectra for various crystalline polyurethanes synthesised on the basis of 1,6-hexamethylene diisocyanate and 2,4- and 2,6-toluylene diisocyanates allowed one to reveal a number of absorption regions in the interval of 70–400 cm⁻¹ typical of the vibrations of the urethane group, namely, 110–114, 140–170, 180–230, 270–290, 306–340, and 360–375 cm⁻¹. It was attempted to reveal the absorption bands associated with the intra- and intermolecular modes by means of temperature-dependent measurements. A decrease in temperature appeared to cause the most pronounced changes in the bands at 100–110 and 130–200 cm⁻¹, thus speaking for the assignment of these bands to the intermolecular modes (Fig. 9). A high-frequency shift of the former band, as in the case of crystalline amides, is insignificant (1–5 cm⁻¹). It is this band that is related to intrinsic vibrations of the hydrogen bond in amides³³ and in the above-considered polyurethane.¹²⁶ As for the region of 130–200 cm⁻¹, the most significant shift (15–25 cm⁻¹) as the temperature dropped to –140 °C was observed in the spectra of diurethanes synthesised from aliphatic diisocyanate. The 'Amide VII' band in which the torsional motion about the C–N bond makes the main contribution is known to lie in this region.^{33, 57, 129} The torsional mode of the urethane group neighbouring the flexible polymethylene chain is supposed to depend on the conformation of the latter and on the hydrogen bond formed in the crystal, thus leading to a temperature dependence of this band. It is also possible that in the

Figure 9. The IR spectra of diurethanes CH₃CONH(CH₂)₆NHC(=O)Bu (a) and CH₃CONHC₆H₄CH₂C₆H₄CONHCH₃ (b) in the region of 40–400 cm⁻¹ measured at 25 (1) and –140 °C (2).¹²⁷

case of aliphatic urethanes, the intrinsic vibration of the hydrogen bond contributes significantly to the absorption at this frequency.

In the spectra of urethanes containing the benzene ring, there is an absorption band at 350 cm⁻¹, which can be assigned to the vibrations of this group rather than to the torsional modes about the C–N bond.¹²⁶

Interurethane hydrogen bonds play a substantial role in the formation of associates in amorphous oligourethanes based on oligodivinyisoprene. The features of structure formation in these associates have been studied by IR spectroscopy.¹³⁰

The investigation of the FIR spectra for oligourethanes containing terminal and internal urethane groups has revealed an interesting feature.¹³¹ It was found that the spectral picture in the region of 60–250 cm⁻¹ is independent of the type of diisocyanate used in the synthesis, but is determined only by the arrangement of the urethane block. When the urethane fragments are terminal, association is facilitated for these compounds as compared to that for the compounds in which the urethane fragments are located inside the chain. In the latter case, the oligodivinyisoprene chains tend to block the urethane groups. Nevertheless, in this case, hydrogen bonds between the urethane groups are also formed. The data on the FIR spectra and on the bands of the NH– and C=O stretching vibrations indicate that not only the degree of association but also the system of hydrogen bonds are different for the oligomers with the terminal and internal positions of the urethane fragment, for the frequencies of the absorption bands of the bonded NH–, CO–, and NH...OC groups differ from one another.¹³¹ It might be supposed that the bands at 105 and 85 cm⁻¹ observed in the FIR spectra of oligourethanes with terminal and internal positions of the ure-

Figure 10. The IR spectra of urethane oligomers in the region of 60–140 cm⁻¹ with the terminal (1) and internal (2) arrangements of the urethane fragment.¹²⁸

thane groups, respectively, result from the vibrations of hydrogen bonds of various energies (Fig. 10).

Some polyurethanes have been studied by FIR spectroscopy.^{127, 128} Temperature and polarisation measurements have revealed the absorption bands in the ranges of 130–200 and 80–100 cm⁻¹ which are sensitive to the hydrogen bonds. As in the spectra of model diurethanes (see Fig. 9), two bands in the regions of 90 and 200 cm⁻¹ appeared to be temperature sensitive (Fig. 11). Both bands exhibit preferentially a perpendicular dichroism (Fig. 12). The results obtained allowed the authors to suppose that the band at 200 cm⁻¹ belongs to the torsional vibrations about the C–N bond and that at 90 cm⁻¹ is assigned to vibrations of the hydrogen bond formed between the urethane groups.

The FIR spectra of more complex cross-linked polymers^{127, 128} are very similar and independent of the nature of the diisocyanates used for the synthesis and of the concentration of cross-linkages in the polymer network. The authors of Ref. 131

Figure 11. The IR spectra of polyurethane synthesised from polybutylene glycol adipate and diphenylmethane diisocyanate in the region of $60\text{--}400\text{ cm}^{-1}$ at 120 (1), 25 (2), and $-140\text{ }^{\circ}\text{C}$ (3).¹²⁸

Figure 12. Polarised spectra of polyurethane synthesised from polybutylene glycol adipate and diphenylmethane diisocyanate extended by 350% .¹²⁸

connect the presence of the band at 85 cm^{-1} with the vibrations of the hydrogen bond.

Hence, from the FIR spectroscopic studies of urethanes that have recently been started, the absorption band was found that corresponds to the vibration of the hydrogen bond in these systems. This is a new step in research on the structure of polyurethane systems.

VIII. Conclusion

The presented material shows that the application of low-frequency vibrational spectroscopy to the investigation of amides and urethanes, and in particular, of biological objects, extends the capabilities of the analysis of molecular vibrations. Thus, many tasks connected with the studies of intramolecular and intermo-

lecular vibrations can be successfully solved for low-molecular-weight and especially crystalline compounds. However, the application of low-frequency spectroscopy to the studies of such complex biological objects as proteins resulted in a modest success. In this case, the spectrum consists of broad diffused bands with weak separate peaks on the background of this band. The comparison of calculated and experimental spectra for simple proteins indicates that only a small part of the bands expected from calculations is observed in the experimental spectra. That is why the interpretation of the bands becomes problematic.

The use of low-frequency spectroscopy for the studies of relatively simple polymeric systems such as polyamides and polypeptides is undeniably successful. In many cases, it provides unique information. Certainly, only this method makes it possible to observe experimentally the bands of intermolecular vibrations including intrinsic vibrations of hydrogen bonds. The complex of techniques has been developed to assign experimentally the bands observed in the spectra to these modes. The technique of the $R(\nu)$ representation used in Raman spectroscopy provides a possibility to investigate hydrogen bonds in liquid amides.

The use of FIR spectroscopy in studies of conformational transformations in polyamides and polypeptides has shown its advantages over spectroscopy in the middle region, for the low-frequency region is especially sensitive to chain conformations. Low-frequency spectroscopy can be useful in studies of polymorphism in polymers and of the conformational composition of macromolecules both in the qualitative and quantitative aspects.

As a rule, IR spectroscopy is beneficial for investigations of polyamides and polypeptides in the low-frequency region, whereas the Raman spectra have been less studied. Therefore, investigations of Raman spectra in the region close to the excitation line are promising, because according to existing ideas the frequencies of longitudinal acoustic modes in helices of polypeptides, proteins, and nucleic acids as well as 'breathing' modes of globular systems are located in this region. The elucidation of the mechanism of these vibrations can provide a new tool for studies of vibrations of large molecular aggregates or macromolecules as a whole.

As far as the class of urethanes is concerned, it should be noticed that despite the obvious advantages of the low-frequency method, it has scarcely been used for studies of these objects. There is rather voluminous literature on the spectra of polyurethanes in the middle region. The role of the hydrogen bond and conformations of the molecules is very important for these compounds, that is why the examination of the low-frequency region of vibrational spectra is a very interesting and promising task for understanding the structure of the substance.

III. Regioselective synthesis. C-Metal-coordinated ligand systems	407
IV. Conclusion	409

Abstract. Data on the problem of competitive coordination, obtained mainly during the last 10 years, are surveyed and treated systematically. The competitive binding of metals in complexes of bi- and poly-dentate ligand systems — simple diatomic and triatomic compounds (N_2 , O_2 , CO , CO_2 , CS_2 , *etc.*), ambident anions (CN^- , NCX^- , NO_2^- , SO_3^{2-} , *etc.*), and neutral aliphatic, aromatic, and heterocyclic compounds, including chelating organic ligands — is examined. Attention is specially concentrated on non-traditional ways in which typical ligand systems are coordinated and on regioselective synthesis as a method for the specific synthesis of metal complexes with a specified location of the coordinate bond. The bibliography includes 575 references.

I. Introduction

Competitive coordination is the term applied to the ability of bidentate and polydentate ligands to react with metal atoms at different donor (nucleophilic) centres. Investigators encountered the problem of competitive coordination for the first time a quarter of a century ago.^{1,2} Review publications^{2–24} have been devoted to individual aspects of this problem. They include reviews on the coordination of nitrogen,^{4,7,8} oxygen,^{9,10} carbon monoxide,^{11–13} and carbon dioxide^{14,15} molecules. The interest in the problem under consideration can be accounted for by the fact that it embraces problems of donor–acceptor interaction,^{18,25,26} bond isomerism,^{3,5,6,17,18,27–32} and the synthesis of complexes of a particular type (stereoselective synthesis)^{4,22,31–34} and with a specified location of the coordinate bond (regioselective synthesis)^{17,22,33–35} and specific coordination of metals in biologically important systems.^{35–39}

In order to account for the different ways in which bidentate and polydentate ligands are coordinated, Pearson's principle of hard and soft acids and bases (HSAB) was applied.^{40–42} In relation to competitive coordination,² it is formulated as follows: in polydentate ligand systems, it is possible to identify hard

(mainly N and O) and soft (P, As, Sb; S, Se, Te; π , σ -donors) reaction centres, and the HSAB principle itself indicates in this instance² the preferential binding of hard Pearson acids (metal salts) to hard donor centres and of soft acids to soft nucleophilic atoms or π -donor groups of ligands.[†]

The concepts of the 'hardness' and 'softness' of acids and bases have been examined many times.^{2,3,18,25–27,40–42,45,46} The collective nature of these concepts, embracing characteristics of the reactants such as polarisability, electronegativity, and ion size, were emphasised in this connection.^{2,3,18} Nowadays attempts are being made to develop the quantitative aspects of the HSAB concept (see, for example, Pearson⁴⁵). Pearson's attempts⁴⁵ to estimate hardness and softness theoretically merit special attention. According to Pearson⁴⁵, the future developments of these studies will involve the establishment of the relation between the difference in the energies of the highest occupied and lowest unoccupied molecular orbitals and the hardness of the system. In a later study, Datta⁴⁶ emphasises that, although hardness is an important reactivity index and has been estimated quantitatively, a full theoretical justification of the HSAB principle, *i.e.* the principle that 'hard likes hard' and 'soft likes soft', has not yet been achieved. In a study of the thermodynamics of exchange reactions of the type

with participation of lithium hydrides and halides, hydrogen halides, monohalo-derivatives of methane and silane, and other reagents,⁴⁶ he concluded that the formation of the hardest of the possible compounds is the driving force of the exchange reaction and that the average hardness of the products becomes greater than that of the initial compounds.

It is noteworthy that, although bidentate and polydentate ligand systems with soft and hard donor centres include a wide range of compounds, they do not embrace the entire series of ligands. Thus they do not include molecules which contain only hard or only soft nucleophilic centres and are capable of binding to the metal in different ways.

Evidently the HSAB approach reduces the number of ligand systems which could be considered within the framework of the problem of the competitive coordination of bidentate and polydentate ligands.

In the present review, we tried to examine all the possible ways in which the coordinate bond can be located in complexes with the

[†] The possibility of employing the HSAB concept to explain the different ways in which ligands are bound to metals in complexes was first demonstrated in relation to complexes of pseudohalide anions.^{43,44}

most familiar ligands — both with simple inorganic molecules and with complicated organic compounds having several donor atoms and groups. Attention is concentrated on the nontraditional ways in which typical ligands are coordinated and on regioselective synthesis. Mainly the literature of the last 10 years has been used in the review.

II. Types of competitively reacting ligands

For a correct understanding and assessment of the regioselectivity of complex formation reactions, it is necessary to consider only thermodynamically stable products (complexes) formed under the conditions of kinetic control.^{3, 47} In other words, one is dealing with the thermodynamic stability of the products of the initial attack by the metal (complex-forming agent) on the nucleophilic centre of the ligand. This postulate is extremely significant, since in many cases complexes in which the ligands are prone to tautomerism undergo various metallotropic processes.^{48–56} The latter are frequently accompanied by a change in the centre where the coordinate bond is located in relation to the expected location.

Ligand systems forming bond isomers comprise bidentate and polydentate and homogeneous and heterogeneous inorganic compounds, ambident[‡] anions,¹ and diverse organic compounds.

1. Inorganic molecules

The homoatomic nitrogen,^{4, 8, 57–66} phosphorus,^{67–69} and arsenic^{69, 70} molecules in coordination compounds of metals function as monodentate or bidentate ligands and are coordinated in three main structurally demonstrated ways (structures 1–3).

E = N, P, As.

Apart from the structures indicated, complexes described by formulae 4,^{8, 71} and 5⁸ (see also the footnote below⁸) have been noted.

The bond isomers of the nitrogen complexes 1 and 2 may be in equilibrium. Thus exchange described by the following equilibrium reaction has been detected for the compound $[(\eta^5\text{-C}_5\text{Me}_5)\text{Re}(\text{CO})_2\text{N}_2]$ by ¹⁵N NMR.⁶²

Bond isomers similar to complexes 1–3 are characteristic also of the complexes formed by diatomic oxygen (structures 6–8),^{9, 10, 72} sulfur,^{73–75} selenium,^{76, 77} and tellurium^{77–82} molecules.

Among inorganic homoelement ligands, compounds containing three and more atoms are encountered. This is particularly characteristic of phosphorus, for which metal complexes based on trimeric,⁸² tetrameric,⁸³ pentameric,⁸⁴ and hexameric^{85–87} phosphorus-containing ligand systems with different locations of the coordinate bond have been obtained. It is striking that the P₆

molecule can behave not only as a η^6 -coordinated ligand (for example, in the triple-deck complex 9),⁷⁶ but also as a η^3, η^3 -binding ligand system (complex 10).⁸⁷

Different types of coordination of Se_n and Te_n molecules have been considered in a review.⁸²

The heteroelement diatomic CO,^{4, 11–13, 27, 28, 69, 88–90} CS,^{69, 91–93} and NO^{69, 94–96} molecules also behave as monodentate and bidentate ligands and can function as both terminal and bridging ligands. For example, the formation of the following structures has been demonstrated for carbon monoxide:

Similar types of coordination are characteristic of carbon monosulfide^{91–93} and nitrogen monoxide.^{94–96}

There are various types of coordination of heteroelement triatomic molecules: CO₂,^{14, 15, 69, 97} COS,¹⁵ CS₂,^{15, 98–100} and SO₂.^{5, 69, 101–105} The formation of three types of metal — ligand bonds (compounds 15–17) has been demonstrated^{15, 97} for carbon dioxide complexes with the aid of X-ray diffraction (XRD) data.

The type 15 (X = O) structure is characteristic of the cobalt complex 18,⁹⁷ while structure 17 (X = O) occurs in the nickel complex 19.¹⁵

Like CO₂, carbon disulfide is bound to the metal in different ways.¹⁵ For example, in the dinuclear complex $[\text{Mn}_2(\text{CO})_9(\text{CS}_2)\text{PPh}_3]$ ¹⁰⁰ the above ligand behaves as a S-monodentate species, while in the manganese complexes 20 and 21 (Cy = cyclohexyl) the same ligand system behaves as a C–S bridge.¹⁰⁰

20: L = L' = CO;

21: L = L' = Ph₂PCH₂PPh₂.

[‡] Ambident systems are inorganic and organic molecules and ions with conjugated donor atoms.

§ R J Deeth, S A Laytord *J. Chem. Soc., Dalton Trans.* 1 (1995); N Desmangles, H Jenkins, K B Rupp, S Gamborotta. *Inorg. Chim. Acta* **250** 1 (1996)

Five modes of coordination (compounds **22–26**) are characteristic of sulfur dioxide complexes,^{69, 101–105} two of the compounds (**22** and **23**) being stereoisomeric.

In particular, it has been demonstrated by X-ray diffraction¹⁰¹ that structure **27** with a cis-planar dioxide fragment (type **22**) occurs in the complex $[\text{RhCl}(\text{PCy}_3)_2(\eta^1\text{-SO}_2)]$.

The pyramidal O,S-binding of the SO_2 group is characteristic of the complexes $[\text{Mo}(\text{CO})_3(\text{Bipy})(\eta^2\text{-SO}_2)]$ and $[\text{Mo}(\text{CO})_3(o\text{-Phen})(\eta^2\text{-SO}_2)]$ with the same fragment (structures **28** and **29**, type **24**).

Bond isomers of metal complexes of heteroelement ligands, the molecules of which incorporate four (N_2S_2),¹⁰⁶ six (N_2S_4),¹⁰⁷ and eight (N_4S_4)¹⁰⁸ heteroatoms, have been described.

2. Ambident inorganic anions

Among ambident anions, the following have been most thoroughly investigated as competitively reacting ligands: cyanide^{5, 16, 27, 28, 109–113} nitrite,^{3, 5, 18, 27, 28, 114–119} sulfite,^{5, 18, 103, 117, 118, 120} and triatomic pseudohalides,^{2–5, 17, 18, 31, 32, 43, 44, 121–125}

The formation of structures of three types (**30–32**) has been demonstrated for the cyanide anion.^{5, 16, 27, 112}

In addition, the coordination types **33–37** are possible^{16, 27} (the last two types of coordination correspond to the two stereoisomers **36** and **37**).

The above C,N-isomerisation has been observed in the following bimetallic complexes: Cr, Ag; Co, Co; Cr, Co.

Eight types of bond isomers (**38–45**) have been proposed for complexes of nitrite anions.^{5, 27, 114, 119}

The stereoisomers of anionic metal nitrite complexes have also been described:⁵ angular (**46**) and *trans*-planar (**47**).

Numerous specific examples of nitrite complexes have been presented in a review.⁵

The complexes of the sulfite anion are represented by bond isomers in which the SO_3^{2-} fragment behaves as S- (**48**),^{2, 3, 5, 103, 118} O- (**49**),^{5, 18, 103} and O,O-chelate (**50**)^{5, 103} ligands or an O,S-bridging ligand (**51**).^{103, 117, 118}

Other variants of coordination have also been put forward for dinuclear and polynuclear complexes of the SO_3^{2-} anion.¹⁰³ In the majority of these complexes the location of the coordinate bond has been established from vibrational spectroscopic data and the results of kinetic studies.^{5, 103} Definite progress has been achieved in the study of the structures of sulfite complexes by NMR spectroscopy involving different nuclei.^{117, 118, 125, 126} It has been established by X-ray diffraction^{118, 125} that the three cobalt atoms in the trinuclear anion of the complex $\text{Na}_4[\text{Co}_3(\text{NH}_3)_6(\text{SO}_3)_6]$ are linked by the bridging SO_3 group. The SO_3 groups are bound to two cobalt atoms via sulfur atoms and to the third cobalt atom *via* an oxygen atom.^{118, 125} The metal atoms are coordinated *via* oxygen and chalcogen atoms in complexes of the selenite^{5, 118, 125} and tellurite^{118, 125} anions. On the other hand, the sulfate anion is usually bound to the metal atoms *via* an oxygen atom and performs mainly a bridging function.^{127–130}

For complexes of pseudohalide anions (NCX , where $\text{X} = \text{O}, \text{S}, \text{or Se}$), the structures with ten modes of coordination (**52–61**) of the NCS anion as an example have been proposed.^{4, 5, 17, 18, 43, 44, 124}

Extensive compilations of X-ray diffraction data for different modes of coordination of NCX anions are available in monographs^{17, 44} and reviews.^{5, 124} The greatest number of complexes contain the $\text{M}-\text{N}=\text{C}=\text{X}$ fragment (**52**). This type of coordina-

tion is characteristic of, for example, gallium,¹³¹ indium,¹³² tin,^{133, 134} iron,^{135–137} cobalt,^{138, 139} manganese,^{140, 141} nickel,^{142, 143} and copper^{144–149} complexes.

An analogous M–NCS coordination has been observed also in chelate complexes, for example complexes **62**¹⁵⁰ and **63**.¹⁵¹

The Fe–NCS coordination in the adducts **62** and **63** was demonstrated by X-ray diffraction. The number of structures of the pseudohalide complexes in which the M–X–C≡N coordination (**53**) occurs is significantly smaller. Such structures are observed mainly in complexes of soft metals.^{2–5, 17, 18, 43, 44, 124, 152, 153} It is striking that there are virtually no descriptions of structures with a pure M–SCN bond in the literature of recent years, although in certain cases (see, for example, Maurya *et al.*,¹⁵⁴) its occurrence has been postulated.

Complexes with a bridging M–NCS–M' bond occupy an important place among the coordination compounds of pseudohalides. Early information about such structures is available in reviews^{5, 34, 44, 122, 124, 152} and monographs.^{4, 17, 18} Among the studies in recent years, we shall mention those devoted to the structures of bismuth(III),¹⁵⁵ antimony(III),¹⁵⁶ molybdenum(IV),¹⁵⁷ nickel(II),^{158, 159} copper,^{160, 161} and ruthenium(IV)¹⁶² pseudohalide complexes as well as the heterodinuclear lanthanum–mercury complex.¹⁶³ Soft–hard Hg–SCN bonding and hard–hard La–CNS bonding are observed in the La–Hg complex. The latter type of bonding is characteristic also of the mononuclear lanthanum thiocyanate compound La(NCS)₃·2(Me₂N)₃PO.¹⁶⁴

The structure of the complex AgLSCN·0.25L (L = α,α-bipyridyl),¹⁶⁵ in which the rarely encountered type **55** coordination occurs, is of undoubted interest.

The data presented above on the competitive reactions of pseudohalide ions refer mainly to soft–hard interactions,^{2, 3, 5, 18} i.e. they take into account the nature of the donor N,X atoms on the complex-forming metals. At the same time, one should bear in mind that the nature of other ligands and the conditions in the synthesis of the pseudohalide complex exert an extremely significant influence on the nature of the binding of NCX anions to metals. Extensive data, partly published in Refs 4, 17, 122, 124, 153, 165, and 166, have accumulated on these problems. Bond isomerism of the type MNCS⇌MSCN is quite frequently observed in complexes of this type.^{4, 123, 167}

It is noteworthy that the results of a recent *ab initio* quantum-chemical calculation for pseudohalide ions¹⁶⁸ indicate the possibility of the chelation of the NCX groups. However, there are as yet no experimental data confirming this conclusion.

There are data on various modes of coordination of other ambident anions also: CNO[–] (see, for example, Refs 5 and 17), CNS[–],⁵ [C(CN)₃][–],¹⁷ NO₃[–],^{27, 28, 169, 170} NSO[–],^{5, 169} SNO[–],⁵ NSO₂[–],¹⁶⁹ S₂O₃^{2–},^{3, 5, 18, 103, 117, 118, 171} S₂CO₃^{2–},⁵ OSNH[–],⁵ and NS₃[–].¹⁶⁹

3. Organic bidentate and polydentate ligand systems with donor atoms — the elements of the main Group V and VI subgroups

Extensive data on the competitive coordination of organic bidentate and polydentate ligands have been collected in reviews^{2, 3, 5, 6, 29, 30} and monographs.^{4, 17, 18, 25, 26} In the present review, the fundamental results in this field achieved in recent years will be considered.

Two reviews^{172, 173} contain compilations of data on ligands with N,P-donor atoms and the complexes obtained from them. It had been shown earlier that mainly the phosphorus atom participates in the coordinate bond formed in complexes of these ligands. However, when the disposition of the nucleophilic centres is favourable for the formation of a bridge or chelation, metalocyclic structures with participation of N and P atoms are obtained regardless of the hardness or softness of the metal salts. Thus the formation of at least seven types of transition metal complexes (**A–G**) is possible for the amides of the imidophosphonous acid R¹R²N–P=NR³.¹⁷²

The possible structures **H** and **I**, in which coordination is achieved *via* the nitrogen atom, were not considered in the above study¹⁷² for reasons which are not clear.

A similar situation is characteristic also of ligands containing a donor oxygen atom (compounds **65**,¹⁷⁵ **66**,^{176, 177} **67**, and **68**,^{173, 178}) apart from the N,P atoms (compound **64**¹⁷⁴).

An increase in the electron-donating activity of the carbonyl oxygen compared with the ester oxygen (structure **65**) and a disposition of the donor centres suitable for chelation lead to the chelate structure **69**.¹⁷⁸

Phosphazenes, the coordination chemistry of which involves a series of complexes with hard (N) and soft (P) coordination, are N,P-donor ligands.^{18, 179} Several examples of complexes obtained from N,As(Sb)-containing ligands are known,^{18, 175} but these do not allow a discussion of the characteristic features of their competitive reactions.

There are comparatively few new data on the competitive coordination of N,O-donors. The study of the structures of the complexes SnCl_4 and EtSnCl_3 with tetramethylurea confirmed² that the latter is a predominantly monodentate O-donor ligand.^{180, 181} Thus an O–Sn bond is formed in the complex between 1,3-dimethylurea and SnCl_4 . This conclusion was reached on the basis of IR and Mössbauer spectroscopic data.¹⁸¹ We may note that reliable information about the possibility of the involvement of the urea nitrogen atoms in coordination is lacking in the studies published previously. Complexes with N-coordinated urea **70**, obtained as a result of the reaction¹⁸²

are therefore of undoubted interest.

The coordination chemistry of organopseudohalides of the type RNCX ($\text{X} = \text{O}, \text{S}, \text{Se}, \text{Te}$) has been examined in a review.¹⁸² It is remarkable that the interaction of ligands of this type with metal salts and carbonyls is accompanied not only by the formation of the adducts $(\text{RNCX})_m \cdot \text{RX}_n$ but also by chemical reactions of the ligand systems.¹⁸²

Among the ligands containing N- and S-donor centres, thiourea (L) and its derivatives are widely represented. Thus complexes between thiourea and ruthenium(III) trifluorosulfonate¹⁸³ and copper(II) bis(dimethylglyoximate),¹⁸⁴ between 1,3-dimethylurea and tin chloride,¹⁸¹ between 1,3-diphenylurea and rhodium(I) chloride,¹⁸⁵ and between ethylenethiourea and copper(I) sulfate¹⁸⁶ have been obtained. It has been suggested that S–N coordination obtains in the chelate complexes **71**.^{187, 187} **72**,¹⁸⁷ **73**,¹⁸⁸ and **74**.¹⁸⁸

$\text{R} = \text{H}, \text{Alk}, \text{Ar}; \text{R}^1, \text{R}^2 = \text{Alk}, \text{Ar};$

$\text{M} = \text{Cu(I)}, \text{Ag(I)}; \text{X} = \text{Cl}, \text{Br}.$

Whereas the occurrence of structures **73** and **74** is not open to serious objections, the possibility of the involvement of S and not N atoms of the thiazole ring (structures **71** and **72**) is hardly realistic.^{189, 190} The chelate structure **75** is believed probable for

the complex between a diaminodithioether and palladium chloride.¹⁹¹

Coordination compounds of N,Se-containing ligands are mainly represented^{2, 18, 192–194} by selenourea complexes in which the Se–M bond is formed (compound **76**). In particular, such a bond has been found (on the basis of XRD data) in the complex of selenourea with triphenylphosphinegold(I) chloride **76** ($\text{MX}_n = \text{Ph}_3\text{PAuCl}$).¹⁹⁴

The interest in complexes containing N,Te-donor ligands has increased recently, although individual examples of such compounds had been examined also in earlier investigations.^{18, 81, 193, 195–197} A series of studies^{198–211} (among them a review²⁰⁴) devoted to complexes of ligands with N,Te-donor centres have been published during the last six years. However, the problem of competitive coordination was not discussed in these publications. In our view, this can be explained by the fact that in most other investigations conditions were created for the monodentate M–Te coordination of the ligands considered or for the formation of N–M–Te metalocycles. Thus, owing to the high donor activity of the chalcogen atom and the steric effects preventing the occurrence of M–N coordination, the ligand behaves as a monodentate Te-donor in the tellourea complex **77**,¹⁹⁵ as in the thio- and seleno-analogues examined above.

The steric effect apparently prevents the involvement in chelation of the potentially bidentate ligand **78**, the mercury bromide complex of which has the structure **79** according to X-ray diffraction data.²⁰¹

At the same time, it is believed²⁰³ that ligands **78** and **80** form with rhodium(I) and rhodium(III) chlorides chelate structures having N,Te-coordination.

The formation of the chelate structure **81** has been demonstrated by X-ray diffraction.²¹² A similar structure is characteristic also of type **82** complexes.^{207, 209}

The tellurium-containing azomethines **83** must also be regarded as potential N,Te-chelating ligands.²¹³ However, the ligand system in the palladium dichloride complexes obtained from them behaves as a Te-monodentate system, forming, in particular, complex L_2PdCl_2 with structure **84**.²¹⁰

Although the location of the coordinate bond in complex **84** is justified from the standpoint of the HSAB principle, one cannot rule out that the decrease in the denticity of ligand **83** can be accounted for by the formation of the intramolecular Te...N bond,^{212, 217} which virtually deprives the azomethine nitrogen atom of the possibility of becoming coordinated to the metal. Ligands **85**^{18, 218} and **86**²¹¹ are free from the above disadvantages.

A cycle of reactions of *N*-alkyltellurazines **85** has been achieved with Pearson acids: soft (MX_n = rhodium carbonyl chlorides, palladium, silver, and mercury halides) (with formation of complexes **87**), intermediate ($CuCl_2$) (with formation of complex **88**), and hard (TaF_5) (with formation of complexes **89**).^{18, 219}

The structures of the products formed have been justified by IR and NMR spectroscopic data and by studying their chemical behaviour.^{18, 196} In conformity with the HSAB principle,¹⁸ ligand **86** (L) interacts with chromium, molybdenum, and tungsten (M) hexacarbonyls to form complexes of the type $LM(CO)_5$ with a

M–Te bond, which has been rigorously demonstrated²¹¹ by X-ray diffraction in relation to complex **90**.

Fairly numerous publications have been devoted to complexes with ambident ligands containing O, S-donor centres.^{2, 18, 103} Those devoted to the competitive reaction of organosulfoxides, especially dialkyl(aryl) sulfoxides forming O-bonded (compounds **91**)^{220–227} and S-bonded (compounds **92**)^{228–239} isomers are outstanding among them.

The occurrence of O→M coordination **91** has been demonstrated by X-ray diffraction in relation to complexes of dimethyl sulfoxide (DMSO) with trichlorodiphenylantimony(V)²²⁰ and zirconium tetrachloride,²²² ionic complexes of osmium,²²³ and heterometallic compounds.^{224–227}

It also follows from X-ray diffraction data that S→M bonding is characteristic²²⁸ of the isomeric adducts of DMSO and the platinum chelate complexes of pyridine- α -carboxylic acid **93** and **94**.

The same type of coordination is observed in the complexes $\{[Pt(NH_3)_4][PtCl_3(DMSO)]_2\}$,²²⁹ $\{[PtCl_3(DMSO)_2L]DMSO\}$,²³⁰ $[Pt(DMSO)(CH_3CN)Cl_2]$,²³¹ $[Pt(DMSO)(Py)Cl_2]$,²³² $\{K[Pt.(Et_2SO)Br_3]\}$,²³³ $[RuCl_2(DMSO)_3(NH_3)]$, $\{[Ru(DMSO)_2.(NH_3)_2]H_2O\}$,²³⁴ $\{[H(DMSO)_2]^+[RuCl_4(DMSO)_2]^- \}$,²³⁵ $\{[H(DMSO)_2]^+[OsNO(DMSO)Cl_4]^- \}$.²³⁶

We may note that the structure containing the $[H(DMSO)_2]^+$ cation had been described earlier for the complex between iridium chloride and DMSO.²³⁷

S,S'-Coordination has also been observed in the complex between palladium chloride and the podand **96**.²³⁸

It has been suggested that several types of coordination of the ligand (O-, S-, or bridging O,S-coordination) may occur simultaneously in the DMSO complexes. It is believed²³⁹ that such a situation is observed in complexes of dibenzyl and tetramethylene sulfoxides of the type $[PtL_2Cl_2]$ and $[ML_3Cl_3]$, where M = Ru(III), Rh(III), and Ir(III). Finally, we may draw attention to the

extremely unexpected result obtained in a study²⁴⁰ of the structure of the complex $\{[\text{EuL}_3\text{Phen}(\text{H}_2\text{O})_2]\text{DMSO}\}$, where $\text{L} = \text{C}_5\text{H}_4\text{NCO}_2^-$ is the anion of nicotinic acid. In this complex, the DMSO molecule is not involved in coordination with the metal but forms a hydrogen bond with the oxygen atom of one of the coordinated water molecules.

Analysis of the data presented shows that in virtually all cases DMSO is coordinated in accordance with the HSAB principle: hard Pearson acids are bound to the oxygen atom and soft acids are bound to the sulfur atom.

There are comparatively few examples of complexes containing O,Se- or O,Te-donor atoms.^{18, 204} It is believed that the M–O bond is mainly formed in dimethyl selenoxide complexes.¹⁸ It is so far difficult to discuss competitive coordination in the series of O,Te-containing compounds presented,^{204, 216, 241–243} since there are no structural data for the few available O,Te-containing ligands which have not been used to obtain complexes.^{18, 204, 241, 244, 245}

In conclusion of this section we may note that the review of Singh and Srivastava²⁰⁴ contains data on the complexes of a series of ligands containing the N-, P-, S- and Se-donor atoms in addition to tellurium, for example, compounds **97** and **98**.

Ligands **99** and **100**, containing three donor atoms, are not without interest in connection with the problem of competitive coordination under discussion.²⁴⁶

4. Heteroaromatic compounds and their derivatives

Heteroaromatic compounds belong to ambident $\sigma, \sigma', \sigma, \pi$ -, and π, π' -ligand systems,^{247–249} which interact with metals or their salts and also with organometallic derivatives to form complexes in which these ligands are bound to the metal atom either *via* the heteroatom or *via* the π -system.^{2, 18–21} When competitive coordination is considered, the ligands of this type can be usefully divided into two varieties:^{19–21} π -excess and π -deficient ligands. According to the literature,^{250, 251} five-membered heterocyclic compounds of type **101**, in which the number of π electrons exceeds the number of atoms in the ring, belong to ligands of the first variety. These are pyrrole (**101**: A = NR; R = H, Alk, Ar), phosphole (**101**: A = PR), arsole (**101**: A = AsR), stibole (**101**: A = SbR), furan (**101**: A = O), thiophene (**101**: A = S), selenophene (**101**: A = Se), and tellurophene (**101**: A = Te) ligand systems. The ligands of the second type include pyridine (**102**) and other six-membered nitrogen-containing heterocycles (azines) with one or several heteroatoms (**103**). The azoles **104** can be formally^{250, 251} assigned to π -excess systems.

A = NR, PR, AsR, SbR, O, S, Se, Te.

A = NR', O, S, Se, Te; R = H, Alk, Ar, benzo.

It has been shown in numerous investigations that the π -excess ligand systems form mainly type **105** $\eta^5(\pi)$ -complexes, while π -deficient ligands give rise to $\eta^1(\text{N})$ -metallo-derivatives of type **106**.

A = NR, PR, AsR, SbR, O, S, Se, Te.

The azole ligands behave in complex formation reactions as π -deficient species (complexes **107a, b**).

A = NR, O, S, Se.

It will be shown below that, although these rules hold for numerous examples of complexes of heteroaromatic ligand systems, there are quite a few complexes of type **101** and **102** ligands with a non-traditional location of the coordinate bond.

a. Complexes of five-membered heterocycles containing one heteroatom

Reviews^{19, 20, 84, 252} and other publications^{18, 253} contain numerous examples indicating the formation of type **105** $\eta^5(\pi)$ -complexes based on pyrrole (A = NR), phosphole (A = PR), arsole (A = AsR), stibole (A = SbR), thiophene (A = S), selenophene (A = Se), and tellurophene (A = Te). Fragments of metal carbonyls, mainly $\text{Mn}(\text{CO})_3$ and $\text{Cr}(\text{CO})_3$, usually serve as the Lewis acids MX_n .

In addition to complexes of this type, sandwich structures of type **108** and **109** are quite widely represented among η^5 -coordinated systems.

The $\eta^1(\sigma)$ -coordinated structures **110** and **111** have been obtained mainly from pyrroles **105**: A = NR, R = H, Alk, Ar) and phospholes (**105**: A = PR, R = H, Alk, Ar). Apart from the N-metal-substituted compounds **110** (see, for example, Refs 253 and 254), the organometallic compounds **112** and **113** have been described²⁰ among the N-coordinated pyrrole complexes.

The P-coordinated phosphorus complexes are represented,^{20, 84, 255, 256} by structures of two types (**114** and **115**), structure **114** being more common than structure **115**.

We are not aware of type **110** and **111** complexes in the arsole (A = As), stibole (A = Sb), and bismuthole (A = Bi) series.

The question of the possibility of the involvement in coordination of the furan ring oxygen atom remains unelucidated. We may note in this connection a recently published communication²⁵⁷ in which the hitherto unique example of a complex with a O—M coordinate bond is described (complex **116**).

In the absence of X-ray diffraction data, the structure of compound **116**, described on the basis of IR and ¹H NMR spectroscopic studies,²⁴⁷ gives rise to doubt.

The involvement in coordination of the furan ring oxygen atom forming part of the composition of macrocyclic ligands, for example compound **117**, is more realistic.²⁵⁸

R = Alk, CH₂CH₂OAlk.

The stabilisation of structures **116** and **117** is apparently associated with chelate and macrocyclic effects.²⁵⁹ We may also note that an organometallic compound with a M—C bond may be formed from furan (see, for example, Selna and Merob²⁶⁰).

In contrast to furan complexes, thiophene complexes with the sulfur-centred coordinate bond are represented by a large set of structures.^{20, 261} In particular, such coordination has been observed in the ionic complex **118**.²⁰

$\eta^1(\text{S})$ -Coordination is also characteristic of the dibenzothiophene complexes **119**.²⁶²

An example of the involvement in coordination of the selenophene Se atom (complex **120**) is known.²⁶³

$\eta^1(\text{Te})$ -Coordinated tellurophene complexes are represented by the palladium chloride compounds **121** and **122**, the structures of which have been frequently considered, for example in reviews.^{81, 193, 195} A similar coordination has apparently been observed in complexes of tellurium-containing heterocycles with univalent and trivalent rhodium chlorides and carbonyl chlorides.²⁶⁴

In a number of instances, type **101** ligand systems behave as bidentate and even tridentate ligands.²⁰ Complexes have been formed in which A(σ)- or A(σ), π -metal bonds are formed. Such nonstandard $\eta^3(\text{N}, \sigma)$ -coordination has been observed in the pyrrole cluster **123**.²⁰

M = MN, Re; A = P, As.

Complexes with η^2 -coordinated phosphorus are particularly widely represented in the series of phosphole and its derivatives.²⁰ In particular, such coordination has been observed in the manganese and rhenium dimers **124**.²⁰ The reaction of 3,4-dimethyl-2-phenylphosphocymantrene **125** with the benzonitrile complex of palladium dichloride in methylene chloride afforded the dinuclear palladium cluster **126** with η^2 -coordinated phosphorus.²⁶⁵

The same type of coordination of phosphorus occurs in the trinuclear cluster **127** obtained in the course of the following reaction:²⁶⁵

DBA = dibenzylideneacetate anion.

η^2 -Bonding is observed also in the analogous arsole complexes **124** (A = As)²⁰ and also in the thiophene complexes **128**²⁶⁶ and **129**.²⁶⁷

In this connection, we may mention the polymeric iron complex of pyrrole in which the heterocycle is involved in coordination of the $\eta^1(\sigma)$ - and $\eta^5(\pi)$ -types.^{20, 268} The same coordination is characteristic²⁰ of phosphole complexes, for example compound **130**.

A heteronuclear complex of *C*-phenylphosphocymantrene with tungsten pentacarbonyl (compound **131**), in which phosphole also behaves as a σ, π -donor ligand system, has been described.²⁶⁹

The complexes of phospholes containing several phosphorus atoms in the heterocycle are quite widely represented.⁸⁴ The possible variants of their bonding to metals are presented below (structures **A** – **M**).⁸⁴

Other examples of complexes with heterocycles **101** bound to the metal in different ways have been described in reviews^{20, 270} and other communications.^{271–274}

b. Complexes of azines

The commonest and well known mode of coordination of pyridine and other six-membered nitrogen-containing heterocycles is N(σ)-bonding to the metal, which is indicated by the early reviews.^{18, 19, 275–277} Among the studies published in recent years, we shall mention data concerning the complexes of N-coordinated pyridine with BH_2CN ²⁷⁸ and the ruthenium-cyclopentadienyl fragment²⁷⁹ and a series of publications by Italian investigators^{280–284} devoted to the properties and structures of the adducts of pyridine and chelates modelling the fragments of biologically important systems (in particular vitamin B₁₂) and the corrole complex of iron.²⁸⁵

The structure of the adduct of pyridine and copper(II) acetate, in which N – Cu coordination also occurs, has been revised.²⁸⁶

Studies in which the metal is coordinated to several pyridine molecules with formation of the complexes MPy_n are of interest.^{287, 288} The $\eta^1(\text{N})$ -coordination of pyridine in the dinuclear rhodium complexes $[\text{Rh}_2(\text{MeCOO})_3\text{Py}_4]\text{CF}_3\text{SO}_3$ and $[\text{Rh}_2(\text{MeCOO})_2\text{Py}_6](\text{CF}_3\text{SO}_3)_2$ has been demonstrated by X-ray diffraction.²⁸⁹

The $\eta^1(\text{N})$ -coordination of azines was believed to be the only one possible up to the middle of the 1970s, to a considerable extent as a result of the unsuccessful attempt to obtain $\eta^6(\pi)$ -coordinated pyridine complexes by Fischer — a Nobel Laureate.²⁹⁰ However, the unusual $\eta^6(\pi)$ -complexes of pyridine **132**,²⁹¹ **133**,^{292, 293} and **134**^{294–296} were synthesised in independent investigations in the course of 1975–1976.

Complexes of types **133**²⁹⁷ and **134**²⁹⁸ with unsubstituted pyridine (R = H) were later obtained and in both cases trimethylsilylpyridine derivatives served as the starting compounds.

We may note that the direct gas-phase synthesis of the type **132** and **134** π -complexes of pyridine from the zerovalent metals played a decisive role.^{299, 300}

The η^6 -2,4,6-collidine(triphenylphosphine)chromium dicarbonyl complex **135** has been synthesised³⁰¹ and characterised by X-ray diffraction.³⁰²

Complexes similar to complex **132** have also been obtained from molybdenum (complex **136**³⁰³).

The mixed-ligand complex **137** has been obtained by the gas-phase cocondensation of three components — pyridine, benzene, and zerovalent chromium.²⁹⁸

The complexes of the phosphorus analogue of pyridine — phosphabenzene — (compounds **138**–**141**) are represented by a fairly wide range of compounds. Among them, the coordination compounds **138**^{304, 305} and **139**^{306–309} are $\eta^1(\sigma)$ -coordinated, while compounds **140**^{304, 310} and **141**^{304, 311, 312} are $\eta^6(\pi)$ -coordinated.

Complex **142**, in which mixed $\eta^1(\sigma)$ - and $\eta^6(\pi)$ -coordination of 4-phenylphosphabenzene occurs,³⁰⁴ and the heteroligand sandwich complex of four- and six-membered diphosphorus heterocycles **143**²⁷⁴ are also of undoubted interest.

α, α' -Diphosphaphenyl (the phosphorus analogue of α, α' -bipyridyl) is bound to nickel in a way similar to that in compound **139**³¹³ with formation of complex **144**.

Complexes of $\eta^6(\pi)$ -coordinated arsa-1,3,5-cyclohexatriene **145** (M = Cr,³¹⁴ Ti,³¹⁴ and V³¹⁵) have been described.

c. Coordination compounds of azoles

Until recently, it was believed that, in contrast to the heterocycles **101** and the azines **102** and **103**, azoles form only complexes in which the ligands are bound to the metal *via* the N atom of the pyridine ring. The ligand systems then behave as monodentate species (**107**)^{1–3, 18, 21, 189, 276, 316–318} or perform a bridging function (**146**).^{21, 139, 276, 319–323}

$\eta^1(\sigma, N)$ -Bonding to the metal has been observed in the pyrazole complexes **147**^{21, 189, 317, 318, 324, 325} and **148**.^{41, 319–323, 326–330}

Type **149** organoelement derivatives of pyrazoles^{1, 21, 139} and numerous complexes¹⁵⁰ obtained from them are of special interest (see the relevant reviews^{21, 321–323} and the literature quoted therein).

Like the pyrazole complexes, the imidazole complexes are represented by structures **151** (monodentate coordination of the ligand)^{1–3, 318, 331–339} and **152** (bridging coordination).^{1, 2, 340–342}

Among the studies devoted to imidazole (L) complexes, we shall mention the following: the unexpected formation of the monomeric copper acetate complex CuAc₂L₂,³³⁴ the synthesis of

previously unknown complexes ZnS_6L_2 and ZnSe_4L_2 ,³³³ and also the isolation of the imidazole adduct of the chelate pyrazole complex **153**.³³⁹

**153**

$\sigma(\text{N})$ -Coordination is characteristic also of 1,2,4-triazoles **154**³⁴³ and tetrazoles **155**.^{344, 345}

**154****155****156**

We emphasise that the tetrazole fragment in the dinitrodiaquobis(phenyltetrazole)copper(II) complex is coordinated *via* the N(4) atom of the heterocycle (complex **156**).³⁴⁴

1-Ethyltetrazole **155** ($\text{R} = \text{Et}$) is bound to the metal *via* the same donor centre in the complex with copper dinitrate.³⁴⁵

The bond isomerisation (**157** $\rightarrow$ **158**) observed in the cations of 5-methyltetrazole complexes of pentamminecobalt(III) is of undoubted interest in connection with the problem of competitive coordination.^{346–348}

**157****158**

As in the case of azoles, the metal complexes of the benzo-analogues of azoles are N-coordinated compounds. For example, such coordination is characteristic of 2-substituted derivatives of benzimidazole **159**,^{1, 189, 317, 349} tetrahydrobenzotriazole **160**,³⁵⁰ and 1-methylbenzotriazole **161**,³⁵¹ *i.e.*

159 ($\text{R} = \text{H, Et, Pr, Pr}^i, \text{Bu}$;
 $\text{M} = \text{Co, Ni}$;
 $\text{X} = \text{NCS, ClO}_4$;
 $m = 2, 3$)

160

161
 $(\text{X} = \text{Cl, Br, NCS, NO}_3)$

The $\eta^1(\text{N})$ -coordination in complexes **160**³⁵⁰ and **161**³⁵¹ ($\text{X} = \text{NO}_3$) has been demonstrated by X-ray diffraction.

A type of binding of the metal analogous to that in complex **160** occurs in the copper complex of 5(6)-methyl-1,2,4-triazolo[1,5a]pyrimidine **162**.¹⁴⁴

**162****163****164** ($\text{R} = \text{Alk, Ar, H}$)

The N–M coordination also occurs in oxazole and isoxazole complexes^{352, 353} (complexes **163** and **164**). At the same time, the possibility of the involvement of the O atom of the oxazole ring (complex **165**) has been discussed.³⁵³ In our view, this donor atom can hardly compete with powerful nucleophilic centres such as the N atom.

**165****166** ($\text{R} = \text{H, Alk}$)**167**

C-Organometallic derivatives of oxazole **166**³⁵⁴ and isoxazole **167**³⁵⁵ are of undoubted interest.

The complexes of chalcogen-containing azoles, for example complex **168**, N–M and benzazoles, for example complex **169**, contain mainly N–M bonds.^{1, 2, 189, 336, 356–364}

**168****169**

$\text{A} = \text{CH, N}$; $\text{B} = \text{O, S, Se}$.

The location of the coordinate bond in the complexes of benzo-2,1,3-thiadiazole and of its selenium analogue (coordination types **170** and **171**) has aroused an especially great deal of controversy.

**170****171**

$\text{A} = \text{S, Se}$.

At the same time, X-ray diffraction studies indicate unambiguously^{359, 360} that only type **170** N–M coordination occurs in the coordination compounds under consideration. The same mode of coordination is characteristic of the rhodium chloride dicarbonyl complexes of 1,2,3-thiadiazole and 1,2,3-selenodiazole (coordination type **172**).³⁶¹ In connection with the data under discussion, the X-ray diffraction studies^{211, 365} in which direct evidence for the possibility of the involvement of the tellurium atom of benzotellurazole in coordination to the metal (complex **90**) was obtained for the first time must be emphasised.

**172****173****174** ($\text{R} = \text{Alk, Ar}$)

$\text{A} = \text{S, Se, Te}$.

This type of coordination can probably be accounted for by the high electron-donating activity of the tellurium atom in the complexes of N,Te-containing ligands, which were considered previously in the present review.

In connection with the problem of the competitive reaction of chalcogenazoles with metals, it appears important to carry out X-ray diffraction studies on a series of metal carbonyl complexes of benzothiazole **173** ($\text{A} = \text{S}$) and benzoselenazole **173** ($\text{A} = \text{Se}$), for which the equilibrium **173** $\rightleftharpoons$ **174** exists in solution according to ¹H NMR data.³⁶⁶ Furthermore, it appears important to carry out specific studies on the complex formation reactions of other tellurium-containing azole ligands for the same purpose.^{196, 367, 368} In particular, the deliberately synthesised tellurodiazole **175**, from which complexes **176** with a Te–M bond, hitherto unknown in the series of chalcogenodiazoles (*cf.* complexes **170** and **171**), may be obtained with a high degree of probability, is of undoubted interest.

175

176 (M = Cr, Mo, W)

d. Complexes of exocyclic substituted heteroaromatic ligands

The complex formation reactions of heteroaromatic ligands with coordination-active groups result in the formation, apart from the metal derivatives of types **106** and **107** examined above, also of complexes involving exocyclic groups and also bimetallic complexes involving two donor centres.

Particularly numerous data indicating the occurrence of these types of coordination of heteroaromatic ligand systems with coordination-active side substituents have been obtained in relation to complexes of amino- and hydroxy(chalcogen hydride)-derivatives of five- and six- membered heterocycles of types **177** and **178**.

177

X = NR', O, S, Se;
Y, Z = CR, N;
R = H, Alk, Ar, benzo;
E = NH, O, S, Se, Te.

178

A = CH, N;
E = NH, O, S, Se, Te.

Aminoazoles **177** and aminoazines **178** (E = NH) are involved in both monodentate (**179–183**) and bidentate bridging (**184** and **185**) binding of the metal.

179

180

181

182

183

184

185

The coordination types **179** and **182** are the most common.³⁵ Apart from the extensive compilation of data presented by Garnovskii *et al.*³⁵, there are data on the type **179** structure obtained by X-ray diffraction for the 2-aminoimidazole complexes of copper dichloride³⁶⁹ and dibromide³⁷⁰ and of the 2-aminothiazole complex of zinc dichloride.³⁷¹ The same type of location of the coordinate bond arises from the quantum-chemical interpretation of the regioselective coordination in the series of metal complexes of 2-aminoazoles.^{372–374} In contrast to earlier calculations,³⁷⁴ Garnovskii and coworkers^{372,373} determined the relative thermodynamic stabilities of the bond isomers **179–181**³⁷² and their geometry.³⁷³ The preferential N-coordination (type **179**) of the proton and BH₃ arises also from the results of quantum-chemical calculations³⁷⁵ by the MNDO method.

The location of the coordinate bond at the N atom (type **179**) is also characteristic³⁷⁶ of more involved complexes, for example of the adducts of 2-amino-1-methylbenzimidazole (L) with the chelate complexes of tridentate Schiff bases (complex **186**).

186

M = Cu, Co; n = 1, 2.

These complex adducts are of interest because they have been obtained electrochemically.^{376,377} Complexes of aminoazoles with a bridging function of type **184** have been described.^{35, 141, 378–380}

The complexes of aminopyridines **182** (A = CH),^{35, 130, 382, 385–390} and fragments of biologically important systems (amino-derivatives of pyridine)–cytosine **187**,^{35, 38, 381, 391–396} adenine **188**,^{35, 38, 381, 397, 398} and guanine **189**^{399,400} — are represented by a wide range of structures in which metal salts are coordinated *via* endocyclic N atoms of the pyridine type.

187

188

189

Apart from complex **188**, the formation of the dimeric ruthenium complex **190** involving the N(3) and N(9) atoms has been postulated⁴⁰¹ for adenine **188** (R = H) on the basis of ¹H NMR data. According to X-ray diffraction data, the bridging type of binding of this ligand with deprotonation of the NH group of the imidazole ring and the formation of a tetranuclear η⁶-benzeruthenium(II) cluster is also possible.⁴⁰²

190

191

L = EDTA anion.

Coordination of type **189** is mainly characteristic of guanine.^{35, 38, 381, 399} At the same time, complexes in which guanine is coordinated *via* the N(1) atoms and also *via* the N(1) and N(7) atoms are known.⁴⁰³ Thus the complex of 9-methylguanine with ethylenediamineplatinum(II) has the structure **191**.⁴⁰³

We may note⁴⁰⁴ the very unexpected O-coordination of cytosine in complex **192**. In this case, the ligand is coordinated in the enolic tautomeric form.

192

In the series of complexes of aminoazoles and aminoazines, there is virtually no direct evidence for the formation of structures **181** and **183** with a coordinated NH_2 group, although in individual instances such types of coordination have not been ruled out from consideration.^{35, 353}

Numerous studies have been devoted to heterocyclic amino-complexes in which the ligand is bound *via* two donor centres: nitrogen atoms of the pyridine type and an unaltered or deprotonated amino-group. The interest in this type of complex arose a fairly long time ago,^{35, 405} mainly in connection with the formation in the latter of multiple metal–metal bonds,^{405, 406} but the greatest number of complexes with this type of coordinate bonds have been obtained recently.^{35, 406–418}

η^2, μ -Coordination with the simultaneous binding of an endocyclic nitrogen atom and the nitrogen atom of an amino-group occurs in the following complexes: for example, in the ruthenium cluster **193**,³⁵ in the trinuclear complex adduct $\{[\text{Ru(III)Ru(III)Ru(II)OAc}_6\text{L}_3]\text{L}'_3\}$, where $\text{L} = 2\text{-aminopiperazine}$ and $\text{L}' = \text{EDTA}$,⁴¹⁶ in the platinum(II) nitrate complex of 9-methyladenine and trimethylphosphine **194**,^{418, 419} and in the silver complex $[\text{Ag}_3(\text{Py}-\text{NH}_2)_4(\text{NO}_3)_4]$.⁴¹⁹

The structure of metal clusters of type **195** with a deprotonated amino-group has been discussed in a number of publications.^{35, 405, 406} Both mononuclear^{35, 414, 418} and polynuclear^{35, 407, 415} complexes have been noted among complexes with a deprotonated NHR group. In particular, complexes of 2-methylamino- and 2-(2'-pyridyl)aminopyridines **196** with pentavalent phosphorus halides and CF_3 -substituted derivatives may be assigned to the former.⁴¹⁴

$\text{R} = \text{Me}, 2\text{-Py}; \text{X} = \text{F}, \text{Cl};$
 $\text{Y} = \text{F}, \text{Cl}, \text{CF}_3.$

$\text{R} = \text{H}, \text{Me}, \text{Ph}; \text{R}' = \text{H}, \text{Me}.$

Cluster structures of the type considered, for example **197**, have been discussed in a review.³⁵ The nitrogen atom of the NR fragment may participate in the simultaneous bonding to two metal atoms, forming trinuclear clusters which are very common among aminopyridine complexes of ruthenium (complexes **198**).^{408–413}

Instances of substitution of a hydrogen atom of the NH_2 group by a metal atom are also known in the series of other aminoheterocycles, for example in cytosine³⁵ and in 9-amino-acridine.⁴²⁰

In conclusion, we may note that the involvement of both nucleophilic N centres in coordination is characteristic of aminoheterocycles where the disposition of the pyridine and amine nitrogen atoms promotes the formation of chelate structures. Such a structure was first proposed for cobalt complexes of adenine **199** and **200**.³⁵

The formation of structures with a N, N' -five-membered metalocycle was later demonstrated in relation to trinuclear and tetranuclear gold(I) clusters with 8-aminoquinoline **201**⁴²¹ and polymeric copper and rhodium acetate clusters **202**.⁴²²

A wide variety of structures is characteristic of complexes obtained from type **177** and **178** ligand systems containing O, S, and Se donor centres in the exocyclic substituent. Metalocyclic (chelate) structures of types **203** and **204** ($\text{E} = \text{O}, \text{S}, \text{Se}$) are most common among them.^{423–425}

The coordination chemistry of oxygen-containing ligands, represented mainly by the pyridinone **205** complexes, has been examined in another review⁴²⁵ and will not be discussed in detail here.

Rawson and Winpenny⁴²⁵ examined the mononuclear (**206–208**), dinuclear (**209** and **210**), and trinuclear (**211** and **212**) binding of metals by the ligand **205**, taking into account tautomerism of the type $\text{205a} \rightleftharpoons \text{205b}$.

They paid particular attention⁴²⁵ to the bridging function performed by the ligands **205** in complexes with multiple metal–metal bonds.

It is noteworthy that chelate structures of type **208** are fairly common among complexes **203** and **204** with an endocyclic oxygen substituent ($\text{E} = \text{O}$). A metalocyclic structure **213** of this type occurs, for example, in the mercury complex of 1,3-oxazolidin-2-one.⁴²⁶

Chelate structures of types **203** (E = S)^{423, 424–430} and **204**^{423–425, 431–441} are quite widely represented among complexes of 2-mercapto-derivatives. These compounds are obtained preferentially in the interaction of type **177** and **178** ligands with metal salts^{423–425, 427–430} and also from disulfides (for example, compound **214**) and zerovalent metals under the conditions of electro-synthesis.^{432–437, 440}

Apart from complexes **215**, adducts of the type $ML_2 \cdot nL'$ are formed in the presence of various N-bases (L'), where LH = mercaptoazoles or mercaptoazines and $L' = \text{Py}$, Bipy, *o*-Phen and other N-donors.^{299, 431, 432, 437, 438} It has been shown recently⁴⁴¹ that a transformation of the type **214** → **215** can be achieved not only under the conditions of electrosynthesis but also in chemical syntheses carried out for zerovalent lanthanides (samarium and yttrium) in tetrahydrofuran (THF) in the presence of hexamethylphosphamide.

The presence of N- and E-donor centres in the ligands considered and also prototropic tautomerism lead to the occurrence of various structures of the complexes of mercaptoazoles and mercaptoazines, which can be represented by the following types:

Compounds **216**, which behave as monodentate thione ligands (LH), are represented by a fairly large series of complexes having the composition $(LH)_mMA_n$ (see the relevant review⁴²³ and the subsequent publications, for example, Refs 442–444). Complexes obtained from 1-methyl-2(3*H*)-imidazolinethione **222**,⁴⁴² quinoline-2-thione **223**,⁴⁴³ and 4,6-dimethylpyrimidine-2-thione **224**⁴⁴⁴ have been characterised structurally among them.

Naturally the $=S \rightarrow M$ coordination is observed in metal complexes with fixed thione forms of the ligand — in the complexes of 1,3-dimethyl-2(3*H*)-imidazolinethione **225**,⁴⁴⁵ *N*-alkylimidazolidine-2-thione **226** (A = NR'),⁴⁴⁶ and thiazolidine-2-thione **226** (A = S).⁴⁴⁶

The number of structurally characterised complexes of type **217** with the thiol form of the ligand, which is of interest because chelate structures are not formed with its participation, is significantly smaller. Such monodentate S-coordination has been observed in the anion of the complex $\{[Bu_4N]^+[ZnL_3]^- \cdot H_2O\}$ **227**⁴²³ and in the cationic complex of an unusual trisulfide derivative of benzothiazole **228**.

X-Ray diffraction data have shown⁴⁴⁰ that such mononuclear binding of the ligand is characteristic also of the adduct of the zinc salt of 2-mercapto-benzothiazole with *o*-phenanthroline (compound **229**).

In connection with the $\eta^1(S)$ -monodentate coordination of 2-mercaptoazoles being discussed, we may note that the same type of binding of the metal is observed in complexes of triphenylphos-

phinegold with 2-mercapto-1-methylimidazole **230**,⁴⁴⁷ 8-mercaptotheophylline **231**,⁴⁴⁸ 2-mercaptobenzoxazole **232**,⁴⁴⁹ and purine-6-thiol **233**.⁴⁵⁰

Structures **218** with bridging N,S-coordination are quite common for the dinuclear complexes of the heterocycles considered.^{423, 451–454} Studies^{451, 454} in which the detailed influence of the complex formation reaction conditions on the type of complexes formed was detected are of special interest. In particular, a scheme has been published⁴⁵¹ showing that molecular mono-S-coordinated adducts **235** and **236** with the thione tautomeric form of the ligand and the dinuclear complex **237** in which the thiol and bridging binding of the ligand system occur simultaneously may be obtained for the same ligands, for example compound **234**, depending on the nature of the solvent, temperature, and the pH of the medium.

Coordination of type **219** has been observed in a series of complexes,^{423, 455, 456} for example in the recently described dimeric copper complex of benzothiazole **238**.⁴⁵⁶

In this connection, we may point out that, in the dodecanuclear cluster $[\text{Cu}_{10}\text{Cu}_2(\text{C}_4\text{H}_5\text{N}_2\text{S})_{12}(\text{MeCM})_4]$, where $\text{C}_4\text{H}_5\text{N}_2\text{S}$ = 2-mercapto-1-methylimidazole, the thiol sulfur can participate simultaneously in coordination with three copper atoms.⁴⁵⁷ The coordination of type **239**, not considered previously, in which the above imidazole derivative behaves as a tetradentate bridging ligand, occurs in this instance.

The same type of bonding has been established⁴⁵⁸ for the clusters $\text{Ru}_9\text{H}_3(\text{Py})(\text{CO})_{21}$. The complexes of the selenium-containing analogues **203** and **204** ($\text{E} = \text{Se}$) are represented by single investigations. For example, it has been demonstrated by X-ray diffraction⁴⁵⁹ that the mercury complex of pyridine-2-selenol has the structure **240**, whereas the chelate and bridging configurations occur simultaneously in the cadmium dimer **241** obtained from the same ligand.

When the disposition of the donor centres is favourable for the formation of the metallocycle, the hydroxy-, mercapto-, and hydroseleno-derivatives form chelate structures like the amino-substituted nitrogen heterocycles examined above. They are represented particularly widely among complexes of 8-hydroxy- and 8-mercapto-quinolines **242** ($\text{E} = \text{O}$ ^{424, 460, 461} and $\text{E} = \text{S}$ ^{424, 462–467}). Thus the chelate complexes **242** ($\text{E} = \text{O}$; $\text{R} = \text{H}$, Alk ; $n = 3$) of trivalent indium, gallium, thallium, cobalt, antimony,⁴⁶⁰ osmium, ruthenium, and rhodium⁴⁶¹ have been synthesised from 8-hydroxy-quinoline and its substituted derivatives (LH) and characterised structurally. The complexes have an octahedral structure and contain the $\text{C}_2\text{H}_5\text{OH}$ (In, Ga, Co), H_2O (Te), and CHCl_3 (Os, Ru, Rh) molecules as additional ligands. The antimony complex does not contain other molecules and has the composition SbL_3 .

$\text{E} = \text{O}, \text{S}$.

Data on the structures of nickel, cobalt, copper, zinc, and cadmium bishydroxyquinolates (type **242**, $n = 2$) are presented in a review⁴²⁴. The structures of nickel,⁴⁶² indium,⁴⁶³ palladium,⁴⁶⁵ rhodium,^{464, 466} and iridium⁴⁶⁷ 8-mercaptoquinolates

were described subsequently. We may note the synthesis and the rigorous demonstration of the structures of two heterovalent complexes between vanadyl and 8-mercaptoquinoline (LH):⁴⁶⁸ in one of them, having the composition $(VL_3)^-(PPh_4)^+$, the vanadium entering into the composition of the anion has a oxidation state of two, whilst in the other, neutral complex having the composition VL_3 , the oxidation state of vanadium is three. The above oxidation states of vanadium have been confirmed by magnetochemical measurements: the experimental magnetic moment is 3.73 B.M. for the first of the above complexes and 2.78 B.M. for the second.

Organometallic derivatives of 8-hydroxyquinoline^{469–473} and 8-mercaptoquinoline^{470,474–477} are of special interest. Judging from the literature data,^{424,470–477} the question of the denticity and the modes of coordination of 8-mercaptoquinoline in mercury,^{469,471,473} gold,^{472,474–476} tin,⁴⁷⁰ lead,⁴⁷⁰ and antimony⁴⁷⁷ complexes is controversial. It has been suggested^{470,477} that the chelate structure **243**, which is standard for 8-mercaptoquinoline, occurs in these complexes.

243

244

M = Sn, Pb, Sb; $n = 2, 3$. M = Hg, Au; R = Ph, PPh_3 ; E = O, S.

At the same time, a non-standard coordination interaction has been proposed for complexes of 8-hydroxy- and 8-mercaptoquinolines with phenylmercury and triphenylphosphinegold fragments (complex **244**): the presence of only one covalent E—M bond and the formation of a secondary N...M bond.^{471–473,474–476}

Apparently the coordination in the molecules of the adducts of 8-hydroxy- and 8-mercaptoquinolines with Lewis acids (complex **245**) should also be non-standard. However, although their synthesis has in fact been achieved,²² we are not aware of data on the structures of these complexes.

245

246

By analogy with molecular complexes of *o*-hydroxyazomethines,^{22,23} the remaining option is to assume that the coordinate bond in the adducts **245** can be located on the donor atom E. The structures of complexes of 8-hydroselenoquinoline are not clear either, although the chelates **246** themselves have been known for a fairly long time.¹⁸²

So far as we are aware,^{76,193,195,368} the complexes of telluroderivatives of types **203** and **204** (E = Te) have not been described.

5. Competitive coordination of chelating ligands

Competitive coordination in the series of chelating ligands leads to the formation of structures of several types and to intrachelate isomerism involving the closure of metalocycles with different numbers of 'members'. This aspect of competitive coordination has been most clearly investigated in relation to complexes of β -diketones, *o*-hydroxyazomethines, and their structural analogues.

a. Complexes of chelating ligands

It is well known that β -diketones and their thio- and selenoanalogues **247** give rise to metal chelates of type **248** on interaction with metal salts^{4,103,478,482} and under the conditions of gas-phase synthesis or electrosynthesis.^{299,483}

247 (X, Y = O, S, Se)

248

The structure of type **248** β -diketonates (X = Y = O) has been demonstrated by X-ray diffraction.^{478,481,484–501} The structures of copper,^{485–487,499–501} tungsten,^{493,494} yttrium,^{489,496} and lanthanides^{490,491,496–498} β -diketonates have been investigated. Type **248** (X = O, Y = S) metal chelates are formed¹⁰³ also in the case of monothio- β -diketones. It has been suggested that chelate complexes of dithio- β -diketones **248** (X = Y = S) have a structure similar to that of the β -diketonates.¹⁰³

Together with the above mode of coordination, other (chelate and nonchelate) types of binding of the ligands have been observed for complexes of β -diketones. Coordination can be achieved with participation of the oxygen atom as well as the carbon atom or with participation of both donor centres. Similar types of coordination (**249–262**) have been frequently discussed in a number of publications.^{4,24,31,481,484,502,503}

249

250

251

252

253

254

255

256

257

258

259

260

261

262

It follows from the data presented in a review⁴⁸⁴ that an unusual monodentate type **250** O-coordination occurs in the complexes $Mn(HAA)Br_2$ and $Re(HBA)Cl(CO)_3$, where HAA = acetylacetone and HBA = benzoylacetone, while the diketone form of acetylacetone **251**, coordinated as a bidentate species, is encountered in the chelates $\{[Ni(HAA)_2]Br_2\}$ and $\{[Ni(HAA)_2(H_2O)_2](ClO_4)_2\}$.⁴⁸⁴

Among the mononuclear β -diketone C-coordinated complexes, we shall differentiate univalent gold compounds **263**,

having a structure of type **253**, which have been recently obtained and characterised structurally.^{504–507}

It has been suggested⁵⁰⁸ that a structure with acetylacetonate fragments of type **255** coordinated in different ways is characteristic of complex **264**, but rigorous evidence for its occurrence is lacking.

The complexes of β -diketones with additional O-coordinations have been discussed in relation to dinuclear and trinuclear barium complexes.^{509,510} Their coordination units can be represented by formulae **265–268**.

We emphasise that the β -diketone fragment behaves as a tridentate ligand in complex **265** and as a tetradentate ligand in complexes **266** and **267**. However, in contrast to complex **266**, a bischelatate structure occurs in complex **267**.^{511–514} Structure **267** has been detected by X-ray diffraction in the barium complexes of the dipivaloylmethane anion (DPM): $\text{Ba}_2(\text{DPM})_4(\text{NH}_3)_4$,⁵¹¹ $\text{Ba}(\text{DPM})\text{Et}_2\text{O}$,⁵¹² $\text{Ba}_4(\text{DPM})_8$,^{509,513} and $\text{Ba}_2(\text{DPM})_4(\text{Bipy})_2$.⁵¹⁴ The structure with the fragment **268** has been noted in the complex $\text{Ba}_5(\text{DPM})_9\text{H} - \text{DPM}$. According to Drozdov and Trojanov⁵¹³, it contains a pentadentate dipivaloylmethane anion.

According to the information available to us, structures similar to **249–268** are unknown in the series of chalcogen-containing analogues of β -diketones. Such complexes have apparently not been obtained.

A situation similar to that described above for the β -diketone complexes observed also for *o*-hydroxyazomethines and their structural analogue **269** (see the relevant reviews^{22,23,33,34,503} and the literature quoted therein).

$\text{X} = \text{NR}^5$ ($\text{R}^5 = \text{H, Alk, Ar, Het, Ts}$), O, S, Se.

The accumulated literature data show that type **269a,b** ligands form mainly type **270** chelate compounds ML_m ($m = 1-4$). The chelates obtained from ligands **269a,b** ($\text{X} = \text{O}$) and 3d metals — cobalt,^{23,515} nickel,^{23,516–519} copper,^{23,520,521} and zinc^{23,522} — are the most common.

The complexes in which the ligands **269** are involved in type **271** bonding are less well known. In this case, neutral azomethine molecules function as the ligands.^{22,23,34} Taking into account the tautomerism of ligands **269a,b** ($\text{X} = \text{O}$)^{23,33} and intramolecular hydrogen bonding,²³ structures with non-standard formation of a coordinate bond were attributed to these complexes.

In complexes **272–275**, *o*-hydroxyazomethines **269** ($\text{X} = \text{O}$) and their structural analogues ($\text{X} = \text{NR}^4$, S) behave as monodentate ligands, whereas they are involved in bidentate coordination in complexes **276** and **277**.

Conclusions concerning the modes of coordination of the ligands in type **271** adducts indicated above have been reached mainly on the basis of data obtained in comparative studies of the IR spectra of these complexes and the corresponding ligands **269**, which is not sufficiently rigorous.²² X-Ray diffraction studies have demonstrated unambiguously that, out of the six structures **272–277**, only one (**274**), containing the monodentate azomethine ligand in the ketoamine tautomeric form and having an intramolecular hydrogen bond, is actually formed. This situation has been established, for example, for the zinc chloride complex of 2-oxo-1-naphthylideneaniline (complex **278**)⁵²³ and the molybdenum dioxide chloride complexes of β -aminovinyl ketones (complexes **279**)^{524,525} and also in the case of adducts of uranyl acetylacetonates with acetylacetonate imine **280**⁴⁸⁴ and the type **281** manganese complexes of salicylaldimines.⁵²⁶

The coordination of salicylaldimines *via* the oxygen atom in type **281** complexes has been confirmed by the O-binding of these ligands to various metal salts.⁵²⁷

The molecular complexes **271** of structural analogues of β -aminovinyl ketones — β -aminovinylimines **269** ($\text{X} = \text{NR}^4$) and β -aminovinyl thiones **269** ($\text{X} = \text{S}$) — have been described.^{22,23} However, the structures of these molecular complexes have not been investigated by X-ray diffraction, so that the location of the coordinate bond in them remains obscure.

Molecular complexes are also formed by other chelating ligands, for example by formazans **282** and *S*-hydroxy- and *S*-mercapto-quinolines **245** ($\text{X} = \text{Y} = \text{S}$).²²

282 ($R^1, R^2, R^3 = \text{H, Alk, Ar, Het}$)

283

Interesting results have been obtained in a study⁵²⁸ in which a molecular complex of 1-ethylenedihydroxypyrazole **283** was described and characterised structurally.

b. Intrachelate isomerism

In the presence of several donor atoms in the chelating unit of the ligand, the possibility of their competitive reaction and of the closure of metalocycles with different numbers of members arises. This type of competitive coordination is particularly characteristic of the azo-compounds **284** and the formazans **285**.

284

285

$X = \text{NR}^3$ ($R^3 = \text{H, Alk, Ar, Ts}$), O, S;
 $R^1 = \text{Ar, Het}$;
 $R^2 = \text{H, Alk, Ar, benzo, Hal, NMe}_2$, etc.

It is well known that six-membered metalocycles **286** ($X = \text{O}$) are produced in chelate complexes of *o*-hydroxyazobenzenes.^{34, 529}

286 ($X = \text{O}$)

287

288

At the same time, when $X = \text{NR}$ or S, five-membered chelates are formed together with six-membered ones.^{23, 34, 530, 531} The number of members in type **287** chelate compounds is determined by the nature of not only the donor atom X but also of the metal. Thus, according to X-ray diffraction data, when $X = \text{S}$ five-membered metalocycles are formed in the nickel and zinc complexes, whereas five- and six-membered chelate units are produced in the palladium complexes **288** (see the relevant review³⁴ and the literature therein).

A similar situation is characteristic of complexes formed by type **285** formazan ligands, which afford chelate complexes of type **289–291** depending on the nature of the substituents R and the metal (see the relevant reviews,^{37, 532} a communication,⁵³¹ and the literature therein).

289

290

291

$A = \text{NR}^3, \text{O, S}; n = 3, 4.$

Another type of intrachelate isomerism is associated with the formation of metalocycles, differing in the number of members in complexes of heteroarylmino(hydroxy)azo-compounds.⁵³¹ In the case of ligands of this type, one has to expect, apart from type **286–288** coordination ($R = \text{Het}$), the involvement of the N atoms of the hetero-fragments in additional bonding to the metal with formation of complexes **292** or **293** (see Garnovskii *et al.*⁵³¹ and the literature quoted therein).

292

293

$X = \text{NR, O}; A = \text{CH, N}.$

The controversy, extending over a period of many years, concerning the formation of five-membered (complexes **292**) or six-membered and four-membered (complexes **293**) metalocycles has been recently resolved in favour of the first combination by solving the structure of the palladium complex **294**.⁵³¹

294

295

296

$M = \text{Mn, Cu};$
 $A = \text{Cl, NCS}$

Bond isomerism involving different ring sizes has been observed also in the case of the monohydrazones of β -dicarbonyl compounds. Thus complex **295**, with a five-membered metalocycle, has been described in a monograph,⁵³³ while the structure of the six-membered hydrazone metal chelate **296** was established in another study.⁵³⁴

An interesting instance of chelate isomerism **297**→**298** has been observed in cobalt complexes of aminoethanesulfonates.⁵³⁵ Not only the ring size in the coordination unit but also the ligand environment changes in these complexes.

297

298

Tren = tri(2-aminoethyl)amine.

The competitive coordination of bidentate and polydentate chelating ligands occupies an important place in modern coordination chemistry.⁵³⁶ With the aid of these ligands, it is possible to vary the number and nature of the donor centres involved in bonding with the metal. The potentially tridentate ligands of type **299–301** are convenient models for the study of competitive coordination of this type.

299

$X = \text{NTs, O};$
 $A = \text{N, O, S}, n = 3, 4.$

X = NTs, O, S, Se;
R¹, R² = H, Alk, Ar, Het;
A = N, O, S; n = 3, 4.

X, Y = NTs, O, S;
R¹, R² = H, Alk, Ar.

Analysis of published data (see the relevant reviews^{23,34}) shows that the denticity of type **299** and **300** ligands depends on the structure of the chelates which they form: bidentate coordination without the involvement of the nitrogen atom of the heterocycle in the binding of the metal is characteristic of planar complexes (complex **302**), whereas additional coordination to the nitrogen atom of the heterocycle is observed in tetrahedral structures (complex **303**).

Structures **304**–**308** may be attributed to the complexes of ligands **301** on the basis of the structure of the latter (X = Y = O)⁵³⁷ and data^{23,34} indicating the formation of six-membered and five-membered metallocycles by azomethine ligands.

So far as we are aware, the mononuclear complexes **304** and **305** have not so far been described. The formation of structures **306**^{538–544}, **307**,^{545,546} and **308**⁵⁴⁷ has been unambiguously demonstrated by X-ray diffraction. Comparison of structures **307** and **308** revealed an intrachelate bond isomerism due to the ability of type **301** ligands to form metal-bridge fragments involving various donor atoms (X in compounds **308** or Y in compounds **307**).^{546,548}

The dimeric complexes **307** possess antiferromagnetic properties (see, for example, Refs 541, 542, and 549). The magnetic behaviour of the dimeric compounds **308** should evidently be

similar. However, structures similar to that of compounds **308** have not been described for paramagnetic metals.

III. Regioselective synthesis. C-Metal-coordinated ligand systems

We consider regioselective synthesis from the standpoint of competitive coordination as a method for the preparation of complexes with a specified site (region) where the metal is bound to the ligand. Such synthesis may be based on allowance for the specificity of the soft–hard interactions.^{1–3,18} Thus hard and intermediate Pearson acids are used for the synthesis of complexes of the N-coordinated NCX group (X = S, Se),^{2,18} whereas complexes with the M–XCN fragment may be obtained mainly with participation of soft Pearson acids.^{2,18} A similar situation is observed also in the case of regioselective syntheses with participation of other ligands containing donor centres differing in hardness and softness: N, P; N, As; N, S; N, Se; N, Te; O, S; O, Se; O, Te.^{2,18}

Specific regioselective complex formation is in many respects determined by the methods of synthesis of the coordination compounds. Thus, under the conditions of chemical synthesis from substituted pyridine derivatives **309**, the molecular adducts **310** are produced, whereas gas-phase synthesis^{299,300,550} opens a path to the π -complexes **311** of these ligands, which are difficult to obtain.

The use of electrosynthesis (path *a*)^{299,551} makes it possible to obtain the chelate complexes **313** from chelating ligands with weakly acid NH groups (for example, the azomethines **312**), whereas complexes **314** are formed¹ in the usual chemical syntheses (path *b*) (cf. Teom *et al.*⁵⁵²).

The cyclometallation^{553–558} and 1,3-dipolar cycloaddition^{559,560} reactions are used widely for the synthesis of metal complexes of azomethines, azo-compounds, and nitrogen-containing heterocycles with non-standard C-bonding of the ligands. Thus type **315** monodentate azomethines, which usually form $\eta^1(\text{N})$ -molecular adducts **316** with Lewis acids (MX_n), exhibit the properties of bidentate $\eta^2(\text{C},\text{N})$ -chelating ligands under the conditions of the cyclopalladation reaction and lead to chelate compounds,^{558,561} for example to compounds **317**.

X = Cl, Br, SCN;

R¹, R² = H, Alk, OAlk, OCOAlk, Hal, CN, NO₂.

The formation of complex **317** (R¹ = 4-OMe, R² = 4-OBu) has been demonstrated by X-ray diffraction.⁵⁶¹

Cyclometallation, leading to a new Pd₄ cluster, is observed also in the acetolysis of bis(salicylaldiminato)palladium.⁵⁶² When the cyclometallation reaction is carried out with a series of aldazines,^{553, 555, 558, 563} chelates with C,N-coordinated ligands, for example complex **318**, are formed, as in the case of the azomethines considered above.

X = Cl, Br, NCS.

The same non-standard type of C,N-chelation occurs in cyclometallation reactions involving azo-compounds,^{358, 555, 556, 564} whereupon complexes **319** and **320** are formed.

R¹, R² = Alk, OCOAlk; L = Py, quinoline.

We may also note the increase in denticity in the cyclometallation reactions of nitrogen-containing heterocycles: azoles, benzazoles (for example, compounds **321**),^{565, 566} and azines (for example, compounds **322** and **323**).^{553–558, 567–569}

R¹ = H, Alk, Ar; R² = H, Alk, Ar, benzo.

Cyclometallation alters the location of the coordinate bond also in the series of complexes of more involved nitrogen-containing heterocycles, for example dibenzodiazepine derivatives (see Stoccoro *et al.*⁵⁷⁰ and the literature quoted therein). Thus 1,4-benzodiazepin-2-one usually affords adducts of types **324** and **325** on interaction with metal salts and organometallic compounds, whereas cyclometallation leads to the C,N-metal chelates **326**.⁵⁷⁰

In a number of instances, the direction of coordination attack in regioselective synthesis is determined by the type of solvent. When aprotic solvents are employed, molecular adducts with a fully preserved ligand system may be obtained from typical chelating ligands (complexes **249–252** and **274**).^{22, 23, 503}

Other examples of the regulation of regioselective coordination by the type of solvent have been quoted in a review.⁵⁵⁶ In this connection, we may note the reaction

This regioselective synthesis, occurring in methanol or hexamethylphosphoramide (HMPA) with participation of N-thiobenzoylpyrrolidine **327**, is accompanied by the formation of two complexes, **328** and **329**, in which different cyclic systems are coordinated to the palladium atom. It is interesting because it demonstrates the possibility of the involvement in coordination of the S-donor ligand centre and of the saturated (and not aromatic or heterocyclic) CH fragment. We emphasise that the cyclometallation reactions can involve not only the C–H but also the C–Hal bonds.

Dipolar 1,3-cycloaddition^{16, 559} is interesting as regards the specific regioselective synthesis of a series of C-metal derivatives of nitrogen-containing heterocycles. The tetrazole derivatives **330** may be assigned to the latter.⁵⁵⁹

M = Hg, Pt, Pd.

The mode of the reactions in the regioselective synthesis depends on the fine structure of the ligand system, which has been demonstrated in relation to different types of coordination of the NCX group in palladium complexes of diphosphines with different lengths of the alkyl chain (complexes **331**–**333**).^{4, 31}

However, there are so far few examples of such regioselective reactions.

IV. Conclusion

The use of the concept of competitive coordination enabled us to survey extensive modern data concerning the regioselective binding of metals in complexes of bidentate and polydentate ligands. It is noteworthy that, in the majority of the publications which we have examined, only a particular mode of coordination was elucidated fairly reliably without analysis of the causes which would account for its regioselectivity. Nor is the situation saved by the application of the HSAB principle, since the latter can be used only for a limited range of ligands with soft and hard donor centres.

We believe that the main task in the development of the competitive coordination method is, firstly, the identification of the factors determining the centres at which the coordinate bond is located in complexes of bidentate and polydentate ligand systems. The solution of this problem will permit the specific regioselective synthesis of coordination compounds and will assist in studies devoted to the specific features of the binding of metals in biologically important systems.

The second task is the specific selection of ambident ligand systems with nitrogen–phosphorus and nitrogen–selenium (tellurium) donor centres and the synthesis from them of new metal complexes, the establishment of the structures of the latter, and the discovery of the causes of the regioselective coordination in these complexes. Despite the fact that continued interest has been shown in ligands of this type and the complexes obtained from them,^{77, 571–575} they still remain the least investigated objects in coordination chemistry.

In conclusion, one would wish to note that members of the Kurnakov Institute of General and Inorganic Chemistry of the Russian Academy of Sciences, the 80th Anniversary of which occurs next year, have made a major contribution to the development of the problem of the binding of metals in complexes of ambident ligands.

This review has been prepared with the financial support by the Russian Fundamental Research Fund (Grant No. 96-03-32026a).

Abstract. The state of research on the catalytic liquid-phase hydrogenation of 2- and 3-thiolene 1,1-dioxides to thiolane 1,1-dioxide is analysed. Data on the activities and selectivities of Group VIII metals and their complexes and sulfides, both massive and supported, as well as the reaction conditions and hydrogenation mechanisms are considered. The causes of the deactivation of catalysts in the synthesis of thiolane 1,1-dioxide and procedures for increasing their resistance to sulfur are described. Certain general problems of the resistance of hydrogenation catalysts to sulfur are discussed. The bibliography includes 130 references.

I. Introduction

Thiolane 1,1-dioxide, which has a series of valuable properties,¹ was first obtained in 1910 by the oxidation of thiolane.² However, a procedure proposed later^{3–5} and based on the reduction of 2- and 3-thiolene 1,1-dioxides by hydrogen in the presence of catalysts proved to be more convenient.

The initial compounds for the synthesis of thiolane 1,1-dioxide are fairly readily available: the interaction of buta-1,3-diene with sulfur dioxide affords a 95 mol. % yield of 3-thiolene 1,1-dioxide and isomerisation of the latter in a basic medium leads to 2-thiolene 1,1-dioxide in up to 60 mol. % yield.⁶

Nowadays, thiolane 1,1-dioxide is widely used as a reaction medium, as a plasticising and stabilising additive, as a component of hydraulic liquids, and as an anticorrosion additive to oils. It is also employed to purify resins and plant oils, to prepare a sulfur emulsion in water, etc. It is particularly important to note the use

of thiolane 1,1-dioxide as the extractant for the isolation of aromatic hydrocarbons from reformed petroleum products and as the solvent for the elimination of acid components from natural and industrial gases (see the relevant reviews^{1,7,8}). The need for this product stimulated the development of studies on the catalytic hydrogenation of thiolene 1,1-dioxides and led to the initiation of industrial production.^{7,9}

Up to the 1960s, information about the hydrogenation of thiolene 1,1-dioxides and thiolane 1,1-dioxide could be found only in the patent literature and a few research communications. Analysis of the results published at that time showed¹ that traditional low-temperature hydrogenation catalysts, such as platinum (platinum black and dioxide), palladium (palladium black and Pd/C), or nickel (Raney nickel and Ni/SiO₂) may be used for the hydrogenation of 2- and 3-thiolene 1,1-dioxides and their substituted derivatives to the corresponding thiolane 1,1-dioxide. The hydrogenation is usually carried out at 20–40 °C and atmospheric or reduced pressure in ethanol, isopropyl alcohol, water, acetic acid, dioxane, benzene, or thiolane 1,1-dioxide. The complete reduction of unsubstituted thiolene 1,1-dioxide in the presence of an excess of the catalyst relative to the substrate (34 mass %–250 mass %) requires several minutes, whereas in the presence of a low content of the catalyst (1 mass %–4 mass %) up to 20 h is required.

Various investigators studied the hydrogenation of thiolene 1,1-dioxides under different conditions. In a number of instances, the catalytic activity was determined without testing for the presence or absence of diffusional complications and without taking into account the surface area of the active component, which greatly hinders comparison of the results. Extensive experimental data have now accumulated. Nevertheless, important factors such as the dependence of the activity of the metal on its surface concentration on various carriers, the mechanism and kinetics of the hydrogenation reaction, and the resistance of the catalysts to sulfur have not been considered in detail in the very brief reviews available.^{10–14} It has therefore become necessary to analyse all the existing data and to determine the possible aspects of further research.

II. Hydrogenation of 2- and 3-thiolene 1,1-dioxides on massive and supported transition metal sulfides

Group VI–VIII metal sulfides are used as catalysts in the hydrogenation reactions of sulfur-containing raw material. They are not poisoned by sulfur compounds and exhibit an adequate activity at elevated temperatures and pressures and for prolonged contact

times.¹⁵ Such severe conditions arise in the first place from the difficulty of activating hydrogen, which requires the transfer of its electrons to the acceptor centres, arising as a result of the displacement of electron density from the metal to the sulfur atom of the catalyst. The metal atoms in the sulfide are separated by sulfur atoms and this hinders the activation of unsaturated compounds which requires a structural correspondence.¹⁶

Molybdenum, tungsten, nickel, cobalt, and iron sulfides are not effective catalysts of the synthesis of thiolane 1,1-dioxide by the hydrogenation of thiolene 1,1-dioxides. Thus patent data (see the present author's earlier review¹) indicate that the hydrogenation of 2-thiolene 1,1-dioxide on these sulfides proceeds with formation of thiolane:

while thiophene is formed from 3-thiolene 1,1-dioxide (250–425 °C, 2–20 MPa). In the latter case, the 3-thiolene 1,3-dioxide formed probably decomposes to buta-1,3-diene and sulfur dioxide. The reaction is known to proceed at a high rate at temperatures above 100 °C.⁶ On metal sulfides at an elevated temperature, buta-1,3-diene is dehydrogenated with formation of the $-\text{CH}=\text{CH}-$ fragments, which interact with the catalyst sulfur atom to form thiophene. The loss of sulfur by the catalyst is made good by its interaction with the hydrogen sulfide formed on reduction of sulfur dioxide (Scheme 1):¹⁷

Ct = catalyst.

It has been demonstrated experimentally^{10–14, 18–22} that, at a lower temperature in the presence of certain transition metal sulfides, thiolene 1,1-dioxides are reduced to thiolane 1,1-dioxides (Table 1). The hydrogenation is carried out in the liquid phase in the presence of both massive and supported catalysts. The degree of conversion of the substrate, the yield of thiolane 1,1-dioxide, the selectivity (S), and the rate of formation of the dioxide (W), as well as the stability of the catalyst depend on the reaction conditions, namely on the nature of the solvent, temperature, hydrogen pressure (P), contact time (t), the initial thiolene 1,1-dioxide concentration (c), and the content of the catalyst in solution (g_{ct}).[†]

It follows from Table 1 that, in the hydrogenation of 3-thiolene 1,1-dioxide, dissolved in isopropyl alcohol, at an elevated temperature and pressure in the presence of $\gamma\text{-Al}_2\text{O}_3$ modified with 0.5 mass % of osmium, platinum, rhenium, or rhodium sulfides or 2.4 mass % of palladium sulfide, and also in the presence of the 5% $\text{RuS}_2/\text{SiO}_2$ catalyst, the yield of thiolane 1,1-dioxide does not exceed 1 mol. % with $S \leq 10\%$ and $W = 0.008\text{--}0.025 \text{ mmol h}^{-1} \text{ g}^{-1}$. On the catalyst obtained by depositing 20 mass % of Re_2S_7 on $\gamma\text{-Al}_2\text{O}_3$, the rate of reaction increases by an order of magnitude ($W = 0.25 \text{ mmol h}^{-1} \text{ g}^{-1}$)

[†] All the data presented below are expressed in identical units: the rate of reaction is expressed in moles of thiolane 1,1-dioxide formed per unit time on 1 g of the catalyst, on 1 g-atom of the metal, or on 1 m² of the surface of the active component; the stability of the catalyst is expressed in millimoles of thiolane 1,1-dioxide obtained during the period of the complete deactivation of 1 g of the catalyst or 1 m² of the metal; the content of the substrate in the solution hydrogenated is expressed on the molar scale and that of the catalyst in g litre^{−1}.

Table 1. Hydrogenation of 2- and 3-thiolene 1,1-dioxides on metal sulfides in isopropyl alcohol ($c = 0.25\text{--}0.4 \text{ M}$, $g_{\text{ct}} = 10 \text{ g litre}^{-1}$).^{18, 19}

^a The values of S_{sp} expressed in m² g^{−1} are given in brackets. ^b Expressed in mmol h^{−1} g^{−1}.

and the yield of thiolane 1,1-dioxide is 10% for $S = 14\%$. When massive Re_2S_7 is used, the yield reaches more than 50% and $W = 1.3 \text{ mmol h}^{-1} \text{ g}^{-1}$. The unsatisfactory results can be explained by the decomposition of the unstable initial substrate under the conditions of a high temperature (100 °C) and a long contact time (7 h). Indeed, when the contact time is reduced to 1–2 h the hydrogenation of 3-thiolene 1,1-dioxide on the 2.5% $\text{PdS}/\text{Al}_2\text{O}_3$ catalyst in dilute solutions in methanol, butanol, and dimethylformamide leads to the formation of thiolane 1,1-dioxide in 50%–90% yield with $W = 0.42\text{--}0.85 \text{ mmol h}^{-1} \text{ g}^{-1}$ and $S \leq 90\%$ (100 °C, $P = 5 \text{ MPa}$, $c = 0.04 \text{ M}$, $g_{\text{ct}} = 50 \text{ g litre}^{-1}$).

A decrease in temperature to 20 °C induces a rise of the selectivity in the formation of thiolane 1,1-dioxide. Thus, in the hydrogenation of 3-thiolene 1,1-dioxide on massive platinum, palladium, or rhodium sulfides at $P = 5 \text{ MPa}$, the product yield is only 2%–5%, but $S = 100\%$ and $W = 21\text{--}62 \text{ mmol h}^{-1} \text{ g}^{-1}$.¹⁸ Under these conditions, the activity of rhodium sulfide calculated per gram of the massive catalyst is twice as high as that of palladium sulfide and three times as high as that of platinum sulfide (Table 1). The specific activities, calculated per unit area, of rhodium and palladium sulfides are approximately the same and exceed by more than an order of magnitude the specific activity of platinum sulfide (6.84, 5.13, and 0.32 mmol h^{−1} m^{−2} respectively).

In the hydrogenation of the thermally more stable 2-thiolene 1,1-dioxide on transition metal sulfides, satisfactory parameters likewise cannot be always attained.^{19,20} Thus in isopropyl alcohol the hydrogenation does not take place on massive V_2S_3 ($S = 7 \text{ m}^2 \text{ g}^{-1}$) and MnS ($S_{sp} = 2.3 \text{ m}^2 \text{ g}^{-1}$), whereas on tungsten, nickel, and cobalt sulfides the yield of thiolane 1,1-dioxide does not exceed 6% for a reaction rate of $1.5 \text{ mmol h}^{-1} \text{ g}^{-1}$. When massive rhenium, platinum, osmium, rhodium, or palladium sulfides are used as the catalyst, the yield of thiolane 1,1-dioxide reaches 50%–90% in 1 h, the selectivity is less than 100% owing to the partial decomposition of the substrate, and the rate of hydrogenation per gram of the catalyst exceeds by an order of magnitude the rate of reaction on tungsten, nickel, and cobalt sulfides ($W = 12\text{--}23 \text{ mmol h}^{-1} \text{ g}^{-1}$). However W decreases when the sulfides are deposited on Al_2O_3 or SiO_2 ($100\text{--}150^\circ\text{C}$, $P = 11\text{--}25 \text{ MPa}$, $c = 0.2\text{--}0.37 \text{ M}$) (Table 1).

In terms of their specific activity in the hydrogenation of 2-thiolene 1,1-dioxide at 150°C at $P = 11 \text{ MPa}$, the massive metal sulfides can be arranged in the following series (the values of W expressed in $\text{mmol h}^{-1} \text{ m}^{-2}$ are given in brackets):

Nickel sulfide has the lowest specific activity, while platinum, rhenium, cobalt, and tungsten sulfides are approximately four times more active and rhodium and palladium sulfides are up to 60–80 times more active than nickel sulfide. Under the same conditions, the greatest selectivity in the formation of thiolane 1,1-dioxide is obtained on massive rhodium, palladium, osmium, and cobalt sulfides ($S \approx 90\%$). It is somewhat lower on rhenium and platinum sulfides ($S \approx 70\%$), and is especially low on tungsten and nickel sulfides ($S < 50\%$).

The hydrogenation of 2-thiolene 1,1-dioxide has been investigated in greater detail on palladium sulfide, 0.5 mass %–7.6 mass % of which had been deposited on $\gamma\text{-Al}_2\text{O}_3$.^{11,19}

In the presence of 0.5% $\text{PdS}/\text{Al}_2\text{O}_3$, an increase in temperature from 50 to 200°C with the remaining parameters unaltered leads to an increase in the yield of thiolane 1,1-dioxide from 14% to 70% for $S = 70\%$ ($P = 25 \text{ MPa}$, $c = 0.26 \text{ M}$, $g_{ct} = 10 \text{ g litre}^{-1}$, $t = 7 \text{ h}$). On the 4.7% $\text{PdS}/\text{Al}_2\text{O}_3$ catalyst, such an increase in temperature induces an increase in yield from 5% to 36% for $S = 100\%$ ($P = 11 \text{ MPa}$, $c = 0.21 \text{ M}$, $g_{ct} = 10 \text{ g litre}^{-1}$, $t = 1 \text{ h}$).

On the 2.4% $\text{PdS}/\text{Al}_2\text{O}_3$ catalyst at 150°C , $P = 25 \text{ MPa}$, and $g_{ct} = 10 \text{ g litre}^{-1}$, the degree of conversion of 2-thiolene 1,1-dioxide is independent of its initial concentration in the range from 0.02 to 0.12 M, while the rate of hydrogenation is proportional to the concentration of the substrate. The rate of reaction at $c = 0.37 \text{ M}$ is proportional to the hydrogen pressure in the range from 1 to 15 MPa. For higher values of c and P , the rate ceases to change, i.e. the reaction is of zero order with respect to 2-thiolene 1,1-dioxide and hydrogen.

On the 2.4% $\text{PdS}/\text{Al}_2\text{O}_3$ catalyst, the degree of conversion of 2-thiolene 1,1-dioxide dissolved in isopropyl alcohol may attain 100%, but the yield of thiolane 1,1-dioxide does not then exceed 70% (150°C , $P = 25 \text{ MPa}$, $c = 0.37 \text{ M}$, $g_{ct} = 10 \text{ g litre}^{-1}$), since hydrogenolysis products are formed together with thiolane 1,1-dioxide. The degree of conversion does not affect the selectivity. On the basis of these data, it was concluded¹⁹ that the initial 2-thiolene 1,1-dioxide, and not its hydrogenation product, undergoes hydrogenolysis, i.e. the hydrogenation and hydrogenolysis reactions proceed independently.

The $\text{PdS}/\text{Al}_2\text{O}_3$ catalyst is stable under the conditions of the hydrogenation of 2-thiolene 1,1-dioxides even after the formation

of $\sim 415 \text{ mmol}$ of thiolane 1,1-dioxide on 1 g of the catalyst, the rate of reaction remains unchanged.

III. The activities and stabilities of metal complexes in the hydrogenation reactions of 2- and 3-thiolene 1,1-dioxides

Metal complexes are promising catalysts for the reduction of various unsaturated compounds.²³ Certain platinum, palladium, and rhodium complexes exhibit an enhanced resistance to sulfur.^{24–29} The use of Group VIII metal complexes for the hydrogenation of 2- and 3-thiolene 1,1-dioxides has so far been investigated in insufficient detail.

Rhodium complexes. In the hydrogenation of 3-thiolene 1,1-dioxide in the presence of tris(*tert*-phosphine)- or tris(*tert*-arsine)-rhodium nitrosyl complexes, a quantitative yield of thiolane 1,1-dioxide is attained after 16 h at 56°C and $P = 4 \text{ MPa}$.³⁰

Nickel complexes. In the presence of nickel acetylacetonate in solution in benzene to which aluminium isobutoxide has been added at a concentration of 31.6 M, exhaustive hydrogenation of 3-thiolene 1,1-dioxide takes place (25°C , $P = 1.4 \text{ MPa}$, $c = 1.8 \text{ M}$, $g_{ct} = 5.3 \text{ mmol litre}^{-1}$, $t = 35 \text{ min}$).³¹ The rate of formation of thiolane 1,1-dioxide per gram-atom of nickel is 576 mol h^{-1} .

Platinum complexes. In the presence of the complex $\text{PtCl}_2(\text{H}_2\text{O})[\text{P}(\text{C}_6\text{F}_5)_3]$ reduced by hydrogen, 3-thiolene 1,1-dioxide, dissolved in butanol, is hydrogenated to thiolane 1,1-dioxide in a yield of about 100%.³² The isomerisation of the initial substrate to 2-thiolene 1,1-dioxide also takes place to a slight extent (0.5%) (25°C , $P = 0.1 \text{ MPa}$, $c = 0.12 \text{ M}$, concentration of the complex 0.01 M , $t = 1.5 \text{ h}$). The rate of hydrogenation is $11.4 \text{ mol h}^{-1} (\text{g-atom Pt})^{-1}$. A kinetic study showed³³ that the order of this reaction with respect to platinum at a platinum concentration in the range $[\text{Pt}] = (2.5\text{--}10) \times 10^{-3} \text{ M}$ is unity. Hence it was concluded that the catalyst contains no ligands capable of splitting off from the initial complex under the influence of the solvent. The rate of hydrogenation at $c < 0.01 \text{ M}$ increases with increase in the 3-thiolene 1,1-dioxide concentration raised to a power of 0.55, whilst at $c = 0.05\text{--}0.1 \text{ M}$ it remains unchanged. The order of the reaction with respect to hydrogen at pressures close to atmospheric is zero, whilst at low partial pressures ($\sim 0.006 \text{ MPa}$) it increases to 0.7. In the temperature range from 0 to 62.5°C , the activation energy for the reaction is 46 kJ mol^{-1} .

It has been suggested³³ that the reaction proceeds *via* consecutive stages involving coordination to the complex of 3-thiolene 1,1-dioxide and hydrogen and the formation of a hydride complex and its decomposition (Scheme 2).

Scheme 2

Here L is the stabilising ligand in the reduced platinum complex formed from $\text{P}(\text{C}_6\text{F}_5)_3$, while $k_1\text{--}k_4$ are the rate constants for the corresponding stages. The rate of reaction is limited by the formation of the hydride complex (stage 3) and is described by the equation

$$W = \frac{k_3 K_1 K_2 c_1 c_2 c_3}{1 + K_1 c_2 + K_1 K_2 c_2 c_3},$$

where K_1 and K_2 are the equilibrium constants of stages 1 and 2, c_1 is the overall concentration of the complexes formed in all the reaction stages, c_2 is the concentration of 3-thiolene 1,1-dioxide, and c_3 is the concentration of hydrogen in solution, equal to P_{H_2} multiplied by the solubility coefficient of the gas.

At a high substrate concentration, the equation becomes

$$W = \frac{k_3 K_2 c_1 c_3}{1 + k_2 c_3},$$

and at a high hydrogen concentration it assumes the form

$$W = k_3 c_1.$$

These equations agree with experimental data.

On consecutive hydrogenation of several portions of 3-thiolene 1,1-dioxide in the same contact solution, the reaction rate diminishes from experiment to experiment. After the formation of 100 mmol of thiolane 1,1-dioxide per mg-atom of platinum, the initial activity becomes smaller by a factor of two. It can also be postulated that the deactivation of the platinum complex is associated with the formation of small amounts of buta-1,3-diene and sulfur dioxide on decomposition of the substrate. However, the addition of buta-1,3-diene at a concentration of $(3.3 - 16.7) \times 10^{-3}$ M did not decrease but actually increased the activity of the catalyst by a factor of 1.3–3. On the other hand, sulfur dioxide is a poison for the platinum complex, its introduction into the solution hydrogenated at a concentration of 1.2×10^{-3} M (molar ratio $SO_2 : Pt = 0.1$) reduces the initial activity of the catalyst approximately by a factor of 80. In the presence of the above platinum complex, SO_2 is not reduced to hydrogen sulfide even after 3.5 h and it was therefore concluded³² that the poison for the catalyst considered is sulfur dioxide itself.

Homogeneous palladium complexes. The hydrogenation of 2-thiolene 1,1-dioxide has been investigated³⁴ in the presence of palladium complexes with sulfur- and nitrogen-containing ligands in solution in dimethyl sulfoxide. The potassium tetrahydroborate-reduced palladium complexes of dimethyl sulfide and dimethyl sulfoxide, $PdCl_2 \cdot (DMS)_2 \cdot KBH_4$ and $PdCl_2 \cdot (DMSO)_2 \cdot KBH_4$, in which the degree of oxidation of palladium is reduced, accelerate the hydrogenation of 2-thiolene 1,1-dioxide. The reaction proceeds at a high rate $W = 1 \text{ mol min}^{-1} (\text{g-atom Pd})^{-1}$ (20°C , $P = 0.1 \text{ MPa}$, $c = 0.127 \text{ M}$). The analogous palladium complexes of diethyl sulfide or thiolane are less active [$W = 0.06$ and $0.03 \text{ mol min}^{-1} (\text{g-atom Pd})^{-1}$ respectively] and decompose under the influence of the reaction medium with liberation of metallic palladium.

The homogeneous palladium complex of dimethylformamide ($PdCl_2 \cdot DMF$) proved to be approximately 45 times more active than the complexes with sulfur-containing ligands.

However, the addition of divalent sulfur compounds reduces the initial activity of the homogeneous palladium complexes. Thus, when thiophene or thiolane were added to the hydrogenated solution at a concentration of 50×10^{-3} M, the activity of the palladium complex of dimethyl sulfide diminished by a factor of 2 and the complex decomposed with liberation of metallic palladium. In order to poison the palladium complex of dimethyl sulfoxide to the same extent, it is necessary to introduce ten times more of thiolane to the hydrogenated solution. This can be accounted for by the difficulty of the incorporation of thiolane in the coordination sphere of the palladium complex, since palladium forms bonds with the sulfur and oxygen atoms of dimethyl sulfoxide.

The activity of the complex $PdCl_2 \cdot DMF$ diminishes by a factor of 2 after the introduction into the solution of thiophene at a concentration of 60×10^{-3} M or thiolane at a concentration of 0.3×10^{-3} M. Such a high difference between the toxicities can be accounted for by the fact that dimethylformamide, which is a stronger electron donor, can compete with thiophene for coordination to palladium, whereas thiolane substitutes dimethylformamide in the coordination sphere of palladium, forming a complex

with the latter. The complex is unstable in a reducing medium and decomposes to metallic palladium, which is readily deactivated (see Section V). In terms of resistance to poisoning by thiolane, $PdCl_2 \cdot DMF$ is inferior to palladium complexes with sulfur-containing ligands by 2–3 orders of magnitude.

The cause of the deactivation of homogeneous palladium complexes has been investigated³⁴ by UV and NMR spectroscopy. Absorption bands characteristic of the $Pd^{2+} - S$ bond (26 000 and 34 000 cm) appear in the UV spectrum of the complex partly deactivated by the addition of $(5 - 10) \times 10^{-3}$ M thiolane (poison : Pd = 2–5). At a thiolane concentration of 50×10^{-3} M (poison : Pd = 50), all the absorption bands vanish from the spectrum, which indicates the decomposition of the complex.

The ^{13}C NMR spectra of a $PdCl_2 \cdot (DMS)_2 \cdot KBH_4$ specimen to which small amounts of thiolane have been added exhibit signals belonging to thiolane coordinated to palladium ($\delta = 40.3$ and 32.8 ppm) and to free dimethyl sulfide ($\delta = 20.6$ ppm). On this basis, it was concluded that deactivation occurs as a result of the displacement by thiolane of the initial ligand from the coordination sphere of the complex and the disruption of the initial structure of the latter. In hydrogen, the newly formed complex decomposes with liberation of metallic palladium, which is readily poisoned by sulfur compounds.

Heterogenised palladium complexes. The hydrogenation of 2- and 3-thiolene 1,1-dioxides on mononuclear and polynuclear Pd^{2+} and Pd^0 complexes immobilised on silicon dioxide has been investigated.^{34–38} These complexes include the mononuclear Pd^{2+} complexes

the mononuclear Pd^0 complex

and polynuclear complexes of the type

or

In the presence of heterogenised complexes in methanol and isopropyl alcohol, thiolene 1,1-dioxides are fully reduced to thiolane 1,1-dioxide (20°C , $P = 0.1 \text{ MPa}$, $c = 0.127 \text{ M}$, $g_{\text{ct}} = 1.5 - 10 \text{ g litre}^{-1}$). Depending on the composition of the complex, the rate of hydrogenation ranges from 1 to $90 \text{ mol min}^{-1} (\text{g-atom Pd})^{-1}$ (Refs 35, 36), i.e. has the same order of magnitude as on the homogeneous complex $PdCl_2 \cdot DMF$ and on supported metallic palladium (0.2 mass %–5 mass %).³⁴

The catalytic activity of mononuclear Pd^{2+} complexes increases with increase in the instability constant of the complex.³⁵ The hydrogenation reaction must involve the coordination of thiolene 1,1-dioxide with formation of a π -complex and the activation of hydrogen *via* the formation of palladium hydride. Palladium hydride is formed on the Pd^{2+} complex on transfer of electron density from hydrogen to palladium.²⁹ It has been suggested^{37,38} that the rate-limiting stage of the hydrogenation of thiolene 1,1-dioxide on Pd^{2+} complexes is the activation of hydrogen. After the enhancement of the electron-donating prop-

erties of the ligands, the instability constant decreases. This shifts the equilibrium

towards a decrease in the concentration of palladium hydride and hence leads to a decrease in the rate of hydrogenation.

Polynuclear diphosphine Pd^0 complexes, immobilised on silicon dioxide, are somewhat less active than the mononuclear complexes. Their activity increases with increase in the number of palladium atoms from 2 to 6. The monophosphine Pd^0 complex is the most active. The rate of reaction on this complex reaches $92 \text{ mol min}^{-1} (\text{mol Pd})^{-1}$, which can be accounted for by its conversion under the hydrogenation conditions into the coordinatively unsaturated immobilised complex $(\text{Si})-(\text{CH}_2)_2\text{PPh}_2\text{Pd}^0$, which activates hydrogen and multiple bonds more readily.²⁹

In the course of one experiment, the activity of the heterogenised complex does not change, but, after prolonged hydrogenation of 2- and 3-thiolene 1,1-dioxides, a slow deactivation of the catalyst is observed. It is probably caused by the effect of the divalent and tetravalent sulfur compounds formed. The resistance of the complexes to sulfur was determined by adding thiolane and thiophene to the hydrogenated solution.^{34–38} It was found that the resistances of the mononuclear Pd^{2+} and polynuclear Pd^0 complexes to poisoning by the above substances are approximately the same. The immobilised palladium complexes with nitrogen-containing ligands are 40–500 times less resistant to poisoning by thiolane and thiophene than the homogeneous palladium complex of dimethylformamide.³⁴

The causes of the deactivation of the heterogenised palladium complexes by thiolane and thiophene have been investigated.^{13, 34–38} Thiolane is a stronger poison than thiophene adsorption measurements have shown that the formation constant of the thiophene–catalyst complex is three times smaller than the corresponding constant for the thiolane–catalyst complex. It follows from desorption experiments that the deactivation by thiophene is partly reversible, whilst thiolane poisons the complex irreversibly. In dimethylformamide, which is an effective complex-forming agent and competes with the sulfur-containing poison, the resistance of the complex to poisoning is greater than in isopropyl alcohol (for the ratio poison: Pd = 100:1). The stability of the mononuclear Pd^{2+} complexes depends on the electron-donating capacity of the inner ligands, characterised by the instability constant of the complex with decrease in the latter, the strength of the $(\text{Si})-\text{L}-\text{Pd}$ linkage increases, while the ability of palladium to be coordinated to the poison $(\text{Si})-\text{L}-\text{Pd} \leftarrow \text{S} <$ diminishes. The stability of the polynuclear complexes is determined both by the strength of the bond between palladium and the inner ligand and by steric factors. The role of the latter increases with increase in nuclearity. Owing to the small size of the framework of the cluster, not all the palladium atoms are sterically capable of forming bonds with the molecules of the poison, but they can activate hydrogen.

According to XPS data, the mononuclear Pd^{2+} complexes change after treatment with thiolane. In the $\text{Pd}3d$ spectral range, the binding energy diminishes from 337.2 to 336.7 eV for $B = 3.4\text{--}3.5 \text{ eV}$, which indicates a decrease in the valence of palladium. The intensity of the $\text{Pd}3d/\text{Si}3p$ lines then decreases slightly (from 0.23 to 0.21). In the region of $\text{S}2p$ and $\text{S}2s$, sulfur lines were observed. A shoulder appears in the UV spectrum of the specimen treated with the poison in the range $34\,000\text{--}24\,000 \text{ cm}^{-1}$, which corresponds to the bond between Pd^{2+} and sulfur. The XPS spectra of the initial Pd^0 complex and the same complex treated with thiolane are characterised by a constant binding energy (336.1 eV) and line half-width (4.4–4.1 eV). The decrease after the treatment of the catalyst in the intensity of the $\text{Pd}3d/\text{Si}2p$ lines from 0.36 to 0.26 can be explained by the shielding of the palladium signal by the adsorbed molecules of the poison.

Analysis of the UV spectra also indicates the preservation of the structure of the complex when it is treated with thiolane

(absorption bands at $28\,000$, $22\,000$, and $16\,000 \text{ cm}^{-1}$). Treatment with a large amount of the poison at an elevated temperature induces the decomposition of the initial structure of the complex, which is indicated by the decrease in the binding energy, the line half-width, and the intensity of the signals in the XPS spectrum and also by the disappearance from the UV spectrum of the bands characteristic of the initial complex. It may be that the decomposition of the complex is accompanied by the formation of the $\text{Pd} \leftarrow \text{S} <$ bond. Thus the deactivation of the palladium complexes immobilised on silicon dioxide takes place as a consequence of the displacement of the outer ligand by the sulfur poison entering into the coordination sphere of palladium and of the formation of a bond between palladium and sulfur. Under certain conditions, the structure of the complex is fully disintegrated.

IV. The activities of massive and supported metals in the hydrogenation reactions of thiolene 1,1-dioxides

Group VIII metals are used widely for the low-temperature hydrogenation of various unsaturated organic compounds.^{17, 39}

The multiple bond in thiolene 1,1-dioxides is activated by virtue of the presence of the electron-accepting sulfonyl group.^{6, 40} This facilitates the formation of a complex with participation of the $\text{C}=\text{C}$ bond, which may become saturated in the presence of activated hydrogen in the system (Scheme 3).

Scheme 3

The reaction mechanism involves the postulate that the unsaturated organic substrate and hydrogen are activated on different active centres as a result of the transfer of electron density from the occupied atomic orbital of the metal to the $\text{C}=\text{C}$ bond and to the unoccupied antibonding molecular orbitals of hydrogen.^{17, 39, 41} This is to some extent confirmed, particularly by the results of experiments involving the introduction into the reaction mixtures of additives competing with the reactants for the formation of bonds with the metal. Thus, in the interaction of sulfur dioxide — a strong electron acceptor⁴⁰ — with the metal, electrons are transferred to the d orbital of the sulfur atom and this prevents the formation of a π -olefin complex by the metal. Hydrogen sulfide forms a coordinate bond as a result of the transfer of the lone pair of sulfur to the unoccupied orbital of the metal, which ultimately leads to the formation of a surface metal sulfide, which poorly activates hydrogen.¹⁵

It has been shown in a series of studies that 2- and 3-thiolene 1,1-dioxides are hydrogenated on Group VIII metals under mild conditions to thiolane 1,1-dioxide with 100% selectivity.^{10–14, 42} More studies have been devoted to the reaction involving 3-thiolene 1,1-dioxide than to the reaction in which 2-thiolene 1,1-dioxide is hydrogenated because of the relative availabilities of the two dioxides. However, 3-thiolene 1,1-dioxide readily dissociates to buta-1,3-diene and sulfur dioxide. Its vigorous decomposition begins above 100°C , but it decomposes partly even at room temperature. 3-Thiolene 1,1-dioxide therefore always contains a certain amount of sulfur dioxide, which has a definite effect on the catalytic properties of metals. 2-Thiolene 1,1-dioxide is free of this disadvantage because it is thermally more stable.⁶

The hydrogenation of thiolene 1,1-dioxides on Group VIII metals is carried out in solutions at a low temperature and atmospheric or elevated pressure. The liquid-phase hydrogenation of 3-thiolene 1,1-dioxide has been studied in greatest detail on

metallic rhodium, nickel, and palladium, and in much smaller detail on osmium, iridium, ruthenium, and platinum. The results obtained on hydrogenation of thiolene 1,1-dioxides in the presence of Group VIII metals are examined below.

Iridium and osmium. The hydrogenation of 3-thiolene 1,1-dioxide on iridium and osmium has been investigated at 20 °C and $P = 5$ MPa in isopropyl alcohol to which 10 mass % of thiolane 1,1-dioxide had been added (Table 2).⁴² In the presence of iridium black, exhaustive reduction of 3-thiolene 1,1-dioxide took place in 5 min ($g_{ct} = 10.7$ g litre⁻¹, $[SO_2] < 0.03 \times 10^{-3}$ M). The initial rate of reaction in the kinetic region (for 20% conversion) was 0.39 mol h⁻¹ g⁻¹. Iridium, deposited in an amount of 1 mass %–2 mass % on γ -Al₂O₃, exhibited a somewhat higher activity than iridium black ($W = 0.5$ mol h⁻¹ g⁻¹). It may be that the degree of dispersion of iridium in the supported catalyst is somewhat greater, since the rate constant on the supported metal, referred to its unit surface, agrees with the value found for iridium black.

The 1.8 mass % Os/ γ -Al₂O₃ catalyst has a lower activity than the iridium catalyst; for $g_{ct} = 21.5$ g litre⁻¹, complete reduction

Table 2. The activities and stabilities of osmium, iridium, ruthenium, and platinum catalysts in the hydrogenation of 3-thiolene 1,1-dioxide (20 °C, $P = 5$ MPa, $c = 0.4$ M, solvent — isopropyl alcohol to which 10% of thiolane 1,1-dioxide has been added).⁴²

^a Specific surface calculated per unit mass of the metal. ^b The activity given in this and subsequent tables represents the rate constant. It was determined to within ± 10 rel. % per unit surface of the metal. ^c Expressed in mol h⁻¹ g⁻¹. ^d Expressed in mol h⁻¹ m⁻².

of 3-thiolene 1,1-dioxide is attained after 30 min ($W = 0.04$ mol h⁻¹ g⁻¹).

The rate of hydrogenation on iridium is proportional to the concentration of 3-thiolene 1,1-dioxide (at $c = 0.07$ –0.6 M) and the hydrogen pressure (at $P = 0.1$ –2 MPa). In the range of higher values of the above parameters, the rate of reaction remains unchanged.

Ruthenium. The activity of ruthenium in the hydrogenation of 3-thiolene 1,1-dioxide is close to that of iridium (Table 2). On ruthenium black, the 100% yield of thiolane 1,1-dioxide is attained after 6 min at the reaction rate in the kinetic region $W = 0.4$ mol h⁻¹ g⁻¹ ($c = 0.36$ M, $g_{ct} = 10.7$ g litre⁻¹, $[SO_2] < 0.03 \times 10^{-3}$ M).⁴² Under the same conditions, the rate of hydrogenation on supported ruthenium (1 mass %–2 mass % of Ru on γ -Al₂O₃) is 0.1–0.2 mol h⁻¹ g⁻¹. The specific activities of ruthenium on a carrier and of ruthenium black are the same (Table 2). However, if the hydrogenation of 3-thiolene 1,1-dioxide takes place under the conditions of diffusional complications (large catalyst grains, inadequate stirring of the mixture), the supported ruthenium catalyst exhibits a reduced activity:⁴³ exhaustive hydrogenation of 3-thiolene 1,1-dioxide in isopropyl alcohol is attained on this catalyst only after 0.5–1 h {20 °C,

$P = 0.1$ –10 MPa, $c = 0.2$ M, $g_{ct} = 9$ –18 g litre⁻¹, $[SO_2] < 0.03 \times 10^{-3}$ M}.

The activity of supported catalysts can be influenced by the chemical composition of the initial ruthenium compounds, which were potassium ruthenate and ruthenium chloride subjected to successive reduction with hydrogen at 300 °C. At atmospheric pressure, the activity of the catalyst prepared by depositing on charcoal the ruthenium obtained from potassium ruthenate was higher than the activity of the catalyst obtained from ruthenium trichloride. On the other hand, the aluminoruthenium catalysts obtained from potassium ruthenate and ruthenium trichloride have approximately the same activities. The catalyst on silicon dioxide, obtained by depositing ruthenium obtained from the trichloride, is appreciably more active than the specimen prepared from potassium ruthenate.

When the same initial ruthenium compound is used, the catalytic activity is influenced by the nature of the carrier. Thus the activities of the catalyst on γ -Al₂O₃ and activated charcoal are an order of magnitude higher than the activity of ruthenium on silicon dioxide. It has been suggested⁴³ that this is caused by the different degrees of dispersion of ruthenium and the different chemical compositions of the active component, which consists of a mixture of metallic ruthenium and its oxide, the activities of which differ by a factor of 2.⁴²

When 5 mass % of ruthenium is deposited on the Ni/Cr₂O₃ or Ni/SiO₂ industrial nickel catalyst, the activity of the latter either does not change or decreases. On the other hand, the introduction of 5 mass % of ruthenium (obtained from ruthenium trichloride) into an industrial aluminoplatinum catalyst increases its activity by a factor of 2.⁴³

A kinetic study showed⁴² that at $P < 2$ MPa the rate of hydrogenation is proportional to the hydrogen pressure and is independent of the concentration of the substrate. The process is apparently limited by the activation of hydrogen. When 3-thiolene 1,1-dioxide is introduced into a hydrogenated solution containing the hydrogen-saturated 5% Ru/Al₂O₃ catalyst, the potential undergoes a very marked shift to the anodic region (by 600–700 mV), which indicates a significant displacement of hydrogen from the surface by the substrate. An increase in pressure to 2–5 MPa alters the mechanism of the reaction, its rate at 20 °C becomes proportional to the concentration of 3-thiolene 1,1-dioxide (at $c = 0.07$ –0.7 M), but is independent of hydrogen pressure.

Platinum. The hydrogenation of 3-thiolene 1,1-dioxide on supported platinum catalysts is slow.^{44,45} In ethanol on the 4.8 mass % Pt/C catalyst, the yield of thiolane 1,1-dioxide was 81% with $W = 0.017$ mol h⁻¹ g⁻¹ (20 °C, $P = 0.1$ MPa, $c = 0.35$ M, $g_{ct} = 4.8$ g litre⁻¹, $t = 3.5$ h).⁴⁴ The industrial aluminoplatinum catalyst AP-56 also exhibited a low activity in isopropyl alcohol. The rate of reaction on this catalyst was 0.08 mol h⁻¹ g⁻¹ (20 °C, $P = 0.1$ MPa, $c = 0.4$ M, $g_{ct} = 20$ g litre⁻¹).⁴⁶ However, according to other data, catalysts containing 0.6 and 2 mass % of Pt on γ -Al₂O₃ have a much higher activity in isopropyl alcohol to which 10 mass % of thiolane 1,1-dioxide has been added. On these catalysts, $W = 1.1$ –1.2 mol h⁻¹ g⁻¹ {20 °C, $P = 5$ MPa, $c = 0.4$ M, $[SO_2] < 0.03 \times 10^{-3}$ M}.⁴² This discrepancy can apparently be accounted for by the fact that Mashkina *et al.*⁴² hydrogenated a substrate from which sulfur dioxide had been thoroughly removed and carried out the reaction in the absence of diffusional complications, whereas these conditions were not maintained in the studies of Virobyants and coworkers.^{44,45} In the hydrogenation of 3-thiolene 1,1-dioxide on platinum black under thoroughly controlled conditions, the 100% yield of thiolene 1,1-dioxide was attained after 1.5 min with $W = 1.5$ mol h⁻¹ g⁻¹ (20 °C, $P = 5$ MPa, $c = 0.37$ M, $g_{ct} = 10.7$ g litre⁻¹).⁴² In the presence of platinum obtained by the reduction of its dioxide, the rate of hydrogenation per unit mass of the catalyst increases under the conditions indicated by a factor of 32, which can be explained by the increase in the specific surface of the metal. The activities of massive

platinum and platinum deposited on γ - Al_2O_3 , calculated per unit surface, are the same (Table 2).

The rate of hydrogenation on platinum black at 20 °C in isopropyl alcohol to which 10 mass % of thiolane 1,1-dioxide has been added is proportional to the concentration of 3-thiolene 1,1-dioxide ($P = 5$ MPa, $c = 0.05$ – 0.6 M) and the hydrogen pressure ($c = 0.4$ M, $P = 0.1$ – 2 MPa).⁴² At $P > 2$ MPa, the rate of reaction ceases to depend on the pressure. At atmospheric pressure on platinum black in ethanol, the reaction was found to be of first order with respect to 3-thiolene 1,1-dioxide (30–45 °C, $c = 0.077$ M). The increase in the rate of hydrogenation with increase in temperature is characterised by an activation energy of 22 kJ mol⁻¹.

The ratio of the concentrations of the reactants on the surface of the platinum catalyst was estimated in the course of the process by measuring the catalyst potential.⁴⁷ The reversible hydrogen potential of platinum, which is 600–660 mV, shifted by only 50 mV during the hydrogenation reaction. This permitted the conclusion that most of the catalyst surface is occupied by hydrogen and that the rate of reaction is limited by the activation of 3-thiolene 1,1-dioxide. In 0.1 N alcoholic solution of hydrochloric acid, the rate of hydrogenation is approximately twice as high as in a neutral medium and the reaction order with respect to thiophene 1,1-dioxide approaches zero.

Rhodium. Metallic rhodium exhibits a very high activity in the hydrogenation of 3-thiolene 1,1-dioxide.^{42, 48–50} In isopropyl alcohol to which 10 mass % of thiolane 1,1-dioxide has been added, exhaustive hydrogenation is attained on rhodium black after 0.5 min with $W = 54$ mol h⁻¹ g⁻¹ (at 20 °C $P = 5$ MPa, $c = 0.37$ M, $g_{\text{ct}} = 8.6$ g litre⁻¹).⁴⁸ When rhodium is deposited on a carrier, its activity becomes even higher. This can be explained by the increase in the degree of dispersion of the metal, which has been confirmed by data on the chemisorption of oxygen.⁵¹ The degree of dispersion of supported rhodium is inversely proportional to its content, the greatest decrease in the degree of dispersion being observed on silicon dioxide (Table 3). The activity of the catalyst reduced by hydrogen at an elevated temperature can be increased by a factor of approximately four by treating it with air at 50–200 °C.^{48, 50} This effect has been explained by the removal of hydrogen strongly bound to the surface, which reacts with difficulty.⁴⁸ On treating the rhodium catalyst with air, rhodium oxide is not formed.

With increase in the degree of dispersion of the supported rhodium, the per activity of the catalyst per unit mass of the latter increases, whilst the activity per unit surface of the metal remains approximately constant and close to that of rhodium black (Table 3).

Kinetic studies have shown^{42, 48} that in the presence of rhodium black the increase in the rate of reaction with increase in temperature in the range 15–28 °C at $P = 5$ MPa and $c = 0.4$ M corresponds to an apparent activation energy of 34 ± 2 kJ mol⁻¹. When the content of 3-thiolene 1,1-dioxide is between 0.07×10^{-3} and 0.8×10^{-3} M, the rate of reaction (20 °C, $P = 5$ MPa) on rhodium black and on 5% Rh/ Al_2O_3 is proportional to the concentration of the substrate. In the range of pressures P from 0.4 to 2 MPa (at 20 °C and $c = 0.4$ M), the rate of hydrogenation is proportional to the hydrogen pressure, whilst at a higher pressure ($P = 2$ – 7 MPa) it remains unchanged.

Nickel. The hydrogenation of 3-thiolene 1,1-dioxide in the presence of nickel catalysts has been investigated in fair detail. The patents published in the 1940s–1950s present numerous examples of hydrogenation on Raney nickel and nickel deposited on silicon dioxide.^{52–56}

In the absence of a solvent, the yield of thiolane 1,1-dioxide on Raney nickel was ~30% and the hydrogenation was accompanied by the marked decomposition of the substrate (65 °C, $P = 0.01$ MPa, $t = 20$ h).⁵⁴ In solutions in ethanol, water, and thiolane 1,1-dioxide at 20–30 °C and $P \leq 0.01$ MPa, the yield of the target product increased to 58%–100% with $W = 0.006$ – 0.29 mol h⁻¹,^{52, 53, 56} In the presence of an excess of

Table 3. The influence of the content of metallic rhodium in the supported catalyst on its specific surface, activity, and stability in the hydrogenation of 3-thiolene 1,1-dioxide (20 °C, $P = 5$ MPa, $c = 0.4$ M).^{42, 48}

the catalyst, the 100% yield of thiolane 1,1-dioxide was attained already after 5 min (20 °C, $P \geq 30$ MPa, $c = 4.24$ M, $g_{\text{ct}} = 170$ g litre⁻¹), but for $g_{\text{ct}} = 5$ g litre⁻¹ it did not exceed 85% even after 7 h.⁵⁵ On the 72% Ni/ SiO_2 catalyst in thiolane 1,1-dioxide, exhaustive hydrogenation of 3-thiolene 1,1-dioxide in a flow system was attained at 27–30 °C, $P > 7$ MPa, and with the solution supplied at a space velocity of 3 h⁻¹.⁵⁴

Subsequently the study of this reaction in the presence of metallic nickel catalysts was continued. Unfortunately the results of different investigations do not always agree, possibly owing to the different degrees of purification of 3-thiolene 1,1-dioxide and the lack of monitoring of diffusional limitations.

According to the results of Virobyants and coworkers,^{44, 45} on Raney nickel at atmospheric pressure the hydrogenation of 3-thiolene 1,1-dioxide in solution in ethanol is slow and terminates only after 1.5–9.5 h (20 °C, $c = 0.19$ – 0.64 M, $g_{\text{ct}} = 0.7$ – 5 g litre⁻¹). An increase in pressure facilitates the hydrogenation and, for example, in methanol the rate of reaction reaches 0.23 mol h⁻¹ g⁻¹. The hydrogenation is slowest in thiolane 1,1-dioxide and water; in benzene, ethanol, and methanol, the reaction rates increase by factors of 2.5, 4, and 8 respectively (20 °C, $P = 6$ MPa, $c = 1.7$ M, $g_{\text{ct}} = 6$ g litre⁻¹). This agrees with other data,⁵⁷ according to which the rate of hydrogenation on Raney nickel in isopropyl alcohol is higher by a factor of 7–10 than in thiolane 1,1-dioxide (20 °C, $P = 4$ MPa). In the pressure range from 3 to 9 MPa, the rate of hydrogenation is proportional to P and at $P = 7$ – 14 MPa it changes little (20 °C, $c = 1.4$ M).⁴⁵ The slowness of the hydrogenation reaction of 3-thiolene 1,1-dioxide on Raney nickel even at an elevated hydrogen pressure has been confirmed by the results of Sapozhnikova *et al.*⁵⁸ An 87%–100% yield of thiolane 1,1-dioxide in isopropyl alcohol, thiolane 1,1-dioxide, or its mixture with water is attained after 6.5–8 h (30–40 °C, $P = 10$ MPa, $c = 1.4$ M). On the other hand, according to the results of Mashkina *et al.*⁴² in the kinetic region on Raney nickel ($S_{\text{sp}} = 70$ m² g⁻¹) thiolane 1,1-dioxide was formed with 100% yield after only 11 min and the rate of

reaction was $0.3 \text{ mol h}^{-1} \text{ g}^{-1}$ (20°C , $P = 5 \text{ MPa}$, $c = 0.4 \text{ M}$, $g_{\text{ct}} = 7.2 \text{ g litre}^{-1}$, $[\text{SO}_2] < 0.03 \times 10^{-3} \text{ M}$).

The modification of Raney nickel by adding metals increases its activity.⁵⁹ The catalytic properties are determined by the ratio Ni:Al in the alloy and by the method used to introduce additives. If the modification of nickel is carried out in the leaching stage by adding 0.1 mass %–1 mass % of copper, cobalt, chromium, or platinum, the activity of the catalyst increases by a factor of 1.1–1.6, whereas in the presence of 0.1 mass %–2 mass % of added vanadium and molybdenum the increase is by a factor of 1.5–3.0. The addition of molybdenum, vanadium, zirconium, or niobium to nickel in the fusion stage leads to the preparation of a catalyst the activity of which is higher by a factor of 3–6 than that of the unpromoted Raney nickel (Table 4). The surface of the nickel, determined from the degree of adsorption of thiophene, does not change as a result of the promotion.

Table 4. The influence of the promotion of Raney nickel on its catalytic properties in the hydrogenation of 3-thiolene 1,1-dioxide (20°C , $P = 5 \text{ MPa}$, $c = 0.25\text{--}0.38 \text{ M}$, $g_{\text{ct}} = 2.7\text{--}6.3 \text{ g litre}^{-1}$, $[\text{SO}_2] < 0.07 \times 10^{-3} \text{ M}$).⁵⁹

The Raney nickel catalyst obtained from a Ni–Al alloy doped with a series of metals exhibits an enhanced activity also in the hydrogenation reactions of other unsaturated compounds.⁶⁰ It has been postulated that doping with niobium and zirconium leads to an increase in the content of the intermetallic compound NiAl₃ in the alloy; molybdenum aluminides, which influence the degree of dispersion of nickel, are formed in the molybdenum-containing alloys.⁶¹ Doping of vanadium-containing alloys alters the energy of the bond between hydrogen and the surface and the rate of production of hydrogen.⁶²

Nickel on a carrier is also used as a catalyst of the hydrogenation of 3-thiolene 1,1-dioxide. In the presence of 50 mass % of nickel on chromium trioxide or silicon dioxide, the initial rate of reaction (1 min after its onset) in isopropyl alcohol at atmospheric pressure is $0.10\text{--}0.15 \text{ mol h}^{-1} \text{ g}^{-1}$, but exhaustive hydrogenation

is attained only after 1 h and the average rate of reaction over this period is only $0.017 \text{ mol h}^{-1} \text{ g}^{-1}$ ($20\text{--}30^\circ \text{C}$, $c = 0.42 \text{ M}$, $g_{\text{ct}} = 20 \text{ g litre}^{-1}$).^{46, 63–66} The addition of platinum to the nickel–chromium catalyst does not alter its activity.^{67, 68} An increase in pressure promotes an increase in the rate of hydrogenation of 3-thiolene 1,1-dioxide, which is $0.19\text{--}0.33 \text{ mol h}^{-1} \text{ g}^{-1}$ at $P = 2\text{--}5 \text{ MPa}$ ($20\text{--}35^\circ \text{C}$, $c = 0.4\text{--}1 \text{ M}$).^{64, 65}

The kinetics of the hydrogenation of 3-thiolene 1,1-dioxide on Raney nickel and on the nickel–chromium catalyst are approximately the same.^{46, 47, 57, 63–65, 69–72} In the hydrogenation of pure 3-thiolene 1,1-dioxide ($[\text{SO}_2] < 0.03 \times 10^{-3} \text{ M}$), the reaction takes place in the kinetic region, provided that the catalyst grain size does not exceed 0.1 mm. The reaction order depends on the substrate concentration and hydrogen pressure ranges.

At atmospheric pressure, the reaction is of zero order with respect to 3-thiolene 1,1-dioxide dissolved in isopropyl alcohol or thiolane 1,1-dioxide in the concentration ranges $c = 0.5\text{--}5 \text{ M}$ (35°C , Ni/Cr₂O₃) and $c = 0.1\text{--}0.8 \text{ M}$ (20°C , Raney nickel).^{63, 70} On the other hand, when the reaction was carried out in another study⁴⁷ on Raney nickel in ethanol, it was found to be of first order with respect to 3-thiolene 1,1-dioxide ($c \leq 0.07 \text{ M}$, $15\text{--}45^\circ \text{C}$). At an elevated pressure, the reaction order with respect to 3-thiolene 1,1-dioxide changes from zero in the range $c = 1.5\text{--}5.3 \text{ M}$ (30°C , $P = 0.7\text{--}4 \text{ MPa}$) to first in the range $c = 0.1\text{--}2.5 \text{ M}$ ($30\text{--}35^\circ \text{C}$, $P = 0.7\text{--}4 \text{ MPa}$). The reaction order with respect to hydrogen also changes from first in the pressure range $0.01\text{--}2.5 \text{ MPa}$ ($20\text{--}35^\circ \text{C}$, $c = 0.53\text{--}3 \text{ M}$) to zero at $P = 0.7\text{--}4 \text{ MPa}$ ($30\text{--}35^\circ \text{C}$, $c = 0.53\text{--}3 \text{ M}$).^{57, 63, 64, 70}

The dependence of the reaction order on Raney nickel on the reaction conditions has been explained by the change in the mechanism of the hydrogenation of 3-thiolene 1,1-dioxide.⁵⁷ At $P \leq 0.1 \text{ MPa}$ (zero order with respect to the substrate and first order with respect to hydrogen), 3-thiolene 1,1-dioxide is hydrogenated under conditions where its concentration in solution greatly exceeds the concentration of hydrogen owing to the low solubility of the latter. The ratio of the reactant concentrations on the catalyst surface during the reaction at $P = 0.1 \text{ MPa}$ may be inferred from the change in the catalyst potential. The reversible hydrogen potential of Raney nickel is $540\text{--}610 \text{ mV}$ (30°C). When 3-thiolene 1,1-dioxide is introduced into the solution, the potential shifts to the anodic region by a $300\text{--}400 \text{ mV}$,^{47, 57, 65} which indicates the preferential adsorption of the substrate and the displacement of a large proportion of hydrogen from the surface by the latter. The 3-thiolene 1,1-dioxide substrate is rapidly adsorbed on nickel and the limiting degree of its adsorption from solutions is $\sim 0.2 \text{ g per gram of nickel}$. Under these conditions, the degree of surface coverage of nickel by 3-thiolene 1,1-dioxide is high and the rate of hydrogenation is therefore independent of the substrate concentration. The rate of the process is limited by the activation of hydrogen.⁵⁷ Sokol'skaya and Reshetnikov,⁴⁷ who investigated the hydrogenation of 3-thiolene 1,1-dioxide in ethanol on Raney nickel ($15\text{--}45^\circ \text{C}$, $P = 0.1 \text{ MPa}$, $c < 0.1 \text{ M}$), arrived at the same conclusion. At pressures above atmospheric, the concentration of hydrogen in solution and on the nickel surface increases and the reactant ratio on the surface changes, which affects the reaction mechanism.

In order to account for the observed kinetics in the absence of diffusional complications, one employs the kinetic schemes for liquid-phase hydrogenation reactions on inhomogeneous surfaces and the corresponding specific kinetic equations.⁷³ It has been suggested that there is equilibrium between the concentrations of the reactants on the surfaces and in the liquid phase. The lack of dependence of the rate of hydrogenation of 3-thiolene 1,1-dioxide on the weight of the catalyst sample permitted the conclusion that the rate of the process is not limited by the dissolution of hydrogen and that one may use instead of the hydrogen concentration in solution the hydrogen pressure, which is proportional to it.

The first order of the reaction with respect to the substrate at a constant hydrogen pressure, the high rate of adsorption of

3-thiolene 1,1-dioxide, and the occurrence of the reaction at high surface coverages by the substance hydrogenated⁵⁷ provide grounds for the hypothesis that at $c \leq 1.6$ M the reaction takes place in accordance with the Scheme 4.

Scheme 4

If the rate of reaction is limited by the interaction of the dissolved 3-thiolene 1,1-dioxide with the adsorbed hydrogen and the reaction proceeds at high surface coverages by hydrogen, its rate is described by the equation

$$W = kc_1.$$

Here c_1 is the concentration of 3-thiolene 1,1-dioxide and

$$k = \frac{(\vec{k}_2)_0}{m'},$$

where $(\vec{k}_2)_0$ is the rate constant for the second stage in the forward direction and m' is a constant characterising the degree of inhomogeneity of the catalyst surface.

The overall zero order of the reaction with respect to both reactants, observed under the conditions of hydrogenation of Raney nickel at a high 3-thiolene 1,1-dioxide concentration in solution and an elevated hydrogen pressure, has been explained⁴⁷ by the occurrence of the reaction *via* a stage involving the formation of a complex incorporating hydrogen, 3-thiolene 1,1-dioxide, and nickel (Scheme 5).

Scheme 5

If the process is limited by the consumption of the complex (stage 2) and proceeds at a high surface coverage by both reactants, its rate is described by the equation

$$W = k,$$

$$\text{where } k = \frac{(\vec{k}_2)_0}{m'}.$$

In a flow system on large 50% Ni/Cr₂O₃ catalyst grains, the rate of hydrogenation of 3-thiolene 1,1-dioxide is lower than in a static system on fine grains.^{64, 69, 71, 72, 75} The rate of hydrogenation increases with decrease in the catalyst grain size and with increase in the linear rate of supply of the starting material. The activation energy is only 8.4 kJ mol⁻¹. These results indicate that the reaction proceeds in the external diffusion region. At $c = 1.06$ – 2.65 M and $P < 0.6$ MPa, the rate of hydrogenation is proportional to the hydrogen pressure and is independent of the concentration of 3-thiolene 1,1-dioxide. Under these conditions, the process is limited by the rate of supply of hydrogen to the outer surface of the catalyst (external diffusion region with respect to hydrogen). At pressures exceeding 0.6 MPa, the rate of supply of hydrogen to the surface increases and the rate of reaction ceases to depend on the hydrogen pressure (zero order with respect to hydrogen) but becomes proportional to the concentration of 3-thiolene 1,1-dioxide. The slowest stage determining the rate of hydrogenation becomes the rate of arrival of the substrate on the outer surface of the catalyst, *i.e.* the process passes to the external diffusion region with respect to 3-thiolene 1,1-dioxide.

In the kinetic region, the rate of reaction in a flow reactor is expressed by the equation

$$W = kHXP,$$

where k is the reaction rate constant, H the solubility coefficient of hydrogen, the X concentration of hydrogen, and P the pressure.

On the other hand, if the rate of mass transfer is less than the rate of reaction and the process proceeds either at low hydrogen concentrations or low 3-thiolene 1,1-dioxide concentrations, then the equations for the rate of reaction assume the following forms respectively:

$$W = aHk_1P \quad \text{and} \quad W = k_2X,$$

where a is the stoichiometric coefficient and k_1 and k_2 are the mass transfer coefficients of hydrogen and 3-thiolene 1,1-dioxide respectively in the direction of the diffusion flux. These equations describe satisfactorily the experimental data on the hydrogenation of 3-thiolene 1,1-dioxide to thiolane 1,1-dioxide in a flow reactor.

Since under the conditions where the reaction takes place in the external diffusion region with respect to hydrogen the flow reactor becomes similar to the packed column employed for the adsorption of gases, the equations for mass transfer in a film adsorber may be employed for the calculations if it is assumed that the catalyst assumes the role of the packing and the column operates in the film regime.^{69, 71} The principal technological parameters of the process have been selected and a scheme for the synthesis of thiolane 1,1-dioxide has been recommended on the basis of a detailed study of the kinetics of the hydrogenation of 3-thiolene 1,1-dioxide on the nickel-chromium catalyst.^{64, 69, 75}

Palladium. In the early studies (see the present author's previous review¹), it was already noted that, in the presence of metallic palladium catalysts, the multiple bond of 3-thiolene 1,1-dioxide is fully saturated and thiolane 1,1-dioxide is formed in 100% yield. At atmospheric pressure in aqueous solution on colloidal palladium, the reaction is slow with the rate $W = 0.004$ mol h⁻¹ g⁻¹ (20 °C, $c = 0.2$ M, $g_{\text{ct}} = 250$ g litre⁻¹).⁴ When palladium is deposited on charcoal, the rate of reaction in ethanol increases to 0.017–0.05 mol h⁻¹ g⁻¹ (20 °C, $c = 0.35$ – 1.0 M).^{44, 76} In the presence of 5% Pd/BaSO₄ in ethanol, exhaustive hydrogenation takes place over a period of 3–4 min (30 °C, $P = 0.1$ MPa, $c = 0.077$ M, $g_{\text{ct}} = 1.72$ g litre⁻¹) at the rate $W = 0.92$ mol h⁻¹ g⁻¹.⁴⁷

At an elevated pressure, the rate of hydrogenation of purified 3-thiolene to which 1,1-dioxide in the kinetic region in isopropyl alcohol 10 mass % of thiolane 1,1-dioxide has been added increases appreciably. Thus on palladium black the 100% yield of thiolane 1,1-dioxide is attained after less than 1 min and $W = 13.7$ mol h⁻¹ g⁻¹ {20 °C, $P = 5$ MPa, $c = 0.37$ M [SO₂] = 0.028×10^{-3} M}.⁴² Under these conditions, the reaction rates are 4.2, 4.0, 3.4, and 1.3 mol h⁻¹ g⁻¹ on catalysts containing 2 mass % of Pd on γ -Al₂O₃, AlSi, SiO₂, and activated charcoal respectively.⁷⁷

The rate of hydrogenation of 3-thiolene 1,1-dioxide is influenced by the nature of the solvent. On the 5% Pd/Al₂O₃ (20 °C, $P = 5$ MPa, $c = 0.4$ M) in isopropyl alcohol, the reaction was very rapid, in 1-butanol the rate of hydrogenation fell by a factor of 1.2, and in *tert*-butyl alcohol and thiolane 1,1-dioxide it fell by a factor of 10.⁷⁸ In a mixture of isopropyl alcohol and 5 mass %–20 mass % of thiolane 1,1-dioxide, the rate of reaction was the same as in pure isopropyl alcohol. The addition of 2 mass %–10 mass % of water to isopropyl alcohol reduces the rate of hydrogenation by a factor of 1.2–2.5. In isopropyl alcohol, the rate of reaction is a maximum in a neutral medium, the rate diminishing approximately by a factor of 2 when potassium hydroxide or hydrochloric acid is added to the solution at a concentration of 2.5×10^{-3} M.⁷⁸

The kinetics of the hydrogenation of 3-thiolene 1,1-dioxide in pure isopropyl alcohol or isopropyl alcohol to which 10 mass % of thiolane 1,1-dioxide had been added were investigated on palladium-containing catalysts of different compositions.^{42, 78, 79}

On palladium black and on the 2.5% Pd/Al₂O₃ catalyst, the reaction takes place in the kinetic region where the grain size is 0.06–0.1 mm (20 °C, $P = 5$ MPa, $c = 0.4$ M). On catalysts of

different composition in the range of pressures P from 0.1 to 1.0 MPa, the rate of hydrogenation at 20 °C and $c = 1.4$ M is proportional to the hydrogen pressure, but at pressures in the range 1–6 MPa it remains constant. At $P = 5$ MPa, the rate of hydrogenation is proportional to the concentration of 3-thiolene 1,1-dioxide (at $c = 0.1$ –1 M), but at $P = 0.1$ MPa it remains unchanged in the range of concentrations c from 0.04 to 0.21 M.^{42, 78, 79} However, it has been found⁴⁷ that the rate of hydrogenation of 3-thiolene 1,1-dioxide on the 5% Pd/BaSO₄ catalyst in ethanol is proportional to the substrate concentration (at $c < 0.077$ M); the activation energy for the reaction was 19 kJ mol⁻¹ (15–45 °C, $P = 0.1$ MPa).

The mechanism of the hydrogenation of 3-thiolene 1,1-dioxide on palladium-containing catalysts is apparently the same as on nickel catalysts.^{47, 48} The necessary stages of the formation of thiolane 1,1-dioxide are the adsorption of the reactants and their activation on the catalyst surface.

The adsorption of 3-thiolene 1,1-dioxide on palladium at 20 °C and $P = 0.1$ MPa is very rapid and its rate cannot therefore be determined. The ratio of the surface concentrations of the reactants during the reaction was estimated by measuring the catalyst potential at atmospheric pressure in alcoholic solutions.^{47, 67}

The reversible hydrogen potential of the palladium catalyst is 630–640 mV. After the introduction of 3-thiolene 1,1-dioxide into a neutral solution, the potential shifted to the anodic region by 100–120 mV (5% Pd/BaSO₄, 30 °C, $c = 0.077$ M, solution in ethanol)⁴⁷ or by 130 mV (2% Pd/C, 20 °C, $c = 0.25$ M, solution in isopropyl alcohol).⁶⁷ According to the existing ideas,⁴⁷ such a potential shift indicates a relatively weak bond between hydrogen and the catalyst and the displacement of hydrogen from the surface by the adsorbed 3-thiolene 1,1-dioxide and also a high surface coverage by the dioxide.

In principle, it is possible that at $P > 2$ MPa the reaction proceeds *via* an impact mechanism, *i.e.* *via* the interaction of molecular hydrogen with the adsorbed 3-thiolene 1,1-dioxide. However, in this case the rate of hydrogenation should have depended on the hydrogen pressure. Since this conflicts with experimental results, it was concluded⁴⁷ that the hydrogen adsorbed on the palladium surface participates in the reaction.

Hydrogen, which can be adsorbed on palladium at a high rate,³⁹ can participate in the hydrogenation. Thus, on hydrogen-saturated palladium black (20 °C, $P = 0.1$ MPa, $t = 30$ min) in nitrogen, 3-thiolene 1,1-dioxide is hydrogenated at a rate of 14 ml H₂ min⁻¹ g⁻¹. However, this is an order of magnitude less than the rate of hydrogenation in a H₂ atmosphere, *i.e.* the hydrogen dissolved in palladium hydrogenates only part of the substrate and a continuous resupply of the surface by hydrogen is required. The strength of the bond between hydrogen and the catalyst should then lie within definite limits.^{39, 78} This has been confirmed by the results of experiments on hydrogenation on palladium-containing catalysts in which the bond between hydrogen and palladium was changed by means of modifying additives.⁸⁰ Thus, on a hydrogen-saturated 1.5% Pd + 0.5% Pt/C specimen, the anodic potential shift on hydrogenation of 3-thiolene 1,1-dioxide is 90 mV, *i.e.* smaller by 40 mV than on an unpromoted 2% Pd/C specimen.⁶⁷ This indicates a strengthening of the bond between hydrogen and the surface. The rate of hydrogenation of 3-thiolene 1,1-dioxide in isopropyl alcohol on the promoted catalyst decreases from 0.032 to 0.018 mol h⁻¹ g⁻¹ (20 °C, $P = 0.1$ MPa, $c = 0.254$ M). The introduction of alkali into the hydrogenated solution leads to the formation of an unduly strong bond between hydrogen and the palladium surface³⁹ and the activity of the catalyst diminishes. Thus, on the 4% Pd/Al₂O₃ catalyst the rate of hydrogenation of 3-thiolene 1,1-dioxide in a neutral solution is higher by a factor of 3 than after the addition of sodium hydroxide at a concentration of 2.25×10^{-3} M (20 °C, $P = 5$ MPa, $c = 0.4$ M).²²

Under the conditions of the reduction of the catalyst at an elevated temperature (300 °C), a strong hydrogen–palladium

bond is formed and such hydrogen is insufficiently reactive and is desorbed with difficulty.⁸¹ Its removal from the surface *in vacuo* (10⁻³ mm Hg at 300 °C, $t = 20$ h) or on treatment with air (50–250 °C, $t = 2$ h) increases the activity of the catalyst in the hydrogenation of 3-thiolene 1,1-dioxide by a factor of 2.⁸² On comparing the specific surfaces of palladium found from the chemisorption of oxygen and by the method involving the poisoning of the catalyst during hydrogenation, one may conclude that the increase in activity is due to the increase in the number of active sites on the surface after the removal of hydrogen by oxidative treatment.

On palladium black and supported catalysts (2 mass %–10 mass % Pd/γ-Al₂O₃) the reaction orders with respect to hydrogen and 3-thiolene 1,1-dioxide in isopropyl alcohol with added 10% of thiolane 1,1-dioxide depend on the hydrogenation conditions (see above).

The activity of palladium decreases after the introduction into the hydrogenated solution of very small amounts of sulfur dioxide and hydrogen sulfide. The exponential decrease in the activity of the catalyst with increase in the concentration of the poison in solution observed under these conditions is associated with the energy inhomogeneity effect in the real adsorbed layer.

The kinetics observed on palladium catalysts have been examined in a generalised form.⁷⁸ At low pressures ($P = 0.1$ –1 MPa), the concentration of 3-thiolene 1,1-dioxide in solution appreciably exceeds the concentration of hydrogen because of the low solubility of the latter. Under the reaction conditions, the substrate displaces hydrogen from the surface and the latter proves to be saturated by 3-thiolene 1,1-dioxide. It is most likely that the reaction proceeds in accordance with the Scheme 6.

Scheme 6

The zero order of the reaction with respect to 3-thiolene 1,1-dioxide and the first order with respect to hydrogen can be accounted for by the limitation of the process by the stage involving the interaction of the adsorbed substrate with hydrogen. The kinetic equation assumes the following form in this instance:

$$W = k,$$

$$\text{where } k = \frac{(\vec{k}_2)_0 c_2}{m'}.$$

At a hydrogen pressure in excess of 2 MPa, the process kinetics change owing to the alteration of the reaction mechanism. It has been suggested⁷⁸ that an increase in pressure promotes an increase in the concentration of hydrogen in solution and facilitates its access to the catalyst surface. This induces an increase in the degree of surface coverage by hydrogen, which becomes comparable to the degree of surface coverage by the substrate. In this case, the process is described by the kinetic equation which follows from Scheme 4.

The activity of palladium-containing catalysts in the hydrogenation reaction of 3-thiolene 1,1-dioxide depends significantly on the area of the accessible palladium surface. Massive palladium, obtained by the reduction of an aqueous solution of palladium chloride by formalin in an alkaline medium, is characterised by $S_{sp} = 5$ m² g⁻¹, while the specimen prepared by oxidising palladium chloride with sodium nitrate and subsequent reduction with hydrogen is characterised by $S_{sp} = 22$ m² g⁻¹. The activities of these catalysts per gram of palladium (20 °C, $P = 5$ MPa, $c = 0.4$ M) are significantly different (466 and 1850 mol h⁻¹ g⁻¹ respectively), but their activities per unit surface are similar (93 and 84 mol h⁻¹ m⁻² Pd respectively).⁴²

It has been established that the degree of dispersion of palladium on carriers exerts a strong influence on the activity of hydrogenation catalysts.^{77, 79, 83} The degree of dispersion of palladium was measured by several independent methods: by X-ray phase analysis (XPA), by electron microscopy (EM), from the chemisorption of oxygen, carbon monoxide, and sulfur dioxide, and by the method involving the poisoning of the catalyst by a sulfur poison in the course of hydrogenation. All the methods yielded similar degrees of dispersion of palladium. It follows from the data obtained that most of the palladium is in the crystalline state. The degree of dispersion of palladium depends on its content in the catalyst, the nature of the carrier, its specific surface, the method of preparation of the specimen, and the presence of certain additives.

Palladium deposited on alumina, aluminosilicate, and activated charcoal has a high degree of dispersion, whilst palladium deposited on a zeolite, corundum, and carborundum has a low degree of dispersion (Tables 5 and 6).^{77, 79, 83, 84}

Table 6 shows that the degree of dispersion of palladium increases linearly with decrease in its surface concentration. The smallest change in the degree dispersion as a function of the metal concentration on the surface is observed when palladium is deposited on activated charcoal and the greatest change is observed when it is deposited on silicon dioxide. This difference can be explained by the different strengths of the Pd-carrier bond and the associated difference between the surface mobilities of palladium. However, on the whole the overall surface area of the metal increases up to a certain limiting content of the metal on the

carrier and the rate of hydrogenation of 3-thiolene 1,1-dioxide calculated per unit mass of the catalyst therefore increases.

For a constant content of palladium, the degree of its dispersion may be regulated not only by varying the nature of the carrier but also by varying the composition of the impregnating solution and by subjecting the specimen to an additional chemical treatment before reduction. We shall consider this in relation to the Pd/Al₂O₃ catalyst prepared by impregnating the carrier with an aqueous solution of a palladium compound with subsequent reduction by hydrogen at 300 °C for 30 h.^{84–88} The degree of dispersion of palladium in specimens obtained by employing a palladium chloride solution in hydrochloric acid proved to be various (Table 6). In the presence of an excess of hydrochloric acid (HCl: PdCl₂ = 2:1), the Pd²⁺ complex contains only chloride ligands, is weakly bound to the γ-Al₂O₃ surface, and is relatively mobile. Its heat treatment therefore results in the formation of comparatively large palladium agglomerates (specimen No. 1 in Table 6). For the ratio HCl: PdCl₂ = 1:1 (specimen No. 2), the composition of the palladium ion complex includes also OH groups, which promotes stronger binding of palladium to the γ-Al₂O₃ surface and hence a decrease in the degree of crystallisation of the metal. However, unduly strong binding of the Pd²⁺ ion to the carrier, as happens for example when the Pd(NH₃)₄Cl₂ complex is employed (specimen No. 3), makes it necessary to increase the reduction temperature to 400 °C and this tends to intensify crystallisation and promotes a sharp decrease in the degree of dispersion of palladium. Aluminium oxide impregnated with a hydrochloric acid solution of PdCl₂ and subjected to an additional treatment with potassium

hydroxide, sodium carbonate, or hydrogen sulfide before reduction with hydrogen (specimens Nos 4–6) or the same specimen impregnated with palladium nitrate (No. 7) contain a water-insoluble palladium oxide or sulfide, which reduces the mobility of the metal on the surface during reduction and promotes an increase in its degree of dispersion.

With increase in the specific surface of palladium, its activity in the hydrogenation of 3-thiolene 1,1-dioxide per unit mass of the specimen also increases, *i.e.* from the standpoint of increasing the productivity of the catalyst it is convenient to employ specimens with a higher palladium content on the carrier. However, the activity per m² of the palladium surface when the size of the crystallites is up to 20 Å remains approximately constant (within the limits of 20 rel. %) and hardly differs from the specific activity of palladium black (Tables 5 and 6). Thus in this case too Borekov's rule holds.⁷⁴ According to this rule, the specific catalytic activities of catalysts having the same composition are approximately constant.

In many instances, the degree of dispersion of palladium increases when other elements are added to it.^{67, 89, 93} The addition of 3 mass % of boron to palladium black or the 5% Pd/Al₂O₃ catalyst increases the specific surface of palladium and the activity of the catalyst per unit mass of the latter increases by a factor of 1.5–2.^{89, 93} In order to increase the activity of palladium (both massive and deposited on γ -Al₂O₃), it has been suggested that other Group VIII metals be added to the catalyst.^{67, 90, 93} The activity depends on the concentration of the additive introduced and passes through a maximum at a definite content of the latter (Table 7). The passage of the catalytic activities of mixed palladium-containing catalysts through a maximum as a function of composition has been observed also in the hydrogenation of other unsaturated compounds. This phenomenon has been unambiguously explained.³⁹ It has been postulated that the additives alter the amount and form of the sorbed hydrogen and also the energy of its bond with the surface. However, it is difficult to test this experimentally. It may be that the alloy should have a definite electronic structure and that an activity maximum is attained when the number of vacancies in the *d* layer per metal atom is unity.³⁹ However, contrary to experimental data, a catalytic activity maximum should not be observed in this case on Pd–Pt alloys, since both metals have the same number of vacancies (0.6). The additives can influence the electronic configuration of palladium or can alter the degree of its dispersion.^{91, 92}

It is difficult to determine the surface areas of two different supported metals separately. Therefore, in order to justify the important role of the degree of dispersion of palladium, indirect evidence, obtained in a study of mixed oxides without a carrier which are solid solutions according to XPA data, was resorted to.^{67, 93} It was found that the activity of palladium oxide ($S_{sp} = 25$ m² g⁻¹) in the hydrogenation of 3-thiolene 1,1-dioxide is very high and amounts to 1700 mol h⁻¹ g⁻¹, so that complete reduction is attained after 1 min (20 °C, *P* = 5 MPa, *c* = 0.38 M,

$g_{ct} = 0.54$ g litre⁻¹). The palladium oxide is then fully reduced to the metal. Ruthenium and iridium oxides ($S_{sp} = 114$ and 162 m² g⁻¹ respectively) are appreciably less active under the conditions indicated (54 and 2.5 mol h⁻¹ g⁻¹ respectively), while rhodium oxide ($S_{sp} = 160$ m² g⁻¹) is completely inactive. Ruthenium and iridium oxides are reduced much more slowly in alcohol

Table 7. The influence of the modification of palladium catalysts on their activity and stability in the hydrogenation of 3-thiolene 1,1-dioxide (20 °C, *P* = 5 MPa, *c* = 0.38 M).^{67, 89, 93}

at 20 °C than palladium oxide. The complete reduction of Rh_2O_3 by hydrogen to metallic rhodium does not occur until 300 °C over a period of 2 h. Under the conditions of brief (0.5–1 min) saturation of the catalyst with hydrogen before the experiment and when 3-thiolene 1,1-dioxide is hydrogenated during the same period, only palladium oxide is reduced but not the oxides of other metals. The overall surface area of palladium and other platinum group metals in the mixed catalyst is greater than the surface area of unpromoted palladium. One may therefore assume that the increase in the activity of the catalyst in the presence of additives is associated with the increase in the degree of dispersion of palladium. A similar conclusion was reached also in the study of other palladium-containing bimetallic systems. When ruthenium is introduced into PdC or when lanthanum is introduced into Pd/SiO₂, the degree of dispersion of palladium increases.

V. The resistance of metallic catalysts to sulfur

For metallic catalysts used in the low-temperature hydrogenation of various unsaturated substances, sulfur compounds are frequently catalytic poisons. The metal is deactivated as a result of the competitive chemisorption of the poison on the active centres (see the relevant reviews^{94–97}).

Sulfur compounds are strongly chemisorbed on the metal, forming a donor-acceptor bond with the latter.⁹⁴ Compounds of bivalent and tetravalent sulfur, having lone electron pairs, can participate in this process. However, sulfur-containing molecules lose their toxicity when all the valence orbitals of sulfur are saturated as a result of the formation of strong bonds with other elements, as happens, for example, in hexavalent sulfur compounds. The decrease in activity may be caused also by the change in the composition of the catalytically active component. Thus the interaction of hydrogen sulfide or certain organic sulfur compounds with the metal may entail the formation of the metal sulfide, which only weakly activates hydrogen and therefore exhibits a low activity in low-temperature hydrogenation processes.¹⁵

The chemical properties of sulfones have been considered in a number of studies.^{6,40,98} The sulfur atom of the sulfone has no lone pairs and therefore has no electron-donating capacity. The bond between sulfur and oxygen is mainly semipolar ($\text{O} \leftarrow \text{S} \rightleftharpoons$) but it also has partial double bond character (the $p_\pi-d_\pi$ $\text{O}=\text{S}$ bond). It is formed as a result of the interaction of the lone pair of oxygen with the unoccupied d orbital of the sulfur atom. The presence of a large positive charge on the sulfur atom increases the capacity of sulfones for $p-d$ conjugation and this tends to increase the acidity of the α -hydrogen atom of the sulfone. The oxygen atom in the sulfone has excess negative charge and this permits the formation of adducts *via* the oxygen atom. Thus metal compounds in solution form a donor-acceptor bond with charge transfer from the oxygen atom of sulfonyl group to the metal atom.^{14,98}

Knowing the properties of sulfones, one may put forward a hypothesis concerning the probable surface forms of 3-thiolene 1,1-dioxide formed when it comes into contact with the metal and the carrier. Apart from the π -olefin complex, the formation of which activates the multiple bond and leads to its reduction with formation of thiolane 1,1-dioxide (see Scheme 3), other surface structures can also arise (Scheme 7). The formation of bonds between the metal and the oxygen atoms of the sulfonyl group (**A**) is most probable. There is also a possibility of the coordination of the α -hydrogen atoms of the sulfone to the oxygen atoms of the carrier (**B**) and of the α -carbon atoms to the metal atoms (**C**) as well as the formation of a complex as a result of the interaction of the electrons of the metal atom with the d orbital of sulfur

Scheme 7

(a $d_\pi-d_\pi$ bond) (**D**). The formation of a complex on the catalyst surface may entail the weakening and dissociation of the C–S bonds in the 3-thiolene 1,1-dioxide molecule.¹⁴

On dissociation of both C–S bonds in 3-thiolene 1,1-dioxide, buta-1,3-diene and sulfur dioxides are formed.

This reaction occurs even at room temperature and is accelerated as the temperature is raised. Above 100 °C, vigorous decomposition of 3-thiolene 1,1-dioxide begins. Since the hydrogenation of 3-thiolene 1,1-dioxide is an exothermic reaction (with a heat of 113 kJ mol^{–1}), inadequate removal of the heat evolved may promote the decomposition of the substrate. The primary products of the decomposition of 3-thiolene 1,1-dioxide under hydrogenation conditions react with formation of polysulfones and 3-alkoxythiolane 1,1-dioxides.

Divalent sulfur compounds, which are poisons for metallic catalysts may also be formed.

When the degree of poisoning of catalysts is estimated, it is very important to select correctly the criteria of resistance to sulfur. There is no unanimous view concerning this question. In order to compare catalysts, the reactions of the sulfur-containing raw material are frequently carried out under standard conditions (at a definite temperature, pressure, contact time, and concentration of the poison)¹⁰⁰ and the resistance of the catalyst to sulfur is inferred from the yield of the product or from the degree of conversion of the substrate after a specific time interval. Such a measure of resistance to sulfur cannot be regarded as correct, its unsuitability being particularly evident when catalysts with different surface areas are compared.

Since the reaction rate referred to unit surface of the active component, measured in the kinetic region, is the generally accepted characteristic of catalytic activity, in determining the resistance of catalysts to sulfur it is useful to estimate the change in specific activity under the influence of poisons. In order to determine the resistance to sulfur, in the general case it is sufficient to determine the amount of poison in the reaction mixture for

which the specific activity falls to a specified value. The main cause of the deactivation of the catalyst is frequently the decrease in the number of accessible active centres as a consequence of the chemisorption of the poison on them. At a constant temperature, the rate of adsorption and the amount of the adsorbed substance depend only on the concentration of the poison in the reaction mixture. In this case, it is more correct to consider the change in the specific activity of the catalyst as a function of the concentration of the poison in solution and not as a function of the poison: catalyst ratio frequently employed. It has been established^{79, 100} that the specific rate of hydrogenation of 3-thiolene 1,1-dioxide in isopropyl alcohol on the 1% Pd/Al₂O₃ catalyst (20 °C, $P = 0.1$ MPa, $c = 0.127$ M) remains constant ($W = 0.2$ mmol min⁻¹ m⁻² Pd) with the concentration of the poison (thiolane) remaining unchanged at 0.5×10^{-3} M and for different ratios (0.5–4) of the number of moles of the poison to the number of gram-atoms of palladium. If this ratio is kept constant at unity and the concentration of thiolane is increased from 0.1×10^{-3} to 1.75×10^{-3} M, then the specific rate of hydrogenation of 3-thiolene 1,1-dioxide falls by an order of magnitude (from 1.2 to 0.15 mmol h⁻¹ m⁻² Pd).

When the specific surface of the catalyst remains constant as a function of time, it is useful to measure not the specific activity of the catalyst but the productivity or degree of conversion of the substrate (if it is less than 100%) in order to obtain an approximate estimate of the resistance to sulfur. The resistance of catalysts to poisoning has been determined in the kinetic region.^{18, 42, 66, 79} For this purpose, the activities of the catalyst in reactions using the pure starting material and the starting material to which a definite amount of poison had been added were compared. A fresh portion of the catalyst was taken for each experiment and the reaction was carried out during the same time interval. In order to determine the resistance of catalysts in the hydrogenation of 3-thiolene 1,1-dioxide to the poisons present in the initial solution and those generated in the course of the process, the experiments were performed for the same catalyst sample, several portions of the substrate being introduced successively into the hydrogenated solution, the composition of which was kept constant. The concentration of the poison or the amount of thiolane 1,1-dioxide for which different catalysts are deactivated to the same level was assumed to be a measure of the resistance to sulfur. This level was as a rule characterised by the ratio W/W_0 , where W is the current reaction rate and W_0 is its initial value.

In the initial stage, the ratio W/W_0 decreases almost linearly as the concentration of the poison introduced or the amount of thiolane 1,1-dioxide formed on hydrogenation increases. Afterwards, the rate of change of the activity decreases and it is finally stabilised at a constant, lower than initial, level. The nonlinear decrease in activity is caused by the inhomogeneity of the catalyst surface and the attainment of the limiting level is due to the establishment of a new stationary state of the catalyst under the influence of the reaction medium. This may be associated with a change in the nature of the active component, for example with the conversion of the metal into the sulfide or with the appearance of steric hindrance in the interaction of the sulfur-containing poison with the active centre of the catalyst.

The results of studies of the resistance of various metals to sulfur in the hydrogenation of 3-thiolene 1,1-dioxide are described below.

Iridium, osmium, ruthenium, and platinum. In the hydrogenation of 3-thiolene 1,1-dioxide, iridium, osmium, ruthenium, and platinum blacks as well as the same metals deposited on γ -Al₂O₃ are unstable and their activity diminishes as the reaction proceeds.^{42, 93} The complete deactivation of 1 g of the catalyst occurs after the formation of between 8 and 42 mmol of thiolane 1,1-dioxide (Table 2).

It has been established for the Ru/Al₂O₃ catalyst that the resistance to sulfur is independent of the hydrogen pressure in the range 0.1–10 MPa and amounts to ~ 40 mmol g⁻¹. The resist-

ance of platinum to sulfur is influenced by the acidity of the hydrogenated solution. Thus, in the hydrogenation of the second portion of 3-thiolene 1,1-dioxide, the initial activity of the same platinum sample decreases by a factor of 3 in a neutral solution and by a factor of 1.2 in a hydrochloric acid solution.⁴⁷

The specific resistances of ruthenium, iridium, and platinum blacks per unit surface are the same as the resistances of these metals deposited on γ -Al₂O₃ (Table 2).

Sulfur dioxide and hydrogen sulfide are strong poisons for ruthenium and platinum.⁴² For complete deactivation of these metals, the hydrogenated solution should contain 0.05×10^{-3} and 0.7×10^{-3} M of hydrogen sulfide respectively or $\sim 0.14 \times 10^{-3}$ M of sulfur dioxide.

Rhodium. Metallic rhodium is relatively stable in the course of the hydrogenation of 3-thiolene 1,1-dioxide: the complete deactivation of 1 g of rhodium black occurs only after the formation of 1330 mmol of thiolane 1,1-dioxide.⁴² The resistance to sulfur referred to unit mass of the catalyst is higher the higher the degree of dispersion of rhodium and the resistance calculated per m² of the metal is independent of the degree of dispersion of the latter (Table 3).

Rhodium is deactivated by sulfur dioxide.^{42, 48, 49} When the hydrogenated solution contains SO₂ at a concentration of 0.08×10^{-3} M, the activity of rhodium black decreases by a factor of 2 and at [SO₂] = 0.125×10^{-3} M the catalyst loses its activity altogether. Divalent sulfur compounds are also poisons for rhodium. For example, when H₂S is introduced at concentrations of 0.6×10^{-3} and 1×10^{-3} M, the activity of rhodium black decreases by 50% and 100% respectively. Treatment of rhodium black with gaseous sulfur dioxide and hydrogen sulfide (20 °C, $P = 0.1$ MPa, $t = 5$ min) reduces sharply its initial activity in the hydrogenation of 3-thiolene 1,1-dioxide (20 °C, $P = 5$ MPa, $c = 0.4$ M). Whereas the rate of formation of thiolane 1,1-dioxide on fresh rhodium is 52.5 mol h⁻¹ g⁻¹, after treatment with gaseous SO₂ and H₂S it decreases to 0.14 and 0.06 mol h⁻¹ g⁻¹ respectively.⁴⁹ When the rhodium catalyst is treated with hydrogen sulfide, its temperature rises to 200 °C, but this effect is absent in the interaction of rhodium with sulfur dioxide. It has been suggested that sulfur dioxide is adsorbed on rhodium associatively, whereas hydrogen sulfide is adsorbed dissociatively.^{42, 49}

The deactivated rhodium catalyst cannot be regenerated by washing with water, acetone, isopropyl alcohol and hydrogen peroxide with subsequent heat treatment in an inert medium or in hydrogen at 100–300 °C. Oxidative treatment of the deactivated rhodium catalyst at 50–300 °C also fails. One of the causes of such failure may be the oxidation of metallic rhodium to the oxide Rh₂O₃, which does not exhibit an activity in the hydrogenation of 3-thiolene 1,1-dioxide (20 °C, $P = 5$ MPa, $c = 0.4$ M, $g_{\text{cat}} = 1.8$ g litre⁻¹, $t = 1$ min). After its reduction with hydrogen at 300 °C for 2 h, the specific surface diminishes from 162 to 9.5 m² g⁻¹ and the metallic rhodium formed greatly accelerates the hydrogenation of 3-thiolene 1,1-dioxide (specific activity 230 mol h⁻¹ g⁻¹).^{48, 93} The XPA spectrum of rhodium black treated with air at 100–500 °C shows lines characteristic of metallic rhodium (2.20, 1.90, 1.345, and 1.146 Å). Rh₂O₃ lines (3.68, 3.62, 2.722, and 2.623 Å) appear in the spectrum of specimens oxidised at 400–500 °C.⁸²

The oxidation-reduction regeneration of rhodium catalysts may be difficult because of the high stability of the surface compounds, the decomposition of which requires severe conditions, in particular the use of high temperatures, which promotes the sintering of the metal. Thus, when the Rh/Al₂O₃ catalyst treated with hydrogen sulfide or sulfur dioxide at 20 °C as well as authentic rhodium sulfide and sulfate deposited on γ -Al₂O₃ are heated in air, the evolution of sulfur dioxide does not begin until 600 °C.

Nickel. The hydrogenation of 3-thiolene 1,1-dioxide has been studied in detail⁵⁷ in the kinetic region on Raney nickel obtained by leaching an alloy containing 53.2 mass % of Al, 44.1 mass % of Ni, and 2.7 mass % of Ti. With increase in contact time, the

reaction rate constant fell (20°C , $P = 4\text{--}5\text{ MPa}$, $c = 0.37\text{ M}$). This may be a consequence of the deactivation of the catalyst. Indeed on successive hydrogenation of several portions of 3-thiolene 1,1-dioxide for a constant composition of the hydrogenated solution, the rate of reaction fell with increase in the amount of thiolane 1,1-dioxide formed.

The rate of hydrogenation is influenced by the composition of the solvent: in thiolane 1,1-dioxide and in the mixture of isopropyl alcohol with 10 mass %–15 mass % of thiolane 1,1-dioxide, the reaction rates differ almost by an order of magnitude (0.83 and $5.42\text{ mol h}^{-1}\text{ g}^{-1}$ respectively). However, the stability of the catalyst is independent of the nature of the solvent and is determined solely by the amount of hydrogenated 3-thiolene 1,1-dioxide. The stability of the catalyst is influenced by the hydrogenation temperature. Thus, when the reaction is carried out at 21 and 25°C ($P = 5\text{ MPa}$, $c = 0.37\text{ M}$), the complete deactivation of 1 g of Raney nickel takes place after the formation of 133 and 75 mmol of thiolane 1,1-dioxide respectively.

The rate of hydrogenation is influenced also by the content of the sulfur dioxide impurity in the solution: at SO_2 concentrations of 0.2×10^{-3} and $40 \times 10^{-3}\text{ M}$, the reaction rates are 0.83 and $0.3\text{ mol h}^{-1}\text{ g}^{-1}$ respectively. The absence of a direct proportionality between the rate and the SO_2 concentration is probably due to the additional formation of sulfur dioxide during the reaction. The linear decrease in the activity of nickel with increase in the amount of hydrogenated 3-thiolene 1,1-dioxide and the independence of the activation energy of the degree of deactivation of the catalyst ($E = 25 \pm 8\text{ kJ mol}^{-1}$) permitted the conclusion that the deactivation of nickel is induced by the decrease in the fraction of the working active surface of the catalyst.⁵⁷

At the end of the hydrogenation of 3-thiolene 1,1-dioxide, the nickel potential is found to be below the hydrogen potential before the reaction, which may be a consequence of the partial dehydrogenation of the surface. The decrease in the stability of the catalysts as a consequence of dehydrogenation may be reduced by carrying out the process in the external diffusion region (in relation to the compound hydrogenated).¹⁰¹ However, the stability of the 50% Ni/Cr₂O₃ nickel catalyst is virtually independent of the region in which the reaction is carried out.^{46,63,69} Thus in the kinetic region (30°C , $P = 2\text{ MPa}$, $c = 0.4\text{ M}$, solution in thiolane 1,1-dioxide), in the external diffusion region in relation to 3-thiolene 1,1-dioxide (35°C , $P = 5\text{ MPa}$, $c = 1\text{ M}$), and in the external diffusion region in relation to hydrogen (20°C , $P = 0.1\text{ MPa}$, $c = 0.2\text{ M}$, solution in isopropyl alcohol), complete deactivation occurred after the formation of 167 , 150 , and 130 mmol of thiolane 1,1-dioxide per gram of the catalyst respectively.

The degree of dehydrogenation can also be diminished by increasing the strength of the bond between hydrogen and the surface, for example by increasing the pH of the medium.³⁹ Thus, in the hydrogenation of 3-thiolene 1,1-dioxide on the nickel-chromium catalyst in solution in isopropyl alcohol at pH 10.4, the anodic shift of the catalyst potential is smaller by 100 mV than at pH 6.5. This indicates a strengthening of the bond between hydrogen and the surface at the high pH. However, this factor does not affect the stability of the catalyst, its deactivation occurring after the formation of $150\text{--}170\text{ mmol}$ of thiolane 1,1-dioxide per gram of the catalyst.

The strengthening of the bond between hydrogen and the surface of the nickel-chromium catalyst is promoted by the addition of 1 mass % of platinum.^{65,67,68} This is indicated by the results of the measurement of the catalyst potentials. After the introduction of 3-thiolene 1,1-dioxide into a neutral solution (20°C , $P = 0.1\text{ MPa}$) the shift of the Ni/Cr₂O₃ potential was $250\text{--}300\text{ mV}$ and that of the (Ni + Pt)/Cr₂O₃ potential was 100 mV . The initial activity of the nickel-chromium catalyst does not change after the addition of 0.1 mass %–4.0 mass % of platinum ($W = 33\text{--}35\text{ mol h}^{-1}\text{ g}^{-1}$). This is explained by the fact that the hydrogenation reaction is limited by the activation of the substrate.¹⁷ The Pt/Cr₂O₃ catalyst exhibits an extremely low activity and a low stability in the hydrogenation of 3-thiolene 1,1-

dioxide. On the other hand, the (Ni + Pt)/Cr₂O₃ specimen is much more stable than the unpromoted specimen. Thus Ni/Cr₂O₃ was fully deactivated after the formation on it of 150 mmol of thiolane 1,1-dioxide per gram of the catalyst, while the deactivation of specimens containing in addition 1 mass % and 4 mass % of platinum required the formation of 260 and 420 mmol g^{-1} of thiolane 1,1-dioxide. The increase in the stability of the (Ni + Pt)/Cr₂O₃ system is probably due to the decrease in the degree of dehydrogenation of the surface as a consequence of the strengthening of the bond between hydrogen and the catalyst. This reduces the rate of interaction of the poison in the starting material with the catalyst and, what is most important, hinders the dissociative adsorption of 3-thiolene 1,1-dioxide with formation of contact poisons.

In the hydrogenation of 3-thiolene 1,1-dioxide to thiolane 1,1-dioxide in isopropyl alcohol, the resistance of Raney nickel to sulfur may be increased by modifying it by adding certain metals.⁵⁹ The stability of modified Raney nickel depends on the Ni : Al ratio in the alloy and on the method used to introduce the additives (in the fusion stage or during the leaching process). In the modification of Raney nickel by the addition of 0.1 mass %–1 mass % of copper, cobalt, chromium, or platinum in the leaching stage, the stability of the catalyst increases by a factor of only 1.1–1.6, whilst after the addition of 0.1 mass %–2 mass % of vanadium or molybdenum the increase is by a factor of 2–3. The addition of molybdenum (1 mass %–12.5 mass %), vanadium (4.7 mass %–14.8 mass %), and zirconium or niobium (1 mass %) to nickel in the fusion stage leads to the formation of a catalyst more stable by a factor of 2–7 than unpromoted Raney nickel (Table 4).

The hydrogenation of 3-thiolene 1,1-dioxide on the nickel catalyst may be complicated by the occurrence of side reactions involving the formation of buta-1,3-diene, sulfur dioxide, butanethiol, and hydrogen sulfide (see above). The activity of the nickel-chromium catalyst in the hydrogenation of 3-thiolene 1,1-dioxide in the kinetic region in the presence of these substances diminishes (30°C , $P = 0.1\text{ MPa}$, $c = 0.85\text{ M}$, solution in thiolane 1,1-dioxide).⁶⁶

Thiolane is a powerful poison for the nickel-chromium catalyst: the initial rate of hydrogenation ($16\text{ mmol h}^{-1}\text{ g}^{-1}$) decreased by a factor of approximately 6 after the introduction of thiolane at a concentration of $4 \times 10^{-3}\text{ M}$ into the hydrogenated solution. However, a further increase in the thiolane concentration does not alter the rate of hydrogenation. The existence of a limit to poisoning by thiolane can be explained by the fact that, in the interaction with the relatively large thiolane molecules (effective size $\sim 60\text{ \AA}$), a proportion of the nickel atoms are protected. Taking into account the size of the thiolane molecule and the Ni–Ni interatomic distance, one may claim that the maximum degree of surface coverage by thiolane does not exceed 50%.¹⁰² The limiting capacity of the nickel-chromium catalyst with respect to thiolane, determined from the adsorption of the latter from solutions in xylene, is $0.17\text{ mmol per gram}$ of the catalyst and is attained at a thiolane concentration of $16 \times 10^{-3}\text{ M}$. In the presence of this content of the poison, the catalyst nevertheless still possesses some activity. Part of the thiolane is probably adsorbed on the surface sites which are not involved in hydrogenation.

Butanethiol at a concentration of $(1\text{--}2) \times 10^{-3}\text{ M}$ hardly affects the activity of the nickel-chromium catalyst presaturated with hydrogen. The rate of hydrogenation on the catalyst which has not been saturated with hydrogen initially diminishes after the addition of butanethiol at a concentration of $\sim 1 \times 10^{-3}\text{ M}$, but, as the reaction proceeds, it increases again and becomes the same as in the absence of the additive. It has been stated¹⁰³ that nickel is reversibly poisoned by phenylmethanethiol. The observed effect can be accounted for by the fact that the thiol is weakly adsorbed on the surface, forming either a Ni–S bond, which is weakened owing to the reduced electron-donating capacity of the sulfur in the thiol,⁴⁰ or a weak Ni–C bond.¹⁰⁴ The thiol weakly bound to

the surface is gradually displaced into the solution by 3-thiolene 1,1-dioxide or hydrogen.⁶⁶

The hydrogen sulfide present in the hydrogenated solution at a low concentration (up to 0.2×10^{-3} M) increases the rate of hydrogenation of 3-thiolene 1,1-dioxide on the nickel-chromium catalyst by a factor of 1.5. However, at a higher concentration ($2.3\text{--}17 \times 10^{-3}$ M) the rate of hydrogenation decreases by a factor of approximately 5.⁶⁶ Similar effects involving the promotion and poisoning of nickel by divalent sulfur compounds have been observed by Kinza *et al.*¹⁰⁵ They were explained by the fact that, as a consequence of the transfer of p electrons of the sulfur atom in hydrogen sulfide to the d band of nickel, the reactant--catalyst bond is loosened. At a low concentration of the sulfur compound, the optimum bond strength, most suitable for hydrogenation, is attained and this increases the rate of reaction. At a high hydrogen sulfide concentration in solution, the promotion effect is overlapped by the effect involving the blocking of the catalyst surface by the sulfur-containing poison and the rate of hydrogenation falls.

Sulfur dioxide is reduced on the nickel-chromium catalyst to hydrogen sulfide at a rate of $2 \text{ mmol h}^{-1} \text{ g}^{-1}$ (30°C , $P = 0.1 \text{ MPa}$, $g_{\text{ct}} = 50 \text{ g}^{-1} \text{ litre}^{-1}$, $[\text{SO}_2] = 9.4 \times 10^{-3} \text{ M}$). When sulfur dioxide is introduced into the hydrogenated solution, the same effects are therefore observed as in the presence of hydrogen sulfide.⁶⁶

Buta-1,3-diene at its concentration in solution of $(0.19\text{--}35) \times 10^{-3} \text{ M}$, increases by a factor of 2 the rate of hydrogenation of 3-thiolene 1,1-dioxide on the nickel-chromium catalyst. In the absence of 3-thiolene 1,1-dioxide, the hydrogenation of buta-1,3-diene is extremely slow and leads to the rapid deactivation of the catalyst, possibly as a consequence of polymerisation. However, the deactivation has been explained⁶⁶ by the interaction of the π electrons of the conjugated system with the d band of nickel *via* the mechanism proposed by Kinza *et al.*¹⁰⁵ At a concentration of $(35\text{--}208) \times 10^{-3} \text{ M}$, buta-1,3-diene induces a small decrease (by a factor of ~ 1.2) of the rate of hydrogenation of 3-thiolene 1,1-dioxide, probably owing to the formation of a butadiene film on the nickel surface or as a consequence of the displacement of part of the substrate from the catalyst by butadiene.

Thus the poisons for the nickel-chromium catalysts are thiolane, hydrogen sulfide, and sulfur dioxide, which can be arranged in the following sequence in terms of their toxicity (the concentration of the poison expressed in mmol litre^{-1} at which the rate of hydrogenation of 3-thiolene 1,1-dioxide decreases by a factor of 2):

For the complete poisoning of the nickel-chromium catalyst, the content of the poison in solution should be $(2.3\text{--}3.9) \times 10^{-3} \text{ M}$. The poisoning of the catalyst is apparently associated with the formation of the Ni-S bond. It was therefore concluded that the above poisons deactivate the same active centres of the catalyst.⁶⁶

The introduction of certain compounds is recommended for the neutralisation of the sulfur dioxide present in the hydrogenated solution.^{53, 106-112} The stability of Raney nickel in the hydrogenation of 3-thiolene 1,1-dioxide increases by a factor of 2-4 after the addition of hydrogen peroxide to a neutral or alkaline ($\text{pH} < 8$) solution.¹¹¹ The hydrogenation of 3-thiolene 1,1-dioxide on massive nickel was carried out in benzene, dioxane, alcohol, and thiolane 1,1-dioxide to which small amounts of the carbonates, hydroxides, and alkoxides of alkali metals or organic amines had been added.⁵³ According to the author's claim, this makes it possible to carry out the process at an elevated temperature and to increase the lifetime of the catalyst. In the presence of added sodium bisulfite or its mixture with sodium hydroxide, at a concentration of 0.5 mass % - 2 mass %, the stability of Raney nickel increases: the additives increase the maximum yield of

thiolane 1,1-dioxide (20°C , $P = 0.1 \text{ MPa}$, $c = 0.3\text{--}0.6 \text{ M}$) from 55% to 85%. The modified nickel ($30\text{--}40^\circ\text{C}$, $P = 10 \text{ MPa}$, $c = 1.4 \text{ M}$, $t = 6.5\text{--}8 \text{ h}$) also works more steadily in the hydrogenation of 3-thiolene 1,1-dioxide in isopropyl alcohol or in thiolane 1,1-dioxide and, its mixture with water (1:1) in the presence of 2 mass % - 4 mass % of pyridine.¹¹² The maximum yield of thiolane 1,1-dioxide in the absence of additives was 87% - 89%, whilst in the presence of pyridine it increased to 100%. 3-Thiolene 1,1-dioxide decomposes on the catalyst which has not been washed free of alkali and polymeric compounds, tentatively polyacrolein, are formed on the surface.¹¹²

However, Mashkina *et al.*⁵⁷ established that the introduction of additives which, according to other data,¹⁰⁶⁻¹¹² are detoxifying agents in relation to the poisons formed during the process (primarily sulfur dioxide), does not allow an increase in the stability of Raney nickel. Thus, in the hydrogenation of 3-thiolene 1,1-dioxide to thiolane 1,1-dioxide in the kinetic region (20°C , $P = 4 \text{ MPa}$, $c = 0.28 \text{ M}$, $[\text{SO}_2] = 39 \times 10^{-3} \text{ M}$), the addition of hydrogen peroxide and sodium, potassium, or ammonium hydroxides did not prevent the poisoning effect of sulfur dioxide (Table 8).

In the successive hydrogenation in the kinetic region of several portions of thoroughly purified 3-thiolene 1,1-dioxide (sulfur

Table 8. The influence of the addition of certain substances on the hydrogenation of 3-thiolene 1,1-dioxide on Raney nickel in thiolane 1,1-dioxide in the presence of sulfur dioxide.⁵⁷

dioxide concentration $0.14 \times 10^{-3} \text{ M}$) under the conditions of a constant composition of the hydrogenated solution, 1 g of nickel was fully deactivated after the formation of 183 mmol of thiolane 1,1-dioxide. Nor did the stability of the catalyst change after the addition to the hydrogenated solution of sodium hydroxide, ethyl methyl ketone, ionol, or triethylamine, while the addition of sodium bisulfite and large amounts of ionol actually reduced the rate of hydrogenation of 3-thiolene 1,1-dioxide by a factor of 2-3. Under these conditions, the additives did not influence the initial activity of the catalyst (Table 8).

The nickel catalyst deactivated by sulfur compounds is difficult to regenerate.^{113, 114}

Palladium. Like other Group VIII metals, palladium is deactivated in the course of the hydrogenation of 3-thiolene 1,1-dioxide. On the 2% Pd/SiO₂ catalyst, the yield of thiolane 1,1-

dioxide falls from 100% to 80% after the formation of 250 mmol of the latter on 1 g of the catalyst (20 °C, $P = 7.8$ MPa, $c = 1.4$ M, space velocity 4.5 h).¹¹⁵

After the completion of the hydrogenation of one portion of 3-thiolene 1,1-dioxide on the 5% Pd/BaSO₄ catalyst (30 °C, $P = 0.1$ MPa, $c = 0.07$ M), the potential of the latter becomes less than the reversible hydrogen potential (630–640 mV), which indicates partial poisoning of the surface.⁴⁷ On repeated hydrogenation, the initial activity of the catalyst, amounting to 0.92 mol h⁻¹ g⁻¹, decreases by a factor of 4. It was established that this is associated with the deactivation of the catalyst and not with the accumulation of the reaction product in solution.

At a low temperature (10–30 °C), the stability of palladium-containing catalysts is determined solely by the amount of hydrogenated 3-thiolene 1,1-dioxide and not by the rate of its conversion.^{42,93} For this reason, changes in the hydrogen pressure, the nature of the solvent, and in the content of the substrate in the latter do not affect the stability of the catalyst. However, with increase in temperature, the stability falls at unchanged pressure and 3-thiolene 1,1-dioxide concentration. Thus the stabilities of the 5% Pd/Al₂O₃ catalyst at $P = 5$ MPa, $c = 0.4$ M, and temperatures of 20, 30, 50, 70, and 80 °C were respectively 1040, 808, 433, 30, and 8 mmol g⁻¹. This is associated with the increase in the rate of decomposition of 3-thiolene 1,1-dioxide as the temperature rises with formation of products which poison palladium.

The degree of deactivation of the palladium-containing catalyst in the hydrogenation of 3-thiolene 1,1-dioxide depends on the purity of the hydrogenated solution. Thus, when the sulfur dioxide contents were 0.014×10^{-3} , 0.029×10^{-3} , and 0.04×10^{-3} M, 1 g of the 5% Pd/Al₂O₃ catalyst was fully deactivated after the formation on the latter of 416, 833, and 1833 mmol of thiolane 1,1-dioxide respectively.⁴²

An increase in the palladium content increases the stability of the catalyst. The nature of the carrier (aluminium oxide, aluminosilicate, silicon dioxide, activated charcoal) also exerts a definite influence. Palladium deposited on γ -Al₂O₃ (Table 5) is the most stable.^{77,83,93} It was shown above that the nature of the carrier and the surface concentration of palladium influence the degree of dispersion and activity of the latter. It was found that the more accessible becomes the palladium surface the greater the increase not only in the activity but also in the stability of the catalyst. The factors which tend to increase the activity per unit mass of the catalyst (a large area of the carrier, a high palladium content, the addition of boron, manganese, or platinum group metals, activation of the catalyst by air, and the optimum preparation procedure) have a favourable effect also on the stability of the palladium-containing catalyst (Tables 5–7).

Thus an increase in the stability of the palladium catalyst is promoted by a decrease in the hydrogenation temperature, by an increase in the accessible surface of the metal, and by the thorough elimination of sulfur dioxide from 3-thiolene 1,1-dioxide. Nevertheless, this does not fully protect the catalyst against deactivation.

The deactivation of palladium-containing catalysts is caused by their poisoning by tetravalent and divalent sulfur compounds.

Sulfur dioxide is capable of interacting with palladium. After the treatment of palladium with gaseous SO₂ (20 °C, $P = 0.1$ MPa, $t = 5$ min), the specimen contains 0.4 mass % of sulfur. Sulfur dioxide is adsorbed on palladium-containing catalysts (1 mass %–8 mass % of Pd on γ -Al₂O₃, AlSi, SiO₂, or C) from solution in isopropyl alcohol with added 10 mass % of thiolane 1,1-dioxide at a rate of 0.006–0.012 mmol h⁻¹ m⁻² Pd.^{18,42} SO₂ is rapidly adsorbed on palladium films even at –80 °C. For surface coverages up to 0.8, dissociative chemisorption takes place, but part of the sulfur dioxide is adsorbed without decomposition. The fraction of the associatively adsorbed SO₂ increases with increase in the degree of surface coverage. Sulfur dioxide may be removed by evacuation.¹¹⁶

After the desorption of sulfur dioxide, the activity of the palladium catalyst in the hydrogenation of 3-thiolene 1,1-dioxide

is restored to the previous level. The addition of sulfur dioxide to the 3-thiolene 1,1-dioxide solution diminishes the activity of palladium. It follows from the analysis of the poisoning isotherms^{18,42} that, when the SO₂ content is 0.18×10^{-3} M, the rate of reaction diminishes by a factor of 2, while at its concentration of 0.28×10^{-3} M complete deactivation of the catalyst takes place (20 °C, $P = 5$ MPa, $c = 0.4$ M). The activity of the 5% Pd/Al₂O₃ catalyst with adsorbed sulfur dioxide in the hydrogenation of 3-thiolene 1,1-dioxide (20 °C, $P = 5$ MPa, $c = 0.4$ M) is 15 times smaller than that of the initial specimen (13.3 and 0.03 mol h⁻¹ g⁻¹ respectively).^{18,42} The stability of the catalyst therefore depends greatly on the purity of 3-thiolene 1,1-dioxide. Sulfur dioxide is formed to some extent also in the hydrogenation of 3-thiolene 1,1-dioxide because of the ready dissociation of the latter.

It has been established¹¹⁷ that sulfur dioxide, which is a powerful π -electron acceptor, forms a dative bond with the central metal atom of the complex catalyst as a result of electron transfer from the metal to the unoccupied orbital of sulfur. It may be that this is true also of the solid metallic catalyst. The ability of palladium on which sulfur dioxide has been adsorbed to activate hydrogen may be retained under these conditions. Thus palladium treated with sulfur dioxide at 20 °C adsorbs hydrogen, but its activity in the hydrogenation of 3-thiolene 1,1-dioxide reduced.^{18,116} This is apparently induced by the decrease in the dative capacity of palladium, which hinders the formation of a π -olefin complex ensures the activation of the C=C bond of the sulfone.

In the hydrogenation of 3-thiolene 1,1-dioxide contaminated by sulfur dioxide, the palladium-containing catalyst is deactivated and cannot be regenerated either by washing with solvents (water, acetone, and isopropyl alcohol), or by oxidation with hydrogen peroxide, or by exposure to a stream of an inert gas at 200–300 °C. The regeneration is achieved only as a result of the reduction of the specimen with hydrogen at 300 °C for 6 h.⁸⁸

In a hydrogen atmosphere, the sulfur dioxide adsorbed on palladium is reduced to hydrogen sulfide and the rate of hydrogenation is 0.3 mol min⁻¹ g⁻¹ {20 °C, $P = 0.1$ MPa, solution in isopropyl alcohol, [SO₂] = 0.1 M} and increases with increase in pressure. It was therefore concluded²² that the change in the catalytic properties of palladium is associated with the effect on the latter by the hydrogen sulfide arising during the reduction of sulfur dioxide.

Hydrogen sulfide also readily interacts with palladium. When the palladium-containing catalyst is treated with gaseous H₂S (20 °C, $P = 0.1$ MPa, $t = 5$ min), the specimen heats up to 200 °C. After such treatment, the catalyst contains 5 mass % of sulfur.⁴² The adsorption of hydrogen sulfide on palladium is irreversible. The rate of hydrogenation of 3-thiolene 1,1-dioxide on the sulfided specimen is 80 times lower than on the fresh catalyst: at 20 °C, $P = 5$ MPa, and $c = 0.4$ M, it is respectively 13.3 and 0.16 mol h⁻¹ g⁻¹. The introduction of hydrogen sulfide into the solution also reduces the rate of formation of thiolane 1,1-dioxide; at [H₂S] = 0.1×10^{-3} M, the activity decreases by a factor of 2 and at [H₂S] = 0.2×10^{-3} M the catalyst is fully deactivated. The complete deactivation of catalysts of different composition requires ~ 0.05 mmol of hydrogen sulfide per m² of palladium.

In the interaction of hydrogen sulfide with metallic palladium, palladium sulfide is probably formed even at room temperature. Like other metal sulfides, it is appreciably less active than the metal itself (see below).

The regeneration of Pd/Al₂O₃ poisoned with hydrogen sulfide can be achieved only after its reduction with hydrogen at 300 °C for 6 h.

Organic compounds of divalent sulfur also deactivate metallic palladium. The influence of various divalent sulfur compounds on the activity of the 4.7% Pd/Al₂O₃ catalyst in the hydrogenation of 3-thiolene 1,1-dioxide (20 °C, $P = 5$ MPa, $c = 0.4$ M, $t = 0.5$ –1 min) has been investigated.¹¹⁸ It was found that the

stability of the catalyst, estimated as the amount of sulfur required for the complete deactivation of 1 g of the catalyst (α_S), depends on the structure of the sulfur compound. In terms of their toxicity in relation to the catalysts of the hydrogenation of 3-thiolene 1,1-dioxide, the compounds can be arranged in the following sequence corresponding to the changes in the electron-donating capacity of the sulfur entering into their composition (the values of α_S expressed in mg-atom g⁻¹ are indicated in brackets):

A linear relation has been established between the Taft inductive constants and the toxicity of dialkyl sulfides, which indicates the formation of a surface donor–acceptor complex $\text{Pd} \leftarrow \text{S}^{14, 118}$

There exists the view that the resistance of metallic palladium to sulfur may increase when it is deposited on an acidic carrier (a zeolite or $\gamma\text{-Al}_2\text{O}_3$ with added boron) or on activated charcoal.^{119–121} In order to elucidate the contribution of the carrier to the resistance of palladium to the poisoning effect of divalent sulfur compounds, a study has been made^{79, 122} of the hydrogenation of 3-thiolene 1,1-dioxide with added (0.05–5.0) $\times 10^{-3}$ M thiophene and thiolane on metallic palladium deposited on aluminium oxide, an aluminosilicate, silicon dioxide, activated charcoal, and zeolites. In order to avoid the distortion of the sulfur resistance data by effects due to the occurrence of side processes, the authors confined themselves to the measurement of the initial activity, which was inferred from the rate of absorption of hydrogen at the beginning of the stationary section on the kinetic curves (20 °C, $P = 0.1$ MPa, $c = 0.127$ M, conversion 25%–50%). The relative change from the initial rate of hydrogenation in the presence of the poison (W/W_0), determined from the poisoning isotherms, was adopted as the criterion of the resistance of the catalyst to sulfur. In the absence of the poison, the hydrogenation on all the catalysts investigated occurred at a high rate and with 100% yield of thiolane 1,1-dioxide. The rate of reaction remained constant up to the absorption of $\sim 70\%$ of the theoretically required amount of hydrogen and was independent of the size of the catalyst sample ($g_{\text{cat}} = 0.5\text{--}2.5$ g litre⁻¹). The catalysts differed as regards their activities referred to unit mass of the specimen, but the activities calculated per unit surface of the metal were approximately the same (Table 9). The introduction of thiophene and thiolane into the reaction mixture reduced the rate of hydrogenation, the fall being most marked at a poison concentration up to 0.2×10^{-3} M. At higher concentrations, the rate of decrease in the activity fell and at a poison concentration in excess of 2×10^{-3} M the catalyst was fully poisoned. At a concentration $> 1.5 \times 10^{-3}$ M the toxicity of thiolane is higher by a factor of 1.5–3.0 than that of thiophene, but at a lower concentration their toxicities are virtually the same.

Palladium black and palladium deposited in an amount of 1 mass % Al_2O_3 , AlSi , SiO_2 or C have similar resistances to sulfur: a twofold decrease in activity occurs in all cases at a thiolane concentration of $\sim 0.06 \times 10^{-3}$ M, i.e. the nature of the carrier does not affect the stability of the catalyst. At a constant concentration of the poison, the values of W/W_0 for supported catalysts with different palladium contents are virtually the same and close to the corresponding value for palladium black. Since the specific surfaces of the test specimens differed by approximately one order of magnitude, one may conclude that the degree of dispersion of palladium does not affect the stability of the catalyst in relation to the poisoning effect of divalent sulfur compounds. experiments on the hydrogenation of 3-thiolene 1,1-dioxide with added thiolane

Table 9. The resistance of various palladium-containing catalysts to sulfur in the hydrogenation of 3-thiolene 1,1-dioxide (20 °C, $P = 0.1$ MPa, $c = 0.127$ M).^{79, 122}

showed that the 1% Pd/HNaY catalyst has a low activity (Table 9), but at a poison concentration of $(0.15\text{--}2.0) \times 10^{-3}$ M the quantity W/W_0 on this specimen is approximately twice as high as on other supported palladium catalysts. This is associated with the partial adsorption of thiolane on the zeolite. However, the zeolite carrier does not fully protect metallic palladium against poisoning and, when thiolane is introduced into the solution at a concentration of 2.5×10^{-3} M, the ratio W/W_0 is only 3%. The different acidities of the palladium-zeolite catalyst containing 0.9 mass %–7.8 mass % of sodium do not affect their resistance to sulfur. The acid centres of the zeolite framework influence the electronic state of palladium, but this is hardly reflected in its resistance to poisoning by divalent sulfur compounds. The results failed to confirm the hypothesis^{119–121} that the deposition of palladium on an acid carrier or charcoal significantly protects it against poisoning by sulfur compounds.

Thus, during the hydrogenation of 3-thiolene 1,1-dioxide, metallic palladium is deactivated by various sulfur compounds. At a low temperature, the poisons in relation to palladium are sulfur dioxide as well as the hydrogen sulfide appearing when the latter is hydrogenated, while at a high temperature organic divalent sulfur compounds are also formed in addition during the process.

The poisoning of metallic palladium by sulfur-containing impurities may be diminished by introducing acid or alkaline additives into the hydrogenated solution.¹²³ Thus, in the hydrogenation of 2-thiolene 1,1-dioxide in a neutral solution in isopropyl alcohol (20 °C, $P = 0.1$ MPa, $c = 0.127$ M), the activity of the 2.5% Pd/ Al_2O_3 catalyst decreases by a factor of 2 following the addition of thiolane at a concentration of 0.1×10^{-3} M. On

the other hand, in the presence of KOH at a concentration of $(0.25-2.5) \times 10^{-3}$ M, the concentration of thiolane required to achieve this effect is $(0.6-1.25) \times 10^{-3}$ M, *i.e.* the resistance of the catalyst to sulfur increases approximately by an order of magnitude. The strength of the bond between hydrogen and the surface probably increases in an alkaline medium and this hinders the chemisorption of thiolane on the active centres. The stability of the same catalyst in the hydrogenation of 2-thiolene 1,1-dioxide in isopropyl alcohol containing an admixture of sulfur dioxide increases by a factor of 2 after the acidification of the solution with hydrochloric acid (0.25×10^{-3} M). It may be that the catalytic poison is the hydrogen sulfide evolved on reduction of sulfur dioxide. Its interaction with palladium leads to the formation of palladium sulfide, while hydrochloric acid ruptures the Pd-S bond.¹²³ Alkali is introduced into the 3-thiolene 1,1-dioxide solution in order to neutralise sulfur dioxide.

The activity of the 2.5% Pd/Al₂O₃ catalyst in the presence of 0.1×10^{-3} M SO₂ in a neutral solution is lower by a factor of 2 than in the hydrogenation of pure 3-thiolene 1,1-dioxide. In the presence of $(0.25-2.5) \times 10^{-3}$ M potassium hydroxide, the poisoning of the catalyst to the same level requires the introduction into the solution of 0.2–0.4 mmol of SO₂ per litre, *i.e.* the stability of the catalyst increases by a factor of 2–4.¹²³ In the hydrogenation of 3-thiolene 1,1-dioxide thoroughly freed from sulfur poisons, an increase in the basicity of the medium, for example by the introduction into the latter of KOH at a concentration of 2.25×10^{-3} M, also tends to increase the stability of palladium, since alkali neutralises the sulfur dioxide formed as a result of the partial decomposition of the substrate.⁴² After the introduction of 0.5 mass % of potassium hydroxide into the 2% Pd/Al₂O₃ catalyst, its stability increases by a factor of two.^{89,93} The stability of the 5% Pd/Al₂O₃ catalyst increases by a factor of 2.5–3.5 also when alkaline adsorbents (the NaY zeolite, Al₂O₃, or SiO₂, all containing 5 mass % of potassium) are added to the solution.^{42,93} However, the activity of palladium-containing catalysts in a basic medium is lower than in a neutral medium. Thus the rate of hydrogenation of 3-thiolene 1,1-dioxide (20 °C $P = 5$ MPa, $c = 0.4$ M) on 4.5% Pd/Al₂O₃ in a neutral medium is $500 \text{ mol h}^{-1} \text{ g}^{-1}$, while after the addition of 0.01 mass % NaOH it is $150 \text{ mol h}^{-1} \text{ g}^{-1}$.⁴²

A more detailed study confirmed^{22,93} that the rate of hydrogenation of 2- and 3-thiolene 1,1-dioxides diminishes in alcoholic solutions (Table 10). At atmospheric pressure, the rate of hydrogenation in isopropyl alcohol {20 °C, [KOH] = $(0.1-10) \times 10^{-3}$ M} and 1-butanol {20 °C, [KOH] = $(13-150) \times 10^{-3}$ M} decreases in proportion to the concentration of potassium hydroxide raised to the power 0.5. If the reaction is carried out in isopropyl alcohol (to which 10% of thiolane 1,1-dioxide has been added) at an elevated hydrogen pressure (5 MPa), the above relation holds only for a NaOH concentration $< 2.3 \times 10^{-3}$ M while at a higher sodium hydroxide concentration the rate of decrease in the rate of hydrogenation of thiolene 1,1-dioxide diminishes.

The decrease in the activity of metallic palladium in the hydrogenation of 3-thiolene 1,1-dioxide in an alkaline medium may be induced by various causes. In principle, one cannot rule out the possibility of the blocking of the active centres of the catalyst by the products of the alkaline cleavage of thiolene 1,1-dioxide or thiolane 1,1-dioxide, but such cleavage occurs at an appreciable rate only on refluxing in an aqueous alkaline medium.¹²⁴ The second cause may be the increase in the alkaline medium of the strength of the bond between hydrogen and palladium.³⁹ The hydrogenation of 3-thiolene 1,1-dioxide on metallic catalysts at atmospheric pressure is limited by the activation of hydrogen,¹⁷ so that the strengthening of its bond with palladium may decrease the rate of reaction. With increase in pressure, the mechanism of the hydrogenation of 3-thiolene 1,1-dioxide changes and a strengthening of the bond between hydrogen and the surface therefore has a smaller effect on the activity of the catalyst.

^a Expressed in mmol litre⁻¹. ^b Expressed in mol h⁻¹ g⁻¹. ^c Hydrogenation of 2-thiolene 1,1-dioxide. In the remaining cases, the hydrogenation of 3-thiolene 1,1-dioxide is meant.

The rate of hydrogenation of 3-thiolene 1,1-dioxide in an alkaline medium may also change owing to a transformation of the substrate unrelated to the catalytic hydrogenation. Thus the double bond in the 3-thiolene 1,1-dioxide ring may migrate under the influence of bases in alcoholic solutions with formation of 2-thiolene 1,1-dioxide.

The isomerisation in the presence of an alkaline agent occurs even at room temperature and is accelerated on heating.⁶ However, the conversion of 3-thiolene 1,1-dioxide into 2-thiolene 1,1-dioxide cannot be regarded as the cause of the decrease in the rate of formation of thiolane 1,1-dioxide in an alkaline medium in view of the following considerations. 2-Thiolene 1,1-dioxide is known to be hydrogenated at a high rate in a neutral medium.¹ Under comparable conditions, the rate of formation of thiolane 1,1-dioxide from 2-thiolene 1,1-dioxide is actually somewhat higher than the rate of its formation from 3-thiolene 1,1-dioxide. Thus, on the 2.5% Pd/Al₂O₃ catalyst in isopropyl alcohol, the rates of hydrogenation of 3- and 2-thiolene 1,1-dioxides are respectively 1.12 and 1.33 mol h⁻¹ g⁻¹ at 20 °C, $P = 0.1$ MPa, and $c = 0.4$ M and 3.8 and 4.5 mol h⁻¹ g⁻¹ at 20 °C, $P = 5$ MPa, and $c = 0.13$ M. Under the conditions of the hydrogenation of 2-thiolene 1,1-dioxide in a neutral medium at 20 °C, the palladium catalyst works more steadily than in the hydrogenation of 3-thiolene 1,1-dioxide: the initial rate of hydrogenation of 3-thiolene 1,1-dioxide on a 2.5% Pd/Al₂O₃ specimen, amounting to 12 mol h⁻¹ g⁻¹ decreases to 0.01 mol h⁻¹ g⁻¹ after the formation of 1000 mmol of thiolane 1,1-dioxide per gram of the catalyst, while 2-thiolene 1,1-dioxide is hydrogenated virtually at a constant rate of 12–14 mol h⁻¹ g⁻¹ (20 °C, $P = 5$ MPa, $c = 0.4$ M).²² This is probably due to the fact that 2-thiolene 1,1-dioxide is predisposed to decompose with elimination of sulfur dioxide, which is a poison for palladium. In an alkaline medium, the rate of hydrogenation of 2-thiolene 1,1-dioxide on 2.5% Pd/Al₂O₃ decreases in proportion to the concentration of potassium hydroxide raised to the power 0.5, *i.e.* as happens in the hydrogenation of 3-thiolene 1,1-dioxide (Table 10). One may therefore conclude that the isomerisation of 3-thiolene 1,1-dioxide to 2-thiolene 1,1-dioxide does not decrease the rate of its hydrogenation in alkaline alcoholic solutions.

The isomerisation of 3-thiolen 1,1-dioxide to 2-thiolen 1,1-dioxide in primary and secondary alcohols is accompanied by the addition of the alcohol to the double bond activated by the electron-accepting sulfonyl group in the ring. This results in the formation of 3-alkoxythiolane 1,1-dioxides (sulfolanyl esters).⁶ For example, 3-butoxythiolane 1,1-dioxide is formed in butanol.

The reaction is reversible, the content of 3-butoxythiolane 1,1-dioxide amounting to $94\% \pm 2\%$ in the presence of primary alcohols in the equilibrium mixture and to $88\% \pm 2\%$ in the presence of secondary alcohols. In an alkaline solution, 3-alkoxythiolane 1,1-dioxide may decompose with formation of 2-thiolen 1,1-dioxide. This reaction is also reversible.⁶ However, if it is carried out under a hydrogen atmosphere in the presence of a hydrogenation catalyst, then the 2-thiolen 1,1-dioxide formed is hydrogenated and this shifts the equilibrium towards the formation of elimination products.

The occurrence of the above reactions results in the complete conversion of 3-thiolen 1,1-dioxide into thiolane 1,1-dioxide. The possibility of this transformation in the presence of 2.5% Pd/Al₂O₃ has been established in the hydrogenation of authentic 3-alkoxythiolane 1,1-dioxides having the general formula

where $R = C_1 - C_{12}$ ($20 - 85^\circ\text{C}$, $P = 0.1 - 5\text{ MPa}$, $c = 0.06 - 1.4\text{ M}$, $[\text{KOH}] = 0 - 1.42\text{ M}$).¹²⁵ 3-Butoxythiolane 1,1-dioxide is the most reactive. Its hydrogenation takes place in alkaline alcoholic (isopropyl alcohol and *tert*-butyl alcohol), aqueous, and thiolane 1,1-dioxide solutions. In the absence of alkali the rate of reaction is very low. The quantitative yield of thiolane 1,1-dioxide is attained in an aqueous alkaline solution at an elevated temper-

ature and a high content of alkali. The rate of formation of thiolane 1,1-dioxide in the presence of 2.5% Pd/Al₂O₃ from 3-butoxythiolane 1,1-dioxide is much lower than the rate of its formation from 3-thiolen 1,1-dioxide in a neutral medium (Table 11). With increase in temperature from 20 to 85°C , the rate of formation of thiolane 1,1-dioxide from the ether increases, the activation energy being $25 \pm 4\text{ kJ mol}^{-1}$. The rate of reaction depends little on the hydrogen pressure: when it increases from 0.1 to 5 MPa, the rate increases by a factor of 1.3. In an aqueous alkaline solution, the rate of reaction of 3-butoxythiolane 1,1-dioxide initially increases in proportion to its concentration (up to 0.1 M) and then (at a concentration up to 1.5 M) remains constant. The rate of reaction is proportional to the concentration of potassium hydroxide raised to the power 0.5 [for $[\text{KOH}] = 0.013 - 0.89\text{ M}$]. Overall, the rate of formation of thiolane 1,1-dioxide from 3-butoxythiolane 1,1-dioxide is described by the equation

$$W = kc_1^n c_2^{0.5} P^{0.2},$$

where c_1 and c_2 are the concentrations of 3-butoxythiolane 1,1-dioxide and potassium hydroxide respectively, P is the hydrogen pressure, k is the reaction rate constant, and $n = 0$ or 1.

In the presence of alkali, the initial rates of hydrogenation of authentic 2-thiolen 1,1-dioxide and 3-butoxythiolane 1,1-dioxide are of the same order of magnitude. For example, at 85°C , $P = 0.1\text{ MPa}$, $c = 0.127\text{ M}$, and $[\text{KOH}] = 0.89\text{ M}$, they are respectively 32 and $12\text{ mmol h}^{-1}\text{ g}^{-1}$. This observation and the fact that the rate of reaction depends little on the hydrogen pressure permit the conclusion that the formation of thiolane 1,1-dioxide from 3-butoxythiolane 1,1-dioxide is limited by the elimination of the alcohol and not by the reduction of the 2-thiolen 1,1-dioxide formed.¹²⁵

In the hydrogenation of 2- and 3-thiolen 1,1-dioxides as well as 3-butoxythiolane 1,1-dioxide in alcoholic solutions, the rates of formation of thiolane 1,1-dioxide on the 2.5% Pd/Al₂O₃ catalyst are similar (Table 11). One may therefore postulate that the conversion of 3-thiolen 1,1-dioxide in alcoholic alkaline solutions proceeds *via* stages involving isomerisation and addition of the alcohol to the 2- and 3-thiolen 1,1-dioxides with formation of alkoxythiolane 1,1-dioxide and its subsequent hydrogenation to thiolane 1,1-dioxide. In order to attain an acceptable rate of formation of thiolane 1,1-dioxide, the hydrogenation must be carried out at an elevated temperature.

During the hydrogenation of 2- and 3-thiolen 1,1-dioxides and 3-butoxythiolane 1,1-dioxide on 2.5% Pd/Al₂O₃ at atmospheric pressure and a temperature in excess of 70°C , the catalyst is

Table 11. Hydrogenation of 2- and 3-thiolen 1,1-dioxides and 3-butoxythiolane 1,1-dioxide on aluminopalladium catalysts at $P = 5\text{ MPa}$.²²

rapidly deactivated despite the high content of alkali in the solution. For example, at 70–85 °C, $[\text{KOH}] = 0.45\text{--}0.89\text{ M}$, and $c = 0.13\text{ M}$, the rate of reaction in an alkaline solution is a maximum in the first minute and then falls sharply (by an order of magnitude).^{22, 125} The rate of formation of thiolane 1,1-dioxide from portions of the substrate introduced successively into the solution on the same catalyst sample (for a constant composition of the solution) does not remain constant. The amount of thiolane 1,1-dioxide formed on 1 g of the catalyst before the decrease in the initial activity by a factor of 20 is independent of the substrate concentration and amounts to $(2\text{--}5) \times 10^{-3}\text{ M}$. At an elevated hydrogen pressure (5 MPa), the catalyst works more steadily: its initial activity does not decrease after the formation of $\sim 400\text{ mmol}$ of thiolane 1,1-dioxide per gram of the catalyst.

The dependence of the stability of metallic palladium on the hydrogen pressure is determined by the ratio of the rates of isomerisation and hydrogenation of 2-thiolene 1,1-dioxide. At atmospheric pressure, the rate of hydrogenation is relatively low and 2-thiolene 1,1-dioxide isomerises to a large extent to 3-thiolene 1,1-dioxide, which is a source for the formation of catalytic poisons. At an elevated pressure, the contribution of the isomerisation process falls since the rate of hydrogenation increases markedly. The significance of the presence of 3-thiolene 1,1-dioxide in the hydrogenated solution for the deactivation of palladium has been confirmed also by experiments on hydrogenation at elevated temperatures, which promote its dissociation. Thus the rate of formation of thiolane 1,1-dioxide from 3-thiolene 1,1-dioxide on the 5% $\text{Pd}/\text{Al}_2\text{O}_3$ catalyst in isopropyl alcohol ($P = 5\text{ MPa}$, $c = 0.53\text{ M}$, conversion 70%) increases from 10 to $54\text{ mol h}^{-1}\text{ g}^{-1}$ with increase in temperature from 8 to 50 °C. At 70–85 °C, it falls sharply, reaching values from 0.4 to $0.01\text{ mol h}^{-1}\text{ g}^{-1}$, since the catalyst is fully deactivated.⁹³

The sulfur dioxide evolved on decomposition of 3-thiolene 1,1-dioxide, is readily reduced in the presence of the palladium catalyst to hydrogen sulfide, which interacts with metallic palladium. Thermodynamic calculations indicate a high probability of the formation of palladium sulfide under these conditions. This process proceeds at a low temperature and accelerates when the latter is increased.¹²⁶ It has been established experimentally that metallic palladium is fully converted into palladium sulfide after treatment with hydrogen sulfide at 200 °C for 30 min.¹⁹ On the other hand, thermodynamic calculations for the $\text{PdS} + \text{H}_2 \rightleftharpoons \text{Pd} + \text{H}_2\text{S}$ system and experimental studies by the XPS and thermostimulated exoelectron emission methods^{16, 127} indicate the possibility of the partial reduction of PdS to metallic palladium (and Pd_2S) at moderate temperatures. However, the reduction of palladium sulfide by hydrogen is much slower than the conversion of metallic palladium into the sulfide: at 200 °C, the degree of reduction is 2% and 83% after 1 and 10 h respectively.¹⁹ One may therefore assume that the catalyst of the formation of thiolane 1,1-dioxide from thiolene 1,1-dioxides in an alkaline medium at an elevated temperature and pressure is not metallic palladium but its sulfide.

In the presence of palladium sulfide (2.5% $\text{PdS}/\text{Al}_2\text{O}_3$) at an elevated temperature and a high hydrogen pressure, the hydrogenation of 2- and 3-thiolene 1,1-dioxides in a neutral medium and of 3-butoxythiolane 1,1-dioxide in an alkaline solution proceeds at the same rate as in the case where metallic palladium is employed as the catalyst (Table 11). In the hydrogenation of 3-thiolene 1,1-dioxide in an alcoholic alkaline solution on the 2.5% $\text{PdS}/\text{Al}_2\text{O}_3$ catalyst, the same behaviour is observed as in the hydrogenation of 2-thiolene 1,1-dioxide in a neutral medium.^{22, 128} The rate of reaction is proportional to the substrate concentration and the hydrogen pressure. With increase in temperature from 80 to 110 °C, the yield of thiolane 1,1-dioxide obtained from 3-thiolene 1,1-dioxide on palladium sulfide in an alkaline medium initially increases from 78% to 90% ($P = 5\text{ MPa}$, $c = 0.04\text{ M}$, $[\text{KOH}] = 0.45\text{ M}$, $g_{\text{cat}} = 25\text{ g litre}^{-1}$), but then falls to 58% at 135 °C and 22% at 200 °C. In the presence of $\text{Pd}/\text{Al}_2\text{O}_3$, the dependences of the rates of hydrogenation of 3-thiolene 1,1-

dioxide and 3-butoxythiolane 1,1-dioxide on the concentration of alkali in the alcoholic solution are the same: the rate of reaction is proportional to the concentration of alkali raised to the power 0.5.^{22, 125}

The similarity of the kinetics and of the rates of hydrogenation of 2- and 3-thiolene 1,1-dioxides and of 3-alkoxythiolane 1,1-dioxide in an alcoholic alkaline medium at an elevated temperature in the presence of Pd and PdS is a consequence of the similarity of the reaction mechanisms on catalysts of identical composition formed under the influence of the reaction medium. Thiolane 1,1-dioxide is formed from 3-thiolene 1,1-dioxide *via* stages involving its isomerisation to 2-thiolene 1,1-dioxide, the addition of the alcohol with formation of 3-alkoxythiolane 1,1-dioxide, and the reduction of the latter by hydrogen. The low activity of metallic palladium under the given conditions is due to the change in the nature of the active component — the conversion of Pd into PdS .

Thus the hydrogenation of 3-thiolene 1,1-dioxide on palladium-containing catalysts in the presence of added alkali has no advantage over the hydrogenation in a neutral medium on metallic palladium.

Metallic palladium catalysts deactivated in the hydrogenation of 3-thiolene 1,1-dioxide cannot be regenerated by washing them with solvents (water, alcohol, and acetone), by oxidation with hydrogen peroxide, or by exposure to a stream of nitrogen at 200–300 °C for 10 h. Treatment with hydrogen at 300 °C partially restores the activity of palladium (to the extent of $\sim 80\%$), but full regeneration occurs only after additional treatment with air.¹¹⁵

The XPA spectra of palladium-containing specimens treated with air for 10 h at 100–400 °C exhibit only lines characteristic of metallic palladium (2.23, 1.94, 1.371, and 1.170 Å). In the specimens treated with air at 500 °C, the above lines vanish and those of PdO appear (3.046, 2.667, 2.664, and 2.153 Å).⁸² For the activity of the catalyst, this is unimportant because palladium oxide is readily reduced to the metal even at 20 °C. The thermal stability of palladium compounds is low¹²⁹ and they are therefore relatively easily removed from the surface of the deactivated catalyst. On heating in air, the compounds weakly bound to palladium are desorbed, liberating part of the catalytically active surface. The substances strongly bound to the catalyst, for example a thiol and thiolane, may be oxidised to compounds which have a low toxicity or are nontoxic. Palladium sulfide, formed on interaction of palladium with hydrogen sulfide, is oxidised with evolution of sulfur dioxide, which reacts with palladium in an oxidising medium, affording a surface palladium sulfate. Palladium sulfide and sulfate, deposited on $\gamma\text{-Al}_2\text{O}_3$, are completely inactive in the hydrogenation of 3-thiolene 1,1-dioxide at 20 °C and $P = 5\text{ MPa}$. The activity of $\text{PdS}/\text{Al}_2\text{O}_3$ treated with hydrogen at 300 °C for 20 h is low, but after additional oxidation with air at 200–300 °C for 2 h the catalyst acquires the same activity as metallic palladium deposited on $\gamma\text{-Al}_2\text{O}_3$. A similar treatment of a $\text{PdSO}_4/\text{Al}_2\text{O}_3$ specimen proved ineffective. One cannot rule out the possibility, however, that the surface compounds formed on deactivation of palladium decompose more readily than the bulk-phase PdS and PdSO_4 . Sulfur dioxide, water, and carbon dioxide are evolved on oxidative regeneration of palladium catalysts. They are formed on oxidation of the products of the decomposition of 3-thiolene 1,1-dioxide accumulated on the surface and also as a result of the conversion of the sulfided palladium and not as a result of the oxidation of adsorbed 3-thiolene 1,1-dioxide, alcohol, or thiolane 1,1-dioxide. In the oxidative regeneration of the deactivated $\text{Pd}/\text{Al}_2\text{O}_3$ catalyst, 5–7 times more sulfur and carbon dioxides are evolved than on treating with air a specimen wetted with a 10% solution of the substrate in a mixture of isopropyl alcohol and thiolane 1,1-dioxide. It has been established that the hydrogenation–regeneration cycles involving aluminopalladium catalysts can be repeated many times and that this does not alter the initial activity and duration of the interregeneration period.⁸⁸

VI. Conclusion

As shown above, thiolane 1,1-dioxide can be synthesised by hydrogenating 2- and 3-thiolene 1,1-dioxides in the presence of various catalysts — metals, their complexes, and their sulfides. Group VIII metals have been investigated in greatest detail in this respect. The catalysts based on them exhibit a high activity and make it possible to obtain thiolane 1,1-dioxide in 100% yield by hydrogenation under mild conditions.

The most correct data on the relative activities and stabilities of the metals are obtained when thiolene 1,1-dioxides are hydrogenated in the absence of the distorting influence of mass-transfer processes and in estimating the catalytic properties account is taken of the specific surface of the active component. In terms of their activities in the hydrogenation of 3-thiolene 1,1-dioxide, the massive metals can be arranged in the sequence⁴²

The activities of iridium, ruthenium, and nickel per gram of the metal are approximately the same. Platinum is 6.5 times more active than the above metals and palladium and rhodium are 70 and 280 times more active respectively. When the activities are calculated per m² of the metal surface, the difference is more significant: nickel is the least active; the activities of ruthenium, iridium, and platinum exceed that of nickel by 1–2 orders of magnitude, and rhodium and palladium are more active by 3 orders of magnitude (Table 12). The activity series presented for the metals is close to the series established in the hydrogenation of other unsaturated compounds, for example cinnamic acid.³⁹ In all the hydrogenation reactions, a correlation is observed between the activities of the metals and their properties such as the criterion indicating the extent to which the *d* shell is unfilled, the electron work function, the energy of the bond between hydrogen and the metal, the heat of sublimation, and the crystal lattice parameters. This is explained by the fact that the electronic structure affects the hydrogenating activity of the metal.

The mechanisms of the hydrogenation of 3-thiolene 1,1-dioxide on various Group VIII metals are similar, so that identical kinetics are observed. At a constant 3-thiolene 1,1-dioxide concentration, the rate of hydrogenation is proportional to the hydrogen pressure at *P* up to 2 MPa and, when the latter is increased further, the rate remains unchanged. At a constant hydrogen pressure, the rate of reaction is proportional to the concentration of 3-thiolene 1,1-dioxide up to *c* > 0.1 M, remaining constant at *c* ≈ 0.1 M. The transition from the first to the zero reaction order is associated with the change in the rate-limiting stage as a function of the degree of surface coverage of the catalyst by the reactants, which depends in its turn on the hydrogenation conditions.

Table 12. Comparison of the activities and resistances to sulfur of Group VIII metals in the hydrogenation of 3-thiolene 1,1-dioxide in isopropyl alcohol to which 10% of thiolane 1,1-dioxide has been added at 20 °C, *P* = 5 MPa, and *c* = 0.4 M (according to the data of Mashkina *et al.*⁴²).

Metal	Activity ^a /mol h ⁻¹ g ⁻¹	Specific stability ^b /mmol g ⁻¹	Specific catalytic stability ^b /mmol g ⁻¹	
			in the pres- ence of SO ₂	in the pres- ence of H ₂ S

Ni	7 (0.1)	140 (2)	1.70 (0.025)	0.15 (0.002)

^a The activity calculated per m² of the metal (mol h⁻¹ m⁻²) is given in brackets. ^b The stability of the catalyst calculated per m² of the metal (mmol m⁻²) is given in brackets.

Group VIII metals are all sensitive to the addition of substances competing with the reactants for adsorption on the catalyst: complete deactivation occurs when less than 0.14 mmol of SO₂ or H₂S per m² of the metal is introduced into the solution (Table 12). In terms of the specific stability in the hydrogenation of 3-thiolene 1,1-dioxide, determined from the amount of thiolane 1,1-dioxide formed on 1 m² of the metal up to the complete deactivation of the catalyst, the Group VIII metals can be arranged in the same sequence as that based on the specific catalytic activity. Thus, the more active the metal the greater its stability (Table 12). A similar behaviour has been found also for supported catalysts: the factors ensuring an increase in activity promote also an increase in the resistance to sulfur. The causes of the existence of a direct relation between the activities and stabilities of the catalysts have been explained in a number of studies.^{22, 93, 100} The stability of the catalyst (*Y*) depends on the ratio of the rates of hydrogenation of 3-thiolene 1,1-dioxide (*W_h*) and deactivation of the specimen (*W_d*). The latter is associated with the amount of poison present in the substrate (*c_p*), the rate of formation of the poison (*W_p*), and the rate of its adsorption (*W_{ads}*).

$$Y = \frac{W_h}{W_d} = \frac{W_h}{c_p W_p W_{ads}}.$$

The content of sulfur dioxide in solution is determined mainly by the purity of 3-thiolene 1,1-dioxide and the reaction temperature but not the nature of the catalyst. For the same degree of purification of the substrate and for the reaction carried out under relatively low-temperature conditions, the concentrations *c_p* are approximately the same. The rates *W_p* on different metals are also similar. The rates of adsorption of SO₂ on catalysts containing 1 mass %–8 mass % of palladium on γ-Al₂O₃, SiO₂, AlSi, or charcoal, calculated per m² of palladium, are of the same order of magnitude (0.4–0.8 mg h⁻¹). Therefore the more active the catalyst in the hydrogenation of 3-thiolene 1,1-dioxide the more stable its operation in this process.

Complexes of Group VIII metals have specific activities in the reactions considered which are not inferior to those of the metals themselves or are actually superior to them. In many instances the binding of the metal in a complex increases the resistance of the catalyst to sulfur. For example, the heterogenised palladium complexes are 3–50 times more stable and the homogeneous platinum complex is an order of magnitude more stable than the corresponding metals.^{32, 35} However, the poisoning of the complexes by compounds of divalent and tetravalent sulfur cannot as yet be fully prevented. In the hydrogenation of 3-thiolene 1,1-dioxide, the complexes undergo a change in their initial structure or are fully decomposed. The possibility of their regeneration has not been investigated, but one may predict the appearance of a number of difficulties in the application of such a procedure.

Transition metal sulfides accelerate the hydrogenation of 2- and 3-thiolene 1,1-dioxides at an elevated temperature and pressure. Rhodium and palladium sulfides exhibit, like the metals themselves, a much higher activity than nickel sulfide; rhenium hemisulfide (Re₂S₇) also exhibits a high activity. However, the specific activities of all the metal sulfides investigated are lower by 2–3 orders of magnitude than those of Group VIII metals. Their advantage consists in the lack of sensitivity to sulfur compounds. However, the stability of the sulfides in the real reaction involving the hydrogenation of thiolene 1,1-dioxides has been very little investigated and one cannot rule out the possibility that the metal sulfides, exhibiting an activity under relatively severe conditions, will also be deactivated by the ring cleavage products condensing on the surface in the form of polymeric deposits. There is virtually no information about the regeneration of such deactivated catalysts.

The catalysts are more stable in the hydrogenation of 2-thiolene 1,1-dioxide. However, this substrate is less readily available than 3-thiolene 1,1-dioxide, from which it is obtained by its

isomerisation. This reaction is reversible and the content of 2-thiolene 1,1-dioxide in the equilibrium mixture is 50% – 60% and, when the product is isolated from the mixture by heating, 3-thiolene 1,1-dioxide decomposes fully. In the hydrogenation of 2-thiolene 1,1-dioxide, the yield of thiolane 1,1-dioxide relative to the more readily available 3-thiolene 1,1-dioxide does not exceed 60%. More rational ways of synthesising 2-thiolene 1,1-dioxide have not so far been found and it still remains more useful to obtain thiolane 1,1-dioxide by hydrogenating 3-thiolene 1,1-dioxide.

In practice, it is preferable to use Group VIII metals, which exhibit a high activity under mild conditions, as catalysts for the hydrogenation of 3-thiolene 1,1-dioxide. Rhodium is more active and stable than palladium, but the latter is less scarce, is cheaper, and is more readily regenerated. It is useful to employ catalysts on a carrier, since the supported metal is more highly dispersed and the catalyst itself exhibits an enhanced thermal stability. In terms of activity per unit surface, palladium is superior by 2–3 orders of magnitude to nickel. However, when a supported nickel catalyst with a high metal content, for example 50 mass % of Ni on Cr₂O₃ or SiO₂ or Raney nickel, is used, it is possible to attain a relatively high productivity and stability per unit mass of the catalyst. A serious disadvantage of nickel catalysts is their high sensitivity to sulfur-containing poisons and the lack of readily available regeneration methods.

As a result of systematic studies at the Institute of Catalysis of the Siberian Division of the Russian Academy of Sciences, catalysts have been proposed for the hydrogenation of 3-thiolene 1,1-dioxide to thiolane 1,1-dioxide — the industrial nickel–chromium catalyst and the palladium-containing IK-71-1 catalyst — and the optimum process conditions have been determined.^{64, 69, 75}

The process is carried out on scaled up apparatus at a temperature below 25 °C and a pressure of 2–5 MPa. After the yield of thiolane 1,1-dioxide has fallen from 100% to 98% (600 h), the IK-71-1 catalyst is regenerated. High-quality thiolane 1,1-dioxide has been produced in this way on the experimental plant of the Salavat Petrochemical Group.¹³⁰

Metallic catalysts, which are traditionally employed in low-temperature hydrogenation processes, suffer from significant disadvantages, the main one being their high sensitivity to poisoning by sulfur compounds in the synthesis of thiolane 1,1-dioxide. Because of this, the starting material must be thoroughly freed from sulfur, the process must be carried out under rigorously controlled conditions, and the catalyst must be regenerated periodically.

Taking into account the growing need for thiolane 1,1-dioxide, which is finding practical application on an increasing scale, it is necessary to intensify the research on the catalytic liquid-phase hydrogenation of thiolene 1,1-dioxides. The principal aspect of such research involves the creation of sulfur-resistant catalytic systems based on a detailed investigation of the hydrogenation and deactivation mechanisms. In this connection, further study of the properties of metal sulfides, both individual sulfides and sulfides modified by means of certain functional additives, in order to create catalysts with an increased activity in low-temperature hydrogenation processes, is becoming a task of primary importance. Another promising aspect may become the study of the catalytic properties of various metal complexes. One may hope that, by varying the type of metal and the nature of the ligands, it will be possible to create an active and sulfur-resistant catalyst for the hydrogenation of thiolene 1,1-dioxides. Such studies may not only lead to the formation of more effective catalysts for the synthesis of thiolane 1,1-dioxide, but they may also help to develop the theory of catalysis and in particular its inadequately elucidated branch — the catalysis of reactions of organosulfur compounds.

VII. Modification of the properties of polypyrrole films	452
VIII. The potential for polypyrrole applications	454

Abstract. The synthesis, properties and applications of polypyrrole (PPy), a representative of conducting polymers, are reviewed. Chemical and electrochemical methods for the preparation of PPy and PPy films and the effect of the reaction conditions on the properties of the polymer produced are discussed. The mechanisms of electrochemical polymerisation of pyrrole are compared. The physicochemical properties of the polymer, its morphology and structure are discussed. The mechanism of charge transfer in PPy is considered within the framework of the model of quasi-equilibrium concentrations of polarons and bipolarons. The methods for modification of the electrochemical performance of PPy are reviewed, in particular, synthesis of PPy from pyrrole derivatives with the appropriate electroactive groups and introduction in the PPy of electroactive dopant anions and the effect of those on the electrochemical performance of PPy films are considered. Examples of the use of PPy are given and the prospects for its application in various areas are discussed. The bibliography includes 254 references.

I. Introduction

Not more than two decades ago, researchers considered exclusively polymeric dielectrics or semiconductors that could be made conductive only by means of dramatic changes in their chemical nature (*e.g.*, by heat causing pyrolysis and partial graphitisation of the polymer). The discovery in 1977 of the high conductivity of doped polyacetylene^{1–4} stimulated studies on the synthesis and study of various conjugated polymers. As a result, an entire class of polymeric conductors was developed. Typical representatives of this class are poly(*p*-phenylene),⁵ polypyrrole,⁶ polythiophene⁷ and its 3-methoxy- derivative,⁸ polyaniline.⁹ The common feature of the structure of conducting polymers is polyconjugation in the π -system of their backbone (for polyaniline, this holds only in the case of doped polymer).

The conducting polymers (also called synthetic metals) are polyconjugated, which possess electronic (conductive, magnetic, optical) properties of metals, while retaining the mechanical properties and processibility of conventional polymers. They acquire high conductivity due to incorporation of a small concentration of dopants into the matrix of the initial polyconjugated polymers having conductivity ranging from 10^{-10} to 10^{-5} S cm⁻¹. The resulting materials have conductivities typical of metals or semiconductors, 1 to 10^5 S cm⁻¹.

The doping is performed by means of chemical or electrochemical oxidation (*p*-doping) or reduction (*n*-doping) of a polymer. As a result, the polymeric chains acquire positive or negative charges, respectively.¹⁰ Electroneutrality of the material as a whole is preserved by incorporation of dopants (counterions) from electrolyte solution into the polymeric matrix. The doping is reversible; as a result of dedoping (removal of dopant), the initial polymer can be obtained with its polymeric structure intact. Regulation of the level of doping provides a possibility to prepare polymers with widely varied electric conductivity, from insulating or semiconducting forms of the polymer in the undoped state to highly conductive ones in the strongly doped state.

The conducting polymers attract attention of researchers and engineers from a variety of fields in science and technology as promising electrode materials for energy storage devices (electrochemical batteries and capacitors), electrocatalysts and biosensors based thereon, photoluminescent and electroluminescent materials, 'artificial muscles', gas separating membranes, anticorrosive coatings, electromagnetic shields, materials for microlithography, electrophotography, *etc.*¹¹ In addition, the possibilities to produce conducting polymers electrochemically and to control their properties by electrochemical means are of interest on their own. To date, a number of reviews and books on conducting polymers have been published. Unfortunately, the topic is not extensively reviewed in the Russian literature. In this paper, we review the properties of polypyrrole (PPy), which is a typical representative of conducting polymers and manifests characteristic features of this class of materials.

II. Methods of polypyrrole preparation

1. Chemical synthesis

Among other conducting polymers, PPy and its derivatives are of particular interest, owing to their high conductivity, stability in the oxidised state and interesting redox properties. The simplicity

Received 1 July 1996

Uspekhi Khimii 66 (5) 489–505 (1997); translated by T V Vernitskaya

of the synthetic procedures and availability of the initial monomers are also attractive features of PPy.

Chemical synthesis of PPy has a long history.¹² Polypyrrole prepared by oxidation of the monomer with chemical oxidants has a form of black powder. Aqueous or anhydrous FeCl₃,^{12–15} other salts of iron(III) and copper(II) are widely used as chemical oxidants.^{16–19} The use of halogens and organic electron acceptors as oxidants for PPy synthesis has also been reported.^{20,21} The yield and conductivity of the PPy produced are affected by a variety of factors, among which are the choice of solvent and oxidant, initial pyrrole/oxidant ratio, duration and temperature of the reaction. At the optimal ratio¹³ of Fe(III)/monomer which is 2.4, the yield of PPy approaches 100%. Shorter times of polymerisation and lower temperatures (0 to 5 °C) result in enhanced conductivity of PPy produced.¹⁸ For PPy prepared by monomer oxidation with FeCl₃ in various solvents (water, alcohols, benzene, tetrahydrofuran, chloroform, acetone, acetonitrile (AN), dimethylformamide),¹⁴ the highest conductivity was observed for PPy prepared in methanol solution (190 S cm^{–1}). Controlled variation of the oxidising potential of the reaction medium [it was changed through the ratio of FeCl₃ to FeCl₂ (Ref. 14) and also using a binary AN/methanol solvent²²], provided a possibility to enhance conductivity of PPy to 220 S cm^{–1} in the former case and to 328 S cm^{–1} in the latter. When PPy is produced by oxidation in the presence of FeCl₃, the polymer is doped with Cl[–] anions; the overall reaction can be represented by the following stoichiometric equation^{12,14}

where y is the degree of PPy oxidation (doping level).

In earlier works, the degree of PPy oxidation was determined from the Cl/N ratio using the data from elemental analysis. The Cl/N ratio varied from 0.21 (see Ref. 12) to 0.34 (Refs 13, 14). In Ref. 19, the Cl/N ratio for PPy prepared from aqueous solution was 0.33 and substantially exceeded that for the polymer produced from methanol and AN. X-Ray photoelectron spectroscopy (XPS) revealed that chlorine atoms in the polymer are in three chemical states, namely, ionic, covalently bonded and an intermediate one; the latter is similar to the chloride anions in metal chlorides (including FeCl₃ and FeCl₂). It was noticed¹² that when PPy was treated with solution of FeCl₃ in nitromethane, the iron-containing FeCl₄[–] anions were incorporated in the polymer. Possibly, the intermediate species of chlorine is related to iron chlorides.¹⁹ In spite of the high concentration of incorporated chlorine, only a Cl/N ratio equal to 0.25 corresponded to y (25% of oxidised monomer units). Thus, the elemental analysis is insufficient to determine the true degree of PPy oxidation.

The conductivity and stability of PPy powder produced by means of chemical oxidation were substantially improved. However, formation of PPy films or coatings on another material remained problematic. This problem was partially solved by PPy deposition from gas with FeCl₃ used as an oxidant.^{23–25} This method provided a possibility of producing free film or PPy coatings having high mechanical properties on substrates of any shape. The mechanical performance of PPy powder could also be improved by preparation of composites filled with it, composites with poly(ethylene oxide) in particular.^{23,26,27}

The method of chemical oxidative polymerisation constituted a basis for the layer-by-layer deposition of PPy and polyaniline (PAni).²⁸ The authors of this work report that the polymers have more regular structure and higher crystallinity than those produced electrochemically.

2. Electrochemical synthesis

Electrochemical polymerisation provides a number of advantages over chemical methods. The first is that the reaction product is an electroactive film attached to the electrode surface and having high conductivity. Second is that the yield in charge terms is close to 100%; this provides a possibility of controlling the mass and

thickness of the film. And finally, the properties of the film produced can be controlled directly in the course of preparation. In 1968, Dall'Olio *et al.*²⁹ obtained a PPy film with conductivity of 8 S cm^{–1} by electrolysis of pyrrole solution in the presence of sulfuric acid; the polymer was obtained in the form of powder deposited on the electrode surface. In 1979, Diaz *et al.*^{6,30} prepared the polymer in the form of flexible films with conductivity of 100 S cm^{–1} by electrolysis of an aqueous solution of pyrrole. This work gave a start to the extensive use of electrochemical synthesis of PPy (and other conducting polymers). The PPy films are obtained in doped (conducting) form directly in the course of synthesis; they can be transferred to neutral (insulating) form by means of electrochemical reduction.

Electropolymerisation (EP) of pyrrole (and electrosynthesis of other conducting polymers) differs from other polymerisation reactions, including the radical ones, that are initiated electrochemically.³¹ The anodic oxidation, which results in the formation of conducting polymer, has the stoichiometry of 2.07 to 2.6 F per mole of monomer.^{32,33} Of those, only 2 F mol^{–1} are related to the polymerisation as such and extra charge, to the oxidation (doping) of the polymer film. Since the oxidation potential of the monomer is always markedly higher than that for the polymer, the two processes, the formation of polymer and its oxidation proceed in parallel and are accompanied by the incorporation of counterions into the polymer matrix. The structure of the PPy formed can be represented as³⁴

where A[–] is an anion.

The doping level for PPy (number of anions per monomer unit), depending on the nature of anions and conditions of synthesis, varies within 0.1 to 0.5. Switch-off of the current in the course of PPy electrosynthesis is immediately followed by the arrest of the chain growth; the mass of the polymer film is directly proportional to the charge passed.^{35–37}

Electropolymerisation of pyrrole can be performed in both aqueous and non-aqueous media, such as AN, propylene carbonate (PC), dichloromethane.^{32,38–41} However, with increasing nucleophilicity of solvent, the film growth is inhibited due to the interaction of solvent with the primary products of monomer oxidation. The film does not form in such nucleophilic aprotic solvents as dimethylformamide, dimethyl sulfoxide, hexamethylphosphoramide, unless the nucleophilicity of solvent is reduced by addition of a protic acid.⁴² Apart from that, the side reactions occurring on the film surface can affect EP in these solvents. Thus, a thick PPy film was prepared from a NaClO₄ solution in dimethylformamide.⁴³ An increase in the rate of EP was observed when the temperature decreased. This increase was explained by the relative inhibition of the side reaction of film passivation, which resulted in lower conductivity. The rate of EP grew with increasing concentration of ClO₄[–] anions that act as retardants for the passivating reactions in the electrolyte.

According to the extensively used procedure of Diaz,³⁰ 1% of water is added to AN solution; this results in improved properties of the film (adhesion to electrode, uniformity). The better PPy films were obtained with 2% of water in AN electrolyte.⁴⁴ However, a high content of water in the electrolyte (over 20%) results in deterioration of such film properties as tensile strength and electroconductivity.

The working electrode for electrosynthesis of conducting polymers is usually made of corrosion-resistant materials that are stable at high anodic potential, namely Pt, Au, Pd, Rh, Ir,^{38,39,41} conducting In₂O₃–SnO₂ glasses,^{45–47} carbonaceous materials (graphite, vitreous carbon).^{39,40,48} Syntheses of conducting polymers on Al,^{41,49,50} Ta,^{41,51,52} Fe, Cu, Ti, Ni, Cr, Nb, stainless steel^{41,53} were reported. It was found⁴¹ that the nature of metal substrate virtually does not affect the kinetics of PPy

synthesis. Ta, Ti, Nb, and Al are exceptional; their behaviour is substantially affected by the oxide layer between a metal and PPy. The PPy film was reported to act as a protective coating on a Ta substrate.⁵⁴ Such semiconducting materials as Ge, GaAs,⁵⁵ CdS,^{56,57} CdSe,⁵⁷ doped TiO₂⁵⁸ were also used as electrodes; for these materials EP occurs under additional illumination.

In order to obtain reproducible results, one must carefully prepare the electrode surfaces before synthesis and also use high-purity chemicals.^{39,55} High quality polymer films are usually produced in three-electrode cells with the regions of the working and the auxiliary electrodes separated with a diaphragm. Stirring of the electrolyte solution hinders polymer deposition on both pure and PPy-coated electrodes.^{39,59} Prior to the experiment, the electrolyte solution should be purged with nitrogen or argon in order to remove oxygen, because films prepared in the presence of oxygen have inferior properties.⁶⁰

In conventional EP of pyrrole, the polymer film grows as a coating on the anode immersed in electrolyte solution. When a platinum electrode floating on the surface of electrolyte was used,⁶¹ a uniform thin film that grew along the gas-liquid interface from the electrode to the cell walls was formed. The structure and properties of this film differ from those of PPy films prepared using the conventional method. Supposedly, the polymer has a branched (possibly, three-dimensional network) structure.

Electropolymerisation of pyrrole can be performed in various regimes, in particular, potentiostatic,^{32,62} galvanostatic,^{35,40,63} potentiodynamic^{36,64} and pulsed one.⁶⁵ The mechanical properties of the films, their morphology and electrochemical behaviour depend on the conditions of preparation, including the nature of solvent, pH of the electrolyte, the purity and concentration of the initial monomer, and the nature and concentration of electrolytic salt.^{32,36,42,62,66-68}

III. The mechanism of electrochemical synthesis of polypyrrole

The oxidation of pyrrole to PPy is irreversible. The mechanism of this reaction was extensively studied;^{33,37-39,41,44,45,59,64,68-81} yet, the problem still remains not fully resolved. Among the mechanisms proposed, two have gained the greatest interest. One of those is the oxidative coupling of monomer molecules (Scheme 1).³⁷ The first stage of the reaction is the electrode oxidation of monomer molecules yielding radical cations with the radical state delocalised over the pyrrole ring (B). The maximum spin density is at the α -position;⁶⁹ hence, of the three possible resonance states, C, D and E, the latter is the most stable. The radical cations dimerise (this is the rate-controlling stage of the reaction^{37,64,81}) and expel two protons. The dimers, owing to stronger conjugation, are more readily oxidised under the given reaction conditions than the monomer. The chain growth proceeds by addition of a newly formed radical cation to an oligomeric one. Some authors deny the possibility of dimerisation of radical cations because the latter experience strong Coulombic repulsion.^{38,39,45}

The alternative mechanism proposed for polymerisation of pyrrole is the free radical reaction (Scheme 2).^{38,45} This scheme implies that formation of a radical cation on the anode is followed by the loss of a proton and attack of the radical on a neutral monomer. After reoxidation of the dimeric radical and proton loss, the dimeric molecule can experience subsequent oxidation, which results in chain growth. The release of protons in the course of oxidation of pyrrole was observed experimentally.⁷²

Kinetic studies using isotopically labelled reactants and experiments with radical traps⁷⁰ showed that Scheme 1 is more probable. According to Scheme 2, any free-radical initiator would trigger the polymerisation of pyrrole, which is not the case. In addition to that, Scheme 2 cannot account for the experimentally observed fact that polymerisation proceeds only when monomer oxidation occurs in parallel with the oxidation of the polymer (the

Scheme 1

Scheme 2

oxidation potentials for the dimer and oligomers of pyrrole are lower than that for the monomer).

The pyrrole dimers were detected in the electrolyte.^{71,72} Spectroelectrochemical studies showed⁶⁴ that radical cations and dications of bipyrrrole are the primary species observed at the early stages of electrolysis. Chronoamperometric methods with two-step variation of potential (using ultramicroelectrodes) showed⁷⁷ that EP of pyrrole proceeds according to the mechanism of oxidative coupling and that dimerisation of the radical cations is the rate-controlling stage. The lifetime of the radical cation was estimated⁷⁷ to be $\sim 20 \mu\text{s}$. The experiments using rotating ring-disc electrodes provided an estimate of the rate constant for the formation of the radical cations of pyrrole⁸² within the range 10^7 to $10^8 \text{ litre mol}^{-1} \text{ s}^{-1}$.

The stability of radical cations is an important factor in EP. The radical cations with moderate stability possess the chemical selectivity which favours radical coupling in the film formation. More stable radical cations diffuse away from the surface of the

electrode; this results in the formation of soluble oligomers. The radical cations with lower stability are more reactive and react with solvent or other nucleophiles close to the electrode surface. Therefore, EP of pyrrole in the presence of nucleophilic anions (halides, hydroxides, cyanides, acetates) results in lower yield and smaller molecular mass of the polymer and formation of soluble products.⁸³ The yield of polymer and its conductivity grow with the increasing donor number of the solvent (which reflects the strength of interaction between a solvent and radical cations) in the series nitromethane < nitrobenzene < benzonitrile < AN < PC.⁸⁴ In solvents with large donor numbers (AN, PC), the intermediate radical cations selectively react with the monomer in α -position; this results in formation of polymer with highly regular structure.

It was supposed in the earlier studies^{37,38} that, prior to oxidation, the neutral monomer molecule is adsorbed on the electrode surface. However, further studies using a rotating ring-disc electrode and differential ellipsometry showed that the first stage in polymer deposition is polymerisation in solution and that nucleation of PPy on the electrode surface occurs only after the oligomer chain acquires a certain length at which it becomes insoluble.^{39,74}

The growth mechanism of nuclei of conducting polymers is debated in the literature. In a number of studies,^{38,75,82} the EP is considered as nucleation and growth of the polymer coating analogous to the electrochemical deposition of metals. This analogy is supported by the nucleation loop present in the cyclic voltammograms^{38,74,75} and by the increase in the current on the $I-t$ curve during potentiostatic EP.^{27,38,44,75} The mechanism of these electrochemical phenomena (especially the rising $I-t$ transients) implies an increase in the electroactive surface of the electrode in the course of the process. It was reported^{27,38,76} that addition of a pyrrole monomer to the end of a polymer chain does not bring about an increase in the electroactive polymer surface and implies unidimensional growth of the polymer; under such conditions, dendrites grow in the direction of the electric field on the electrode surface. The experiments on 10- μ m-diameter electrodes⁵⁹ showed that the polymer growth resulting in the nuclei expansion occurs primarily due to deposition of oligomeric species on top of the existing nuclei rather than due to monomer addition to a polymer chain. Here, similar to electrochemical deposition of metals, the pyrrole and its oligomers from solution are preferentially oxidised on the polymer surface rather than on the electrode.

There are two regions in the Tafel plot of the synthesis current versus potential.^{45,78} The inflection in the $\lg I-E$ curve indicates that the reaction mechanism gradually changes with the changing nature of the electrode surface. In the first region, the oxidation of pyrrole results in the polymer nucleation on platinum (the reaction order with respect to pyrrole is unity). When the electrode is covered with a polymer film, both the slope of the curve and reaction order with respect to pyrrole (equal to 0.5) change; the film growth is controlled by the electrochemical reaction on the polymer. The reaction order in the second region coincides with that measured using coulometry and microgravimetry *ex situ*.^{64,79} The earlier electrochemical studies that considered the initial stages of electrochemical synthesis reported the pyrrole oxidation to be first order on a platinum electrode.^{39,41,80} The reaction order of 0.5 with respect to pyrrole (at greater conversions) may indicate that the growth of polymer is fractal in its geometry.⁸⁵

The rate of EP and yield of the polymer are substantially enhanced by addition of 2,2'-bipyrrole in the electrolyte in the course of the PPy synthesis.⁸⁶ The addition of 2,2'-bipyrrole also shortens the delay time associated with the stage of dimerisation of radical cations.

An increase in the rate of pyrrole EP is also observed with a trace of water in AN electrolyte;^{68,81} this is related to reduced Coulombic repulsion of two hydrated radical cations of pyrrole. Addition of bromide anions to the electrolyte causes electrocatalytic promotion of pyrrole EP.⁶⁸ The electropolymerisation

is also markedly accelerated in the presence of small amounts of iron(III) and copper(II) chlorides.⁸⁷

In potentiodynamic regime, EP from aqueous solutions starts at lower potentials than in AN (0.35 V compared with 0.65 V *vs.* Ag/AgCl).^{36,88} In aqueous solutions, the film grows faster than in AN (the increment of the mass in each cycle is higher). The measurements of anodic charge related to EP suggested that the film grew proportionally to the number of cycles. Use of electrochemical quartz microbalance showed that in both electrolytes the PPy films grow nonlinearly at the initial stage of EP and constant-rate growth is attained further.⁸⁸

The rate of EP depends on the nature of the anions in electrolyte.^{41,62,88} For example, the PP/poly(styrenesulfonate) film grows much faster than the PPy/Cl⁻ film. It is supposed⁶² that larger anions are more strongly adsorbed on the electrode surface and this promotes the first stage of EP. Table 1 summarises the parameters of EP of pyrrole in the presence of various electrolytes.⁶²

Table 1. Effect of the nature of organic anion on the rate of pyrrole EP and the properties of the film.⁶²

Electrolyte anion	Conductivity /S cm ⁻¹	Growth rate /nm s ⁻¹	Yield of PPy /cm ³ mQ ⁻¹
Dodecyl sulfate	15.3	25.6	1.3
Toluene sulfonate	9.8	20.1	1.0
Dodecylbenzene sulfonate	4.7	23.8	1.2
Poly(<i>p</i> -styrene-sulfonate)	7.3	7.9	0.4

A mechanism of electrochemical synthesis of PPy from aqueous solutions is proposed;⁴¹ according to this mechanism, the EP involves a complex of pyrrole with anion and proton. The existence of such a complex was confirmed by means of IR spectroscopy. It was supposed⁸⁹ that protonated pyrrole is the active species.

EP of pyrrole, in the presence of water, in addition to the above-described dimerisation of the pyrrole cation radicals (see Scheme 1), can involve the side reaction of the cation radicals with water yielding undesirable electrochemically inert products.^{90,91}

This polymer formed thus has shorter chains and, hence, poorer mechanical and electronic properties compared with PPy prepared from AN solution.

IV. Physical and mechanical properties of polypyrrole

PPy films thinner than 1 μ m have different spectral properties depending on the conditions of synthesis and degree of PPy oxidation; with the increasing degree, the colour of the films changes from yellow to the blue and, ultimately, black.^{32,92} The films have good adhesion to the substrate but at a thickness of over 10 μ m are relatively easily peeled off the electrode.^{34,93} The adhesion depends on a number of factors including the nature, coarseness, hydrophobicity of the electrode surface and the solvent used.^{39,53,94}

The stability in air of the doped PPy films is relatively high; their degradation occurs only above 150–300 °C (depending on the dopant anion).^{6,34,93,95,96} Thermal degradation of PPy starts with the loss or decomposition of dopant.⁹⁷ Further deprotonation (or further dopant loss) at higher temperatures is always

accompanied by formation of imine-like structures in the polymer. The thermal stability of the films obtained by means of EP improves after their treatment with H_2SO_4 , Na_2SO_4 or NaHSO_4 ; upon such treatment, no morphological changes are observed in the polymer.⁹⁸ The films of reduced (insulating) PPy are relatively stable when stored under an inert atmosphere and unstable in air; initially transparent and yellow, they rapidly turn dark, their conductivity increases to 0.01 S cm^{-1} and the films irreversibly lose their ability to undergo redox transition.^{32, 94, 99}

The films prepared by electrodeposition in the presence of inorganic anions are relatively brittle; their mechanical properties are usually higher than those of the films doped with bulky organic anions.^{42, 66, 100} The tensile strength for PPy films with different dopant anions varies from 8 to 100 MPa; the elongation at break, is within 2%–8%; the Young's modulus, 0.4–4 GPa.^{42, 100, 101} The elongation at break can be substantially enhanced (to 70%), when PPy is synthesised at low temperatures.¹⁰¹ According to Ref. 102, the elasticity of the freshly prepared films, which contain solvent, is higher, their elongation at break reaches 60%. The films reversibly absorb solvent (water, AN); they also absorb water vapour from air.^{35, 103}

Studies by means of scanning and transparency electron microscopy showed that PPy films are compact and have no voids.^{6, 32, 67} The apparent surface of the PPy-coated electrode measured using impedance spectroscopy and small-angle neutron scattering is 40–50 times higher than the area of underlying platinum electrode, according to scanning electron microscopy it is 2.2 times higher.¹⁰⁴ The latter method does not provide a possibility to assess microporosity of the polymer. The microstructure and porosity of the polymer depend on the dimensions of the dopant anion.¹⁰⁵ Thus,¹⁰⁶ the density of $\text{PPy}/\text{ClO}_4^-$ films is 1.52 and that of $\text{PPy}/\text{toluenesulfonate}$, 1.37 g cm^{-3} . The films prepared from aqueous solutions are more porous and have lower density than those synthesised in AN.^{36, 107} In microphotographs, the surface of PPy films prepared in aqueous solutions looks like a cauliflower.^{32, 35} The films synthesised in non-aqueous media and those with large organic anions have a smoother-looking surface.^{36, 62, 107, 108}

Polypyrrole is amorphous and usually gives only a diffuse halo in X-ray diffraction patterns.^{6, 101} The electron diffraction showed that there are up to 15% (of total volume) of crystalline domains in the bulk of amorphous PPy.⁶⁶ The experimental data indicate that the crystalline regions have a monoclinic lattice; the pyrrole rings are oriented so that nitrogens of neighbouring rings are oriented in opposite directions.

The data from IR spectroscopy,¹⁰⁹ NMR,^{109, 110} analysis of the products of oxidative decomposition of PPy¹¹¹ indicate that pyrrole rings couple at α – α' -positions. This inference is confirmed by the fact that α -substituted pyrrole derivatives do not polymerise upon oxidation.⁴² The calculations show that a certain number of bonds are formed at the β -position.⁹⁵ Electropolymerisation of 3-methyl- and 3,4-dimethyl-substituted monomer yields a polymer with a more regular structure and higher conductivity because for these monomers coupling at the β -position is blocked.¹¹²

The PPy chains are planar and are arranged in layers parallel with respect to the film surface; the interplane distance is 0.341 nm.¹¹³ Alkyl substituents in PPy do not affect the planar arrangement of the chains.¹¹⁴ The PPy chains within the planes are not oriented. The dopant anions intercalate the interplane spaces between the PPy chains.¹¹⁵ X-Ray photoelectron spectroscopy showed that¹¹⁶ electrostatic interactions between the oxidised PPy chains and dopant anions (ClO_4^- , polyvinylsulfonate) occur *via* the π -system of the rings rather than *via* heteroatoms of the rings. The sandwich structure is also formed in the case of PPy doped with alkylsulfate and arenesulfonate anions.¹¹⁷ PF_6^- anions pre-

serve their structure in the polymer matrix of PPy,¹¹⁸ whereas FeCl_4^- anions experience strong distortion of their tetrahedral structure due to the formation of hydrogen bonds.^{119, 120} There are also indications that there is a strong interaction between charged PPy chains and dodecylsulfate anions.¹²¹

The data of electron diffraction indicate that polymer chains are ordered.¹²² Studies of conductivity, which is related to both fast charge transfer along the polymer chains and rapid exchange between the macromolecules, also indicate that polymer chains are to some extent ordered.¹⁰⁹ The degree of polymer ordering strongly affects its conductivity.¹²³ X-Ray diffraction showed that PPy films prepared in the presence of multicharged anions are more regular than those with single-charged anions.¹¹⁹

Numerous studies of the chemical structure of PPy indicate that its elemental composition fits the formula $\text{C}_4\text{H}_3\text{NA}_{0.3}$, where A is the anion in the presence of which electrosynthesis was performed.^{6, 32, 34, 93} The percentage of carbon and hydrogen in the polymer often exceeds the theoretical values, sometimes oxygen is also present. The actual cause of these deviations is not unambiguously understood; it was however found that the polymer contains water or another solvent,^{35, 103} and that PPy chemically reacts with the atmospheric oxygen.^{6, 32, 40, 94} Polypyrrole is insoluble in organic solvents and this makes measurements of its molecular mass a difficult problem.

V. The nature of electronic conduction of polypyrrole

The interest in the electronic properties of polyconjugated polymers was boosted by the 1964 paper by Little,¹²⁴ where the possibility of superconductivity in unidimensional structures was predicted.

The neutral (undoped) PPy is a dielectric with the gap of 4 eV.¹²⁵ Upon oxidation (doping), the π -electrons are removed from the upper level of the valence zone with a simultaneous shift of the boundary π -levels (the highest occupied and the lowest vacant) to lower energies. The gap reduces to $\leq 2.5 \text{ eV}$ and the polymer becomes a semiconductor.

Of special interest in PPy conduction is the mechanism of charge transfer. The charge carriers are the polarons and bipolarons formed upon doping.^{126, 127} In chemical terms, the formation of a polaron is equivalent to formation of a radical cation

and of a bipolaron, to dication

The polaron and bipolaron in PPy are extended structures spread over three to four monomeric units of the chain.¹²⁸

The separation of the positive charge on the chain in the bipolaron structure predetermines the energy of the system. The further the positive charges are apart the lower the stability of the system, since it contains more rather unstable quinoid rings. The calculations of the energetics showed that formation of a bipolaron requires 0.45 eV less than formation of two polarons.^{126, 127} This result led to a suggestion that bipolaron is the major charge carrier in PPy.^{129, 130} This suggestion was to a certain extent confirmed experimentally by the studies of optical absorption spectra^{131, 132} and ESR.^{133, 134} The ESR spectroscopy is extensively used for studies of doping in PPy, because it provides a possibility to measure the concentration of spins associated with polarons ($S = \pm 1/2$). Bipolarons that are spinless ($S = 0$) are not detectable by means of ESR. The authors of Ref. 134 claim that

only spinless charge carriers are present in the polymer because there is no correlation between the conductivity and concentration of spins in the polymer. The experimental data of Refs 135 and 136 were interpreted in terms of quasi-equilibrium concentrations of polarons and bipolarons formed in the two-step redox process:

where E_1 and E_2 are the quasi-standard potentials of formation for polarons ($\text{PPy}^{\bullet+}$) and bipolarons (PPy^{2+}).

The data of Refs 135 and 136 agree well with the measurements of PPy conductivity as dependent on the partial charge per monomer unit.¹³⁷ The strong correlation between the enhanced PPy conductivity and concentration of polarons is illustrated by Fig. 1. When the conductivity reaches the plateau, the concentration of polarons decreases; this decrease can be attributed to the formation of bipolarons. The obvious relation of the conductivity to concentration of polarons at low doping levels disproved the previous hypothesis^{133,134} that conduction in PPy is solely spinless. The spectroelectrochemical measurements showed¹³⁸ that polarons in PPy and PANi are stable species and their maximum concentrations in respective polymer are 80% and 90% at 50% of the reversible charge. Further investigation of PPy by means of *in situ* impedimetry¹³⁹ showed that polarons and bipolarons equally contribute to conductivity, being charge carriers with the same mobility. Further,¹⁴⁰ it was inferred that in PPy the polaron and bipolaron are partners and electron hopping is easier between a polaron and bipolaron than it is between a neutral chain fragment and polaron; this is due to the fact that in the former case planarity of the states is similar and this reduces the conformational activation energy. Similar results were obtained for PANi.¹⁴¹

The concentrations of polarons and bipolarons in PPy in the

Figure 1. The dependences of (1) spin concentration¹³⁵ and (2) conductivity¹³⁷ on the oxidation charge (Q).

course of oxidation and reduction were studied using ESR spectroscopy and laser electroreflectance.¹⁴² The equilibrium concentration of polarons in PPy increases with potential growing from 0 to 200 mV and reduces for $E > 200$ mV, owing to the formation of bipolarons.

The conducting polymers are quasi-unidimensional conductors rather than unidimensional. Of particular interest are interchain interactions and charge transfer. It was noted¹⁴³ that dopant not only compensates the charge of the free charge carriers but also enhances the probability of interchain charge transfer due to a strong overlap of the atomic orbitals of the dopant with the π -orbitals of the carbon atoms. Since the polymer chains are oriented mainly parallel to the film surface, the conductivity along the surface ($s_{\parallel}$) is usually higher than that perpendicular

($s_{\perp}$). In the former case, conductivity involves less interchain charge hops. The anisotropy of conductivity ($s_{\parallel}/s_{\perp}$) amounts to 360.¹⁴⁴

The most regular alignment of the macromolecules (more ordered structure) and, therefore, higher conductivity of the films is achieved when the synthesis is performed at low temperatures.^{100,101,112} The conductivity of PPy films prepared in PC solution at -20°C is 300 S cm^{-1} and for $+20^{\circ}\text{C}$ it is 97 S cm^{-1} .¹⁰¹ Due to the alignment of the polymer chains the highest conductivity achieved for PPy, 3000 S cm^{-1} , was attained under conditions of low-temperature electrosynthesis.¹⁴⁵

The temperature dependence of the conductivity fits the equation

$$\lg \sigma = A + BT^{-1/(n+1)},$$

where $n = 1, 2, 3$.

Such a dependence is typical of the hopping mechanism of conduction with a variable hop length.¹⁴⁶ With decreasing temperature, the conductivity drops (which is characteristic of semiconductors). However, there are also reports (cf.¹⁴⁷) that the conductivity increases with decreasing temperature (such behaviour is inherent in metals).

The conductivity of the polymers strongly varies depending on the conditions of their synthesis. Major changes in the conductivity usually occur at the earlier stages of doping, its further increase is insignificant.^{100,148}

The conductivity of PPy films varies by several decimal orders depending on the nature of an anion introduced into it during synthesis (Table 2). A change in the nature of solvent changes the order of anions in the series of conductivities. Usually, the PPy films prepared in AN electrolytes are more conductive than those synthesised in aqueous solutions. This is due to a larger conjugation length of the polymer and better contact with the metal electrode in the former case.³⁶ The electrical conductivity is, in the majority of cases, higher for anions with lower nucleophilicity.¹⁴⁹ Electrosynthesis of PPy in aqueous solutions in the presence of bulky organic anions (toluenesulfonate, dodecylbenzenesulfonate, dodecylsulfate) results in enhanced quality and conductivity of the films produced, compared with those of the PPy/Cl^- and $\text{PPy}/\text{ClO}_4^-$ films (see Refs 62, 108, 149).

At the same time, the exchange of a counterion in as-grown

Table 2. Conductivity of PPy films synthesised from aqueous electrolytes and from AN.^{42,93,149}

Dopant anion	Conductivity (S cm^{-1})	
	aqueous solution	AN
BF_4^- (fluoroborate)	2–2.5	30–100
ClO_4^- (perchlorate)	5–6.5	60–200
AsF_6^- (hexafluoroarsenate)	2.4–2.8	30–100
HSO_4^- (hydrosulfate)	3.5	0.3
CF_3SO_3^- (triflate)	3.4	0.3–1.0
CF_3COO^- (trifluoroacetate)	1.0–1.3	12
$p\text{-CH}_3\text{C}_6\text{H}_4\text{SO}_3^-$ (tosylate)	89–121	20–105

PPy for other anions from electrolyte but slightly affects the conductivity of PPy; the replacement of an anion changes the structure of the polymer matrix, yet not to the extent that it will change the barrier height and hopping frequency.^{40,150} On the other hand, for the films being prepared with a particular anion, the structure of the forming polymer matrix substantially depends on the nature of dopant and, therefore, the conductivity is strongly affected by the nature of an anion.

The effect of pH of electrolyte on conductivity of PPy films synthesised therein was extensively studied^{38,62,117,149} (Fig. 2). In alkaline media, thin insulating films are formed.³⁸ The conductivity goes through a maximum at the synthesis potential of 0.6 V (vs. saturated calomel electrode) in aqueous solution¹⁰⁰ (Fig. 3), the

Figure 2. The dependence of PPy conductivity on pH of the electrolyte.¹¹⁷

corresponding maximum is observed in the dependence of conductivity on the current density.^{117, 151} Electrosynthesis of PPy films at current densities over 5 mA cm^{-2} results in reduced conductivity of the films with both organic and inorganic dopant anions.¹⁰⁸

The structure of PPy films doped with ClO_4^- , BF_4^- and,

Figure 3. The dependence of conductivity of PPy films on oxidation potential (vs. saturated calomel electrode); synthesis from aqueous solution of 0.25 M pyrrole + 0.8 M sodium tosylate.¹⁰⁰

correspondingly, their conductivity depend on the nature of solvent (due to above-described causes). The films doped with strongly basic anions (high pK_a)⁸⁴ do not show such a dependence (Fig. 4).

Figure 4. The dependence of conductivity (σ) of PPy films prepared in the presence of ClO_4^- (1), BF_4^- (2), tosylate anion (3) on the donor number of solvents (N):⁸⁴ nitromethane (NM), nitrobenzene (NB), benzonitrile (BN), acetonitrile (AN), propylene carbonate (PC).

When conducting PPy films are stored in air, their conductivity decreases.¹⁵¹ The conductivity of the films with bulky organic anions reduces much more slowly. Thus, the electrical properties of PPy/dodecylbenzenesulfonate do not change after a 6-month storage in air.¹⁴⁹

VI. Electrochemical properties of polypyrrole

The very first electrochemical studies showed that PPy is sufficiently stable and can be used as a non-metallic electrode material.^{30, 93, 152} Its intrinsic redox reaction associated with doping and dedoping must be taken into account as was first shown by Diaz *et al.*^{32, 93, 153} in 1980. The following equation for this reaction was proposed on the basis of electron balance and elemental composition.

where A^- is the anion.

The positive charge of oxidised segments in PPy chains is counterbalanced by the anions of electrolyte that are incorporated in the polymer; the anions leave the polymer matrix and return to the solution when PPy is reduced. The method of cyclic voltammetry (CVA) is extensively used in studies of redox processes in conducting polymers. In this method, the potential is linearly scanned up to a certain preset limit and then is reversed to the initial value.^{32, 38, 88, 91, 107, 154–158} Figure 5 shows a typical voltammogram (VA) of a PPy film. The anodic peak in VA is related to the oxidation of PPy, the cathodic one, to its reduction to the neutral form according to the above equation. The maxima of the peaks in VA correspond to the maximum polaron concentration in PPy.¹⁵⁹ In the cycling of PPy films to potentials lower than -0.8 V , the currents are close to zero and down to -2.3 V (in AN solution) no peaks are observed because at these potentials the neutral film has low conductivity. At anodic potentials over $0.8–1.0 \text{ V}$, irreversible oxidation of PPy starts; it results in the loss of electrochemical activity and a drop in the conductivity of

Figure 5. The cyclic voltammograms of 20-nm PPy/ BF_4 film in $\text{Et}_4\text{NB-F}_4/\text{AN}$ solution³² at varied scan rate 10 (1), 20 (2), 40 (3), 50 (4), 60 (5), 80 (6), 100 mV s^{-1} (7) (E vs. saturated calomel electrode).

the films.^{32, 35, 91, 160} The films can be repeatedly cycled without any sign of polymer degradation within a certain potential range where no side reactions occur (the so-called stability window); here the redox reaction of PPy is reversible.^{32, 35, 54, 107, 161}

A distinctive feature of VA of PPy films is, in the case of anodic oxidation, the steep anodic wave at the start of doping followed by a flat plateau. In the reverse scan of the potential, a cathodic wave appears at the end of the capacitive-type plateau; this wave is shifted in potential with respect to the anodic one. The current of the cathodic peak is usually lower than that of the anodic (whereas the surface areas of the anodic and cathodic parts of VA are the same). Such a behaviour is not typical of redox-active films. The theory predicts that thin redox-active films must show mirror-symmetric anodic and cathodic waves with identical peak potentials and currents.¹⁶² However, even the high quality films of conducting polymers manifest this potential shift between the anodic and cathodic peaks in their VA. The theory of redox-active polymers interprets such a behaviour as a kinetic effect of slow heterogeneous charge transfer.³²

The thermodynamic redox potential of the system is defined as the mean of the anodic and cathodic maxima ΔE_p (for the PPy film in Fig. 5 it is -0.2 V). As a first approximation, one can assume that the interaction between the charged segments of the polymer chains can be neglected and that there is only one redox state with a characteristic redox potential depending on the nature of the monomer unit. However, one must keep in mind that the redox potential of nominally the same system depends on the conditions of measurements and the regime of PPy synthesis (chemical nature and composition of the solvent and electrolyte, scan rate, thickness of the PPy film).^{32, 154, 163, 164} The redox potential of a polymer also depends on the time during which it was stored in a dielectric state.¹⁶⁵

The interrelation between the Faradaic and capacitive processes in the course of reduction and oxidation is closely related to the redox mechanism. It was reported¹⁶⁶ that in CVA, the Faradaic oxidation associated with the charge transfer *via* interphase boundary is limited to the region of peaks, whereas the broad anodic plateau corresponds to the large capacity of the double layer at the surface (charge accumulation at the interphase boundary); the interphase surface is largely due to the porosity of the film. This problem remains debatable.¹⁶⁷ On the basis of the studies using impedance spectrometry and CVA, the following model for redistribution of charges in polymer was proposed.¹⁶⁸ In the electrochemical redox cycling of a polymer film, which is associated with penetration and removal of the anions, the polymer becomes subdivided in aggregates with the diameter about 6 nm. The capacity of the double layer formed reaches 200 F cm^{-2} . The capacitive behaviour of the conducting polymers is due the fact that they are porous and conductive and also due to the number of electroactive sites in the polymer not being fixed but dependent on the potential. The Faradaic charge results from the penetration of dopant anions into the aggregates, which is diffusion-controlled. The rate of the Faradaic process is lower than that of the capacitive.

The shape and parameters of VA are affected by a number of factors including the range of potential cycling, the scan rate, solvent used, composition of the electrolyte, film thickness, conditions under which it was prepared and its treatment and storage history. Synthesis under similar conditions does not always provide a possibility of obtaining similar VA of PPy films. Stirring of the solution of background electrolyte does not affect the shape of VA.³²

The shape of VA is indicative of the quality of PPy films. The rate of the charge transfer in conducting polymer and, therefore, its conductivity correlate with sharp anodic and cathodic peaks and narrow ΔE_p .^{103, 160, 169} The redox capacity of the film (the surface area under the anodic and cathodic branches of VA), in its turn, is related to the doping level of the polymer.^{32, 38}

The EP of pyrrole in galvanostatic regimes in the LiClO_4/PC system at low current density ($i \leq 0.3 \text{ mA cm}^{-2}$) yields PPy with a

high degree of conjugation (the energy of $\pi-\pi^*$ transition is 2.83 eV) and high doping level ($y = 0.37$), which shows narrow peaks in VA.⁶³ At high density of polymerisation currents ($i \geq 0.5 \text{ mA cm}^{-2}$), the VA of the polymer produced is distinguished by broad peaks, its doping level and degree of conjugation are low (the energy of $\pi-\pi^*$ transition is 3 eV). A similar effect of the EP current density on electrochemical properties of the polymer was reported in Ref. 81; overoxidation of the polymer at high anodic potentials of EP ($0.8-1.2 \text{ V vs.}$ saturated calomel electrode), results in reduced redox capacity of PPy films (Fig. 6). This effect is most pronounced in anhydrous electrolytes. It was supposed¹⁷⁰ that the decrease in conductivity is due to formation of saturated oligomers in the reaction initiated by the protons released in the oxidation of monomers near the electrode surface at high current density.

Addition of water to the electrolyte inhibits this reaction due to solvation of the protons.

Figure 6. The dependence of anodic potential of polymerisation (E_p vs. saturated calomel electrode) and redox capacity (Q_{red}) of $1 \mu\text{m}$ PPy films on the current density (i) in galvanostatic electropolymerisation⁸¹ from solution of 0.1 M pyrrole + 0.1 M Bu_4NBF_4 in AN (1) with addition of 10 (2) and 50 (3) mM H_2O .

The thickness of a PPy film (and, correspondingly, charge in EP) is one of the major controlling parameters for VA of the films. The charge of reduction and oxidation of PPy during cycling (redox capacity) is proportional to the charge in synthesis. The redox capacity of PPy during cycling in AN comprises $8\% - 12\%$ of the EP charge in the Diaz electrolyte ($\text{AN} + 1\% \text{ H}_2\text{O}$) and up to 19% for EP in aqueous solution; this corresponds to a doping level of $20\% - 30\%$ in the former case and 47% in the latter.³⁸

An important electrochemical characteristic of the redox reaction on the electrode is the dependence of the anodic peak current i_{pa} on the scan rate v :

$$i_{pa} = Av^x,$$

where A is a constant and x is the exponent, which characterises the mobility of counterions in the PPy matrix. The redox reaction is controlled by the rate of electron transfer (adsorption, $x = 1$) for PPy films doped with small mobile anions (Cl^- , ClO_4^-) or in the opposite case of polymer doped with very bulky multicharged

anions (e.g., benzenetrisulfonate anion). For PPy films with medium-size anions (benzenesulfonate, toluenesulfonate) the electrode reaction is diffusion-controlled ($\alpha = 0.5 - 1$).^{46, 108} When the film thickness increases (over 1 μm), the electron transfer is superimposed by the diffusional restrictions, which result in broadening of the peaks in VA and their wider separation.^{32, 35, 46}

The VA of PPy films differ substantially when the latter are tested in aqueous media and aprotic solvents.^{88, 103, 107} In the former case, the currents are higher, owing to higher mobility of anions in the porous film. At the same time, the films synthesised in AN have better electrochemical reversibility of redox transition than those synthesised in aqueous electrolytes.^{36, 107} The former films are distinguished by a higher rate of electron transfer and narrower ΔE_p . The PPy films obtained in aqueous solutions are more porous and manifest higher capacitive currents in VA (their capacity is 460 F cm^{-3} compared with 390 F cm^{-3} for PPy synthesised in AN).³⁶

In the course of cycling, the PPy can exchange its initial dopant anion for another anion of electrolyte.^{88, 154, 155} The diffusion processes are controlled by the dimensions of the pores and the nature (dimensions, mobility) of the penetrating anion. The Cl^- anions in PPy/Cl^- upon cycling are replaced by the electrolyte anions F^- , ClO_4^- (Fig. 7).¹⁶⁴ In a solution of sodium poly(styrenesulfonate) (Na/PSS^-), PPy/Cl^- film loses its electroactivity as the anions of the polyelectrolyte are too large to penetrate into the film, while diffusion of Cl^- anions through the adsorbed layer of PSS^- anions is suppressed.

PPy synthesised in aqueous NaNO_3 solution, upon reoxida-

Figure 7. The voltammograms of PPy/Cl^- in 0.1 M aqueous solutions of: ¹⁶⁴ NaCl (1), NaClO_4 (2), NaF (3), NaPSS (4) (E vs. Ag/AgCl).

tion, manifests selectivity with respect to anions in the solution decreasing in the following series¹⁷¹ $\text{NO}_3^- > \text{ClO}_4^- > \text{Br}^- > \text{Cl}^- > \text{F}^-$.

Active control of the ion transport is possible when the mobile species can be identified. The problem is complicated by the fact that several ionic species are often present in the system. There are two pathways for the charge transfer in the oxidation–reduction of the polymer^{46, 154, 155, 164, 172}

The former process implies diffusion of A^- anions away from the film upon reduction of oxidised polymer, while the latter, penetration of C^+ cations, which compensate the negative charge of immobile anions that become redundant after reduction of the polymer. Use of an electrochemical quartz microbalance provided a possibility of following the changes in the mass of the film during cycling in solution and, thus, of elucidating the nature of the ions penetrating into the film.^{88, 164, 173} The anionic transport predominates when small single-charged anions (Cl^- , ClO_4^- , H_2PO_4^- , NO_3^-) are used in electrochemical synthesis of PPy. In such a film,

Figure 8. The changes in currents and frequency shifts of quartz resonators for the films:¹⁶⁴ PPy/Cl^- (a) and $\text{PPy}/\text{dodecyl sulfate}$ (b) in aqueous solution of 0.1 M NaCl (E vs. Ag/AgCl).

anions rather than cations penetrate into the film and are removed in the course of cycling. When the polymer is synthesised with bulky immobile anions, multicharged anions or polyelectrolytes [dodecylsulfate, toluenesulfonate, phthalocyanine tetrasulfonate, SO_4^{2-} , HPO_4^{2-} , poly(styrenesulfonate)], which are firmly fixed in PPy, then the cationic transport through the polymer–electrolyte boundary predominates. Figure 8 shows the VA of PPy/Cl^- and $\text{PPy}/\text{dodecylsulfate}$ films and also the change (decrease/increase) in the resonance frequency due to the changed (higher/lower) effective mass related to electrochemical processes.

The cationic transport also predominates in self-doped polymers where dopant anions are covalently bonded with the polymer matrix, e.g., poly{pyrrole-co-[3-(pyrrol-1-yl)propanesulfonate]}, and for a molecular PPy/Nafion composite where the dopant anion is polymeric.¹⁶⁴ The frequency response of these films depends on the nature of the cation of the electrolyte in which the films are tested.

For the $\text{PPy}/\text{SO}_4^{2-}$ film in an aqueous solution of CsCl, a mixed anionic–cationic transport is observed depending on the cycling potential.¹⁷³ The migration of cations into electrolyte prevails at the initial stages of oxidation of PPy/poly(styrenesulfonate), but upon further growth of the potential this process is complicated by the anionic counterflow.¹⁷⁴ The mixed type of charge transfer often results in the appearance of several peaks in anodic or cathodic parts of VA.^{107, 175}

The type of charge transfer is governed also by the choice of a solvent. The bulky dodecylsulfate anion is always firmly fixed in the PPy film synthesised in its presence, irrespective of the solvent used. However, the mobility of the ions in the bulk of the film during redox switching depends on the solvent. Upon reduction in AN, dodecylsulfate anions leave the film, whereas in aqueous solutions they remain trapped in the polymer matrix;^{176, 177} upon reduction, Na^+ cations are inserted into the film. The stronger interaction between the charged polymer chains and dodecylsulfate anions in aqueous solutions is due to the hydrophobic nature of the aliphatic part of the anion. For the polymer doped with the

highly mobile ClO_4^- anion, prolonged cycling in aqueous solution results in the cationic transport substituting for anionic.⁸⁸ In AN, the anionic transport prevails in this film.

The exchange of the dopant anion in the polymer can result in a changed type of ionic transport.¹⁵⁶ The ionic charge transfer can be controlled by creating in the polymer an ion pair of immobilised anion and multicharged cation of electrolyte.¹⁷³

The contribution of anionic and cationic charge transport strongly depends on the EP potential.^{178, 179} The redox switching in PPy synthesised at 1.0 V (vs. Ag/AgCl) are accompanied by simultaneous mass transport of anions and cations, whereas in the films prepared at lower potentials of EP, the charge transport is separated into either anionic or cationic regions. The cathodic shift of the first cycle of reduction in VA is related to the phase transition in the polymer and indicates that cations are inserted into the film. This was confirmed using an electrochemical quartz microbalance and X-ray emission analysis.¹⁰³ The potential of the anomalous reduction peak in the first reduction cycle of PPy film depends on the size of electrolyte cation (in AN solution).¹⁷⁷ During the first reduction cycle, a large uptake of electrolyte by the film is observed (up to 3 M). The measurements using impedance spectroscopy¹⁰³ showed that over several initial cycles the resistance of the PPy film drops (ionic conductivity grows) and remains virtually unchanged in further cycling. In reoxidation of the polymer, the uptake of the anions by the film exceeds the release of cations (the anionic type of the charge transport predominates); this results in formation of a non-equilibrium state in the polymer containing excess of the electrolyte. The mobility of the anions in such a polymer is greatly enhanced; the redox transition in AN solution proceeds fast only for the non-equilibrium form of the polymer. The PPy films prepared from aqueous solution with Et_4NClO_4 originally possess a high ionic conductivity. The strong difference between the ionic conductivity of the PPy films prepared from aqueous and AN solutions can be related to lower mobility of anions due to the better solvation of the polymer in aqueous solution.

Possibly, it is the excess of electrolyte in the film that causes wide scatter of the data for the diffusion coefficient of anions measured using different methods, 10^{-11} to 10^{-9} $\text{cm}^2 \text{s}^{-1}$ for ClO_4^- , BF_4^- in AN^{32, 34, 35, 37, 47} and 10^{-10} to 10^{-8} for Cl^- , ClO_4^- in aqueous solutions.^{108, 180, 181}

Since the properties of the polymer are to a large extent governed by the dopant anion, the choice of the latter depends on the properties to be imparted to the polymer. If hydrophilic anions such as ClO_4^- or BF_4^- are used in EP, the polymer produced also becomes hydrophilic, in contrast to PPy doped with hydrophobic polymeric counterions. In the latter case, sensitivity of PPy to humidity is greatly reduced. In the presence of optically active anions (e.g., camphorsulfonic acid), the polymer acquires optical activity, which can be used to separate chiral stereoisomers.⁶⁶ In order to prepare flexible and smooth films that easily detach from the electrode, organic dopant anions are used. Aromatic and bulky surfactant sulfonate anions provide better conductivity and stability of the polymers. Thin PPy films with small anions manifest the most pronounced electrochromic properties and the fastest response.^{182, 183} In order to make PPy coating with strong adhesion to aluminium electrode, hydroxyanthraquinonesulfonic acid is recommended, because it forms a complex with aluminium.⁶⁶

VII. Modification of the properties of polypyrrole films

Modification of the electrochemical properties of PPy is a promising and diverse field of research. This can be achieved using a variety of methods, viz. by the synthesis of polymer from pyrrole derivatives with corresponding electroactive substituents, by introduction of electroactive dopant anions, by modification of the film surface through immobilisation of certain reactants

thereon. These methods are supplemented by copolymerisation and preparation of PPy-based composites.^{184–186}

Numerous examples of preparation of PPy derivatives containing electro- and catalytically active groups are given in Ref. 187. The *N*-substituted PPy with grafted electroactive groups, derivatives of viologen,¹⁸⁸ anthraquinone,¹⁸⁹ and porphyrins of Co, Ni, Mn were studied.^{190, 191} The PPy with a covalently bonded three-nuclear ruthenium cluster showed high chemical and electrochemical stability, especially at positive potentials. This electrode was used for electrocatalytic oxidation of benzyl alcohol.¹⁹² The cluster $[\text{Fe}_4\text{S}_4(\text{SPh})_4]^{2-}$ was inserted in the electrode surface covered with the ion-exchange polymers based on *N*-substituted PPy.¹⁹³

EP of pyrrole with bulky alkyl substituents provides a route to prepare a polymer soluble in organic solvents. This facilitates its further processing, including preparation of coatings of well defined structure and thickness using the Langmuir–Blodgett technique.¹⁹⁴

Substitution in the monomer ring causes a decrease in the conductivity of PPy films.³² However, in many cases, the conductivity does not change strongly when dopant anion is replaced with another one.¹⁴⁹ Various organic and inorganic electroactive anions were used as dopants for PPy matrix; these include tetrathiomolybdate,^{195–197} tetrachloroferrate,^{151, 198, 199} ferrocyanide,^{61, 119, 155, 172, 200} metal phthalocyanines and porphyrins,^{73, 201–205} ferrocenesulfonates,^{206, 207} sulfonates of quinones,^{208, 209} isopolyanions,²¹⁰ heteropolyanions.^{211–216} A wide array of conducting polymers with various incorporated functional molecules is described in Ref. 217.

Studies on the growth of PPy in the presence of the above-mentioned anions and on the properties of the polymers obtained revealed a number of common features inherent in these polymers: (1) the rate of EP in the presence of multicharged anions is unusually fast; (2) it is difficult to replace electroactive anions in the polymer matrix with another anion; (3) ΔE_p shifts to the cathodic region; (4) the electroactivity of a polymer doped with electroactive dopant anions is substantially enhanced due to the inherent redox reaction of the anions incorporated in the polymer matrix. The enhanced electroactivity of the conducting polymers is a desirable feature for the ones to be used as electrode materials in rechargeable batteries.

The synthesis and electrochemical properties of PPy films doped with FeCl_4^- anions were discussed in Refs 198, 199. The introduction of tetrachloroferrate anions to the electrolyte at the stage of EP results in acceleration of the process and brings about enhanced coarseness of the PPy films formed.¹⁹⁸ Supposedly, the large FeCl_4^- anion, which is connected to the polymer matrix with hydrogen bonds,¹²⁰ decreases the Coulombic repulsion of two radical cations thus promoting the dimerisation. The incorporation of FeCl_4^- into PPy improves the reversibility of the redox transition and permits the synthesis of conducting films in galvanostatic regime without degradation of the polymer material even at high current density (2 mA cm^{-2} , further studies showed that the current density up to 8 mA cm^{-2} can be used). It was assumed on the basis of CVA studies¹⁹⁹ that due to the cage effect FeCl_4^- anions are reversibly reduced in the polymer matrix. This contributes to the redox capacity of the polymer. The VA of PPy/ FeCl_4^- films are stable in the course of cycling in acetonitrile solutions of Et_4NClO_4 and $\text{Et}_4\text{NFeCl}_4$, whereas in solution of NaClO_4 they are unstable. In AN/ $\text{Et}_4\text{NFeCl}_4$ electrolyte, the PPy/ FeCl_4^- films do not experience degradation even when the cycling range is extended to +1.5 V, the redox capacity of the films increasing more than threefold. The surface of PPy/ FeCl_4^- films is covered with crater-like¹⁹⁹ or dendrite-like structures¹⁵¹ depleted of FeCl_4^- anions.

The VA of PPy film doped with $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$ anions shows two pairs of redox peaks,⁶¹ the additional pair near 0.1 V appears due to the reversible redox transition $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$. The PPy film doped with $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$ is more electroactive than PPy/ ClO_4^- , its redox capacity is higher, the current

peaks are sharper and are shifted to more negative potentials. Upon cycling of $\text{PPy}/\text{Fe}(\text{CN})_6^{4-/3-}$ in a broad range of potentials including the region of redox reaction of the polymer, the NO_3^- anions of electrolyte substitute for $\text{Fe}(\text{CN})_6^{4-/3-}$. When the cycling range is restricted to the oxidised state of the polymer, this system behaves as a conducting ion-exchange membrane. Oxidation (reduction) of $\text{Fe}(\text{CN})_6^{4-/3-}$ immobilised in the polymer matrix is accompanied by migration of the cations of electrolyte from (into) the film.¹⁵⁵ The $\text{Fe}(\text{CN})_6^{4-}$ anions leave the film at potentials more negative than -0.4 V for thick and -0.6 V for thin films.¹⁷² Reduced PPy contains, in addition to ferrocyanide anions, cations that neutralise the anionic charge. At the same time, there are indications²⁰⁰ that cations penetrate the film already at the stage of synthesis, because each positive charge of the polymer matrix is compensated with a multicharged ferricyanide anion. X-Ray diffraction revealed that $\text{PPy}/\text{Fe}(\text{CN})_6^{4-}$ has a more regular structure than PPy doped with single-charged anions.¹¹⁹ Mössbauer spectroscopy showed that PPy film prepared at anodic potential of 0.75 V (vs. saturated calomel electrode), when the ferrocyanide–ferricyanide transition must have occurred, contains only $\text{Fe}(\text{CN})_6^{4-}$ anions.¹¹⁹ In other words, the charge is redistributed between the anions and polymer matrix.

The PPy/ferrocenemonosulfonate (PPy/FMS) and PPy/ferrocenedisulfonate (PPy/FDS) showed²⁰⁶ a higher redox capacity and lower electrochemical stability than $\text{PPy}/\text{ClO}_4^-$. The PPy/poly(vinylferrocenesulfonate) films (PPy/PVFS) are smooth and uniform; the anion immobilised in the film is retained for hundreds of cycles. The maximum discharge capacity of a Li/PPy/PVFS battery was 120 A h kg^{-1} . The PPy/PVFS is a promising electrode material for rechargeable batteries. The instability of PPy/FMS and PPy/FDS is related to degradation of PPy, because in the region of redox transition of ferrocenesulfonates (0.7 – 1.2 V vs. Ag/AgCl) overoxidation of PPy can occur. In order to reduce the redox potential of ferrocenic (F) dopants, the polymeric dopant, poly(styrenesulfonate-co-vinylferrocene) (PVFSS) was synthesised.²⁰⁷ In this polyanion, sulfogroup is not directly bonded with the ferrocene ring. PPy/PVFSS showed two pairs of redox peaks, at -0.1 V and $+0.35$ V (vs. Ag/AgCl), which correspond to PPy/PPy^+ and F/F^+ transitions. The latter transition is shifted by 0.4 – 0.5 V to cathodic region as compared with PVFS. The zinc battery with PPy/PVFSS showed a higher (1.5 times) discharge capacity and energy density and improved charging–discharging performance compared with a lithium cell. Its Coulombic efficiency remained unchanged during 500 cycles.

The preparation, composition and electrochemical properties of PPy films incorporating quinoid dopant anions was reported in Ref. 208. The redox transitions of the quinone/hydroquinone pair of tiron (T), naphthoquinone (NQ) and anthraquinone (AQ) are superimposed on the large background signal of PPy. The position of the redox pair of quinones on the potential axis depends on the dimensions of their conjugated π -systems; $\Delta E_T > \Delta E_{NQ} > \Delta E_{AQ}$. The electrochemical properties of their redox transition are similar to those for quinones adsorbed on the electrode. The redox capacity for AQ on the electrode reaches its limiting value, whereas for PPy/AQ it grows linearly with increasing charge in EP. The PPy/NQ film is highly stable, its VA did not change after a four-days' storage in electrolyte. The electrocatalytic oxidation of ascorbic acid was performed on a PPy/NQ electrode. Tiron plays the role of both a catalyst and dopant in EP of pyrrole ($\Delta E_T = 0.605$ V vs. saturated calomel electrode at pH = 1); initially it is oxidised to quinone and the latter oxidises pyrrole to a radical cation that initiates polymerisation. The charge–discharge properties of PPy/AQ, PPy/NQ and PPy/ ClO_4^- films synthesised at the same charge of EP in the system of $0.1 \text{ M Et}_4\text{NClO}_4/\text{AN}$ at 0.02 mA cm^{-2} were investigated.²⁰⁹ For PPy/AQ, the charge–discharge capacity (119 mQ cm^{-2}) and charge density (150 A h l^{-1}) more than twice exceed respective values for PPy/NQ and PPy/ ClO_4^- . The choice of an electrolyte plays an important role; Li^+ cations in aprotic solvents form

insoluble compounds with dianions of quinoid derivatives and this makes the redox transition irreversible.

The incorporation of metal porphyrins (MP) and phthalocyanines (MPHC), isopoly- and heteropolyacids (HPA) into the matrix of a conducting polymer can be useful for electrocatalysis. The immobilisation of catalysts in the films of conducting polymers provides a number of advantages over monolayers of catalysts grafted to or adsorbed on a support. First, the surface concentration of the catalyst can be electrochemically controlled due to the mechanism of polymerisation inherent in conducting polymers; the second is that the active form of the catalyst can be easily regenerated.

The effect of the nature of isopolymolybdate species on EP of pyrrole and aniline and the electrochemical behaviour of the polymer films doped with polymolybdate anions were investigated using CVA.²¹⁰ The number of molybdenum atoms in the polymolybdate anion that predominates in solution and is incorporated as a dopant in the growing polymer film was controlled through the ratio of acid and molybdenum in electrolyte. The polymolybdates promote the film growth and, owing to their intrinsic electrochemical activity, enhance its redox capacity. In the course of cycling polymer films, the polymolybdate anions are easily removed to the electrolyte from PPy, whereas they remain firmly immobilised in PANi due to formation of complex.

The electrochemical properties of Keggin-type tungstates and molybdates, the effect of pH on the properties of HPA and stability of HPA derivatives in strongly acidic aqueous solutions were studied in detail.²¹⁸ Pyrrole (and similarly, aniline) in aqueous and AN solutions forms soluble complexes with HPA, where it substitutes the co-ordinated water molecules

EP of these complexes results in formation of PPy films doped with anions of HPA.^{211, 212, 214} The VA of these films are distinguished by the reversible peaks of the polymer itself and of multistep reversible redox transitions of HPA. The electrochemical behaviour of HPA immobilised in the polymer differs from the behaviour of the same HPA in solution due to low conductivity of PPy and poly(*N*-methylpyrrole) (PNMPy) in the potential range of HPA reduction.²¹¹ The peaks of HPA are characterised by diffusion-controlled charge transport. Since HPA anions are firmly immobilised within the film, the charge transport involves the Li^+ cations. The maximum doping level for PPy is ²¹⁴ 27% for $(\text{PMo}_{12}\text{O}_{40})^{3-}$, 26% for $(\text{PW}_{12}\text{O}_{40})^{3-}$, 23% for $(\text{SiW}_{12}\text{O}_{40})^{4-}$. The conductivity of the PPy/HPA films is 2.6 S cm^{-1} ; PNMPy/HPA, $5 \times 10^{-3} \text{ S cm}^{-1}$. The comparatively high conductivity (taking into account the very high molecular mass of HPA) can be explained by the contribution of a number of factors. First, the delocalisation of the negative charge in HPA anion facilitates the uniform charge distribution along the polymer chain. This factor also facilitates formation of the polymer with a more regular structure. And finally, the HPA anions can play the role of charge carriers between the polymer chains.

According to Ref. 212, PPy must be prepared from fresh aqueous solutions of HPA because fast trimerisation of pyrrole in solution results in formation of PPy films with poorly reproducible properties. Use of aqueous solutions with neutral salts of HPA allows one to prepare PPy with high conductivity and stable electrochemical properties. The PANi/HPA films are also stable in acidic solutions. The EP of pyrrole in aqueous solutions of Dawson-type HPA (which have the dimensions two times larger than the Keggin-type HPA)²¹⁵ and of aniline in AN solutions of these HPA²¹³ also yields electroactive and highly stable polymers. The redox capacity for PPy/ $\text{P}_2\text{W}_{18}\text{O}_{62}^{6-}$ was²¹⁵ 50 mA h g^{-1} (or 190 mA h cm^{-3} , as the density of the film is very high, 3.9 g cm^{-3}). The incorporation of HPA anions in conducting polymers brings about substantial changes in their electrocatalytic and catalytic properties²¹⁹ due to interactions with the polymer matrix and molecular dispersion of the anions. In the case of PANi

doped with HPA ($\text{PMo}_{12}\text{O}_{40}^{3-}$, $\text{PMo}_{11}\text{Fe}^{2+}\text{O}_{39}^{4-}$, $\text{PMo}_{11}\text{Mn}^{2+}\text{O}_{39}^{4-}$), an enhanced selectivity in formation of acetone in catalytic decomposition of propan-2-ol was observed.²¹⁶ In catalytic conversion of ethanol on PAni/ $\text{PMo}_{12}\text{O}_{40}^{3-}$, mainly acetaldehyde is formed (redox activity), whereas on PAni/ $\text{PW}_{12}\text{O}_{40}^{3-}$ and PAni/ $\text{SiW}_{12}\text{O}_{40}^{3-}$, ethene is the main product (acid–base properties).²²⁰ The activity of the catalysts depends on the preparatory procedure for PAni/HPA.

The PPy films modified with MPhC ($M = \text{Fe}, \text{Co}$) showed high electrocatalytic activity in electroreduction of oxygen^{201, 203, 204} and those modified with MP, in the oxidation of phenol derivatives.²⁰⁵ Reduction of thionyl chloride was performed on PPy electrode modified with iron tetrasulfophthalocyanine.²²¹ The introduction of MPhC in the PPy matrix brought about enhanced currents of thionyl chloride reduction, compared with a PPy/ ClO_4^- electrode and even with a platinum one. The reaction mechanism was not changed. Apparently, the enhancement of currents is due to elevated concentration of adsorbed SOCl_2 on the electrode surface, owing to formation of complexes with MPhC.

PPy was also modified by non-ionic species, in particular metals,²²² metal oxides,^{223–225} and enzymes.^{226, 227} On a PPy film with peroxidase, direct bioelectrocatalysis of cathodic reduction of hydrogen peroxide was observed.²²⁷

VIII. The potential for polypyrrole applications

The PPy is a promising material for rechargeable lithium batteries.^{228–230} The advantages of the polymeric electrodes include light weight combined with high energy storage capacity and a possibility to manufacture and use them in the form of thin films. Table 3 summarises some parameters of the polymer-based lithium batteries and, as a reference, also the properties of lead and nickel–cadmium batteries.²³¹

Table 3. Comparison of characteristics of some electrochemical batteries.²³¹

Battery	U /V	W /W kg ^{−1}	Q /A h kg ^{−1}	E /W h kg ^{−1}
PAC/PC, LiClO ₄ /Li	3.7	3.5	105	80
PAC/PC, LiClO ₄ /PAC	3.0	1.1	85	50
PPh/PC, LiClO ₄ /Li	4.4	7.0	–	80
PPy/PC, LiClO ₄ /Li	3.2	2.8	85	55
PTh/PC, LiClO ₄ /Li	3.4	2.5	75	50
PAni/PC, LiClO ₄ /Li	3.3	0.4	–	60
Lead	2.1	1.2	–	40
Nickel–cadmium	1.35	–	–	35

Note. PAC is polyacetylene, PPh is polyphenylene, PPy is polypyrrole, PTh is polythiophene, PAni is polyaniline, PC is propylene carbonate.

A comparison of energy storage capacity shows that polymer-based batteries are superior. Note also that Li/PPy batteries have a high Coulombic efficiency. In addition to the energy storage advantages, the conducting polymers provide also operational ones. During discharge of the battery, the polymers do not dissolve and this eliminates the problem of the changes in the electrodes' shape in the solution–deposition cycles. The flat discharge that usually destroys conventional batteries is not dangerous in the case of conducting polymers. However, there are certain problems associated with the use of conducting polymers in batteries. First, in the course of charge–discharge, the bulky ions enter and leave the polymer film giving rise to mechanical stresses; this brings about the problem of mechanical integrity of the polymeric electrodes during their operational life. Second, the use of a lithium electrode requires high purity of the electrolyte and perfect sealing of the battery in order to prevent

penetration of water or oxygen into it. A battery with PPy/ Cl^- cathode and PPy/polyvinylsulfate anode was developed;¹⁵² the discharge of the battery is accompanied by removal of Li^+ ions from the anode and Cl^- anions from the cathode. Upon charging, these ions again are inserted into the electrodes. An all-solid rechargeable lithium battery with electrolyte based on polyacrylonitrile extended with organic solvent has been proposed.²³⁰

Amorphous MoS_3 is often used as a cathodic material in lithium batteries.²³² Yet, its conductivity is exceedingly low, $5.2 \times 10^{-4} \text{ S cm}^{-1}$, and a conductive carbonaceous additive must be used. Introduction of MoS_3 into the PPy matrix in the course of EP of pyrrole in the presence of ammonium tetrathiomolybdate provided a possibility of enhancing the conductivity of thin-film MoS_3 electrodes to 2.6 S cm^{-1} (see Refs 195, 196). The VA of PPy/ MoS_4^{2-} film shows a shift of ΔE_p by 200 mV to the cathodic region; this is a typical feature of immobilised anions. The capacitive currents are low, cations take part in the charge transport. The EP of pyrrole from aqueous KCl solution on the substrate matrix Pt/ MoS_3 results in the formation¹⁹⁷ of a film having electrochemical behaviour typical of the polymers doped with small anions and with a higher ionic conductivity than that of PPy/ MoS_4^{2-} . Apart from MoS_3 , for rechargeable lithium batteries, the PPy/ V_2O_5 ²²⁴ and PPy/ MnO_2 ^{223, 225} composites were used as cathodic materials.

PPy doped with alkyl naphthalenesulfonates was used in an all-solid electrolytic capacitor with aluminium electrodes.²³³ The PPy was prepared by EP on the surface of anodised aluminium foil that was preliminarily covered with a thin layer of pyrolytic MnO_2 . Substantially improved thermostability of the capacitor (1000 h at 120 °C) was achieved by means of introduction of nitrophenol in the electrolyte at the stage of pyrrole EP. The properties of this capacitor were superior compared to the common aluminium electrolytic, multilayered ceramic and tantalum capacitors with solid electrolyte and the thin-film organic ones.

The electric conductivity of the conducting polymers is sensitive to chemical agents; this provides a possibility of developing various sensors based on them. It was reported that PPy can be used as a sensor for certain components in gas mixtures, including both inorganic (NO , CO_2 , CO , NH_3 , H_2S)^{234, 235} and organic (acetone, methanol, ethanol)²³⁶ compounds.

The amperometric biosensors based on PPy with incorporated enzymes such as glucose oxidase,^{237, 238} alcohol dehydrogenase,²³⁹ glutamate oxidase and peroxidase²⁴⁰ can find extensive applications. The electrocatalytic activity of the glucose oxidase was enhanced by the introduction of a redox mediator, tiron, and a polymeric dopant, alton (a water-soluble analogue of Nafion).²³⁸ The latter, owing to the high content of fluorine in the polymer, enhances solubility of oxygen and thus promotes oxidation of glucose. In the near future, one might anticipate development of preparations on the basis of PPy, by EP of monomers with grafted enzymes or drugs.²⁴¹ Since PPy is biocompatible and non-toxic, it is possible, by electrochemical reduction of oxidatively doped polymer, to controllably supply an organism (cell) with microscopic doses of a drug that has been immobilised in ionic form, e.g., glutamate, aspartate, dopamine.^{242, 243} Separation of some drugs using PPy was reported;²⁴⁴ caffeine and theophylline are selectively absorbed by PPy, whereas protein molecules are not. PPy can be used as an efficient conductor in biological media (e.g., for regeneration of a nerve tissue).²⁴⁵

A promising field is the application of PPy as a protective coating for semiconducting anodes in photoelectrochemical cells. Usually, when photochemical reactions on inorganic semiconductors are carried out in humid media, the surface of semiconductor rapidly oxidises and electrodes become inoperative. The PPy film covering semiconductor prevents passivation of its surface and simultaneously allows formation of the electron holes, which pass to the polymer (in other words, the electrochemical reaction will now occur on the polymer surface). Such systems were studied for GaAs,²⁴⁶ CdS,^{56, 57} CdSe.⁵⁷ Photochemical cells with solid poly-

electrolytes were developed.²⁴⁷ The photoelectrochemical oxidation of water could be performed by combining the photoeffect on PPy-film-protected CdS^{56, 57} and CdSe⁵⁷ with electrocatalysis on RuO₂, Pt, Rh particles dispersed in the polymer.

Flexible films of conducting polymers can be used as protective electromagnetic shields.^{3, 248} For example, 50- μ m-thick PPy films provide 30-dB attenuation; in many cases, this is sufficient for practical applications.²⁴⁹

The PPy films electrochemically deposited onto a surface of porous silicon were used as electrical contacts in the structure of an electroluminescent diode.²⁵⁰

The PPy antistatic coatings on synthetic polymer fibres (polyethylene,^{251, 252} nylon²⁵³) were produced by polymerisation from gas with the oxidants (iron and copper salts) applied onto the fibre surface.

Microscopic electrochemical transistors were prepared²⁴³ by means of electrocopolymerisation of pyrrole and *N*-methylpyrrole between microelectrodes (emitter and collector) separated with a narrow slit. The conductivity of the polymer channel can be controlled by varying the voltage applied to the auxiliary control electrode. The latter was embedded in a solid or fluid polymeric electrolyte placed over the conducting polymer coating.

The capability of the polymer to reversibly change its volume in the range from 1% to 100% upon electrochemical doping was used²⁵⁴ to make 'electrochemical muscles' based on bilayered strips comprising PPy and polyethylene layers. Upon doping, the free end of the strip strongly deflected from its initial position and returned back upon dedoping.

Abstract. Theoretical and experimental data on the electronic structure, chemical bonding, and charge distributions in condensed boron and solid-phase boron compounds with a number of *sp*-elements are reviewed. The applicability of quantum chemistry methods to a description of the physicochemical properties of boron and borides of nonmetals, as well as prospects of using computational methods in the theoretical materials science of borides, are discussed. The bibliography includes 452 references.

I. Introduction

Boron and its compounds with *sp*-nonmetals form an important class of chemical substances of great scientific, industrial and commercial importance, due to their unique physicochemical properties. Their well known application fields include synthesis of chemically inert and refractory borides, abrasives, dopants to heat-resistant alloys, components of multi-purposes ceramic materials, nuclear energy (boron), elements of cutting tools, composites, abrasives (boron carbides), high-temperature ware, semiconducting devices, chemical engineering (nitrides, phosphides, and arsenides), important precursors for the preparation of other numerous boron compounds (oxides).

Here lies the main reason for an intense development of the synthesis of novel, more complex boron-containing phases and materials, as well as for studies of their crystallography, thermodynamics, and other physicochemical properties, like electromagnetic, thermal, *etc.* Extensive experimental data obtained in these studies are presented in numerous original publications and summarised in a number of fundamental reviews and monographs.^{1–41}

Recently, substantial progress in the investigations of the electronic structure and chemical bonding in the compounds under discussion was achieved using advanced computational quantum chemistry methods. The aim of these studies was to

gain insight into the particular properties of different borides on a microscopic level, including interpretation of experimental physical chemistry data, and direct theoretical modelling of structures and properties of the novel boron-containing compounds and materials.

In this paper, we have attempted to discuss the state-of-the-art and some prospects for computational solid state quantum chemistry studies of the fundamental electronic properties of boron and its compounds with nonmetals. Emphasis was placed on the most widely studied boron compounds such as carbides, nitrides, carbonitrides, B-containing nanostructures, as well as on boron phosphides, arsenides, and oxides.

Results of quantum chemistry calculations are discussed with the use of experimental (mainly spectroscopic) data that give additional information on the electronic structure of these phases.

II. Chemical bonding and electronic structure of condensed boron

1. Crystalline boron

Among few other elements, boron forms a wide range of various phases in solid state. More than 10 polymorphous crystal modifications of boron may be prepared under specific conditions (temperature, pressure, various impurities, *etc.*).^{1–8, 17, 22–25, 32, 36–42}

Up to now, three most stable forms of solid boron with the known crystal structures were obtained unequivocally: α -rhombohedral B₁₂, α -tetragonal B₅₀, and β -rhombohedral B₁₀₅. There are several indications of other forms, such as β -tetragonal B₁₉₂ and orthorhombic phases detected at high temperatures ($T \sim 1500$ K).^{37–42} Crystal structures of these phases differ in the arrangement of B₁₂ icosahedra, which are the fundamental building blocks of boron phases.

According to^{1, 8, 28, 32, 36, 43}, the crystallographic and physicochemical properties of crystalline boron are defined by electronic structure of isolated boron atom, which has s^2p^1 valence electron configuration. This configuration is unfavourable, and it should transform to the more stable s^1p^2 when the solid state is formed (the transformation proceeds as a one-electron transition $s^2p^1 \rightarrow s^1p^2$). For the latter configuration further transition can occur according to the scheme: $s^1p^2 + s^1p^2 \rightarrow s^1p^3 + s^1p^1$. Therefore, in the real modifications of crystalline boron a number of $s^x p^y$ electron configurations due to electronic exchange between

A L Ivanovskii Institute of Solid State Chemistry, Ural Branch of the Russian Academy of Sciences, Pervomaiskaya ul. 91, 620219 Ekaterinburg, Russian Federation. Fax: (7-343) 244 44 95

Received 8 August 1996

Uspekhi Khimii 66 (6) 511–536 (1997); translated by Ya V Zubavichus

boron atoms is possible. Since the relatively stable electron configurations in multi-particle system can be achieved in many ways, a variety of crystal structures with different properties might be formed.

Below we consider the results of quantum chemistry computations of electron energy spectra for the different forms of solid boron.

Rhombohedral α -B₁₂. The unit cell of α -rhombohedral boron (α -B₁₂) with parameters $a = 5.057$ Å and $\beta = 58.10^\circ$ consists of 12 boron atoms.^{44–48} The basic polyhedron is an icosahedron conjugated with the neighbouring icosahedra (Fig. 1a). High precision structural studies of α -B₁₂ indicate slight distortions of ideal B₁₂ polyhedra due to the Jahn–Teller effect, which lowers its symmetry from I_h to D_{3d} .

The problem of interatomic interactions and stability of the B₁₂ icosahedron, the main building block of crystalline boron, was considered for the first time by Longuet–Higgins and Roberts⁴⁹ in terms of molecular orbital (MO) theory. Using theoretical group analysis orbitals of B₁₂ were classified into irreducible representations. Two main blocks of MOs were defined depending on their spatial orientation. The first block consists of hybrid sp -MOs that are responsible for the ‘intracluster’ bonding. The second block includes B $2p$ -like orbitals oriented outside the cluster moiety that in turn are subdivided into bonding and non-bonding ones. The sequence of filling of the MO system in the overall B₁₂ spectrum places only 2 electrons on ‘outer’ bonding orbitals. In terms of the common theory of covalency, this fact

attests to the instability of the isolated icosahedron hindering formation (under normal conditions) of boron crystal structures of high symmetry with low coordination number (n). According to the estimates,⁴⁹ the electronic configuration of boron atoms in the icosahedron is close to the s^1p^2 in contrast to s^2p^1 configuration for the isolated boron atom.

The assumptions made in Ref. 49 were confirmed in later studies,⁵⁰ where a qualitative scheme of orbital configurations and interparticle interactions in solid α -B₁₂ is compared to that in isoelectronic Al metal.

Quantitative estimates of MO energies and compositions for isolated B₁₂ fragments were performed using cluster quantum-chemical approaches. The scattered waves X_α method (X_α SW) was applied to the studies of the electron energy spectrum (EES) of the icosahedral B₁₂.⁵¹ In the calculations interatomic B–B distances were varied in the range of 1.75–2.05 Å. The equilibrium value of 1.96 Å⁵¹ was determined using the total one-electron energy of the fragment, which exceeds the experimental value for α -boron by 10%.^{44–48, 52} This inconsistency may be due to the fact that the model cluster has an open outer shell, which is in agreement with its chemical instability.

Chemical bonding in crystalline boron has a delocalized and electron deficient nature.⁵³ Taking this into account, an empirical ‘ $3n+2$ ’ rule (where $n = 12$) was formulated⁵³ stating that two additional electrons are needed for a closed electron shell to stabilise the crystalline boron and the higher borides containing B₁₂ icosahedra as the structural elements.

The calculated MO diagram⁵¹ (Fig. 2) is in good agreement with a qualitative scheme.⁴⁹ The cluster states may be subdivided into bonding (oriented to the neighbouring centres) and non-bonding (directed to the outer parts) states. The energy gap between the T_{2u} HOMO and the H_g LUMO (‘forbidden zone’) obtained with transition state formalism⁵⁴ is 1.6 eV. It is close enough to the experimental estimate of this value in α -B₁₂.⁵⁵

The MO system of B₁₂ group, similar to that obtained in study⁵¹, was reproduced under the tight binding (TB) approximation.⁵⁶ The probable interactions between bonding and non-bonding states were neglected.^{57, 58} The calculated values of equilibrium interatomic distances and bonding energies are 1.85 Å and 5.7 eV atom^{–1}, respectively. Electron energy spectra for a number of isolated atomic polyhedra B₄, B₆, and B₁₂ were also simulated using extended Hückel (EH)⁵⁹ and Hartree–Fock (HF) methods.⁶⁰

The dependence of EES transformations for boron micro-particles on their geometry and dimensionality was studied by X_α

Figure 1. Fragments of crystal structures for (a) α -B₁₂ and (b) α -B₅₀.

Figure 2. Energy levels (E /eV) of (a) boron atom and (b) B₁₂ icosahedron; (1)—bonding, (2)—antibonding orbitals; the values in brackets are degeneracies of the corresponding MOs.

SW method [clusters with nuclearity $n = 0, 1, 2, 3, 4, 6$; i.e. $B(0)$, B_2 (D_{∞}), B_3 (D_{3h}), B_4 (T_d), and B_6 (I_h) that contain only structurally identical centres were considered].⁶¹ The touching spheres approximation was applied; the exchange correlation parameters were taken from the published tables.⁶² The results of calculations indicate the presence of vacant p -states in the MOs system of the clusters, so they should have a prominent acceptor character and require introduction of additional electrons to achieve a stable configuration.

As it was pointed out,⁶¹ an increase in the n and valence electron concentration (VEC) results in an increase in the width of the occupied band. During this process, redistribution and delocalisation of atomic s - and p -states occur (since delocalized chemical bonds are formed), and the average one-electron energy (per boron atom) changes

$$\varepsilon \approx \frac{1}{N} \sum_i n_i \varepsilon_i,$$

where N is a number of atoms in the cluster, n_i is occupancy and ε_i is the energy of the i th orbital. For instance, energy values for B_2 and B_6 are 25.6 and 33.8 eV, respectively. These results indirectly support higher stability of high-coordinated structures of boron⁶¹ and its compounds.⁶³

The instability of the ideal B_{12} icosahedron was explained⁶⁵ by possible Jahn-Teller distortions due to a partial filling of degenerate higher orbitals.⁶⁴ In the calculations, a molecular dynamics method using the non-empirical Car-Parrinello scheme⁶⁶ under local electron density approximation (LDA)⁶⁷ was applied. The simplest version of this scheme was applied⁶⁸ to the reduction of icosahedral symmetry $I_h \rightarrow D_{3d}$.

Basic concepts of the method are given in Refs 69–73. The existence of a local minimum of $E(\varphi, R)$ (where φ is a wave function and R are atomic coordinates) for a polyhedron of C_i symmetry typical of boron crystalline compounds was established by the total energy minimisation method.⁶⁵ The maximum stability corresponded to the 'open' cluster framework B_{12} with C_i symmetry (Fig. 3), that possesses the minimum energy $\Delta E = E(C_i) - E(C_s) = 0.62$ eV. In the latter case, despite the decrease in the number of interatomic bonds from 30 (C_i) to 27 (C_s), the stability of the C_i form of B_{12} is higher due to the absence of the 'outer' non-bonding cluster orbitals (Fig. 4).

The first band theory calculation of crystalline α - B_{12} was performed by Perrot⁷⁴ using the muffin-tin orbitals (MTO) method⁷⁴ and Cohn–Sham potential parameters.⁷⁶ The calculations were done for 14 k -points in the irreducible part of the Brillouin zone (IPBZ) (Fig. 5). Bands energy dispersion in the direction $G \rightarrow Z$ is shown in Fig. 6. According to calculations,⁷⁴ 18 low energy bands are filled and separated from the lowest unoccupied bands by a forbidden gap (FG) with an energy of indirect transition $\Delta E_g = 2.88$ eV. This value is in accordance with experimentally proved non-metallic behaviour of α -boron.^{37–41}

Figure 3. Optimised structure of B_{12} polyhedron in α -boron structure with atom numbers (1–12).

Figure 4. Wave function profiles of the optimised B_{12} structure [lower left part of the polyhedron; planes going through the atoms 1, 7, 12, 2 (A); 3, 6, 8, 11 (B); 4, 5, 9, 10 (C) as in the Fig. 3].

It is noteworthy, that the width of the filled band d (9.87 eV)⁷⁴ is significantly lower than the value 15.5 eV obtained from X-ray emission spectroscopy (XES) measurements.⁷⁷ The reason for this inconsistency lies in the application of the touching spheres model to loosely packed structures like α - B_{12} (in this case, it is necessary to take into account non-muffin-tin corrections) and also in the neglected correlation effects, which, as it is known,⁷⁸ may strongly

Figure 5. Irreducible part of the Brillouin zone for α - B_{12} .

Figure 6. Energy bands for α -B₁₂ (E, eV).

influence the width of the forbidden zone. Minimisation of the intersphere region (structural factor S was varied in the range of 1.25–1.50 R_{MT} , where R_{MT} is muffin-tin radius) has lead⁷⁴ to a noticeable increase in both FG (5.33 eV) and the valence zone width (16.13 eV): the latter appeared to be substantially closer to the experimental values.

According to the data of non-SCF calculations using augmented plane waves method (APW)⁷⁹, α -B₁₂ should exhibit semi-

conducting properties. A qualitative scheme of interatomic bonds in α -boron based on the analysis of the energy dispersion was proposed. This scheme includes bonds of a boron atom with five nearest neighbours in the B₁₂ fragment and two- and three-centre bonding interactions with boron atoms of the neighbouring polyhedra.

The energy band structure of α -rhombohedral boron was also calculated by the pseudopotential method⁸⁰ with Bassani and Brust parameters.⁸¹ Initial calculations gave the value $\Delta E_g = 5.0$ eV, which is noticeably higher than the experimental value 2.0 eV (see Refs 82, 83) obtained from optical absorption data. Further fitting was performed by cutting of the potential $y(q)$ at $q = 3.2$ (a.u.)⁻¹, and satisfactory agreement with experimental data was achieved for $q = 3$ k_F [where $k_F = 1.2$ (a.u.)⁻¹ (see Ref. 84)]. A more precise *ab initio* calculation of a crystal built of B₁₂ fragments was done using a basis set of 2870 plane waves.⁸⁵ Both energy functions $E(k)$ and equilibrium interatomic distances were obtained. Analysis of the dispersion curves $E(k)$ lead to the values of 1.427 eV for indirect transition across a forbidden zone (between the top of valence zone X and the bottom of the conduction zone Γ), and -1.780 eV for the direct forbidden zone (in Γ point).

Charge distribution patterns in the planes defined by centres of icosahedra and by three independent faces of B₁₂ (Fig. 7) are quite informative. Additional charge density is concentrated on the atoms along the z axis indicating larger contribution of these atoms to chemical bonding in the icosahedron compared to the atoms in the (100) plane. It was concluded⁸⁵ that intracluster bonding in B₁₂ crystals as well as bonding between icosahedra situated in different planes are the most substantial, while the

Figure 7. Charge density profiles inside α -B₁₂ crystal.

bonds between clusters lying in the same plane are much weaker. Another electron band calculation of α -B₁₂ using the orthogonalised linear combination AO method (OLCAO),^{86,87} was done with the set of $1s, 2s, \dots, 3p$ orbitals.⁸⁶ The form of the dispersion function $E(\vec{k})$ allowed one to assign⁸⁶ α -B₁₂ to semiconductors with an indirect FG of 1.8 eV. Table 1 lists the corresponding experimental data along with the values of ΔE_g obtained in other calculation schemes. The observed differences between the calculated FG values are mostly the result of different correlation exchange formalism and different basis sets.

Figure 8 shows the total and local densities of states (TDOS and LDOS respectively) in α -B₁₂.⁸⁶ The ‘ A ’ band (with occupation

**Figure 8.** Total density (a) and local density of B 2s (b) and B 2p states (c) in α -B₁₂.⁸⁶

number, ON=8 e) is composed mainly of B 2s AOs and is separated from the ‘ B ’ and ‘ C ’ bands (ON=12 and 16 electrons, respectively) by a narrow (~ 0.5 eV) gap. The ‘ B ’ band has a mixed p – s -character, while the ‘ C ’ band corresponds mainly to boron 2p- AOs. The calculated optical characteristics of α -B₁₂⁸⁶ are in reasonable agreement with the experimental data,^{88,89} which makes it possible to reproduce the general shape of the optical absorption spectrum and to explain the positions of its major maxima.

Finally, the paper⁹⁰ aimed at the theoretical modelling of probable structural transformations of α -boron under high pressures (P), has to be mentioned. The model assumed that the kinetic energy (E_k) of the electron subsystem increases at the expense of its potential energy (E_p). This assumption is well known for condensed phases with covalent interactions, where substantial localisation of electron density on interatomic bonds is observed. Since E_p and E_k are proportional to $V^{-1/3}$ and $V^{-2/3}$ respectively (where V is a cell volume), an increase of pressure associated with a decrease in V , will probably result in a faster increase in E_k . So, it will lead to a more uniform distribution of the electron density and in a closer packing as a consequence. This tendency was confirmed in many experimental^{91–97} and theoretical^{98–103} solid state studies.

The analysis of this effect was based⁹⁰ on calculations of boron crystal total energy (E_{tot}) as a function of volume. The calculations were performed using a non-empirical pseudo-potential (PP) method in LDA approximation^{104–107} and the linearised MTO method (LMTO).¹⁰⁸

As possible boron allotropes, α -B₁₂, diamond-like, simple cubic (c), face-centred cubic (fcc), body-centred cubic (bcc), and hexagonal closely packed (hcp) structures were considered. Probable distortions of boron structure from bcc to body-centred tetragonal (bct) form were also taken into account.

The dependence of the total energy on volume [$E_{\text{tot}}(V)$] obtained in the LMTO calculations⁹⁰ is shown in Fig. 9. A similar correlation was found in PP calculations. Table 2 summarises the equilibrium volume, bulk modulus, and the corresponding minimum values $E_{\text{tot}}(V_0)$ from PP and LMTO calculations for all structures along with the experimental data.¹⁰⁹ These data demonstrate that α -B₁₂ is the most stable structure at normal pressures, whilst on a pressure increase (and volume decrease), a structural phase transition α -B₁₂–bct (at $P \sim 210$ GPa) should occur followed by a stabilisation of the bcc form (at $P \sim 360$ GPa).

**Figure 9.** Total energy vs. volume for α -B₁₂ (1), boron with diamond structure (2), simple cubic (3), body-centred cubic (4), face-centred cubic (5), and hexagonal closely packed (6) boron sublattice. LMTO calculations.⁹⁰

This transitions should be accompanied by a weakening of certain localised covalent B—B bonds, a decrease in the forbidden zone, and a transition of bcc structure to a metallic-like state as observed in aluminium.¹¹⁰

Tetragonal $\alpha\text{-B}_{50}$. The crystal structure of $\alpha\text{-B}_{50}$ has been described.^{111–116} The tetragonal cell with the parameters $a = 8.75$, $c = 5.06$ Å includes 4 ideal icosahedra and 2 boron atoms [B(A)] with 4-fold coordination. Boron atoms composing icosahedra can be subdivided into 4 types [B(1)...B(4)] depending on their position relative to other B_{12} polyhedra and B(A) atoms (see Fig. 1b). Only one type of boron atom that does not belong to the icosahedron may be present.

Quantum-chemical calculation of $\alpha\text{-B}_{50}$ by simple LCAO method⁷⁹ allowed one to describe a general structure of its electron energy spectrum. It includes partially filled valence band formed by boron $2s$ and $2p$ AOs, which determines metal-like properties of the tetragonal $\alpha\text{-B}_{50}$. This band is separated from the lowest unoccupied band by FG of ~ 1.43 eV. To fill the valence band during the corresponding transition from the tetragonal phase into the more stable semiconducting phase, 10 additional electrons per unit cell are needed. This explains a known tendency of $\alpha\text{-B}_{50}$ to form stable compounds with electron-rich p -elements (C, N).

To date the best of the most rigorous calculations of $\alpha\text{-B}_{50}$ was performed by OLCAO method.⁸⁶ Analysis of TDOS shapes for $\alpha\text{-B}_{50}$ demonstrated the metallic character of the phase with the FG of about 2.16 eV width lying above the Fermi level by 1.38 eV. The spectrum of the filled states consists of three main subbands with the occupation numbers of 8, 24, and 128 e, respectively. The main differences in EES parameters for $\alpha\text{-B}_{12}$ and $\alpha\text{-B}_{50}$ are clearly seen in Table 1. The decomposition of TDOS onto partial components [corresponding to atom types B(A), B(1)...B(4), see Fig. 1b] shows that the electronic states of B(A) and B(1) that form local bonding orbitals of the [B(A)B(1)₄] tetrahedron make the main contribution to the Fermi level (*i.e.* are responsible for the metal character of $\alpha\text{-B}_{50}$).

Analogies between atomic structures of $\alpha\text{-B}_{50}$ and fullerene C_{60} as well as electronic structures of $\alpha\text{-B}_{50}$ and $\text{YBa}_2\text{Cu}_3\text{O}_7$ were observed.⁸⁶

In the latter case, both $\alpha\text{-B}_{50}$ and the superconducting oxide possess a subband of hole states near the Fermi level separated from the higher virtual states by a semiconductor gap.^{117–119} The analogy allows one to suggest that $\alpha\text{-B}_{50}$ may exhibit superconductivity.⁸⁶

The relative instability of $\alpha\text{-B}_{50}$ may be explained by the presence of unfilled states between E_F and the bottom of the forbidden zone. The tetragonal $\alpha\text{-B}_{50}$ structure can be stabilised by doping with electron-rich nonmetals to form phases like $\text{B}_{48}\text{B}_2\text{C}_2$ or $\text{B}_{48}\text{B}_2\text{N}_2$ ^{120, 121} or with d/f -elements to form higher borides. Calculations of E_{tot} vs. volume dependence, estimates of

**Figure 10.** Total energy vs. volume (a) and pressure vs. volume (b) for $\alpha\text{-B}_{12}$ (1) and $\alpha\text{-B}_{50}$ (2), V_0 is the equilibrium volume.

V_0 , B_0 , and $P(V/V_0)$ for $\alpha\text{-B}_{50}$ showed that $B_0(\alpha\text{-B}_{50}) > B_0(\alpha\text{-B}_{12})$ (Fig. 10). This fact indicates higher hardness of the tetragonal phase. The $P(V/V_0)$ function indicates a higher thermodynamical stability of $\alpha\text{-B}_{50}$ (at 0 K), although a phase transition $\alpha\text{-B}_{50} \rightarrow \alpha\text{-B}_{12}$ is possible when the external pressure is increased up to ~ 360 GPa. This high pressures can result in substantial structural distortions of both phases and does not exclude a possibility of formation of alternative structural modifications,⁸⁶ similar to those discussed elsewhere.⁹⁰

Figure 11 shows the calculated optical characteristics of $\alpha\text{-B}_{50}$:⁸⁶ the interband absorption (σ), real (ϵ_1) and imaginary (ϵ_2) parts of dielectric functions, and energy loss function (ELF) in the range of 0–10 eV. The $\sigma(E)$ function contains peaks at the energies ~ 1.1 and 1.5 eV related to the transitions from the filled band to the unoccupied band near the Fermi level. The minimum

**Figure 11.** Changes of σ (a), ϵ_1 (b), ϵ_2 (c), and ELF (d) for $\alpha\text{-B}_{50}$ in the photon energy range 0–10 eV (for notations see text).

of $\sigma(E)$ in the region 2.0–5.5 eV corresponds to the forbidden zone in the energy spectrum. Above 5.5 eV, the absorption intensity increases abruptly (due to transitions to unoccupied states above the forbidden zone), and the structure of $\sigma(E)$ in this region becomes similar to that of α -B₁₂.⁹⁰

Rhombohedral β -B₁₀₅. The crystal structure of β -B₁₀₅ has been determined.^{122–125} The main building block of the structure is a B₈₄ polyhedron (Fig. 12) that includes a central icosahedron coordinated by 12 pentagonal pyramids B₆. The unit cell of β -B₁₀₅ contains 15 structurally non-equivalent positions occupied by boron atoms.

The complexity of the β -B₁₀₅ structure hampers strict non-empirical quantum chemistry calculations of its EES. Thus, the

Figure 12. The structure of the central part of 84-atomic polyhedron, which is the principal building block in β -B₁₀₅ crystal lattice.

energy spectrum of β -B₁₀₅ was calculated only using a simplified LCAO approach under the two-centre approximation.⁷⁹ The TDOS histogram obtained (Fig. 13) exhibits fine structure. However, assignment of its peaks to structurally non-equivalent groups of boron atoms was not performed.⁷⁹ Complete filling of the valence band requires 320 electrons while unit cell contains only 315 e. Therefore, β -B₁₀₅, like α -B₅₀, should exhibit metal-like

properties. The width of the forbidden zone (in the region of unoccupied states) in β -B₁₀₅ is estimated as ~ 2.7 eV.

Numerous experimental data (see, for example, a review¹²⁶) demonstrate that filling of cell cavities in β -B₁₀₅ by transition metal atoms results in certain cases in the increase in microhardness of the phase and dramatically changes its conductivity.^{127–129}

It should be generally noted that experimental studies of β -B₁₀₅ [using XES,^{130–134} XPS,^{135,136} optical absorption,^{137–143} Raman spectroscopy,^{144–146} Auger electron spectroscopy (AES),¹³⁵ and ESR^{147–151}] lead to inconsistent conclusions as to its conductivity. For instance, according to optical absorption and XPS data,^{136,138–143} β -boron is a semiconductor with an indirect FG equal to 0.65–1.73 eV. However, according to ESR data,^{147–151} the forbidden zone of β -B₁₀₅ contains a system of ‘trap’ levels composed of different states of non-equivalent B atomic groups, which causes several types of jumping conductivity. An empirical scheme of β -B₁₀₅ band structure reflecting this feature has been proposed¹⁵² (Fig. 14). Werheit¹⁵³ confirmed and developed this model based on the recently obtained experimental results^{154–159} (mainly from visible, IR, and Raman spectra, conductivity measurements and magnetic parameters) both for pure and doped β -boron.

The correct interpretation of all experimental data on β -B₁₀₅ (see also Refs 160, 161) definitely requires further detailed calculations of its spectral fine features.

Figure 13. Total density of states of β -B₁₀₅. LCAO calculations.

2. Amorphous boron

The electronic factors that determine the relative instability of crystalline forms of boron are responsible for the existence of its amorphous state. Amorphous boron usually exists as films deposited on certain supports. Numerous studies were devoted to the formation conditions and the properties of amorphous boron^{2, 5, 25, 37–41} though most technological and scientific interest lies in its amorphous alloys with metals (like $M_{80}B_{20}$, *etc.*). In the experimental studies dedicated to amorphous boron (AB), the main attention has been paid to the investigation of the mechanism of its transition into the crystalline state.^{162–165} According to conductivity measurements, AB is an amorphous semiconductor.^{151, 166, 167} The structure of AB may be described as a conglomerate of atomic clusters composed of B_{12} polyhedra^{168–176} with a size in the range 2–5 nm.¹⁷⁷

Data on EES of AB are rather scarce and in most cases are based on XES.^{130–132, 177, 178} According to literature data,^{130, 177, 178} the boron K_{α} -spectrum in AB is similar to that of β - B_{105} except for a shoulder at 179 eV that is more intense for β -boron.

The combination of XES and extrinsic photoeffect quantum yield spectrum on a common scale allowed one to estimate a FG for AB as 1.2 ± 0.2 eV,¹³¹ which is in a reasonable agreement with the photoconductivity data (1.27 ± 0.05 eV¹⁷⁹) and estimations from measurements of high-temperature conductivity of AB films (~ 1.00 eV¹⁴²). The analogy of the optical properties of AB and β - B_{105} was also observed,¹⁶⁶ the study of optical absorption and photoeffect for AB gives indirect FG value equal to 0.56 ± 0.03 eV.

III. Boron carbides

Boron carbides (B_xC_y) exhibit very interesting properties.^{1, 7, 11, 15, 25, 28, 32–41, 180} Phase relations in B–C systems were investigated in much detail, and the existence of a number of individual phases as well as interstitial solid solutions (for example, of boron or carbon in $B_{12}C_3$, see^{37–39, 41}) was clearly demonstrated. According to recent data,^{38, 39, 41, 180–186} structures of carbides with lower carbon content (from 9 at.% to 20 at.%, *i.e.* from $B_{10}C$ to $B_{12}C_3$) are connected with the parent structures of solid boron. The main building blocks of these structures are B_{12} -like icosahedral clusters.

In a number of studies,^{187–189} the synthesis of carbon-rich carbides $BC_{3 \pm x}$ with layered graphite-like structure was reported. In addition to the phases mentioned above, numerous heterogeneous boron carbide phases ($B_{13}C_2 + C$), non-stoichiometric boron-carbon compounds $B_{1-x}C_x$,^{183–186, 190} and B_xC_y -based composites¹⁹¹ are also known. The electromagnetic,^{192–196} spectroscopic,^{197–199} and thermal²⁰⁰ properties of B_xC_y phases as well as their behaviour in reactions with metals,²⁰¹ oxides,²⁰² ferroalloys,²⁰³ *etc.* have been thoroughly investigated.

A phenomenological model of chemical bonding in boron carbides containing B_{12} polyhedra ($B_{13}C_2$, $B_{12}C_3$)¹⁸⁰ describes these polyhedra as electron-deficient systems with ‘delocalised’ covalent bonding. A possibility of different electronic configurations (sp^2 and sp^3) for carbon atoms is suggested. Using atomic-term energies for B and C, the heat of boron carbide formation and atomisation of boron and carbon, the degree of metallicity, covalency, and ionicity has been estimated to be 0.58, 0.93, and 0.35 respectively.¹⁸⁰ In fact, the qualitative character of these estimates cannot be a serious basis for the micro-level description (and, moreover, predictions) of the fundamental electronic properties of B_xC_y phases.

Three ordered phases, *viz.* $B_{13}C_2$, $B_{12}C_3$, and BC_3 , were the subject of several studies using advanced computational methods of quantum chemistry. Special attention has been paid to the calculation of EES parameters and to the problem of reliable determination of crystal structures. The relative stability of the possible icosahedra (B_{12} and $B_{11}C$) composing the $B_{13}C_2$ and $B_{12}C_3$ carbides is still under discussion. The composition of

triatomic ‘intercluster’ linking chains also remains obscure (the suggested variants are CBC, CCC, BBC).

Boron carbide $B_{13}C_2$. The structure of $B_{13}C_2$ is still a subject of lively discussions. $B_{11}C$ clusters and (BBC) chains were suggested as main building blocks of the structure.^{194, 195, 197} On the other hand, an alternative variant of B_{12} clusters and CBC chains (Fig. 15) was discussed^{204–206} on the basis of X-ray diffraction data. Experimental difference electron density maps were also obtained.^{204–206} Analysis of these maps lead to a conclusion that B(3)–C σ -bonds dominate within C–B(3)–C chains, between these chains and icosahedron [C–B(1)] and between atoms of the icosahedron [B(2)–B(2)].

A structural model^{203–207} was used for the band structure and cluster calculations of the electronic properties of $B_{13}C_2$.²⁰⁸ It was found that the dispersion $E(k)$ in all symmetrical directions of the

Figure 15. Structure of $B_{13}C_2$.²⁰⁴

Brillouin zone (BZ) does not exceed ~ 3 eV, the carbide VZ is filled only partially and is separated from the forbidden zone ($\Delta E_g \sim 4$ eV) by a subband of unfilled states. According to data,²⁰⁸ $B_{13}C_2$ should exhibit metal-like properties. It was concluded²⁰⁸ that the conductivity of the carbide phase will decrease as the content of carbon increases (in the row $B_{13}C_2 \rightarrow B_{12}C_3$, *i.e.* on filling of unoccupied upper region of the VZ). It agrees generally with an empirical interpretation of changes in conductivity of B_xC_y .²⁰⁹

Pseudomolecular calculations²¹⁰ with Born–Karman boundary conditions were performed in order to determine bond and charge state parameters for $B_{13}C_2$ (Table 3). It is clearly seen that bond populations in icosahedra are noticeably lower than for the ‘chain’ bonds. Relative charges on different atoms (B or C) are in accordance with their electronegativities. This conclusion also

Table 3. Bond populations (I) and effective charges (q) of atoms and groups of atoms in $B_{13}C_2$ phase.²¹⁰

Bond ^a	I / e	Atom ^a	q / e
B(1)–B(1)	0.50	B(1)	0.20
B(1)–B(2)	0.49	B(2)	–0.16
B(2)–B(2)	0.52	B(3)	0.81
B(3)–C	1.05	C	–0.57
B(1)–C	0.83	I ^b	0.33
		II ^c	–0.33

^a For atom notations, see Fig. 15. ^b I is a B_{12} icosahedron. ^c II is a CBC chain.

holds for atomic groups of the elements considered. The general tendency of charge density polarisation (in the direction $B \rightarrow C$) agrees with experimental data.^{204–206}

In the most rigorous non-empirical calculations of the energy band structure for $B_{13}C_2$,²¹¹ two alternative structures of the carbide $B_{12}(CBC)$ and $B_{11}C(BBC)$ were considered. For the latter, three possible arrangements of carbon atoms in the icosahedron and in the chain were taken into account.²¹² In two cases (α and γ), the carbon atoms occupied the terminal positions of the chain, and the ‘icosahedral’ carbon lay in the equatorial plane of the polyhedron near the chain carbon atom (α) or far from it (γ). The case β implies that a carbon atom is situated in the lowest vertex with no direct $C-C$ bonds.

The relative stabilities of the above structural types were compared based on their bonding energies (Table 4). The $B_{12}(CBC)$ form appeared to be the most stable. This conclusion is supported by comparison of the free energy values F ; for $B_{11}C(BBC)$, taking account of the number of possible configurations (α, β, γ) is given by a formula:

$$F[B_{11}C(BBC)] = -kT \ln \left[6 \exp \left(-\frac{15E_\alpha}{kT} \right) + 12 \exp \left(-\frac{15E_\beta}{kT} \right) + 6 \exp \left(-\frac{15E_\gamma}{kT} \right) \right],$$

and for $B_{12}(CBC)$, by

$$F[B_{12}(CBC)] = -15E[B_{12}(CBC)].$$

Bonding energy values (see Table 4) give $F[B_{12}(CBC)] - F[B_{11}C(BBC)] = -1.669$ eV per unit cell.

Along with the energetic characteristics, the lattice constants, the equilibrium cell volume, bond lengths, and bond angles were calculated.²¹¹ The result for the $B_{12}(CBC)$ structure are in the best

involves only four electrons. This fact may cause the instability of the carbide and opens broad prospects for variations of the carbon content (from 4 at.% to 26 at.% of C).^{213,214}

The first simplified band theory calculation of $B_{12}C_3$ [$B_{12}(CCC)$ structure] was accomplished⁷⁹ using a basis of the valence $2s, 2p$ AOs of boron and carbon; a crystal potential was approximated by superposition of the atomic potentials. The results of the calculation showed a typical semiconducting structure of the VZ including a FG of ~ 3.8 eV. Semi-quantitative estimates of the effective atomic charges gave a transfer of two electrons from the central (in the CCC chain) carbon atom to $C-B_{12}$ bonds.

The features of the band spectra for $B_{12}(CCC)$ and $B_{11}C(CBC)$ were compared using the so-called ‘universal form’ of matrix elements within the pseudopotential scheme.⁵⁶ Estimates of one-electron bonding energies in the icosahedra composing the structures mentioned demonstrated that the corresponding value for $B_{11}C$ polyhedron exceeds that for B_{12} by ~ 3 eV. This may be considered as a qualitative confirmation of the CBC preferable chain configuration in $B_{12}C_3$.

A pseudopotential method was used²⁰⁸ to compare three possible structural forms of $B_{12}C_3$. The following structures were analysed: (1) $B_{11}C(CBC)$, where B(1) atom was replaced by carbon (Fig. 15); (2) $B_{11}C(CBC)$, where B(2) atom was replaced, and (3) $B_{12}(CCC)$, where B(3) atom was replaced. The E_{tot} values (Table 5) point to the instability of (3). IR data²¹⁵ and $^{13}C, ^{11}B$ NMR spectra^{216,217} also indicate the most probable formation of CBC chains oriented along the [111] direction in the structure of $B_{12}C_3$.

The cohesion energy for $B_{12}C_3$ [structure (2)] was estimated by the non-empirical self-consistent pseudopotential method²¹⁸ together with the equilibrium value of the lattice parameter. Calculated data conformed with the experimental value with the accuracy of 0.5%.

The most stable structure for $B_{12}C_3$ has been modelled²¹⁹ by the cluster Hartree–Fock method. The structure of boron carbide was approximated by a $B_{12}C_3H_6$ molecule, hydrogen atoms being introduced to compensate the ‘cleaved’ bonds. The analysis of E_{tot} for clusters with different configurations of the intericosahedral chains lead to a conclusion that the formation of the $C-B-C$ chains is preferable as compared to the $C-C-C$ chains.

The most comprehensive of the reported calculations for $B_{12}C_3$ [$B_{11}C(CBC)$ configuration] has been performed²²⁰ with the basis set of 3580 plane waves for 32 points of the IPBZ. Parameters of the energy band structure, equilibrium lattice constants, the value of (indirect) FG (2.781 eV), and effective atomic charges have been determined. Comparison of the cohesion energies (E_{coh}) for $B_{11}C(CBC)$ and alternative $B_{12}(CCC)$ configuration indicates that the former is more probable.

‘Devolution’ of the electron density maps for the faces of $B_{11}C$ icosahedron allows one to trace the charge distribution therein (Fig.16). This analysis demonstrated that the character of $B-B$ and $B-C$ bonds is mostly covalent.

Table 4. Cohesion energy (E_{coh} /eV atom⁻¹) for different $B_{13}C_2$ structures and diamond.²¹¹

Structure ^a	E_{coh}	Structure ^a	E_{coh}
$B_{12}(CBC)$	7.1408	$B_{12}(BBC)$	6.9312
$B_{11}C(BBC)$		$B_{11}C(CBC)$	7.2592
α	7.0013	B_{12}	6.8402

γ	6.9482		

^a For notations of $B_{11}C$ (BBC) $\alpha-\gamma$, see text.

agreement with experimental data.^{204–207}

Thus, rigorous quantum chemistry calculations of energies for different structural models proposed for $B_{13}C_2$ give a convincing argument for a $B_{12}(CBC)$ form and allow one to reject all alternative variants.^{194,195,197}

Boron carbide $B_{12}C_3$. General information on the properties and structural features of the $B_{12}C_3$ phase has been summarised.^{37,39,41}

One of the first studies devoted to the qualitative description of the nature of chemical bonding in $B_{12}C_3$ ⁵⁰ stated that bonding of terminal and central carbon atoms in the $C-C-C$ chain

Table 5. Energy positions of the valence zone (E_{VZ}), conductivity zone (E_{CZ}), value of the forbidden gap ΔE_g , charges (q) on atoms B(1), B(2) and on icosahedra (q_n), and total energy per unit cell (E_{tot}) for different $B_{12}C_3$ structures.²⁰⁸

Figure 16. Charge density distribution in the faces of the $B_{11}C$ polyhedron in $B_{12}C_3$ [$B_{11}C(CBC)$ ordering type]. B(1) and B(2) atoms have, respectively, one and two carbon atoms in their closest environment. Numbers correspond to ρ values in 10^{-3} electrons per atomic unit.

The known²²⁰ value of E_{coh} for $B_{12}C_3$ was⁸⁵ used to calculate the heat of formation (ΔH) of the carbide according to the scheme:

$$\Delta H(B_{12}C_3) = 15E_{coh}(B_{12}C_3) - 3E_{coh}(C) - 12E_{coh}(B_{12}).$$

$E_{coh}(B_{12})$ was found in Ref. 85. The final calculated value of $\Delta H(B_{12}C_3)$ was 1.632 eV per unit cell, which is close to the experimental estimates of 1.795 and 1.940 eV per unit cell (see Refs 221 and 222, respectively). The somewhat smaller theoretical value of ΔH is probably due to the use of the valence approximation in this study.²²⁰

Boron carbide BC_3 . Synthesis of a layered boron carbide BC_3 via a reaction

has been reported.^{187–189}

It was pointed out, that partial B→C substitution in the graphite-like structure proceeds in a regular way with B_6 hexagons surrounding C_6 rings (Fig. 17). The density of the thus produced material is lower (since interatomic B–C distances are longer than C–C distances by ca. 10%) and its conductivity is higher than that of graphite.¹⁸⁸

The higher conductivity of the BC_3 may be caused by the lack of electrons in the carbide (as compared to graphite), which favours the appearance of a certain concentration of holes at Fermi level. In order to check this suggestion and to determine the nature of chemical bonding in BC_3 , a number of quantum-chemical calculations were performed.^{188, 223–225} According to estimates using the Hückel method,¹⁸⁸ the value of the forbidden gap in BC_3 is close to 1.8 eV and the Fermi level is located near the bottom of the π -band.

More rigorous *ab initio* calculations²²⁴ were performed using the pseudopotential LCAO method with a basis set of *s*- and *p*-AOs.²²⁶ Since interlayer separation in BC_3 (3.35 Å) is substantially larger than bond distances in the layer, calculations for a single layer of the carbide structure were carried out as the first step. Comparison of the electron density distribution in BC_3 monolayers (Fig. 18c) and graphite (Fig. 19) leads to a conclusion that the lesser electron density is concentrated on boron

Figure 17. Structure of layered BC_3 (unit cell is shown).

atoms. However, electron distribution within C_6 rings is rather unperturbed, since the C–C interatomic distances in graphite and BC_3 are close.

The distribution of the density of states (DOS) for BC_3 single layers is shown in Fig. 18 and for graphite (Fig. 19). There is a FG between filled and unfilled states with the value of indirect transition ~ 0.66 eV. Account for interlayer interactions²²⁴ (with AA and AB possible relative orientations of neighbouring layers) results in a disappearance of the FG; the material acquires the properties of a metal with higher conductivity for the AA packing.

The conductivity of BC_3 carbide, therefore, is defined by interlayer interactions.²²⁴ However, the energy of these interactions is relatively small (according to some estimates,²²⁴ not higher

Figure 18. Density of states in BC_3 with (a) AA layers arrangement, (b) AB layers arrangement, (c) single layer.²²⁴

Figure 19. Density of states in graphite.²²⁴

than ~ 0.1 eV), although the total cohesion energy is about 7.8 eV.

The detailed analysis of changes in composition of states near the Fermi level for BC_3 compared to graphite was done²²⁵ using energy band calculations for single layers of graphite and BC_3 (Fig. 20). The analysis of the energy band distribution shows that the former σ -like bands are rather remote from the Fermi level and cannot take part in conductivity processes. However in the carbide the Fermi level (situated lower due to a decrease in general electron concentration) intersects the σ -band in the Γ point.

Figure 20. Energy band dispersion for single layers of (a) graphite and (b) BC_3 . The states with σ - and π - symmetry are marked, upper numbers denote a degeneracy.²²⁵

These bonds, along with π -like states, govern the conductivity properties of BC_3 (hole conductivity).

The above considerations were applied to a description of the electronic properties of boron carbides with a definite stoichiometry. However, along with such phases, a number of solid solutions (SS) with a variable composition are formed.

Recently,²²⁷ model calculations of electronic and structural parameters for one of these solid solutions, B_xC_{1-x} , with graphite-like structure have been carried out using the pseudopotential method under a local electron density approximation.²²⁷

It should be noted that the layered boron-carbon SS are usually prepared as films.¹⁸⁹ SS with a boron content less than 4% (intercalated graphites) can also be attributed to this type.²²⁸

The main goal of a study (Ref. 227) was to determine the most probable type of ordering for boron atoms in the graphite lattice. To this end, the total energy values for ordered and disordered structures of B_xC_{1-x} were compared. It was pointed out that intercluster interactions promote segregation of boron atoms and long-order formation in the case of SS with low boron content ($x \leq 0.25$). It was suggested²²⁷ that the increase in boron content should violate the ordered atomic arrangement with a transformation of the initial graphite-like crystal structure. This effect is primarily caused by the substantial difference in the atomic radii of boron and carbon.²²⁷

IV. Boron nitrides

Crystalline boron nitride BN, due to its unique properties and exceptional technological importance,^{15, 20, 26, 28–34, 36} is one of the best studied compounds of boron with p -elements. There are three known structural modifications of BN: hexagonal (graphite-like h-BN), cubic (sphalerite-like c-BN), and wurtzite-like (w-BN). The latter can be prepared from the h-BN as a result of a phase transition under high temperature/pressure treatment.

Synthetic methods, crystal structures, conditions of phase transitions (including the influence of lattice defects, admixtures, etc.) for boron nitrides were discussed in detail.^{26, 229–237}

Extensive experimental data obtained using XES, AES, XPS, absorption spectroscopy^{238–244} allow one to determine general features of EES of boron nitrides. The anisotropy of band dispersion for the layered BN was investigated²⁴³ using the polarised XES technique. This effect was also discussed in studies of Compton profiles in h-BN²⁴⁵ and of the electron inelastic scattering.²⁴⁶

Infrared and VIS-UV spectroscopies are widely used for characterisation of dielectric properties of nitrides.^{247–257} Their detailed comparison with the results of quantum chemistry calculations published before 1987 has been made.²⁵⁸ Electron energy loss spectroscopy has been used^{259–262} in order to obtain the EES parameters. The luminescence properties of BN were considered in Refs 263–267.

Theoretical studies of the fundamental properties of BN are also rather extensive. The first band theory calculation of the c-BN, which is a semiconductor of III–V type, in simplified TB approximation was performed in 1952.²⁶⁸ Since then, theoretical calculations of EES and many other properties have been carried out using almost all of the known band and cluster schemes for h-BN,^{269–286} c-BN,^{287–325} and w-BN.^{325–332}

Without going into discussion of the results of theoretical studies and some inconsistencies between the particular results (unavoidable because of different computational schemes, basis sets, potential parameters, etc.), we shall consider general electronic properties for all three modifications of BN calculated within the same approaches.^{324, 325}

The results of OLCAO band structure calculations for h-BN and w-BN are shown in Fig. 21a,b. Low energy bands of h-BN are composed mainly of $(\text{N}, \text{B})2s$ -states separated from the main hybrid $(\text{N}p-\text{B})2p$ band by an energy gap. The band structures for c-BN and w-BN are similar (Fig. 21c). Principal differences in the electronic structure parameters for the nitrides are clearly seen

Figure 21. Energy bands of (a) h-BN, (b) w-BN, and (c) c-BN.

from Table 6. For the layered nitride, energy dispersion $E(\vec{k})$ along the direction k_z is relatively small. All BN modifications have indirect FG. For h-BN, the width of the VZ is minimum; in c-BN and w-BN it has comparable values due to a similarity of their atomic environments. This points to the local character of interatomic interactions that have a heteropolar nature in boron nitrides, determined, for instance, by B→N charge transfer (Table 6).

Recently, greater attention was paid to studies of EES in boron nitride crystals containing various structural defects. Investigations of complex systems (ceramics, composite materials based on boron nitrides, *etc.*) at the micro level will probably result in a substantial progress in the nearest future. However,

only a few studies have been performed in this field to date. The most interesting results are the following.

Studies of h-BN films^{326–329,331} (promising as inhibitory dielectric films and X-ray membranes) revealed a substantial dependence of their optical properties on stoichiometry (B/N ratio). To explain this fact, calculations were performed³³⁰ using TB approximation. A two-dimensional graphite-like structure was used as a model; variations in the composition of $\text{h-B}_x\text{N}_y$ (with assumption of random B→N substitution) were taken into account in coherent potential approximation.³³¹

The distribution of the π -type states indicates the absence of the FG in contrast to the experimental data³²⁹ that give decrease of the ΔE_g for h-BN from 5.0 to 2.5 eV when the B/N ratio changes from 1 to 5.1.

Accounting for a partial ordering of atomic configurations leads to appearance of the FG (Fig. 22) linked with the emerging of additional subband of the boron p-states, whose width is proportional to B/N ratio.³³⁰ Therefore, thin films of $\text{h-B}_x\text{N}_y$ should exhibit regular spatial distribution of the atomic components similar to that in the crystalline h-BN.

Figure 23. Energy bands of the heterogeneous phase system (110) diamond – boron nitride.

The features of the energy states, typical of the heterogenous system diamond/(boron nitride), have been analysed using the linearised method of augmented plane waves (LAPW).³³² A supercell that models the atomic geometry of the interface region including N/N layers ($N = 1; 3; 5$) of the C/BN (100) plane was used. It was found that energies of the internal layers and atomic charges for the central layer of each component become close to the corresponding values for the ideal C and BN crystals already for $N=3$. Band distribution near the Fermi level for the 5/5 layered system is shown in Fig. 23. It should be noted that, though the bottom of the conductivity zone is composed of BN bands (a gap between zones at the X point is about 0.7 eV), the top of the VZ relates to the ‘diamond’ states. The magnitude of the gap between zones is about 1.42 eV.

In Ref. 333, the method of an effective Hamiltonian^{334,335} (in Del Re parametrisation³³⁶) has been used as a theoretical basis for optimisation of the carbamide technology for h-BN preparation. In particular, carbamide $(\text{NH}_2)_2\text{CO}$ (1) was replaced in the technological process by cyanuric acid $\text{H}_3\text{C}_3\text{N}_3\text{O}_3$ (2) or melamine $(\text{NH}_2)_3\text{C}_3\text{N}_3$ (3). Atomic charges and energies of bonding states for the molecules (1)–(3) as well as for orthoboric acid and boric anhydride were estimated.³³³

Taking into account the electronic structure of the initial reagents and reaction products, it was pointed out³³³ that formation of h-BN in the interaction of carbamide, cyanuric acid, and melamine with H_3BO_3 may be considered as electrophilic substitution. In this mechanism, the boron and carbon atoms in H_3BO_3 , boric anhydride, and initial compounds 1–3 may be ranged in the order of decreasing activity towards orthoboric acid: $(\text{NH}_2)_3\text{C}_3\text{N}_3 > \text{H}_3\text{C}_3\text{N}_3\text{O}_3 > (\text{NH}_2)_2\text{CO}$. This has lead to a conclusion³³³ that the replacement of $(\text{NH}_2)_2\text{CO}$ by melamine in the multi-stage carbamide technology provides (due to its higher activity) a decrease in a number of stages. Replacement of carbamide by cyanuric acid results in a decrease in NH_3 output, *i.e.* in the increase of the environmental safety of the process.

V. Boron carbonitrides

Synthesis of a series of layered SS based on graphite and h-BN^{188,337,338} led to studies of their electronic spectra. Theoretical modelling of atomic ordering character in these systems was also carried out.^{339–341}

The electronic structure of a cluster composed of three hexagons of the h-BN single layer, where a central nitrogen atom is replaced by C, was calculated³³⁹ using the Gaussian orbitals LCAO (GO LCAO) method.³⁴² It was assumed that the carbon atom is situated 0.76 Å above the h-BN plane. Using the value of the constant of hyperfine interaction with ^{13}C nucleus (~ 1.8 Gs), it was possible to qualitatively explain the ESR splitting in a boron nitride enriched by carbon.^{343,344}

Figure 24. Models of atom ordering in boron carbonitride single layer (*a–c*) and Brillouin zone used for BC_2N calculations (*d*). Atomic ordering type: (*a*) *I*; (*b*) *II*; (*c*) *III*. Unit cell boundaries are shown.

Boron carbonitride BC_2N was considered as a two-dimensional crystal, and Extended Hückel (EH) band calculations of the BC_2N single layers were accomplished for three different atomic arrangements of the atomic in 8-atomic planar unit cell (Fig. 24).³⁴⁰ Interlayer interactions were not considered. It was found that the conductivity properties of the system depend strongly on the ordering type. For instance, the energy diagram for π -like band of BC_2N with the structure *I* (see Fig. 24 *a*) does not contain a forbidden gap, but for the ordered structures *II* and *III* (Fig. 24 *b,c*) ΔE_g is equal to ~ 1.8 and 2.9 eV, respectively. According to photoemission data and conductivity experiments,³⁴¹ the SS of BC_2N exhibits the metallic properties; therefore, the structure *I* was considered as the most probable for the BC_2N .³⁴⁰

The problem of atomic ordering and its influence on the electronic properties of BC_2N were also analysed using the pseudopotential method.³⁴¹ The same three models of structural ordering in the single layer were discussed (Fig. 24 *a–c*). According to the values of the adhesion and chemical bonding energies (Table 7), form *II* should be the most stable. According to the FG values obtained (Table 7), the phase *I* should exhibit the metallic properties, while the phases *II* and *III* are semiconductors (Fig. 25). It is noteworthy that the two-dimensional structural model (neglecting interlayer interactions) can substantially affect

Table 7. Chemical bonding energies (E_b), cohesion energies (E_{coh}), and forbidden gap values (ΔE_g) for boron carbonitride BC_2N with different structures of single layers.³⁴¹

the results of calculations. It was demonstrated,^{224, 307} that the interlayer interactions (in the *c* direction for h-BN and BC_3) increase the energy dispersion of π -bands which determine the conductivity properties of solid solutions. Further calculations that will take it into consideration are therefore required for a reliable theoretical description of conductivity.

VI. Nanostructures based on boron, boron carbides, and boron nitrides

The term ‘nanostructure materials’ usually refers to metastable cluster structures, *viz.*, nanospheres, nanoclusters, nanotubes. Rapid development of chemistry and technology of nanostructure materials is stimulated by a search for new substances without analogues in nature possessing unique topological, superconducting, catalytic and other properties.^{345–349} Most progress in the field recently is related to the synthesis and studies of carbon nanospheres, fullerenes.^{348, 350–356}

In the first attempt to prove theoretically the existence of polyhedral carbon C_n or hydrocarbon C_mH_m clusters, the Hückel model of the π -electron system has been used.³⁵⁷ MOs and resonance energies for the unsaturated carbododecahedron C_{20} and carbo-*s*-icosahedron C_{60} were calculated. Later, features of the electronic structures of buckminsterfullerene C_{60} , its isomers, and higher fullerenes were discussed in numerous publications;^{358–370} their structure and properties were extensively studied theoretically (see review 371). For spheroid fullerenes with a higher number of carbon atoms C_n ($n > 78$, giant fullerenes) a series of rather complicated structures were proposed (barrellenes, capsullenes, torrenes, *etc.*).^{372–375} The properties of cylindrical carbon macromolecules (tubulenes) and thread-like crystals formed on the base of the nanotubes have been discussed.^{376–378}

Recently, along with development of the technology for the preparation of new nanomaterials, a noticeable progress was achieved in the quantum chemistry of nanostructures formed in part on the basis of boron and/or its compounds with non-metals.

Direct modifications of the properties (including superconductivity) of the solid fullerenes C_n were carried out by including doping components into their structures, for instance, alkali metals, which act as electron donors.^{364, 379–382} An opposite effect (doping fullerenes with holes) may be achieved by partial substitution $\text{B} \rightarrow \text{C}$,³⁸³ or by an inclusion of halogen admixtures.³⁸⁴

The role of boron as a hole donor in the formation of the electronic properties of crystalline BC_{59} was examined by non-empirical band theory.³⁸⁵ Calculations of equilibrium lattice parameters (a_0) demonstrated that the $\text{B} \rightarrow \text{C}$ substitution results in a contraction of the BC_{59} polyhedron (as compared to the C_{60}) and a decrease in a_0 from 14.2 Å for C_{60} (see Ref. 386) to 13.5 Å for BC_{59} . DOS distributions in the valence zone region for C_{60} ³⁸⁰ and BC_{59} are similar. The only difference consists in an additional partially filled peak near the Fermi level (Fig. 26a) composed of the boron states with the admixtures of the π -type C $2p$ states of the neighbouring carbon atoms. The formation of these states (similar to the formation of the acceptor levels in a usual semiconductor) are clearly seen in the map of total charge density (Fig. 26b). Therefore, the result of the inclusion of boron into the solid-state C_{60} will be that fullerene will acquire more metallic character due to an appearance of dopant acceptor states in its valence spectrum. Estimates made of the energy²⁸⁵ showed that the above mentioned process is exothermic; the most probable product of the synthesis is a mixed C_{60}/BC_{59} fullerene.

The $\text{B} \rightarrow \text{C}$ substitution leads to a decrease in the electron concentration (per C_{60} molecule), BC_{59} MO system has an open electron shell. The increase in electron deficiency as the boron content increases will create progressive difficulties in the preparation of boron-rich fullerenes $\text{B}_x\text{C}_{60-x}$.

The electronic properties of mixed polyhedral clusters $\text{B}_n\text{C}_m\text{N}_k$ were discussed in a number of papers.^{387–396} Heats of formation of B_2C_{58} , C_{58}N_2 , BC_{58}N , $\text{B}_{24}\text{C}_{12}\text{N}_{25}$, and $\text{B}_{30}\text{N}_{30}$ were calculated and used for a discussion of stabilities of these molecules relative to C_{60} .³⁸⁷

Figure 26. Total density of states for BC_{59} (a) and isoelectronic contours of charge density in the energy range $E_F - 0.1$ eV (b).

Figure 27. Illustration of the $\vec{c}_h$ vector selection that defines diameter and chirality of nanotubes formed by rolling single layers (point A conforms with A') (a) and possible vectors for chiral graphite nanotubes (b); m is metallic character of the nanotube, p is a semiconducting character.⁴⁰¹

Figure 29. Deformation energies for nanotubes based on BC_3 (I) and graphite (II). (n,m) : (1), (6,0); (2), (7,0); (3), (4,4); (4), (8,0); (5), (9,0); (6), (4,0); (7), (2,2); (8), (3,0).

Taking into account the isoelectronic nature of a BH unit and the C atom, the existence of BH-formed nanospheres, which may be structural analogues of C_{60} , was predicted.³⁹⁷ For the synthesis of these species, laser ablation of layered graphite-like borides of alkali-earth metals in hydrogen atmosphere was suggested. It is noteworthy that the idea of the synthesis of stable boron-carbon clusters comes from the early works of Longuet-Higgins and Roberts,⁴⁹ in which the so-called ‘ $n+1$ ’ rule was proposed on the basis of MO theory. This rule gives electron concentrations of

Table 8. Cohesion energies for clusters based on BH and C .³⁸⁹

C_{60}	8.50		

stable borohydrides with composition $\text{B}_n\text{H}_n^{2-}$ as in systems with close electron shells.

In order to examine the validity of the hypothesis proposed (cf. Ref. 397), the relative stability of $(\text{BH})_{60}$, an analogue of C_{60} , as well as those of $(\text{BH})_{32}$, $(\text{BH})_{12}$, and some other homologues, were estimated using local electron density functional theory.³⁹⁸ The analysis shows that borohydride nanocomplexes are more stable in ionic form. Their stability also increases as the average cross-section radius of the group decreases (Table 8).

Along with nanospheres, nanotubes, i.e. coaxially oriented fibres forming needle-like crystals, also attract considerable attention due to their unusual mechanical properties and conductivity.

These systems can be considered theoretically as a set of nanotubes (NT) with diameter of several nanometers. Each NT is formed by rolling up the corresponding planar atomic net and is characterised by a diameter and by the type of helicoidal ordering (chirality). If an NT is designed in this way, its diameter (d) and chirality may be described by a vector $\vec{c}_h = n\vec{a}_1 + m\vec{a}_2$ [the so-called (n,m) -NT] (Fig. 27). Then

$$d = \frac{|\vec{c}_h|}{\pi} = a \frac{[3(n^2 + m^2 + nm)]^{1/2}}{\pi},$$

where a is a bond distance in the planar network.

Figure 30. Band structure in achiral BC_3 nanotubes depending on their diameter. (n,m) : (a), (3,0); (b), (4,0); (c), (5,0); (d), (6,0).

Figure 31. Possible atomic geometries of the nanotubes based on hexagonal boron carbonitride. Conductivity type: (a) *I*; (b) *II*.

Structures of graphite NT^{372, 399–406} revealed the dependence of their electronic properties on the diameter and chirality. For instance, depending on d , the conductivity type changes from semiconducting to metallic.

Attempts to forecast the electronic properties of a number of nanosized tubular structures have been made.^{407–409} These might be formed on the basis of the known layered boron-containing phases with a hexagonal lattice: h-BN, BC₂N, and BC₃.

The electronic structure of boronitride nanotubes⁴⁰⁷ was considered in terms of the Slater–Coster TB method.⁴¹⁰ It was assumed that taking into account the specific type of chemical bonding in h-BN (noticeable contribution of the ionic component), the electronic properties of NTs based on h-BN should be less sensitive to the size and structure compared to the graphite-based NT. This is of great technological importance for the preparation of nanomaterials with desired properties. As it was demonstrated,⁴⁰⁷ all NT considered are semiconductors with FG varying in the range from 4.5 to 1.0 eV with the decrease in the tube diameter. This change is related to the change in ΔE_g of h-BN under external pressure (see chapter IV). In contrast to $(n,0)$ -NT, chiral (n,m) -NT are less sensitive to variations of the diameter. Besides, $(n,0)$ -NT are semiconductors with direct FG (transition $\Gamma-\Gamma$), while (n,m) -NT have indirect FG (transition $\Delta-\Gamma$). The change in chiral angle θ (see Fig. 27) is more critical for tubes with a smaller diameter, while NT with a $d > 12$ Å possess broad FG with weak dependence on chirality. This may be qualitatively explained by the fact that the distance between the diametrically opposite boron and nitrogen atoms on the surface of NT with small radius is comparable with the interlayer separation in h-BN, so its change [depending on chirality: $d(4.0) = 6.4$ Å and $d(4.4) = 10.6$ Å] should strongly influence direct interactions between these atoms.

The above discussed energy band transformation for nanotubes of h-BN depending on their structure is illustrated in Fig. 28, where the results of a Hückel calculation for NT a h-BN⁴¹¹ are compared with the band states of isostructural carbon quasi-one-dimensional systems.

The electronic structure of NT based on the highest boron carbide BC₃, has been studied.⁴⁰⁹ In order to estimate the mechanical properties of BC₃ nanotubes, calculations of elastic deformation energies were performed that gave smaller values in comparison with graphite-like NT (Fig. 29). This may indicate higher stability of BC₃ nanotubes.⁴⁰⁹

Band structures of BC₃ $(n,0)$ -NT ($n = 3, 4, 5$, and 6) are shown in Fig. 30. The conductivity type unequivocally changes from metallic to semiconducting as the diameter increases. This effect is associated with noticeable deviations of bond angles (for NT of

small size) from 120°. As a consequence, both sp^2 - and sp^3 -hybridised atoms are involved in s-interactions. The sp^3 type determines energies of borders for valence and conductivity zones, i.e. the magnitude of FG. With the increase in the NT diameter, the interbond angles approach the limiting value in the planar net (120°), and ΔE_g for NT approaches the FG value in BC₃ single layers. More adequate studies of BC₃ nanotubes should take into consideration not only single NT, but a system of coaxial NT as well⁴⁰⁹ that can be formed by the rolling of several boron carbide nets. This is due to the fact that an account of interlayer interactions plays a decisive role in simulations of the conductivity properties of boron carbide.²²⁴

It is well established that planar nets of boron carbonitride BC₂N can manifest either the metallic or semiconducting properties depending on the ordering type of atoms therein.³⁴¹ Thus, one may expect that rolling a BC₂N single layer of the types *I* and *II* (see Fig. 24 *a,b*) into cylinders will result in NT with distinctly different properties. Geometry of BC₂N (n,n) -NT of types *I* and *II* for $n = 4$ is shown in Fig. 31. Band structure calculations by TB method⁴⁰⁸ indicate that NT with a small diameter ($n = 2$) maintain the conductivity properties typical of parent single layers. However, for (n,m) -NT of type *I* the change in the conductivity type from metallic to semiconducting, depending on diameter and chirality, is possible (like for graphite NT). Presumably, (n,n) -NT of the type *II* should be the most stable (see Fig. 31), since their atomic configuration provides the maximum number of strong C–C and B–N bonds.⁴⁰⁸

Anisotropy of conductivity in BC₂N single layers allowed one to suggest that chiral NTs can conduct helicoidal current, and therefore act as nanocoils.⁴⁰⁸ Many questions that require deep theoretical considerations are related to the capillary effect in boron-containing nanotubes. Microlevel modelling of the influence of various impurities and structural defects that can appear during synthesis on their properties is also of great significance.

One of the examples of deviations from the ‘ideal’ structure for BC₂N has been discussed.⁴⁰⁸ In the experiment, carbon atoms as an admixture substituted boron or nitrogen atoms. It was pointed out that the C→N substitution gives rise to the appearance of an acceptor level above the top of VZ by 0.03 eV, and the C→B substitution generates a donor level lower than the bottom of the conductivity zone. As a consequence, a conductivity type for semiconducting carbonitride nanotubes (n - or p -type) may be regulated by changing their stoichiometry, since the electron or hole concentration can increase in B_{1-x}C_{2+x}N or BC_{2+x}N_{1-x}, respectively.

A number of papers devoted to the synthesis of tubular carbon nanostructures containing admixtures (boron, nitrogen)^{412, 413} have been published recently.^{414–417} In particular, the topology of terminal groups in NT has been discussed.⁴¹⁷

VII. Boron phosphides and arsenides

Among the known boron phosphides and arsenides,^{5, 7, 10, 22, 32} the sphalerite-like BP and BAs attributed to semiconductor type *III–V*, are the best studied.^{258, 293, 295, 297, 302, 306, 418–423} Band structures of BP and BAs calculated by the APW method (Fig. 32) are typical of this type of semiconductors. The valence zone includes a low energy subband mainly of s -states that is separated from the zone of hybrid $p-p$ states by an energy gap, and the dispersion $E(k)$ is much larger for BAs than for BP. Most attention in the papers mentioned was paid to the estimations of the FG. Data shown in Table 9 allows one to judge the order of these values. It is clearly seen that on going from BP to BAs, ΔE_g for indirect FG decreases by ~ 1.1 eV and for direct FG increases by ~ 0.2 eV.

Calculations of the optical properties^{258, 295, 297, 302, 306, 418–423} allow reliable interpretation of the experimental results. The most intense peak $\varepsilon_2(\omega)$ for BP ($E = 6.8$ eV) is caused by the interband transition $X_{5v} \rightarrow X_{3c}$, and the next (as regards intensity), ($E = 7.6$ eV) is caused by the $\Gamma_{15v} \rightarrow \Gamma_{15c}$ transition.⁴²³ The

Figure 32. Valence bands of sphalerite-like BP (a) and BAs (b). APW calculations.⁴²³

Table 9. Calculated results and experimental values of direct (ΔE_g^d) and indirect (ΔE_g^i) forbidden gap, lattice constant (a), and volume modulus (B) for BP and BAs.

Parameter	Calculation	Experiment	Ref.
Results for BP			
ΔE_g^d /eV	5.0	—	297
	4.0	—	423
ΔE_g^i /eV	6.2	2.0	424, 426
	6.0	2.1	425, 427
	4.2	2.0	418, 230
	2.2	2.4	297, 428
	2.4	—	423
a /Å	4.60	4.54	315, 431
B_0 /GPa	171	173	315, 431
Results for BAs			
ΔE_g^d /eV	3.6	—	421
	4.2	—	423
ΔE_g^i /eV	1.6	1.5	421, 429
	1.3	1.4	423, 430
a /Å	4.83	4.78	315, 431
B_0 /GPa	149	—	315

maximum at the energy 5.7 eV is attributed to the $L_{3v} \rightarrow L_{1c}$ transition. For BAs, the main peak $\varepsilon_2(\omega)$ can be attributed⁴²³ to the $L_{3v} \rightarrow L_{1c}$ transition and the next one (the same as for BP) is associated with the $\Gamma_{15v} \rightarrow \Gamma_{15c}$ transition.

Band calculations of the bulk modulus and lattice constants for BP and BAs have been performed,⁴²³ the divergence with experiment did not exceed $\sim 1.5\%$ (see Table 9).

To our knowledge, only one XES study of a more complex system $\text{BP}_x\text{As}_{1-x}$ has been carried out.⁴³² Comparison of parameters of P $L_{2,3}$, P K_β , and B K_α spectra for the SS with the corresponding XES data for BP and BAs (see Refs 81, 433–436) leads to the conclusion that,⁴³² along with XES peaks that reflect P $3s, 3p - B 2p$, P $3s, 3p - B 2s$, and P $3p - B 2p$ interactions, P $L_{2,3}$, P K_β , and B K_α bands of a quasi-binary system BP-BAs constitute an additional substructure that can be attributed⁴³² to the formation of direct P–As interactions.

Data on the electronic structure of other phases that are formed in a B–(P,As) system involve only XES results for B_{12}P_2 (see Refs 81, 436) and calculations for B_{12}P_2 and B_{12}As_2 performed by the APW,⁵³ TB,¹¹⁰ and pseudopotential⁴³⁷ methods. According to,¹¹⁰ the electronic structure of B_{12}P_2 and B_{12}As_2 is close to that of $\alpha\text{-B}_{12}$. These phases have a flat valence zone with indirect FG equal to ~ 2.5 (B_{12}P_2) and ~ 2.3 eV (B_{12}As_2).

VIII. Boron oxides

In a rather numerous group of boron oxides and other more complex oxygen-containing compounds described in the literature,^{5, 7, 14, 32, 34} the EES of boron trioxide B_2O_3 ^{131, 238, 241, 438–443} and boric acid H_3BO_3 ^{131, 241, 438, 444} were extensively studied with XES, AES, and XPS. These two substances that play an important role, for instance, in the technology of boron-containing glasses, have similar crystallographic characteristics.

Preliminary studies of B K_α emission and absorption spectra for B_2O_3 ^{131, 238, 438–441} revealed a number of spectral maxima that reflect^{399–402} mixing of boron states with O $2s$ states (high wavelength satellites in XES) and O $2p$ subbands. Selective maxima in the absorption spectra can be explained by an exciton mechanism of their formation. This interpretation was qualitatively confirmed by semiempirical CNDO cluster calculations for a minimal group that model B_2O_3 (BO_3^{3-} and BO_3B clusters) and H_3BO_3 (cluster H_3BO_3).⁴⁴⁵ In particular, a low-energy absorption peak is due to an excitation of B $1s$ -electrons and their transition to vacant $2a_2$ MOs (in the MO system of BO_3^{3-}) composed of $2p_z$ -orbitals of the boron.⁴⁴⁵ The broad absorption subbands that follow in energy may be assigned to subbands of B $2p_{x,y}$ -states.

A detailed study of B_2O_3 and H_3BO_3 was carried out²⁴¹ using XES, AES, and XPS spectroscopy. Comparison of measured binding energies for B $1s$ levels in the diboron trioxide with MO calculation data⁴⁴⁵ allowed one to evaluate the effective charge on the B atoms ($+0.6$ e). Figure 33 illustrates the structure of the B_2O_3 valence band. XPS and (O,B) K_α X-ray emission spectra contain two distinct filled subbands. O $2s$ and B $2s$ states contribute to the lower subband, and the higher corresponds to a mixed B $2s - O 2p - B 2p$ type. The Fermi level coincides with a short-wavelength maximum in the B K_α spectrum.

It should be mentioned that the X-ray photoelectron spectrum reflects virtually no contribution of B $2p$ states to the VZ due to low magnitude of the photoionisation cross-section of B $2p$ states (0.0002) as compared to the others: 0.0193 (O $2p$), 0.022 (B $2s$), and 0.1405 (O $2s$).⁴⁴⁶ Two peaks in the XPS spectrum with the energies of 10.7 and 6.9 eV correspond to the peaks (11.5 and 7.2 eV) in O K_α -XES spectrum and form the II doublet band (see Fig. 33) that overlaps the broad subband with a maximum at 14.4 eV (peak I). Taking into account the values of photoionisation cross-sections, the latter can be attributed to B $2s$ states. Comparison of experimental intensities for peaks I and II with theoretical values obtained under assumption of atomic and hybrid sp^2 -configuration of the atomic components allows one to suggest the presence of covalent bonds in the planar layers

Figure 33. XPS (a) and X-ray emission O K_{α} (b) and B K_{α} (c) spectra of B_2O_3 .

composed of atomic triangles (the crystal structure of B_2O_3 is described, for example, in Refs 447–449) and formed mainly due to the B ($2p$)–O ($2p$)–B ($2s$) overlap.

Results of B_2O_3 and H_3BO_3 studies by secondary ion mass spectrometry²⁴¹ indicate a weakening of several B–O bonds in boric acid in comparison with diboron trioxide. It may be attributed to the formation of additional O–H interactions in H_3BO_3 .

Auger electron spectra for B_2O_3 and H_3BO_3 (Fig. 34) consist of six distinct peaks.^{241, 450} Calculations of the possible KLL Auger transitions, including interatomic ones, were performed²⁴¹ using binding energy values for core and valence states. It was demonstrated that peaks 5 and 6 are due to several probable transitions of the KLL series, and the low energy peaks 1–4 probably have a plasmon nature. More narrow peaks for H_3BO_3 might indicate the simpler structure of the VZ for boric acid in comparison with that of B_2O_3 .²⁴¹

Figure 34. Derivative AES spectra of B_2O_3 (a) and H_3BO_3 (b). 1 to 6 see text.

Further studies of B K_{α} -XES for B_2O_3 ^{443, 444} have confirmed a typical three-peak structure of the spectrum; its interpretation has been proposed. A low-energy maximum (K_{α} satellite separated by ~ 14.5 eV from the main peak) is formed due to a contribution of p-states of the emitting centre to the O ($2s$) subband. High-energy substructure of K_{α} spectrum near the absorption edge have a resonance nature.⁴⁴⁴ It is formed with participation of orbitals attributed to virtual levels with π^* symmetry (in the non-excited state). In order to confirm it, B K_{α} bands for a number of minerals { $AlBO_3$, $Be_2(BO_3)OH$, $Mg[(OH)_3BOB(OH)_3]$, $CaB_2Si_2O_8$, BPO_3 }, where the first two species contain boron in trigonal coordination and the other — in tetragonal coordination, were compared.⁴⁴⁴ B K_{α} XES spectra contain a prominent high-energy satellite (for trigonal coordination the lowest unoccupied states

have σ^* and π^* symmetry), although for the tetragonal coordination (with unoccupied states of only σ^* symmetry) this spectral maximum is virtually absent.

B K_{α} spectrum of boron suboxide $B_{13}O_2$ was also studied.⁷⁷ Oxygen atoms in this structure form O–B–O chains between B_{12} icosahedra.⁴⁵¹ Therefore, the emission line of the sesquioxide appears to be very similar to that in α - B_{12} . However, the width of the B K_{α} band for $B_{13}O_2$ is ~ 0.3 eV less than in the crystalline α -boron.

The detailed description of the chemical bonding nature and EES features for the boron oxides definitely requires quantum chemistry calculations.

IX. Conclusion

This paper reviews data on several classes of solid state compounds of boron with nonmetals most frequently studied by quantum chemistry methods. Fundamental and technological properties of other borides of nonmetals either in the crystalline or molecular state, *i.e.* boron hydrides (boranes), halogenides, silicides, *etc.* are also of great interest.

Studies of properties of the borides considered above, and their application in the search for new high-technology materials are developing intensively. This can be judged, in particular, by the range of problems discussed at the International Symposium on boron and borides: investigations in the field of the amorphous state of boron; boron doped with different dopants (including transition and rare-earth metals); amorphous alloys of boron; the role of nonmetallic borides in thin-film technology; problems of deposition and functionality of boron-containing coatings; polytypism among borides; factors which determine polytypes formation; ultradispersed and single crystal borides and their properties; design of supersolid materials, multi-purpose ceramics (B_4C – TiB_2 , Al – B – C , Al – B – Ti , *etc.*), bi- and multi-layer composite materials with borides.

These trends in the investigation of material science of borides, in our opinion, will determine the principal directions in the development of theoretical quantum chemistry models, methods for the description and prediction of properties of borides.

Abstract. The advances in the study of energy exchange in the reactions of highly excited polyatomic molecules are analysed. The possibilities of spectroscopic methods for the observation of nonequilibrium energy distributions are demonstrated. Various models of intramolecular and intermolecular energy exchange as well as the reactions of highly excited states of polyatomic molecules are considered: spontaneous unimolecular decomposition and bimolecular reactions. Application of emission techniques in the visible, UV and IR spectral regions, both in the traditional version and especially with Fourier transformation, is very effective for detection of distributions of highly excited states in reacting systems with thermal and laser pumping. Several predictive comments are made in conclusion. The bibliography includes 130 references.

I. Introduction

The history of chemical kinetics is indissolubly linked with the reactivity of highly excited molecules.^{1–3} The rates of the vast majority of reactions depend significantly on the fraction of species where the internal degrees of freedom contain an amount of energy comparable to the reaction threshold E_0 or the barrier E_d separating the electronic configuration of the products from that of the reactants.

In the case of highly excited molecules, the number of species capable of reacting is determined by the simultaneous influence of many elementary processes — nonelastic scattering (energy exchange), collisions with rearrangement (chemical reactions), and interactions with external fields.

The macroscopic experimentally measured rate constant has an internal structure reflecting the relationship (frequently sophisticated) between the energy exchange processes and chemical reactions. The first and hitherto unsurpassed advance in the elucidation of this internal structure is the statistical theory of unimolecular reactions.^{4–8} By virtue of the distinct physical basis and the high degree of development of the computational methods, this theory has found so many applications that it has stimulated the extension of the 'unimolecular ideology' to the entire wide variety of bimolecular reactions. The achievements in this field are illustrated in the present review.

In the case of rapid energy exchange, the distribution of the reactants with respect to rates and energy levels corresponds to equilibrium. Under these conditions, the kinetics of chemical reactions are described by equations for concentrations which include the rate constants averaged thermally and the reaction rates are determined solely by the pressure, temperature, and mixture composition.

The development of experimental techniques and the requirements of modern technology have favoured a shift of the interest of investigators into the field of study of rapid reactions, which not only compete with energy exchange processes and processes involving the establishment of distributions but under certain specific conditions fully determine the form of these distributions.

For molecules with a small number of atoms and low excitation energies, the necessary information about the elementary processes is usually obtained in beam experiments, with laser methods for the generation of beam species in well defined quantum states and laser methods for the observation of the states of the product species.

By virtue of the progress in the development of computational techniques in quantum chemistry and in atomic collision theory, it has become possible to obtain reliable information about the elementary processes also by purely computational methods.^{5,6} For polyatomic and highly excited molecules, these methods are being used with increasing frequency and the reviews in this field therefore rapidly become obsolete.

Molecular spectroscopy has exerted a definite influence on the establishment of the fundamental concept associated with molecular structure. The 'kinetic' aspect appeared in this field in

Received 12 January 1996

Uspekhi Khimii 66 (6) 537–563 (1997); translated by A K Grzybowski

connection with the study of the absorption spectra of unstable species. The direct kinetic application of spectroscopy involves the analysis of the width of spectral lines. The CH_3 radical may serve as a characteristic example. Its predissociative line width of 60 cm^{-1} in the 216 nm absorption band^{9,10} may be assigned to a predissociative lifetime of $\sim 88\text{ fs}$ (for CD_3 , the corresponding values are 8 cm^{-1} and 663 fs , which can be accounted for by the considerable isotope effect). After four decades of experimental studies in this field, the number of examples of this kind has increased greatly and the range of lifetimes extends from femtoseconds to microseconds.

Later examples, associated with molecular dynamics, include nonradiative transitions in polyatomic molecules (see, for example, Jortner and Bixon¹¹) and also the interaction of coherent laser radiation with molecular systems.^{7, 12, 13}

Analysis of the possibilities of spectroscopic methods together with the description of their applications to specific systems represents the main content of the present review.

II. Molecular kinetics and molecular spectroscopy

The extensive introduction of spectroscopic methods into chemical kinetics during the last 30 years has completely altered its features and has caused a shift in priorities. The subdivision of the methods of study employed into 'direct' and 'indirect' has little justification. Firstly, there are no methods which would yield kinetic information without interpretation within the framework of some kind of model. Secondly, the systemic approach with analysis of the entire available information is the most productive.

The true history of any science is the history of concepts. In this respect too, the kinetics of unimolecular reactions yield a striking example of the way that the use of indirect methods has created a firm basis, which was merely strengthened on subsequent application of the entire available range of modern optical spectroscopic techniques.

In fact, all the principal concepts constituting the foundation of the modern theory of unimolecular reactions have been formulated on the basis of experiments carried out by traditional methods of chemical kinetics:⁴ the identification of the stages involving activation and spontaneous decomposition of the active molecules; the concept of a quasi-continuum of vibrational-rotational states; the correct estimation of the intramolecular relaxation time of the vibrational energy of active molecules.

Paradoxically, after the discovery of the IR laser-induced dissociation of polyatomic molecules, many efforts were wasted on attempts to interpret the results within the framework of modified one-oscillator models before it was recognised that the principal results fit within the framework of the Rice–Ramsperger–Kassel–Marcus (RRKM) theory, which had already been used by kineticists for many years.

1. Models of polyatomic molecules for kinetic applications

Qualitatively new features, consisting of an increase in the density of states and a considerable acceleration of the energy exchange between them, arise in polyatomic and highly excited molecules. As a consequence of the rapid intramolecular energy exchange (electronic-vibrational conversion, intermode transitions, or rotational-vibrational exchange), with increase in the excitation energy the simple picture of motion, characteristic of molecules with a small number of atoms or weakly excited molecules, disintegrates. The energy spectrum becomes much more complex because vibrational motion becomes stochastic.⁷

A high degree of specification of details in the description of the structure of a polyatomic molecule is not required for kinetic applications or for the interpretation of the results of measurements with a moderate spectroscopic resolution. Fig. 1 presents the simplest scheme, which clearly illustrates the majority of the phenomena discussed in the present review. A 'spaced out' vibrational spectrum in the lower parts of the ground and electronically excited terms, transforms into a quasi-continuum with rapid

Figure 1. Principal kinetic processes in the activation of a polyatomic molecule.

mixing of the vibrational modes. The types of activation ('from below' and 'from above') are indicated. The vertical arrows designate the collision and vibrational-translational ($V-T$) transitions, whilst the horizontal arrows designate chemical reactions: on the left — activation as a result of exothermic chemical reactions, on the right — spontaneous decomposition, which intensifies with increase in the vibrational energy; $E-V$ represents the electronic-vibrational exchange between the terms.

Any external influence on the molecular system leads rise to a nonequilibrium distribution with respect to energy levels, the form of which is determined by the competition between the pumping and relaxation processes and chemical reactions.

The methods for the interpretation of non equilibrium energy distributions have also developed in parallel with the development of diagnostic methods in relation to highly excited states (HES). In this connection, it is instructive to turn to the hierarchical picture of the models of nonequilibrium processes (specifically, we have in mind the unimolecular decomposition reactions):

the two-level Lindemann scheme for unimolecular decomposition deals with the ground state of a polyatomic molecule and its excited (active) state in the region of the barrier to chemical reactions; this model operates with the corresponding kinetic equations for the concentrations of above states and yields a level of description necessary for the interpretation of macroscopic rate constants;

the model based on the use of the concept of the vibrational temperature T_v for a separate ensemble of vibrational degrees of freedom, which, generally speaking, is not in equilibrium with the surrounding gas at a temperature T_g ; in fact, in this description the form of the nonequilibrium distribution function is assumed to be identical with the Boltzmann distribution; in order to find T_v , the system of chemical kinetic equations is supplemented by the balance equation for the vibrational energy and then the rate constant for unimolecular decomposition is a function of two temperatures — T_v and T_g ; ^{10–17}

interpretation of kinetics 'in the language' of the distribution function with respect to the internal energy of molecules; the experimental data are analysed using the solution of the fundamental microkinetic equation [(FME) — master equation].

With the aid of Fig. 1, it is convenient to elucidate the sense of the term 'highly excited states' of polyatomic molecules. In the context of the current review, these are states for which there is no possibility of subdividing vibrations into modes and the energy of which is consequently higher than the threshold of the transition of vibrational motion to the stochastic regime.

2. Spectroscopic methods for the study of highly excited molecules

Highly excited states of molecules with average energies $\langle E \rangle \simeq E_0$ may be obtained as a result of the thermal heating by a shock wave, single photon optical excitation with subsequent intramolecular $E-V$ conversion, or multiphoton excitation in the field of intense IR radiation, electron impact, *etc.*^{14–16}

Mainly optical methods are used for the recording of HES and for the observation of energy distributions, although others, for example corpuscular or field methods, may also be useful. There are many versions of optical methods, for example the absorption and emission methods, in which the radiation in various wavelength ranges (IR, visible, UV) is used. The optical methods are characterised by a high time resolution and yield the most complete information about the evolution of intramolecular and intermolecular energy distributions.

The methods for the study of the collision deactivation of the HES of polyatomic molecules may be divided into two groups. The methods of the first group are used to record processes associated with the highly excited molecules themselves, whilst those of the second group record the responses of the surrounding system to the HES relaxation process. The thermal lens¹⁷ and optoacoustic methods have been used to find the energy flux from the HES to the translational degrees of freedom in the course of relaxation.^{9,18} The methods involving the recording of the HES themselves belong to the group of methods with the highest information content.

3. Characteristic features of the principal methods for the generation of HES

The advantages and disadvantages of various methods for the generation of HES are determined by the degree of their universality, the range of available energies, and the possibility of the establishment of HES distributions of a specified type. The types of activation considered below are illustrated in Fig. 1.

The thermal heating method, which can be readily applied in experiments with shock waves, is one of the most universal. It makes it possible to achieve a virtually instantaneous heating of molecules to temperatures of several thousands of degrees.

The method involving the resonance multiphoton IR excitation of polyatomic molecules has come to be widely employed immediately after the appearance of CO₂ pulse lasers.^{7,9,12,13} At the present time, the physics of the interaction of the intense IR radiation with polyatomic molecules has been examined in numerous publications in which all the principal features of this method for the study of the spectra and reactions of HES are dealt with. The resonance pumping of molecules by an IR laser in the pulse regime makes it possible to obtain HES over a period $t \simeq 10^{-8}$ s, whereupon the molecules form two ensembles — ‘cold’ and ‘hot’. (The temperature of the latter may reach thousands of degrees.)

The single-photon UV excitation method (with subsequent intramolecular $E-V$ conversion) is used to generate the HES of molecules having an electronically excited state in the range of energies investigated. This state is mixed by a nonadiabatic interaction with the high vibrational levels of the ground state. Typical examples of such molecules are SO₂ and NO₂. The energies of the initial excitation, accessible to the resonance single-photon UV excitation method, are of the order of several electron-volts. The initial energy distributions of the HES are close to the δ -distributions and may be regarded as microcanonical.

4. Molecular spectroscopy and the development of methods for the study of highly excited states

Molecular spectroscopy is one of the principal methods yielding information about the dynamics of processes involving the HES of polyatomic molecules. Bearing in mind the special interest in the purely chemical aspects of such processes, we have given preference to the absorption-emission diagnostics based on moderate

spectral resolution with a characteristic time range of 0.1–1000 μ s.

If an external perturbation induces a jump in one or several parameters (temperature, pressure, electric field strength, or another macroscopic parameter), then the subsequent evolution of the system towards an equilibrium state (or most often a quasi-stationary state) can be monitored by classical kinetic spectroscopic methods.^{2,7,9}

The time resolution of flash photolysis has increased during the last 30 years from microseconds to femtoseconds and, when combined with coherent spectroscopic methods in the femtosecond range, this makes it possible to follow the real dynamics of the formation and dissociation of chemical bonds.

In contrast to the classical kinetic spectroscopic technique, which is designed primarily for the investigation of the so called global reaction mechanism and the corresponding rate constants, the modern technique employing laser methods in molecular beams with coherent nanosecond and femtosecond pulses, leads to the possibility of the observation of the detailed features of molecular dynamics.^{19,20} Several scientific centres, particularly those with the necessary financial resources, are leaders in research of this kind.[†]

5. The method of competing channels with application of fluorescence spectroscopy

The initial concepts of the method of competing channels using fluorescence spectroscopy arose in relation to proton and electron transfer processes in solutions.²⁰ Later this method came to be widely employed for the study of intramolecular kinetics and of the redistribution of vibrational energy in electronically-excited states of polyatomic molecules.^{21,22} An essentially analogous approach has been applied in experiments with chemical activation and intramolecular relaxation²³ under the conditions of stationary photolysis at high pressures,²⁴ where collisions in a gas are used as a time reference standard (‘clock’). However, it is not always easy to answer the question which particular competing channels have to be considered in interpreting the results.

6. The line form in optical spectra

The Lorentzian optical line width Γ in optical spectra may be related to the rate constant k for a quasi-unimolecular process by the simple equation

$$k = \frac{2\pi\Gamma}{\hbar},$$

where $\hbar$ is the Planck constant.

Predissociation and similar processes are suitable examples of the applicability of this approach. The same method has been used to record high overtones for polyatomic molecules under beam conditions in order to obtain information about the rates of relaxation processes,^{25,26} but it is then necessary to take into account very thoroughly the contributions of the uniform and nonuniform line broadening.^{27,28}

Detailed analysis of the experimental methods used to investigate the dynamics of the HES of polyatomic molecules is an object of separate detailed consideration. In this communication, these methods will not be dealt with. In order to obtain an idea about the modern diagnostic possibilities, one may refer to monographs and reviews.^{9,12,13,29}

Amongst spectroscopic methods, the laser methods involving molecular beams with application of the Fourier transformation

[†] The experimental technique has become so complex in this case too that the maintenance of a prestige level of research has become more of a contest between capacities for investment rather than between concepts. Furthermore, one should note also a degree of uncertainty in the interpretation of the results of measurements with ultrashort pulses — the rate of some kind of fast process is measured but it is sometimes not understood which particular process this is.⁹

of the spectra are correctly regarded as the most fruitful for the study of processes with participation of HES.

The possibilities of various optical methods for the probing of molecules and radicals using laser radiation sources have been described in fair detail in reviews.^{9,29} The high spectroscopic resolution of these methods makes it possible to employ them for the detection of species in fixed quantum states, but in the study of the kinetics of energy exchange, unimolecular decomposition, and bimolecular reactions the simpler and at the same time fairly informative absorption methods with a moderate spectral resolution are preferable. These methods have in fact proved to be the most convenient to obtain the isoenergetic distributions $f(\langle E \rangle)$ which enter into the fundamental microkinetic equation (FME).

III. Molecular 'hot' band absorption spectroscopy

1. Fundamental relations

It is known that the UV absorption spectra of many polyatomic molecules have the characteristic form of bell-shaped curves with temperature-dependent moments.^{10,30} With increase in temperature, the spectra shift towards the long-wavelength region and are broadened; a molecular 'hot' band is then said to be produced. It is related to the increase in the population of the excited molecules (Fig. 2).

Figure 2. Dependence of the absorption cross-section for the 'hot' bands of the CF_3I (a) and N_2O (b) molecules on the wavelength. $T(\text{K})$: a: (1) 300; (2) 625; (3) 1050; (4) 1250; b: (1) 300; (2) 470; (3) 670; (4) 770; (5) 870; (6) 950; (7) 1430; (8) 1620; (9) 2070.

The 'quasi-diatomic' molecule model, with the linear-oscillator fitting of the terms between which a vertical transition takes place following the absorption of a photon, is used for the simplest interpretation of these spectra. Subject to additional hypotheses concerning the nature of the fitting³¹ of the wave functions for the dissociated states of the electronically excited molecule and the independence of the transition point of the vibrational energy of the initial state, the linear-oscillator model of the vertical transitions leads to the well known Wieland–Sulzer formula³²

$$\sigma(\nu, T) = \sigma_0 \text{th} \left(\frac{\theta}{2T} \right)^{1/2} \exp \left[\text{th} \left(\frac{\theta}{2T} \right) \left(\frac{\nu - \nu_0}{\Delta \nu} \right)^2 \right]. \quad (1)$$

Here $\sigma(\nu, T)$ is the experimentally measured absorption cross-section, σ_0 a phenomenological parameter, θ the vibrational quantum of the oscillator, ν the optical transition frequency, ν_0 the frequency of the vertical transition from the equilibrium position, $\Delta \nu = F^2/\mu\theta$, F the strength of the interatomic interaction in the dissociated state, and μ the reduced mass.

Formula (1) describes fairly well the form of the main part of the absorption spectrum, but it does not take into account the weak but experimentally clearly observed shift of the maximum of the absorption curve.^{32,33} The temperature dependence of the absorption cross-section can be obtained if account is taken in the calculation of $\sigma(\nu, T)$ of the anharmonicity of the vibrations, the curvature of the form of the electronically excited state, or the dependence of the electronic matrix element on the interatomic coordinate.^{34,35} Here it is also possible to eliminate the systematically observed discrepancy between theory and the measured quantities in the long-wavelength region.

For the Morse exponential model, the parameters of the interaction potential are expressed by the relations

$$U_i(R) = D[1 - \exp(-\alpha R)]^2,$$

$$U_f(R) = A \exp(-\beta R) + \Delta,$$

$$M_{if}(R) = M_{if}(0) \exp(\alpha R).$$

where D , α , A , β , and Δ are the parameters of the potential in the initial (i) and final (f) states as a function of the interatomic distance R (the numerical values for the CF_3I molecule have been published³⁴), U_i and U_f are the electronic terms of the molecule before and after the absorption of a photon, and M_{if} is the electronic matrix element.

The Gaussian fit to the central part of the absorption spectrum (*i.e.* the generalised Wieland–Sulzer formula) was first obtained by Dalidchik *et al.*³⁴ It was established that the first moments of the absorption spectrum are a little 'sensitive' to the form of the distribution of the molecules with respect to vibrational levels, but do depend on the dynamic parameters of the model and on the average energy of the initial excitation $\langle E \rangle$. Optical measurements in the central part of the absorption spectrum may be used either for the determination of the parameters of the potential curves or for the measurement of the first moment of the vibrational energy distribution function.

Numerous examples of the measurements of $\langle E \rangle$ based on the UV absorption spectra have been published by Troe and co-workers,^{14,36–39} Letokhov and coworkers,^{12,40–42} and other investigators.^{43,44} However, the possibilities of UV absorption spectroscopy are not restricted solely to the measurement of the average excitation energy. It has been shown⁴⁵ that the long-wavelength edges of the absorption spectra of CF_3I and N_2O exhibit a distinct Arrhenius relation:

$$\sigma(\nu, T) \simeq \exp \left(-\frac{E_a(\nu)}{T} \right),$$

where $E_a(\nu)$ is the activation energy, which decreases monotonically with increase in the photon frequency ν .

Within the framework of the one-dimensional model, *i.e.* in terms of the 'quasi-diatomic molecule' approximation, such relations can be understood if use is made of the concept of vertical transitions between classical turning points.

The classical approximation may be used if the contributions of the ground and weakly excited vibrational states are negligible at the given absorption frequency. The corresponding criteria, quoted by Dalidchik *et al.*,³⁴ usually hold in the long-wavelength region.

In the classical approximation for the one-dimensional model, the average photoabsorption cross-section assumes the form^{34,35,46}

$$\sigma(v) = \frac{4}{3} \pi v f\{U_i[R_0(v)]\} |\{M_{ij}[R_0(v)]\}^2 [U_i'(R_0) - U_f'(R_0)]|. \quad (2)$$

Here $f(U_i)$ is the normalised distribution of molecules with respect to vibrational energy and $R_0(v)$ is the root of the equation

$$U_i(R) + v = U_f(R), \quad (3)$$

where U_f is the potential energy surface for the electronically excited state of the molecule.

The results of absorption measurements in the long-wavelength region are related directly to the vibrational energy distribution of molecules [see Eqn (2)].

Eqns (2) and (3), which demonstrate the possibilities of the UV absorption technique, can be applied directly only in the case of diatomic molecules. On the other hand, experiment has shown that, for a reasonable parametrisation Eqns (2) and (3) can be used successfully also for the interpretation of the UV absorption spectra of more complex molecules such as those of CS_2 ,³⁶ N_2O ,⁴⁵ SO_2 ,⁴⁷ etc.

When the spectra of complex molecules are described in terms of the formulae of the one-dimensional model, the theory of the UV absorption method is faced by the fundamental question of the physical significance of the concept of the 'optically active' oscillator in the most general form.⁴⁶

The multidimensional generalisation of formula (2) assumes the form

$$\sigma(v) = \sigma^0 f\{U_i[R_0(v)]\}, \quad (4)$$

where σ^0 is a known multiplier which varies little, quoted by Dalidchik *et al.*,⁴⁶ U_i the potential energy surface of the molecule in the initial electronic state, and $R_0(v)$ the trajectory of the coordinate of the absolute minimum of the function $U_i(R)$ on the hypersurface $\sum(v)$, satisfying the condition for the classical vertical transition (3) (R is the set of all vibrational coordinates).

For equilibrium conditions,

$$f(U_i) = N \exp\left(-\frac{U_i}{T}\right),$$

i.e. the role of the 'activation energy' for the absorption spectrum is assumed by the function $U_i[R_0(v)]$.

Having compared Eqn (4) with the corresponding classical expression for the one-dimensional model, it is possible to elucidate the significance of the concept of the 'optically active' oscillator. In the vicinity of the extremum, $v = v_0$, where v_0 is the root of the equation

$$\frac{d}{dv} U_i[R_0(v)] = 0,$$

the function $f\{U_i[R_0(v)]\}$ may be fitted by a Gaussian function. For agreement with the results based on the one-dimensional model, it is then sufficient that the following simple condition should hold:

$$\frac{d^2}{dv^2} U_i[R_0(v)] = 0.$$

The 'optically active' oscillator is identical with the n th normal oscillator if the trajectory of the point $R_0(v)$ lies in a plane which is sufficiently close to the oscillations plane of the n th normal oscillator.^{34,35}

Experimental data (Fig. 2) as well as the results of the numerical solution of Eqn (4) for the two-dimensional model of the photodissociation of the CF_3I molecule^{46,48} have shown that, in the photodissociation of this molecule, the conditions for which the quasi-diatomic approximation may be applied holds satisfactorily (at any rate for $\lambda > 300$ nm), so that the 'optically active' oscillator may be identified with the stretching vibration of the C–I bond.

The formalism developed for the description of 'hot absorption bands' has in the main proved suitable also for the description

of the characteristics of heated molecular gases. The possibilities of the emission diagnostics for HES have been clearly demonstrated⁴⁵ and are also briefly considered below in connection with the survey of the results of the study of the wave characteristics of the relaxation of the HES.

2. 'Calibration' of absorption and emission spectra

The main result of the above analysis of 'hot' absorption bands is that the absorption cross-section for the far wing is proportional to the HES population [Eqns (2) and (4)]. However, the effectiveness of a specific application of the relations obtained depends in many respects on how well the disposition of the terms is known. The exact knowledge of these parameters is an exception rather than the rule. The role of the empirical information about the temperature and frequency dependences of the absorption cross-section for the test molecules therefore increases.

A sufficiently complete amount of information of this kind is obtained when shock-wave heating is employed. The essential feature of the approach, developed by Zaslonko and co-workers,^{45,46} reduces to the following. It is necessary to measure the relation $\sigma(v, T)$ at temperatures and pressures which guarantee the equilibrium distribution with respect to energy. The principal factor which prevents the maintenance of equilibrium is the reaction of the HES in the region of chemical reaction barriers. For unimolecular decomposition, equilibration implies that the reaction occurs at the high pressure limit, whilst for bimolecular processes this entails the occurrence of the reaction at low concentrations of the reactants whereupon the distorting influence of the reaction is minimal.

Thus when equilibrium has been attained, the equation for the absorption cross-section 'activation energy' can be represented in the following form:

$$E_i = E_v + \bar{E}_v + \bar{E}_r,$$

where E_i is the energy of the vibrational state, E_v the absorption cross-section activation energy, and $\bar{E}_v$ and $\bar{E}_r$ are the average vibrational and rotational energies of the excited molecule.

The dependences of the energy levels of the excited states, obtained in the calibration of the 'hot' absorption bands and on the basis of the thermal emission of SO_2 and NO_2 , on the transition wavelength are presented in Fig. 3. Evidently the combination of the absorption and emission methods is applicable to a wide range of energies of the excited states. Here we are dealing with differentiated optically active states. In order to apply these methods in the kinetics of nonequilibrium processes, it is necessary to find the relation between the population of optically active molecular states and total vibrational energy of the molecules.

Figure 3. Dependence of the recorded excitation energy of the optically differentiated states of some molecules on the transition wavelength. Absorption: (1) NO_2 ; (2) SO_2 ; (3) N_2O ; (4) CS_2 ; (5) CO_2 ; emission: (6) NO_2 ; (7) SO_2 .

IV. Relation between the partial and total distribution functions with respect to the vibrational energy of polyatomic molecules

It is necessary to emphasise the differences in the description of processes involving HES in spectroscopy and kinetics. In kinetics, the principal parameter is the total HES energy, whilst in spectroscopy it is the population of an optically active oscillator or group of oscillators.

The vibrational energy distributions obtained on the basis of the analysis of the ‘hot’ bands in the absorption-emission spectra, refer to an optically active vibration of the molecule. In contrast to the distribution function (DF) with respect to the total energy, such distributions will be referred to as partial (PDF). The total number of independent partial distributions is equal to the number of normal vibration modes in the molecule.

In the solution of problems in chemical and molecular kinetics, we are as a rule interested in the distribution with respect to the total energy. In this connection the problem of finding the DF with respect to the total energy from spectroscopic PDF measurements arises.

The method for the finding of a relation between the PDF and the DF⁴⁹ is based on the hypothesis that, during the period of the observation of the PDF, there is sufficient time for the total energy of the molecule to be randomly redistributed between all the types of vibrations of the polyatomic molecule.[‡] The probability of observing a molecule with an energy E_i of a differentiated type of vibration for the total energy E is specified by the conventional distribution $\varphi(E_i|E)$, which is proportional to the number of states accessible for the specified E and E_i :

$$\varphi(E_i|E) = \frac{\rho_i(E_i)\rho_{s-i}(E-E_i)}{\rho_s(E)}.$$

Here $\rho_i(E)$ and $\rho_{s-i}(E-E_i)$ are respectively the densities of states of the differentiated (i) and remaining ($s-i$) oscillators of a polyatomic molecule in which the number of modes is s and $\rho_s(E)$ is the total density of states of a molecule with a total energy E .

In order to obtain the partial distribution function $f_i(E_i)$, it is necessary to average $\varphi(E_i|E)$ with respect to the total energy distribution $f(E)$:

$$f_i(E_i) = \int_{E_i}^{\infty} \varphi(E_i|E)f(E)dE. \quad (5)$$

Eqn (5) serves as a basis for the reconstruction of the DF from the experimentally measured PDF, since it establishes a mutually unambiguous relation between them.

It is convenient to express Eqn (5) in terms of the dimensionless Boltzmann distributions $f_{i0}(E_i)$ and $f_0(E)$ and the functions $h_i(E_i) = f_i(E_i)/f_{i0}(E_i)$ and $h(E) = f(E)/f_0(E)$. The Boltzmann distribution is specified in the form

$$f_0(E) = \frac{\rho(E)}{Q} \exp\left(-\frac{E}{RT}\right),$$

where $\rho(E)$ is the density of the spectrum and Q the vibrational partition function.

Taking into account this relation, we express Eqn (5) in the form

$$h_i(E_i) = \frac{Q_i(T)}{Q_s(T)} \int_{E_i}^{\infty} h(E)\rho_{s-1}(E-E_i) \exp\left(-\frac{E-E_i}{RT}\right)dE, \quad (6)$$

where Q_i and Q_s are respectively the partial and total vibrational partition functions.

It is useful to examine certain limiting cases. In particular, it follows from Eqn (6) that, if the distribution with respect to total energy corresponds to equilibrium [$h(E) = 1$], then the PDF also corresponds to equilibrium [$h_i(E_i) = 1$]. In the other limiting case for the δ -distribution, $f(E) = \delta(E-E^*)$, where E^* is the total excitation energy, the PDF is defined by the microcanonical distribution

$$f_i(E_i) = \varphi(E_i|E^*).$$

The relation between $f(E)$ and $f_i(E_i)$ is found from the integral transformation of Eqn (5). In the general case, this cannot be done analytically. If the Whitten–Rabinovitch approximation⁴ is used for the density of states, *i.e.*

$$\rho_n(E) = \frac{[E + a_n(E)E_{z_n}]^{n-1}}{(n-1)! \prod_n \hbar \nu_n}, \quad (7)$$

where $a_n(E)$ is a parameter close to unity and is weakly dependent on E ^{4, 8, 50} and

$$E_{z_n} = \frac{1}{2} \sum_{k=1}^n \hbar \nu_k,$$

is the energy of the zero-point vibrations of n vibrational modes of the molecule, then the problem may be solved.

For sufficiently high values of the total energy, it is possible to neglect the energy of the zero-point vibrations in Eqn (7). The integral Eqn (6) may be solved with the aid of the Laplace transformation.⁴ Direct substitution of the equation

$$h(E) = \frac{(s-i) \prod_k \hbar \nu_k Q_{s-i}}{Q_i} \left(\exp \frac{E}{RT} \right) (-1)^{s-i} \times \\ \times \frac{d^{s-i}}{dE^{s-i}} \left[h_i(E) \left(\exp \frac{-E}{RT} \right) \right],$$

in Eqn (6) makes it possible to make sure that the former is a solution of the integral Eqn (6).

For example, for a molecule in which the number of oscillators is $s = 3$, we have

$$h(E) = h_i(E) - 2RT h'_i(E) + (RT)^2 h''_i(E).$$

Evidently the total DF is defined not only by the absolute value of the PDF but also by the $s-i$ derivatives of the functions $h_i(E)$, *i.e.* it depends on the number of oscillators in the polyatomic molecule. The reconstruction of the DF on the basis of the PDF therefore requires definite types of fitting of the experimentally measured PDF.

We shall examine specific distributions obtained on thermal heating of polyatomic molecules in shock waves. Fig. 4 presents the results of the measurements of the PDF for the CF_3I , N_2O , and CO_2 molecules obtained by absorption methods and the reconstruction of the DF on the basis of the total energy is illustrated in Fig. 5. In particular, for the CF_3I , N_2O , and CO_2 molecules, a satisfactory fit to the measured PDF is provided by the function

$$h_i = 1 - C \exp \frac{E_i}{\gamma},$$

where C and γ are the constants determined in the fitting process.

The examples presented indicate the scale of the ‘depletion’ of the DF in the vicinity of the chemical reaction barriers. Further analysis of the DF within the framework of the solution of the fundamental microkinetic equation (FME) makes it possible to obtain quantitative information about the mechanism of the activation of a highly excited polyatomic molecule and about its reactivity.

[‡] This hypothesis is valid for energy levels higher than the barrier to the state where the vibrational energy becomes stochastic.

Figure 4. Dimensionless PDF with respect to the vibrational excitation energy of molecular states in reactions behind shock waves: (1) SO₂; (2) NO₂; (3) CF₃I; (4) CO₂; (5) N₂O; E₀ — reaction barrier; E_{abs} and E_{em} — excitation energies of the optically differentiated degrees of freedom measured by absorption and emission methods respectively.

V. Fundamental microkinetic equation

For reactions occurring under thermal conditions and also for the majority of processes with laser excitation, the use of balance equations for the energy-averaged quantities is justified — for example in the case of the DF for species with respect to states having a fixed energy E between which repeated rapid transitions take place during the characteristic energy exchange time. When account is taken of the energy exchange processes, chemical reactions, and energy sources (sinks), the corresponding fundamental microkinetic equation assumes the form^{4,6,7}

$$\frac{d[A(E)]}{dt} = [M] \int_0^\infty z(E')P(E|E')[A(E')]dE' - \left[z(E)[M] + \sum_i w_i(E) \right] [A(E)]. \quad (8)$$

Here $[A(E)]$ and $[A(E')]$ are the populations of the molecules A at the levels E and E' respectively, $[M]$ is the overall concentration of species, $z(E)$ and $z(E')$ are the rate constants for the binary collisions when the energies of the molecule are E and E' respectively, $P(E|E')$ is the probability of the transition of the k th species in unit time from the state with the energy E' to the state with the energy E [the kernel of the integrodifferential equation (8)], and $w_i(E)$ is the specific rate constant for the

'external' energy sources at the energy level E . The real distribution function $f(E)$, which in the general case is different from the Boltzmann function as a consequence of the occurrence of the reaction, is defined by the relation

$$f(E) = \frac{[A(E)]}{\int_0^\infty [A(E)]dE}.$$

An important factor in the solution of the FME is the choice of a successful compromise between the physical justification of the model for the kernel of the integral equation $P(E|E')$ and the 'mathematical convenience' in the solution of the FME with the selected kernel.

The most frequently employed characteristic of the energy exchange is the average portion of energy $\langle \Delta E \rangle$ transferred per collisions, which is linked to the kernel $P(E|E')$ by the equation

$$\langle \Delta E(E) \rangle = \frac{\int_0^\infty (E' - E)P(E'|E)dE'}{\int_0^\infty P(E'|E)dE'}. \quad (9)$$

We shall examine the most widely employed functional representations of the kernel $P(E|E')$.

1. Principal models for transition probabilities

a. Exponential model

Within the framework of the exponential model, the kernel assumes the form

$$P_d(E'|E) = \exp\left(-\frac{E' - E}{\alpha_e}\right), \quad 0 < E \leq E'.$$

Here the subscript d means that downward transitions on the energy scale are considered and α_e is a parameter characterising the 'half-width' of the kernel. The transition probabilities in the upward (P_u) and downward (P_d) collisions on the energy scale are linked by the detailed balance relation

$$P_u(E|E') = P_d(E|E') \frac{\rho(E')}{\rho(E)} \exp\left(-\frac{E - E'}{RT}\right),$$

where $\rho(E)$ and $\rho(E')$ are the densities of states for the internal energies of the molecule E and E' respectively; they are usually specified by the Whitten–Rabinovitch formula (7).^{4,7} The dependence of α_e on the energy in Eqn (7) may be neglected. For the ratio of densities, the following approximation is employed:

$$\frac{\rho(E')}{\rho(E)} = \exp[B(E)(E' - E)].$$

For a weak energy dependence of the parameter $B(E)$, the integrals in Eqn (9) are expressed in a closed form.

b. Strong collisions

There are several equivalent definitions of the concept of 'strong collisions' (SC) itself (see, for example, Refs 2, 4 and 6). We shall deal with the following: strong collisions are those that in each collision between a molecule and the thermostat species, the equilibrium function is restored. In fact this is the zeroth approximation for the solution of Eqn (8), which makes it possible to reduce the latter to simple relations; it is then actually unnecessary to employ specific expressions for the kernel. Incidentally the latter assume the form

$$P(E|E') = \frac{\rho(E)}{Q} \exp\left(-\frac{E}{RT}\right).$$

Strong collisions as it were specify the upper limit to the rate of activation of the molecules and make it possible to introduce a specific scale for comparison with experimental data. The so called collision effectiveness is then introduced:

$$\beta_c = \frac{k_{d,0}}{k_{d,0}^{sc}},$$

where $k_{d,0}$ is the measured rate constant for unimolecular decomposition (or recombination) at the low pressure limit and $k_{d,0}^{sc}$ is the same quantity calculated in terms of the strong collision approximation. The analysis of experimental β_c data and also of the relation between β_c and $\langle \Delta E \rangle$ and the effective energy exchange cross-section σ_E may be found in a number of communications.^{4, 6, 7, 14}

c. The statistical energy-exchange model

The statistical energy-exchange model for transition probabilities has a clear cut physical justification and is based on the assumption of a 'collision' complex between the excited molecule A and the thermostat species M during the existence of which a statistical mixing of the energy in the complex takes place. The specific form of the kernel is unduly cumbersome even when simplifying assumptions are made^{6, 51} and we shall therefore not quote it. The statistical model has an upper limit to the portion of energy transferred.

The local-statistical activation model,⁵² using the concept of the number of active oscillators participating in the energy exchange process during collisions, is a much improved version of the statistical model.^{53–55} We may note that, within the framework of the local-statistical model, $\langle \Delta E \rangle$ depends on the parameters of a specific molecule and not only on the number of oscillators.

Another approach to the solution of the FME is based on the concept of the energy spectrum of highly excited molecules in the form of a set of discrete energy levels having the appropriate statistical weight and separated from one another by an amount equal to the average portion of energy transferred in the collisions. The stepwise excitation approximation makes it possible to formulate the so called step-ladder model.

d. The step-ladder model

In this model, transitions between neighbouring levels only are considered. The quantity $\langle \Delta E \rangle$ is the principal parameter varied. The system of kinetic equations, specifying the population of the energy levels, is formulated as follows:

$$\begin{aligned} \frac{d[A_i]}{dt} = & \sum_j W(i,j) - \sum_i W(j,i) - \\ & - \sum_i W(i) - \sum_j W_{E-V}(i), \end{aligned} \quad (10)$$

where $[A_i]$ is the population of the energy level i , $W(i,j)$ and $W(j,i)$ are respectively the rates of activation and deactivation of the level i [the designation (i,j) will be understood as transition from the level j to the level i], $W(i)$ is the term taking into account the occurrence of bimolecular reactions and of spontaneous decomposition (for levels lying above the chemical reaction barriers), and $W_{E-V}(i)$ is the rate of transition between the ground and electronically excited terms (for molecules in which there is an 'inserted' electronically excited term).

Since transitions only between neighbouring levels are postulated, the sums in Eqn (10) consist of only two components:

$$\sum_i W(i,j) = k(i,j)[M][A_{i-1}] + k(i,j+1)[M][A_{i+1}],$$

where $k(i,j)$ is the rate constant for the activation of the level i on transition of the molecule from the level j .

The step-ladder model with allowance for chemical reactions and $E-V$ exchange has been examined in detail by Gaiduchenya *et al.*,⁵⁶ who give, in particular, the energy dependence of the rate constants in Eqn (10) and provide for the possibility of the independent variation of $\langle \Delta E \rangle$ for the ground and electronically excited terms. The authors⁵⁶ solved Eqns (10) by the numerical method proposed in Kalitkin's study.⁵⁷

e. Bimodal exponential model

The bimodal exponential model may be regarded as the reasonable expansion of the simple exponential model in order to take into account explicitly the contribution of two types of collisions with transfer of large and small portions of energy.^{58–61} Analytical relations between the principal parameters of the model have been obtained^{62, 63} in a form analogous to that employed for the simple exponential model.

f. Stochastic modelling

The main advantage of the stochastic model is that it is free from *a priori* assumptions about the functional form of the kernel of the transition probabilities and can be applied with equal success to small and large polyatomic molecules and also to clusters.⁶⁴

g. Weak collisions and the diffusion approximation

In the weak collision limit $\langle \Delta E \rangle/kT \ll 1$, the fundamental kinetic equation (8) is converted into the diffusion equation on the energy scale, for which exact solutions are known. This factor, in particular, has led to the fairly considerable popularity of this approximation. Troe and coworkers,¹⁴ in whose studies the approximation apparently worked satisfactorily, also increased the number of adherents to the weak collision model.

2. Experimental data on the functional form of the kernel $P(E'|E)$

We may note that until recently the exponential model has been the most widely employed. The advantages of this model are its clarity, the possibility of obtaining a solution of the FME in an analytical form, and also the fact that the functional form of $P(E'|E)$ for certain polyatomic molecules is confirmed in broad outline by experimental facts. Direct confirmation of the adequacy of the exponential model has been obtained for the NO₂ molecule in experiments with molecular beams.⁶⁵ In these beams, one of the colliding partners is excited before collision by a laser into the energy region below the dissociation barrier. The probability of a collision jump to the dissociated state, the energy of which is higher than the given barrier, is well described by an exponential relation.

The data of Sanov *et al.*⁶⁵ 'face' the theory also with the more general question of the differentiation of the principal factors which permit the wide scale application of simple exponential relations for energy transitions in various relaxation processes: vibrational–vibrational ($V-V$), vibrational–rotational ($V-R$), and rotational–translational ($R-T$).

The question arises to what extent the above experimental data⁶⁵ may be interpreted within the framework of the more general biexponential model. The results of Sanov *et al.*⁶⁵ and the measurements of $\langle \Delta E \rangle$ based on the emission from NO₂ in shock waves are compared below.

The statistical and collision-statistical energy-exchange models are physically most justified. Other models are employed much more rarely. In most studies, it is emphasised that, in the description of the unimolecular decomposition rate constants (at least in the quasi-stationary approximation), the results of calculations are little sensitive to the functional form of the kernel [see Eqn (8)], but depend on the effective half-width of the kernel — $\langle \Delta E \rangle$. The situation for a nonstationary process is somewhat different. It has been shown⁶⁶ that the incubation characteristics of the decomposition of the N₂O molecule are described quite well

when an exponential kernel with parameters depending on the excitation energy is used.

The diversity of the forms of kernels employed makes it possible to estimate different aspects of the energy exchange processes with participation of HES and to identify the main ones among them when the results of the solution of the FME are compared with experimental data. A reasonable degree of specification of details in the description of the energy exchange involving HES, which is determined by the information content of the experiment, may be established in such a comparison.

Since the choice of a particular model is fairly arbitrary, it is essential to bear in mind certain fundamental limitations of each of them. Thus the statistical model clearly yields an upper limit to the transferred energies, while the step-ladder model fixes a portion of $\langle \Delta E \rangle$ fairly arbitrarily which sometimes requires additional analysis.

A multiplicity of publications have been devoted to the problem of the description of kinetic transformations with participation of HES on the basis of the solution of the FME. Almost all studies deal with the description with the aid of the FME of the results of measurements of the rate constants for chemical reactions with thermal, chemical, and optical activation.

A satisfactory agreement with experiment can be attained within the framework of different energy-exchange models, because the macroscopic rate constants are little sensitive to the level of specification of details in the description of the behaviour of excited states at a microscopic level. Formally this is associated with the fact that the macroscopic rate constant is determined as the result of the averaging of the microscopic rate constant $k(E)$ with respect to the distribution function:

$$k_{\text{macro}} = \int_{E_0}^{\infty} k(E)f(E)dE,$$

where $k(E)$ is the specific rate constant, which depends on the excitation energy E . Clearly, analysis of the directly observed characteristics of the functions $f(E)$ can yield significantly more information about processes with participation of HES.

VI. Steady state distributions of the populations of highly excited states for unimolecular decomposition and bimolecular reactions

We shall consider the characteristic features of the DF in reactions behind shock waves. In the process involving the decomposition of molecules after rapid heating in the shock wave, it is possible to identify two stages — rapid (on thermal excitation in shock waves; its characteristic duration is $\sim 0.5 - 10 \mu\text{s}$; under the conditions of multiphoton laser IR excitation, the duration is $\sim 10^{-8} \text{ s}$), associated with activation processes before the HES chemical reactions barriers, and slow, due to the decomposition of the molecules proper. In the course of the second stage, the DF may be regarded as steady state in terms of energy levels. In this case, the right hand side of Eqn (8) is set equal to zero. It is easy to note that the form of the steady state DF depends only on the ratio of the rate constants for the chemical reaction and the deactivation process.

The CF_3I molecule proved to be one of the most convenient objects for the investigation of processes involving HES with an energy close to that of the barrier to unimolecular decomposition at the C–I bond. We shall specify two approaches to the interpretation of the results of absorption measurements. The first, developed by Dalidchik and coworkers,^{34,45} is based on the use of ‘hot’ absorption bands in order to reconstruct the steady state HES distribution using the procedures described above for the transition from the partial distribution function with respect to the C–I bond to the distribution with respect to the total vibrational energy. The results are presented in Fig. 4.

In the second approach, examined by Abel and Herzog,⁶⁷ the changes in absorption in the ‘hot’ bands after the laser pulse excitation of the CF_3I molecule are recorded. The aim of the experiments of this kind was to find, by comparing the absorption at different wavelengths, the rate of the spontaneous decomposition of HES with an energy higher than that of the decomposition barrier and then to compare the results of the measurements with calculations based on the RRKM theory. The interpretation of the measurements is difficult owing to the presence of ‘cold’ and ‘hot’ ensembles of CF_3I molecules and the influence of collisions.

1. Triatomic molecules

In the study of triatomic molecules, the experiments were carried out with NO_2 , N_2O , SO_2 , CO_2 and O_3 . The NO_2 and SO_2 molecules are particularly convenient for spectroscopic observations. Firstly, they have an excited electronic term ‘inserted’ in the ground state. The term is in quasi-equilibrium with high vibrational levels of the ground state. This makes it possible to carry out measurements based on both ‘hot’ absorption bands and on the emission in the UV and visible regions of the spectrum.^{45,49}

Reliable results of measurements of the rate of relaxation at the lowest vibrational levels as a function of temperature and the collision partners as well as data on the relaxation of the HES make it possible to ‘construct’ a full picture of the energy exchange from the ‘bottom’ of the potential well to the states above the barrier, including $E - V$ transitions.

Secondly, bimolecular reactions with activation energies significantly lower than the decomposition barriers have been investigated for the NO_2 and SO_2 molecules. We may recall that the question of the role of the vibrational excitation of molecules in overcoming the bimolecular reaction barrier is still far from being solved. Analysis of the experimentally observed depletion of the distribution of the populations of the energy levels in the vicinity of the barriers to the bimolecular reactions

therefore yields data, which, when combined with the interpretation within the framework of the solution of the FME, may assist in significant progress towards the understanding of problems concerning the reactivity of highly excited molecules in collisions.

The attempts to find bimolecular exchange reactions occurring via a mechanism involving the subdivision of the process into the activation stage and the subsequent chemical stage proper have a long history, which does not lack certain dramatic features.⁶⁸

Here AB and CD are molecular reactants, M is any of the species in the mixture, including an inert partner, and AB^* is an active molecule which acquired a vibrational energy in stage (I) sufficient for chemical interaction with exchange of an atom or radical in the rearrangement process (II). The first model example

which was ineptly chosen¹⁴ for experimental studies (because of its high sensitivity to the distorting influence of impurities), to a large extent compromised the idea of the activation mechanism of bimolecular reactions.

The activation mechanism of bimolecular reactions received the first experimental confirmation in relation to reactions involving nitrogen oxides.^{69–71} The macroscopic manifestation of the state of nonequilibrium induced by the depletion of the populated states of AB^* in reaction (II) has been discovered in the form of the dependences of the observed rate constant k_{obs} on the ratio of the reacting components and on the presence of an inert diluent. By analogy with the curves for unimolecular reactions, the corre-

sponding curves for bimolecular reactions were referred to as fall-off curves. The depletion, compared with the equilibrium distribution of the HES of the reacting SO_2 and NO_2 molecules, found with the aid of spectroscopic methods in shock waves (Fig. 5), directly confirms the activation mechanism of the exchange reactions. The distribution obtained is well correlated with the macroscopic dependences of k_{obs} on the mixture composition.

A detailed discussion of all the aspects associated with the macroscopic manifestations of the state of nonequilibrium in bimolecular reactions may be found in the communications of Zaslonko and Mukoseev.^{69–71} We may note that the idea of the activation mechanism of bimolecular reactions and hence of the possibility of the manifestation of nonequilibrium effects has again begun to attract the attention of investigators in recent years.^{72–74} However, the calculations are of a purely illustrative character.

2. Iron clusters

Vlasov *et al.*⁷⁵ observed nonequilibrium effects in the high-temperature decomposition of clusters in shock waves. In particular, such effects are indicated by the fact that the temperatures of the clusters T_c and of the surrounding gas T_g may differ greatly with $T_c < T_g$. The current level of development of the spectroscopy of clusters does not allow the probing of the distribution of the HES as in the case of molecular objects. However, it has been possible to demonstrate directly by spectroscopic methods the depletion of the HES distribution for iron clusters containing thousands of atoms.

VII. The energy-exchange mechanism and experimental data

1. Trajectory calculations

Trajectory calculations belong to the class of the most effective methods for the study of the dynamics of the HES energy exchange for polyatomic molecules in collisions. Until recently, these calculations were mainly illustrative in character for several reasons. Firstly as a rule, a trial potential is employed. Secondly, such calculations are technically difficult to carry out for a sufficiently large number of trajectories and there is no clear-cut criterion separating elastic and nonelastic collisions from which the completion of energy exchange might be inferred. Thirdly, the relation between the results of trajectory calculations and calculations within the framework of the FME is not clear. Fourthly, trajectory calculations performed with a specific pair of colliding partners and the possibility of transferring the relations established to other pairs of colliding molecules constitutes a separate problem.

Only recently has it become possible to overcome to some extent the majority of these difficulties. For example, the distribution of the probabilities $P(E|E')$ over the entire energy range from 0 to 100 kcal mol⁻¹ has been found⁵⁹ with the aid of trajectory calculations for collisions of CS_2 with CO and was then used in the solution of the FME for the description of the relaxation of the initially excited molecules.

The systematic approach to the solution of the problem of the HES energy exchange must be regarded as the most productive and the qualitative features discovered^{61, 76, 77} must therefore be specified.

1. The results of trajectory calculations for the transitions in the collisions of CS_2 with CO agree well with calculations employing the biexponential model for the probabilities of transitions subject to the condition that the exponents depend linearly on the energy.

2. The solution of the FME with a biexponential function for $P(E|E')$ agrees well with the trajectory calculations.

3. The calculations employing the simple exponential model with an energy-independent characteristic magnitude of the 'energy jump' agree poorly with the trajectory calculations, but the introduction of a linear dependence of this parameter on the

energy alters the situation significantly. Calculations based on this 'improved' exponential model satisfactorily reproduce the characteristic features of the energy exchange.

4. Collisions which transfer of large portions of energy (strong collisions) make a much greater contribution to the overall energy exchange flux than the weak collisions. In other words, the contribution of the strong collisions to the average amount of energy transferred is the main one despite the fact that the fraction of such collisions is relatively small.

Trajectory calculations for small polyatomic molecules are used mainly to determine the ratio of the weak and strong collisions (in particular, the contributions of the $V-V$ and $V-R$ transitions).^{59, 76, 77} For large molecules, such calculations demonstrate the importance of multiple 'chattering' § collisions.^{77, 78}

Trajectory calculations make it possible to most fully discover the details of various mechanisms of the relaxation of the HES of polyatomic molecules in collisions. It is possible to identify four types of collisions with HES energy exchange.⁷⁹

1. Direct single collisions of a buffer gas atom with an atom of the excited molecule lasting less than 300 fs. Thus ~ 60% of the nonelastic collisions of toluene molecules and an argon atom may be classified as direct and these constitute 50% of the energy exchange flux.

2. 'Chattering' collisions, the duration of which is greater than that of the direct collisions but is shorter than that required for the complete intramolecular redistribution of τ_{rel} (IVR). During the collision, the atom, as it were, executes several jumps from one site to another at the multidimensional atom-polyatomic molecule potential. Such collisions constitute ~ 30% of all the nonelastic collisions.

3. Collisions with formation of a complex the lifetime duration of which is greater than τ_{rel} (IVR). In such a complex, the energy is distributed statistically among all the vibrational modes and the RRKM theory is applicable to the calculations. The fraction of such collisions for toluene molecules and argon atoms is very small.

4. Supercollisions in which a very large amount of energy is transferred. However, their fraction is small, only ~ 0.1%.

The first three types of collisions may be interpreted with the aid of the modified relaxation equation taking into account the vibrational energy balance. Furthermore, equations have been obtained for $\langle \Delta E \rangle$ in various limiting cases of the energy-exchange mechanisms and the independence of $\langle \Delta E \rangle$ of temperature has also been justified.⁷⁹

One of the clearest mechanisms of the energy exchange of the HES of polyatomic molecules in collisions reduces to a sequence of $R-T$ transitions with subsequent rapid intramolecular mixing of the energy.⁸⁰ The characteristic quantity $\langle \Delta E \rangle$ for this mechanism amounts to ~ RT . The results of trajectory calculations for the collisions of SO_2 molecules and an Ar atom agree well with the results of calculations using the $V-R-T$ relaxation model. This means that the dynamics of the vibrational motion on the single collision time scale is insignificant for such calculations.

2. The influence of excited electronic terms in the HES reactions and energy exchange

In the course of the unimolecular decomposition and the reverse recombination process, species with unfilled electron shells frequently participate. Consequently one may expect the manifestation of fine structure effects. Several examples illustrating the possible scale of these effects have been examined.⁸¹ The first example refers to the reaction

considered on the hypothesis that it proceeds within the limits of only one main potential energy surface. We then have

§ This term designates the ability of a monatomic collision partner to collide successively, several times, with several atoms of the excited polyatomic molecule.

$$k(T) = f_{\text{el},0}(T) k_0(T),$$

where $f_{\text{el},0}(T) = g_{\text{el},0}/Q_{\text{el}}(T)$ is the thermal population of the two lowest electronic states, leading to the formation of a complex, $g_{\text{el},0}$ is the statistical weight of the state, $Q_{\text{el}}(T)$ is the combined partition function of the reactants, and $k_0(T)$ is the rate constant for the reaction between species in the lowest electronic states. Experiments have shown that the decrease in the thermal population of the lowest components of the fine electronic structure of the OH radical and the O atom with increase in temperature entails a decrease in the rate of reaction, because the highest components apparently do not contribute to the reaction. Consequently the above relation for $k(T)$ has been confirmed experimentally.

The second example concerns the reaction

for which the high pressure limit (k_∞) has been found experimentally. The reaction regime at low pressures (k_0) is well known. The first stage of the reaction is determined by capture, whilst in the second stage the reverse process — the decomposition of the active complex HOCO^* — exerts an appreciable influence. If only the lowest components of the OH fine structure contribute to the reaction, then, by comparing the calculated and experimental rate constants, it is possible to find the expected contribution of the fine structure effect.

The possible influence of electronic terms on collision energy exchange processes has been tested in relation to the NO_2 molecule. The $^2B_2$ and $^2A_1$ states are known to be greatly mixed. Other electronic states, which are not linked optically, may be linked by collisions. The strong linkage between the $^2B_2$ and $^2A_1$ states promotes intramolecular exchange and, on laser excitation of molecules in the region of the dissociation barriers, the vibrational motion of the highly excited NO_2^* molecule is randomised. Apparently this in fact accounts for the absence of effects associated with the separate states for the spectrum of the products of the collision-induced dissociation.

The hypothesis of the important role of the electronic term in the NO_2 relaxation process is supported by the data of Toselli *et al.*⁸² and Hartland *et al.*⁸³ In conformity with these data, the portion of energy transferred in collisions increases sharply starting with the levels corresponding to the location of the excited term. However, measurements in crossed beams did not demonstrate the influence of this term on the energy-exchange parameters.⁶⁵ The above contradiction can be resolved only on the basis of a more detailed description of the HES relaxation.

3. Reverse electronic relaxation. $V-E$ exchange

Molecules having an electronically excited term, the 'bottom' of which lies below the dissociation barrier, are favourable objects for the investigation of energy exchange. The electronically excited states of such molecules are as a rule found to be strongly linked to the vibrational levels of the ground state (Fig. 1). However, knowing the rate of energy exchange between these states, it is possible to infer how strong this linkage is.

In the collisionless regime, the mixing of the states (the Douglas effect) greatly lengthens the radiation lifetime, for example for NO_2^* it is more than 50 μs in the vicinity of the dissociation barrier. The long lifetime of molecules in the excited state (τ) is convenient for the 'transportation' of the excitation in the molecular beam.⁶⁵ For SO_2 , this effect is most marked.

The phenomenon of the reverse electronic relaxation (RER) has been used in direct measurements of the time required for the establishment of the steady state association regime (t_{ss}) for the NO_2 and SO_2 molecules.^{56,84,85} By varying the content of SO_2 in a mixture with argon, the total pressure, temperature, and the spectral range in the recording of emission, it has been possible to identify the component associated with the $V-E$ exchange

processes in the overall time required for the attainment of the steady state dissociation regime.

The effectiveness of the RER has been estimated in relation to the resonance IR excitation process.^{12,88}

4. Vibrational relaxation of molecules in electronically excited states

The relaxation of vibrational energy within the limits of the electronically excited terms has been poorly investigated because the overall energy in these states is small and it is difficult to separate the vibrational relaxation process from the accompanying energy-exchange processes.

It has recently been possible to measure the vibrational relaxation times for the OH⁸⁹ and SO_2 ⁹⁰ molecules with the aid of laser excitation and high-resolution LIF spectroscopy. The relaxation of diatomic molecules is somewhat outside the main topic, but the situation for SO_2 merits a comment.

The rate constant for the vibrational relaxation of SO_2 within the ground term at $T = 300\text{ K}$ is $5 \times 10^{-14}\text{ cm}^3\text{ s}^{-1}$ ($\text{M} = \text{Ar}$).⁹¹ On the other hand, the relaxation within the excited term is ~ 20 times faster,⁹⁰ *i.e.* the rate of relaxation is much higher than the rate of quenching of the fluorescence of the $^3B_1(0,1,0)$, $^3B_1(0,2,0)$, and $^3B_1(1,0,0)$ states of the SO_2 molecule. We may note that the fluorescence of the $^3B_1(0,0,0)$ state is quenched 20 times more slowly. Theoretical models for the description of experimental data have not yet been developed.

5. Dependences of the relaxation of the molecular highly excited states on temperature, collision partners, and the degree of excitation

The questions raised in the heading of the present section have been almost fully resolved in relation to the relaxation of the lowest vibrational levels of small molecules, which has been reflected in the literature (see, for example, Gordiets *et al.*¹⁵).

The situation is not quite so favourable as regards the HES of polyatomic molecules, particularly since it is necessary to take into account the vibrational degrees of freedom of not only the ground but also of the electronically excited terms.

We shall now turn to the energy dependence of the rate of relaxation of the HES. There are molecules for which it is possible to construct a complete relaxation pattern from the lowest vibrational levels up to the dissociation barrier. In the first place, this applies to the NO_2 molecule, characterised by exceptionally convenient spectroscopic features. For this reason, diverse methods have been tested on this molecule.

If one is dealing with a description in terms of the language of rate constants, then the problem formulated for triatomic molecules, (including NO_2) has been solved.^{49,51} The temperature dependences of three fundamental relaxation characteristics — the decomposition rate constant at the low pressure limit and the durations of the incubation phase and relaxation via the lowest levels — have been described in the above studies within the framework of a single approach based on the solution of the FME (Fig. 6).

As regards $\langle \Delta E \rangle$, the situation is more contradictory. According to the results of a number of studies,^{69–71,86,87} the contribution of collisions with transfer of large portions of energy to the overall flux of activating collisions is notable (Table 1). Analysis of experimental data obtained in shock waves permits the following conclusions.

Firstly, in the lowest part of the energy scale the $V-T$ exchange proceeds with transfer of $600\text{--}2000\text{ cm}^{-1}$ vibrational quanta, depending on the temperature, with a probability from 10^{-2} to 10^{-3} .

Secondly, in the middle of the energy scale the portion of energy transferred $\langle \Delta E \rangle$ for NO_2 amounts to $\sim 60\text{ kJ mol}^{-1}$ (Table 1), *i.e.* is equal to $\sim 4RT$ at $T \approx 2000\text{ K}$.

Thirdly, the activation mechanism of bimolecular reactions yields β_c for the highly excited states of the NO_2^* molecule with an energy close to the bimolecular reaction barrier.

Figure 6. Experimental and calculated temperature dependences of the rate constants for various kinetic processes involving HES for the (a) NO_2 , (b) N_2O , and (c) SO_2 molecules:⁵¹ (1) relaxation rate constant; (2) incubation stage rate constant; (3) dissociation rate constant in the steady state regime; lines — fitting of experimental data in shock waves; symbols — results of the numerical solution of the FME.⁵¹

Fourthly, for transitions around the dissociation barrier there are independent β_c data in the range 0.1–0.01 ($M = \text{Ar}, \text{He}, \text{CO}_2$).⁶⁹

In the two-channel model for the parallel occurrence of bimolecular and unimolecular reactions, $\langle \Delta E \rangle \simeq RT$ and $\sigma_E/\sigma_g = 0.1$ –0.01 (see Refs 69–71 and the comments on these parameters in Refs 104 and 105).

Thus it has been possible to construct a self-consistent picture for the entire molecular vibrational energy scale on the basis of experiments employing the competing channels method and moderate-resolution emission-absorption spectroscopy.

The situation is different for data obtained by the high spectral resolution methods. Hartland *et al.*⁸³ found that the average portion of transferred energy for the NO_2 molecule is $\sim 1300 \text{ cm}^{-1}$, i.e. equal to $10 RT$ at 300 K, which agrees with the results presented in Table 1 and is also supported by measurements of the rate of V – T transitions.⁹¹ However, the results of measurements in a beam⁶⁵ yield $\langle \Delta E \rangle_{\text{up}}$ in the range of only 110–310 cm^{-1} . Furthermore, this occurs for a relative energy of

the collisions of the NO_2 molecules with Ar, He, O_2 and CO of ~ 750 – 2400 cm^{-1} .

What then is the problem? One of the causes of the discrepancies in the present author's view is the simplified interpretation of the experimental results. For instance, Pureskii⁸⁸ used for this purpose the simplest diffusion-type relaxation equation, which yields fairly good results for the upper energy scale but greatly distorts the results for relatively low excitation levels (according to the results of Zaslonko and Mukoseev,⁸⁷ in the region of the singular point).

One may postulate that the application of the exponential model for the transition probabilities will greatly improve the possibilities for the description of the primary data.⁸³ Even more interesting results may be obtained if the evolution of the DF with respect to total energy is reproduced on the basis of the observed transformation of the NO_2 high-resolution spectrum (antisymmetric vibrational spectrum). This function can then be interpreted on the basis of comparison with the solution of the nonstationary FME.

In relation to the conclusion that the activating collisions in experiments in molecular beams⁶⁵ obey the exponential model, one may assume that, for the present accuracy of the measurements, the experimental data may be fairly well described also by the biexponential model taking into account a certain hitherto unknown admixture of collisions with transfer of large portions of energy.

6. Characteristic features of the collision energy exchange of large molecules

The energy exchange in the collisions of complex molecules has been most fully investigated with the aid of the IR emission recording technique with laser pulse excitation (see the review of Barker and Toselli¹⁸).

Together with the properties characteristic of the HES of molecules with a small number of atoms, certain specific features are characteristic of polyatomic molecules.¹⁸

Firstly, the V – R energy exchange is manifested in collisions with all partners apparently by virtue of the contribution of interactions over short distances. The model of such interactions is in essence close to the model of random multiple collisions.

Table 1. Results of the measurements of the average portion of transferred energy in collisions (ΔE) and of the ratio of the energy-exchange (σ_E) and gas-kinetic (σ_{gk}) cross-sections for the lowest energy of the term (E_0) in the range of observed energies ($\langle E \rangle$).

Molecule	Term	E_0 /kJ mol ⁻¹	$\langle E \rangle$ /kJ mol ⁻¹	ΔE /kJ mol ⁻¹	T/K	$\sigma_E/\sigma_{\text{gk}}$	Excitation method

Secondly, the $V-V$ exchange occurs by virtue of the dipole--dipole interaction of the partners over large distances and the closeness to resonance between different vibrational modes is therefore significant.

Thirdly, the rate of the $V-R$ exchange increases in those cases where the molecules of the quenching gas have a permanent dipole moment, which may interact with the oscillating dipoles of the exciting molecule.

Fourthly, the presence of low-lying excited electronic terms may significantly accelerate the energy exchange.

The possibilities for the manifestation of different mechanisms of the $V-T/R$ and $V-V$ energy exchange have been examined in a study¹⁸ based mainly on the results of mode-by-mode measurements of the induced IR emission by the molecules of CO_2 used as the 'quenching' gas in collisions with the excited molecules.

Gilbert and Zare⁹² discussed the possible manifestation of quantum effects in energy exchange processes. The deactivation of the HES of azulene molecules in collisions with Ar and He was examined as an example. The appreciable difference between the effectiveness of ^3He and ^4He predicted in the above study was not confirmed experimentally.¹⁸ In contrast to the azulene--argon system, the energy exchange in the azulene--helium system is poorly described by the method of trajectory calculations apparently because of the unsuccessful choice of the potential energy surface for the given pair.

7. The possible role of supercollisions in chemical kinetics

The question of the amount of energy transferred in collisions of excited polyatomic molecules with various partners has long interested kineticists. Owing to the lack of reliable data, the majority of their theoretical studies have been carried out in terms of the approximations of strong collisions (SC) or weak collisions (WC). The controversy concerning the question which of the mechanisms is more realistic has a correspondingly long history. In many respects, the majority of investigators have been inclined to assume the dominant role of WC under the influence of the studies by Troe and coworkers (see, for example, Refs 6 and 14).

This controversy became especially intense after the observation (experimentally and by a computational procedure⁶⁰) of a significant fraction of collisions with transfer of large portions of energy. However, it had also been emphasised in earlier studies⁶⁹⁻⁷¹ that a whole series of multichannel reactions cannot be interpreted within the framework of the WC mechanism and that $\langle \Delta E \rangle$ is of the order of magnitude of RT . Since the effectiveness of the collisions β_c is much less than unity, *i.e.* the collisions can be in no way classified as purely 'strong', it became clear that it is more justified to apply the terms 'weak--strong' or 'strong--weak' collisions. Later the term 'supercollisions' (SUC) was introduced in the literature to designate the fact that in the overall energy exchange flux there is a fraction of collisions with transfer of large portions of energy.

We shall illustrate the possible role of SUC on kinetics by two examples. The first refers to the influence of SUC on the position and form of the transition curves for unimolecular decomposition reactions for a variable admixture of SUC in weak collisions.⁶⁰ Even when the fraction of SUC is 0.5%, their influence is considerable and exceeds the typical experimental errors. In view of the very common occurrence of decomposition and recombination 'transition regimes' in combustion processes and in atmospheric chemistry, much attention must be devoted to them.

The second example concerns multichannel transformations in atom-radical bimolecular reactions. The majority of such reactions occur with formation of a long-lived complex and are interpreted within the framework of the statistical theory of bimolecular reactions. The probability of a particular channel depends decisively on two parameters: the magnitude of the energy barrier for the corresponding channel and $\langle \Delta E \rangle$. In atom-radical reactions, one set of radicals is very often replaced by another set of radicals, which have different reactivities in chain

reactions. This may intensify the sensitivity of the overall reaction to the type of a particular radical by a large factor.

Model calculations have been performed^{93,94} for two-channel decompositions within the framework of the exponential energy-exchange model. However, in the light of what has been said above about the possible role of SUC, it is necessary to investigate at least the 'sensitivity' of the recommended formulae to an admixture of SUC.

8. Energy exchange in collisions with clusters

The most detailed information about the energy exchange of clusters has been obtained on the basis of the method of trajectory calculations and also the molecular dynamics method.^{95,96} The cluster is usually modelled with the aid of the Morse pair potential and the Lennard--Jones pair interaction between clusters. The results of trajectory calculations for the energy exchange of specific clusters are naturally of independent interest. However, they are still more interesting as regards the applicability of different models to the energy exchange of macromolecules and clusters in collisions. We shall differentiate the following results among those obtained:

- 1) the energy exchange parameters depend on the structure of the cluster (for a fixed mass);
- 2) the energy exchange with clusters is more effective if the vibrational frequencies are reduced; the mass of the incoming atom and the relative velocities of the partners increase.

These results are fully consistent with the predictions based on Machan's pulse model,⁹⁷ according to which the $T-V$ transitions are accelerated as Massey's adiabaticity parameter diminishes. The relations found for the maximum energy transferred in a collision when the impact parameter is zero are useful for estimates.

$$\Delta E_{\max} = \frac{4m_g m_a}{(m_g + m_a)^2} E_{\text{rel}}.$$

In the above relation m_g is the mass of the buffer gas atom and m_a is the mass of each of the atoms constituting the macromolecules m_M . The equation is most accurate for $m_a \ll m_M$ and $m_g \ll m_M$. On averaging over all possible orientations in collisions, the change in the internal energy of the cluster is

$$\langle \Delta E_{\text{int}} \rangle = \frac{\Delta E_{\max}}{2}.$$

If all other factors (*i.e.* E_{rel} and m_a) are kept constant, the energy transfer within the framework of the collision model increases with increase in m_g up to the maximum value $\langle \Delta E_{\text{int}} \rangle / E_{\text{rel}} = 0.5$ (E_{rel} is the relative translational energy of the colliding partners).

The above formulae are well supported by trajectory calculations for the collisions of Ar with Al_6 or with Al_{13} , *i.e.* $\langle \Delta E_{\text{int}} \rangle / \langle \Delta E_{\text{rel}} \rangle$ tends to 0.5 in the limit if the mass of the buffer gas atom is large, the vibrational frequencies are low, and Massey's adiabaticity parameter is small.

Estimates of $\langle \Delta E \rangle$ by the above formulae for collisions of iron clusters with an argon atom agree well with the value obtained in the theoretical description of the difference between the temperatures of the clusters and of the gas in thermal decomposition in shock waves.⁹⁸

The details of the energy exchange mechanism in the collisions of clusters with inert gas atoms have been elucidated by comparing the results of trajectory calculations with the predictions of the ergodic collision model.⁹⁶

We list below the features of such energy exchange closest to the subject of the present review.

The mechanism of energy exchange in the collisions of clusters depends on the intensity of the interaction and varies from the weak collision (WC) limit to the statistical strong collision (SC)

limit as the interaction energy varies from the scale of the van der Waals forces to values characteristic of a normal chemical bond.

For a weak interaction, the functional form of the transition probabilities in collisions $P(E|E')$ is well modelled by the relations of the partially ergodic collision theory. The functional form of $P(E|E')$ depends significantly on the parameter of the effectiveness of the collisional energy exchange β_E .

In collisions with strong interaction, a bimodal dependence of the transition probabilities $P(E|E')$ on the portion of transferred energy is observed. The central peak on this relation corresponds to weak collisions, whilst the 'wings' take into account the contribution of strong collisions.

VIII. Nonstationary distributions of the populations of highly excited states

1. The incubation phase of unimolecular decomposition reactions and the activation limit of bimolecular reactions

In the classical mechanism of a unimolecular reaction, the activation process is considered as the first stage, being followed by the chemical dissociation process proper or a rearrangement of the bonds in the activated molecule having an energy higher than the barrier to the corresponding process. For simplicity, we shall confine the treatment to the two commonest types of activation — thermal in collisions and optical in multiphoton excitation by IR irradiation (Fig. 1). Both types of activation are an example of activation 'from below'. The overall rate of the process is low up to the instant when the population of the active states of the molecules attains a steady state (not necessarily equilibrium) level. In such activation, it is necessary to pass through the entire 'ladder' of vibrational states before the barrier. In the majority of studies, the duration of this process is referred to as the incubation period and the latter is as a rule short compared with the main reaction time for an established steady state distribution function. It is more correct to call this time interval the relaxation time of the distribution function. For thermal reactions, these times approach one another with increase in temperature and conditions may be realised where the entire decomposition phase takes place as a nonstationary process and the population is small for most of the distribution function (including the region in the vicinity of the maximum). In such situations, the subdivision into incubation and steady state phases is no longer legitimate.

Naturally, the results of the measurement of the duration of the incubation phase τ_{inc} in the studies of unimolecular decomposition carry important information about energy exchange processes over the entire energy scale (from below up to the barrier). The measurement of τ_{inc} for unimolecular decomposition in shock waves is a difficult task. This problem has been solved sufficiently fully (with application of the emission technique for the excited electronic terms) only for triatomic molecules.^{45, 49}

The results obtained were interpreted within the framework of the solution of the FME with reference to experimental relaxation data for the lowest vibrational levels (Fig. 6).

The theoretical calculations for the incubation phase in a collisionless dissociation process induced by resonance IR radiation have been carried out by Troe.⁹⁹ The durations of the incubation and steady state phases for this process are comparable and, if no account is taken of this fact, misunderstandings may arise when the results obtained by different workers for the rate constants and the product yields are compared. Comparison with the results of measurements of macroscopic rate constants is valid only when the form of the distribution function with respect to the internal energy of the reactants is the same!

Despite the fact that the duration τ_{inc} is in essence a characteristic of an integral process, the interpretation of the τ_{inc} yielded interesting results for the energy dependence, the rate of relaxation as a function of the degree of vibrational excitation of the molecule.⁶⁶

A detailed analysis of studies on the incubation characteristics τ_{inc} of unimolecular decomposition reactions with thermal activa-

tion in the gas and as a result of collisions on the wall has been carried out.⁵⁰ In particular, the deficiencies of the calculations of τ_{inc} within the framework of the simplest exponential model with energy independent energy exchange parameters have been noted. These deficiencies have been overcome in other studies.^{49, 51}

2. Transformation of the distribution of highly excited states

The modelling of kinetic processes involving HES has shown that measurements of only the integral parameters of the relaxation processes in chemical reactions and also of the steady state distribution functions are insufficient for the elucidation of the detailed mechanism of the energy exchange and reactions of highly excited molecules. The problem of the diagnostics of nonstationary distribution functions and of securing information about kinetic parameters involving highly excited molecules at a microscopic level therefore arises. Owing to the limited possibilities of the recording apparatus and a lack of satisfactory theoretical models, there has been little development of this field of study hitherto.

Detailed information about the energy-exchange processes can be obtained by creating a significantly nonequilibrium initial situation and by observing the subsequent transformation of the distribution function for a polyatomic molecule as a result of collisions with thermostat species. In this case, the average energy of the polyatomic molecules should differ greatly from the average energy of the thermostat species. Such situations occur in the laser excitation of molecules (the molecules are 'cooled' in the collision process) and also on thermal excitation of the molecules in shock waves (the molecules are 'heated' as a result of collisions).

There have been fairly numerous communications whose authors investigated the transformation of the initial distribution functions having a sharp maximum in the region of high energies. Such a 'narrow' distribution is generated as a result of chemical or optical pumping. The method employing intramolecular conversion, accompanying the absorption of a laser photon in the UV or visible region of the spectrum (Fig. 7), has come to be most widely used for the generation of 'narrow' HES distributions. The advantages of this method have been clearly demonstrated in

Figure 7. Transformation of the population distribution function on laser pulse excitation (a) and the dependence of the absorption coefficient of cycloheptatriene molecules on the wavelength and excitation energy $\langle E \rangle$ (b):¹⁴ a: T/K : (1) 600; (2) 1200; (3) 1800; (4) 2800; (5) 300; b: λ/nm : (1) 180; (2) 200; (3) 250.

relation to a family of substituted cycloheptatrienes, CS₂, SO₂, CrOCl₂, azulene, *etc.*^{100–104} The primary absorption step with subsequent rapid intramolecular conversion makes it possible to generate a microcanonical HES distribution within the limits of the ground electronic state. The electronic transition in the UV region is due to the optically active vibration of the polyatomic molecule, while the remaining vibrational modes play the role of an intramolecular thermostat. The vibrational energy at the $E_{\text{int}} \simeq \hbar\nu$ level becomes stochastic in a picosecond time interval. A significant advantage of this method is a clear-cut energetic definition of the initially generated distribution of molecules with respect to the total energy.

It has been concluded¹⁴ that the relaxation of the average energy of the molecules may be described by the simple equation

$$-\frac{d\langle E(t) \rangle}{dt} \simeq z(\langle E \rangle) \langle \Delta E(E) \rangle, \quad (11)$$

where $z(\langle E \rangle)$ is the number of collisions of a ‘hot molecule’ having an energy $\langle E \rangle$ with the thermostat species. This relation is of the usual kind and has been used to interpret the primary experimental data for the relaxation of HES with UV laser excitation of the molecules. In order to be able to apply this relaxation equation, it is necessary to measure the average energy $\langle E \rangle$ of the molecule. This can be done by employing UV absorption spectroscopic,^{48, 49} IR fluorescence, and IR absorption^{12, 13} methods. Almost all investigators calibrate the measuring absorption channel if the distribution function with respect to the internal energy is known; for example, in terms of the empirical experimental dependence of the absorption cross-section of the molecule on the average store of the total energy ($\langle E \rangle$) (Fig. 7). The spectra of polyatomic molecules under equilibrium conditions (a canonical distribution of the molecules with respect to internal energy) and with UV laser excitation (a microcanonical distribution) are virtually the same, provided that the average energies of these ensembles are identical.¹⁴ For the triatomic SO₂ and CS₂ molecules, the calibration is less satisfactory.¹⁰⁵

The possibility of selecting a suitable wavelength in the UV absorption spectrum, for which an unambiguous relation between the absorption cross-section $\sigma(t)$ and the average energy of the molecules holds, has been justified.^{67, 103, 104} Subsequently the kinetic absorption curve is transformed with the aid of the $\sigma(\langle E \rangle)$ relation into the $\langle E \rangle(t)$ relation, which is in fact used in Eqn (11). The cross-section of the deactivation process is then assumed equal to the gas-kinetic cross-section. As a result, the values of $\langle E \rangle$ for collisions with inert monatomic gases in the region of $(0.01 - 0.001) RT$ are obtained for CS₂ and SO₂ in the lower part of the potential well, which is frequently even less than the energy of the rotational quanta of the molecule. This agrees poorly with the overall picture of the vibrational relaxation of polyatomic molecules.

The above conclusions are a consequence of the limited applicability of the initial postulates underlying the interpretation of the experimental data. Firstly, analysis of the fundamental kinetic equation, carried out by Zaslonko and Mukoseev,⁸⁷ showed that Eqn (11) has a limited applicability. It is valid only for systems without vibrational energy sources or sinks as a result of the occurrence of chemical reactions of the HES and also for excitation energies significantly higher than the level of the average thermal energy of the thermostat molecules and subject to the condition that $\langle \Delta E \rangle \ll E$. In particular, neglect of this important factor (see Nikitin¹⁴ and the literature quoted therein) led to a strong dependence of $\langle \Delta E \rangle$ on the excitation energy (or, what amounts to the same thing in the context of the above study, a strong temperature dependence of $\langle \Delta E \rangle$).

Secondly, the dependence of the absorption cross-section on the average energy of the molecules is not universal and for certain wavelengths may depend on the form of the distribution function and hence on the external conditions governing the activation of molecules.

3. Wave characteristics of the transformation of the distribution of populations on pulse excitation

We shall now consider the results of the analysis of the properties of the system of microkinetic equations for the population of the highly excited states of polyatomic molecules with pulse excitation. A generalised FME has been obtained^{86, 87} for the dimensionless distribution function of the populations in the presence of sources and sinks of excited states. With the aid of this equation, it is possible to find the correct limiting transitions to special cases of activation in the diffusion approximation and via the strong collision mechanism.

A fundamental feature of the analysis is the identification of singular points of the kinetic system, described within the framework of the FME, separating different dynamic energy-exchange process regimes. Depending on the energy function of the activation cross-section in collisions, the singular point is determined either by the average energy transferred in the collision $\langle \Delta E \rangle$ or by the average thermal energy of the species in the ensemble sRT , where s is the number of oscillators in the molecule. In the vicinity of the singular point, the energy-exchange kinetics can be satisfactorily described by a diffusion mechanism. Under conditions far from the singular points in the region of energies $E > \max\{\langle \Delta E \rangle, sRT\}$, the solution of the generalised FME is expressed in the form of a population travelling wave. The clearest results are obtained when the method of characteristics is employed. In the coordinate system linked to the moving population front, the solution has an exponential form with a characteristic region of the population gradient, which depends on $\langle \Delta E \rangle$. Under conditions far from the sources and sinks of the excited states and also for $E \gg \langle \Delta E \rangle$, the rate of movement of the population front is constant and only then can be fitted by the simple equation

$$\frac{dE}{dt} = \langle \Delta E \rangle k_i^{(+,-)},$$

where $k_i^{(+,-)}$ are the rate constants for activation or deactivation and the ‘plus’ or ‘minus’ sign denotes the direction of motion of the population front, which depends on the initial conditions. In the absence of an energy dependence of $\langle \Delta E \rangle$ and $k_i^{(+,-)}$ the movement of the population front is of the automodel type: its form is retained and there is no dispersion in the distribution. When the population front approaches the barrier to the spontaneous decomposition of the excited molecules, the wave is retarded (there is a dispersion in the distribution) (Fig. 8).⁸⁷

The above analysis provided a basis for a new method whereby the parameters of the energy exchange of highly excited states of polyatomic molecules may be determined experimentally. Its essential feature reduces to the measurement of the phase and amplitude characteristics of the relaxation process and the determination of the form of the population distributions. In the simplest formulation, for the solution of the problem it is sufficient to measure simultaneously the rates of change of the absorption (emission) at two wavelengths corresponding to two energy levels of the excited states. The simplest and at the same time fairly informative parameters of the experimental kinetic curves are the induction phase related to the time of arrival of the population front at the given energy level (τ_1 and τ_2 in Fig. 9) and the rate constant for the population of the given level ($\langle \Delta E \rangle$ characterises the form of the distribution of populations and $k_i^{(+,-)}$ characterises the amplitude of the populations in the given instant).

Two methods for the spectroscopic recording of the wave characteristics of the HES relaxation in shock waves have been applied. The first involves the recording of the emission from triatomic molecules in the UV and visible regions of the spectrum. The high sensitivity and a time resolution which is record-breaking for the shock wave technique have been achieved as a result of a spatially integrated emission system along the axis of the shock wave tube. The second procedure involves the recording of the ‘hot’ absorption bands of the molecules. An important precondition

Figure 8. Examples of the numerical solution of the FME for the time evolution of the dimensionless DF, $h(E) = f(E)/f_{eq}(E)$, for vibrational energy on thermal activation in the shock wave; h_e — level of equilibrium population; E_0 — decomposition barrier; E_1 and E_2 — recorded energy levels; Δt — the time taken to traverse the population level over the specified energy range. *a*: form of DF at different times fitted by the relation $h(E) \approx e^{-\alpha E}$, where $\alpha \approx 1/\langle \Delta E \rangle$; $\Delta h(E)/[h(E)(E_2 - E_1)] = 1/\langle \Delta E \rangle$; *b*: trajectory of the motion in time of the constant-population level $0.1 h_e$ fitted by the equation $dE/dt = \langle \Delta E \rangle k_{rel}[M]$, where $(E_2 - E_1)/\Delta t = \langle \Delta E \rangle k_{rel}[M]$ and k_{rel} is the relaxation rate constant.

Figure 9. 'Distance traversed' by the population wave in the range of energies of NO_2 molecules of 212–240 kJ mol^{-1} (emission in shock waves): (a) relaxation 'from above' in the recombination process $O + NO \rightarrow NO_2^*$; (b): relaxation 'from below' in the collisions $NO_2 + Ar \rightarrow NO_2^* + Ar$; $\lambda(\text{nm})$: (1) 585; (2) 500; $E(\text{kJ mol}^{-1})$: (1) 210; (2) 240.

tion for the quantitative measurements is the possibility of calibrating the emission and absorption recording channels with respect to wavelength.

The measurements were performed with SO_2 , NO_2 , and CO_2 molecules.^{86,87} The temperature range of the measurements was

1800–4000 K, the pressure was 2–5 atm, the diluent gas was argon, and the fraction of the molecular component was from 0.5% to 20%. The range of vibrational excitation energies capable of being recorded amounted to 10–130 kJ mol^{-1} for the absorption method and 180–500 kJ mol^{-1} for the emission method. In all the experiments, measurements were made simultaneously at at least two wavelengths. The energy gap between the energies of the recorded excited states was as a rule 30 kJ mol^{-1} .

The selected recording scheme made it possible to determine accurately the distance traversed by the population wave for the specified energy interval (Fig. 9). Opposite directions of wave travel were observed for NO_2 molecules with shock wave heating (relaxation 'from below') and in the recombination reaction $O + NO \rightarrow NO_2$ (relaxation 'from above'). The phase shifts of the signals in the two-channel recording, caused by the difference between the induction periods τ_1 and τ_2 were in the range 0.3–6 μs , while the rate constants for the population of the highly excited states in collisions were in the range 3×10^{10} – $4 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ (in an argon atmosphere). The recording of the propagation of the population waves permits the direct determination of an important energy exchange parameter — $\langle \Delta E \rangle$. The clearest estimate of $\langle \Delta E \rangle$ is obtained from the law governing the motion of the population front:

$$\frac{E_1 - E_2}{\tau} = \langle \Delta E \rangle k_i^{(+,-)},$$

where E_1 and E_2 are the energy levels of the recorded excited states. We emphasise that this approach to the determination of $\langle \Delta E \rangle$ does not employ any additional (as a rule arbitrary) hypotheses concerning the energy-exchange mechanism.

The interpretation of the emission and absorption data in shock waves made it possible to determine the quantity $\langle \Delta E \rangle$ for the SO_2 and NO_2 molecules in the ground and excited electronic states and also for the CO_2 , N_2O and CS_2 molecules in the ground states, which in all cases proved to be appreciably greater than RT , while the effective energy exchange cross-section σ_E is significantly smaller than the gas-kinetic cross-section σ_{gk} (Table 1). This result is of fundamental importance, because it provides a reliable basis for the elucidation of the real mechanism of the activation of polyatomic molecules in collisions without being restricted, as has been the usual practice hitherto in the vast majority of studies, to an arbitrary choice between two limiting mechanisms — strong collisions and the diffusional approximation. Unfortunately in the earlier determinations of $\langle \Delta E \rangle$ published previously the form of the distribution of populations during the relaxation of highly excited molecules was not monitored and in the interpretation of experimental data the authors introduced the seemingly obvious but in essence arbitrary assumption that $\sigma_E = \sigma_{gk}$.¹⁴ The results of a number of investigations^{69–71,86,87} have shown that the single-channel spectroscopic methods for the recording of the relaxation of highly excited molecules make it possible to determine only the product $\langle \Delta E \rangle \sigma_E$. For the separate determination of the multipliers, two-channel measurements with monitoring of the form of the distribution of the populations during relaxation are necessary. We may note that the spectroscopic recording of the steady state distribution of the populations of the HES of the molecules in the course of thermal decomposition behind shock waves, achieved earlier by Zaslonko and coworkers,^{45,106} also makes it possible to determine only the product $\langle \Delta E \rangle \sigma_E$.

The recording of the nonstationary distributions of the populations of the HES of molecules during relaxation is free from the disadvantages noted above and permits the separate determination of $\langle \Delta E \rangle$ and σ_E . Evidently the application of high-resolution spectroscopy is promising for the monitoring of the distribution function in the course of the relaxation of the HES in collisions. This has been most strikingly demonstrated in relation to the NO_2 molecule: a Fourier spectrometer was used for the recording of the IR emission spectrum of NO_2 molecules excited by a laser in the range 800–10 000 cm^{-1} with a spectral reso-

Figure 10. Transformation of the emission spectrum of the NO_2 molecule after excitation by a pulse laser.⁸³ Recording by the time-resolved Fourier transformation method. Resolution 1 cm^{-1} ; NO_2 pressure 1.7 Torr. The numerals against the spectra represent the time interval (μs) after the laser pulse up to the start of the measurement.

lution of 1 cm^{-1} and a time resolution of $0.5 \mu\text{s}$.⁸³ These are indeed excellent apparatus parameters and they led to impressive results. It was possible to measure the energy dependence of $\langle \Delta E \rangle$ for the $\text{NO}_2^* - \text{NO}_2$ collisions (a sharp increase from $\langle \Delta E \rangle < 50 \text{ cm}^{-1}$ with $\langle E \rangle \simeq 13\,000 \text{ cm}^{-1}$ up to $\langle \Delta E \rangle \simeq 1300 \text{ cm}^{-1}$ with $\langle E \rangle \simeq 20\,000 \text{ cm}^{-1}$) and a narrowing of the HES distribution as the relaxation process proceeds (Fig. 10).

In the initial instants of the relaxation, the NO_2 bands investigated (ν_3) have undergone a 'red' shift relative to the 'normal' frequency of 1617 cm^{-1} because the initial part of the emission signal is due to the emission from high levels with pronounced anharmonicity.

Unfortunately, no attempt was made⁸³ to relate the observed spectrum in the narrow frequency range to the total vibrational energy of the molecules and the simplest relaxation equation was used for the interpretation of the results of this study. We suggest that appreciably more information may be extracted from these data⁸³ on the basis of the description of the HES relaxation in the travelling population wave regime (see above).

This is well illustrated by the treatment of the primary experimental data on absorption in the 'hot' bands of the highly excited CS_2 molecules, such bands being generated on laser pulse excitation in the form of an initial δ -distribution (Figs 7 and 11).¹⁰³ If the shift of the absorption band observed in two-channel recording is ignored and they are treated by the single-channel method, as was done by Hippler *et al.*,¹⁰³ then the values of $\langle \Delta E \rangle$ obtained for the 'bottom' of the potential well are found to be very low. However, the observed shift of the absorption curves indicates the wave character of the propagation of the population wave. The values of $\langle \Delta E \rangle$ found agree well with the results for the SO_2 , NO_2 , CO_2 , and N_2O molecules in shock waves (Table 1).

The average values of $\langle \Delta E \rangle$ and σ_E obtained by Zaslonko and Mukoseev⁸⁷ lead to the possibility of solving the problem of the reconstruction of the real functional form of the energy dependence of the transition probability $P(E|E')$ in collisions and also demonstrate the presence of an appreciable fraction of collisions

Figure 11. Time dependence of the absorption of light in the regions of $\lambda = 240 \text{ nm}$ (1) and 260 nm (2) by CS_2 molecules on pulse excitation by an excimer laser with an emission wavelength of 316 nm at $T = 1500 \text{ K}$. Circles — experiment;¹⁰⁵ lines — calculation based on the model developed by Zaslonko and Mukoseev;⁸⁷ agreement with experiment at $\langle \Delta E \rangle = 100 \text{ kJ mol}^{-1}$; $k_{\text{rel}} = 3 \times 10^7 \text{ s}^{-1}$.

involving transfer of large portions of energy. Recently, such collisions have attracted the attention of investigators, since their appreciable role in high-temperature chemical kinetics has been suggested.⁶⁰

IX. Intramolecular relaxation

The problem of finding the characteristic rates of the intramolecular exchange of vibrational energy arose first in the interpretation of data on the kinetics of unimolecular reactions, vibrational predissociation, and the theory of mass spectra (see Refs 4 and 9 and the literature quoted therein).

Model ideas about the nature of the intramolecular relaxation (IVR) are used in all modern theories of elementary chemical reactions. The close relation between IVR and the chemical reaction step proper is illustrated by the energy diagram for the isomerisation process (Fig. 12). The quasi-harmonic description of the vibrations in the lower parts of the potential wells of the initial molecules and products becomes inapplicable on moving to the reaction barrier and at least one of the normal vibrations degenerates into translational motion along the reaction coordi-

Figure 12. Energy diagram illustrating the transitions between various vibrational motion regimes in polyatomic molecules during the isomerisation process; $3n-6$ normal vibrations of the initial molecules in the region of the initial reactants (I) pass to the stochastic vibrational regime in the vicinity of the reaction barrier with degeneration of at least one vibration to translational motion along the reaction coordinate with subsequent generation of a new set of $3n-6$ normal vibrations in the region (II) of the reaction products; (III) transition region.¹⁰⁷

nate [the vibrational frequency then becomes imaginary: $\omega = (k/\mu)^{1/2}$, $k < 0$].

The current state of studies on IVR has been described in a series of reviews (see, for example, Refs 107–109). Three dynamic IVR regimes, corresponding to different levels of excitation on the potential energy diagram, are distinguished. For a low level of excitation, whereupon the IVR times are relatively long, the application of IR diagnostic methods with high spectral resolutions is especially effective. In the second more extensive intermediate range of vibrational excitation energies, the IVR kinetics are usually followed by spectroscopic methods involving high vibrational overtones and methods involving the generation of HES with the aid of stimulated emission and fluorescence spectroscopic recording. The third group of studies refers to the region of highly excited states above the thresholds of dissociation, isomerisation, *etc.* reactions.

We shall quote two examples of specific IVR results. The first illustrates the dependence of the IVR rates on the structure and/or density of the states. The measurements were performed by the IR spectroscopic method with high (0.0005 cm^{-1}) spectral resolution in relation to the C–H bond in hydrocarbon molecules cooled in an ultrasonic jet. The results for a family of R–C≡C–H molecules with different end groups are presented in Table 2.

It can be seen that the rate of IVR depends little on the nature of the substituent groups: it changes by not more than a factor of

Table 2. Characteristic IVR times for the family of substituted ethyne derivatives.¹⁰⁷

Molecule	τ_{IVR} /ps	Density of vibrational spectrum /No. of states per cm^{-1}
$\text{CH}_2(\text{OH})-\text{C}\equiv\text{CH}$	500	20
$\text{HC}\equiv\text{CCH}_2\text{CH}_3$	270	22
$(\text{CH}_3)_3\text{CC}\equiv\text{CH}$	200	490
<i>gauche</i> - $\text{CH}\equiv\text{CC}(\text{CH}_3)_2\text{H}$	240	2400
<i>trans</i> - $\text{CH}\equiv\text{CC}(\text{CH}_3)_2\text{H}$	440	2400
$(\text{CD}_3)_3\text{CC}\equiv\text{CH}$	40	2800
$(\text{CF}_3)_3\text{CC}\equiv\text{CH}$	60	10^{11}

two when the density of states varies by ~ 2 orders of magnitude. The decrease in τ_{IVR} by approximately an order of magnitude is observed only for fluoro-substituted derivatives when the density of the vibrational spectrum increases by seven orders of magnitude.

The second example refers to the competition between IVR and predissociation. An interesting scheme for observations of this phenomena has been used for weakly bound clusters where even the excitation of the ground state in the near IR yields an excitation energy which is higher than the bond strength. Fig. 13 presents the measured and calculated spectra of the ν_5 antisymmetric DF stretching vibration in the trimer $(\text{DF})_3$ with hydrogen bonds.¹¹⁰ The average band contour corresponds to a D_{3h} cyclic structure. Fine structure, corresponding to a much denser spectrum (a difference by three orders of magnitude) than expected for a rigid molecule at 10 K can also be seen. This spectrum corresponds to the DF vibration with ring modes in the presence of mixing of various structures as a result of IVR. Mixing of this kind ensures an excitation energy sufficient to dissociate one hydrogen bond in the ring and to form the entropically more favourable flexible linear isomer, the characteristic time of the transition being ~ 40 ps. The opening of the trimer ring, which also corresponds to the dissociation of hydrogen bonds, is 10–100 times faster than the predissociation in the DF dimer. Such a large

Figure 13. High-resolution IR spectrum in the region of the antisymmetric DF vibration in the $(\text{DF})_3$ trimer formed on cooling in an ultrasonic jet to a temperature of 10 K (a) and schematic illustration of the transitions between two structures of the trimers with hydrogen bonds (b).¹⁰⁷ (1) experiment; (2) calculation.

difference between the rates may be associated with the influence of the strain in the ring structure on the dynamics of the dissociation of hydrogen bonds.

Interesting questions concerning the characteristic features of IVR in spaced out and dense spectra have been discussed in a number of communications (see, for example, Quack and Kutzelnigg⁹). The latest advances in the IVR theory have been described by User.¹¹¹

1. The mechanisms of intramolecular relaxation and spectroscopic data

We shall examine the results of the study of the mechanisms and rates of IVR. The presence of heavy atoms in the molecule may induce a retardation of IVR.¹¹² This phenomenon may be interpreted both within the framework of simple models of molecules of the type XY_n with identical light atoms Y and a heavy central atom X¹⁰ and within the framework of the model of local vibrational modes.^{113, 114}

In another mechanism, leading to a higher rate of IVR, the linkage between vibrational modes via a series of lower-order resonances is considered.^{115, 116}

One of the most important facts observed during the last decade is that there exists a fairly wide range of possible time scales for IVR with markedly different scales within the limits of one molecule^{117, 118} and large differences for different types of chemical groups.^{119, 120} The highly excited C–H vibrations in the alkyl and acetylenic groups may serve as a characteristic example. Vibrations have been investigated also by overtone vibrational spectroscopy for molecules ensuring a spectral resolution better than 0.1 cm^{-1} (Table 3).

The existence of internal rotations (such as those of methyl groups) also promotes a higher rate of IVR.^{22, 121}

Table 3. Intramolecular IVR relaxation times for the initial excitation of the vibration of the CH group in alkanes and ethynes.⁹

Compound	$\tau_{\text{IVR}}/\text{ps}$

^a ν = number of vibrational level.

2. The rate of intramolecular relaxation as a function of the excitation energy

For the interpretation of kinetic data on the reactions of HES of polyatomic molecules, it is important to have sufficiently accurate and at the same time simple relations suitable for estimates of the rate of IVR. This problem has been solved⁷¹ by employing the procedures of the theory of random functions. Relations were obtained for the estimation of the energy dependence of the time required for the vibrational motion to become stochastic, which agrees well with the results of trajectory calculations:

$$\tau_c \omega = (7 - 20) \frac{E_0}{\hbar \omega \nu^3},$$

(E_0 is the dissociation barrier, ω the average vibrational frequency, and ν the average number of vibrational states) and with the critical number of the average vibrational quantum ν_c for which the regular vibrational motion degenerates to random motion:

$$\nu_c = \left[\frac{64}{15} \frac{(s-1)!}{s^{s-1}} \frac{E_0}{\hbar \omega} \right]^{1/(s+2)}.$$

3. Unimolecular decomposition

The question arises whether unimolecular reactions, the kinetics of which should be interpreted outside the framework of the RRKM theory, can be observed. This question has for a long time troubled kineticists. The initial analysis of the problem was given in a communication¹²² in which the most promising formulations of experiments for the observation of deviations from RRKM kinetics were noted.

The discovery of the collision-free dissociation of polyatomic molecules on resonance IR multiphoton laser excitation and the successful highly selective separation of isotopes naturally required an adequate theoretical interpretation and the discussion concerning the limits of applicability of the statistical theory of unimolecular reactions was therefore revived (see, for example, Refs 12, 13, and 16). It was found that, at least on the time scale of a $\sim 10^{-9}$ s pulse, the RRKM theory described quite satisfactorily the kinetics of the spontaneous decomposition of active polyatomic molecules excited by a pulse from an IR laser.

Simultaneously with the development of spectroscopic methods, attempts were made to seek molecules on which one can demonstrate the nonstatistical features of the spontaneous decomposition rate constants $k(E)$, but these were unsuccessful. The constant $k(E)$ depends decisively on the rate of IVR (see above).

We may also note a novel approach, proposed for the observation of kinetic phenomena, which goes beyond the framework of the traditional RRKM theory.¹²³ This concerns the mechanism of reversible unimolecular reactions and the possibility, in principle, of determining the equilibrium canonical rate

constants at low pressures without resorting to a laborious measuring procedure and treatment of fall-off curves. It has been demonstrated on model examples using the solution of the FME that such paradoxical behaviour is realistic and methods for the corresponding observations have been noted. However, an experimental test of the ideas put forward by Quack¹²³ has not so far been carried out.

One of the latest attempts to discover deviations from the theory of unimolecular reactions on the decomposition time scale of the order of several microseconds has been made by Schlag and Levin.¹²⁴ The attempt to revise the statistical theory was stimulated by the apparently anomalously short decomposition times for large polyatomic molecules on excitation by electron impact in a mass spectrometer chamber. The authors used the classical version of the statistical theory but they introduced the hypothesis that for large polyatomic molecules the IVR process in the range of energies above the decomposition barrier does not ensure the complete mixing of the energy, as a result of which the number of effective oscillators s_{ef} is significantly smaller than the total number of oscillators $s = 3n - 6$. The large difference between s and s_{ef} is equivalent to an appreciable decrease in the lifetime of the active states of the large molecules. The question therefore arises to what extent the hypothesis that the IVR process may be so slow is valid. However, it was found that the above discrepancy between the observed and measured lifetimes of the active states of large molecules may be satisfactorily accounted for within the framework of a modified version of the statistical theory in which the vibrational temperature of the molecule has been taken into account and by calculating on this basis s_{ef} without resorting to the hypothesis that IVR is slow.¹²⁵

X. Reactions of highly excited states of polyatomic molecules

1. Spontaneous unimolecular decomposition

The first successful attempts to measure the specific rate constants $k(E)$ for the spontaneous decomposition of polyatomic molecules with an energy greater than the barrier D involved photoactivation in stationary and pulse regimes.⁶ In full conformity with the RRKM theory, the values of $k(E)$ found for the molecules of the cycloheptatriene family varied as the number of groups adjoining the main ring was altered (Fig. 14). The results of direct measurements of $k(E)$ in the decomposition of ions have been described.^{7,8}

Figure 14. Energy dependence of the specific rate constants for the spontaneous decomposition of active molecules of cycloheptatriene (CHT) (I) and its methyl derivative (Me-CHT) (II) and ethyl derivative (Et-CHT) (III, IV): (I) determination from the rate constant for isomerisation $k_{\infty}(T)$ under thermal conditions at the high-pressure limit; (2) interpretation of the stationary photolysis on the basis of the Stern–Volmer curves; (3) laser pulse photolysis with recording of the evolution of the ‘hot’ absorption bands.⁷

Figure 15. Femtosecond dynamics of the isomerisation of stilbene:¹²⁶ (a) transitions between different structures of stilbene and the trajectories of the motion of the representative point on the potential energy surface; (b) dependence of the rate constant for the spontaneous decomposition of stilbene (1), 4-methoxystilbene (2), 4,4'-dimethoxystilbene (3), and 2-phenylnidenestilbene (4) on, the amount by which the vibrational energy exceeds the barrier.¹²⁷

For direct measurements of $k(E)$ for reactions with neutral molecules, it is most effective to employ the following methods for the preparation of HES with a clearly defined energy state: single-photon excitation of high vibrational overtones within the limits of the ground electronic state; single-photon excitation of electronically excited states followed by rapid internal conversion to high vibrational levels of the ground state (Figs 1 and 7).

The methods based on the molecular 'hot band' spectroscopy proved entirely capable of ensuring the necessary level of sensi-

tivity and time resolution for measurements of $k(E)$. Sufficiently 'broad' HES distributions are also obtained on multiphoton IR excitation.

The results of direct measurements of $k(E)$ by various methods have been published.^{126, 127} The isomerisation reactions of stilbene (Fig. 15) and the spontaneous decomposition of NCNO molecules by ultrashort laser pulses (Fig. 16) have been examined. The manifestation of threshold effects for isomerisation and appre-

Figure 16. Energy diagram for the transitions on laser excitation of NCNO molecules and the spontaneous decomposition of NCNO* molecules excited by a laser pulse to an energy region above the spontaneous decomposition barrier (a) and dependence of the spontaneous decomposition rate constant on the amount by which the vibrational energy of the NCNO* molecules exceeds the decomposition barrier $E_{\text{th}} = 17083 \text{ cm}^{-1}$ (b).¹²⁷ Results of theoretical calculations of $k(E)$: (1) calculation based on the canonical theory of the reaction phase space; (2) and (3) calculation using modified versions of the statistical theory; circles — experimental data.

cial changes in the position of the barrier and in the rates of isomerisation as a function of structure can be seen in Fig. 15.

2. Bimolecular reactions of highly excited molecules

The characteristic features of bimolecular reactions of diatomic and polyatomic molecules with a moderately high vibrational excitation have been examined in several reviews (see, for example, Bauer⁶⁸ and Zewail¹²⁶).

We are interested in bimolecular reactions of polyatomic molecules with a sufficiently high vibrational energy. The concept of the vibrational mode loses significance for such molecules and their reactivity depends primarily on the total vibrational excitation energy or, more precisely, on the distribution function with respect to the total vibrational energy.

Analysis of the activation characteristics of bimolecular reactions remains the first and so far the only systematic method for the kinetic determination of the specific rate constants for bimolecular reactions of the HES of polyatomic molecules.⁶⁹

The principal idea underlying the activation mechanism is illustrated by the following Scheme 1.

Scheme 1

Unimolecular reactions	Bimolecular reactions
$A \longrightarrow \text{products}$	$A + B \longrightarrow \text{products}$
$A + M \xrightleftharpoons[k_{-a}]{k_{+a}} A^* + M$	$A + M \xrightleftharpoons[k_{-a}]{k_{+a}} A^{**} + M$
$A^* \xrightarrow[k(E \geq E_m)]{k(E)} \text{products}$	$A^{**} + B \xrightarrow[k(E \geq E_{\text{bim}})]{k_b(E)} \text{products}$
$k_d = \frac{k(E)(k_{+a}/k_{-a})}{1 + (k(E)/k_{-a}M)}$	$k_{\text{bim}} = \frac{k_b(E)(k_{+a}/k_{-a})}{1 + (k_b(E)[B]/k_{-a}[M])}$
Limiting cases	
Equilibrium regime	
$[M] \longrightarrow \infty$	$\frac{k_b(E)}{k_{-a}} \xi_B \ll 1$
$k_{d,\infty} = \frac{k(E)k_{+a}}{k_{-a}}$	$k_{\text{bim},\infty} = \frac{k_b(E)k_{+a}}{k_{-a}}$
Regime limited by activation	
$[M] \longrightarrow 0$	$\frac{k_b(E)}{k_{-a}} \xi_B \gg 1$
$k_{d,0} \simeq k_{+a}[M]$	$k_{\text{bim},0} \simeq \frac{k_{+a}}{\xi_B}$

A^* and A^{**} are active molecules which have acquired in activating collisions an amount of energy greater than the barrier to the unimolecular (E_m) and bimolecular (E_{bim}) reactions respectively; ξ_B is the mole fraction of component B in the mixture.

The dependences of the observed bimolecular reaction rate constant on mixture composition can be conveniently referred to as transition curves by analogy with unimolecular reactions. We shall now formulate the relations which have been established on the basis of the interpretation of the fall-off curves for the rate constants for bimolecular reactions involving nitrogen oxides (Table 4).

1. The ratio $\bar{k}_b/k_{-a}$ is in the range 4–20. Here $\bar{k}_b$ is the rate constant for the bimolecular reaction averaged for the energies above the barrier E_{bim} and k_{-a} is the deactivation rate constant.

2. The constant k_b depends both on the store of vibrational energy and on the gas temperature. The translational barrier to the bimolecular reaction of the HES is $\sim 10\%$ of the overall barrier.

Table 4. Rate constants for bimolecular reactions (k_{bim}) and the effectiveness of collisions (β_c) for highly excited states of the NO_2^* and N_2O molecules.

Reaction	$\bar{k}_b/Z_{\text{gk}}^a$	T/K	E_b /kcal mol ⁻¹	$10^2\beta_c^b$
$\text{N}_2\text{O}^* + \text{NO}$	0.08	1680	41	0.4
$\text{N}_2\text{O}^* + \text{CO}$	0.06	1590	54	0.3
$\text{NO}_2^* + \text{NO}_2$	0.14	1670	39	0.3

Note. 1. The results for k_b and β_c were obtained on the basis of a theoretical description of the transition curves (Fig. 17). 2. The dependence of β_c on the excitation energy is fitted by the relation $\beta_c \simeq E^2$. 3. The dependence of k_b on the translational temperature T_g is fitted by the equation $k_b \simeq \exp(-E/RT)$, where E is the translational barrier to the reaction of the vibrationally excited molecule.

^a $\bar{k}_b$ is the average value in the region $E > E_b$ (the bimolecular reaction barrier) and Z_{gk} is the frequency of the gas-kinetic collisions. ^bThe value of β_c for the excitation energy in the vicinity of the barrier to the bimolecular reaction: $\beta_c \simeq \langle E \rangle^2$.

3. The observations for k_b have been interpreted on the basis of the collision-stochastic model, according to which during the period of the interaction of the reactants all the vibrational modes of the polyatomic molecules contribute to the reaction rate (we may note that this property is fully correlated with the multiple ‘chattering’ collisions mechanism).

4. The activation characteristics are observed only for reactions with a high barrier, *i.e.* their rates increase markedly at high temperatures.

The question arises why nonequilibrium effects involving depletion of the distribution function with respect to vibrational energy in the vicinity of the barrier are manifested precisely for reactions with fairly high barriers. This can be naturally attributed to the fact that, for reactions of polyatomic molecules with a sufficiently high level of excitation, the vibrational motion of the active molecules is nearly stochastic and the reactivity therefore increases as a consequence of the contribution of all the vibrational modes. Furthermore, the ratio k_b/k_{-a} , which determines the scale of the depletion of the distribution functions, increases with increase in temperature.

The distorting influence of bimolecular reactions of the HES of the NO_2 and SO_2 molecules on the form of the distribution function with respect to energy has been demonstrated.^{49, 56} In

Figure 17. Transition curve for the rate constant for the exchange reaction $\text{N}_2\text{O} + \text{NO} \rightarrow \text{N}_2 + \text{NO}_2$: (1) 1% $\text{N}_2\text{O} + 2\%$ NO , 2.5% $\text{N}_2\text{O} + 97.5\%$ NO , Ar diluent; (2) recalculation of data in terms of inflammation limits; (3) 2.5% $\text{N}_2\text{O} + 25\%$ NO , CO_2 diluent. Data (1) and (3) were obtained in shock waves; ξ_i —mole fractions of the components; $\Sigma \xi_i \beta_{c,i}$ —the effectiveness of the partners $\beta_{c,i}$ in activating collisions averaged over the mixture; k_{obs} and k_{eq} —the observed rate constant for the bimolecular reaction and its equilibrium value respectively.

particular, this influence is fully correlated with the macroscopic manifestations of the state of nonequilibrium (Fig. 17).^{69–71}

An interesting development of the idea concerning the role of internal excitation on the reactivities of the partners in bimolecular reactions has been put forward.⁷⁴ The high effectiveness of the reactions under conditions where the reactants are ‘dissolved’ in a cluster which undergoes impact heating can be explained by the fact that the internal degrees of freedom of one or both reactants are excited by the cluster.

3. Generalising concepts for the bimolecular reactions of highly excited polyatomic molecules

It appears at first sight that the family of bimolecular reactions is so diverse that it is difficult to speak of any kind of generalising concepts. Fortunately such is not the case and we shall in fact attempt to illustrate this.

The statistical theory of bimolecular reactions rightfully occupies the central place in the list of such concepts. The possibilities of this theory have been best demonstrated in Troe’s review, which has been justifiably given the emotive title ‘The Colourful World of Bimolecular Reactions’.⁶²

Why is the rating of the statistical theory so high? There are two main reasons. Firstly, the wide occurrence of bimolecular reactions, proceeding via a stage involving the formation of a long-lived complex, has an effect; secondly the entire procedures of the RRKM theory are applicable to reactions of this kind, which creates the necessary preconditions for the development of an overall computational set up.

The second concept may be regarded as heuristic systematic treatment. Such systematic treatment is based on the subdivision of the activation barrier for the reaction into the contributions due to the vibrational and translational degrees of freedom and the significance of the coefficient of the utilisation of the vibrational energy in overcoming the barrier is assigned to the ratio of these contributions.^{2, 3, 129}

The collision-stochastic model may be considered as the third concept.⁷¹ Initially this concept was put forward to account for the high preexponential factors for the bimolecular exchange reaction rate constants (Table 5), after which experimental data confirming it were obtained also by laser activation of polyatomic molecules.

Table 5. The Arrhenius parameters for the rate constants for certain bimolecular exchange reactions of valence-saturated diatomic and triatomic molecules ($k = Ae^{-E/RT}$).

Reaction	$\lg A^a$	E^b	T/K
$N_2O + CO \longrightarrow CO_2 + N_2$	16.0	53	1400–3000
$N_2O + NO \longrightarrow NO_2 + N_2$	15.2	48	1360–1890
$NO_2 + NO_2 \longrightarrow NO_3 + NO$	14.8	34	1400–2300
$NO_2 + CO \longrightarrow CO_2 + NO$	14.4	33	1400–2300
$SO_2 + SO_2 \longrightarrow SO_3 + SO$	15.0	70	3000–4000
$CO_2 + C^{18}O \longrightarrow C^{18}O_2 + CO$	16.33	66.7	3000–4000
$CO_2 + ^{13}CO \longrightarrow ^{13}CO_2 + CO$	13.94	48.9	3000–4000

^a The dimensions of A are $\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}$. ^b The dimensions of E are kcal mol^{-1} .

If all the internal degrees of freedom contribute to the overcoming of the reaction barrier, then the equilibrium rate constant for bimolecular reactions k_{eq} is defined by the equation

$$k_{\text{eq}} = A_{\text{eq}} \exp\left(-\frac{E_0}{RT}\right) = \int_{E_0}^{\infty} k_b(E_V, E_R T) f_0(E_V, E_{RT}) dE_V dE_{RT}. \quad (12)$$

Here A_{eq} is the pre-exponential factor, E_0 the activation energy for the equilibrium bimolecular reaction, $k_b(E_V, E_{RT})$ the rate constant for the bimolecular reaction as a function of the vibrational (E_V) and rotational-translational (E_{RT}) energy, and $f_0(E_V, E_{RT})$ the distribution function, proportional, in particular, to the density of the energy spectrum $\rho(E)$. The proportionality of k_{eq} to the total density of the spectrum $\rho(E)$ therefore follows from Eqn (12), which is in fact the reason for the high pre-exponential factors for the equilibrium bimolecular reaction rate constants.

If one is dealing with a detailed kinetic analysis of equilibrium rate constants for bimolecular reactions and hence for processes involving HES during the collision of the partners, then the simplest two-level mechanism must be supplemented by a more detailed consideration of processes involving excited molecules at the ‘inlet’ (initial reactions) and ‘outlet’ (reaction products). One of the versions of such consideration of the reaction

where AB and C are polyatomic molecules and P_1 and P_2 are the products, is presented in the following scheme:

Here $AB^*(E)$ is a molecule with an internal energy E , which is sufficient for it to react, $k_a(E)$ is the rate constant for activation in the energy range $E + dE$, $[AB^*(E) \cdot C]$ is the collision complex in which the distribution of energy is determined by the initial distribution of the internal energy of the fragments before collision and the relative motion of AB^* and C at the effective interaction potential, $k_B(E, E_t)$ is the rate constant for the ‘capture’ process indicated above, E_t is the energy of translational motion, $k_r(E)$ is the rate constant for the redistribution of energy in the collision complex, $(ABC)^*$ is the activated molecule in the traditional sense as understood in the RRKM theory, and $[AB^*(E') \cdot C]$ is the collision complex.

The flux of species through the configuration of the activated state is proportional to the partition function, so that the ratios of the vibrational-rotational partition functions of the collision complex (Q^*) and the activated molecule ($Q^{\#}$) must be compared in making a choice of the rate-limiting stage in the chain of transformations of the states involved in bimolecular reactions of active molecules. For the ratio of the vibrational-rotational partition functions, one may write

$$\frac{Q_{\text{vr}}^*}{Q_{\text{vr}}^{\#}} = \frac{Q_{\text{rot}}^*}{Q_{\text{rot}}^{\#}} \left(\frac{E_0}{RT}\right)^{(1/2)s_r^* + s_v^{\#}} \times \times \frac{E_0^{s_v^{\#} - s_v^*} F_E}{\Gamma[s_v^* + (1/2)s_r^* + 1]} \times \frac{\prod_i \hbar \nu_i^{\#}}{\prod_i \hbar \nu_i}, \quad (13)$$

where the * and # superscripts refer to the collision and activated complexes respectively, Q_{rot}^* and $Q_{\text{rot}}^{\#}$ are the rotational partition functions, s_v and s_r are the numbers of vibrational and rotational degrees of freedom, and F_E is a multiplier taking into account the energy dependence of the number of states of the collision complex with an energy greater than E_0 .

The ratio of partition functions defined by Eqn (13) depends on temperature. There exists a boundary temperature T_k at which

the ratio is close to unity. At $T > T_k$, the processes in the collision complex become rate-limiting and the bimolecular rate constant is determined by the redistribution of energy.

Turning now to specific examples, we may note that calculations of T_k by Eqn (13) yield 800–1400 K for the $N_2O^* + CO$ and $N_2O^* + NO$ reactions depending on the hypotheses concerning the parameters of the activated complex.⁷³

Thus the manifestation of nonequilibrium effects in bimolecular exchange reactions of polyatomic molecules depends greatly on the relation between the rate-limiting stages presented in Eqn (13) and is most probable for fairly high temperatures.

We may note, incidentally, that the deviations of the bimolecular rate constants from the equilibrium values are less pronounced than for the unimolecular decomposition reactions (Fig. 13). This is apparently one of the reasons why the non-equilibrium effects in bimolecular reactions were assumed to be relatively insignificant and did not receive sufficient attention.

One may postulate that the collision-stochastic model of bimolecular reactions is capable of yielding satisfactory results also for laser-stimulated reactions.

As an illustration, we shall consider the calculations for the reactions of BCl_3 molecules, excited by IR laser radiation, with H_2 molecules (energy ~ 1 J per pulse, duration of pulse 0.2 μs),¹³⁰ which confirms the principal postulates of the collision-stochastic model for bimolecular reactions. At a sufficiently high level of excitation, the chlorine atoms in the BCl_3 molecule are considered to have lost their permanent locations (as happens in the melting process in a solid) and they then move more independently and within the limits of the molecule may have significantly longer ‘free paths’. The ‘partly free’ chlorine atom subsequently reacts with the incoming H_2 molecule:

Several assumptions, taking into account the limitations to the mobility of the reactants within the limits of the initial molecules, are used in the calculations.

This model is a natural development of the ideas concerning the influence of the stochastic nature of the vibrations on the occurrence of bimolecular reactions and furthermore, as regards calculation, it represents a successful example of the application of relations employed in gas-phase and liquid-phase kinetics. In conformity with the model adopted, the reaction rate constant k_1 may be written in the form

$$k_1 = P_1 v_1 Q_1 \exp\left(-\frac{E_1}{T_1}\right),$$

where P_1 is the probability of the reaction

v_1 is the average relative velocity of BCl_3 and H_2 , Q_1 is the overall cross-section for the collision of H_2 and BCl_3 , E_1 is the activation energy for the reaction, and T_1 is the thermal energy of the H_2-BCl_3 ‘reacting mixture’. The reaction probability P_1 can be written in the form

$$P_1 = Z_{12} k_2 n_2 t,$$

where Z_{12} is the steric factor for the reaction of chlorine and hydrogen within the limits of the collision complex and k_2 is the gas-phase rate constant:

$$k_2 = v_2 Q_2 \exp\left(-\frac{2650K}{T_2}\right),$$

where v_2 is the relative velocity of BCl_3 and H_2 , Q_2 is the overall scattering cross-section for the H_2-Cl system, T_2 is the temperature at the centre of mass of the incoming hydrogen molecule and

chlorine in BCl_3 , and n_2 is the density of chlorine atoms in BCl_3 . The ‘contact time’ of the reactants is represented by the equation

$$t = \frac{1}{n_2 Q_2 v_2}.$$

The temperature of the chlorine atoms in this model is proportional to the kinetic energy of the atoms, equal to half the absorbed energy of the laser pulse (the second half represents the potential energy):

$$T_{Cl} = \frac{\hbar c n_v \bar{\nu}}{2 n_a (3/2) k_B} + T,$$

where n_v is the number of quanta of the laser radiation absorbed by the molecule, $\bar{\nu}$ the energy of the radiation quantum in cm^{-1} , n_a the number of atoms in the ‘hot molecule’, k_B the Boltzmann constant, and $(3/2)k_B$ the heat capacity of the translational degrees of freedom.

In the example of the heating of BCl_3 by the radiation from a CO_2 laser ($\nu = 950 \text{ cm}^{-1}$, $n_v = 10$, $n_a = 4$) considered by Kueba and Wolfrum,¹²⁸ $T_{Cl} \approx 1140 \text{ K} + T_1$ was obtained. The temperature at the centre of mass of the interacting H_2-Cl system is defined by the equation

$$T_{H_2-Cl} \approx T_{H_2} \left(1 + \frac{T_{Cl}}{T_{H_2}} \frac{M_{H_2}}{M_{Cl}}\right),$$

where T_{Cl} and M_{Cl} are respectively the temperature and the atomic weight of chlorine, $T_{H_2} = 300 \text{ K}$, and M_{H_2} is the molecular mass of hydrogen. T_{H_2-Cl} is found to be relatively low ($\sim 380 \text{ K}$) for the parameters quoted above.

Calculations performed with the aid of the above relations for the collision-stochastic model agree well with experimental data for the laser stimulation of the BCl_3-H_2 reaction.

In conclusion we shall note the most significant characteristic features of the activation mechanism of bimolecular reactions.

1. The vibrational energy of a polyatomic molecule is particularly effective in the bimolecular interaction of the partners when the reaction barrier is higher than the threshold of the transition to stochastic motion.

2. The stochastic nature of the vibrational motion explains the phenomenon of the so called multiplicity of collisions in the interaction of partners (the concept of a differentiated reaction coordinate then loses its significance; all these features together with the effect of the mixing of the modes are responsible for the high pre-exponential factors for the equilibrium rate constants [see Teitelbaum⁷³ and Table 5]).

3. The existence of the ‘translational barrier’ for bimolecular HES reactions is in essence equivalent to the introduction of the temperature at the centre of mass of the ‘hot’ molecule and the ‘cold’ partner.⁷¹

The above comparison indicates the conditions under which the traditional versions of the transition state method fail to work and should be replaced by the collision-stochastic model.

XI. Conclusion

The ‘hot’ band absorption spectroscopy of molecules makes it possible to investigate the influence of the form of the energy distribution function and of the dynamic parameters of the molecules on their absorption spectra, which constitutes the basis for the observation of highly excited molecules. The data on the properties of the distribution function then obtained are used in the analysis of kinetic processes with participation of HES on the basis of the solution of the fundamental microkinetic equation.

The emission technique in the visible, UV and IR regions of the spectrum, both in the traditional version and especially with Fourier transformation by virtue of the high sensitivity and high

time resolution, is very promising for the probing of HES distributions in reacting systems with thermal and laser pumping. The linkage between the optically active emitting electronic states and the highly excited states of the ground electronic term provides an instrument for the detection of these states and the energy distributions within the limits of both terms by virtue of reverse electronic relaxation.

The possibility of calibrating the 'hot' band absorption and emission spectra of polyatomic molecules constitutes one of the most important preconditions for the successful application of these methods in the study of nonequilibrium HES distributions.

Measurement of the kinetics of the transformation of HES distributions on thermal or laser pulse excitation is most productive in the determination of the HES energy exchange parameters in collisions.

The most realistic description of experimental data on the HES energy exchange kinetics in collisions is based on the superposition of strong and weak collisions.

In order to create an integral picture of the energy exchange and reactions of HES and also for the development of generalising concepts, it is necessary to carry out a joint analysis of the information obtained on the basis of both direct spectroscopic methods and indirect kinetic methods.

In conclusion, we shall make several predictive comments. Firstly, the ratio of computational and experimental studies will steadily change in favour of the former; the contribution of trajectory calculations will increase greatly. Secondly, the most promising way of developing the theory of processes with participation of HES involves the combination of trajectory calculations and simple basic models. Thirdly, DF calculations will be closely related to the spectra of the reacting components and calculations of this kind will become a standard procedure for investigators in the field of molecular and chemical kinetics.

Abstract. Data on the processes of electrochemical reduction and oxidation of organosilicon compounds of various classes as well as on the interaction of these compounds with electrically generated reagents are generalised and surveyed systematically. The electrochemical reactivity of organic derivatives of silicon is considered taking into account their structures and reaction conditions. The bibliography includes 245 references.

I. Introduction

Electrochemical procedures are widely used for the synthesis of various organic and organoelement compounds including organic derivatives of silicon, the chemistry of which has developed especially intensely in recent years. Up to now, vast experimental material has been accumulated in this field. On the one hand, numerous highly selective preparative procedures for the synthesis of target products or intermediates of the functionalisation of organosilicon compounds have been developed. On the other hand, in the studies of redox reactions involving these compounds, a clear-cut relationship between various intramolecular interactions and electrochemical reactivity has been elucidated. Thus, the electrochemistry of organosilicon compounds, apart from its purely preparative aspect, is necessarily concerned with the problems of physical organic chemistry, *i.e.* the structures of the frontier orbitals, transfer of electronic effects in the molecules and their influence on reactivity.

The purpose of this review is to consider systematically the known processes, classifying them according to the type of reaction and to follow, where possible, the roles of various factors determining the reactivity of organosilicon compounds in electrochemical transformations.

II. Electroreduction of chlorosilanes

Chlorosilanes are among the first organic derivatives of silicon synthesised. At present, they are the most frequently encountered and most readily accessible organosilicon compounds. Apparently, it is for this reason that chlorosilanes were first to attract the attention of electrochemists. Chlorosilanes themselves are difficult to reduce electrochemically, and the cathodic processes involving them are associated most frequently with the initial electrogeneration of a carbanion (or another nucleophile), which then replaces a Cl atom in the chlorosilane molecule. Most of the cathodic reactions involving chlorosilanes are versions of this process. Anodic processes involving organosilicon compounds are more diverse (regarding the types of compounds and reactions), although the number of publications dealing with reduction is much greater than that on oxidation.^{1–13}

The first studies on the electrochemistry of chlorosilanes (R_nSiCl_{4-n} , where $R = Me, Et, Vin, Ph$) were published more than twenty years ago;^{14–16} however, they were only indirectly associated with the problem under consideration, because they described electroreduction of the protons of the hydrogen chloride arising *via* hydrolysis of chlorosilanes.^{14, 17–20} Nevertheless, these studies have resulted in the development of two efficient methods: a method for electrochemical dehydration of dimethylformamide (DMF)²¹ and a procedure for determining the quantity of water in this solvent.²² Both methods are based on fast hydrolysis of chlorosilanes.

Later, various researchers have obtained electrochemical characteristics for the reduction of chlorosilanes (Table 1); these characteristics were markedly dissimilar even for the same compounds. Since the reduction of chlorosilanes is irreversible and they are highly electrophilic and extremely susceptible to hydrolysis, the effective reduction potentials of these compounds are influenced by many factors (material of the electrode, solvent, supporting electrolyte and, obviously, nucleophilic impurities). Therefore, the fairly contradictory data presented in Table 1 can be rather regarded as an illustration of the confusion reigning in this field. It can be only noted that the nature of the halogen (all other factors being equal), apparently, exerts no significant influence on the reduction potentials.^{23, 24} The nature of the organic substituent at the Si atom is more important. Chlorotrimethylsilane **1** accepts an electron at a more negative potential than chlorotriphenylsilane **2**,²⁵ although the discussion about the

potential for the cathodic reduction of the silane **1** has not yet been completed.^{23, 26–37}

The reduction potentials of most of the studied chlorosilanes, determined by various authors, have relatively large negative values (Table 1). Evidently, this is due to an activation mechanism of the electron transfer, which is accompanied by the simultaneous rupture of the Si–Cl bond. Jammegg *et al.*³⁶ claim that the peaks they detected at -0.1 and -0.2 V (vs SCE) refer to the products of reduction of this bond, although no products with the Si–Si bond were detected after the electrolysis of the chlorosilane **1** at $E \approx -1$ V. It follows from the experimental procedure described in this study that the researchers aimed at minimising the content of the residual water and HCl but ignored the presence of dissolved oxygen, which produces reduction peaks in this range of potential. Therefore, the signals at -0.1 and -0.2 V are most likely associated with the reduction of oxygen.³⁶

An important role in the electrochemical reduction of chlorosilanes belongs to the solvent^{23, 24, 32–34} and to the supporting electrolyte used,³⁵ because nucleophilic solvents can be coordinated by chlorosilanes, and, consequently, the silicon atoms acquire a planar configuration favourable for nucleophilic reactions.

The reduction of 6,6-dichloro(or fluoro)-6*H*-dibenzo-[*c,e*][1,2]oxasilanes in the DME/Bu₄NI system occurs as a single-electron reduction of the phenanthrene type ring ($E_{1/2} = -1.96$ and -0.96 V vs Hg pool for fluoro- and chloro-derivatives, respectively) and the subsequent two-electron transfer accompa-

nied by the abstraction of a halogen ($E_{1/2} = -2.31$ and -1.41 V vs Hg pool).⁴⁷

The products obtained by electroreduction of chloro(phenyl)silanes in DME have been identified as phenylsilanes based on a comparison of their UV spectra with the spectra of individual compounds.³⁹

(The E values are given with respect to 0.001 M Ag/AgClO₄.)

It has been believed that DME or the Bu₄N⁺ cation serves as the source of the hydrogen atoms needed for the formation of silanes. According to more recent studies,^{37, 48–52} reduction of chloro(phenyl)silanes under similar conditions yields mostly di- and tetra-silanes. Nevertheless, the results of the electrolysis of chlorotriphenylsilane **2** in the presence of phenol serving as a donor of protons²³ attest to the formation of the Ph₃Si[−] anion, because this reduction affords hydride **8** rather than the dimer. The fact that 1 F of electricity is consumed for the reduction of 1 mole of the chlorosilane **2** indicates that the electrode process includes the reaction between the nucleophile PhO[−] and the initial chlorosilane molecule.

When chlorotrimethylsilane **1** was reduced in MeCN using Bu₄NClO₄ as the supporting electrolyte, hexamethyldisiloxane was obtained, whereas in the presence of Bu₄NCl, the process gave hexamethyldisilane **9**.²⁵ Electroreduction of chlorosilane **1** in DME with a platinum or lead cathode and mercury anode^{48, 53} under non-controlled conditions (output voltage 80 V, current density 1–6 mA cm^{−2}) for 4–10 days gives rise to disilane **9** in a current yield of 100%.³⁷ The researchers³⁷ mentioned that the disilane **9** was also produced at the anode; however, since the electrolysis was carried out in an undivided cell, they were, most likely, mistaken.

It is assumed that the electrosynthesis of disilanes from chlorosilanes R₃SiCl in aprotic solvents follows two competing pathways.^{23, 24, 40} The first pathway includes nucleophilic interaction of the R₃Si[−] anion (resulting from the two-electron reduction of chlorosilane) with the initial chlorosilane, while the second pathway consists in the radical dimerisation of the products of its single-electron reduction (R₃Si[•] radicals).

Electroreduction of a great number of monochlorosilanes occurs with the consumption of 1 F mol^{−1} of electricity and yields symmetrical disilanes (Table 2).

Table 3 presents the results of preparative electroreduction of mixtures of chlorosilanes giving asymmetrical disilanes with various substituents at the silicon atoms. Electrolysis of a 1 : 1 mixture of triarylchlorosilane and chlorotrimethylsilane **1** yields an asymmetrical disilane as the only product; hence, this is a convenient method for the synthesis of these compounds.

R = Ph, *p*-FC₆H₄, *p*-MeC₆H₄.

The above proves that triarylchlorosilane rather than chlorotrimethylsilane is the first to be reduced.³⁷ The reduction of

^a Current yield; ^b TDA is tris(3,6-dioxaheptyl)amine; ^c using Me_2Bu^tSiCl instead of Me_3SiCl ; ^d 4% of a symmetrical tetrasilane was also obtained.

chloro(methyl)diphenylsilane **3** (to give disilane in 90% yield) and dichloro(methyl)phenylsilane **5** occurs according to a similar scheme.^{57†} In the latter case, trisilane **11** is formed in 25% yield, together with the monosilylation product formed in 75% yield.

† From this point on, the amounts of electricity (Q) consumed in the electrolysis per mole of the substance were taken from the original publication; in those cases where the original source contains no coulometry data, the numbers of electrons per molecule (n) calculated according to the stoichiometry of the process are presented in the schemes.

Since the chlorosilane **1** is more difficult to reduce than most other chlorosilanes,^{27–29} while the rate of nucleophilic substitution in **1** is markedly higher than the rate of the S_N2 reaction

involving the second chlorosilane, asymmetrical chlorosilanes are formed predominantly. It is noteworthy that Bordeau *et al.*⁴⁹ obtained only an asymmetrical product in the reduction of a mixture of two chlorosilanes, whereas other researchers^{37, 58} have detected some quantity of a symmetrical disilane (derived from the chlorosilane, the reduction potential of which was less negative) in the reaction products; finally, Shono⁵⁶ has reported that equal amounts of symmetrical and cross-disilanes are formed.

The reduction of chlorosilanes R_3SiCl and $R_2R'SiCl$ yields symmetrical dimeric derivatives $(R_3Si)_2$ and $(R_2R'Si)_2$ as the major products (see Table 3). In the case of the chlorosilanes **1** and **2**, these dimers are obtained in nearly quantitative yields,³⁷ while in the case of bromotrimethylsilane, the yield of the dimer is 20%, and iodotrimethylsilane gives no dimer at all.^{25, 43} It should be noted that symmetrical and asymmetrical disilanes are produced in good yields in the electrochemical reactions of appropriate chloro-derivatives even in those cases where the corresponding chemical reactions with metals give no results.

The main products resulting from the reduction of dichlorosilanes are the corresponding polysilanes.^{37, 43, 48} Thus the electroreduction of dichlorodiphenylsilanes under conditions similar to those described in Ref. 37 yields insoluble octaphenylcyclotrasilane **12** and some quantity of polymeric products.⁴⁸

Reduction of chloropentaphenyldisilane has led to a mixture of products.⁴⁸

The reactions of chloro(methyl)phenylsilanes follow a more complex pathway. For example, in the case of dichloro(methyl)phenylsilane **5**, apart from the dimer, a product resulting from reaction with DME used as the solvent was obtained.

Data on the cathodic reduction of trichlorosilanes are contradictory. It has been reported⁴⁸ that electrolysis of PhSiCl_3 **13** also affords a product formed in reaction with the solvent.

The fact that no polymeric compounds with Si–Si bonds were detected among the reaction products was explained⁴⁸ by steric reasons. Conversely, the electrolysis of MeSiCl_3 results in the formation of the polymer $(\text{MeSiCl}_{0.22})_n$ unstable in air, while the electrolysis of SiCl_4 gives rise to the polymer $(\text{SiCl}_{0.77})_n$.^{28, 59}

A rare case where tetramesityldisilene is formed in the reduction of dichlorodimesitylsilane has been described.⁴⁴ This is the only example of electrosynthesis of a compound incorporating a Si = Si double bond.

7

The reduction of dichlorodimesitylsilane **7** was carried out in the potentiostatic regime at $-3.2 \text{ V vs Ag/Ag}^+$ in DME/ $\text{Bu}_4\text{N}-\text{ClO}_4$ using an Hg cathode and an Ag anode with separated

cathode and anode chambers. The yield of tetramesityldisilene of the 'pure for analysis' grade amounted to 20%.

Electroreduction of terminal dichlorosiloxanes affords cyclic compounds containing Si–O and Si–Si bonds.^{30, 60, 61} The five-membered cyclic product is formed in one step, while the six-membered product is formed *via* a linear dimeric dichlorodisiloxane, which can be isolated from the reaction mixture.

R, R' = Me, Vin, Et.

When silyl intermediates generated at the cathode react with 2,3-dimethylbutadiene, 1,1-disubstituted 3,4-dimethyl-1-silacyclopent-3-enes **14** are produced together with linear polysilanes.³⁸

The results of cathodic electrosynthesis of substituted silacyclopentenes **14** under various conditions are presented in Table 4.

Electrosynthesis involving the monochlorosilane **3** and carried out in DME with tetrabutylammonium perchlorate as the supporting electrolyte yields symmetrical disilane **15**, some quantity of disiloxane and products resulting from the addition to the diene, namely, 1-(methyldiphenylsilyl)-2,3-dimethylbut-2-ene and 1,4-bis(methyldiphenylsilyl)-2,3-dimethylbut-2-ene.

Trimethyl(phenylethynyl)silane **16** is formed in the electroreduction of halotrimethylsilanes Me_3SiHal (Hal = I, Cl, F)^{31, 62–64} in the presence of phenylacetylene **17**. Using the method of latent limiting currents, the stoichiometry of the interaction of the latter with electrically generated silyl anions was found to be 1 : 1. This corresponds to the protonation of the silyl anion by phenylacetylene to give the $\text{PhC}\equiv\text{C}^-$ carbanion, which substitutes

Table 4. Electroreduction of dichlorosilanes in the presence of 2,3-dimethylbutadiene.

nucleophilically the chlorine in a molecule of the initial chlorosilane **1**.

The compound **16** can be once again silylated. In this case, the process is accompanied by a decrease in the multiplicity of the bond and affords a nucleophilic addition product, 1,2-bis(trimethylsilyl)-1-phenylethene **18**.

It is of interest that when this process is conducted at a **1**:**17** ratio of 4:1 by passing 5 F mol⁻¹ of electricity in a flow-type electrolyser consisting of two coupled cells³¹ (an ECE cell), in which the R¹R²R³Si⁻ anions electrically generated at the cathode of the first cell are partially oxidised in the second cell to give R¹R²R³Si[•] radicals, disilylated product **18** is obtained in a yield of up to 75%.

Under similar conditions, styrene yields only products of addition at the double bond.⁶³

Silyl anions resulting from the reductive cleavage of the Si–Cl bonds in chlorosilanes can be ‘stabilised’ as organometallic intermediates *via* the formation of a Si–M bond (M is the metal that forms the soluble anode). The nature of these intermediates is not completely clear, but they can be kept in solution for several days and used in reactions with electrophilic reagents.^{27, 65, 66}

Cyclohexylsilyl derivatives have been prepared by electroreduction of a number of chlorosilanes in the presence of cyclohexene.^{63, 67–70} Since cyclohexene is not prone to enter into nucleophilic substitution, this reaction was suggested to occur by a radical mechanism.

It has been reported⁴⁵ that the intermediates formed in the electroreduction of tetrachlorosilane do not react with acrylonitrile, although the same researchers have described⁴⁶ a reaction of silyl anions electrically generated by the reduction of the Si–H bond in trichlorosilane (at $E = -1.6 \text{ V vs Ag/AgCl}$) with acrylonitrile to give trichloro(β-cyanoethyl)silane **19**.⁴⁶

The compound **19** can also be obtained from trichlorosilane and acrylonitrile by a purely chemical procedure, namely, radical hydrosilylation. Therefore, it is quite probable that either the signal of reduction of SiCl₄ (Table 1) does not refer to the reduction of a Si–Cl bond or the rate of interaction of the electrically generated Cl₃Si⁻ anions with the highly electrophilic SiCl₄ molecule is much higher than the rate of the addition at the double bond.

III. Cathodic syntheses of tri- and poly-silanes

Polysilanes (–Si–)_{*n*} containing more than two silicon atoms in the chain can be obtained by coupling of two chlorosilanes during their joint reduction, which leads to the formation of one or two Si–Si bonds. Chloro-derivatives of di-, tri- and poly-silanes are used as the initial monomers, depending on the required length of the chain of silicon atoms.

Electrosynthesis of trisilanes is carried out by the following schemes.

Trisilanes are also formed in the reductive coupling of chlorodisilanes and the chlorosilane **1**, for example:

Electrosynthesis of tetrasilanes is accomplished by coupling of disilanes.

Electrosynthesis of pentasilanes is accomplished by coupling of dichlorosilanes and chlorosilanes.

Electroreduction of a number of chlorosilanes [for example, dichloro(methyl)phenylsilane **5** and 1,4-bis(dialkylchlorosilyl)benzenes^{51,56}] at Mg electrodes in an undivided cell affords polysilanes in 5%–26% yields. It has been noted that treatment of the reaction mixture with ultrasound with a frequency of 47 kHz leads to a substantial increase in the yield of polysilanes (to 33%–45%).⁵¹

It has been assumed that the formation of polysilanes in the electroreduction of dichlorosilanes involves an ionic mechanism for the chain lengthening consisting of a number of electroreduction– S_N2 successive steps.⁵⁶ The initial molecule characterised by a more negative reduction potential undergoes the nucleophilic attack.

The reduction of 1,4-bis[chloro(methyl)phenylsilyl]benzene in THF/LiClO₄ with polarisation by alternating current and with ultrasonic treatment of the reaction mixture leads to a polymer consisting of the (–C₆H₄–SiSi–) units.

When the amount of the electricity passed is increased from 8 to 12 F mol^{–1}, the molecular mass of the polymer M_n (at $\text{R} = \text{Et}$) increases to 9960.⁵⁶

The reduction of *ortho*- and *meta*-substituted bis[chloro(methyl)phenyl]benzene at a Pt cathode (Cu anode, DME/Bu₄NClO₄ or Bu₄NBPh₄) in the galvanostatic regime also yields disilanylene polymers.⁷¹

Polymeric products with high molecular masses consisting of the (–CH₂CH₂–SiSi–) fragments have been prepared by electroreduction of 1,2-bis[chloro(methyl)phenylsilyl]ethane and 1,2-bis[chloro(methyl)(*p*-tolyl)silyl]ethane at Cu electrodes.^{35,71}

Optimisation of this process using various solvents (DME, MeCN, DME/DMF, DME/propylene carbonate) and various supporting electrolytes [Bu₄NBF₄, Bu₄NClO₄, Bu₄NOC(O)CF₃, Bu₄NBPh₄, LiCl] showed that the best conditions for polymerisation are created by conducting the process in DME/Bu₄NBPh₄.⁷¹ When a supporting salt incorporating a trifluoroacetate anion was used, chlorine in the initial chlorosilane molecules was found to exchange with fluorine.⁷¹

A series of studies have been devoted to electropolymerisation of dichlorodimethylsilane **4**.^{42,58,72} Umezawa *et al.*⁷² studied the influence of the conditions of electrolysis (ion-exchange membrane in a divided cell, metals and alloys of various purity grades as electrode materials) on the efficiency of electroreductive polymerisation. High yields of the products are achieved when the process is carried out in the DME/Bu₄NCl system in a diaphragmless cell with polarisation of Al electrodes by alternating current.

Since the reduction of chlorotriphenylsilane **2** in the presence of Me₃SiCl yields cross-disilane (*cf.* Refs 37, 49), while that in the presence of Me₂SiCl₂ yields a polymer containing both phenyl and methyl groups,⁵⁸ a nucleophilic rather than a radical mechanism for the formation of polysilane units has been assumed. It has been noted^{16,73} that dichloropolysilanes with longer chains are reduced at more positive potentials than short-chain polysilanes.[‡] Therefore, it has been assumed that polymerisation occurs *via* a nucleophilic attack by the monochloropolysilyl anion on the silicon atom in the initial molecule^{42,58,72} (*cf.* Ref. 56), according to the following scheme

Termination of the polymerisation chain was assumed to occur either *via* intramolecular nucleophilic attack yielding cyclic polysilane or *via* protonation.

[‡] This regularity is apparently valid, taking into account the effects of σ -Si conjugation in polysilane chains;⁷⁴ however, judging from the potentials reported in one of these studies,⁷³ the researchers did not deal with the reduction of Si–Cl bonds.

Therefore, in order to ensure initiation of the polymerisation and chain termination, it has been proposed to add to the electrolyte small amounts of a monochlorosilane (for example, Ph_3SiCl), which is reduced at less negative potentials than the dichlorosilane **4** forming the chain.⁷⁵

Dimethylpolysilane was prepared in a current yield of 72%–90% by electroreduction of dichlorodimethylsilane **4** without a solvent or with the addition of hexamethylphosphoric triamide (HMPT) or tris(3,6-dioxoheptyl)amine as a complex-forming agent in an undivided cell with a stainless-steel cathode and Al anode.⁷⁶ The highest yield is achieved when the mixture is treated with ultrasound with a frequency of 35 kHz.

Electrosynthesis of heterosubstituted polysilanes by joint reduction of the dichlorosilanes **4** and **5** has been reported.⁴⁹ The composition of the polymer varies as a function of the ratio of the initial silanes.

A similar polymer has been obtained by electroreduction of 1,2-dichloro-1,1,2-trimethyl-2-phenyldisilane.⁵¹

Electroreduction of trichloro(phenyl)silane **13** in a THF/ LiClO_4 solution at a Mg electrode results in the formation of polysilanes with a two-dimensional structure of the silicon skeleton.⁷⁷ The electrolysis was carried out with ultrasonic treatment of the mixture and potential sweep from 0 to -3 V (vs Ag/Ag^+) during the process. The yield of the polymer ranged from 13% to 71%. The molecular weight of the resulting polyphenylsilane was estimated as $M = 5000-7100$.⁵⁶

A series of studies have been devoted to reductive polymerisation of polyfunctional silanes R^1SiX_3 , $\text{Cl}(\text{SiR}_2^1)_n\text{Cl}$, R^1SiCl_3 , SiCl_4 and $\text{ClR}^1\text{R}^2\text{SiR}^3\text{R}^4\text{X}$ ($\text{R}^{1-4} = \text{H, Alk, Ar, AlkO, NR}_2, \text{SiR}_3$) (see, for example, Refs 37, 78–81). This process giving rise to polysilane products is of interest as an alternative route for the synthesis of compounds used in the production of ceramic materials.

Poly(pentafluorophenylsilylene) has been synthesised by cathodic polymerisation of trichloro(pentafluorophenyl)silane.⁸²

In conclusion, it should be noted that studies on electroreduction of chlorosilanes are mostly synthetic. At present, there is scarcely any information on the kinetics and thermodynamics of the electron transfer and rupture of the $\text{Si}-\text{Cl}$ bond, and the conclusions about the nature of species resulting from the transfer

of electrons have been based on the structures of final products of electrolysis or on retro-synthetic analysis.

IV. Reactions of electrically generated nucleophiles with an electrophilic silicon atom

1. C-Nucleophiles

Electroreduction of organic compounds that are converted into carbanions by two-electron cleavage of the $\text{C}-\text{X}$ bond ($\text{X} = \text{H, Hal, OCR, OAc}$) is widely used in the preparative organic electrochemistry of silicon to synthesise various compounds with $\text{Si}-\text{C}$ bonds. In this case, the role of the electrode reduces to the generation of C^- -nucleophiles, which replace chlorine in chlorosilane molecules. It has been assumed that only relatively stable carbanions (All, Vin, Ar) are suitable for these reactions. Later, it has been found that when a soluble anode is used (Mg, Al, Zn, Cu) and the process is conducted in the presence of a complex-forming agent [DMF, HMPT, tetramethylurea, tris(3,6-dioxoheptyl)amine], electrically generated aliphatic carbanions can also be involved in the reaction.

Evidently, the first example of this type of synthesis is provided by the cathodic synthesis of benzyltrichlorosilane⁸³ by electrolysis of benzyl chloride in MeCN/ Et_4NCl at a Pb cathode in the presence of silicon tetrachloride (Eqns 1 and 2).

Benzyltrichlorosilane is formed in a substance yield of 19.1% and a current yield of 5%. When chlorosilane **1** is used instead of SiCl_4 ,^{59,84} this process gives benzyltrimethylsilane **20**.

β -Silylated compounds with functionally substituted phenyl, naphthalene and alkenyl fragments were also obtained in good yields by a similar scheme.

$\text{R} = \text{H, Me};$
 $\text{X} = \text{Br, Cl};$
 $\text{Y} = \text{H, Me, MeO, CN, CO}_2\text{Me}.$

Isomeric allyl chlorides that differ in the position of the chlorine atoms in their molecules undergo cathodic silylation to give the same compound with a terminal Me_3Si group as the only product.⁵⁹

Chemical silylation with a Grignard reagent usually affords a mixture of products with inner and terminal Me_3Si groups.

Electroreduction of PhCH₂Cl, PhCl and PhBr in various solvents susceptible to complex formation [DMF, HMPT, (Me₂N)₂CO] in an undivided cell with a soluble Mg anode⁸⁴ leads to similar results. Carbanions resulting from electroreduction of allyl, vinyl, aryl and hetaryl halides (DMF/Et₄NOTs, divided cell, Pt electrodes) react with chlorosilanes **1**, **3** and **10** according to Eqns. (1)–(2) to give the corresponding organosilicon compounds⁸⁵ in preparative yields (47%–98%). Only chlorosilanes are suitable as silylating agents under these conditions; *O,N*-bis(trimethylsilyl)acetamide **21** and methoxytrimethylsilane **22** are inactive in this reaction.

Aryl halides containing two different halogen atoms in their molecules (in particular, 4-bromiodobenzene) are selectively silylated with the chlorosilane **1** at the C–I bond thus yielding (4-bromophenyl)trimethylsilane.⁸⁶

Cinnamyltrimethylsilane can be obtained by electrosynthesis not only from cinnamyl chloride but also from other cinnamyl derivatives. In fact, the intermediates of reductive decarboxylation of cinnamyl acetate are converted into a silylated product in a yield of 25%–50%. Cinnamyl carbonate and cinnamyl sulfone can be converted into the same product in lower yields.⁸⁶ Evidently, this process occurs according to the following general scheme that includes formation of allylic anionic intermediate **23**:

X = Cl, OAc, OCO₂Me.

Allyltrimethylsilanes have also been obtained by homogeneous reduction of allyl acetates with Pd(PPh₃)₄ in the presence of an excess of chlorotrimethylsilane.⁸⁷ This reaction yields an inner alkene as the major product. This has been suggested to be due to the fact that the chlorosilane attacks the electrically generated carbanion from its sterically less shielded side.

Electrocatalytic reduction of PhBr and hex-1-ene with the [NiL₃]⁰ complex (L is 2,2-dipyridyl, PPh₃) in the presence of the silane **1** also affords cross-coupling products.¹⁰

Electroreductive silylation of α,β-unsaturated esters, nitriles or ketones in an undivided cell with a Mg, Al or Zn anode results in the formation of the corresponding β-silyl derivatives (β-silyl propionates, nitriles or ketones).⁸⁸ When this process is conducted with a graphite or Pt anode, it gives no silylation products.

X = CO₂Et, CN, COMe.

When individual (*E*)-vinyl halides are introduced in this reaction, mixtures of (*E*)- and (*Z*)-isomers of vinyl silanes are always formed. Disubstituted (*E*)-vinyl halides yield mostly silylated (*Z*)-derivatives. This isomeric distribution is due to the fact that the following equilibrium involving the intermediate vinylic radical is established.

Since the (*E*)-radical is more stable than the (*Z*)-radical, it is the former that is reduced predominantly to give an (*E*)-vinylic anion; this anion reacts with **1** yielding (*Z*)-vinylsilane. A similar *cis-trans* isomerisation of the radical controls the stereochemistry of silylation of halostyrenes (Hal = I, Br, Cl).⁸⁶ Since the potential for the transfer of the second electron (*E*_{R·/R⁻}) does not depend on the nature of the halogen, whereas the reduction potential of the halide is, conversely, determined by the nature of the halogen (*E*_{C–I} > *E*_{C–Br} > *E*_{C–Cl}), the styryl radicals generated from the iodo-derivatives, for kinetic reasons, have more time to isomerise than those generated from the corresponding chlorides. Thus, the proportion of the *cis*-isomer varies in the opposite direction with respect to the ease of reduction of the halostyrene.

1-Methoxy-3,6-bis(trimethylsilyl)cyclohexa-1,4-diene, a precursor of ketoprofen, was prepared in a current yield of 70% by electroreduction of anisole (undivided cell, a stainless-steel cathode and an aluminium anode) in the presence of Me₃SiCl in a solution in THF/HMPT (4 : 1) or without THF but with addition of a complex-forming agent (HMPT).⁸⁹

Based on an approach proposed in a series of studies,^{84, 85, 90–93} an electrochemical technique for the synthesis of carbosilanes, including cyclic ones, has been developed and described in a patent.⁹⁴

When this process is carried out with iodo-derivatives, the yields of the products are higher than in the case where bromides and chlorides are used.

Reduction of organic dihalides in the presence of Si-containing dichlorides under similar conditions^{95, 96} affords cyclic carbosilanes. Their yields (7%–91%) depend on the structure of the initial dihalide (the nature of the halogen and the length of the chain) and on the strain in the resulting ring. As the size of the ring increases, the yield of the reaction product first increases, reaches its maximum, as should have been expected, for 5- and 6-membered rings and then diminishes. The yields of cyclic disilanes depend also on the concentration of the halogenated substrates and on the electrode potential; an increase in either of these parameters leads to a decrease in the yields of silacycloalkanes.

It is assumed that at the step of the linear silylated intermediate,⁹⁵ an orienting influence of the cathode is manifested; owing to this influence, silicon assumes a penta- or hexa-coor-dinated configuration favourable for the intramolecular nucleophilic attack.

Electroreduction of 1,4-dibromobutane in the presence of tetrachlorosilane at a 1,4-dibromobutane : tetrachlorosilane ratio of 2:1 permits preparation of a bicyclic product, 5-sila-spiro[4.4]nonane, in a yield of 24%.

Electroreductive silylation of CCl_4 , CHCl_3 and CH_2Cl_2 ⁹⁰ is much more selective than the classical silylation. The use of soluble anodes made of various metals (Zn, Al, Mg), the cations

of which are reduced at different potentials, permits selective preparation of chlorine-containing products of partial silylation, the reduction potentials of which are more negative than those of the M^+ . For example, monosilylation of CCl_4 and $CHCl_3$ is carried out using a Zn anode, while disilylation occurs with a Mg anode and for trisilylation, an Al anode is used.

Mono- and disilylation of CH_2Cl_2 (Al anode) have been carried out in a similar way.^{57, 90}

Under similar conditions, chloro(chloromethyl)dimethylsilane **24** is converted into a mixture consisting of cyclic 4-, 6- and 8-membered carbosilanes, a linear dimerisation product and polycarbosilanes^{26,69,91} (the yields were taken from Ref. 26).

When a Mg anode is used (DMF/MgCl₂), the four-membered product is not formed.²⁶ It is of interest that the yield of the intermediate linear terminal dichlorocarbosilane increases from 4% to 43% when the solution is diluted 8-fold,^{26, 97} although this compound is formed by an intermolecular S_N2 mechanism and, hence, its proportion should have decreased following a decrease in the concentration.

The reduction of the chlorosilane **24** in the presence of dichlorodimethylsilane²⁶ (used as an electrophilic trap for the chlorodimethylsilyl carbanion) has given rise to bis(chlorodimethylsilyl)methane **25** in a preparative yield (60%). The high chemical selectivity of the process was achieved by maintaining the 1:1 ratio of the reactants during the electrolysis. For this purpose, Me₂SiCl₂ was gradually added to the reaction mixture, and its excess in the solution was thus avoided.

The electroreduction of benzal chloride in DMF/LiClO₄ in the presence of the chlorosilane **1** results in the formation of (α -chlorobenzyl)trimethylsilane or geminal benzaldisilane, depending on the amount of electricity passed.⁹⁸ Since the reduction potential of the dihalide is 560 mV more positive than that of the (α -chlorobenzyl)silane, the reduction of the latter yielding benzaldisilane starts only when the initial dichloride has reacted almost completely. Chromatographic monitoring of the process makes it possible to stop the reaction at the stage of monosilylation and thus to obtain the product in 57%–98% yield. The subsequent electrolysis affords the disilylated product (yield 72%–91%). When a stainless-steel cathode is used, the yields of mono- and

Scheme 1

Cleavage of the ring in tetrahalothiophene is accompanied by the formation of hexamethyldisilathiane **26**.

X = Br, Cl.

Silylation of 3-halo-2-trimethylsilylthiophene also yields products of ring opening in almost quantitative yield.

Using the correlation between the reduction potentials (E_p) of 1-R-3,4-dichloro- or 4-R-1,2-dichlorobenzenes and the sum of the σ_m and σ_p constants of substituents, it has been shown that substituents for which the $\sigma_m - \sigma_p > 0$, direct silylation to the *meta*-position, while those with $\sigma_m - \sigma_p < 0$ lead to *para*-silylation.

An interesting regularity has been observed in the silylation of disubstituted chloromethylbenzenes. Only *meta*-derivatives undergo monosilylation, whereas *ortho*- and *para*-isomers afford no monosilylation products.¹⁰¹ When 2.2 F mol⁻¹ of electricity is passed, the latter are immediately converted (by approximately 50%) into disilylated derivatives. It has been assumed that this is

due to the intermediate formation of *o*- or *p*-xylylene, which is converted into the corresponding polymer in 52% yield.

Silylation of the C–F bond in trifluoromethylbenzene carried out under the same conditions¹⁰² permits preparation of any of the three possible products by passing the appropriate amount of electricity (chromatographic yields are presented).

Synthesis of trimethylsilylcyclopentadiene (in a current yield of 96% based on the single-electron process) by the reaction between the electrically generated cyclopentadienyl anion and the chlorosilane **1** has been reported.¹⁰³ Cyclopentadiene was reduced at a Fe cathode in a divided cell in MeCN in the presence of Et₄NBr. Then a solution of the chlorosilane **1** in MeCN was added to the resulting catholyte (the solution contained some NaBr

added in order to shift the equilibrium in the reaction between $C_5H_5^-$ and **1** through binding the liberated chloride anion into insoluble NaCl).

A reduction of monochlorotoluenes in the presence of the chlorosilane **1**, more extensive than the two-electron reduction, involves the aromatic ring and leads to the loss of aromaticity.^{76, 92}

(a) *ortho*- and *meta*-isomers, (b) *para*-isomer.

trans-Isomers predominate in the product mixture. When the DMF/MgCl₂/Mg system is used, only bromobenzene is silylated.

The nature of the unsaturated products resulting from silylation of aromatic compounds depends on the structure of the initial compound (chromatographic yields are given in parentheses).⁹²

Benzene and toluene are converted into bis(trimethyl-silyl)cyclohexa-1,4-dienes. In the case of benzene, a 7 : 3 mixture of *trans*- and *cis*-products was obtained, while toluene gave only the *trans*-isomer.

Chemical silylation of systems of this type yields at once pentakis(trimethylsilyl)cyclohexanes, whereas electrochemical silylation can be selectively terminated when tris(trimethylsilyl)-containing conjugated dienes have been formed. The stereochemical control of the electrosilylation of aromatic systems is due to the steric effect of the first trimethylsilyl group entering the molecule. In fact, the second silylation occurs from the less shielded side of the molecule. This attack affords the kinetically controlled product; in the case of *trans*-isomer, this is also the thermodynamically controlled product.⁹²

The electrochemical method for the synthesis of Ruppert's reagent was proposed in two publications at almost the same time.^{104, 105} In these studies, CF₃Br served as the source of the CF₃ group; the solution was saturated with this compound at -30 to -15 °C.

The authors of both studies advise the same electrodes (an Al anode and a Ni cathode) but different solvents and supporting electrolytes [DMF/Bu₄NBr¹⁰⁴ and PhOMe:HMPT (10 : 1)/Bu₄NPF₆¹⁰⁵].

It is of interest that together with F₃CSiMe₃, 10%–15% of hexamethyldisilane is formed,¹⁰⁵ although the chlorosilane **1** is not yet reduced at the potential of electrolysis. It was assumed that the disilane is formed from the Si–Br derivative, which appears in the mixture *via* the Br/Cl exchange accelerated by Al³⁺ ions.

Successive substitution of the Br atoms in 1,1-dibromocyclopropanes by Me₃Si groups has been accomplished by electroreduction of this compound in the presence of the chlorosilane **1**.¹⁰⁶ The same process involving 8,8-dibromobicyclo[5.1.0]octane affords various silylated derivatives with moderate selectivity.¹⁰⁷ In addition to the silylated products, 10% of the unreacted initial dibromide was detected in the product mixture. Ultrasonic treatment of the reaction mixture doubles the apparent current yield. Since the process was carried out with a Mg anode, it was assumed that in this case, the silylated product has also been formed in a competing purely chemical (sonochemical) reaction with the participation of Mg.

Since sonochemical processes usually stop at the monosilylation stage, the electrochemical version yielding disilylated products is a convenient method for the synthesis of these cyclopropane derivatives.¹⁰⁷

Successive reduction of tetrachlorocyclopropene in the presence of the chlorosilane **1** made it possible to prepare its mono-,¹⁰⁸ di- and trisilylated derivatives.¹⁰⁹ When this process was carried out in the THF/HMPT (10 : 1) system using a Ni cathode, an Al anode and 8 F mol^{−1} of electricity, hexakis(trimethylsilyl)-3,3'-bi(cyclopropenyl) **28** was obtained in 40% yield; silylated dichloropropene **27** was formed simultaneously.

When a Mg anode is used, compound **28** is scarcely formed.¹⁰⁹

Thus, the reduction of a C–Hal bond is, obviously, the most convenient method for the electrical generation of C-nucleophiles, because most organic halides are reduced at less negative potentials than chlorosilanes. Generation of a carbanion by reduction of a C–H bond requires more negative potentials and it often can be accomplished only at cathodes made of transition metals.¹⁰³ The reduction of aromatic systems is accompanied by their degradation; however, this process can be used for electrosynthesis of silylated dienes and alkenes, which are of interest for Diels–Alder reactions.

2. Organoelement nucleophiles

This Section deals with processes consisting of electrical generation of nucleophiles based on Ge^- , Sn^- , O^- , N^- , S^- , Se^- and so on, *i.e.* elements other than carbon, and their subsequent reactions with reagents containing electrophilic silicon, most frequently, with the chlorosilane **1**.

Electroreduction of chlorotrimethylgermane¹¹⁰ in the presence of the chlorosilane **1** (Mg anode and Mg cathode, THF/ LiClO_4) affords a heteroelement dimer containing a Ge–Si bond, whereas its reduction in the presence of the dichlorosilane **5** gives rise to a heterocopolymer.

Reduction of tributylchlorostannane in the presence of the chlorosilane **1** under similar conditions and at ratios of the initial chlorides of 1:1, 1:5 and 1:10 leads to tributyl(trimethylsilyl)stannane (10%, 35% and 50%) and hexabutylstannane (59%, 55% and 41%, respectively).²⁹

Esters of carboxylic acids^{50, 111, 112} are reduced with Mg electrodes (anode and cathode) in an undivided cell in the presence of Me_3SiCl to give products of the acyloin condensation.

The same process involving an unsaturated ester that has a more positive reduction potential than the chlorosilane **1** results in the formation of a bicyclic spiro-compound.¹¹³

Electroreduction of unsaturated carbonyl compounds under aprotic conditions in the presence of *O,N*-bis(trimethylsilyl)acetamide **21** or the chlorosilane **1** affords products identified as silyl ethers.¹¹⁴ It is of interest that acetamide **21** is inactive in the reaction with C-nucleophiles^{85, 86} but reacts with the O-nucleophile to give dimeric trimethylsilyl unsaturated diether **29**.

The product of two-electron reduction of 1,2-dibenzoyl ethene attacks nucleophilically the chlorosilane **1** to give 1,4-diphenyl-1,4-bis(trimethylsilyloxy)buta-1,3-diene.

2-Phenyl-1,3-bis(trimethylsilyloxy)isoindole has been prepared by two-electron reduction of *N*-phenylphthalimide in MeCN/ Et_4NCl in the presence of the chlorosilane **1**.¹¹⁵

The resulting isoindole was not isolated in a pure state owing to its high sensitivity to moisture and air; however, this compound is quite stable in a catholyte under a layer of dry argon and can be trapped by an appropriate dienophile after the electrolysis.¹¹⁵

Single-electron reduction¹¹⁵ of *N*-methylphthalimide under the same conditions yields a dimeric silylated bis-lactam.

This process is assumed to include the formation of a radical anion, which is able either to react directly with an electrophile in two $\text{E} + \text{C}_{\text{S}_\text{N}2}$ steps (two-electron process) or to undergo dimerisation followed by silylation to give the bislactam (single-electron process).

Electroreduction of acylimidazoles in the presence of the chlorosilane **1** gives rise to acylsilanes¹¹⁶ including those containing Cl and C(O)OAlk groups.

The products of electroreduction of Me_3SiCN react with the chlorosilane **1** affording silylated products **30** and **31**, the protolysis of which makes it possible to synthesise bis(trimethylsilyl)-methylamine.¹¹⁷

R = H, Cl.

The same products, together with tris(trimethylsilyl)amine **33a** and hexamethyldisiloxane **33b** were obtained by electrochemical silylation of trimethylsilylcarbodiimide (Z = NSiMe₃) **32a** and trimethylsilyl isocyanate (Z = O) **32b**.¹¹⁷

Magnesium salt **34** prepared by electroreduction of 2-pyrrolidone in an undivided cell with a soluble Mg anode¹¹⁸ has been used as an electrically generated base for functionalisation of carbonyl compounds. Thus the magnesium enolate formed upon addition of ketone **35** to two equivalents of the electrically generated base at a low temperature reacts with the chlorosilane **1** to give enoxysilane **36**; *N*-trimethylsilyl-2-pyrrolidone is formed as a side product.

Magnesium thiolate electrically generated upon reductive rupture of the S–H bond in dodecanethiol¹¹⁹ reacts with the chlorosilane **1** to give thiosilane **37** in a current yield of 78%.

Reduction of diorganodisulfides and -diselenides as well as thio- and seleno-phenols (in the two latter cases, a Fe cathode is used) carried out in the presence of mono- and dichlorosilanes^{63, 120, 121} gives rise to the corresponding thio- and selenosilanes in good preparative yields (60%–87%). Chromatographic analysis of reaction mixtures shows that the reaction proceeds almost quantitatively.

R = Ar, Alk; X = S, Se.

By means of an electrochemical variant of the method of competing reactions in the classical and reversed schemes (Scheme 2), it has been shown that the rates of *S_N2* reactions of electrically generated PhS[−] and PhSe[−] anions with chlorosilanes (Me₃SiCl, MeVinSiCl₂, Me₂SiCl₂ and SiCl₄) are related as 1 : 1.97 : 2.34 : 4.61 and 1 : 1.45 : 2.5 : 4.1, respectively. The rate of

nucleophilic selenation is 9.3 times higher than the rate of thiolation due to the higher nucleophilicity of the Se-containing anion.¹²²

Scheme 2

Cathodic arylselenation of α,β-unsaturated carbonyl compounds has been described. It was assumed that trimethylsilyl selenide resulting from interaction of the electrically generated ArSe[−] anion with the chlorosilane **1** participates in the process.¹²³ Methanolysis of the silyl selenide yields arylselenol, and the latter acts as the reactive intermediate in this *in situ* silylation of enones.

Electrically generated silyl chalcogenides have been used for functionalisation of carbonyl compounds (Scheme 3).^{121, 124–128}

It is assumed that the addition of selenosilane to the C=O bond under the conditions of electrolysis involves anionic catalysis by the anion of the supporting electrolyte.^{121, 129}

Electroreductive cross-hydrocoupling of α,β-unsaturated esters with aldehydes or ketones²⁸ in the presence of the chlorosilane **1** results in the formation of γ-lactones in good yields (51%–86%). Similarly, α,β-unsaturated nitriles are converted into γ-hydroxynitriles.

Although the molecules of the reaction products do not contain Me₃Si groups, the presence of the chlorosilane **1** is necessary, because coupling does not occur without it. The mechanism of the process has not been studied in detail; however, it is assumed that **1** is coordinated to the carbonyl compound thus activating the carbonyl group. Then this complex reacts with the radical anion resulting from single-electron reduction of the acrylate.

Scheme 3

(a, b) X = Se; R = Ph; divided cell;

(c) X = S, Se; R = Et, Ph; divided cell;

(d) X = S; R = Et, Ph; one-compartment cell, Al(Mg) anode;

(e) X = Se; R = Ph; one-compartment cell, Al(Mg) anode.

Electrocatalytic reduction of Ph_2PCl by the complex NiL_3 (L is 2,2-dipyridyl or PPh_3) in the presence of the chlorosilane **1** yields diphenyl(trimethylsilyl)phosphine.¹⁰

V. Reduction of other classes of organosilicon compounds

The interpretation of the stabilising influence of the silicon atom on radical-anion intermediates has changed following the evolution of the views on the electronic effects of silicon-containing substituents (from the idea that electron-withdrawing properties of α -silyl substituents are associated with participation of the vacant $3d$ orbitals of silicon atoms to the concept rejecting this participation¹³⁰ and based on the acceptor hyperconjugation interactions of σ^* orbitals). At present, none of the theoretical concepts can fully explain the experimental data on the electronic effects of silyl substituents. The concept according to which the overall influence of a silyl substituent on the energies of frontier molecular orbitals (FMO) is determined by a combination of various electronic interactions¹³¹ — inductive effect ($+I$), σ, π and σ, π^* -conjugation, mixing of the $\sigma_{(\text{Si}-\text{C})}$ and $3d$ orbitals of Si, mixing of d, σ^* orbitals with σ, π^* and σ, π orbitals and the formation of LUMO (d, π^*) — should be regarded as the most comprehensive (but also the most complex).

Since the $3d$ -orbital hypothesis (see Refs 130 and 131) agrees qualitatively with general quantum-mechanical views on intramolecular electronic interactions and with statements of the general concept¹³¹ (this hypothesis has been used in a number of original studies), we decided not to introduce the more recent interpretation but to remain within the framework of the $d_\pi-p_\pi$ -conjugation concept used by the researchers cited (see, for example, Refs 132–134).

The results of reversible polarographic reduction of 4-trimethylsilyl- and 4,4'-bis(trimethylsilyl)biphenyls ($E_{1/2} = -2.03$ and -1.94 V vs Hg pool, respectively),¹³² and of a number of

trimethylsilyl-substituted polyphenyls¹⁵ have been used to estimate the ϵ_{LUMO} values, which proved to be close to the ϵ_{LUMO} values obtained using EPR data. Interpretation of the spectra of the radical anions in terms of a model involving d orbitals of silicon made it possible to calculate the multiplicity of the C–Si π -bond, which was found to be approximately 0.18 in all the aromatic compounds studied.

The potentials of the reduction peaks (DMF/ Bu_4NClO_4 , Pt) of *o*-, *m*- and *p*-nitrophenyltrimethylsilanes ($E_p = -1.62$, -1.50 and -1.26 V vs SCE, respectively)¹³³ are several tens of millivolts more positive than the reduction potentials of the corresponding toluene derivatives. The radical anions formed upon the transfer of a single electron are quite stable ($i_a/i_k \cong 1$); however, although the process is reversible, $\Delta E_p/\Delta \lg(v) = 400$ mV for potential sweep rate v ranging from 40 to 400 mV s^{-1} . The reduction of 2,4-dinitrophenyltrimethylsilane **38** is characterised by two reversible peaks and occurs according to the equation

The stabilising influence of the trimethylsilyl group on the radical anion was explained¹³³ by the $d_\pi-p_\pi$ -conjugation of the Si atom with the aromatic ring.

The possible structures of the radical anions derived from *p*- and *m*-trimethylsilylnitrobenzenes have been discussed;¹³⁴ the distribution of the electron density in these species during the reduction was elucidated by EPR.

It has been reported¹³⁵ that α -silyl aryl ketones have lower reduction potentials ($\Delta E_{1/2} = 270$ mV) than their carbon analogues and that the energies of charge transfer in the π -complexes of α -silyl aryl ketones with tetracyanoethylene are higher than those in the complexes of carbon derivatives.

The polarogram of reduction of 5,5-dimethyl-5,10-dihydrodi-benzo[*b,e*]silinone ¹³⁶ exhibits two waves typical of ketones. The first wave ($E_{1/2} = -1.64$ V vs Hg pool, $\Delta E_{3/4-1/4} = 60$ mV) corresponds to the formation of a radical anion; the second wave is irreversible ($E_{1/2} = -2.27$ V, $\Delta E_{3/4-1/4} = 90$ mV). The decrease in the splitting constants in the EPR spectra attests to a decrease in the spin density in the benzene rings, which is due to the electron-withdrawing influence of the silicon atom.

The slight differences between the reduction potentials of 4-biphenyltrimethylsilane ($E_{1/2} = -1.948$ V vs Hg pool) and 4,4'-bis(trimethylsilyl)biphenyl ($E_{1/2} = -1.856$ V) and between those of bis(4-biphenyl)dimethylsilane ($E_{1/2} = -1.904$ V) and 4,4'-bis(4-biphenyldimethylsilyl)biphenyl ($E_{1/2} = -1.801$ V) have been attributed ¹³⁷ only to the effect of the second silicon atom, participation of the *d* orbitals of silicon in the transfer of conjugation between the benzene rings being completely ruled out.

Contrary to this and also to the conclusion made by Makarov and Kazakova ¹³⁸ that the unpaired electron in the radical ions derived from phenylsilanes is not delocalised through the SiMe₂ bridges, Il'yasov *et al.* ¹³⁹ have found, based on the EPR spectra of the electrically generated radical anions Ph₄Si^{•-}, that the unpaired electron does interact with all the phenyl groups.

Reduction of mono- and bis-trimethylsilyl-substituted naphthalenes ¹⁴⁰ occurs by a mechanism typical of reduction of aromatic hydrocarbons with reversible electron transfer giving a radical ion; in this case, the $E_{1/2}$ potentials are more positive than those for reduction of compounds with *tert*-butyl substituents ($\Delta E_{\text{SiMe}_3-\text{CMe}_3} = 220-290$ mV), which is a result of the simultaneous influence of two opposite effects: +*I* effect of the Me₃Si group and the electron-withdrawing effect of vacant 3*d* orbitals of Si on the π -system of the ring.

The reduction of a number of benzoylsilanes substituted in the ring in MeCN/Bu₄NClO₄ at a glassy carbon electrode involves the formation of a relatively unstable radical anion, which was detected at -80 °C by EPR. ¹⁴¹ At room temperature, the process is irreversible and, unlike the electroreduction of arylketones which affords pinacols, it occurs according to Scheme *a* or *b* and yields diketone **39**.

X = PhMe₂.

The potentials of the two reversible steps of electroreduction of 2,5-bis(trimethylsilyl)-1,4-benzoquinone ($E_{1/2} = 0.04$ and -0.51 V vs Hg pool; MeCN/Bu₄NI) are 200 mV more positive than the potentials of electroreduction of the corresponding di-*tert*-butyl derivative, ¹⁴² which is due to the electron-withdrawing influence of the Si atom (the mechanism of $d_{\pi}-p_{\pi}$ -conjugation).

Electroreduction of aryltrimethylsilanes in MeNH₂/LiCl at a Pt electrode in an undivided cell is a promising method for the synthesis of trimethylsilyl-substituted cyclohexa-1,4-dienes. ^{143, 144} This reaction is assumed to proceed as an electrochemical variant of the Birch reaction with participation of the metallic lithium resulting from the cathodic reduction of Li⁺. With substituents occupying various positions in the aromatic ring, the nature of the products is determined by steric and electronic interactions.

In addition to the products mentioned above, disilylated cyclohexenes with a different position of trimethylsilyl groups are formed in 6% yield.

It is noteworthy that at potentials more negative than reduction potentials of arylsilanes, electroreduction of silylated alkenes can also be achieved. ¹⁴⁴

Rupture of the double bond during the reduction of 6-trimethylsilylhept-6-en-2-one and intramolecular cyclisation lead to *cis*-1-methyl-3-trimethylsilylcyclohexanol. ¹⁴⁵

Reduction of trimethyl(phenylethynyl)silane **16** ($E_{1/2} = -2.02$ V vs Hg pool; DMF/Bu₄NI ¹⁴⁶) in an undivided cell in MeNH₂/LiCl at a Pt electrode requires 2F mol⁻¹ of electricity and affords a mixture of products that contains ethylbenzene (38%), phenylacetylene (47%) and trimethyl(2-phenylethyl)silane **40** (13%). ¹⁴³ The reduction occurs presumably *via* the formation of trimethyl(phenylethynyl)silyl radical anion [**16**]^{•-}, which undergoes either fragmentation at the C–Si bond (in MeNH₂) or protonation with retention of the C–Si bond (in the presence of PrⁱOH). In the latter case, compound **40** is formed in a markedly higher yield (31%).

The $E_{1/2}$ values for the reversible reduction of silylbutadienes have been reported. ¹⁴⁷ Since the interactions of silyl-substituted unsaturated compounds in excited states cannot be measured directly, some correlations were made on the assumption that the $E_{1/2}$ potentials of reversible electron transfer reflect the relative LUMO energies in neutral π -electron systems in the ground state. Thus the +*I* effect of the Me₃Si group dominating in the ground state is replaced by $d-\pi^*$ interaction at the singly occupied molecular orbital (SOMO) of the radical anion, and the sequence of potentials of di(trimethylsilyl)-substituted butadienes [$E_{1/2}$ for 1,4-, 1,3-, 1,2- and 2,3-bis(trimethylsilyl)butadienes are -1.80 , -1.85 , -1.90 and -2.13 V, respectively, with respect to the Hg

pool] is consistent with the sequence expected according to the theory of FMO with first-order perturbations ($1,4- < 1,3- \sim 1,2- < 2,3$ -isomers). Moreover, the electrically generated radical anion from 1,4-bis(trimethylsilyl)butadiene is so stable that its EPR spectrum can be observed at room temperature. Splitting constants indicate that the spin density of the radical anion is partly delocalised to the Me_3Si group.¹⁴⁷

Polarograms of silaacenaphthenes, 2-silaphenalanenes and 1,3-disilaphenalanenes and the EPR spectra of the corresponding electrically generated radical anions have been studied.¹⁴⁸ Since the molecules of these compounds are fairly strained, stability of their radical anions is lower than that of the radical anions derived from other silicon-containing aromatic compounds of this series.

The results of the polarographic single-electron reversible reduction of phenyl- and naphthyl silyl ketones,¹⁴⁹ vertical ionisation potentials (IP) and the data of electronic spectroscopy indicate that $E_{1/2}$ of the reduction of silicon-substituted ketones are markedly lower than those of their carbon analogues ($\Delta E_{\text{Si-C}} \cong 250\text{--}270$ mV) and that electron-withdrawing substituents at the carbonyl carbon atom have a greater influence on the electrochemical reactivity than substituents at the *para*-position of the aromatic ring.

Phenyl-substituted polysilanes $\text{Ph}(\text{SiMe}_2)_n\text{Me}$ and $\text{Ph}(\text{SiMe}_2)_n\text{Ph}$ are reduced in the range of potentials $-3.3 < E_{1/2} < -3.2$ V, which is close to the region of electrical activity of the solvent [$E_{1/2} = -3.26$ V for *p*-bis(trimethylsilyl)benzene and $E_{1/2} = -3.23$ V for *p*-bis(pentamethylsilyl)benzene vs Ag/Ag^+], whereas naphthylpolysilanes exhibit one reversible diffusionally controlled wave ($n = 1$, $i/H^{1/2} = \text{const}$, where H is the height of the mercury column in the dropping-mercury electrode; $i/C = \text{const}$) or two single-electron reduction waves in an accessible range of potentials ($-2.845 \leq E_{1/2} \leq -2.781$ V vs Ag/Ag^+).¹³⁰ Since linear permethylpolysilanes $\text{Me}(\text{SiMe}_2)_n\text{Me}$ ($n = 2\text{--}5$) are not reduced,^{130,150} reduction of polysilylated aryl derivatives, evidently, involves one of the degenerate antibonding orbitals of the Ar group. The decrease in $E_{1/2}$ for silylnaphthenes was interpreted taking into account inductive, σ , π , and $d_\pi\text{--}\pi_\pi$ effects of the silyl substituent; the two former effects increase ϵ_{LUMO} , while the latter markedly decreases it.¹³⁰

Cyclic permethylpolysilanes $(\text{Me}_2\text{Si})_n$ ($n = 5\text{--}7$) are reduced in $\text{Me}_2\text{O}/\text{DME}$ (3:1) in the presence of Bu_4NClO_4 to give a radical anion, the EPR spectrum of which recorded at -120°C indicates that the unpaired electron is delocalised over all the Si atoms in the ring.¹⁵¹

The $\text{Si}_6\text{Me}_{11}$ anion is formed upon electroreduction of $\text{Si}_6\text{Me}_{12}$ in HMPT at -1.9 V and can react with various electrophiles;¹⁵² for example, its reaction with EtBr affords the corresponding ethylated product.

Tetraaryldisilenes are reduced irreversibly in the THF/ Bu_4NPF_6 system at less negative potentials ($E_p = -2.03$ to -2.2 V vs SCE) than dialkyldiaryldisilenes ($E_p = -2.6$ V). This is due to the fact that the two aromatic rings and the double bond in the molecules of tetraaryl-derivatives are nearly coplanar; as a consequence, π^* orbitals of the disilene and aromatic fragments are largely mixed and the LUMO energies of the molecules decrease.¹⁵³

In the reduction of iodomethylsilanes,^{154,155} the presence of a Me_3Si group also shifts the $E_{1/2}$ potential to less negative values (Table 5); the corresponding polarograms contain two single-electron diffusion waves rather than one two-electron wave as in the case of primary iodoalkanes. The process was assumed to correspond to the $E + E + C$ scheme.

In the case of $\text{Et}_2\text{SiMeCH}_2\text{I}$, the slope in the plot for the $E_{1/2}$ potential against the logarithm of the period of dropping in the

Table 5. Characteristics of electroreduction of iodo- and chloromethylsilanes in 57% EtOH/0.09 M KCl (the $E_{1/2}$ potentials are referred to SCE).^{154,155}

dropping-mercury electrode (t_1) is $\Delta E_{1/2}^1/\Delta \lg(t_1) \cong 60$ mV, which corresponds to the transfer coefficient $\alpha \cong 0.5$.¹⁵⁴

Using the method of homogeneous redox catalysis, it has been shown that the coordinate of the reaction of reduction of $\text{ClCH}_2\text{SiMe}_3$ **41** contains a point corresponding to the real radical anion.^{156,157} This mechanism of reduction, unusual for alkyl chlorides, is due to the fact that the negative charge arising on the α -carbon atom (more precisely, in the σ^* orbital of the C–Cl bond) upon electron transfer is delocalised by silicon, and this decreases the energy of the ground state of the radical anion, which thus becomes lower than the level of the transition state leading to dissociation. Due to the same effect, the E_p potentials of iodo- and chloromethylsilanes are abnormally small.

The reduction of Ph_3SiH and Ph_2MeSiH in the presence of Bu_4NClO_4 in a divided cell does not lead to the replacement of hydrogen by the halogen, as in the case of germanium analogues;¹⁵⁹ instead, it yields disiloxanes. When the electrolysis was carried out in the presence of Bu_4NBF_4 , formation of traces of Ph_3SiF was detected by GC/MS analysis, $(\text{Ph}_3\text{Si})_2\text{O}$ still being the main reaction product.

VI. Electrooxidation of organosilicon compounds

1. Hydrosilanes

Unlike oxidation of some hydrosilanes at metallic electrodes, which is characterised by low potentials (Table 6), oxidation of Me_2PhSiH at a glassy carbon electrode in $\text{MeCN}/\text{LiClO}_4$ occurs at a high potential⁸ $E_p = 2.2$ V vs SCE.¹⁶⁰ Preparative electro-oxidation of Me_2PhSiH in $\text{DME}/\text{Bu}_4\text{NClO}_4$ in the presence of CuCl_2 or CuCl gives rise to a number of products, the formation of which can be described by the following scheme:

Depending on the copper chloride used (CuCl_2 or CuCl) and on the amount of electricity passed, the chlorosilane **10** is formed in a yield of 46%–95%. Under the same conditions, $\text{Bu}^t\text{Me}_2\text{SiH}$ and Et_3SiH **42** are converted into the corresponding chlorosilanes

§ Since in the presence of CuCl , chloro-derivatives are also formed in a chemical process without passing the electricity, the high E_p values may be due to oxidation at these potentials of compounds other than hydrides.

Table 6. Characteristics of electrooxidation of hydrosilanes.

Silane	E_p /V (vs SCE)	Electrode	i_k/i_a ($v = 0.5 \text{ V s}^{-1}$)	Ref.

^a MeCN/Et₄NClO₄; ^b MeCN/LiClO₄; ^c MeCN/Bu₄NBF₄.

in 83% and 50% yields, respectively. When the supporting electrolyte is replaced by Bu₄NBF₄, Me₂PhSiF is formed in a yield of 90%, presumably *via* exchange reaction between the chlorosilane formed initially and BF₄[−] (*cf.* Refs 27, 35, 71, and 105).

Electrooxidation of hydrosilanes in DME/Bu₄NBF₄ in an undivided cell with Pt electrodes affords polysilanes in overall yields of 32%–70%.

R = Ph, *n*-C₆H₁₃, *n* = 2–6.

The oxidation potentials of hydrosilanes¹⁶⁴ are 200 mV smaller than that of the polymer; this prevents the latter from oxidation with rupture of the polysilane chain according to a scheme similar to that described by Diaz *et al.*^{165, 166}

The electrically catalysed anodic substitution of hydrogen in the molecule of hydrosilane **42** by an acetoxy-group,¹⁶⁷ like processes of direct anodic substitution, occurs without oxidation of the nucleophile (CH₃COOH), the transferring agent being generated from the electrolytic additive (I[−], Cl[−], NO₃[−]). The transferring agent reacts with the hydrosilane **42** by a radical mechanism and at potentials smaller than the potential of oxidation of the acetate anion.

42

X = I, NO₃, ClO₄.

The same process catalysed by bromide ions by a redox mechanism and carried out using (C₁₀H₂₁)₄NBr or Et₄NBr as supporting electrolytes and EtOH or PrOH as nucleophiles yields triethylalkoxysilanes in 30%–95% yields.¹⁶⁸

Radical cations resulting from electrooxidation of silanes R₃SiH have been identified as adducts with tetracyanoethylene.¹⁶⁹ The lifetime of the radical cation derived from the silane **42** and detected using a rotating disc-ring electrode is equal to 0.003–

0.006 s.^{161, 163} In the absence of radical traps, this radical cation decomposes with the abstraction of a hydrogen atom.

In the presence of cyclohexene, the radical cation [**42**]^{+\cdot} adds to the double bond.^{162, 163, 170} The reaction occurs by a chain mechanism, the role of the anode being limited to its initiation (creation of the initial concentration of the radical cations in the solution equal to 10^{−10} M).

R = R' = EtO; R = Cl, R' = Me.

2. Di- and poly-silanes

The redox properties of polysilanes resemble those of carbon compounds with conjugated double bonds: the HOMO energy of polysilanes increases with increase in the number of linked silicon atoms (this increase is more pronounced than the decrease in the LUMO energy), which results in an increase in their electrochemical activity in oxidation reactions.

The potentials of oxidation of aliphatic disilanes (Table 7), like potentials E_p of other derivatives containing two identical or different elements of the silicon group, obey a linear correlation with vertical gas-phase ionisation potentials (IP) with a slope of less than unity. The latter has been attributed to the influence of the fast kinetics of decomposition of the radical cation and the solvent on E_p .¹⁷¹

In the series of diaryltetraalkyl-, arylpentamethyl- and hexaalkyldisilanes, both types of electron transfer during reduction have been found; stepwise electron transfer was observed in compounds in which a silicon atom carries at least one aromatic substituent and dissociative electron transfer was observed for aliphatic disilanes.¹⁷² An electron-withdrawing NO₂ group in the *para*-position of the aromatic ring destabilises the SOMO of the radical cation so markedly that in the case of bis(*p*-nitrophenyl)tetramethyldisilane, the type of electron transfer changes: the stepwise mechanism is replaced by dissociative mechanism, and the oxidation potential E_p is smaller than that calculated from the IP for reversible electron transfer.

The E_0 values calculated for hexamethyldisilane and Me(Si-Me₂)₃Me are approximately 1 V smaller than their effective potentials E_p , which is due to the high energy of reorganisation (38±5 kcal mol^{−1}) for these compounds.¹⁷⁴

Of the two peaks of oxidation of polysilanes of the composition [(MeSiFc)(MeSiPh)_n]_x, where *n* = 5, 7 and 25, with ferrocenyl (Fc) groups, the one corresponds to the process involving the Fc moiety (+ 0.4 V vs SCE), while the other (E_p = 1.15 V) is associated with the oxidation of the polysilane chain.¹⁶⁵

Polysilane films deposited on a platinum electrode exhibit an irreversible oxidation peak,¹⁶⁶ the potentials of which for alkylpolysilanes lie in the range 1.4–1.6 V (vs SCE) and depend only slightly on the nature of the alkyl substituent. Conversely, the potentials for arylpolysilanes depend appreciably on the electronic effects of the substituents in the aromatic ring, which is manifested in the anodic shift of E_p by 0.3–0.6 V (Table 7). This difference is caused by the marked increase in the relative HOMO

Table 7. Oxidation potentials of linear di- and poly-silanes.

^a vs. Ag/AgCl; MeCN/Et₄NClO₄, $E_{p/2} = 1.36 \text{ V}$ vs Fc/Fc⁺ (MeCN/-Bu₄NClO₄, Pt);¹⁷⁵ ^b the E_0 values calculated vs SCE are given in parentheses; ^c vs Ag/0.1 M AgNO₃; ^d vs Ag/AgCl; MeCN/Et₄NClO₄, $E_{p/2} = 1.10 \text{ V}$ vs Fc/Fc⁺ (MeCN/Bu₄NClO₄, Pt).¹⁷⁵

energy of the polysilane chain due to its interaction with the π orbitals of an aromatic substituent.

The E_p potentials for linear permethylpolysilanes decrease as the length of the chain increases and are related almost linearly to the ϵ_{HOMO} value calculated by the Sandorfi method.¹⁷³ A scheme including the formation of a silicenium adduct with acetonitrile ($n = 1$ or 2) has been proposed for the two-electron reduction of the disilane **9**.¹⁷³

During reverse scanning, two peaks (-0.25 and -1.0 V vs SCE) were detected in the cathodic region; they were attributed to reduction of the adducts with different n .

Cyclic polysilanes are oxidised in two steps ($E_p^1 = 1.1 - 1.4 \text{ V}$, $E_p^2 = 1.4 - 1.9 \text{ V}$ vs SCE).¹⁷⁶ The potential of the first step also depends on the number of silicon atoms linked to one another.¹⁷⁷ However, the character of this dependence is disturbed by another factor that determines the electrochemical reactivity, namely, by the magnitude of the Si–Si–Si angles, which varies as a function of the size of the ring. For cyclosilanes with $n = 3 - 7$, the E_p potential diminishes with a decrease in the size of the ring ($7 \approx 6 \approx 5 > 4 > 3$), because the ring becomes more strained. For cyclopolysilanes with $n > 9$ in which the strain of the ring is no longer significant, only a tendency of E_p to decrease, similar to

that observed in the series of linear polysilanes, was pointed out; however, the numerical values of the potentials were not reported.¹⁷⁶

Preparative oxidation of cyclopolysilanes is accompanied by ring opening yielding intermediate **43** in which the charge and spin densities are separated in space.^{176, 177}

When the process is carried out in the presence of Et₄NBF₄ in CH₂Cl₂/MeCN (4 : 1), α,ω -difluorinated products **44** are formed.¹⁷⁶

It was assumed that ring opening occurs *via* the formation of the intermediate radical cation,^{176, 177} although the variation of the E_p potentials in various solvents¹⁷⁷ (MeCN/CH₂Cl₂) indicates that this is rather an electrochemically irreversible process.

3. Disilenes

Sterically hindered disilenes are irreversibly oxidised in THF at a stationary platinum electrode at close potentials (Table 8), which indicates that the HOMO energy levels of these compounds are close to one another.¹⁵³ Since the interaction between the occupied π orbitals of the disilene and the aromatic fragments in tetraaryldisilenes is weak due to the substantial difference between their energies, the redox properties and the low oxidation potentials are determined by the π -electrons of the disilene bridge.

Table 8. Potentials of the oxidation peaks of disilenes R¹R²Si=SiR¹R² in THF/0.1 M Bu₄NPF₆ at a Pt electrode; $v = 0.2 \text{ V s}^{-1}$.

R ¹	R ²	E_p /V vs SCE
Mes	Mes	0.38

4-Bu ^t -2,6-Me ₂ C ₆ H ₃	4-Bu ^t -2,6-Me ₂ C ₆ H ₃	0.48
Mes	Bu ^t	0.54
Mes	1-Adamantyl	0.36

4. Tetraorganosilanes

The potential of oxidation of Et₄Si ($E_p = 2.56 \text{ V}$ vs SCE), like potentials of alkyl derivatives of metals (Ge, Sn, Pb, Hg) obey a linear correlation with the gas-phase IP.¹⁷⁸ Since the steric factors have no influence on the linear ratio of free energies, the process is assumed to occur as an outer-sphere electron transfer followed by a fast chemical reaction, the rate of which is higher than the rate of the transfer of an electron to the radical cation; this accounts for the fact that the process as a whole is chemically irreversible.

Electrooxidation of Ph₄Si ($E_{1/2} = 2.1 \text{ V}$ vs Ag/0.01 M Ag⁺), PhSiMe₃ and Ph₂Si(OH)₂ in CH₂Cl₂/AlCl₃ at a Pt electrode results in black polymeric precipitates being formed on the surface

of the electrode; these precipitates have been found to incorporate conjugated aromatic fragments.¹⁷⁹ When PhSiH_3 is oxidised at a rotating disc Pt electrode, an oxidation peak ($E_p = 2.1$ V) associated with the passivation of the electrode can be observed. Preparative electrolysis afforded a black polymer similar to that resulting from oxidation of the silane **46**, because disproportionation of the initial silane in the presence of AlCl_3 gives rise to the silane **46** and SiH_4 . Oxidation of 2-methyl-2-vinyltetraphenylcyclotrisiloxane gives the same conductive polymer as the oxidation of the silane **46**, since the latter is one of the oxidation products of this phenylcyclotrisiloxane.

Hexakis(trimethylsilyl)-3,3'-bicyclopropenyl **28** undergoes irreversible two-electron oxidation in $\text{MeCN}/(\text{C}_6\text{H}_{13})_4\text{NClO}_4$ being thus converted into a biradical dication, which decomposes to give two cyclopropenyl cations.¹⁸⁰

Oxidation of a number of tetraalkyl- and trialkylaryl-silanes at a controlled potential in the $\text{MeCN}/\text{Et}_4\text{NF} \cdot 3\text{HF}$ system at Pt electrodes results in the anodic substitution of fluorine for one of the alkyl groups in the silane (Table 9).¹⁸¹ In the presence of F^- anions, the oxidation potential of trimethylphenylsilane decreases by 300 mV (+2.6 and +2.3 vs $\text{Ag}/0.1$ M AgNO_3 with Et_4NClO_4 and $\text{Et}_4\text{NF} \cdot 3\text{HF}$, respectively), which is due to the F^- -assisted single-electron oxidation of the organosilane. After the formation of a Si–F bond, the intermediate radical with pentacoordinated silicon eliminates the most stable alkyl radical.

Alkyl radicals with $E_{1/2} > 2.3$ V ($\text{Me}^\cdot$) either dimerise or add an $\text{H}^\cdot$ atom, whereas the radicals with $E_{1/2} < 2.3$ V ($\text{Et}^\cdot$, $\text{PhCH}_2^\cdot$) are oxidised at the anode to give the corresponding carbocations.

Silanes with a Si–H bond can also be fluorinated by an electrochemical procedure;¹⁸¹ however, in the presence of $\text{Et}_4\text{NF} \cdot 3\text{HF}$, catalytic protodesilylation of R_3SiH to give R_3SiF occurs at a Pt electrode, in parallel with the electrochemical process.

Redox processes involving niobocene complexes with silicon-containing cyclopentadienyl rings and the EPR spectra of their cationic forms have been described.¹⁸²

Table 9. Anodic fluorination of organosilanes ($Q = 1.2$ F mol⁻¹).¹⁸¹

		5	CH_4 , C_2H_6

5. Allyl and benzylsilanes

A distinctive feature of compounds containing a silicon-containing substituent in the β -position with respect to the double bond is σ – π -conjugation between the bonding σ orbital of the Si–C bond and π -electrons of the double bond. As a consequence, the energy of the HOMO of the unsaturated fragment increases,^{183, 184} and, hence, the potentials of electrooxidation of these compounds are markedly lower than the oxidation potentials of compounds that do not contain this fragment (Table 10). Another consequence of the β -effect is that the Si atom in the radical cations derived from benzyl- and allylsilanes becomes more electrophilic. This facilitates cleavage of the C–Si bond (Me_3Si^+ is a ‘super-proton’) and the occurrence of nucleophilic reactions involving this centre.^{185–191}

The oxidation potentials of β -silyl-substituted unsaturated compounds obey a linear correlation with their first IP with a regression slope of less than unity.¹⁹⁵

In a study of oxidation of a series of benzyltrialkylsilanes substituted in the ring, it has been shown that in the case of $p\text{-MeOC}_6\text{H}_4\text{CH}_2\text{SiPr}_3$ and $p\text{-MeOC}_6\text{H}_4\text{CH}_2\text{SiMe}_3$, this process involves the formation of a radical cation that was detected by voltammetry.¹⁹¹ In a non-nucleophilic medium, the potential-determining reaction between the radical cations of benzylsilanes is first order (rupture of the C–Si bond). The reactivity of benzylsilanes is described by a three-parameter model that takes into account the polar effect of the substituent in the aromatic ring and also the inductive and steric effects of the alkyl groups at the Si atom. The relative sensitivity of the potential-determining reaction (ρ_c) to the inductive effect of alkyl substituents is higher than the sensitivity of E_0 (ρ_π), and this accounts for the apparent opposite influence of the +I effect of alkyl groups on the effective potential E_p ($\rho_I < 0$).

Oxidation of trimethylsilylmethanes with π -electron substituents (benzyl, allyl) in the presence of alcohols, carboxylic acids¹⁸⁹ or water¹⁸⁷ results in the formation of anodic substitution products incorporating C–O bonds. It is assumed that initially, the benzyltrimethylsilyl radical cation is formed; subsequently, it loses the Me_3Si^+ fragment and the resulting radical is oxidised to a benzyl cation.

When the process is carried out at a glassy carbon electrode (which is favourable for the adsorption of aromatic fragments) in the presence of Et_4NOTs (the surface activity of TsO^- is lower than that of ClO_4^-), dibenzyl and toluene resulting from transformations of the benzyl radical are also formed.

In the absence of additional nucleophiles in the solution, an unoxidised benzyltrimethylsilane molecule can act as a nucleophile. For example, oxidation of benzyltrimethylsilane **20** in the

CH₂Cl₂/Bu₄NClO₄ in a divided cell at a Pt anode gives benzyl-(trimethylsilylmethyl)benzene in 30% yield.¹⁸⁹

Oxidation of allylsilanes, in particular, allyltrimethylsilane **47**, also involves the intermediate formation of a cation, which reacts with a molecule of an O-nucleophile giving the final product.¹⁸⁷

The regioselectivity of the formation of products, which does not depend on the nature of the nucleophile but is governed by the substituents at the double bond is evidence supporting the above mechanism. In the only study¹⁸⁷ where the subsequent transformations of the silyl fragment have been followed, it has been shown that alkoxytriorganosilane is formed as the final product.

When α, α' -bis(trimethylsilyl)xylenes are oxidised in the presence of alcohols, only one Me₃Si fragment undergoes anodic substitution.¹⁹² No α, α' -dialkoxylated xylenes or products of alkoxylation of the ring are formed. This selectivity of the reaction is due to the fact that the remaining Me₃Si group stabilises the cationic intermediate, and the oxidation potential of the mono-alkoxylated product is more positive than that of the initial bis(trimethylsilyl)xylene.

The abstraction of a trimethylsilyl fragment leads to a cation, in which the positive charge is localised on the benzylic carbon atom and does not migrate to the β -position of the ring. This is confirmed by the fact that the reaction products contain no *p*- or *o*-quinodimethanes.¹⁹²

6. 1-Trialkylsilyl-1,3-alkadienes

Oxidation of 1-trialkylsilyl-1,3-alkadienes in solutions of alkali metal chlorides or bromides in water-organic media¹⁹⁸ yields only kinetically and thermodynamically controlled 3,4-adducts.

R = Me, Et; R' = H, Me; X = Cl, Br;

Y = Cl, Br, OH, OMe, OEt, OAc.

The authors cited explained the high regioselectivity of electrochemical halogenation by the occurrence of single-electron reduction of the unsaturated molecule to give a radical cation, the spin density of which, as shown by extended Hückel quantum-chemical calculations, is mostly localised on the terminal carbon atom of the conjugated system. However, according to the Markovnikov rule, regioselectivity of this addition should apparently be governed by the possibility of resonance stabilisation of the cationic intermediate rather than by the spin density.

Oxidation of 1-trimethylsilyl-1,3-dienes in methanol¹⁹⁹ at a carbon electrode gives rise to α, β -unsaturated 1,1,4-trimethoxy-

alkenes (29%–76%). The latter are readily hydrolysed with dilute HCl to the corresponding α,β -unsaturated aldehydes.

The overall process requires ~ 4.2 F of electricity per mole of the diene; the first half of the electricity passed is consumed in the formation of the silylated allylic intermediate, while the rest of the electricity is spent for its further oxidation, similarly to the process described in another study.¹⁸⁷ Only *trans*-products are formed. The diastereoselectivity of the oxidative methoxylation of 5-phenyl-1-trimethylsilyl-1,3-hexadiene is due to the fact that methanol preferably attacks the radical cation from its less sterically hindered side.¹⁹⁹ The overall yield of the stereomers is 53%.

7. β -silyl ethers

The main characteristic feature of compounds containing silicon in the β -position with respect to the heteroatom (O, S, N), so that its p orbitals can be involved in conjugation with a π -system (if it is present in the molecule), is that the σ_{C-Si} bonding orbital interacts fairly strongly with the lone electron pair of the heteroatom. Although this effect depends on the nature of the heteroatom and on the mutual arrangement of the interacting orbitals, it usually markedly increases the HOMO energy of the molecule and thus facilitates its electrooxidation (E_{ox} decreases by 200–800 mV). Owing to this effect, the silicon atom becomes more electrophilic, especially after the transfer of an electron; as a result, nucleophilic reactions at this site occur at high rates.

Quantum-chemical calculations of HOMO energies as functions of the Si–C–O–C torsional angle have shown²⁰⁰ that when this angle is equal to 0° (a configuration with perpendicular arrangement of the C–Si bond with respect to the p orbital of oxygen), the HOMO level is relatively low and mostly corresponds to the σ orbital. The energy of the HOMO increases as the torsional angle increases and reaches its maximum at an angle of $\sim 95^\circ$. In this configuration, the C–Si bond and the oxygen p orbital are nearly parallel and can overlap efficiently with each other. The maximum destabilisation of the HOMO by the silicon atom in this configuration is 0.9 eV. The results of quantum-chemical calculations are in full agreement with the character of variation of the oxidation potentials (E_p) of alkoxy-silanes in which rotation around the C–O bond is hindered and the dihedral angle has a fixed magnitude (cyclic silicon-containing ethers in Table 11). The introduction of one more silyl group in the

molecule results in further decrease in E_p indicating that the HOMO level becomes even higher. An additional oxygen-containing substituent also decreases the oxidation potential (presumably, owing to an increase in the statistical weight of conformers that are favourable for electron transfer) (Table 11).²⁰⁰

Anodic processes involving β -silyl ethers are accompanied, as a rule, by oxidative rupture of the $C_\alpha-Si$ bond and by the addition

of the nucleophile present in the solution to the resulting carbocation.

Oxidation of alkoxyasilanes has been assumed²⁰⁵ to occur according to Scheme 4.

This process was used as one of the stages in the iteration synthesis of optically active polyols.²⁰⁶

Electrooxidation of unsaturated α -silyl-substituted ethers results in the formation of a new C–C bond with the closure of a ring.²⁰⁷ This process conducted in the presence of PF_6^- or BF_4^- gives rise to cyclic fluorinated *cis*- and *trans*-derivatives.

A β -gem-disilane methoxymethyl group acts as a sort of 'latent carboxyl', which can be activated by electrooxidation.²⁰⁸ For example, oxidation of gem-disilane containing a protected (as a *tert*-butyldimethylsilyl ether) hydroxyl group is accompanied by cyclisation. This reaction has been used at the final stage of the synthesis of γ -undecalactone.^{208–210}

Oxidation of alkoxyasilanes containing a trimethylgermyl group, which is more easily eliminated as a carbocation, makes it possible to prepare acylsilanes.²⁰² Tridecanoyltrimethylsilane is formed (yield 49%) together with some methyl tridecanoate; the latter results from oxidation of the acylsilane itself under galvanostatic conditions and is formed in 96% yield when 5 F mol⁻¹ of electricity is passed through the solution.

8. β -Silyl sulfides

The electronic effects acting in the molecules of ethers are also typical of the molecules of β -silyl sulfides, but in the latter case, they are markedly weaker, because the 3*p* energy level of the S

atom is much higher than those of the orbitals forming the C–Si bond, and these orbitals cannot interact as efficiently as those in the molecules of the oxygen analogues. Reactions involving β -silyl sulfides are similar to the corresponding reactions of β -silyl ethers and are determined by the ease of elimination of the trimethylsilyl group as a cation during anodic substitution.

The oxidation potentials of β -silyl-substituted sulfides are somewhat lower than those of unsaturated compounds. The introduction of additional organylthio- or trimethylsilyl groups does not cause further decrease in E_p (Table 12).

Alkoxylation and acetoxylation of β -silyl phenyl sulfides occurs during their anodic oxidation in the presence of alcohols and carboxylic acids (Scheme 5).^{189,197,207} The yields of the reaction products vary depending on the nature of the nucleophile (25%–66%).

Scheme 5

1-Phenylthio-1-trimethylsilylalkanes are oxidised in the presence of monohydric alcohols (overall, 4 F mol⁻¹ of electricity is required) to give the corresponding acetals in high yields (64%–84%).²¹⁰ The process includes two stages. Initially, 1-methoxy-1-phenylthioalkane is formed (2 F mol⁻¹); it can be detected during the reaction by chromatography or isolated from the reaction mixture. The subsequent two-electron oxidation of this compound is accompanied by rupture of the C–S bond and affords acetals.

Conduct of the process in the presence of dihydric alcohols makes it possible to synthesise cyclic acetals.²¹⁰

Upon electrooxidation in MeOH, 1-phenylthio-1,1-bis(trimethylsilyl)alkanes are converted into the corresponding methyl carboxylates.²⁰⁹

Alkoxylation of β -trimethylsilyl aryl sulfides, similar to the process shown in Scheme 5, has been accomplished using homogeneous redox catalysis by a cyclam complex of Ni(III).²¹³

Ar = *p*-Tol, Ph; L is cyclam.

A trimethylsilyl group present at the 2-position of 1,3-dithianes somewhat decreases the potential of their irreversible oxidation but to a lesser extent than an alkyl group (Table 12).²¹¹ The relatively weak effect of the β -Me₃Si group is due to its equatorial position. When two trimethylsilyl groups are attached to the C(2) atom in 1,3-dithianes, the orientation of one of them becomes favourable for interaction of its $\sigma_{\text{C-Si}}$ orbital with the 3*p* orbital of the S atom, which facilitates oxidation of the dithiane. This effect is even more pronounced for a Me₃Sn substituent, because the energy of $\sigma_{\text{C-Sn}}$ bond is closer to that of the 3*p* orbital of the S atom. Oxidation of 2-trialkylsilyl-1,3-dithianes does not involve the C–Si bond; the yields of the corresponding acylsilanes are 70%–96%.²¹⁴ If the substituent R contains an unsaturated fragment, the reaction affords α,β -unsaturated acylsilanes.

R = Me, Bu^t.

In the oxidation of aryl trimethylsilylmethyl selenides,^{121,217} the β -effect of the Me₃Si group changes in principle the character of the potential-determining reaction of the electrically generated radical cations ($\text{E} + \text{C}_{\text{DIM}} + \text{Cl}$ instead of $\text{E} + \text{Cl} + \text{E}$ as for aryl alkyl selenides), despite the fact that this effect is the least pronounced in the series of β -silylated isostructural compounds of Group VIA elements ($\Delta E_{1/2} \cong 50 \text{ mV}$). Oxidation of aryl trimethylsilylmethyl selenides and sulfides in a non-nucleophilic medium²¹⁷ is accompanied by rupture of the Se–C_{sp³} and S–C_{sp³} bonds rather than the Si–C_{sp³} bond (*cf.* Refs 189, 197, 207 and 210).

The voltammetric behaviour of α,α' -silyl-²¹² and β -silyl-substituted polythiophenes,²¹⁵ polythiophenes based on tetrathienylsilane (C₄H₃S)₄Si,²¹⁶ polymers with units

(where Ar are mono- or polynuclear substituted aromatic fragments)²¹⁸ and polymers prepared from 2,5-bis(trimethylsilyl)-thiophene, bis(2-thienyl)dimethylsilane, 1,2-bis(2-thienyl)tetramethyldisilane and bis(2-thienyl)diphenylsilane²¹⁹ have been reported. Electropolymerisation of silyl-substituted thiophenes, like polymerisation of unsubstituted thiophene, has been carried out by galvanostatic oxidation of the monomers in solution in nitrobenzene.^{212, 215, 216, 219}

9. β -Silylamines and carbamates

Based on the voltammetric behaviour of silylated cyclic amines derived from pyrrolidine, piperidine and perhydroazepine,²²⁰ ($n = 1$; $i/v^{1/2} = \text{const}$, the absence of reversibility of the oxidation peak at the sweep rate $v = 1 \text{ Vs}^{-1}$ at -35°C), it has been suggested that a low-stability radical cation is formed. Substituents at the Si atom, the size of the ring and the presence of methyl groups have only a slight influence on E_p (Table 13), whereas in

the presence of a CH₂ fragment between the Si and N atoms, the E_p value becomes 1.3–1.4 V lower than those for compounds containing no silyl substituent.

This type of variation of the potentials, which is also typical of aromatic *N*-(trimethylsilylmethyl)amines,¹⁹⁴ is associated with the resonance interaction between the trimethylsilylmethyl group and the cationic centre of the radical cation induced by the charge transfer. This interaction is enhanced on passing from the initial compound to the transition state.

The decrease in the potentials of oxidation of nitrogen-containing compounds following the introduction of a β -trimethylsilyl group is relatively small for amines and is more significant for carbamates.²⁰⁰ This manifestation of the β -effect is due to the fact that conjugation with the carbonyl group decreases the energy of the p orbital of the nitrogen atom in the molecules of carbamates and thus facilitates its more efficient overlap with the bonding σ_{C-Si} orbital.

Preparative processes involving this type of compound are similar to those involving β -silyl ethers and sulfides. They include anodic substitution of an appropriate nucleophile for the trimethylsilyl group. The carbamates activated by a silyl group undergo electrooxidation with cleavage of the C–Si bond and regioselective methoxylation of the α -carbon atom.²²³ The corresponding α -methoxycarbamates are obtained in yields of 68%–100%.

N-Substituted 4-trimethylsilylazetidin-2-ones **48** are also converted into alkoxylation and acyloxylation products. When Et₃N·3HF is added to the solution of an electrolyte, fluorinated products of anodic substitution are formed.²²⁴

R = H, PhCH₂;

R' = Ac, Me, CH₂CHMe₂, CH₂CH=CH₂, (CH₂)₂CH=CH₂, PhCH₂.

Oxidation of [(*N*-methylbenzylamino)methyl]trimethylsilane in the presence of MeOH or EtOH is the only example of reaction in which the C–Si bond in a β -silyl-substituted nitrogen-containing compound does not undergo oxidative rupture but, instead, the C–N bond is cleaved.¹⁸⁹ This leads to bis(benzylmethylamino)methane rather than to alkoxylation products.

Electrooxidation of tosylhydrazones of acylsilanes in an undivided cell affords the corresponding nitriles.²⁰³ The process requires 3.2–4.4 F mol^{−1} of electricity.

In a divided cell, the formation of nitriles requires a catalytic amount of electricity ($Q = 0.26$ – 0.8 F mol^{−1}); the yields of nitriles are markedly higher.

10. β -Silyl-substituted derivatives of carboxylic acids

Anodic oxidation of β -trimethylsilyl-substituted carboxylic acids affords only terminal alkenes as the final products, because at the carbocation stage resulting from oxidative decarboxylation of the

initial molecule, the process is controlled by the trimethylsilyl group.²²⁶

Oxidative decarboxylation–desilylation has been used in the synthesis of 2,5-norbornadiene.¹⁵⁸

11. β -Silyl-substituted enol acetates

Oxidation of β -silyl-substituted enol acetates yielding α,β -unsaturated β -silylcycloalkenones is the only known reaction in which the trimethylsilyl group does not undergo oxidative elimination from the allylic position.²²⁷

The process is believed to include cyclisation of the primary radical cation, which is converted by deprotonation into an α -radical stabilised by the silicon atom. This effect, together with the antiparallel arrangement of the C $_{\beta}$ –H bond with respect to the C–O⁺ bond being cleaved in the oxonium intermediate, results in the rupture of the C $_{\beta}$ –H bond instead of the C $_{\beta}$ –Si bond which is cleaved in the case of allyl- and benzyl-silanes.

12. Siloxy-derivatives

The oxidation potentials of trialkylsiloxybenzenes are virtually determined by the first siloxy-group attached to the aromatic ring. The introduction of the second group of this type changes E_p only slightly²²⁸ (Table 14).

Table 14. Oxidation potentials of trialkylsiloxybenzenes R¹R²R³R⁴C₆H₂ in MeCN/0.1 M LiClO₄ (Pt electrode, $v = 0.1$ V s^{−1}).

^a 9,10-Bis(trimethylsiloxy)anthracene.

Trimethylsilyl ethers of hydroquinone lose Me_3Si fragments during oxidation and, *via* the intermediate formation of radicals **49**, they are converted into the corresponding quinones in 65%–92% yields.²²⁸

Under similar conditions, monosilylated 4-methoxy-1-(trimethylsiloxy)benzene gives rise to 4,4-dimethoxy-2,5-cyclohexadienone (yield 99%).²²⁸

Anodic oxidation of the trimethylsilyl ether of 4-(2'-alkenyl)phenol **50** carried out in MeOH (Pt anode, 0–10 °C) is accompanied by the elimination of the trimethylsilyl group and by intramolecular cyclisation involving the double bond of the alkenyl substituent.²²⁹

Silyl ethers of enols undergo electrooxidation to give γ -diketones. The latter result from dimerisation of either the primary radical cations or the radicals arising after the oxidative rupture of the Si–O bond.²³⁰

β -Oxoesters are formed in the electrooxidation of 1-trimethylsilyloxybicyclo[*n*.1.0]alkanes²³¹ in ethanol in the presence of $\text{Fe}(\text{NO}_3)_3$ in a divided cell at a Pt electrode.

$n = 4, 5, 10$; $R = \text{H, Me}$; $X = \text{H, Br, Cl}$.

Under the same conditions, 6,6-dichloro-1-trimethylsilyloxybicyclo[3.1.0]hexane yields only the product of ring expansion.

It was noted that the maximum yield of β -oxoesters is observed at –13 to –10 °C, but neither the reason for this effect nor the role of $\text{Fe}(\text{III})$ were discussed.

13. α -Silyl esters

The oxidation potentials of acylsilanes in which the silicon atom is attached to an electron-withdrawing carboxylic group are smaller than the potentials of the corresponding alkoxyasilanes (see Table 11).^{201, 203} In terms of the concept of $\sigma_{\text{C-Si}}-\rho_{\text{O}}$ conjugation, this is explained by the rigid fixing of the orbitals in the carbonyl compound, which ensures their efficient overlap, and by the possibility of free rotation around the C–O bond in alkoxyasilanes, which results in a lower probability of efficient conjugation in the latter case. However, in the case of adiabatic stepwise transfer of an electron during oxidation (which assumes that a primary radical cation is present on the reaction coordinate), stabilisation of the radical cation by the β -effect of the silyl group should be identical for these two types of compound (owing to the free rotation). Therefore, the experimental observation in question is rather associated with the fact that the C=O bond is shorter than C–O. This ensures more efficient overlap of the interacting orbitals, which destabilises the HOMO of the initial molecule and thus decreases the oxidation potential of acylsilanes.

Preparative oxidation of acylsilanes, like the oxidation of allyl- and benzylsilanes, involves rupture of the C–Si bond and affords products of electrophilic reactions of the carbocationic intermediate.^{201, 203, 232} It has been assumed that the carbocation is formed *via* nucleophilic attack on the primary radical cation derived from acylsilane (Scheme 6).

Scheme 6

Electrooxidation of acylsilanes in the presence of a 5–6-fold excess of a nucleophilic reagent gives the corresponding products of anodic substitution in 69%–92% yields.²¹⁰

14. α -Silylamines

The appearance of the silyl group at the nitrogen atom in aniline (see Table 13) increases E_{ox} with respect to that of the unsubstituted compound, which is in agreement with the electron-withdrawing properties of the α - Me_3Si group.¹⁹⁴

The single-electron reduction of silylamines at a Pt electrode has been considered.²²² In the case of alkyl derivatives, the inductive mechanism of the transfer of electron density predominates, whereas, in the case of vinyl derivatives, the EPR data for the electrically generated radical cation $[\text{MeVinSi}(\text{NEt}_2)_2]^{\cdot+}$ made it possible to conclude that the positive charge and spin density are delocalised in the $\text{N}-\text{Si}-\text{N}$ group. However, in the latter case, there is no conjugation over the $\text{C}=\text{C}-\text{Si}-\text{N}$ system of bonds. The $\epsilon_{\text{HOMO}} - E_{\text{p}/2}$ plots for alkyl- and vinyl-substituted silylamines are separate straight lines for each family of compounds, which is due to the differences in the transfer of electronic effects.

Electrooxidation of bis(trimethylsilylmethyl)benzylamine in DMF is a convenient method for generation of 1,3-dipoles, which react with activated alkenes.²³³ The yields of the cycloaddition products vary in the range 8%–61% depending on the nature of the substituent in the alkene molecule.

$\text{R} = \text{H}, \text{CO}_2\text{Me}, \text{Ph}; \text{R}' = \text{OMe}, \text{OBu}^t, \text{H}.$

The use of AcONa or KF as a supporting electrolyte is significant for efficient cycloaddition.

15. Compounds of hypervalent silicon

Comparison of the oxidation potentials of mono- and bis-pentacoordinated systems with silatrane ($E_{1/2} = -0.07$ and $+0.21 \text{ V vs SCE}$) or silylcatecholate fragments ($E_{1/2} = +0.07$ and $+0.31 \text{ V vs SCE}$) with the oxidation potentials of 1,1'-bis-silyl-substituted ferrocene derivatives **51** ($E_{1/2} = +0.55 \text{ V}$)²³⁴ has demonstrated an interesting electronic effect: a substantial decrease in the $E_{1/2}$ potential for the reversible $\text{Fe(II)}/\text{Fe(III)}$ pair is observed in the case of anionic and pentacoordinated compounds, whereas in the case of bis(trimethoxysilyl)ferrocene, a slight increase in this

potential has been found [$\Delta E_{1/2}$ for bis(trimethoxysilyl)ferrocene with respect to unsaturated ferrocene is $+0.09 \text{ V}$].

Thus, the coordination number proves to be an important factor determining the electronic properties of organosilicon compounds: tetracoordinated compounds exhibit electron-withdrawing properties, whereas pentacoordinated compounds are characterised by electron-donating properties (irrespective of their geometry). Although this effect has not yet received a clear explanation, it is assumed that the electron density in pentacoordinated organosilicon compounds is delocalised over the surrounding ligands. In this case, silicon acts as a donor of electrons and thus becomes more electrophilic. In the molecules of silatranes, the electron density is markedly displaced from nitrogen to iron through the silicon atom, owing to the bis-apical arrangement of these atoms in the trigonal bipyramid.

Voltammetric curves for R-silatranes ($\text{R} = \text{Me}, \text{Et}, \text{Vin}, \text{Ph}$) ($\nu = 0.2\text{--}0.5 \text{ V s}^{-1}$) are practically reversible, and the oxidation potential depends appreciably on the nature of R , which indicates that the $\text{N} \rightarrow \text{Si}$ interactions are retained during the electrode process.²²⁵

VII. Electrochemical processes involving organic derivatives of silicon

Electrooxidation of alkenylsilanes in the presence of PhSH and with molecular oxygen being bubbled through the solution requires a catalytic amount of electricity ($Q = 0.16$ to 1.19 F mol^{-1}) and is a direct and regiospecific pathway to α -phenylthio-substituted carbonyl compounds.²³⁵ The yields of the products depend appreciably on the nature of the substituents R and R' .

R	R'	Yield (%)
C_6H_{13}	H	12
H	C_8H_{17}	73
H	$\text{C}_8\text{H}_{17}\text{CH}(\text{OH})\text{CH}_2$	93
C_4H_9	C_4H_9	13

Oxidation ($Q = 0.04\text{--}3.77 \text{ F mol}^{-1}$) of 0.5 mmoles of 1-phenylthio-1-(trimethylsilyl)alkenes in the presence of 2–6 equivalents of thiophenol results in the formation of a product with two phenylthio-groups ($\text{R}' = \text{SPh}$) in a yield of 60%–99%.

During the electrochemically initiated oxygenation of 1-phenylthio-1-(trimethylsilyl)alkenes, only the $\text{C}-\text{Si}$ bond undergoes oxidative rupture, the $\text{C}-\text{S}$ bond remaining intact. A chain radical mechanism for this process has been proposed; this mechanism includes radical addition of the phenylthio radical to the double bond, reaction of the resulting C-radical with oxygen and abstraction of an $\text{H}^{\cdot}$ atom from PhSH by a peroxy radical, which yields hydroperoxide and regenerates the phenylthio radical.

Tetraethylsilane **45** has been obtained both in cathodic and anodic processes as a result of the radical attack by ethyl radicals (electrically generated by oxidation of EtMgBr or reduction of EtBr) on a silicon atom of the electrodes.²⁴¹ When ethyl chloride or acrylonitrile is used in this process, no organosilicon compounds are formed.

Tetraethoxysilane is prepared by oxidation of EtOH in the presence of $(\text{NH}_2)_2\text{CO} \cdot \text{HCl} + (\text{NH}_2)_2\text{CO}$ or $\text{Et}_3\text{N} \cdot \text{HCl} + \text{Et}_3\text{N}$ at a ferrosilicon anode.^{3, 242–245} Depending on the supporting electrolyte and its concentration and on the current density, the yield of the reaction product ranges from 3.3% to 60% based on the dissolved ferrosilicon.²⁴⁴

VIII. Conclusion

The character of silyl substitution (α - or β -substitution) in aromatic or heteroatomic molecules changes their electrochemical reactivity according to the influence of the silyl group on the frontier orbitals. α -Substitution decreases the LUMO energy and facilitates reduction reactions, whereas β -substitution increases the HOMO energy and decreases the IP, which accounts for the easier anodic oxidation of these compounds.

Evidently, electroreduction of chlorosilanes involves the activation type of electron transfer (although the Si–Cl bond is very strong) giving rise to silyl radicals, which are reduced at the potential of formation to silyl anions. For this reason, cathodic processes involving chlorosilanes occur by an ionic mechanism.

The crucial factor determining the behaviour of organosilicon radical-cation intermediates in anodic reactions is that trialkylsilyl groups are eliminated extremely easily in the cationic form. Therefore, organosilicon derivatives are quite attractive for functionalisation of organic compounds in the reactions of anodic substitution.

The publications dealing with the electrochemistry of organosilicon compounds can be clearly divided into two groups. The first group includes theoretical studies in which the electrochemical method is used to obtain characteristics of FMOs and to study orbital interactions, whereas the second group comprises purely preparative studies (synthetic studies based on the electrochemical generation of active intermediates and electrochemical initiation of reactions in the bulk of a solution). The studies of the first group usually deal with potentials of reversible redox pairs (the ion-radical components of which are so stable that they exist in solution over long periods without entering in any reactions), while the studies of the second group occur normally under non-controlled conditions, and potentials are often not used at all to characterise the reactivities of compounds.

It is clear that these two lines of research do not exhaust the potentialities of organic electrochemistry and, therefore, it is quite reasonable to expect that new studies in this field will be published. In particular, one might expect that studies dealing with elementary steps of electrochemical processes, kinetics and thermodynamics of electron transfer and of accompanying chemical reactions will appear, because it is the mechanistic investigations that would create the scientific grounds for controlling the reactivity of intermediates (and, hence, the nature of the final products) as early as at the stage of charge transfer and potential-determining reactions.

IV. Bond blocks	547
V. Conclusion	550

Abstract. The modern mathematical methods which make it possible to describe the kinetics of the formation reactions and the structures of polymers formed via polycondensation are examined: direct differentiation of an infinite system of differential equations, statistical approaches, and the concept of bond blocks. The possibilities and limits of applicability of each method are demonstrated. The bibliography includes 83 references.

I. Introduction

The mathematical procedures for the analysis of the kinetics of chemical reactions, based on the Law of Mass Action,¹ have been well developed. It would appear that the entire problem should reduce to finding procedures for the solution of a more or less complex system of differential equations describing the variation of the concentrations of the reactants as a function of time. However, when the formation reactions of polymers are examined, a series of problems arise. The first of them is that the kinetics of polymerisation processes depend significantly on the state of the reaction medium, which frequently varies in the course of the reaction.² The inhomogeneity of the distribution of the reaction centres in the initial stage of three-dimensional radical polymerisation, leading to cyclisation and ultimately to a high degree of localisation of the process,^{3,4} the variation of the viscosity inducing the gel effect in the radical polymerisation of certain monomers,⁵ as well as the inhibition of the reaction as a result of the vitrification of the system^{2,6–9} may serve as examples. Finally, the system frequently undergoes phase decomposition in the course of the process,¹⁰ which results in a change of the spatial distribution of the concentrations of the reactants. These factors are extremely difficult to take into account within the framework of formal kinetics.

Another difficulty consists in the need to analyse and solve an infinite system of differential equations because in principle, there is a possibility of the formation of an infinite number of reaction products — macromolecules of different size and with different structures. The approaches to the solution of such a system of

equations have already been outlined by Flory¹¹ and were later developed in many studies and surveyed in monographs.^{3,12,13} However, recently a series of new problems arose, particularly in connection with the wide scale employment of numerical methods based on the application of modern computational techniques. The principle of these is how to attain the required accuracy of the numerical solution and how to control it.

The development of modern experimental methods has reached a level such that the calculations of certain average quantities (for example, the number-average and weight-average molecular masses) have already become inadequate; more detailed information about the structure of the polymer is required from the kinetic calculation. However, any experimental methods for the study of the structures of polymers are also subject to an intrinsic error, which in fact determines the required accuracy of the calculation.

Hitherto statistical computational methods have been applied in kinetic investigations, which is due both to their simplicity and to the possibility of obtaining with their aid detailed information about the structures of complex formations such as, for example, network polymers. However, investigators do not always estimate correctly the applicability of these methods to the description of specific kinetic systems.

Finally, a new approach has appeared recently to the analysis of the formation reactions and structures of polycondensation polymers, based on the concepts of bond blocks.

All these factors have led to the writing of the present review.

It has to be stipulated immediately that the review will deal solely with the polycondensation method of synthesis of polymers. The characteristic features of the formation of the chain — unit by unit or from any fragments — actually determine the choice of qualitatively different systems of differential equations.^{3,14,15} The solution and analysis of the system describing polycondensation processes are in fact the most complex. Problems of this class are solved with the aid of the Smoluchowski equation,¹⁶ which was first proposed for the description of coagulation processes.^{17,18}

II. Direct methods for the solution of the Smoluchowski equation

1. Polycondensation of polymers with isotypical functional groups

The Smoluchowski equation has the following general form:

$$\frac{dx_i}{dt} = -x_i \sum_j k(i,j)x_j + \frac{1}{2} \sum_{j=1}^{i-1} k(i-j,j)x_{i-j}x_j, \quad (1)$$

V I Irzhak Institute of Chemical Physics in Chernogolovka, Russian Academy of Sciences, 142432 Chernogolovka, Moscow Region, Russian Federation. Fax (7-096) 515 35 88. Tel. (7-096) 517 16 90. E-mail: irzhak@icp.ac.ru

where x_i is the concentration of the species (in the given instance, macromolecules) with size i ($i = 1, 2, 3, \dots$ is the number of units in the chain) and $k(i, j)$ is the rate constant for the reaction between species with sizes i and j .

This equation describes a process which in the simplest case can be expressed in the form

The Smoluchowski equation is suitable for the description of the kinetics of a wide variety of processes and numerous studies have therefore been devoted to its analysis (see, for example, Refs 16 and 19–25).

When applied to the reactions of polymer formation, Eqn (1) characterises polycondensation as a result of the interaction of isotypical functional groups with one another. The dependence of the kinetic constants on the dimensions of the macromolecules (subject to the condition that Flory's postulate¹¹ of the independence of the reactivity of functional groups on the size of the macromolecules carrying these groups is valid) is due to the fact that the number of functional groups f_i and the size of the macromolecules are directly interrelated (in the absence of intramolecular cyclisation reactions).

In the simplest case of the f -functional polycondensation, we have

$$f_i = (f-2)i + 2. \quad (3)$$

Hence it follows that the effective rate constant for the reaction between macromolecules having the i th and j th sizes is

$$k(i, j) = f_i f_j k, \quad (4)$$

where k is the rate constant for the reaction between the corresponding functional groups.

A thorough analysis of the approaches to the solution of the Smoluchowski equation has been carried out.¹⁶ In their assessment of the functional relations $k(i, j)$, the authors do not confine themselves to Eqn (4) and consider also other more general relations:

$$k(i, j) = A + B(i+j) + Cij, \quad (5)$$

where A , B , and C are parameters the magnitude of which depends on the type of the monomer. Processes during which the relation

$$k(i, j) = A i^n j^m \exp(-Bij),$$

holds preferentially have also been analysed¹⁹ using numerical methods for the solution of Eqn (1).

The general approach to the solution of Eqn (1) is¹³ that they are convoluted with the aid of an integral transformation by introducing the so called generating function $F(s, t)$:

$$F(s, t) = \sum_i x_i(t) s^i, \quad (6)$$

where s is a parameter and t the process time.

As can be seen from Eqn (6), when the function $F(s, t)$ is expanded in series in s , the concentrations of the i -mers assume the roles of the coefficients of the corresponding powers of s . On differentiating $F(s, t)$ with respect to s for $s \rightarrow 1$, we obtain the moments of the distribution of x_i with respect to i . Eqns (1) then assume the form of a partial differential equation:

$$\frac{\partial F(s, t)}{\partial t} = -s \frac{\partial F(s, t)}{\partial s} \frac{\partial F(1, t)}{\partial s} + \frac{1}{2} \left\{ \frac{\partial F(s, t)}{\partial s} \right\}^2, \quad (7)$$

which can be solved by the method of characteristics.²⁶

If it is assumed that the index i in the designation of the concentrations x_i characterises not the size of the macromolecule, expressed as the number of monomer units, but its functionality, then, firstly, the relation $k(i, j)$ becomes universal, namely $k(i, j)$ is proportional to the product ij , and, secondly, Eqn (7) becomes applicable to any polycondensation system with isotypical functional groups.

The solution of Eqn (7) leads to the following result (in a parametric form):

$$F(s, t) = \sum_i x_i(0) \chi^i - \frac{t \left\{ \sum_i i x_i(0) \chi^{i-1} \right\}^2}{2(1 + \Phi t)}, \quad (8)$$

$$s = \chi + \left(\chi - \frac{\sum_i i x_i(0) \chi^{i-1}}{\Phi} \right) \Phi t. \quad (9)$$

Here $x_i(0)$ is the initial concentration of molecules with i functional groups (this quantity characterises the distribution of the initial molecules with respect to the types of functionality), χ is a parameter, and Φ is the initial concentration of functional groups.

It has been shown²⁷ that the solution of Eqns (7) branches at a certain critical point t_c on the time scale. If $t \leq t_c$, then $\chi(s) = 1$ when $s = 1$. Starting from the time t_c Eqn (9) has two roots: $\chi_1(1) = 1$ and $\chi_2(1) < 1$. The critical point corresponds to the onset of gel formation, while the second root χ_2 (less than unity) characterises the sol fraction of the system. On differentiating Eqn (9) with respect to s , we obtain an expression for the critical time:

$$\begin{aligned} \frac{\partial \chi}{\partial s} &= \frac{1}{1 + \Phi t \left\{ 1 - \sum_i i(i-1)x_i(0)\chi^{i-2}/\Phi \right\}} = \\ &= \frac{1}{1 - \Phi t(\bar{f}_w - 2)}, \end{aligned} \quad (10)$$

i.e.

$$\Phi t_c = \frac{1}{\bar{f}_w - 2}, \quad (11)$$

and for the critical conversion we have

$$\alpha_c = \frac{\Phi t_c}{1 + \Phi t_c} = \frac{1}{\bar{f}_w - 1}, \quad (12)$$

where

$$\bar{f}_w = \frac{\sum_i i^2 x_{i0}}{\sum_i i x_{i0}}.$$

Here $\bar{f}_w$ is the weight-average functionality³ of the initial system.

The branching of the solution of Eqn (8) may be confirmed by a general consideration of the initial Eqn (7) without resorting to its solution.²⁸

Indeed, successive differentiation of Eqn (7) with respect to the parameter s leads to the appearance of a chain of equations for the distribution moments:

$$\frac{\partial F'(s)}{\partial t} = -F'(s)F'(1) + F''(s)[F'(s) - sF'(1)], \quad (13)$$

$$\frac{\partial F''(s)}{\partial t} = F''(s)[F''(s) - 2F'(1)] + F'''(s)[F'(s) - sF'(1)], \quad (14)$$

etc. The primes in the equations denote the corresponding derivatives (first, second, and third) with respect to s .

When $s = 1$, the expressions in square brackets in the second terms on the right-hand sides of the equations become zero. As a result of this, the chain of equations is closed and this makes it possible to find explicitly the time variation of the distribution moments $F'(1)$, $F''(1)$, etc. However, as can be seen from Eqn (10), at the critical point the highest distribution moments tend to infinity. Thus the second term on the right-hand sides of the equations becomes indeterminate, because it represents the product of zero and infinity. This indeterminacy must be resolved, as it implies the appearance of the possibility of a different solution.

The size of the macromolecule and its functionality are unambiguously interrelated by a relation of type (3). However, in the general case, for an arbitrary initial distribution with respect

to functionality, it is not so easy to find the specific form of a relation of this kind. It is therefore reasonable, adopting the considerations put forward in a monograph,¹³ to introduce a two-index definition of the chains, where one of the indices characterises the size of the macromolecule and the other its functionality. If the polycondensation takes place as a result of the interaction of different functional groups, then a larger number of indices are introduced, each corresponding to a definite type of such functional groups. Thus it is possible to describe adequately a process occurring in an arbitrarily complex system.

2. Cyclotrimerisation

It is noteworthy that reactions with participation of only isotypical functional groups are encountered extremely rarely. One of the examples is the cyclotrimerisation of isocyanates^{29,30} and cyanic acid derivatives.³¹ Although these reactions can be formally regarded as polycondensation with participation of isotypical groups, a wide variety of aspects of which have been well investigated, the fact that the formation of a trifunctional unit takes place in one step must introduce certain characteristic features into the process kinetics. We shall discuss this problem.

The trimerisation process represents formally the simultaneous condensation of three functional groups, *i.e.* a termolecular reaction. For example, in the case of isocyanates, it can be described as follows:

However, the reaction mechanism is fairly complex.³² For example, the trimerisation of isocyanates takes place as a first-order reaction.^{33–35} It is of first order with respect to both the isocyanate groups and the catalyst and proceeds via a complex system of equilibria. In particular, the first stage is the formation of carbamates.³⁵ The time law governing the consumption of functional groups is determined by this factor. However, since the functional groups are distributed between different macromolecules, the probability of the reaction of each of them (the reaction rate) must be proportional to the product of the rate of reaction of the functional groups and the product of the concentrations of the corresponding macromolecules. Thus the differential equations describing the growth of macromolecules assumes form (1), but in terms of a certain fictitious time. We shall explain this in relation to a simple example.³⁶

Suppose that the functional groups Y are bound in a complex with a reagent Z:

where K is the equilibrium constant.

The rate of formation of the Y–Y bond as a result of, say, the interaction of species bound in a complex has been described by the expression

$$\frac{d[\text{YY}]}{dt} = k \left(\frac{Kz_0y}{1 + Ky} \right)^2, \quad (17)$$

where the symbols z and y designate the concentrations of the corresponding reactants and k is the reaction rate constant.

Evidently, depending on the product Ky , the reaction can be of both second and zero order with respect to the concentration of the functional groups y . However, if the formation reaction of the

dimer X_2 is described, then the multiplier x_1 appears in brackets in the numerator on the right-hand side of the equation whilst the denominator remains the same as before. Thus the kinetic equation for the formation of the dimer assumes the form

$$\frac{d[\text{X}_2]}{dt} = k \left(\frac{Kz_0y}{1 + Ky} \right)^2 x_1^2 = \frac{d[\text{YY}]}{dt} x_1^2, \quad (18)$$

or, after the introduction of the fictitious time,

$$\tau = \int \frac{d[\text{YY}]}{dt} dt, \quad (19)$$

$$\frac{d[\text{X}_2]}{dt} = kx_1^2. \quad (20)$$

A similar problem arises also in the case of reactions between an amine and an epoxide. The interaction of these reactants is also known^{37,38} to proceed via a complex system of donor–acceptor equilibria. The kinetic law governing the consumption of the epoxide groups should therefore be fairly complex.^{37–40} Thus the following kinetic equation has been proposed:⁴⁰

$$\frac{d\alpha}{dt} = k_1(1 - \alpha)^{n_1} + k_2\alpha^m(1 - \alpha)^{n_2},$$

where α is the degree of conversion with respect to the epoxide groups.

The simplest way of taking into account the complexity of the kinetic law consists in the use of an equation of type (19) in formulating the kinetic equations for the concentrations of macromolecules of different size, the consumption of the functional groups and the hydroxy- and epoxide groups (E) being disregarded.⁴¹ In this case

$$\tau = k[\text{OH}][\text{E}]_0^2 t.$$

Evidently, this approach may lead to significant errors. The system of donor–acceptor interactions, which determines the complexity of the process kinetics, varies over the course of the reaction³⁸ because not only the initial system components, the concentration of which falls as the process proceeds, but also the reaction products, the concentration of which increases, may participate directly in the equilibrium. Thus it would be more correct to express the fictitious time in an integral form, as in Eqn (19).

The question whether the complexity of the reaction mechanism may preclude the formulation of kinetic equations in the form of Eqn (1) was apparently first posed in the study of Stanford and Stepto⁴² in relation to the reaction of urethane formation. The problem was solved as follows: the application of Eqn (1) is possible if the degree of conversion is used instead of time as the independent variable. In essence, this claim agrees with Eqn (18). However, this conclusion has not been demonstrated rigorously and is more in the nature of an intuitive postulate.

When equations of type (1) are formulated for a cyclotrimerisation reaction, account is actually taken of its termolecularity,^{43,44} neglecting the complexity of the kinetic law.

Since the reaction products may contain only an odd number of oligomeric units and the chain length obeys the condition

$$i = 2n + 1, \quad (21)$$

whilst the number of functional groups in the macromolecule is defined by the relation

$$f_i = n + 2, \quad (22)$$

where n is the number of ternary knots arising as a result of cyclotrimerisation, an equation of type (1) can be written as follows:^{43,44}

$$\frac{dx_{2n+1}}{dt} = -(n+2)x_{2n+1} \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} (i+2)(j+2)x_{2i+1}x_{2j+1} + \frac{1}{3} \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \sum_{k=0}^{\infty} (i+2)(j+2)(k+2)x_{2i+1}x_{2j+1}x_{2k+1} \quad (23)$$

$$i + j + k = n - 1.$$

Eqn (23) was solved by the method of generating functions.⁴³

If account is taken of the fact that the relation between the degree of polymerisation of the macromolecules i and the functionality is specified by the relation

$$f_i = \frac{i+3}{2}, \quad (24)$$

which follows from conditions (21) and (22), then the equation thus obtained assumes the form

$$\frac{\partial F(s, t)}{\partial t} = -\frac{1}{8} [sF'(s, t) + 3F(s, t)][(F'(1, t) + 3F(1, t))^2 + (sF'(s, t) + 3F(s, t))^3]. \quad (25)$$

It has been shown that the degree of critical conversion $\alpha_c = 0.5$, which agrees with experimental data.^{45–48}

An attempt has been made⁴⁴ to explain the experimentally observed⁴⁹ deviations of the observed value of α_c (0.60–0.66) by the decrease in the reactivity of the ‘suspended’ functional group compared with the initial reactivity, *i.e.* by the effect of substitution in the first sphere. A statistical approach was used as a method for the solution of the problem. The authors⁴⁴ found that, as the reactivity approaches zero, the degree of critical conversion tends to 0.66.

Several comments need to be made concerning the result obtained. Firstly, it has been shown^{32,33} that the reactivities of the initial and ‘suspended’ isocyanate groups are the same, *i.e.* that there is no substitution effect at least in the case of 1,6-hexamethylene diisocyanate. Secondly, as shown above, the gel formation point in the cyclotrimerisation of cyanate esters corresponds to 50% conversion.^{45–48} Finally, it has been established¹³ that the use of the statistical method of calculation in the presence of the substitution effect may lead to erroneous results. A striking confirmation of this conclusion has been obtained.⁵⁰

The kinetic effect of substitution in the first sphere implies that, when a polycondensation reaction, which in the simplest case can be represented by the scheme

is carried out, the kinetic constants are not equal to one another: $k_1 \neq k_2 \neq k_3$. As in Scheme (2), in Scheme (26) the index designates the number of monomer units in the macromolecule and f_i represents the functionality of the i -mer.

As shown in Fig. 1, the degrees of critical conversion calculated for the equilibrium polycondensation (where the results of the statistical calculation are applicable) and nonequilibrium polycondensation differ not only quantitatively but also qualitatively.

The cyclotrimerisation reaction is not of interest solely as a method of synthesis of a wide variety of thermally stable and heat-resistant polymers from a fairly wide class of monomers.³¹ The fact that three functional groups entering into the composition of three different macromolecules participate in the reaction introduces definite characteristic features also into the formal features

Figure 1. Dependence of the critical conversion (gel point) on the constant k_2/k_1 [see Scheme (26)] in irreversible (continuous lines) and equilibrium (dashed lines) 3-functional polycondensation.⁵⁰ The constants k_3/k_1 : (1) and (1') 0.01; (2) and (2') 0.05; (3) and (3') 0.1; (4) and (4') 0.2; (5) and (5') 0.5; (6) and (6') 1; (7) and (7') 2; (8) and (8') 5; (9) and (9') 10; (10) and (10') 100.

of the polycondensation. In particular, the solution of Eqn (25) by the method of characteristics affords the following result for the number-average degree of polymerisation $\bar{P}_n$ and the critical conversion α_c

$$\bar{P}_n = \frac{1}{1 - 2/3(\bar{f}_n \alpha)}, \quad (27)$$

$$\alpha_c = \frac{1}{2(\bar{f}_n - 1)}, \quad (28)$$

where

$$\bar{f}_n = \frac{\sum i x_{i0}}{\sum x_{i0}} \text{ is the number-average functionality.}^3$$

Evidently Eqns (27) and (28) differ from the classical equations, including Eqn (12), which characterises the critical conditions in f -functional polycondensation. This is why monofunctional monomers (for example, 1-chloro-6-hexamethylene isocyanate^{33,34}) do not terminate the network chain but play the role of a chain propagator, displacing the gel formation point towards higher conversions up to the formation of linear polymers. We shall carry out below a more thorough comparison of the cyclotrimerisation and 3-functional polycondensation processes on the basis of statistical analysis. Despite all the differences, these processes lead to the formation of 3-functional knots.

3. Polycondensation of monomers with heterotypical functional groups

The reaction between functional groups of different types (epoxide + amine, isocyanate + hydroxyl, hydroxyl + carboxyl, *etc.*) is a more common instance of polycondensation processes. If the polycondensation takes place as a result of the interaction of heterotypical functional groups and reaction between isotypical groups is impossible, then Eqn (7) is replaced by the expression

$$\frac{\partial F(\bar{s})}{\partial t} = -s_1 \frac{\partial F(\bar{s})}{\partial s_1} \frac{\partial F(\bar{1})}{\partial s_2} - s_2 \frac{\partial F(\bar{1})}{\partial s_1} \frac{\partial F(\bar{s})}{\partial s_2} + \frac{\partial F(\bar{s})}{\partial s_1} \frac{\partial F(\bar{s})}{\partial s_2}, \quad (29)$$

in which $\bar{s}$ is a vector, consisting in the given instance of two components, s_1 and s_2 , which refer to functional groups of two types.

The solution of the above equation by the method of characteristics leads to the following result, which has also been obtained in a parametric form:

$$F(\bar{s}, t) = \sum_i (x_{ai}\chi_1^i + x_{bi}\chi_2^i) - a\alpha_a, \quad (30)$$

$$a\alpha_a = b\alpha_b, \quad (31)$$

$$s_1 = \frac{\chi_1 - \alpha_a \sum_i i x_{bi} \chi_2^{i-1} / b}{1 - \alpha_a}, \quad (32)$$

$$s_2 = \frac{\chi_2 - \alpha_b \sum_i i x_{ai} \chi_1^{i-1} / a}{1 - \alpha_b}, \quad (33)$$

$$\alpha_a = b \frac{e^{(b-a)t} - 1}{be^{(b-a)t} - a}, \quad (34)$$

$$\alpha_b = a \frac{e^{(b-a)t} - 1}{be^{(b-a)t} - a}, \quad (35)$$

where x_{ai} and x_{bi} are the initial concentrations of the reactants carrying i functional groups of types A and B respectively (the initial distribution with respect to types of functionality), α_a and α_b are the degrees of conversion of groups A and B respectively, a and b are their initial concentrations, and χ_1 and χ_2 are parameters.

Differentiation of Eqns (32) and (33) with respect to s_1 and s_2 makes it possible to find the critical conditions:

$$\frac{\partial \chi_1(\bar{1})}{\partial s_1} = \frac{1 - \alpha_a}{1 - \alpha_a \alpha_b (\bar{f}_{wa} - 1)(\bar{f}_{wb} - 1)}, \quad (36)$$

i.e.

$$(\alpha_a \alpha_b)_c = \frac{1}{(\bar{f}_{wa} - 1)(\bar{f}_{wb} - 1)}, \quad (37)$$

where $\bar{f}_{wa}$ and $\bar{f}_{wb}$ are the weight-average functionalities with respect to groups A and B respectively.

4. Certain general comments

An analytical solution of Eqn (1) with the aid of generating functions can be found in rare instances. A kinetically complex system of equations with a large set of kinetic constants is usually susceptible only to a numerical solution. A convenient method involves the creation of a system of equations for the distribution moments. The system can be characterised experimentally by the first three moments (more precisely, the number-average and weight-average molecular masses and the yield of the polymer). In order to find these parameters in the case of the polycondensation of monomers with isotypical functional groups, a system of three equations has to be solved. Additional equations for mixed second moments appear in copolymerisation. Thus the system of equations increases to 10 components. Modern computational techniques makes it possible to readily solve problems of this kind (see, for example, Dzhevadyan *et al.*⁵¹).

However, the applicability of the method of moments is extremely limited. In particular, the equation for the moments cannot be obtained when Flory's principle of the independence of the constants of the size of the macromolecule does not hold or when the system is such that intramolecular cyclisation cannot be neglected. In the latter case, it is impossible to convolute Eqn (1) with the aid of the method of generating functions because an additional term arises in the equation, the dependence of which on the index has a fractional exponent.^{3, 12, 52} The system of equations (1) therefore has to be solved numerically. Complexities due to the incompleteness of the system then arise. Indeed, the first term on the right-hand side of Eqn (1) contains an infinite sum, which represents the overall concentration of the functional groups. In the absence of cyclisation, this quantity can be easily found by solving Eqn (13) with $s = 1$. However, as already stated above, an equation of type (13) cannot be obtained in the presence of the additional term taking cyclisation into account. Therefore the

system of Eqns (1) has to be solved directly and, since it is incomplete, the problem of the termination of infinite series of equations arises.

In the case of a direct solution of the system of equations, the only reasonable approach involves the estimation of the results of the calculation as a function of the number of equations solved. When the latter increases, the accuracy of the calculation should also increase. The attainment of the instant when the result obtained ceases to depend on the number of equations implies the possibility of terminating the chain of equations.

Examples of this approach to the solution of the problem of linear polycondensation when cyclisation reactions take place may be found in a number of communications.⁵²⁻⁵⁴

In the analysis of the results of their investigation, Irzhak *et al.*⁵² observed an interesting phenomenon — the attainment of a limiting yield of cyclic products (Fig. 2). Physically this effect is due to the fact that the rate of cyclisation is lower the longer the chain. Consequently, with increase in the degree of conversion and in the size of the macromolecules, the rate of cyclisation diminishes to a greater extent than the decrease in the rate of polycondensation as a consequence of the exhaustion of functional groups.

Figure 2. Kinetic curves for the accumulation of cyclic condensation products.⁵² Cyclisation constant k : (1) 0.1; (2) 0.5; (3) 1.0; (4) 5.0; (5) 10.0; (6) 20.0; (7) 50.0.

Another example refers to the determination of the conditions for the appearance of a nonmonotonic molecular mass distribution (MMD).

Direct calculation of the concentration of chains^{55, 56} made it possible to find a criterial relation between the kinetic constants of Scheme (26), which determines the nature of the MMD for a linear polymer. It has been observed⁵⁷⁻⁶⁰ that in certain cases a polymer with a nonmonotonic 'saw tooth' MMD is formed (Fig. 3). Analysis showed^{55, 56} that this is possible for a definite ratio of the kinetic constants. The condition

$$\frac{k_2^2}{k_1 k_3} \leq \frac{2}{3}, \quad (38)$$

is necessary, while the condition

$$\frac{k_2^2}{k_1 k_3} \leq \frac{\sqrt{2} - 1}{2}. \quad (39)$$

Figure 3. Numerical MMD function for a linear homopolymer⁵⁵ with the kinetic constants of Scheme (26); k_2/k_1 : (1) 0.1; (2) 3.0; (3) 0.4; k_3/k_1 : (1) and (2) 9; (3) 100. Degree of conversion 0.2.

is necessary and sufficient. As shown in Fig. 4, the above relations make it possible to separate the regions of existence of monotonic (region I) and nonmonotonic (region II) MMD.

Physically the nonmonotonic nature of MMD is due to the decisive role of the dimerisation rate constant. In this case, the formation of polymers with an even number of units is somewhat preferred. If a copolycondensation method is applied, then polymers with heterotypical end groups accumulate preferentially.

Figure 4. Regions corresponding to the existence of the monotonic (I) and nonmonotonic (II) MMD defined by the kinetic constants. Line I corresponds to Eqn (38) and line 2 to Eqn (39). The points in the transition region were obtained by direct calculation.

As early as 1942, Zel'dovich proposed a qualitatively different method for the analysis of an infinite system of differential equations.⁶¹ Its essential feature is that the particle growth process is regarded as random movement in the phase space of their sizes and is described by a partial differential equation. This idea was expressed in a more concrete form in other studies.^{24,25}

In formulating partial differential equations, it is assumed that the parameter Δi is the elementary step in the size space — it is small for a small particle size, *i.e.* for the first members of the series the system of differential equations must nevertheless be regarded as discrete. In this case, the question of the number of the equation from which one should go over to a continuous system and replace the sum by an integral assumes the main importance. In the analysis of a specific kinetic scheme, it has been shown²⁵ that the transition from a discrete series to a continuous equation was impossible up to numbers 50–100. Since the result obtained was expressed in the form of a certain function of particle size, the proposed approach made it possible to establish the distribution function also in the region of large sizes, which cannot be achieved in the numerical solution of a limited number of equations (1).

In conclusion of this section, we emphasise that the subdivision of the formation reactions of polymers in terms of a kinetic feature into polymerisation and polycondensation is extremely arbitrary. Indeed, even in radical polymerisation with formation of linear polymers, chain termination may occur as a result of the recombination of radicals. This implies that, together with the unit-by-unit addition (chain propagation reaction), the chain is formed also as a result of the combination of fragments (macroradicals), which is characteristic of reactions of the polycondensation type. This effect is manifested even more explicitly in three-dimensional polymerisation of any type. The polymerisation results in the appearance of branched macromolecules carrying both active centres and 'suspended' functional groups; the reaction between them leads to the combination of macromolecules. Thus, in this case too the formation of macromolecules from fragments makes a significant contribution to the overall polymerisation process.

However, as a result of the effect of substitution in polycondensation, a considerable proportion of the monomer molecules may begin to fail to react with one another, adding instead to the polymer chains. For example, this may be the result of the process occurring in accordance with Scheme (26) if $k_2 \gg k_1, k_3$.

The principal disadvantage of the kinetic approach is the impossibility of calculating with its aid the structural characteristics of a network polymer (the gel fraction). The structure of the gel may be inferred to some extent from data obtained by analysing the sol fraction with the aid of the kinetic method^{3,62} but these conclusions are extremely indirect.

The full scale structural characteristics of the polymer, without limitations associated with the cyclisation reaction, can be found by the computer modelling of the formation reactions of polymers (see, for example, Refs 63–66). A satisfactory agreement between the data obtained by kinetic calculations and the results of modelling is then often attained.⁶⁷ However, in the present review we shall not be concerned with this approach, which is fairly specific as regards method and object of study.

III. Statistical methods

The structural characteristics of the polymer in any state can be established by statistical methods. A simple approach, based on the application of statistical calculations, was first proposed by Flory.¹¹ Combinatorial computational methods for the determination of the MMD function in the case of *f*-functional polycondensation were already used in classical studies.^{11,68} Later, in the 1960s–1970s, a formalised and therefore simpler and elegant method, based on the theory of branching processes (see the detailed survey in the monograph of Irzhak *et al.*³), was proposed for such calculations. Attempts were made to use this method in order to solve virtually any polycondensation problem, including

represent the bonds and atoms (units) joined by these bonds. The complete set of concentrations of all the blocks G characterises unambiguously the composition and structure of the system. In this sense, the concentration $y(G)$ is analogous to the MMD function of the polymer.

Speaking of ‘bonds’, we have in mind those bonds which are formed as a result of the reaction considered. Consequently the concept of bond blocks is closely related to the chemistry of the process. Each bond is characterised by groups (units) which are joined by this bond: the bond $a-a$ joins the units A , the bond $a-b$ joins the units A and B , *etc.* In other words, the designations of different units have only the significance of a feature (characteristic) of the bonds.

We shall elucidate the significance of the concept of bond blocks in relation to a linear copolymer. As can be seen from Table 3, the chain may contain a large number of blocks (this number is naturally even greater in a set of chains) and larger blocks (for example, $a-a-b-b$) include smaller blocks ($a-a$, $a-b$, $b-b$, $a-a-b$, $a-b-b$). The complete set of blocks (Table 3 presents blocks containing not more than three bonds) characterises unambiguously the structure of the chain.

Table 3. The structure of the copolymer chain $a-b-b-a-a-a-b-a-a-b$ expressed with the aid of the bond block concept.

Bond block	Number of bonds in block	Number of blocks in chain
$a-a$	1	3
$a-b$	1	4
$b-b$	1	1
$a-a-a$	2	1
$a-a-b$ ($b-a-a$)	2	4
$a-b-a$	2	1
$a-b-b$ ($b-b-a$)	2	2
$a-a-a-b$ ($b-a-a-a$)	3	2
$a-b-b-a$	3	1
$a-a-b-b$ ($b-b-a-a$)	3	1

In a linear homopolymer, the bond blocks differ only in length, *i.e.* in the number of bonds constituting the block. Therefore the relation between the bond block concentrations (y_i) and the chain concentrations (x_i) assumes an extremely simple form:

$$y_n = \sum_{i=n}^{\infty} (i-n)x_i. \quad (41)$$

The multiplier $(i-n)$ is equal to the number of ways in which a block comprising n bonds can be accommodated in a chain containing i units. The quantity y_0 represents the overall concentration of monomer units in the system (they include both the units in the polymer and the free monomers, *i.e.* y_0 is a constant quantity), y_1 is the overall concentration of bonds, and y_1/y_0 is the degree of conversion.

The converse relation, which follows from Eqn (41), is also valid:

$$x_i = y_{i-1} - 2y_i + y_{i+1}. \quad (42)$$

The significance of Eqn (42) is most closely related to the very concept of bond blocks. Indeed, as can be seen from Table 3, large blocks include smaller blocks. Consequently the subtraction of the concentrations y_{i-1} from the concentrations y_i yields the concentration of the terminal block of the same dimension (i) and the same operation with the concentrations of terminal blocks makes it possible to find the corresponding concentration of chains by Eqn (42).

Condition (42) may be extended to chains (macromolecules) and blocks of any configuration.

Suppose that we have a bond block of size i (i is the total number of bonds) connected to the overall polymer system *via* n

terminal blocks (bonds). The concentration of blocks of the same configuration but with one ‘broken’ bond of type k (z_i^k) can be expressed as follows:

$$z_i^k = y_i - y_{i+1}^k = y_i(1 - y_1^k), \quad (43)$$

where y_{i+1}^k is the concentration of the block the size of which has been increased by one type k bond compared with the block of size i and y_1^k is the concentration of unit blocks of type k . The product corresponds to symbolic multiplication, *i.e.* the summation of indices (block sizes), just as in the usual multiplication the power exponents are added together.

Similarly for the concentration of blocks having the same configuration but with two ‘broken’ bonds, of types k and m , we obtain

$$z_i^{k,m} = z_i^k(1 - y_1^m) = y_i(1 - y_1^k)(1 - y_1^m). \quad (44)$$

Since the chain (macromolecule) containing $i+1$ units corresponds to a block with the same configuration and size i in which all n terminal bonds are ‘broken’, the overall expression assumes the form

$$x_{i+1} = y_i \prod_{j=1}^{il} (1 - y_1^j). \quad (45)$$

This postulate is illustrated below in relation to copolymer systems.

Thus there is an unambiguous reciprocal correspondence between the concentrations of bond blocks and the MMD of the chains.

It has been shown^{69,71,76,77} that kinetic equations can be formulated for bond blocks and the system of equations is complete in all cases: the concentration of a block of any length and complexity depends on the presence of only those blocks which do not surpass the block under consideration as regards length and complexity. This makes it possible to find by a numerical method the exact concentration of a block of any length and hence the exact concentration of the chains.

As an illustration, we shall quote data taken from Refs 76 and 77 (Table 4), where a direct calculation for the kinetic scheme (26) was carried out.

Table 4. Dependence of the relative error (δ_i) in the calculation of the concentration of chains x_i on the numerical values of the kinetic constants of Scheme (26) and on the number of equations (n) taken into account in the calculation ($k_1 = 1$).

i	k_2	k_3	δ_i			
			$n = 9$	$n = 19$	$n = 29$	$n = 49$
1	1	1	0.191	0.047	0.014	0.001
1	1	9	0.060	0.031	0.019	0.020

9	1	9	—	0.731	0.361	0.139
9	3	9	—	0.414	0.180	0.048
9	9	9	—	0.151	0.051	0.007

Table 4 presents the maximum relative errors δ_i in the calculation of x_i as a function of the number of equations taken into account in the numerical solution of the equations:

$$\delta_i = \frac{x_i - x_{ib}}{x_{ib}}, \quad (46)$$

where x_i is the concentration of the chains calculated on the basis of Scheme (26) and x_{ib} is the concentration of chains calculated by Eqn (42) using the concept of bond blocks and therefore independent of the number of equations considered.

The table shows that the deviations from the exact value may be considerable. At the same time, the employment of the concept of bond blocks makes it possible to find exact concentrations for any number of equations.

The possibility of the exact calculation of the bond block concentrations plays a most important role in the determination of the structures of copolymers. Indeed, the modern experimental methods make it possible to characterise the structure of a copolymer solely in terms of the number (concentrations) of blocks of not too great a size — diad, triad, tetrad.^{12, 72} On the other hand, the kinetic calculation of the structure in the usual version requires the consideration of copolymer chains of all possible configurations. This creates unsurmountable computational difficulties. Furthermore, for a sufficient length and a considerable number of components, the set of possible chain types becomes very large, comparable to the Avogadro number. This means that the number of molecules of each type is insufficient to ensure the operation of the statistical Law of Mass Action. I. M. Lifshits drew attention to this factor for the first time at one of the seminars on polymer physics at Moscow State University. This difficulty disappears when the concept of bond blocks is used in the calculations.

In the formulation of kinetic equations for the calculation of the concentrations of bond blocks, an extremely simple rule is employed: all possible ways in which the given structure can be formed are added together. The concept of the terminal block, which is an extension of the concept of a functional group, therefore assumes key importance in the consideration of kinetic problems in the language of bond blocks. Indeed, as a result of the reaction between functional groups, one bond or, in other words, a bond block of unit length is formed. If a functional group with units attached to it (one, two, and more) is considered, then one may be dealing with the formation of a larger structure, *i.e.* a larger bond block. For example, the reaction between the functional groups $\sim a + \sim b$ leads to the appearance of the bond $\sim a-b\sim$. The following reactions participate in the formation of the block $\sim aabba\sim$:

The formation of terminal blocks with a complex structure, for example $\sim aabb$, is also associated with the occurrence of a series of reactions:

etc. However, as can be seen, all the reactions proceed with participation of reactants the structure of which is not more complex than that of the bond block being sought. Thus the system of equations is closed and the experimental requirements determine in relation to which blocks the kinetic problem is to be

solved. This in fact constitutes the advantage of the approach based on the concept of bond blocks.

Analysis of the structure of the system of kinetic equations describing the bond block accumulation processes^{71, 77} showed that it may be subdivided into groups of equations in such a way that the concentrations of the structures described by these equations are susceptible to direct calculation. The concentrations of larger structures are found by probability computational methods. If the minimum size of a block corresponds to one bond, we arrive at the case of the absolute application of statistical methods. It is almost always possible to identify such structures of minimum size from which any structural formations, however large and complex, are made up. The use of the concept of bond blocks makes it possible to simplify still further the solution of kinetic problems, since it becomes unnecessary to formulate differential equations for blocks of all sizes: it is sufficient to solve these problems for elementary blocks, using statistical calculations for larger formations. In other words, this method combines the advantages of both the kinetic and the statistical approaches.

It was found that the criterion of 'being elementary'^{71, 77} is the absence of the influence of the effects of substitution on the reactivity of the functional groups on the other hand, within an 'elementary' block, these effects do occur. We shall elucidate this postulate by a simple example.

Suppose that a copolycondensation reaction takes place between units carrying functional groups of types A and B and there is a possibility of both A + A and A + B interactions, on the one hand, and B + B interactions, on the other, the effect of substitution in the first sphere being observed in groups A, while in groups B there is no such effect. The reaction results in the formation of blocks of different structure:

In order to calculate blocks of all these types, one has to begin with differential equations describing their formation. However, in more complex blocks, for example $\sim ba...abbba...ababbabb\sim$, it is possible to differentiate smaller blocks $\sim ba...b\sim$, $\sim b\sim$, $\sim bab\sim$, which are 'elementary', and from which the entire block is constructed in accordance with the laws of probability. If, as in the case of homopolycondensation in the presence of effects of substitution, it is not possible to differentiate such elementary blocks, the statistical approaches are found to be completely unsuitable.¹³

As an illustration, we shall calculate the MMD for the chains of a polymer formed as a result of the reaction between the monomers AA and BB, the substitution effect being observed in the former but not in the latter. This scheme corresponds, for example, to the reactions between phenylene diisocyanate (AA) and a diol (BB) and between an amine (AA) and a diepoxide (BB).

The formation reactions of the corresponding bond blocks can be represented in the form

Component a includes functional groups belonging to the initial monomer AA and $\sim a$ is a terminal block of the polymer chain. Since there is no substitution effect in group B, there is no need to differentiate groups B belonging to different molecules. For this reason, b includes any terminal blocks belonging both to the initial monomer BB and to polymer chains. In the general case, the kinetic constants are not equal to one another and

$$\frac{k_2}{k_1} = r \neq 1.$$

The solution of the system of equations describing scheme (49) leads to the following relations:

$$\begin{aligned}
\alpha_A &= 1 - \frac{e^{-r\tau} - (r-1)e^{-2\tau}}{2-r}, \\
\alpha_B &= Q\alpha_A, \\
p_{AB} &= 2 \frac{e^{-r\tau} - e^{-2\tau}}{2-r}, \\
p_{BA} &= 2\alpha_B(1-\alpha_B), \\
p_{BAB} &= \frac{2rQ}{2-r} \left(\frac{1-e^{-r\tau}}{r} - \frac{1-e^{-2\tau}}{2} \right).
\end{aligned} \quad (50)$$

Here α_A and α_B are the conversions of the corresponding groups, Q is the initial ratio of the functional groups A and B, p_{AB} , p_{BA} , and p_{BAB} are the probabilities (relative concentrations) of the terminal bond blocks $\sim ba\sim$ and $\sim ab\sim$ and of the block $\sim bab\sim$ (including both terminal and inner blocks) respectively, and τ is the fictitious time:

$$\tau = \int k_1 b dt. \quad (51)$$

The concentrations of the chains AA, BB, AB, ABA, and BAB are calculated on the basis of the kinetic scheme. The concentrations of larger chains are determined with the aid of relations, analogous to Eqn (42), namely

$$\begin{aligned}
x\{(BA)_i B\} &= y\{(BA)_i B\} - 2y\{A(BA)_i B\} + y\{A(BA)_i BA\}, \\
x\{A(BA)_i B\} &= y\{A(BA)_i B\} - y\{BA(BA)_i B\} - y\{A(BA)_i BA\} + \\
&\quad + y\{BA(BA)_i BA\}, \\
x\{A(BA)_i BA\} &= y\{A(BA)_i BA\} - 2y\{BA(BA)_i BA\} + \\
&\quad + y\{BA(BA)_i BAB\}.
\end{aligned} \quad (52)$$

The concentrations of the blocks $y\{\dots\}$ are determined in accordance with the probability relations:

$$\begin{aligned}
y\{(BA)_i B\} &= (y\{BAB\})^i = (p_{BAB})^i, \\
y\{A(BA)_i B\} &= (y\{BAB\})^i y\{BA\} = (p_{BAB})^i \alpha_B, \\
y\{A(BA)_i BA\} &= (y\{BAB\})^i (y\{BA\})^2 = (p_{BAB})^i (\alpha_B)^2.
\end{aligned} \quad (53)$$

Thus

$$\begin{aligned}
x\{(BA)_i B\} &= B_0 (1-\alpha_B)^2 (p_{BAB})^i, \\
x\{A(BA)_i B\} &= 2B_0 \alpha_B \left(1 - \frac{p_{BAB}}{\alpha_B}\right) (1-\alpha_B) (p_{BAB})^i, \\
x\{A(BA)_i BA\} &= B_0 (\alpha_B)^2 \left(1 - \frac{p_{BAB}}{\alpha_B}\right)^2 (p_{BAB})^i.
\end{aligned} \quad (54)$$

When the equality of the kinetic constants ($r = 1$) holds then $p_{BAB}/\alpha_B = \alpha_A$ and Eqns (54) lead to simple probability formulae.

The indices [subscripts] correspond to the type of end groups in the chain the length of which i is equal to the number of BA bonds contained in it.

Figure 5 presents the concentrations of the BAB molecules found in three ways: by the direct kinetic calculation, by the probability calculation employing kinetic data on the conversion of groups A and B (α_A and α_B respectively), and by the calculation employing bond blocks (the $\{BAB\}$ block). Evidently, in the absence of the substitution effect (when the constants are equal), all three methods yield concordant results. If the rate constants for the first and second additions are different, only the results of the direct kinetic calculation and the calculation based on the concept of bond blocks agree. The statistical calculation leads to an incorrect result.

The concentration of small molecules can be readily calculated. Problems arise with larger structures.

The algorithm of the procedure for the description of the structure of a network polymer, formed, for example, in the

Figure 5. Variation of the concentration of the molecules BAB during the AA + BB copolycondensation process occurring in accordance with Scheme (49): (1) direct kinetic calculation (curve) and calculation based on bond blocks (symbols) with $r = 10$; (2) kinetic calculation with $r = 1.0$ and statistical calculation with $r = 10.0, 1.0$, and 0.1 (curve) as well as calculation based on bond blocks with $r = 1.0$ (symbols); (3) direct kinetic calculation (curve) and calculation based on bond blocks (symbols).

interaction of a diepoxide with a diamine [Eqn (40)], reduces in the general case to the following.

1. The bond block concentrations are calculated kinetically in conformity with Scheme (55) (on the assumption that the substitution effect occurs only for the amine but not for the epoxide oligomer).

2. The statistical calculation is performed for any structural fragments bearing in mind that the $H_2N-R-NH_2$ molecule enters exclusively into the sol fraction of the polymer system, $H_2N-R-NH-$ is the end group of the chains, and $-HN-R-N \begin{array}{c} \diagup \\ \diagdown \end{array}$ and $\begin{array}{c} \diagup \\ \diagdown \end{array} N-R-N \begin{array}{c} \diagup \\ \diagdown \end{array}$ are network nodes.

Thus the use of bond block data in the calculation makes it possible to solve structural problems effectively.

V. Conclusion

We have endeavoured to show that modern methods for the solution of Eqn (1) make it possible to answer all or the majority of formal kinetic questions. Naturally, the most important predictive problems, namely how and under what conditions the process should be carried out in order to obtain a polymer with a specified structure, remained outside the scope of our review. Its subject was only the establishment of a direct relation between the structure of the polymer and the kinetic parameters of the polycondensation process. Evidently, the problems of reactivity should be considered from completely different standpoints. This constitutes another field of science. If, as stated above, real processes are complicated by a possible change in the physical state of the system in the course of the reaction, which alters not merely the numerical values of the kinetic constants but the very process mechanism, then evidently the attempts at prediction become extremely problematical. Certain approaches to the solution of this problem have already been developed to some

extent (for example, attempts to take into account the vitrification of the system are known), but they are either too formal and require physical justification or are speculative and require a broad experimental test.

Reactions between rigid-chain macromolecules,^{80,81} particularly in liquid crystal polymer systems,^{82,83} carried out in order to obtain network polymers from them are nowadays of special interest. In this case the low flexibility of the chains — the carriers of functional groups — necessitates the formulation of more general questions: about the nature of the collisions of the reaction centres, about the influence of chain length on the reactivity, about the influence of the organisation of the medium on the kinetic parameters of the processes, etc. These problems still await their investigators.

The author is grateful to B A Rozenberg for useful discussions.

The review has been written with the financial support of the 'International Science and Technology Centre' (project No. 96-358).

Polytype formation in nonmetallic substances

G S Oleinik, N V Danilenko

Contents

I. Introduction	553
II. Polytypism in nonmetallic crystals	554
III. Practical aspects of polytypism	572
IV. Conclusion	573

Abstract. A systematic account is given of the known data on polytypism in nonmetallic substances with various structures. The existing hypotheses concerning the nature of polytypism are discussed. It is shown that polytype formation in nonmetallic crystals is a solid-state relaxation rearrangement accompanied by the formation of planar defects of various types, inducing the breakdown in the periodicity of the packing of atomic layers. Such defects and hence structural elements of polytypes may be structural (growths, deformation) and chemical packing defects, microtwins, antiphase boundaries, layers of vacancies, as well as layers of other phases coupled coherently with the basic structure. For diamond-like phases (SiC, AlN, BN), intragranular polytype transformations, induced by the migration of boundaries, occur together with intragranular polytype transformations. The bibliography includes 294 references.

I. Introduction

As a property of crystalline solids, polytypism is determined by the possibility that a given substance may exist as a multiplicity of structural forms differing in the packing of identical layers, which are structural elements of the basic lattice. Whereas the characteristic of the latter is the interlayer distance (c_0), the characteristic of the polytype lattice is the distance between blocks (C), which consist, of several layers (n) of the basic lattice:

$$C = nc_0.$$

When n is an integer, one is dealing with commensurate polytypes, while in the case of fractional n the polytypes are noncommensurate.

In terms of the type of ordering, polytypes can be divided into two kinds: ordered polytypes with a distinct repeatability of the blocks and non ordered polytypes [one-dimensionally disordered state (ODS)] distinguished by the fact that the blocks with different C are arranged in a random fashion, *i.e.* without periodicity.

A multiplicity of ways of designating polytypes, reflecting their structure, are known.^{1–3} The Ramsdell designations are

G S Oleinik, N V Danilenko Frantsevich Institute of the Problems of Materials Science, National Academy of Sciences of Ukraine, ul. Krzhizhanovskogo 3, 252680 Kiev-142, Ukraine.
Fax (38-044) 444 20 78.
E-mail:oleinikdep20@ipms.kiev.ua (G S Oleinik)

most often employed as the simplest and clearest. The designation includes the number of layers in the unit cell and a letter indicating the type of symmetry of the cell: H — hexagonal, R — rhombohedral, T — trigonal. For example, 6H is a polytype with a six-layer repeat period along the c axis and a primitive hexagonal cell. For rhombohedral polytypes, the number of layers is a multiple of three.

A new method of describing polytypes as structures with different numbers and types of regular systems of points has been proposed recently.⁴ Bokii and Laptev^{4,5} examined in detail the approach to this kind of description in relation to ZnS, CdI₂, TiO₂, and certain silicates. However, this method of describing polytypes has not as yet found extensive application.

For the majority of polytypes, the repeat period of the layers varies in one direction. For this reason, polytypism is frequently referred to as one-dimensional polymorphism.

Verma and Krishna² defined polytypism as the ability of a substance to crystallise in several different modifications and in all these modifications two unit cell parameters are identical, whilst the third is a variable integral multiple of the same quantity. The structural state of polytypes should also correspond to three essential conditions: firstly, polytypic forms must consist of identical structural units and differ only in the packing of the layers; secondly, each layer should have one chemical composition corresponding to the stoichiometric composition of the crystal; thirdly, each pair of neighbouring layers is equivalent. The foregoing refers to the classical definition based on the study of polytypism in ten single-crystal substances. The compounds examined include SiC, ZnS, CdI₂, PbI₂, CdBr₂, AgI, *etc.*, which had been regarded previously as strictly stoichiometric. The above definition of polytypism was formulated when noncommensurate polytypes had not yet been observed.

Extensive experimental data confirming the tendency towards polytype formation in crystalline solids differing in the types of chemical bonding, crystal lattice, the number of different atoms (substances ranging from monatomic, for example diamond and carbon, to pentaatomic and hexaatomic in minerals) have now accumulated. Accordingly, it has been established that polytypism is characteristic of various classes of substances: metals, ceramics, minerals, intermetallic compounds, and organic substances. It has been observed in the study of not only single crystals but also films, powder particles, and polycrystalline compact materials. Polytype formation is very often associated with the nonstoichiometry of substances. Nonstoichiometry in substances such as SiC,⁶ ZnS,⁷ CdS,⁸ *etc.* has also been discovered.

Thompson⁹ defined polytypism as a special kind of polymorphism in which new modifications arise as a result of different types of packing of structurally compatible units. In other words,

Received 9 September 1996

Uspekhi Khimii 66 (7) 615–640 (1997); translated by A K Grzybowski

polytypes are variants of the packing of simple elements characteristic of the basic structure. In contrast to the definition of polytypism given by Verma and Krishna,² in this definition the condition of the structural and chemical identity of the structural elements in the polytype is not obligatory.

In 1984, the Commission of the International Union of Crystallographers proposed a new definition: polytypism is 'the phenomenon of the existence of elements or compounds in the form of two or more multilayer crystalline structures differing in the sequence in which the layers are packed. The layers need not necessarily be crystallographically identical but they should be similar. Polytypism differs from polymorphism by allowing small differences between the chemical compositions of structures not exceeding 0.25 atom per formula unit of any constituent element. Layered structures which differ from one another to an extent greater than this are referred to as polytypoids rather than polytypes'.¹⁰ However, this terminology has not, found extensive application nowadays. As a typical example, one may quote aluminium nitride, for which a relation between composition and multilayer structures has been established. On the other hand, the latter are referred to as polytypes and rarely as polytypoids or pseudopolytypes.

Polytypism was first observed in 1912 by Baumhauer¹¹ in SiC single crystals. However, the study of this phenomenon did not begin until 1940. At the beginning of the 1950s, the first theory of polytypism appeared (Frank's theory). It referred to the formation of polytypes in the growth of crystals and was therefore called the growth theory. It was based on the hypothesis of the decisive role of screw dislocations in the formation of polytypes with different numbers of layers, in particular the hypothesis that the period of the polytype is determined by the height of the growth step. This theory described satisfactorily the appearance of short-period polytypes in the growth of crystals but could not account for the appearance of long-period structures. The first review of polytype formation in crystals, in which the above theory was also considered, was written by Verma and Krishna.²

Extensive data have now accumulated on the phenomenon of polytypism in crystalline solids of different classes and on the possible mechanisms of its occurrence. The physical and chemical nature of this phenomenon has aroused much interest as a fundamental property of crystalline solids. The practical aspect of this phenomenon is also important. The theoretical and experimental data available at present on polytypism indicate that this phenomenon may be determined by a multiplicity of factors. It is also evident that there cannot be a single mechanism of polytype formation. This is indicated also by the fact that the change in the lattice periodicity in crystals may be induced (as will be shown below) by the formation of planar defects of different nature — structural and chemical packing defects, growth and deformation microtwins, antiphase boundaries, layers of outcrops of other phases, layer-by-layer changes in the coordination numbers and packing motifs of the constituent atoms, *etc.*

The majority of data on polytypism in metallic materials, including pure metals (only the lanthanides), alloys, intermetallic compounds, including Laves phases (compounds of the type AB₂), and ordered alloys, have been surveyed in monographs^{3,12}. In these communications, Nikolin³ identified two kinds of polytypes: stable, formed on crystallisation or annealing at a high temperature, and unstable formed as a result of martensite transformations. For certain Laves phases and ordered alloys (for example in the Cu–Au, Ag–Mn, and Pd–Mn systems), a relation was discovered between the modulation period of long-period structures and the average number of valence electrons per atom, the so called electron concentration e/a (e is the total number of valence electrons and a the number of atoms in the unit cell). On the basis of these data, it was concluded³ that polytype formation in metallic crystals is determined by the band factor, *i.e.* by their band structure.

In recent years, the diversity of polytypic structures and their stability in crystalline solids have been considered on the basis of

the model description taking into account the competitive nature of the interaction between structural units (blocks or polyhedra), the different variants of the packing of which actually determine polytype formation, including two- and three-dimensional polytype formation. The Frenkel' – Kontorova and Ising (spin model) models are best known.^{13,14} The latter is based on the idea of the decisive role in polytype formation of the exchange interaction between the first and subsequent structural units as the basic elements of the crystal lattices of solids (the ANNNI model — Axial Next Nearest Neighbour Ising).

The principal postulates on which the model is based are as follows: polytypes are regarded as a series of different variants of the packing of structurally compatible modules (structural units); the structural units are formed on the basis of coordination polyhedra; the polytype formation and the stability of polytypes are a consequence of the change in the effective energy of the interaction between the structural units; the effective energy is a function of pressure, temperature, and chemical composition of the medium. The agreement, between the model considered and a real system has been demonstrated in relation to the polytypic structures of spinelloids. A satisfactory agreement is observed also for compounds such as SiC and ZnS.^{13–15} The possibility of applying this model to account, for the polytypism in solid solutions of metals with a hexagonal close-packed lattice has been demonstrated.^{16,17}

II. Polytypism in nonmetallic crystals

The available information about the polytypism in nonmetallic crystals having the compositions MX and MX₂ (SiC, ZnS, CdI₂, *etc.*), published up to 1966, has been surveyed.² Certain data on polytypes in minerals can be found in two communications.^{2,18} Extensive information about the polytypism in such materials has now accumulated.

Polytypism as a physical phenomenon in nonmetallic substances may be classified in terms of various features: the thermodynamic conditions under which it occurs, the type of planar defects inducing an ordered alternation of blocks of layers, the classes of substances with an identical type of chemical bonding or crystal lattice, and also the properties and applications of the substances. The classification taking into account the features specified constitutes an independent task. Bearing in mind the discovery of polytypism as a growth phenomenon and its subsequent observation in crystals obtained under various conditions, one may identify four groups of polytypism: growth, thermal, deformation, and concentration. The above terminology reflects the nature of the principal factor governing polytype formation, although in the majority of cases its development is determined by a combination of many factors. Furthermore, such subdivision is suitable only for the group of substances with diamond and diamond-like phase (wurtzite and sphalerite) lattices. The above kinds of polytypism occur in precisely these substances. For example, growth polytypism is characteristic of SiC, ZnS, C (graphite), C (lonsdaleite), Si, and CdS; thermal polytypism is characteristic of SiC, ZnS, and 2H BN, concentration polytypism is characteristic of SiC, ZnS, AlN, ZnO, BeO, and BeSiN₂, and deformation polytypism is characteristic of SiC, ZnS, CdS, C (diamond), 2H BN, 3C BN, and Si (the polytypes are formed on the basis of 3C and 2H phases for SiC, ZnS, and CdS, the 3C phase for Si, and the 2H phase for AlN, BeO, ZnO, and BeSiN₂). For other substances, the combination of such varieties of polytypism is not observed.

Since we shall subsequently discuss briefly also the practical aspect of polytypism in non metallic materials, it is useful to analyse the problem of polytypism as a whole for different groups of materials differentiated in inorganic chemistry as carbides, nitrides, oxides, *etc.* Henceforth we shall consider polytypism in individual groups of substances, but we shall note beforehand certain data on polytypism in organic substances and shall also describe the available information about this phenomenon in

monatomic substances; the polytypism in transition metal carbides and nitrides of the type of interstitial phases¹⁹ will be considered jointly.

The possibility of the formation of polytypes in organic substances was first pointed out by Verma and Krishna.² The direct observation of polytypes by high resolution microscopy in crystalline organic substances (in relation to phthalocyanine) has been reported by Howitt.²⁰ The formation of phthalocyanine polytypes was accompanied by the $\beta \rightarrow \alpha$ shear transformation. Zorkii and Nesterova²¹ observed intralayer polytypism in the selenium-containing organic substances $C_{16}H_{16}O_4Se$ and $C_{13}H_{10}N_4Se$. Its characteristic feature is that blocks having identical outer layers and differing in the structure of the 'core' arise in the structure of the initial substance. As a result, there is a possibility of the formation of homolayer (made up of identical layers) and heterolayer (made up of different layers) structural fragments.

1. Monatomic substances

Silicon and carbon belong to the class of monatomic substances tending to exhibit polytypism. Polytype formation in germanium has been mentioned²² but we are not aware of any concrete information.

a. Silicon

Silicon polytypes have been observed in an electron microscope study of its formations in the form of whiskers and fibres obtained by the decomposition of SiH_4 at 500–520 °C on gold-covered silicon supports.²³ The experimental and calculated unit cell parameters are virtually the same for the identified polytypes.

Polytype	6H	27R	51R	141R
$c(\text{calculation})/\text{\AA}$	18.84	84.65	159.89	442.05
$c(\text{experiment})/\text{\AA}$	18.59	84.61	160.07	442.29

The formation of polytypes on deformation of silicon is apparently also possible. This is indicated by data on the intense disordering of the Si structure with the diamond lattice on impact application of a load and the formation on subsequent annealing of the 2H modification from this structural state.²⁴ Data on the 3C $\rightarrow$ 2H transition in silicon at a high pressure²⁵ and following the application of a concentrated load, *i.e.* under the indenter,²⁶ are available. The above transition occurs also when a large number of arsenic ions are implanted in a silicon support.²⁷

b. Carbon

Three polymorphic modifications — graphite, lonsdaleite (hexagonal diamond), and diamond — are characteristic of crystalline carbon. They all tend to form polytypes.

The commonest polytype for graphite is 3R; the formation of polytypes 6R, 10H, and 12H is also possible.^{28,29}

The formation of a mixture of multilayer polytypes (MP) in lonsdaleite deformed at high pressures and temperatures ($T = 1800$ °C, $P = 7.7$ GPa) under conditions involving the formation of a polycrystalline diamond material has been observed in microdiffraction studies.³⁰ The presence of MP was indicated by a system of point reflections on continuous $h0l$ rows on the electron microdiffraction pattern of sections of the type (1120) through lonsdaleite particles. Subsequently the 6H polytype of lonsdaleite, formed on deposition of carbon films from the gas phase, was identified by electron microscopy.³¹ Calculated X-ray diffraction data for a series of lonsdaleite polytypes (3C, 2H, 6H, 4H, 8H, 10H, 15R, and 21R) have been published.³²

The possibility of the formation of MP from cubic diamond is indicated by the studies of Britun *et al.*³³ The presence of a set of nonsystematic point reflections (in rows parallel to 111) on the electron diffraction pattern of the {110} sections of diamond grains deformed at $T > 2200$ °C and $P = 8$ –10 GPa has been established. The density of the disperse twins on one plane of the

type {111} on the diffraction pattern, extending from boundary to boundary, is usually high in grains of this kind. These twins are formed as a rule only on deformation.

In the crystallisation of carbon from the gas phase, the regraphitisation of diamond, and laser irradiation of graphite, a variety of the carbon phase is formed — carbynes. Carbynes are regarded as linear carbon polytypes.³⁴ Such structures have been classified on the basis of various parameters: the linear relation between the number of atoms in the chain and the length of the c axis, the unit cell volume, and the ratio a/c .

2. Silicon carbide

It was noted above that SiC was the first substance in the study of which polytypism was observed as a physical phenomenon.¹¹ So far more than 150 polytypes with hexagonal, rhombohedral, and tetragonal symmetries have been identified in SiC. The parameter c in these polytypes varies from 0.5 nm for 2H to 1200 nm for 4680R. The polytypes observed up to 1966 have been described by Verma and Krishna² and data on polytypes found later are contained in papers published in periodicals.

The SiC polytypes are distinguished by the ratio of the carbon and silicon concentrations and hence by the X-ray density and the concentration of vacancies (Table 1). The silicon concentration should be 70.05 mass% for stoichiometric SiC, while for 3C SiC it is 71.04 mass% and for 6H SiC it amounts to 70.7 mass%. The data obtained in studies of the nonstoichiometry in SiC have been surveyed.³⁵

The polytypic transformations in SiC may occur under different thermodynamic conditions: only on heating (both in an inert medium and in the presence of impurities dissolving in the lattice), on application of different types of load (rubbing at room temper-

Table 1. Characteristics of certain silicon carbide polytypes.

Polytype	D	q	[Si]/[C]	$10^{-20}N/\text{cm}^{-3}$		h/eV
				N_{Si}	N_C	
3C	0	0.74	1.046	2.0	2.3	2.2
8H	0.25	0.96	1.029	3.3	1.7	2.56
21R	0.29	—	—	—	—	2.77
6H	0.33	1.22	1.022	4.3	1.5	2.86
33R	0.36	—	—	—	—	—
15R	0.40	1.19	1.012	5.7	1.1	2.9
10H	0.40	—	—	—	—	—
27R	0.44	1.30	1.008	6.2	1.0	—
4H	0.5	1.37	1.001	7.1	0.7	3.1

Note. The following designations have been adopted: D = degree of hexagonality, q = effective charge on the silicon atom, N = concentration of vacancies, h = width of the forbidden band. The forbidden band widths have been taken from Knippenberg³⁶ and the remaining parameters from Tsvetkov⁶.

ature, treatment by application of heat and pressure, bending, and a concentrated load under the indenter), and under the conditions of the implantation of impurities and subsequent annealing. Thus all known types of polytypism, occurring in the group of diamonds-like phases, are characteristic of SiC.

A multiplicity of publications have been devoted to the polytype formation in SiC during growth and also partly during post-heat treatment (see, for example, Refs 2 and 36–40). We shall deal briefly only with questions of the stability of the basic polytypes, including those arising on doping and deformation.

The two-layer (2H) wurtzite SiC phase is known, but its formation during growth and treatment is rarely observed. This form was first noted in the gas-phase deposition of SiC at 1400–1500 °C in hydrogen.⁴¹ Subsequently it was identified in combination with 3C SiC on nitrogenation of powdered silicon

pellets placed on a graphite support⁴² and also on decomposition of Si_3N_4 in nitrogen with an admixture of CO .⁴³ The stabilisation of the 2H SiC phase has been explained by the dissolution of oxygen.⁴⁴ Under the conditions of uniaxially oriented [slip along the (0001)⟨10 $\bar{1}$ 0⟩ system] application of a load to SiC crystals at 1600–1800 °C, transitions from the 6H and 3C phases to the 2H phase are possible.⁴⁵

The formation of the 2H phase is also observed in polycrystalline materials formed from SiC in the presence of oxygen and also aluminium or magnesium.^{46,47} This phase is extremely unstable. Its transition to the ODS or the two-phase (2H + 3C) state, characterised by a high concentration of packing defects (PD), occurs already at $T > 400$ °C.⁴⁸

The 3C SiC form is assumed to be stable at $T < 1400$ °C. At higher temperatures (both in the presence of impurities such as B and Al and without them), it is converted into the 6H polytype. The 6H polytype is the high-temperature ($T > 2000$ °C) stable form of SiC in an inert gaseous medium. This has been confirmed convincingly in a study³⁶ where it was established that the 6H polytype is formed in greatest amount in the synthesis of SiC from SiO_2 and C in the range 2000–3000 °C.

Numerous studies (see, for example, Refs 49–52) have shown that the aluminium and boron impurities (in the form of elemental phases or the compounds Al_2O_3 , B_4C , and BN) promote the $3\text{C} \rightarrow 6\text{H} \rightarrow 4\text{H}$ and $3\text{C} \rightarrow 4\text{H}$ transitions. The conversion into the 4H polytype occurs at $T > 1800$ °C; at $T > 2000$ °C, this polytype becomes dominant. It has been suggested that the aluminium and boron impurities stabilise the 4H polytype. The action of the above impurities is most effective in combination with added carbon. According to Tajima and Kingery,⁵³ aluminium and boron dissolve in the SiC lattice with formation of substitutional solid solutions and boron can substitute both silicon and carbon. The positive role of carbon in the polytypic transitions in SiC has been explained⁵⁴ by the operation of two factors: the removal of the oxygen film from the surface of the crystals and the increase in the concentration of vacancies.

The transitions between the 3C and 6H phases, occurring within crystallites under different conditions (only on heating, on heating accompanied by doping, and on deformation), occur in most cases *via* a series of heterophase ($3\text{C} + 6\text{H} + \text{MP}$) states differing in the number of phases. The individual phases and polytypes are represented by plates limited by close-packed (111) and (0001) planes, which determines the microdomain structure of the heterophase crystals (Fig. 1). Monopolytypic crystals can form only after prolonged annealing: for example, in the $3\text{C} \rightarrow 6\text{H}$ transition which is of the single crystal of the initial phase $\rightarrow$ single crystal of the final phase type.⁵⁵ A similar transition has been observed also in the transformation of 2H SiC in the form of whiskers into a lamellar single crystal of the 3C phase.³⁷

Numerous data indicate that nitrogen stabilises the 3C phase. This is manifested by the fact that, during the annealing of 3C SiC even at 2600 °C under nitrogen pressure ($66.5 \times 10^3 \text{ N m}^{-2}$), the

transformation to multilayer structures does not occur.⁵⁶ In the case of the initial 6H phase, the $6\text{H} \rightarrow 3\text{C}$ transformation takes place on annealing under nitrogen pressure [$(0.1 - 3) \times 10^6 \text{ N m}^{-2}$ (Jepps and Page)⁵⁷ and $4 \times 10^6 \text{ N m}^{-2}$ (Kieffer and Gugel)]⁵⁸ and also on hot pressing in the presence of added nitrides.⁵⁹ The formation of the 3C phase is then accompanied by the appearance of twins in the latter.

The $6\text{H} \rightarrow 3\text{C}$ transformation occurs also during annealing above 2000 °C in a silicon-containing medium⁵⁵ as well as on deformation. In the latter case, this is possible on rubbing at the normal temperature,⁶⁰ on uniaxial loading in the range 1800–2000 °C,⁴⁵ and at a high pressure (1–10 GPa) starting from a temperature of 400 °C.^{61–63} Britun *et al.*⁶⁴ established for the first time that this transformation is reversible at $P = 7.7$ GPa and $T > 2000$ °C. The direct $6\text{H} \rightarrow 3\text{C}$ and reverse $3\text{C} \rightarrow 6\text{H}$ transformations in the grains are crystallographically similar: the close-packed planes and directions in the initial final phases are parallel — (0001)∥(111); $[11\bar{2}0] \parallel [110]$.

The polytypic transitions in SiC take place also as a result of implantation. In most cases, marked disordering (the establishment of the ODS) or amorphisation take place after such a procedure. It is believed⁶⁵ that, on insertion of aluminium into epitaxial 6H SiC layers (at 1400 °C), the $6\text{H} \rightarrow 3\text{C}$ transformation occurs. It has been suggested that this is achieved *via* a disordered state. The formation of a twinned 3C phase has been observed after the post-annealing of the 4H + 6H crystals with implanted nitrogen.⁶⁶ It is believed that, on implantation of copper in the SiC ceramic, a polytypic transformation in the surface layers also takes place.⁶⁷ It has been established⁶⁸ that the implantation of boron and aluminium ions in the surface layers of 6H SiC crystals from the side of the (0001) plane leads to amorphisation. On subsequent annealing, a mixture of the 6H + 3C phases or only the 3C SiC phase is formed depending on the irradiation dose and temperature.

The study of polytypism began more than 50 years ago with the investigation of silicon carbide. However, hitherto the nature of the polytypism in SiC has not been established. There are numerous theories, hypotheses, and simply views on this question. We shall only indicate the principal ideas underlying the treatment of the polytypism in SiC.

The first (dislocation) theory of the polytypism in SiC (and of the phenomenon as a whole) has been proposed by Frank. It is based on the idea of the decisive role of screw dislocations in the formation of polytypes during the growth of crystals. Since this theory was first published jointly with Burton,⁶⁹ it is associated also with his name. The polymeric theory of Ramsdell and Kohn explains the appearance of polytypes by the growth of crystals on various atomic (polymer) groups. According to Jagodzinski's thermodynamic theory, the nature of polytypism is accounted for by the vibrational entropy effect. Schneer considered polytypic transformations as second-order transitions on the basis of the available data concerning the energy differences between polytypes. According to Peibst, polytype formation is associated with the thermal vibrations in the structure of the growing crystal. Knippenberg drew attention to the differences between the widths of the forbidden band in the SiC polytypes and therefore concluded that the electron energy plays a decisive role in polytype formation. The above theories have been examined in detail by Verma and Krishna.²

In the subsequent attempts to account for the polytypism in SiC, a decisive role was attributed to the structural packing defects generated in the transformations in the solid state during periodic slip or creep dislocations⁷⁰ and also those arising at the site of contact between the layers of polytypes growing at the boundary of the twinned crystals of the 3C phase.⁷¹ Direct confirmation of the decisive role of packing defects and twinned crystals of the 3C phase along the (111) plane in the $3\text{C} \rightarrow 6\text{H}$ transition in crystals has been obtained in an electron microscope study of thin foils.⁷²

Figure 1. The structure of the heterophase (6H + 3C + MP) SiC crystal.

Data on the energy of the packing defects (EPD) along the (0001) plane are available only for 6H SiC. They are extremely scattered: from 1.9 ± 0.25 ⁷³ to 13.00 ,⁷⁴ $45-65$,⁷⁵ and 72 ± 34 mJ m^{-2} at 20°C .⁷⁶ It has also been established⁷⁶ that the EPD of the 6H SiC phase increases with increase in temperature from 0.4 mJ m^{-2} at 1100°C to 0.45 ± 2 mJ m^{-2} at 2000°C . No information is available about the influence of impurities and deformations on the EPD. However, our studies indicate that the polytypic transformations on doping 6H SiC crystals with boron and aluminium and also on deformation by the application of a high pressure ($P = 4-10$ GPa at $1200-2000^\circ\text{C}$) are always preceded by the appearance of a high concentration of basic packing defects. The latter are a diagnostic sign of a decrease in the energy of the packing defects. The relation between the probability of the formation of the packing defects (α) and the EPD (γ) assumes the following form:⁷⁷

$$\alpha = \frac{Gb^2h\rho}{24\pi\gamma},$$

where G is the modulus of shear, b is the Burgers vector, h is the interplanar spacing, and ρ is the density of dislocations.

It has been suggested that the polytypes in SiC can be formed as a result of martensite transformations.⁶ However, experimental confirmation of the operation of this mechanism has not been obtained.

It has been suggested that the hexagonal SiC polytypes be regarded⁷⁸ as a twinned 3C phase with different concentrations of twinned crystals. Twinned crystal seams in such a phase consist of 2H SiC layers. On this basis, all polytypes (with the exception of 2H) may be regarded as phases differing in the amount of 3C SiC. The 3C SiC content in different polytypes varies from 50% to 75%; the greatest amount of 3C SiC (75%) is present in the 8H polytype. Similar ideas concerning the structure of polytypes with different numbers of layers had been put forward earlier by Ramsdell,⁷⁹ who suggested that multilayer polytypes are formed from basic 6H and 15R structures as a result of the breakdown of the packing periodicity in the latter. Data on the structures of long-period SiC polytypes, obtained in electron microscope studies of crystals by the direct lattice resolution method may serve as confirmation of these ideas. According to the results of Dubey and Singh,⁸⁰ the 126R polytype consists of blocks of rhombohedral polytypes with a smaller number of layers — 33R, 32R, and 48R, formed on the basis of the 6H, 15R, and 12R cells. It has been established⁸¹ that the 201R polytype is formed from the 6H, 15R, and 8H cells.

As already mentioned, the polytypism in SiC has been treated on the basis of the ANNNI model.¹⁵ Cheng *et al.*⁸² later developed a new approach in order to explain the appearance of SiC growth polytypes as equilibrium phases. It is based on the model of the long-range interaction between layers controlled by the background lattice energy. The principal factor is then the postulate that all polytypes may be formed as a result of different types of packing of diatomic SiC layers in the [111] direction of the 3C modification.

Analysis of data on the polytypic transformations in SiC crystals on heating and primarily under doping conditions demonstrates the important role of point defects. Indeed, in most cases (with the exception of heating in N_2) the $3\text{C} \rightarrow 6\text{H}$ transformation takes place. In the initial 3C structure there is an excess of silicon and hence of carbon vacancies (Table 1). Impurities which actively influence the polytypic transformations in SiC dissolve in the SiC lattice also with formation of vacancies. Evidently, on dissolution of B, Al, and N in SiC, heterovalent substitution occurs. The charge compensation in the lattice is then ensured by the formation of vacancies in one of the SiC sublattices⁸³ and the formation of complexes on the basis of the vacancies is inevitable.[†] If the vacancies as constituents of the SiC structure participate in polytype formation, the above process may be considered from the standpoint of nonstoichiometry *i.e.* as a transformation in a

AlN solid solution. An indirect, confirmation of this hypothesis exists. We have established that the $6\text{H} \rightarrow 4\text{H}$ (in the presence of boron or aluminium) and $2\text{H AlN} \rightarrow \text{MP}$ (*i.e.* a transformation in a AlN solid solution) transformations in polycrystalline materials are crystallographically and morphologically similar: the final polytypic structure is formed in a layer bounded by basal planes and enriched by the dissolved impurity (Fig. 2).

We may note the characteristic features of the $3\text{C} \rightarrow 6\text{H}$ and $3\text{C} \rightarrow 6\text{H} \rightarrow 4\text{H}$ transformations in polycrystalline SiC materials which we established. The transitions occur not only within but also between the grains in the stage involving the recrystallisation enlargement of the grains.

Figure 2. The substructure formed in the SiC and AlN crystals in polytypic transitions (in 6H SiC $\rightarrow$ 4H SiC under conditions involving doping with boron, in AlN in the course of the transition $2\text{H AlN} \rightarrow \text{MP}$).

In the first case, they are crystallographically oriented: under these conditions, the final polytype (it is usually formed in combination with MP in the initial stage of the transition) is segregated in the form of a single plate ($0.5-1$ μm thick) intersecting the grain from boundary to boundary (Fig. 2). The shape factor for such a plate (the ratio of the length l to the width d) can reach $10-20$. The plate is bounded by the basal planes and is coupled *via* these planes to the matrix (initial) phase. The formation of such structural states in the grains induces their anomalous growth and subsequently also the appearance of the grains of the final phase in the form of plates. In the course of the growth of the grains, polytypic transformations of the second type, characterised by the migration of the boundaries between grains made up of different polytypes, occur. Bearing in mind the nature of the mass transfer, determining the migration of the grains, one can postulate that such transformations take place *via* a diffusion mechanism. Fig. 3 presents schemes for the changes in the microstructure of the SiC materials obtained under the conditions of the polytypic transitions indicated. Evidently, depending on the structure of the growing grain, not only forward but also reverse ($6\text{H} \rightarrow 3\text{C}$ and $4\text{H} \rightarrow 6\text{H}$) transitions of the diffusion type may occur in the course of the collective recrystallisation. The evolution of the microstructural development of the SiC material in the case of such transitions is analogous to that observed in the AlN materials obtained in the $2\text{H AlN} \rightarrow \text{MP}$ transitions;⁸⁵ for SiC and AlN, these questions have been discussed in detail.⁸⁶ Such unusual shape formation in the subgrain structure and among the anisometric (lamellar) grains in SiC (as well as AlN), induced by polytypic transformations, promotes the formation of self-reinforced materials.⁸⁷

3. Aluminosilicon carbide

Two polytypes of aluminosilicon carbide, differing in the content of constituent atoms, are known: $8\text{H Al}_4\text{SiC}_4$ and $15\text{R Al}_2\text{Si}_2\text{C}_5$.

[†] The conclusion that such complexes are formed in SiC on dissolution of boron and aluminium has been reached⁸⁴ on the basis of data on the rate of diffusion of the above impurities in SiC.

Figure 3. Variation of the granular structure during the development of intergranular polytypic transitions in SiC and AlN.

They have been detected in the products of the interaction of the AlC–SiC mixture⁸⁸ and the natural montmorillonite-polyacrylonite mixture.⁸⁹ The determinations of the cell size and of the interlayer distance led to the conclusion⁹⁰ that the structure of the aluminosilicon carbide may be produced by the substitution of AlN layers by SiC layers in carbonitrides of the type $\text{Al}_5\text{C}_3\text{N}$ and $\text{Al}_6\text{C}_3\text{N}_2$. The latter belong to the class of compounds with the general formula $(\text{AlN})_n\text{Al}_4\text{C}_3$ and are polytypic forms of aluminium nitride in the AlN–C system.⁹¹

The compounds $\text{Si}_3\text{Al}_5\text{N}_5\text{C}_3$ and $\text{Si}_3\text{Al}_4\text{N}_4\text{C}_3$ with the wurtzite lattice^{92,93} and $\text{Si}_3\text{Al}_5\text{N}_9$ ⁹⁴ are also known. However, despite the evident analogy with the structures in the Al–Si–C and Al–N–C systems, they are at present regarded as polytypes in the Si–Al–N–C system.

4. Boron carbide

Deformation polytypism is possible in boron carbide. This has been confirmed indirectly by data indicating the marked disordering in B_4C when the specimens are rubbed.⁹⁵ In the course of electron microscope studies of B_4C deformed at a high pressure and temperature ($P = 7.7$ GPa, $T = 1800$ °C) a similar disordering was also observed.⁹⁶ Furthermore, the formation of a mixture of MP was detected. It was established that the disordering is associated with the disperse twinning along one system of rhombohedral planes of the type $\{10\bar{1}1\}$.

5. Aluminium nitride

Among the nitrides, the most representative series of polytypes has been identified on the basis of aluminium nitride with the wurtzite structure (2H). AlN is represented by only this modification in the powders synthesised by various methods and in known

polycrystalline materials of all types. The AlN sphalerite phase has not been detected (in contrast to its crystallographic analogues — SiC, ZnS, BN, lonsdaleite, etc.). However, the formation of the AlN phase with a NaCl-type face-centred cubic lattice in microvolumes has been established. It is segregated (in the form of needles, plates with a rectangular cross-section) when nitrogenated iron silicide is annealed. Its unit cell parameter is in this case $a = 4.10$ Å. On heating above 600 °C, this phase is converted into the 2H form.⁹⁷ The face-centred cubic lattice of AlN may be formed from the 2H phase on application of high pressures in the course of static⁹⁸ and impact⁹⁹ compression. It has been noted¹⁰⁰ that the transition of AlN to the metallic state is possible at 90 GPa.

a. The Al–N–C system

The phenomenon of polytypism in aluminium nitride was first observed in the Al–N–C system in an X-ray study of single crystal specimens.¹⁰¹ The latter were obtained by recrystallising AlN via the gas phase at $T > 2000$ °C in a graphite crucible. The polytypes were identified in this case in the form of a series of carbonitride phases differing in their space groups (Table 2). These phases have been described⁹¹ as members of the $(\text{AlN})_n\text{Al}_4\text{C}_3$ AlC series ($n = 1–6$) — with the AlN and Al_4C_3 extreme members of the series. It was postulated that the structure of the carbonitrides can be represented as the combination of three types of blocks: $[\text{AlN}]_n$, $[\text{Al}_2\text{C}_2]_n$, and $[\text{Al}_2\text{C}]_n$. For example, the rhombohedral structure can be accordingly described by a set of blocks in the following sequence: $([\text{Al}_2\text{C}_2]_n[\text{AlN}]_n[\text{AlN}]_n[\text{Al}_2\text{C}]_n \cdot [\text{AlN}]_n[\text{AlN}]_n)_3$. This representation of the structure of the carbonitrides was later confirmed by the fact that the calculated (according to the model) and experimental unit cell parameters a and c agreed. The carbonitrides have also been described⁹¹ as multilayer structures in terms of Zhdanov's symbols (Table 2). The compositions Al_4C_3 and $\text{Al}_5\text{C}_3\text{N}$ correspond to the 9R⁸⁸ and 8H¹⁰² polytypes. The latter polytype is analogous to the 8H polytype in the Si–Al–O–N system.¹⁰² The analogy consists in the fact that the carbon atom substituting nitrogen in the case of the Al–N–C system in four nonmetallic layers has a coordination number of 6, whilst other nonmetallic atoms are located in distorted tetrahedra between octahedral layers.

Hitherto the communications of Jeffrey and Wu^{91,101} are the only ones in which the detection of multilayer structures in the AlN–C system has been reported.

b. The Al–N–O system

The polytype formation processes in AlN have been investigated in detail in a study of polycrystalline materials in the AlN– Al_2O_3 , AlN– SiO_2 , Si_3N_4 – Al_2O_3 –AlN, and Si_3N_4 – Al_2O_3 –AlN– SiO_2 systems. 2H AlN–O single crystals have been investigated only by

Table 2. Characteristics of the aluminium carbonitrides $(\text{AlN})_n\text{Al}_4\text{C}_3$ with $n = 0–6$ which are multilayer structures in the AlN–C system.^{91,101}

Note. The following designations have been adopted: A = packing sequence of the metal layers (Zhdanov's symbols are used); B = intence reflection in the 00 l row; l = interlayer distance. ^a Hypothetical phases.

Bartram and Slack.¹⁰³ It has been reliably established that the polytypes in such materials are formed on the basis of the AlN phase with the wurtzite structure and they are therefore referred to as the wurtzite polytypes. However, they are frequently referred to as sialone (in the Si–Al–O–N system) and oxynitride (in the Al–N–O system) polytypes. Evidently these names of the polytypes lack significance since sialones are solid solutions of aluminium and oxygen in the Si_3N_4 lattice of the phenakite type, while aluminium oxynitrides are compounds with a cubic spinel-type lattice.

Three kinds of sialones are known. The phases formed in the region located along the Si_3N_4 – $\text{AlN} \cdot \text{Al}_2\text{O}_3$ line (Fig. 4), for a fixed cation/anion ratio (M/X , where $M = \text{Al}$, Si and $X = \text{N}$, O) of $3/4$, are described by the general formula $\text{Si}_{6-x}\text{Al}_x\text{O}_x\text{N}_{8-x}$ (with $x \leq 4.2$) and are referred to as β' -sialones.¹⁰⁴ These phases have a β - Si_3N_4 lattice. For $x < 0.4$ and the ratio $M/X = 2/3$, phases with the orthorhombic lattice characteristic of Si_2ON_2 , are formed. They are described by the general formula $\text{Si}_{2-x}\text{Al}_x\text{O}_{2-x}\text{N}_{1+x}$ and are called O' -sialones.^{104, 105} Both kinds of sialones are formed on the basis of the β - Si_3N_4 lattice. α -Sialones are formed in the M – Si – Al – O – N ($M = \text{Li}$, Mg , Ca , Y , V , Nd , La) systems on the basis of the α - Si_3N_4 lattice. They are described by the general formula $\text{M}_x(\text{Si}, \text{Al})_{12}(\text{N}, \text{O})_{16}$ ($0 \leq x \leq 2$). The above metals M stabilise the Si_3N_4 α -phase.^{106, 107}

Aluminium oxynitrides with a spinel lattice are formed when the AlN content is in the range from ~ 45 mol.% to 25 mol.%.¹⁰⁸ Since the spinel has the formula AlON, it contains ~ 34.5 mol.% of AlN.¹⁰⁹ In the literature, the spinel is designated as AlON but it is also possible to encounter the term 'nitrogen-stabilised aluminium oxide'. The nonstoichiometric spinel $9\text{Al}_2\text{O}_3 \cdot \text{AlN}$, for

Figure 4. The isothermal section through the Si–Al–O–N diagram at 1750 °C.¹¹²

which there is a possibility of the formation of superstructures, is known.¹¹⁰ The spinel $\text{Al}_2\text{O}_3\text{N}$ is regarded as ideal. It may be obtained when the structural vacancies in Al_2O_3 are completely filled with nitrogen.¹⁰⁹ The phases in the AlN – Al_2O_3 system are formed by the reaction:¹⁰³

(this is pure AlN for $z = 1$ and pure Al_2O_3 for $z = 0$). A whole series of intermediate phases differing in the value of z have been noted. The range $0.889 > z > 0.25$ is characteristic of the oxynitride phases.

The communication of Lejus¹¹¹ about the formation of polytypes in the AlN – Al_2O_3 system must be regarded as the first in which a new phase was detected. Later this phase was identified¹¹² as the 21R AlN polytype. Japanese investigators detected the 2H AlN–O solid solution (the authors called it the 2H pseudopolytype) and the 27R, 16H, 21R, and 12H polytypes in a material based on AlN (the Al_2O_3 content, was up to 12.3%).¹¹³

Communications about the identification of the 20H and 27R polytypes⁹³ and the 12H, 27R, and 21R polytypes¹¹⁴ by X-ray diffraction appeared almost simultaneously. In the first case, they were detected in a study of the single crystals obtained in the course of the resublimation of AlN at $T \approx 2200$ °C in $\text{N}_2 + 5\%$ H_2 , whilst in the second they were detected in a study of a polycrystalline composition having the formula $5\text{AlN} \cdot 9\text{Al}_2\text{O}_3$. In the latter case, they were detected in the range of compositions where a liquid phase is formed in the Al–O–N system.

Kurdyumov *et al.*¹¹⁵ reported the formation of a 165R polytype on sintering a highly disperse AlN powder obtained by plasmachemical synthesis and containing ~ 2 mass% of oxygen. This polytype was detected in a 2H AlN grain in the form of a lamellar interlayer not containing other polytypes (Fig. 2).

In the course of an electron microscope study of a material having the composition AlN – Al_2O_3 , Krishnan *et al.*¹¹⁶ identified the 27R, 16H, and 32H polytypes; they observed the last polytype for the first time. In similar studies of a material obtained from AlN powder contaminated by oxygen as the accompanying impurity, the 33R and 20H polytypes were identified.¹¹⁷ According to the communication of Youngman and Harris,¹¹⁸ the 51R polytype, containing 6.6 at.% of oxygen, is formed in the AlN–O system. In the presence of MgO in this system, the formation of the 27R and 21R polytypes was discovered.¹¹⁹

Schuster¹²⁰ proposed a AlN – Al_2O_3 phase diagram based on the revised data of McCauley and Cowin¹¹⁴ in which the tentative regions corresponding to the formation of the 12H, 27R, and 21R polytypes were identified (Fig. 5).

c. The Si–Al–N–O system

The AlN polytypes were first observed as new phases in the Si_3N_4 – AlN – Al_2O_3 – SiO_2 system by Gauckler *et al.*¹⁰⁴ and Jack¹²¹ in the range of compositions with a high AlN content. These phases were represented¹⁰⁴ as Si–Al–O–N chemical compounds differing in the content of cations and anions. It was

Figure 5. The AlN – Al_2O_3 phase diagram with identification of the regions corresponding to the formation of the AlN polytypes.¹²⁰

established by subsequent X-ray studies¹²² that all the new phases observed have a wurtzite type lattice and can be described in terms of Ramsdell's symbols as multilayer structures (polytypes based on the 2H AlN lattice) (Table 3). Depending on the number of layers (n) in the polytypes, their parameters c are described by the following equations:¹¹²

$$c_R = (n-3) \left(\frac{c}{2} \right)_{\text{AlN}} + 3(4.014),$$

$$c_H = (n-2) \left(\frac{c}{2} \right)_{\text{AlN}} + 2(4.014).$$

Table 3. Characteristics of the identified polytypes in the Si–Al–O–N system.

^a 2H^δ = solid solution of oxygen and silicon in 2H AlN.

A Si–Al–O–N phase diagram, in which the regions corresponding to the formation of AlN polytypes (or X-phases)¹⁰⁴ were identified, has also been put forward (Fig. 4).¹¹² This diagram, confirmed in a further study of the system, is nowadays widely known. According to the diagram, the polytypes are in the region with a high AlN content along a line corresponding to a constant cation/anion ratio. The polytypes described in the above study¹¹² were identified by electron microscopy¹²³ in a study of material having the initial composition Si₃N₄ + AlN + Al₂O₃ hot-pressed at 1600–1750 °C. Later in the course of similar studies of material obtained by sintering AlN + SiO₂, the 33R, 24H, and 39R polytypes were discovered and their characteristics were determined (Table 3).¹²² Overall, the composition of the polytypes in the Si–Al–O–N system is described by the general formula Al_{*x*} + *y*Si_{6–*y*}O_{*x*}N_{8–*x* + *y*}, where *x* = 4 and *y* = 2*n* (*n* is an integer varying from 0 to 10).

Polytypes have also been observed in the M–Si–Al–O–N systems. The 12H, 15R, 21R, and 20H polytypes were identified by X-ray diffraction in hot-pressed material based on the initial composition MgO + Al₂O₃ + Si₃N₄.¹¹² Subsequently the 12H, 15R, 7(21)R, and 8(16)H polytypes were found by electron microscopy in material of the same composition and it was established that they differ in the amounts of Mg–Al and Si–O.¹²⁴ According to the data of Kuang *et al.*,¹²⁴ the 12H polytype with the ratios Mg:Al:Si = 1:0.3:1.2 is formed in the Si–Al–O–N system in combination with MgO. It is also produced at 1400 °C and is stable up to the temperature of the appearance of the new phase.

The 15R polytype has been observed in the Si–Al–O–N system with lithium¹¹² and the 33R polytype was found in the same system with calcium.¹²⁵ Polytypes have been noted also in the system with yttrium. For example, the 15R and 8H polytypes were identified by Ekstrom *et al.*¹²⁶ at a sintering temperature less than 1800 °C, while the 27R polytype was identified by Topfer and Muller.¹²⁷

A characteristic feature of the polytype formation in the Y–Al–Si–O–N system must be pointed out.¹²⁸ The 27R polytype was formed in specimens having the initial composition AlN + SiO₂ at 1700–1800 °C; when Y₂O₃ was introduced into this composition, the amount of the polytype diminished. In the course of the subsequent annealing of a mixture of ground specimens having the first composition to which Y₂O₃ had been added, the content of the polytype fell, starting already at 1400 °C, whilst at higher temperatures it vanished altogether. This feature is due to the formation of oxygen-rich stable phases in the Al₂O₃–Y₂O₃ system above 1250 °C. This in fact induces the binding of the oxygen present in the initial AlN + SiO₂ system and also contained in specimens in which the 27R polytype is present after sintering.

d. Microstructural features of the formation of polytypes

The polytype formation in the Al–O–N and Si–Al–O–N systems is characterised by the following general features.

The formation of polytypes is observed in most cases above 1700 °C, although there have been reports of their appearance in the Si–Al–O–N system at 1400 °C¹²⁹ and 1600 °C.¹³⁰ Polytypes are formed in materials obtained by sintering porous pressed materials produced by the usual hot pressing and isostatic pressing procedures. In the treatment of materials at high pressures and temperatures (starting from 2 GPa at 1700–1800 °C), polytypes are not formed.

In the first stage, polytypes are always formed within the grains. At 1700–1800 °C, the polytypes are in most cases produced in the form of lamellar interlayers in the grains (Fig. 2), whilst at higher sintering temperatures individual grains with the same morphology are formed in the materials.⁸⁵ When highly disperse AlN powders, obtained by plasmachemical synthesis, are sintered, thin lamellar interlayers may be formed within the limits of the entire grain. In rare instances, a polytype with the same number of layers is formed within a single grain.¹¹⁵ A typical example is a mixture of polytypes with different numbers of layers combined with a solid solution of oxygen or of oxygen and silicon in AlN (2H^δ). In the lamellar interlayers, they are usually present in the form of blocks of different thickness grown together, coherently *via* the (0001) planes, *i.e.* they actually constitute a composite modulated structure. The electron microdiffraction patterns of sections of the (1120) type through the grains show a series of non-systematic point reflections in the 00/*l* and *h*0/*l* rows (Fig. 6). In the course of the recrystallisation growth of the grains, the polytypic composition along the length of both the MP interlayer and the individual grains having the same composition remains unchanged. All the variants of the development of the granular structure are presented in Fig. 3. In the course of the growth of the grains, the fraction of MP in the polycrystalline material increases as a result of the diffusional rearrangement, of the 2H phase in the MP within the migrating boundary. It is significant that in this instance the reverse transformation 2H → MP may also take place. Reversible grain → boundary polytypic transitions also occur in SiC-based materials.

An unusual instance of polytype formation has been noted¹³¹ in the Si₃N₄–SiC system to which Er₂O₃ and AlN had been added: the 21R polytype (SiAl₆O₂N₆) crystallises epitaxially on the basal surface of the 6H SiC plates.

There is no information about the regions of stability of the AlN polytypes in the Al–O–N and Si–Al–O–N systems. Data on the tentative regions in which three polytypes are located on the AlN–Al₂O₃ phase diagrams have been published in only one study (Fig. 5).¹²⁰ However, careful investigations on these lines have not been carried out. It has been established reliably that, as the oxygen content in the initial AlN decreases, the number of layers in the polytypes rises. The longest-period 51R polytype has now been identified: it has a 17-layer sequence repeated three times; its oxygen content is 6.6 at.%.¹¹⁸ The 165R polytype identified by Kurdymov *et al.*¹¹⁵ most probably consists of

Figure 6. Interference pattern in the resolution of the 2H AlNO planes (0001) in an oxygen-enriched interlayer and an electron microdiffraction pattern [the (1120) section].

blocks of short-period structures, as is usually observed for SiC polytypes with a large number of layers (126R⁸⁰ and 201R⁸¹). It has also been established¹³² that at high pressures and temperatures (8–10 GPa and > 2200 °C) the multilayer polytypes in the AlN–O system are unstable: they undergo a transition to the 2H phase and the cubic aluminium oxynitride.

e. Models of the structure of AlN polytypes

A model of the structure of the wurtzite AlN polytypes was first proposed by Jack.¹¹² As in the case of the polytypes in the AlN–C system,^{91,101} it is based on the idea of the formation of multilayer structures from blocks of different chemical composition. The unit cell of each polytype contains n layers divided into blocks: two in the case of hexagonal and three in the case of rhombohedral symmetry. Each block consists in its turn of m layers. The number of layers in the hexagonal and rhombohedral polytypes is therefore represented as $n = 2m$ and $n = 3m$ respectively. One layer in each block contains an excess nonmetal atom, while the remaining layers are the basal (0001) 2H AlN layers. This means that the layer specified has the composition MX_2 , in contrast to the composition MX of the basic structure. On these grounds, the composition of the polytypes is described by the general formula M_mX_{m+1} , where m is an integer; we have the ratio $\text{M}/\text{X} < 1$. Hence a difference between the chemical compositions of the polytypes is evident.

The formation of layers having the composition MX_2 is determined by the local change in the coordination number of aluminium from four (characteristic of the 2H structure) to six and is induced by the dissolution of oxygen in AlN.¹¹² The change in the packing sequence in the AlN polytypes is attributed to the number and periodicity of the disposition of the MX_2 layers containing Al atoms with a coordination number of six. It has been suggested that the latter is determined by the appearance of packing defects in the aluminium sublattice of 2H AlN (the change in the AB, AB alternation of aluminium atoms to ABC, ABC), induced by the localisation of the nonmetal atoms and hence by the decrease in the distance between them.

In the subsequent structural studies, data were obtained confirming the proposed model of the structure of polytypes. It has been established by electron microscopy¹²³ that the change in the periodicity of the polytypes in the Si–Al–O–N system is determined by the presence of planar two-layer defects along the basal planes. On the basis of X-ray studies of two polytypes (8H and 15R), it was concluded that they contain 2H AlN layers distributed periodically in the basal planes and containing aluminium surrounded by six oxygen atoms (AlO_6).¹³³ The calculated images for the 12H and 15R polytypes, taking into account the regular alternation of the octahedrally coordinated aluminium atoms, corresponded to the images obtained by convergent beam electron diffraction.¹³⁴

On the basis of the ideas concerning multilayer structures in the AlN–C system developed by Jeffrey and Wu^{91,101} and Thompson's data,¹³³ Bartram and Slack¹⁰³ and Krishnan *et al.*¹¹⁶ suggested that the MX_2 layers in the polytypes of the Al–N–O system be regarded as $\alpha\text{-Al}_2\text{O}_3$ interlayers with a thickness equal to the parameter c of the morphological cell of corundum (the parameter c of this cell is equal to half the parameter c of the structural cell). In this model, the experimental and calculated values of c for the 20H and 27R polytypes agree well. The experimental values were respectively 53.10 and 72.24 Å. In the calculations, account was taken of the determinations of the interlayer distance and of the range of the known values of c for the morphological cell of Al_2O_3 . The following ranges of values of c (Å) were established: 50.92–53.58 for the 20H polytype and 68.77–72.76 for the 27R polytype.¹⁰³

In later studies, new data were obtained concerning the nature of the planar oxygen-containing MX_2 layers (O-defects) in the basal planes of AlN and a series of structural models of their formation were proposed. According to Hagege *et al.*,¹³⁵ such layers represent a packing defect containing an octahedrally

coordinated aluminium atom and arising with participation of vacancies generated on formation of the 2H AlN–O solid solution. It has been postulated¹³⁶ that the O-defects are anti-phase domain boundaries and their thickness in the direction of the [0001] axis of AlN is 1/2 or 1/3 of the $\alpha\text{-Al}_2\text{O}_3$ structural cell. Experimental studies established¹³⁷ that the defects are inversion domain boundaries (IDB) and that they contain lamellar formations enriched in oxygen.

According to the ideas of Harris *et al.*,¹³⁸ the logical sequence of the processes determining the formation of the O-defects is as follows. At an oxygen concentration less than 0.75 at.% in the 2H AlN–O solid solution the complexes $\text{V}_{\text{Al}} + \text{O}_{\text{N}}$, where V is a vacancy, are formed. It has been established experimentally that the formation of the complexes is accompanied by a decrease in the parameter c of 2H AlN and by the contraction of the lattice (Fig. 7). At higher oxygen concentrations, the mode of incorporation of oxygen into AlN changes (this is indicated by the restoration of the volume of the 2H lattice). It has been suggested¹³⁸ that in this case octahedral defects, the formation of which is accompanied by the annihilation of the aluminium vacancies, arise initially. A unit defect consists of a combination of an aluminium atom with six oxygen atoms. With increase in the oxygen concentration, such octahedral defects coalesce with formation of planar IDB, the regular disposition of which in the 2H lattice of AlN is in fact responsible for polytype formation.

A model of the structural rearrangement determining the formation of the O-defects has been proposed.¹³⁸ In this model, the development of a displacement process is postulated with a vector $\mathbf{R} = (1/3)\langle 10\bar{1}1 \rangle$, which may be split into two components: $\mathbf{R} = (1/3)\langle 10\bar{1}0 \rangle + (1/3)\langle 0001 \rangle$. This model has been confirmed.¹³⁹ In later studies, it was demonstrated experimentally that the vector of the displacement of the O-defect is $\mathbf{R} =$

Figure 7. Variation of the volume ($\Delta V/V$) of the AlN unit cell with increase in the concentration of dissolved oxygen.¹³⁸

$(1/3)\langle 10\bar{1}0 \rangle + 0.387\langle 0001 \rangle$ and that this is close to the calculated value $\mathbf{R} = (1/3)\langle 10\bar{1}0 \rangle + 0.394\langle 0001 \rangle$.

The ideas¹³⁸ concerning the formation of planar IDB described are known as Youngman's model of the defect. This model has been confirmed:¹⁴⁰ the experimental oxygen content in the IDB (amounting to 6.0 ± 0.8 mass %) is close to the value calculated (5.7 mass %) in accordance with Youngman's model. We may note that the principal postulate of Youngman's model — the change in the structural state of oxygen in 2H AlN–O with increase in its concentration — has been confirmed also by the results of the study of the structure of this solution in thin films.¹⁴¹ It has been shown that the dissolution of oxygen in AlN with increase in concentration has three stages: I — complete dissolution; II — the formation of aluminium oxynitride; III — the formation of $\gamma\text{-Al}_2\text{O}_3$.

The nature of the periodic segregation of oxygen-containing basal layers in the 2H lattice and the mechanism of polytype formation in the 2H AlN–O solid solution were fully examined by the present authors in another communication.¹⁴² This was based

on the results of a detailed study by transmission electron microscopy in combination with microdiffraction of the evolution of structural transformations in the 2H AlN–O and 2H AlN–O–Si solid solutions, starting with the stage involving the appearance of unit basal packing defects in the grains and ending with the formation of lamellar grains made up of a mixture of multilayer AlN polytypes.

f. The model of the formation of polytypes

The formation of polytypes as a result of the generation of O-defects in the AlN basal layers is associated with two stages in the decomposition of the 2H AlN–O solid solution, which occurs above 1700 °C.¹⁴² According to experimental data, the first stage is the isostructural separation into layers, leading to the segregation in the single-crystal grains of oxygen-enriched lamellar interlayers, along the (0001) plane. A single plate is usually generated in the grain, intersecting it from boundary to boundary; its thickness in the [0001] direction is 0.5–1 µm (Fig. 2). The change in the oxygen concentration of the enriched lamellar interlayer in the [0001] direction is nonperiodic, because separation into layers occurs in each instant at a different concentration in the solid solution, *i.e.* a set of zones with different concentrations is formed in the interlayer.

The separation of the 2H AlN–O solid solution into layers occurs *via* the ascending diffusion mechanism (*i.e.* $\bar{D} < 0$, where $\bar{D}$ is the diffusion coefficient), caused by the sharp decrease in the energy of the basal packing defects within the grains of the 2H AlN–O solid solution.¹⁴² The decrease in energy is induced by the localisation of oxygen (Suzuki segregation) in the region of the packing defect. The occurrence of such segregations determines the appearance of a stress gradient as the driving force of ascending diffusion. The latter is due to the following causes.

Taking into account the conditions for isomorphous heterovalent substitution,⁸³ the 2H AlNO formation reaction is as follows:

The oxygen in such a solid solution exists in the form of the complexes $2\text{Al}_{\text{Al}}^{3+} + 3\text{O}_{\text{N}}^{2-} + \text{V}_{\text{Al}}$. The occurrence of oxygen segregations on the packing defect is associated with the migration of such complexes, *i.e.* with the simultaneous diffusion of aluminium along the cationic sublattice and of oxygen along the anionic sublattice, which means that it is associated with the constant appearance of a compressive stress (as a result of the presence of vacancies) in the vicinity of the packing defect. The magnitude of such stresses ε is proportional to the concentration of vacancies:¹⁴³

$$\varepsilon = \sum \beta_i N_i,$$

where β_i are deformation constants proportional to the difference between the ionic radii of the defects and the matrix and N_i is the concentration of point defects. Under the conditions of ascending diffusion under the influence of the stress gradient, atoms with a larger radius should tend to migrate into the stretched regions, while those with a smaller radius should tend to move into the compressed regions.¹⁴⁴ The latter (bearing in mind that $r_{\text{O}} < r_{\text{N}}$, where r represents the size of the atom) occurs in the case of 2H AlN–O and is responsible for the formation of oxygen-enriched layers along the planes containing the packing defect.

The second stage of the decomposition of the solid solution occurs in the oxygen-enriched interlayer produced on isomorphous separation into layers. It is determined by the sequence of structural transformations, the development of which is in fact responsible for the generation of basal O-defects and hence the formation of polytypes. These transformations occur in three stages.

1. The formation of oxygen clusters. The presence of such clusters is confirmed by the geometry of the reflections on the electron microdiffraction patterns from enriched interlayers (Fig. 8). The clusters are formed already in the process involving the separation of the solid solution into layers and consist of the

basal layers of AlN enriched to different extents by oxygen substituting the nitrogen atoms. It is believed that¹⁴⁵ the establishment of order in the system occurs as a result of the growth of some clusters and the disappearance of others. There is a definite correlation distance between the former clusters (which is due to the need to achieve the condition for the minimisation of their interaction energy). The minimisation condition determines also the form of the clusters, namely as Al–O basal layers. According to the ideas developed by Khachatryan,¹⁴⁶ in solid solutions with a negative anisotropy parameter, formations in the form of plates arranged in the direction of the minimum modulus of elasticity have the minimum elastic energy. For AlN, the anisotropy parameter is -0.07 . Evidently the cluster ordering process takes place, like the separation of the solid solution into layers, *via* the ascending diffusion mechanism. As noted above, a set of concentration zones are generated in the oxygen-enriched interlayers. Within the limits of each zone, clusters with a definite correlation distance are produced.

2. The formation of three-layer oxygen-containing defects from the clusters. This process is determined by the ordering of the vacancies in the AlN cationic lattice, inevitably accompanying the ordering of the clusters formed from associated species having the composition $(2\text{Al}_{\text{Al}}^{3+} + 3\text{O}_{\text{N}}^{2-} + \text{V}_{\text{Al}})$. One of the aluminium vacancies is formed after the substitution of three nitrogen atoms by oxygen, which means that the growth of clusters leads to the

Figure 8. Schematic illustration of the electron microdiffraction pattern of the (1120) section through a grain of the initial 2H AlN–O solid solution (a) and of the interlayer formed as a result of layer formation (b–d); (b) and (c) nonordered cluster state; (d) state with directed stresses.

formation of three-layer defects in the (0001) planes — two oxygen-containing Al–O basal layers separated by a $\text{V}_{\text{Al}}\text{–O}$ layer. The segregation of such defects in the oxygen-enriched zone occurs with a periodicity specified by the motif in the disposition of the clusters. The presence of empty sublayers (V_{Al}) in the defects should lead to the appearance of directed stresses. This has in fact been confirmed by microdiffraction studies (Fig. 8 d).

3. The crystallographic shifts along the (0001) plane in three-layer defects. Such shifts lead to the exclusion of the vacancy sublayer and to a local rearrangement, of the 2H lattice in the defect into a fragment of the lattice of the $\alpha\text{-Al}_2\text{O}_3$ segregation phase. The shifts develop with a periodicity specified by the motif in the arrangement of the defects. The regular formation of layers of the segregation phase modulates the basic 2H structure to give a structure with a different phase composition and a different unit cell parameter c . Such structures actually represent polytypes.

The possible mechanism of the rearrangement of the three-layer defects to the Al–O segregation phase in the 2H AlN lattice is as follows: The bonds between the atoms in the three-layer defect differ from those in the 2H structure, because the appearance of even one vacancy V_{Al} on formation of the solid solution

Figure 9. Schematic illustration of the single bond between diatomic layers in the 2H lattice with formation of aluminium vacancies [the (1120) section]; (a) normal unit; (b) formation of vacancies; (c) relaxation of the bond on formation of vacancies.

inevitably leads to the appearance of the O–O bond. This can be seen in Fig. 9, which represents a schematic arrangement of the atoms in a unit fragment of the 2H structure in the (1120) section. The appearance of a three-layer defect with a V_{Al} sublayer should lead to the formation of the O–O bond between the Al–O layers. The direction of this bond is parallel to the plane of the pyramid of the tetrahedron of the first kind (Fig. 10). The characteristic features of the structure of the electron microdiffraction pattern, of the (1120) sections of the interlayers containing the solid solution and multilayer AlN polytypes, namely the presence of diffuse rows in directions of the type $[10\bar{1}1]$ (Fig. 8d), may be regarded as confirmation of the formation of such a bond. Rows of this kind are known^{146, 147} to be a sign of the generation of directional stresses.

On formation of a continuous layer of vacancies, their collection into a loop is inevitable, which implies the formation of a chemical packing defect.¹⁴⁸ Such defects are characteristic of layered nonstoichiometric compounds, for example Sb_2Te_3 . In the three-layer defects in the AlN structure which we considered, the vacancies are located only in one sublayer of the diatomic layers. They then induce the appearance of directed stresses. Such stresses

Figure 10. Schematic illustration of the formation of the O–O bond in a three-layer AlN defect formed following the ordering of the aluminium vacancies [the (1120) section]; (a) appearance of vacancies in the layer; (b) relaxation of the bond following the appearance of vacancies.

in the 2H lattice should promote a shift along the basal plane. According to the data of Funk and Sochel,¹⁴⁹ this type of shift occurs on disorientation (α) of the $[0001]$ axis and the directions in which the stresses act are in the range $0 < \alpha < 90^\circ$. In our case, the angle between the direction of type $[10\bar{1}1]$ and the $[0001]$ axis is 32° . The occurrence of such a shift promotes the elimination of the V_{Al} sublayer and may be classified in the development of the Wadsley crystallographic shift.¹⁵⁰

The elimination of the V_{Al} sublayer in the defect may be represented by two elementary steps involving the migrations of aluminium atoms under the influence of directed stresses

(Fig. 11a). The first involves the migration of the aluminium atoms from layer I (Al–O) to layer II (V_{Al} –O). Formally, this implies the formation of a packing defect, in the hexagonal close-packed aluminium sublattice, which is accompanied by a local change in the alternation of the atoms from AB AB... to ABC ABC.... The second step involves the migration of aluminium atoms in layer III (Al–O) over an interatomic distance. In this case, there is a shift in the (0001) plane. Such migrations are responsible for the change in the coordination number of aluminium from four to six and hence for the addition of oxygen atoms from layer II (V_{Al} –O). Formally, this can be represented as the combination of four tetrahedra (as elements of the wurtzite lattice) to form an octahedron which is an element of the structure of α - Al_2O_3 . Comparison of Fig. 11b with Fig. 12 shows that the disposition of aluminium and oxygen atoms in the lattice fragment, formed as a result, of the migrations indicated corresponds to their positions in two layers of the unit cell of α - Al_2O_3 .¹⁵¹ A distinctive feature of the structure of such a fragment compared with that of α - Al_2O_3 is that an aluminium atom from one layer is bound to five oxygen atoms and a nitrogen atom, *i.e.* it belongs simultaneously to the 2H lattice and the Al_2O_3 segregation phase. This also applies to the oxygen atom from the second layer because it is bound to an aluminium atom belonging to 2H AlN.

The thickness of two Al–O layers of the segregation phase is $c/4 = 3.24 \text{ \AA}$ (c is the cell parameter) (Fig. 12). We may note that, according to the data of Bartram and Slack,¹⁰³ the quantity $c/4$ may vary from 2.58 to 3.25 $\text{\AA}$. The estimation of the thickness of the layers of this phase in the 2H AlN lattice, taking into account, the distance between the aluminium and nitrogen atoms, yields 3.01 $\text{\AA}$ (the distance between diatomic layers in the direction of the c axis is 1.97 $\text{\AA}$, whilst that between the atoms in the diatomic layer is 0.52 $\text{\AA}$). This indicates the possibility of the formation of a fragment of the α - Al_2O_3 lattice structure in the form of two layers in the 2H AlN lattice. The segregation of AlO in the α -form is determined by the similarity of the ratios c/a in AlN and in this form ($c/a = 1.6$ in the former case and 1.58 in the latter) and also of the distances between the atoms in them: the distances between close unlike atoms are 1.97 and 1.86 $\text{\AA}$ in Al_2O_3 and 1.917 and 1.885 $\text{\AA}$ in AlN. The packing of the chains of oxygen atoms in the basal layers of the α - Al_2O_3 lattice is close to the packing of the nitrogen atoms in the AlN lattice. The principal difference between these structures is associated with the coordination number and also

Figure 11. Schematic illustration of the migration of aluminium atoms in a three-layer defect on elimination of a sublayer of aluminium vacancies (a) and the disposition of the aluminium and oxygen atoms in the two-layer segregation generated after the elimination of the above sublayer (b) [the (1120) section].

Figure 12. Schematic illustration of the disposition of aluminium and oxygen atoms in Al_2O_3 [the (1120) section].

with the disposition of the central aluminium atom: it has a coordination number of 6 and is located in an octahedral environment in an $\alpha\text{-Al}_2\text{O}_3$, whereas in AlN a coordination number of 4 is characteristic of this atom and the latter is located in a tetrahedral environment. Thus the rearrangement in the three-layer defect on development of the shift ensures a change in the location and hence in the coordination number of aluminium.

The lattice parameters of 2H AlN and $\alpha\text{-Al}_2\text{O}_3$ in the coupling plane differ appreciably ($a = 3.11$ Å for AlN and 4.748 Å for Al_2O_3), so that the following question arises inevitably: is the formation of $\alpha\text{-Al}_2\text{O}_3$ layers in the 2H AlN lattice possible? From a formal point of view, the noncorrespondence stress in their coupling plane, estimated from the relation

$$\sigma = \frac{E}{1 - \nu} \frac{a_{\text{Al}_2\text{O}_3} - a_{\text{AlN}}}{a_{\text{cp}}},$$

($E = 350$ GPa is Young's modulus and $\nu = 0.18$ is the Poisson coefficient) should be 178 GPa. This greatly exceeds the theoretical limiting strength for a $\mu/10$ shear (the modulus of shear is $\mu = 30$ ¹⁵²) and 137 GPa.¹⁵³ However, according to Khachaturyan's ideas,¹⁴⁶ in the case where a second phase is segregated in the solid solution in the form of thin plates for a small d/l ratio (d is the thickness and l the length of the plates), the interphase stresses should be extremely insignificant. In our case, this ratio is of the order of 10^{-4} . We may note that the deposition of AlN layers on $\alpha\text{-Al}_2\text{O}_3$ supports with epitaxial intergrowth along the basal planes has been observed by a number of investigators, for example by Dobrynin *et al.*¹⁰⁰

g. Calculation of the parameter c for the polytypes in the Al-N-O and Si-Al-N-O systems

According to modern ideas, the structural elements of the classical polytypes (SiC , ZnS , *etc.*) with hexagonal and rhombohedral symmetries consist respectively of two and three symmetrically disposed blocks with one structural packing defect. According to Oleinik and Shevchenko,¹⁴² in the AlN polytypes there should be for each block, not a packing defect, but a two-layer segregation of Al_2O_3 with a thickness $c/4$. The number of 2H AlN layers per structural cell of the polytype can be determined by subtracting from the total number of layers the number of two-layer Al_2O_3 fragments, which is four for polytypes with hexagonal symmetry and six for those with rhombohedral symmetry. For example, in a 20-layer hexagonal polytype containing four Al_2O_3 fragments (with a thickness $c/4$), there should be 16 2H AlN layers. The compositions (corresponding to the morphological cell, *i.e.* to one block) of the polytypes have been determined by means of this approach with the increase in the number of AlN layers in the formula unit from 1 to 15. The parameters c of these polytypes were calculated from the compositions and dimensions (the parameter d_{002}) of unit AlN and Al_2O_3 layers in the direction of the $[0001]$ axis. This quantity is 2.49 Å for AlN and is equal to the

Table 4. Characteristics of the polytypes in the AlN-Al-O system.

51R	17/18	$\text{Al}_{17}\text{O}_3\text{N}_{15}$, $15\text{AlN} \cdot \text{Al}_2\text{O}_3$	45	6	131.49	—

Note. The following designation have been adopted: I — calculations; II — experiment. ^a Polytypes the designation of which are printed bold were established experimentally, whilst the remaining ones are hypothetical. ^b Data of Bartam and Slack.¹⁰³

thickness of the two-layer lattice fragment, *i.e.* to 3.24 Å, for Al_2O_3 . The above characteristics of the polytypes are presented in Table 4. Evidently all known polytypes fit within the above sequence. The calculated values of c agree well with the experimental results for certain polytypes.

The polytypes in the $\text{Al}_2\text{O}_3\text{-AlN}$ system can be represented by the general formula $z\text{AlN} \cdot \text{Al}_2\text{O}_3$, where z is any integer. The number of layers in the polytypes with rhombohedral (n_R) and hexagonal (n_H) symmetries in the sequence deduced above (Table 4) is described by the following relations:

$$n_R = 9 + 6n,$$

$$n_H = 8 + 4n,$$

where n is an integer: $0 < n < 7$ in the former case and $0 < n < 6$ in the latter.

The proposed mechanism¹⁴² of polytype formation in the 2H AlN-O solid solution can operate in the four-component Al-N-Si-O solid solution. The following considerations lead to this conclusion.

When the above solid solution is produced, the positively charged centres ($\text{Si}^{4+} - \text{N}^{3-}$) and ($\text{Al}^{3+} - \text{O}^{2-}$) are generated. The electroneutrality of the lattice can be ensured, as in the case of the 2H AlN-O solid solution, by the formation of the associated species $\text{Si}^{4+} + \text{Al}^{3+} + 2\text{O}^{2-} + \text{N}^{3-} + \text{V}_{\text{Al}}$. The associated species of the system under consideration include two cations and three anions. This suggests that a similar segregation based on the clusters occurs in the system with silicon but differs in the formula

composition, which corresponds to the composition of the electrically neutral complexes, *i.e.* AlSiNO_2 . The latter is a sialone phase. The existence of such phases with the composition MSiNO_2 ($M = \text{Ce, La, Y}$) has been reported,¹⁵⁴ but their structure has not been investigated. On the basis of conditions for isomorphous substitution in the Si–Al–O–N system, this phase can be represented as a solid solution of silicon and nitrogen in $\alpha\text{-Al}_2\text{O}_3$. Consequently the thickness of the two-layer segregation with the composition AlNSiO_2 in the polytypes based on 2H AlN-SiO should be close to 3.24 Å, which is characteristic of the segregations in the 2H AlNO solid solution.

The thickness of the two-layer segregation in the polytypes of the AlN-SiO_2 system can be calculated with the aid of experimental parameters c for the known polytypes in this system using the following relation:¹¹²

$$(d_{002})_{\text{AlNSiO}_2} = \frac{c - v(d_{002})_{\text{AlN}}}{w},$$

where v and w are the numbers of AlN and AlNSiO_2 layers per unit cell. The calculated thickness of the AlNSiO_2 segregation is ~ 3.25 Å, *i.e.* is close to the thickness of the $\alpha\text{-Al}_2\text{O}_3$ fragment in the polytypes of the $\text{AlN-Al}_2\text{O}_3$ system.

The formula compositions and the parameters c of various polytypes in the AlN-SiO_2 system have been calculated taking into account the composition and thickness of the segregation (3.25 Å) (Table 5). Evidently the calculated and experimental parameters are identical for the known polytypes.

The compositions of the 15R and 12H polytypes were identified as $\text{Al}_4\text{O}_2\text{N}_4\text{Si}$ and $\text{Al}_5\text{O}_2\text{N}_5\text{Si}$ respectively with the aid of X-ray dispersion-energetic spectroscopy and electron loss spectroscopy.¹⁵⁵ Overall, the polytypes in the AlN-SiO_2 system can be described by the general formula $\text{Al}_{x+y}\text{Si}_{6-x}\text{O}_x\text{N}_{8-x+y}$, where $x = 4$ and $y = 2n$ (n is an integer varying from 0 to 10).

h. The role of oxygen in AlN polytype formation

The scheme for the structural transformations in 2H AlN-O examined above suggests that the polytype formation in AlN is determined by the regular endotaxy of the Al_2O_3 layers in the 2H matrix in the direction $[0001]$, while the polytypes are intergrowth microstructures. The latter are characterised by the fact that the intergrowth phases have a common cationic sublattice, but in one of them the sublattice atoms are located in tetrahedral vacancies (AlN), whilst in the other they are in octahedral vacancies (Al_2O_3). Overall, the structural changes in the 2H AlN-O solid solution, which determine polytype formation, are analogous to the changes characteristic of the ageing of solid alloys. The latter is accompanied by a stage of separation into layers and the subsequent stage involving the local formation of the lattice of the segregation phase.¹⁵⁶ Different AlN polytypes can be represented by a series of consecutive stoichiometric ordered phases.

The mechanism of the AlN polytype formation described for systems with only oxygen and for systems with a combination of oxygen and nitrogen makes it possible to account for the exceptional role of oxygen. The key structural transformations, determining the formation of the AlN polytypes (the separation of the solid solution into layers with formation of an oxygen-enriched zone, the formation of three-layer oxygen-containing defects as concentration inhomogeneities with an ordered arrangement in such zones) are associated with the development of ascending diffusion. In the case of the 2H AlNO solid solution, the latter may occur only as a result of the stress gradients generated by the aluminium vacancies. The ordered vacancies V_{Al} , disposed in the O-V_{Al} layer, are also 'responsible' for the shear as the final stage of polytype formation.

Thus the polytype formation in AlN is a vacancy-stimulated process, *i.e.* it occurs only in the presence of vacancies in the system. The energy of formation of structural vacancies in AlN is high (according to Cormack,¹⁵⁷ it amounts to 62.998 eV for V_{Al} and 52.108 eV for V_{N}) and they are therefore manifested in the formation of solid solutions. Among chemical elements the dissolution of which in AlN with formation of vacancies is possible, the nitrogen–oxygen, aluminium–silicon, and nitrogen–carbon pairs satisfy best the isomorphous substitution conditions (isoelectronic structure, chemical indifference, similarity of the atomic radii, and similarity of the electronegativities).

There are few experimental data on the formation of solid solutions in 2H AlN . It has been established¹⁵⁸ that oxygen may substitute up to 1/3 of the nitrogen atoms in thin AlN films; when the degree of substitution is high and $T = 800 - 1000$ °C, amorphisation takes place. The AlN in films may be saturated with oxygen up to the compositions AlN_xO_y and $\gamma\text{-Al}_2\text{O}_3$.¹⁴¹ The dissolution of oxygen in AlN up to 1 at.% induces compression of the lattice,¹¹⁸ whilst at higher concentrations the lattice is restored (Fig. 7). The fact that the replacement of three nitrogen atoms by oxygen leads to the formation of V_{Al} is generally recognised. A positive energy of mixing is characteristic of the 2H AlNO solid solutions. This is confirmed by the heating thermogram for a highly disperse AlN powder containing ~ 3 mass% of oxygen.⁸⁵ Analysis of the thermogram indicates the presence of endothermic effects on heating up to 1450 °C, which suggest a positive deviation of the solid solution from the ideal state, *i.e.* from Raoult's law.¹⁵⁹ The latter actually determines its separation into layers, *i.e.* a solid-state structural rearrangement with formation of two solid solutions — enriched and depleted in the dissolved element. The segregation of the first solution in the form of a plate bounded by the (0001) surfaces is induced by a heterogeneous mechanism of separation into layers (with participation of basal packing defects).

The solubility of silicon in AlN as an individual element has not been determined. An attempt has been made¹⁶⁰ to investigate this process in AlN films. It was established that, with increase in silicon concentration in AlN , the unit cell parameter a diminishes, whilst c initially increases and then falls. On the basis of these data,

it has been suggested that oxygen is present in AlN films together with silicon.

The dissolution of SiO₂ in AlN has been demonstrated reliably. As in the case of the AlN–O system, this process takes place with formation of V_{Al}:

With increase in the SiO₂ concentration in the AlN–SiO₂ system, the parameter c of AlN diminishes (Fig. 13).¹⁶¹

Taking into account the literature data,^{118, 160, 161} one may assume that the simultaneous dissolution of oxygen and silicon in AlN should be regarded as a result of the mutual influence of the donor (Si) and acceptor (O) impurities. The replacement of aluminium by silicon promotes the appearance of an electron in the system and this should facilitate the dissolution of the acceptor impurity.¹⁶² It is seen from the reaction, presented above, involv-

Figure 13. Variation of the parameter c of the AlN unit cell with increase in the concentration of SiO₂ in polycrystalline specimens. Sintering medium: (1) air; (2) nitrogen.

ing the dissolution of SiO₂ in AlN, that V_{Al} is formed on substitution of two nitrogen atoms by oxygen and not on substitution of three atoms as happens on dissolution of oxygen alone. Thus silicon plays the role of the catalyst, in the dissolution of oxygen in AlN.

There is no information about the dissolution of carbon in AlN. Presumably, in conformity with the conditions for isomorphous substitution,⁸³ carbon substitutes nitrogen in AlN with formation of vacancies in the anionic sublattice (V_N). The structural transformations in the 2H AlN–C solid solution may occur in accordance with the scheme proposed for the 2H AlNO solid solution subject to the difference that their development is controlled by anionic vacancies. Data on polytype formation in the BeSiN₂–Be₃N₂ system may serve as confirmation of this hypothesis. In the above system, the vacancies arise in the anionic sublattice of the BeSiN₂ wurtzite phase, on the basis of which polytypes actually appear as a result of the periodic segregation of Be₃N₂ layers in the direction of the [0001] axis of the 2H lattice.¹⁶³

On simultaneous dissolution of oxygen and carbon in AlN, polytypes are not formed (for example in the AlN–Al₂O₃C system).¹⁶⁴ On dissolution, there is in this instance a possibility of the formation of oppositely charged centres, (Al³⁺ – C^{4–}) and (Al³⁺ – O^{2–}), which leads to charge compensation in the AlN lattice without the formation of vacancies. Furthermore, the polarisability of carbon anions is greater than that of oxygen (according to Slabough and Parsons,¹⁶⁵ the polarisability is directly proportional to the ionic volume and the radii of the carbon and oxygen ions are 2.6 and 1.35 Å respectively), *i.e.* carbon shows a greater tendency towards the formation of chemical compounds. This has been confirmed by data on the formation in the Al–N–O–C system of the compound Al₄O₄C with a melting

point < 1700 °C, *i.e.* below the temperature at which the 2H AlNO solid solution separates into layers (the necessary stage of the structural rearrangement in polytype formation). It has been established¹⁶⁶ that, in the joint presence of oxygen and carbon in AlN, the phase with the composition (Al₂O₃)·AlN may be formed. This composition was regarded¹⁶⁷ as a solid solution of AlN in Al₂O₃. In the same study, it was established that, for an AlN content corresponding to 40 mol % of nitrogen, the ordered Al₁₀O₃C₉N₄ phase is segregated in the solid solution.

The mechanism of polytype formation in AlN on dissolution of oxygen in the latter, described above, is supported by the following known experimental facts obtained in the study of AlN-based materials.

1. The decrease in the concentration of vacancies when the oxygen content dissolved in AlN is > 1 at.% (*i.e.* in the range of compositions where polytypes can already be formed).¹¹⁸ The critical nature of this oxygen concentration, which exhibits a radical influence on the AlN structure, has also been confirmed by the analysis of the Raman spectra of the 2H AlN–O solid solution.¹⁶⁸

2. The fact that the short-period polytypes are incommensurate, which may be attributed to the high concentration of Al₂O₃ layers.¹⁶⁹

3. The presence of lamellar O-containing segregations in planar AlN defects.¹³⁷

4. The absence of polytype formation in the 2H AlN–O solid solution and the decomposition of polytypes at a high pressure with the appearance of 2H AlN and aluminium oxynitride.¹³² This can be explained by the thermodynamics of the development of structural rearrangements at a high pressure: the rearrangements involving the formation of vacancies (as happens necessarily on dissolution of oxygen in AlN) are unfavourable, whilst the rearrangements involving the disappearance of vacancies (which happens on formation of aluminium oxynitride as a result of the dissolution of nitrogen in Al₂O₃) are actually favourable.

5. The agreement between the calculated compositions of the 12H and 15R polytypes in the Si–Al–O–N system and the experimental compositions established by Bando *et al.*¹⁵⁵

6. The absence of polytype formation in 2H AlN–O in the presence of impurities ensuring the charge compensation of the lattice following the replacement of nitrogen by oxygen (BeO, SiC).^{170, 171}

7. The presence of the Al₂O₃ band in the luminescence spectrum of AlN containing up to 2.8% of oxygen.¹⁷²

8. The presence of the Al₂O₃ band in the 51R spectrum of a lamellar AlN crystal made up of multilayer polytypes.¹⁷³

9. The agreement between data on the content of oxygen in the 51R polytype quoted by Youngman and Harris¹¹⁸ and Oleinik and Shevchenko¹⁴² (6.6 at.% and 8.5 at.% respectively).

6. Beryllium siliconitride and beryllium oxide

Two series of polytypes exist in the Be–Si–O–N system. On the phase diagram, they are located along the line corresponding to the constant cation/anion ratio in the BeSiN₂–BeO–Be₃N₂ range of compositions. The available information about these polytypes (based on the data of Shaw and Thomas¹⁶³) is presented in a generalised form in Tables 6 and 7. One series of polytypes are formed on the basis of the 2H BeSiN lattice along the BeSiN₂–Be₃N₂ connecting line, whilst another series are formed on the basis of 2H BeO along the BeO–Be₃N₂ connecting line.

The polytypes in the system considered have been observed as individual ternary phases (Be–Si–N and Be–O–N) by Heseby *et al.*¹⁷⁴ in a study of the Si₃N₄–SiO₂–BeO–Be₃N₂ quasi-ternary system along an isothermal section (1700 °C). These phases were identified by X-ray diffraction also in the Si₃N₄–Be₃N₂–BeO system. They were represented as multilayer structures with different M/X ratios and have been described in terms of Ramsdell's symbols.^{175, 176} Thompson and Gauchler¹⁷⁶ constructed the Be–Si–O–N phase diagram on the basis of the results of their own studies and those of Heseby *et al.*¹⁷⁴ The regions where

various polytypes are located were identified on the diagram (Fig. 14).

Clarke *et al.*¹⁷⁷ proposed for the first time a model of the structure of polytypes in the system under consideration. It is based on the motif of a regular defective wurtzite structure with the general formula $M_m + 1X_m$, where the minimum value of m ($m = 2$) corresponds to the Be_3N_2 structure. According to the authors,¹⁷⁷ the formation of polytypes is determined by the periodic incorporation of the M_2X layers into the MX blocks of the basic 2H structure of BeSiN_2 . This model has been confirmed by electron microscope studies on polycrystalline specimens containing the polytypes in the BeSiN_2 – Be_3N_2 system: Shaw and Thomas^{163,178} observed regularly arranged planar defects in the structure of the 2H BeSiN_2 -based polytypes. It was suggested¹⁶³ that this structure of the polytypes is due to the formation of defects having a structure and composition different from those of the basic wurtzite structure. Each defect consists of two cubically packed Be_3N_2 layers forming a hexagonal unit cell. These defects promote the transformation of the 2H structure into a set of structures with different phase compositions and volumes of the

**Figure 14.** The isothermal section through the Be–Si–O–N phase diagram at 1780 °C.¹⁷⁶

unit cells. The size of the unit cell is determined by the distance between the defects. According to Shaw and Thomas,¹⁶³ the appearance of Be_3N_2 layers is induced by the ordering of the vacancies in the nonmetallic BeSiN_2 sublattice and the subsequent exclusion of the resulting sub-layers of vacancies as a result of a crystallographic shift along the (0001) direction. Dislocations with a Burgers vector of the type $1/6\langle 20\bar{3} \rangle$ were identified in the BeSiN_2 structure. The shift probably occurs with the aid of these dislocations.¹⁶³ The development of such a shift is responsible for the appearance of the beryllium-enriched planar defects corresponding to the Be_3N_2 composition.

On the basis of the postulates concerning the structure of the polytypes in the BeSiN_2 – Be_3N_2 system described above and having adopted a similar model for the structure of the polytypes in the BeO – Be_3N_2 system, Shaw and Thomas¹⁶³ determined the tentative compositions of a series of polytypes in these systems and calculated the dimensions of the unit cells in the direction of the c axis (Table 7). Evidently these data agree with the experimental results for the polytypes in the Be–O–N system.

7. Boron nitride

As in carbon, polytypes based on three modifications are formed in boron nitride: graphite-like, wurtzite, and sphalerite. The polytypes based on the first modification are formed as intermediate structures in the 2H BN $\rightarrow$ graphite-like BN transition. This transition, which occurs *via* the mechanism of the explosive martensite transformation, has been observed directly in the study of the 2H BN particles by means of a transmission electron microscope. It involves the type of transformation in which a particle of the initial phase is converted into a particle consisting of the graphite-like BN and the polytypes based on it.¹⁷⁹ On sintering polycrystalline 2H BN specimens, this transformation occurs on the surfaces of the layered region.¹⁸⁰

The 2H BN $\rightarrow$ MP + 3C BN transition occurs at high temperatures and pressures. It has been established by electron microscope studies¹⁸¹ that at $P = 5$ GPa the transition begins already at 1200 °C and takes place intragranularly *via* a shift mechanism with the aid of Shockley particle dislocations and with a Burgers vector of the type $1/3a[10\bar{1}0]$. As a rule, the transformation results in the formation of a mixture of polytypes. In rare instances, only one polytype is obtained. The 15R polytype has been identified¹⁸² on the basis of 2H BN, whilst in another study¹⁸³ the 4H polytype was identified. In the primary recrystallisation stage, which occurs in heterophase crystals (2H BN + 3C BN + MP), the intergranular transformation $2\text{H} \rightarrow 3\text{C}$, due to the migration of the interface, also occurs on sintering polycrystalline materials at high pressures.⁸⁶

As in the case of the dense cubic phase of carbon (diamond), the 3C BN-based polytypes are formed under the conditions of deformation at high pressures and temperatures. Their formation is associated with micro-twinning (the formation of thin high-density twinned crystals) in 3C BN crystals *via* a single system of planes of the type {111}.³³

8. Transition metal carbides and nitrides

The formation of multilayer structures is also characteristic of nonstoichiometric Group IV–VI transition metal carbides and nitrides of the type of interstitial phases. Taking into account the crystal geometry and the chemical composition of the interstitial phases (mainly carbides), a series of hypothetical monophase compounds as well as the mechanism of their formation, have been proposed.¹⁸⁴ It was postulated that these phases are formed as a result of the ordered alternation of hexagonal and cubic layers. They were designated in term of Jagodzinski's and Ramsdell's symbols (Table 8).

Many of the postulated phases (including those in the M–N–C system) were identified.^{19, 185, 186} The relation between the composition and the number of layers in polytypic structures has been found for certain carbides MC_y (M = V, Nb, and Ta):¹⁸⁴

$$y = 1 \quad 5/6 \quad 4/5 \quad 3/4 \quad 2/3 \quad 3/5 \quad 1/2$$

Table 8. The multilayer structures in the interstitial phase type transition metal carbides and nitrides.¹⁸⁴

Phase	Maximum content of non-metal (at.%)	Types and space groups of the possible types of packing

Structure 3C(∞) (51)₃ 41 (31)₃ (21)₃ (32)₃ 2H(11)

Monophase ordered compounds are usually formed in the synthesis in the region of the coupling boundary between monocarbides with a hexagonal close-packed lattice and hemicarbides with a face-centred cubic lattice (this applies also to nitrides)^{185, 186} or during the ordering process.¹⁹ In most cases, these compounds are referred to as superstructures. A characteristic feature of the microstructures of many of them, namely the one-dimensional microdomain structure, has been established experimentally: for example, in V₆C₅,¹⁸⁷ Ta₆C₅,¹⁸⁸ Ti₃N_{2–x},¹⁸⁹ and certain vanadium, niobium, and tantalum carbides.¹⁸⁵

Two models of the ordering in carbides and nitrides of the type of interstitial phases are now known. One of the models takes into account the nonstoichiometry of these substances, namely the presence of vacancies in the nonmetallic lattice. A decisive role in the formation of the ordered state (*i.e.* in the appearance of superstructures) is attributed to the development of the process involving the ordering of the structural vacancies and the N and C atoms in the nonmetallic sublattice.¹⁹ The initial phases are in

essence interstitial solid solutions (dissolution of N and C in the M lattice), which implies a redistribution of the nonmetal atoms among the octahedral interstices of the M sublattice. Kolyagin *et al.*¹⁸⁶ explained the formation of the superstructures by the generation of packing defects of various types in the metallic sublattices of the initial hexagonal close-packed and face-centred cubic phases.

The formation of superstructures in superstoichiometric nitrides with deviations from stoichiometry with respect to the metal is attributed to a redistribution of the M atoms and the structural vacancies in the metallic sublattice.¹⁹ It has been suggested that such structures may be formed as a result of the development of various ordering mechanisms. For example, according to the data of Pushchin and Shagaev,¹⁹⁰ the 3C, 6H₂, 6H, and 4H polytypes were identified by electron microscopy in the Nb–N system on film objects obtained by ionic-plasma sputtering. They are formed in the range of compositions with the ratio M/X close to unity. The 3C polytype is δ-NbN. It is believed¹⁹⁰ that the ordered formation of packing defects in the layers of M atoms of this structure leads to the transition to the 6H and 6H₂ structures, while the combination of such ordering and the ordering of the vacancies entails the appearance of the 4H polytype (Nb₅N₆ — stoichiometric composition).

The formation of multilayer structures is characteristic also of carbides of the type M₇C₃ (M = Cr, Fe). The formation of polytypes based on the monoclinic and rhombohedral modifications of these carbides is associated with the ordered generation of packing defects and microtwinning crystals.¹⁹¹ Indeed, the presence of planar defects such as twinned crystals and antiphase boundaries has been established in the above carbides.¹⁹² These defects may be distributed in the basic lattice of the crystals periodically, quasi-periodically, and randomly and depending on this factor, can give rise to modulated, microdomain, and twinned substructures.

9. Oxygen-containing materials

The polytype formation processes in oxygen-containing materials have been little investigated. We shall therefore consider only the main data available in the literature on this problem.

a. Oxides

BeO. Polytypism in BeO has already been discussed. The known and postulated 2H BeO-based polytypes are presented in Table 7.

2H ZnO. There is no information in the literature about polytypism in 2H ZnO. Our studies established that multilayer polytypes may be formed in the grains of polycrystalline ZnO and ZnO with added ZrO₂. The geometrical and morphological characteristics of crystals under the conditions involving the formation of polytypes are similar to the characteristics of AlN. In particular, the polytypes in the ZnO grains arise in lamellar interlayers segregated along the basal plane, as happens in AlN (Fig. 2).

ZrO_{1/3}. A series of polytypes are formed in the zirconium oxide ZrO_{1/3}, which is obtained on dissolving oxygen in metallic zirconium when the oxygen content varies from 24% to 26%.¹⁹³ They are intermediate structures between the rhombohedral (3R) and hexagonal (2H) modifications, 3R has the composition ZrO_x (*x* < 1/3) and 2H has the composition ZrO_y (*y* > 1.3). The 8H, 5H, 12R, and 7H polytypes arise on the basis of 3R, whereas the 10H, 12H, and 14H polytypes are based on 2H. It has been suggested¹⁹³ that the formation of multilayer structures is determined by the changes in the packing sequence of the oxygen layers. On dissolution in zirconium, oxygen occupies the octahedral interlayer cavities in the face-centred cubic packing. The ZrO_x structure is characterised by an order in the packing of layers of the type ABC ABC..., whilst ZrO_y is characterised by a packing order of the type AB AB.... With increase in the oxygen concentration in zirconium oxide, the sequence in which the number of layers in the polytypes varies is as follows: 3R → 8H → 5H → 12R → 7H → 10H → 9R → 12H → 14H → 2H.

The formation of a set of incommensurate long-period structures in the $\text{ZrO}_2\text{--ZrN}$ system in the region with a high ZrO content (the ZrN content was 2.5 mol.% and more) has been established by electron microscope studies.¹⁹⁴ Similar polytypes have been observed in this system also in another study.¹⁹⁵ It has been suggested¹⁹⁴ that the long-period structures are microstructures produced by the intergrowth of the layers of the basic structure (cubic ZrO_2) and the segregations of the rhombohedral oxynitride $\text{Zr}_7\text{O}_{11}\text{N}_2$, *i.e.* they differ in their phase compositions.

There are data on the formation of multilayer structures in titanium, vanadium, niobium,¹⁹⁶ manganese, and silicon² oxides. In the last case, they are formed on the basis of a polymorphic modification of tridymite. SiO_2 polytypes such as 2H, 4H, 10H, and 20H have been identified.

Multilayer structures have been observed in the orthorhombic aluminium-enriched mullite. The results of studies by high-resolution electron microscopy led to the conclusion¹⁹⁷ that such structures are formed as a result of the ordering of oxygen vacancies. The latter form cavity channels (giving rise to antiphase boundaries) along the *b* axis, the periodic alternation of which actually promotes the formation of multilayer structures. Computer modelling of the structural transitions in mullite with participation of oxygen vacancies confirmed the proposed model of the formation of such structures. It was concluded that the structure formation processes depend on the excess of aluminium.

Polytypism is characteristic also of β -alumina.¹⁹⁸ Two basic forms of alumina, β' and β'' , having the compositions $\text{NaAl}_{11}\text{O}_{17}$ and $\text{Na}_{5/3}\text{Mg}_{2/3}\text{Al}_{21/3}\text{O}_{17}$ respectively, are considered nowadays as the 2H and 3R structures. The formation of two polytypes based on the β'' -form has been observed — 15R and 30R. The polytypes in β'' -alumina differ in the number and regularity of the repetition of oxygen layers of two types. In the first, the oxygen is present at the octahedral and tetrahedral sites, whilst in the second it is present at sites with cubic close packing. The layers of the latter type are conducting. On the basis of the structure of the polytypes, Bovin and Keeffe¹⁹⁸ proposed a new way of designating them: they suggested that the figure corresponding to the number of cationic layers between the conducting layers be enclosed in brackets and added to the usual Ramsdell designation, for example 2H(5), 3R(5), 15R(5), and 30R(5). On decrease in the sodium content in β - Al_2O_3 , the β''' - and β'''' -structures are formed. The number of cationic layers in the structure of the polytypes then increases. The polytypic forms of β''' - Al_2O_3 are designated correspondingly as 2H(7), while those of β'''' - Al_2O_3 are designated as 3R(7).

The polytypism in BaMnO_{3-x} is associated with change in the oxygen concentration. The change in the polytypic composition of this compound on heating has been investigated in the range 1000–1600 °C as a function of the partial pressure of the oxygen in the surrounding medium ranging from 2×10^{-4} to 2×10^{-1} N m⁻¹.¹⁹⁹ In the range of pressures from 2×10^{-1} to 3×10^{-2} N m⁻² with *x* varying from 0 to 0.3, the following polytypes are present in the composition: 15H, 8H, 6H, 10H, and 4H. On increase in *x* from 0 to 0.3 in the temperature range from 1000 to 1600 °C, the following series of polytypes are formed: 2H → 15H → 15H + 8H → 8H + 15R → 8H → 6H → 10H → 4H. For *x* > 0.3, the 4H structure is formed predominantly.

Two polytypic forms are known for SrMnO_3 — α (4H) and β (3C); the perovskite structure is characteristic of the composition SrMnO_{3-x} ²⁰⁰ (in contrast to BaMnO_{3-x} the basic structure of which is 2H).¹⁹⁹

The 4H, 6H, 14H, and 27R polytypes have been identified in barium chromite BaCrO_3 . A model of the structure of the 6H polytype has been proposed.²⁰¹ It is based on the hypothesis of the periodic formation in the basic structure of close-packed BaO_3 layers containing tetravalent chromium atoms in all the octahedral cavities of the oxygen sublattice.

b. Copper-containing metal oxides

Polytypism is characteristic also of layered copper–oxygen compounds belonging to the group of metal oxide superconducting substances. Such compounds are also referred to as cuprates. The available data on polytype formation in substances of this class have been obtained mainly in the study of compounds formed in the following systems: Y–Ba–Cu–O, Bi–Sr(Pb)–Ca–Cu–O, Tl–Ba–Ca–Cu–O, and Hg–Ba–Ca–Cu–O. The polytypes in these substances are regarded as individual phases because they differ in composition. The polytypes are designated by a sequence of figures reflecting the quantitative content of metal atoms in the formula unit, for example $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ is designated by 123, $\text{YBa}_2\text{Cu}_5\text{O}$ by 125, and $\text{BiSr}_2\text{CaCu}_2\text{O}_8$ by 1212.

A common feature of the formation of polytypes in superconducting materials is a tendency towards syntaxy, *i.e.* the formation in individual crystals of a mixture of polytypes (Y–Ba–Cu–O, Bi–Sr–Ca–Cu–O,^{202,203} Hg–Ba–Ca–Cu–O^{204,205}). It has been shown in relation to compounds formed in the Hg–Ba–Ca–Cu–O system that the intergrowth of polytypes in crystals takes place along the same planes, *i.e.* is consistently crystallographically oriented.

The following information is available about the nature of the polytypism in metal oxide superconducting materials. According to Ramesh *et al.*,²⁰⁶ the formation of polytypes is associated with a change in the composition of perovskite blocks. In polytypes of the Y–Ba–Cu–O system, the composition may vary when additional planes, for example Cu–O, are incorporated into the basic structure. These may also be CuO–YO–CuO layers.^{207,208} The results of an electron microscope study of the structure of polytypes have shown²⁰⁹ that such layers are usually segregated in the vicinity of the Cu–O layers existing in the initial structure. The Cu–O layers are displaced relative to one another by 1/2 of the period *b* of the initial tetragonal structure. The number and relative disposition of the Cu–O planes in polytypes vary. This is responsible for the different contents of the quasi-perovskite blocks (*i.e.* the elementary layers bounded by the Cu–O and Cu–O₂ planes) and hence also for the number of layers.²¹⁰ The additional Cu–O layers in the phases of the Y–Ba–Cu–O system have been considered²¹¹ as packing defects. The regular introduction of such layers into the 123 structure (after each Cu–O layer present in the initial phase) promotes the formation of the 248 phase.

According to Alekseevskii *et al.*,^{212,213} the formation of polytypes in superconducting cuprates is determined by the characteristic features of the coupling of the perovskite blocks as elementary constituents of the structure. Two ways of joining such blocks have been proposed. These lead to the formation of polytypes and superstructures.

The principal characteristics of the commonest polytypes in the Y–Ba–Cu–O system have been surveyed²¹⁰ (Table 9). According to the data of Kozo and Wei,²¹⁴ the replacement of Y by Ln in this system leads to a new series of polytypes as individual phases: $\text{LnBa}_2\text{Cu}_3\text{O}_{7-x}$ — Ln123, $\text{Ln}_2\text{BaCuO}_5$ — Ln211, $\text{LnBa}_6\text{Cu}_3\text{O}$ — Ln163, and $\text{LnBa}_4\text{Cu}_3\text{O}$ — Ln143.

The polytypic transitions in the Y–Ba–Cu–O system may also occur on heating,²¹⁵ irradiation by heavy ions,²¹⁶ deformation,²¹⁷ doping by additives such as Co, Fe, and Al,²¹⁸ the replacement of yttrium by the complexes $\text{Cu}_x\text{C}_{1-x}$, and partial replacement of Ba by Ca.²¹⁹

There are numerous publications in which questions concerning the ordering of oxygen atoms and oxygen vacancies in compounds of the Y–Ba–Cu–O system are discussed. According to Chushak *et al.*,²²⁰ the ordering of the oxygen atoms takes place in the basal planes. Ising's model has been used to describe this process.²²¹ On the basis of this model, questions concerning the formation of polytypes in SiC and spinelloids have been discussed.^{13–15} The ordering of the vacancies, accompanied by the formation of superstructures, may be not only one-dimensional but also two- and three-dimensional.²²² The formation of superstructures on the basis of the 123 phase has been reported.²²³

^a The number of elementary layers (quasi-perovskite blocks) in the cell.

^b Thickness of the elementary layer; *c*₀ = *c*/*K*. ^c Temperature of the transition to the superconducting state.

The following polytypes are known for the Bi–Sr–Ca–Cu–O system: 2201, 2212, 2223, 2234, and 2302.^{224–226} It has been suggested that the formation of polytypes in this system is influenced by Pb, which may substitute Bi,²²⁶ and also by the concentrations of Ca and Cu in the crystallisation medium. It has been shown²²⁵ that the 2201 phase, which crystallises in Bi–Sr–Ca–Cu–O glasses, is segregated only in regions depleted in Ca and Cu. The latter occurs as a result of the formation of compounds of the Ca–Cu–O system. The 2223 phase is also segregated under these conditions. The crystals formed in the system considered consist in most cases of a mixture of polytypes, mainly 2223, 2234, and 2212.²⁰³

The crystal-chemical characteristics of the phases formed in the Bi–Sr–Ca–Cu–O system have been examined in detail.²²⁴ It was concluded that the 2201 phase is stoichiometric and can be regarded as the basic structure in this system.

The most characteristic phases in the Tl–Ba–Ca–Cu–O system are 2223 and 2212.²²⁷ In the specific synthesis of the 2223 phase by the application of a high pressure, the 2234 phase is also formed.²²⁸ When Ca is replaced by other metals, new phases are formed, for example on its replacement by magnesium a series of phases may be produced — ranging from 12304 to 12034,²²⁹ while the replacement of thallium by copper results in the appearance of the 2201 phase.²³⁰

The stability of the polytypic structures in Bi- and Tl-containing cuprates were examined as a function of chemical composition²³¹ within the framework of the Ising model with multispin interaction. The compounds in these systems are represented by the homologous series $A_{2x}B_{2x}Ca_{1-x}CuO_{4x+2}$ (*A*, *B* = Bi, Sr or Tl, Ba). It has been shown that, depending on *x*₀, there may be several equilibrium phases (or ideal polytypes):

Phase	2201	2212	2223	4413	0011
<i>x</i> ₀	1	1/2	1/3	2/3	0

For slight deviations of *x* from *x*₀, such phases may be regarded as periodic polytypes containing packing defects. For arbitrary values of *x*, there is a possibility of the combination of a set of disordered phases.

The following main phases have been identified in the Hg–Ba–Ca–Cu–O system: 1212, 1223, 1234, and 1245.²³² They are formed in the synthesis of superconducting phases at both normal²²³ and high²³³ pressures. On combination of the 1212 and 1223 phases and the 1223 and 1234 phases, crystal-oriented intergrowth takes place.²⁰⁴ If Hg and Ca are replaced by Pr, *i.e.* in fact on formation of the new system (Hg, Pr)–(Sr, Ca, Pr)–Cu–O, the 1222 phase is formed together with the 1201 and 1212 phases at the normal pressure.²³⁴

c. Minerals

Polytypism has been observed in a multiplicity of minerals: wollastonite plagioclase, barium feldspar, wenkite, sapphirine;^{18,235} kaolinite, chlorite, pyrosmalite, parasite, synchisite, cronstedtite, hydrotalcite, tridymite, coquimbite;² mica-like minerals, pyrophyllite;^{236,237} ferrite;^{238–240} zirconolite;²⁴¹ spinel;² spinelloids, pyroxenes, and pyroxenoids;^{13,14,242,243} biopyrrol;²⁴⁴ nigerite;²⁴⁵ phyllosilicates;²⁴⁶ silicates containing iron layers — berthierine, glauconites, and biotites.²⁴⁷ (Unfortunately, the available information about the polytypism in minerals is nonsystematic and scattered. Therefore the principal studies in which such information is given are indicated.)

Certain hypotheses concerning the nature of the polytypism in chlorites, micas, and minerals of the kaolinite group, described by Verma and Krishna,² are based mainly on the ideas involving different ways of arranging the layers determining the symmetry and the parameters of the unit cells of multilayer structures. It has been postulated that polytypes are formed *via* the displacement of the layers relative to one another for micas, as a consequence of the periodic introduction of structural packing defects along (100) for wollastonite, and as a result of the appearance of antiphase boundaries along (001) for feldspars.

In micas and mica-like minerals (pyrophyllite, talc), the polytypism is due to the different dispositions in neighbouring layers of pairs of cations which are located along a single normal to these layers.²³⁶ The difference is determined by both the number and kind of the cations superimposed in projection on to the plane of the layer. On the basis of these ideas, the authors deduced the polytypic modifications of micas, and also determined to what extent their formation is favoured by energy factors. A smaller number of superimposed cations constitutes a criterion of their being favoured by such factors.

Polytypes such as 84R, 102R, 40H, and 138R have been identified for hexagonal ferrites.²³⁸ Ideas concerning the nature of the polytypism in such ferrites containing Ca, Ba, Pb, Sr, and K have been described.^{239,240} It has been suggested that the structure of these ferrites is made up of identical spinel type fragments, the so called *S_n* layers, which have two orientations. Layers with both identical and different orientations may be coupled in the structure of the ferrites. Connecting structural elements arise on coupling of the layers. In Ca ferrites, such elements are identical for both types of coupling of the layers, whereas in ferrites containing Ba, Pb, Sr, and K they differ in structure and composition. This factor is actually responsible for the fact that a family of polytypes are formed in Ca ferrites and only fragmentary layered structures are produced in the group of Ba and other ferrites.

The following polytypes are known for the Mg₂Al₄O₈ spinel: 4H, 5H, 6H, 15H, 15R, and 18R.² Horiuchi *et al.*²⁴⁸ established for the first time that a whole family of new structures — spinelloids — are formed on the basis of this spinel structure. In spinelloids, the packing of the oxygen atoms constituting the framework is approximately cubic; they have the ideal stoichiometry corresponding to the composition AB₂O₄. In their structure, 2/3 of the cations occupy sites with octahedral coordination with the oxygen framework; the remaining 1/3 of the cations have tetrahedral coordination. The cations distributed in the oxygen framework constitute the basic structural unit of spinelloids. In the majority of spinelloids, bands are formed on the basis of the packing of the basic structural units, which is invariant in two orthogonal directions. The variation of the arrangement of these bands in three directions actually determines the formation of the set of spinelloid structures. The polytypes in spinels (mainly in the NiAl₂O₄–Ni₂SiO₄ system) have been discussed on the basis of the ANNNI model.^{13,14,242} As already mentioned, a satisfactory agreement between the spin model of polytypism and a real system has in fact been obtained in relation to the family of spinelloid structures.

10. Sulfides

A tendency towards polytype formation has nowadays been discovered in the following sulfides: ZnS, CdS,² FeS, Fe₃S₄,^{12, 18} CuS, NbS₂, TaS₂,^{12, 249} Ti₂S₃,¹² Ti_{1+x}S₂,²⁵⁰ CrNaS₂,¹² ZnIn₂S₄, Zn₂In₂S₅, Zn₂In₂S₄, Zn₃In₂S₆,^{12, 251, 252} GaInS₃,²⁵³ PtS₂, ZrS₂,¹⁵¹ SnS₂, Ti_{1.2}S₂,²⁴⁹ GaS,²⁵⁴ and MoS₂.^{2, 18, 249} This phenomenon has been most thoroughly investigated in the first two sulfides and also in titanium sulfide.^{249, 250, 255} For the remaining sulfides, it has only been established without a detailed discussion and analysis of the characteristics of its occurrence. We shall therefore consider the most interesting data for some of the above series of sulfides.

Hitherto 155 polytypic structures have been identified in ZnS obtained under laboratory conditions; in natural ZnS, only 10 forms have been found: the sphalerite phase and five hexagonal and four rhombohedral polytypes.²⁵⁶

All kinds of polytypism characteristic of substances with the diamond lattice are manifested in ZnS (Table 1).

On heating, the ZnS polytypes are usually formed as intermediate structures in the wurtzite → sphalerite and sphalerite → wurtzite transitions. The first occurs as a rule during the cooling process after synthesis and the second during heating. An intermediate 4H phase is formed in the first transition;²⁵⁷ its appearance in combination with polytypes having a large number of layers is characteristic also of the second transition.

Overall, the polytypic composition of ZnS is influenced by soluble impurities (Cu, Al, O). Their concentration may also stabilise a particular polytype. Thus, according to the data of Kukul',²⁵⁸ the number of layers in the polytypes depends on the Al concentration in the following manner: the 6H polytype is formed mainly for 0.005 mass%, the 4H polytype for 0.04 mass%, and the 2H polytype for 0.1 mass%. With increase in the aluminium and copper content, the concentration of packing defects in ZnS diminishes. It, has been established²⁵⁹ that the decomposition of the solid solution of Cu and O in ZnS promotes the stabilisation of the 3C phase.

The transitions of the hexagonal ZnS polytypes to the 3C phase occur under various load conditions without, special heating: on grinding in a mortar,²⁶⁰ on grinding-polishing,^{261, 262} on oriented (to develop the basal slip) uniaxial loading,²⁶³ and on dynamic compression.²⁶⁴ According to Abdikamalov *et al.*,²⁶³ the conversion of the metastable hexagonal polytypes into the sphalerite phase occurs as a result of plastic displacements in the (0001) plane with the aid of partial Shockley dislocations. It is believed²⁶⁵ that the transition is achieved *via* a layer-by-layer reorientation and may be referred to as deformation recrystallisation.

According to the generally accepted view, the polytypism in ZnS is due to the regular breakdown of the packing of the basal layers as a result of the ordered introduction of packing defects along the (111) and (0001) planes for the 3C and 2H phases respectively. Overall, in the majority of cases the mechanisms of the formation of polytypes in ZnS have been considered not individually but in combination with SiC as a structural analogue. The known theories of the formation of polytypes, briefly considered above in connection with the analysis of the polytypism in SiC, are equally attributed by their authors also to ZnS.

Multilayer polytypes are also characteristic of the compounds Zn₂In₂S₄, Zn₃In₂S₆, and Zn₂In₂S₅, which are formed in the ZnS–In₂S₃ system.^{251, 252} The following structural characteristics have been discovered for such polytypes: the disposition of the indium atoms in the octahedral and tetrahedral cavities and of zinc atoms only in tetrahedral cavities; the presence of layers and packets of cationic vacancies; a marked distortion of the ideal spherical packing of the sulfur atoms. According to the data of Donina *et al.*,²⁵¹ polytypes with the same composition and with identical and different parameters *c* are manifested for the compound Zn₂In₂S₄. A different motif in the alternation of sulfur atoms is characteristic of polytypes of the latter kind.

Polytypes are also formed in the GaInS₃ system.^{253, 266} They have the composition (A,B)_{n-x}S_{n+1} (*n* > 3) and are characterised by the fact that the *n*-stacked layers, consisting of octahedral and

tetrahedral networks, are distributed among close-packed sulfur atoms.

The iron sulfide polytypes have been most thoroughly investigated in relation to pyrrhotites of natural origin (overall formula Fe_{1-x}S) obtained from different deposits.¹⁸ The polytypes of this substance usually differ in the number of iron and sulfur atoms and are considered in most cases as individual stoichiometric phases. For example, the 4C and 2C polytypes have the compositions Fe₉S₁₀ and Fe₁₁S₁₂ respectively. However, there are also polytypes with a wide region of homogeneity, *i.e.* having a non-stoichiometric composition. It has been suggested that the formation of polytypic structures and iron sulfides is associated with the ordering of the metal vacancies in the structure.

The most detailed data about polytypism in the Ti–S system have been published by Palosz²⁴⁹ and Trone and Huber.²⁵⁵ The formation of polytypes with different numbers of layers in the system depends on the temperature.²⁵⁵ The 12R, 12H, 48R, and 696R polytypes are segregated at 800 °C and the 4H, 2H, 8H, 24H, and 40H polytypes are segregated at 900 °C. The polytypes differ in composition: TiS₂ for 2H, Ti_{2+x}S₄ for 4H, and Ti₈S₁₂ for 12R. It has been suggested that the formation of polytypes is associated with the variation of the concentrations of Ti and S atoms in the layers. On this basis, schemes have been proposed for the arrangement of the atoms in the direction of the basal axis for certain polytypes.²⁵⁵

In the compound Ti_{1+x}S₂, ten polytypes with hexagonal and rhombohedral symmetries were identified.²⁵⁰ The presence of screw dislocations in the basal plane has been observed in Ti_{1.18}S₂ crystals by X-ray topography, which may serve as confirmation of the decisive role of these defects in the formation of polytypes.

Data concerning the possibility of the formation of polytypes in MoS₂ and GaS have been published.^{2, 249, 254} The polytypes in MoS₂ may be formed as a result of the alternation of layers with hexagonal and rhombohedral types of packing.²

11. Halides

Among halides tending to form polytypes, one may identify CdI₂, CdBr₂, PbI₂, and AgI; the phenomenon of polytypism has been most thoroughly investigated in these substances.^{2, 249} Polytypes have been observed also in the following halides:¹⁵¹ Mg, Mn, Fe, and Co dibromides and Ti, V, Mn, Fe, Zn, and Co diiodides.

Cadmium and lead dihalides are isostructural. Octahedral coordination of the metal ions is characteristic of these compounds. The 4H, 2H, and 6R (especially 4H) polytypes are most common. Other polytypes have been specified.^{2, 249, 267} The largest number of polytypes (109) have been found for CdI₂.²⁶⁸ It has been suggested that the polytypism in the halides considered is associated with the ordered introduction of structural packing defects.

The following series of polytypes have been identified in AgI: 2H, 4H, 8H, 12H, and 16H.²⁶⁹ The absence of multilayer structures with rhombohedral symmetry as well as the widest occurrence of the 4H polytype should be included among the characteristic features of the formation of polytypes in this substance.²

12. Selenides and tellurides

Polytypism is characteristic of the following substances in the group of selenides: InSe,^{12, 254} GaSe,^{254, 270} CdSe,²⁷¹ ZnSe,²⁷² SnSe,²⁴⁹ TaSe₂, NbSe₂, Bi₂Se₃, In₂Se₃, and Pb₂Bi₂Se₅.¹² Few data are available on the formation of polytypes in these substances. The 24H polytype has been identified by X-ray diffraction in the CdSe crystals obtained from the gas phase.²⁷¹ According to the data of Ollitrault-fichet *et al.*,²⁷⁰ the following series of polytypes have been observed in GaSe: 4H, 9R, 12R, and 15R. The 2H, 4H, and 3R polytypes are known for TaSe while the 2H,²¹⁰ and 4H (see Ref. 2) polytypes are known for NbSe₂.

Polytypes are also known in the group of tellurides: CdTe, ZnTe,²⁷³ In₃Te₄, Se₂Te₃, and Ge₂Te₃.¹² The 15R and 2H poly-

types have been identified in ZnTe crystals grown from the gas phase; the 12H polytype, contained in the 3C phase, has been found in CdTe crystals obtained under analogous conditions.

Among the gallium compounds, polytypism has been observed in GaSe,²⁵⁴ GaP,²⁷⁴ and GaAs.²⁷⁵ The 6H polytype has been identified in the last compound.

III. Practical aspects of polytypism

The influence of polytypism on the properties of nonmetallic crystalline materials has been little studied. We shall consider this problem in relation to several materials.

Various SiC polytypes (mainly 3C, 6H, 4H, 15R, 8H, and 10H) are distinguished by the following properties: the width of the forbidden band; the width of the exciton forbidden band; the effective mass of free electrons; the Hall mobility of electrons; electrical conductivity; luminescence; the energy of phonons; ionisation energy; relative permittivity; the minimum in the conductivity band both as regards position and energy.^{2, 6, 38, 39, 276–279} Other properties of the polytypes also differ.^{280, 281}

The differences in the electrophysical properties of the SiC polytypes make it possible to regard them as a family of wide-band semiconducting materials; However, owing to the difficulty of growing crystals and films with a specified polytypic composition, only the 6H polytype of silicon carbide is used nowadays as a semiconducting material.²⁷⁹

By regulating the polytypic transitions in SiC (3C → 6H, 3C → 4H, 6H → 4H), it is possible to control the subgranular and granular structures in polycrystalline materials. Such transitions promote the formation of a one-dimensional microplastic substructure in the grains, the development of anomalous recrystallisation leading to the formation of self-reinforced materials, and the occurrence of collective recrystallisation of the 'grain to grain type'. Questions concerning the formation of self-reinforced SiC materials of different types have been examined.^{87, 282} It has been shown that the addition of boron, aluminium, and their compounds, which activate the 3C → 4H and 6H → 4H transitions, is effective for the preparation of such materials. The self-reinforced SiC materials are very strong and are distinguished by chemical and structural stability at elevated temperature (> 1300 °C). The latter is determined by the presence of reinforcing grains in the form of plates bounded by basal surfaces; the shape factor for such grains may amount to 10–20. It follows from the data quoted by the present author⁸⁷ that the bending strength of the self-reinforced materials may reach 1000 MPa and may change insignificantly with increase in temperature up to 1500 °C.

The formation of polytypes in aluminium nitride has the opposite effect on properties such as thermal conductivity and strength. With increase in the number of multilayer polytypes in the AlN + Al₂O₃ and AlN + SiO₂ the polycrystalline materials, the thermal conductivity diminishes.^{283, 284} This is induced mainly by the increase in the length of the interfaces between different structural states in the material as a result of the segregation of polytype interlayers within the grains or of grains consisting of multilayer polytypes. The formation of polytypes in AlN, like that in SiC, promotes the formation of self-reinforced materials. The mechanism of the formation of such materials has been examined in detail.⁸⁵ It is possible to obtain three types of microstructure of the self-reinforced AlN. Such microstructures may be made up, firstly, of grains reinforced by interlayers, comprising polytypes in the form of plates. Secondly, they can be produced by the combination of grains with interlayers and fragments of individual grains in a lamellar form; thirdly, they can consist predominantly of lamellar grains. The microstructure of the second type is the most characteristic (Fig. 15). Our studies established that three types of grains and six varieties of interfaces can be distinguished in a material with such microstructure.²⁸⁵ The nature of the differences between the grains is fully determined

by the presence of the AlN polytypes in the material. All the varieties of grains and interfaces are noted in the scheme in Fig. 15 and their most typical combinations and morphological characteristics are also shown.

The formation of self-reinforced AlN materials, due to deformation of polytypes as in the case of SiC, is a positive factor. Such materials are distinguished by improved strength properties at both normal and elevated temperatures. Data indicating the strengthening of the AlN materials obtained under the conditions of polytype formation with oxygen-containing additives such as TiO₂, MoSi₂, TiC, and TiN (in the last three compounds, the

Figure 15. Schematic illustration of the microstructure of a self-reinforced AlN material characterised by the presence of three types of grains and six varieties of internal interfaces. Grain composition: G-I — 2H AlN–O solid solution; G-II — 2H–AlN matrix combined with a plate made up of MP; G-III — individual MP grains; I-1, I-2, I-5, I-6 — intergranular interfaces; I-3, I-4 — intragranular interfaces.

oxygen is present as an impurity) have been published.²⁸⁶ The results presented by the present author⁸⁷ indicate that self-reinforced AlN materials retain their strength up to 1500–1600 °C. Consequently such materials may be used also at high temperatures.

On the basis of the ideas concerning the formation of polytypes in AlN developed by Oleinik and Shevchenko¹⁴² and the analysis of a large number of literature data on this process in AlN materials, it is possible to formulate the physicochemical principles governing the selection of additives to AlN in order to obtain constructional and heat conducting materials. These principles take into account two evident factors. Firstly, in virtually all AlN powders obtained by different methods there is bound oxygen on the surface (aluminium oxides, hydroxides, or oxynitride).²⁸⁷ Secondly, the formation of polytypes as a necessary stage in the structural preparation for the production of a self-reinforced material occurs under conditions involving the formation of the 2H AlNO solid solution, which is stable up to 1700 °C and is formed with the appearance of vacancies in the aluminium sublattice.

Since the vacancies promote a decrease in the thermal conductivity of AlN,²⁸⁸ it is necessary to refine AlN with respect to oxygen or to neutralise the vacancies in order to obtain materials for heat-conducting purposes. The preparation of materials involving the formation of AlN polytypes requires the use as additives of either oxides which do not form stable compounds with Al₂O₃ up to 1700 °C and the dissolution of the cations of which in AlN does not promote charge compensation in the lattice on substitution of nitrogen by oxygen or nonoxide compounds (these are a source of oxygen as an accompanying impurity) which do not form stable compounds with oxygen up to 1700 °C and the dissolution of which in AlN does not promote charge compensation in the lattice on substitution of nitrogen by oxygen.

The following approaches have to be used in order to create materials for heat-conducting purposes.

Firstly, it is necessary to use as additives oxides which form stable compounds with Al_2O_3 up to 1700°C and their stability is higher than that of the 2H AlNO solid solution at $T > 1700^\circ\text{C}$ (Y_2O_3 and CaO are the most effective) and oxides which do not interact with Al_2O_3 and the joint dissolution of the cations and anions of which ensures the charge compensation of the AlN lattice (a typical example of such an additive is BeO).

Secondly, it is necessary to sinter the materials at high pressures and temperatures. Since the formation of vacancies is difficult at high pressures, the 2H AlNO solid solution is not formed. The oxygen contained in the initial AlN powder is bound as Al_2O_3 , which is segregated as disperse particles along the grain boundaries in the sintered material.¹³² Data concerning the formation of a AlN material with a thermal conductivity up to $185\text{ W m}^{-1}\text{ K}^{-1}$ ²⁸⁹ constitute convincing confirmation of this. Our investigations established²⁹⁰ that preliminary treatment of the initial powder in shock waves promotes the refining of AlN on subsequent sintering *via* the formation of oxygen-containing disperse segregations in the grain boundaries.

The polytypes of copper-containing metal oxide compounds (cuprates) are distinguished by the temperature of the transition to the superconducting state (T_c). This is caused by their different contents of conducting copper-containing layers. As an example, one may point to data on T_c obtained²⁹¹ for certain polytypes of the $\text{Bi}_2\text{Sr}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4}$ homologous series (n is the number of CuO_2 layers). The 2201 ($n = 1$), 2212 ($n = 2$), and 2223 ($n = 3$) phases have $T_c = 7, 80$, and 110 K respectively. It has been shown by means of model calculations that T in phases with $n > 4$ may reach 142 K .

The relation between c_0 and T_c has been discovered (Table 9).²¹⁰

Another group of substances which tend to form polytypes and in which this phenomenon has a useful application are the carbides and nitrides of the type of interstitial phases. The conversion of the structure of these phases into a microdomain form, associated with the formation of multilayer structures, is known to strengthen the phases. The degree of strengthening is then determined by the size (the thickness of the cross-section) of the domains, which may be regulated by altering the rate of cooling.²⁹²

IV. Conclusion

The data described permit several general and specific (referring to particular groups of substances) conclusions about the formation of polytypes in nonmetallic materials.

Polytypes are formed both at normal and high temperatures and pressures. Their formation reaction occurs in substances in the form of powders, films (single-crystal and polycrystalline), isolated single crystals, and compact polycrystalline materials; the reaction is characteristic of substances with different energies of the packing defect (from $5.4 \pm 1.8\text{ mJ m}^{-2}$ for ZnS to $279 \pm 41\text{ mJ m}^{-2}$ for diamond),²⁹³ different types of crystal lattice, and different types of chemical bonds; it can occur both during the growth of the crystals and films and on treatments of different kinds (heating, doping, deformation, irradiation, *etc.*).

Polytypic transitions may be of two kinds depending on the nature of their development: intracrystallite and intercrystallite. The intragranular formation of polytypes is associated with the periodic formation of planar defects of different types in the basic structure.

For example, such defects in SiC, ZnS, CdS, CdI_2 , CdBr_2 , PbI_2 , Si, C (graphite, 2H), BN (graphite-like), and wollastonite are structural packing defects; for B_4C , BN (3C), C (3C), and M_7C_3 ($\text{M} = \text{Fe, Cr}$), these are microtwinning crystals; for mullite and barium feldspar, these are antiphase boundaries; for FeS and $\text{Zn}_3\text{In}_2\text{S}_6$, they are layers of ordered vacancies; for Group IV–VI transition metal carbides and MoS_2 , they are layers with face-

centred cubic or hexagonal close packing; for BeO, BeSiN_2 , ZrO_2 , AlN, and $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$, they are layers of other phases. Defects consisting of layers differing from the basic structure by the elemental composition and packing of atoms ($\beta\text{-Al}_2\text{O}_3$), the disposition of cations in adjoining layers (micas, talc), the motif in the alternation of like layers ($\text{Zn}_2\text{In}_2\text{S}_4$), the number of constituent like atoms (compounds in the Ti–S system), the coordination number of like atoms (BaCrO_3), and the arrangement of basic structural units (spinelloids, zirconolite) are characteristic of certain ceramics; planar defects in the arrangement of chains of SiO_2 tetrahedra are typical for hexagonal ferrites and biopyrrol.

The presence of defects such as the elements of the structures of polytypes in many substances (for example, SiC, AlN, BeSiN_2 , and BN) has been confirmed experimentally and in many instances their formation has been postulated on the basis of crystal-chemical and substructural characteristics of substances. Intergranular polytypic transitions have now been discovered only for substances with diamond-like lattices (SiC, AlN, BN). They are due to diffusion and occur in the following cases: (a) on migration of the boundary between grains made up of different polytypes (SiC, AlN — Fig. 3); the development of such transitions is always preceded by intragranular crystal-oriented phase and (or) polytypic transformations;⁸⁶ (b) under the conditions of recrystallisation *via* a liquid phase (deposition of 6H SiC layers on a 6H SiC support on recrystallisation of the 3C phase *via* eutectic melts of metals);²⁹⁴ (c) on recrystallisation *via* the gas phase (sublimation growth of crystals and films).²⁷⁹

In many substances, the polytypes differ in composition, *i.e.* they actually constitute a set of stoichiometric phases. The most typical representatives of such substances are AlN, BeO, BeSiN_2 , ZrO_2 , superconducting ceramics, and compounds in the Ti–S, Fe–S, *etc.* systems.

In the group of diamond-like phases, the energy of the packing defects exerts an appreciable influence on the type of planar defects in the basic lattice, *i.e.* on the block coupling boundaries consisting of layers with identical packing of the atoms.

In the case of low energy of the structural packing defects, the formation of polytypes is determined by this type of planar defects regardless of the formation conditions. SiC and ZnS, in which all kinds of polytypism occur (growth, deformation, and concentration polytypism), may serve as a typical example.

In substances with a diamond-like structure, a high fraction of ionic bonding, and a high packing defect energy (AlN, BeO, BeSiN_2), a special type of concentration polytypism occurs as a result of the regular segregation of two-dimensional layers of the second phase in the basic layers of the 2H structure. Different polytypes in substances of this group may be represented by a consecutive series of ordered stoichiometric phases corresponding to a definite ratio M/X.

The formation of multilayer polytypes based on cubic phases on carbon and BN at high temperatures and pressures indicates the possibility of the transition of these phases to dense hexagonal ones, *i.e.* lonsdaleite and 2H BN respectively. This can be accounted for as follows: In polytype formation processes in diamond and 3C BN in the region of their thermodynamic stability, a decisive influence on the development of this process is exerted not by the chemical driving force (it is the driving force of the phase transition) but by the stresses arising under the influence of an external load. The latter is due to the fact that the geometry of the plastic displacements, inevitably arising on deformation in the cubic phases of diamond and BN, coincides with the slip geometry inducing the deformation rearrangements of these phases to dense hexagonal phases.

The formation of polytypes during growth and the polytypic transitions on treatment (heating, doping, deformation) in the bulk of nonmetallic crystals are processes involving a relaxation structural rearrangement, which takes place *via* the regular formation of planar defects of different nature in the crystal lattice. Such defects are produced mainly in only one crystallo-

graphic direction. This is responsible for the regular modulation of the lattice parameter of the basic structure and for the formation of a new structure from it and modulating defects. The nature of the planar defects is determined by the crystal geometry of the lattice of the substance, which determines the energetically favourable structural relaxation mechanism. The minimum lattice energy increment following the introduction of defects is determined by three factors: the nature of the defects, the mechanism of their coupling with the basic (matrix) structure, and the nature of the distribution of defects determining the minimisation energy of their interaction (elastic, electronic, phonon, etc.).

Intercrystallite polytypic transitions may occur for diamond-like phases (SiC, AlN, BN). Their development is determined by the orienting effect of the force field of the crystal-support lattice. In this case, we have only the inheritance of the packing order of the atoms of the polytype-support in the layer formed on the support as a result of the recrystallisation of another polytype *via* the solid, liquid, and gas phases.

It appears that at the present time there are grounds for classifying polytypism as the fourth kind of fundamental structural rearrangement (together with the three classical kinds — plastic deformation, polymorphic transformation, and recrystallisation). Like the known types of rearrangements indicated above, polytypes may be formed not *via* one but *via* several structural mechanisms of the transformations.

Ion exchange on inorganic sorbents

A B Yaroslavtsev

Contents

I. Introduction	579
II. Thermodynamics of ion exchange	579
III. Kinetics of ion exchange	582
IV. The main types of inorganic ion-exchange substances	584
V. Conclusion	593

Abstract. The principal features of the thermodynamics and kinetics of ion-exchange processes in inorganic ion exchangers are discussed. The literature data on the ion-exchange properties of oxide systems, globular hydrates, and salts of polyvalent cations are surveyed. The methods for carrying out ion-exchange processes and the characteristic features of their occurrence on typical inorganic ion-exchange materials are examined. The bibliography includes 306 references.

I. Introduction

Ion exchange on inorganic substances is characteristic of many natural and industrial processes. Even before the demonstration of the existence of ions as such, it was observed that treatment of soil specimens with solutions of ammonium salts entailed the reversible formation of calcium salts.^{1,2} It was established that this is due to the presence of a series of clay minerals in soil. The first synthetic ion-exchange materials were later obtained — amorphous sodium aluminosilicates, which were used successfully to reduce the hardness of water.³ Amorphous and crystalline substances of this type, called zeolites, were for a long time the main objects for the study of ion-exchange processes. A significant disadvantage of zeolites proved to be their low stability in experiments in highly acid and alkaline solutions. This stimulated chemists to seek new materials with analogous properties. Synthetic ion exchangers on a polymer matrix — ion-exchange resins⁴ — rapidly displaced the inorganic analogues.

The revival of interest in inorganic sorbents began in the early 1960s. This was associated with the fact that ion exchangers with a fairly high thermal stability and resistance to ionising radiation were needed for many branches of industry; furthermore, an extremely high partition coefficient was observed in certain inorganic sorbents even for alkaline earth metal cations, which are comparatively difficult to separate. After the synthesis by Clearfield and Stynes⁵ of the cryptocrystalline acid zirconium phosphate, which is now one of the most familiar inorganic ion exchangers, the stream of studies devoted to ion exchange on inorganic materials increased significantly. Crystalline zirconium

phosphate is distinguished by a higher stability, compared with amorphous specimens, and a higher sorption capacity compared with zeolites. By employing it, it is possible to observe the structural changes in the substance in the course of the exchange. The latter stimulated a series of purely theoretical investigations.

However, one should note that there have been comparatively few review publications on the study of inorganic ion exchangers. Among these, one may point to Amphlett's monograph,⁶ a book edited by Clearfield,⁷ as well as the review by the latter,⁸ devoted mainly to the description of the properties of various classes of ion-exchange substances. The remaining publications are more specific. The aim of the present review is a survey of the thermodynamic and kinetic ideas about ion exchange on inorganic matrices and also the use of these data for the analysis of the properties of various compounds, results that have not so far entered into review publications being emphasised.

II. Thermodynamics of ion exchange

When substances containing groups of $\equiv\text{E}-\text{O}-\text{H}$ fragments accessible to the exchange of H^+ and OH^- come into contact with an aqueous solution, an equilibrium that is determined by the occurrence of the following reactions is established in the system:

where E is a polyvalent element.

As a result, the entire volume of the substance or a proportion of it acquires a negative or positive charge and sorption from a solution of cations or anions becomes possible:

The tendency of a substance to manifest cation- or anion-exchange properties is determined primarily by the acidity of the $\equiv\text{E}-\text{O}-\text{H}$ groups. Zirconium hydrogenphosphate $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ is known to contain O_3POH groups the proton-accepting capacity of which is reduced as a result of their coordination to a cation with an appreciable polarising capacity. These groups tend to dissociate only *via* reaction (1) and the compound exhibits only cation-exchange properties.^{8,9} The hydroxyapatites $[\text{Ca}_x(\text{PO}_4)_y(\text{OH})_{2x-3y}]$ and the hydrogelcites having the compositions

$[M_3^{II}M^{III}(OH)_8]^+x_{1/z}^-$, or $[M_2^{II}M^{III}(OH)_6]^+x_{1/z}^-$,¹⁰ as well as certain complex oxides¹¹ dissociate in accordance with reaction (2) and these substances therefore exhibit anion-exchange properties. Finally, both types of dissociation are characteristic of a series of compounds. This applies in the first place to the large class of hydrated oxides of Group III and IV elements such as aluminium, gallium, tin, and zirconium. The degree of conversion for reactions (1)–(4) and the ion-exchange capacities themselves of these compounds depend significantly on the method of synthesis of the latter and the acidity of the medium. Analysis of the dependence of the ion-exchange capacities of hydrated oxides on the pH of the medium, presented in Fig. 1, shows that the position of the equivalence point for the series of zirconium, tin, and silicon oxides diminishes from ~7 to ~6 and ~2 in strict correspondence with the decrease in the basicities of these compounds; the exchange of anions is altogether not characteristic of $HSbO_3 \cdot H_2O$. Since inorganic sorbents are distinguished by a high selectivity, the position of the equivalence point depends also on the nature of the sorbed ions.

Figure 1. Dependence of the sorption exchange capacities (SEC) of the hydrated oxides of antimony (1), silicon (2, 3), tin (4, 3), and zirconium (6, 7) on the pH of the medium in the sorption of sodium (1, 2, 4, 6) and chloride (3, 5, 7) ions. The figure has been constructed on the basis of data from Kraus *et al.*¹² and Ahrlund *et al.*¹³

It is noteworthy that, among the inorganic materials used as ion exchangers, cation exchangers are more common than anion exchangers. Anions have larger radii and this creates steric hindrance to their insertion into the bulk of the specimen. Furthermore, for the manifestation of anion-exchange activity by a substance, the latter must contain hydroxy-groups and must be able to substitute them by anions. However, the salts of polyvalent elements the OH groups of which more often possess distinctly acid properties show a greater tendency to sorb cations. In view of this, the thermodynamic features of ion exchange will henceforth be considered in relation to cations.

For reaction (3), which proceeds *via* a stage involving the formation of the solid solutions $xR-O-A_{1/z} \cdot yR-O-H$, the thermodynamic equilibrium constant may be represented by the expression

$$K_a = \frac{a(H_3O^+)_{\text{soln}} a(A^{z+})_s}{a(H_3O^+)_s^z a(A^{z+})_{\text{soln}}}, \quad (5)$$

where a are the activities of the corresponding cations in solution (soln) and in the solid phase (s). By expressing the activity as the product of the concentration (c) and the activity coefficient (γ), we obtain

$$K_a = \frac{c(H_3O^+)_{\text{soln}}^z \gamma(H_3O^+)_{\text{soln}}^z c(A^{z+})_s \gamma(A^{z+})_s}{c(H_3O^+)_s^z \gamma(H_3O^+)_s^z c(A^{z+})_{\text{soln}} \gamma(A^{z+})_{\text{soln}}}, \quad (6)$$

or, for the concentration equilibrium constant, we have

$$K_c = \frac{[H_3O^+]_{\text{soln}}^z [A^{z+}]_s}{[H_3O^+]_s^z [A^{z+}]_{\text{soln}}} = \frac{K_a \gamma(H_3O^+)_{\text{soln}}^z \gamma(A^{z+})_{\text{soln}}}{\gamma(H_3O^+)_s^z \gamma(A^{z+})_s}. \quad (7)$$

A certain complication arises because the activity coefficients of the cations in the solid phase are difficult to estimate. On the other hand, in order to determine the thermodynamic functions of the exchange reactions it is necessary to know the thermodynamic equilibrium constant. Gaines and Thomas¹⁴ proposed the following procedure for this purpose. The so-called 'mixed' equilibrium constant

$$K_{ac} = \frac{a(H_3O^+)_{\text{soln}}^z N(A^+)_{\text{s}}}{N(H_3O^+)_s^z a(A^+)_{\text{soln}}}, \quad (8)$$

where N is the mole fraction of the corresponding cation in the solid phase, is calculated initially. The thermodynamic constant is found from the relation

$$\ln K_a = \int_0^1 \ln K_{ac} dN(A^+)_{\text{s}} \quad (9)$$

It is noteworthy that the equilibrium exchange constant is usually not a constant quantity as a consequence of the change in the entropy of the system on contamination of the cationic sublattice of the initial substance or the product by microamounts of an impurity in the initial and concluding stages of the exchange reaction.^{15–18}

Furthermore, in layered compounds the interplanar spacing and the size of the coordination polyhedra itself vary in the course of the exchange from values typical for the ion to be substituted to those characteristic of the incoming ion. The enthalpy and Gibbs free energy of exchange therefore decrease, while the equilibrium constant increases somewhat as the process proceeds (Fig. 2).

In many inorganic ion-exchange substances, the exchange proceeds in a two-phase region — the region corresponding to the existence of the substituted and unsubstituted forms. The process then takes place as a result of the displacement of the interface between these phases for a virtually unchanged composition of the latter. The formation of two phases during exchange on layered acid phosphates of tetravalent elements [α -Ti(HPO₄)₂ and α -M^ITiH(PO₄)₂ or α -M^ITiH(PO₄)₂ and α -M^ITi(PO₄)₂] may

Note. All the thermodynamic parameters were calculated for substitution of one mole of cations. ^a Amorphous.

serve as a typical example. The procedure for the determination of the thermodynamic parameters of the exchange described above is therefore inapplicable for compounds of this kind, but it has been used nevertheless in a large number of studies. Since the activities of the incoming cations A^{z+} and of the hydrogen in the solid phase remain constant, the equilibrium constant should be expressed by the relation¹⁸

$$K_a = \frac{a(H_3O^+)_{\text{soln}}}{a(A^{z+})_{\text{soln}}} = \frac{[H_3O^+]_{\text{soln}} \gamma(H_3O^+)_{\text{soln}}}{[A^{z+}]_{\text{soln}} \gamma(A^{z+})_{\text{soln}}} = \frac{K_c \gamma(H_3O^+)_{\text{soln}}}{\gamma(A^{z+})_{\text{soln}}} \quad (10)$$

The error due to the calculation of the equilibrium constant using Eqns (6) and (7), which are erroneous for the given process, is to a large extent abolished on further mathematical treatment with the aid of Eqn (9). For this reason, the values of K_a and of the free energy of exchange obtained with the aid of this procedure may approach the true values.

There are several standard approaches to the description of the ion-exchange equilibrium. A number of workers have investigated the equilibrium after adding a definite amount of a salt to the ion exchanger in the hydrogen-form (hydroxo-form) and the reaction is frequently carried out with microamounts of a salt, which makes it possible to describe the equilibrium only in the initial stages of the exchange process. The most promising method involves the study of the curves for the titration of cation exchangers with alkali in the presence of a salt of the corresponding metal. The process then reduces to the neutralisation of the acid produced. This makes it possible to carry out experiments only in acid and weakly alkaline media and to reduce to a minimum the effect of hydrolysis even for readily hydrolysable compounds such as, for example, tantalum hydrogenphosphate.¹⁷ In order that the exchange of ions occurs *via* the stage involving the formation of solid solutions, the concentration of hydrogen ions $[H^+]$ should vary in proportion to the mole fraction of the protons in the solid phase [in accordance with Eqn (8)]. For layered hydrogenphosphates of polyvalent elements, the equilibrium involving solid phases with different degrees of substitution should seemingly lead to a constant overall concentration of protons and metal cations.⁶ However, when alkali is added, the concentration diminishes somewhat owing to the neutralisation reaction. For this reason, the titration curve is skewed for all the processes described in the literature.^{19, 20}

Certain values of the thermodynamic parameters for exchange reactions on inorganic sorbents are presented in Table 1. It is noteworthy that the significant discrepancies between the parameters for the sorption of alkali metal cations on amorphous zirconium phosphate are due to the difference between the methods used to determine the required quantities and the methods for the preparation of the sorbents (in the course of their preparation, the ratio P/Zr varied from 1.2 to 1.9). Whereas for a high degree of reaction the equilibrium constant depends on the properties of the equilibrium phases, for a low degree of reaction it depends only on the nature of the active groups on the surface. Furthermore, for an equilibrium process there should be a possibility of attaining the final state from both the starting materials and from the final products. On the other hand, in the case of layered hydrogenphosphates of tetravalent elements, the reverse exchange frequently leads to the formation of compounds with a degree of hydration exceeding that for the initial substance and hence to a change in the equilibrium constant. Some investigators therefore do not believe at all that it is legitimate to employ the term 'equilibrium constant' for such quantities.

We shall now consider the factors that influence the thermodynamic parameters of ion exchange processes described by reaction (3). In the transfer of a cation A^{z+} with a radius R_A from a dilute solution to a singly charged ion-exchange group with a radius R_X , the electrostatic interaction energy

$$\Delta G = \frac{-z_A e^2}{R_A + R_X}, \quad (11)$$

is liberated and the hydration energy E_A is consumed. The change in energy on desorption of the cation B can be described similarly:

$$\Delta G = e^2 \left(\frac{z_B}{R_B + R_X} - \frac{z_A}{R_A + R_X} \right) + E_A - E_B. \quad (12)$$

Using this relation, Eisenman⁴⁰ has calculated series of the variation of the affinity of alkali metal cations for the sorbent as a function of R_X .

The relations presented 'work well' in the case of biological systems and ion-exchange resins on a polymer matrix. On the other hand, for inorganic sorbents their use is limited. This is due primarily to the fact that the concentration of the groups with the affinity for cations in such sorbents is high and the coordination sphere of the A^{z+} ion with a fixed distance between the ionogenic groups is formed in the ion exchanger matrix. The energy of the interaction of the cation with the ion exchanger matrix is found to be initially specified fully or partially (if a displacement of the cation in the coordination polyhedron is possible). It follows from simple geometrical calculations that, when the cation A^{z+} is localised at the centre of an octahedron made up of oxygen atoms in the interlayer space in the layered phosphates $A_X Y(PO_4)_2$ ($Y = \text{Ti, Zr, Hf, Sn, Pb, Sb, Ta}$), the distance $A-O$ may vary from 4.8–5.2 Å in the absence of distortion to 2.8–3.0 Å for the unlikely limiting model of a planar hexagon when the octahedron is compressed along the threefold axis. Evidently, the cavity formed is large for any cation. The affinity of the matrix for the alkali metal cation therefore increases with increase in the heat of hydration, *i.e.* with increase in the radius of the given cation. This can explain the increase in the selectivity of the sorption in the $\text{Li}^+ - \text{Cs}^+$ series. This type of effect is often abolished when part of the water is retained in the coordination spheres of the cations when the latter are incorporated in the ion exchanger matrix. The H_2O molecules also participate in the filling of the free volume.

The entropy of the sorption process may be determined as the difference between the entropies of the incoming and leaving groups in the sorbent and in the solution. The entropy is determined primarily by the change in the degree of hydration of the cations following their incorporation in the solid phase.³¹ The transfer of one water molecule from the ion exchanger to the solution at room temperature is on average accompanied by an increase in the entropy of the system by 25 kJ mol^{-1} . The insignificant tendency of large cations to be hydrated is responsible for the additional increase in the partition coefficients when the cations are sorbed in the anhydrous or weakly hydrated form.

III. Kinetics of ion exchange

In the study of the kinetics of ion exchange on polymeric matrices, diffusion within the grain, the migration of ions in a thin film surrounding the ion exchanger grain (the so-called film kinetics), and diffusion in the liquid phase, which may make an appreciable contribution only for dilute solutions, are usually considered as the main processes.⁴¹ In the study of ion exchange on inorganic sorbents, only the first two processes are considered, since the diffusion in solutions is significantly faster.

The quantitative description of diffusion processes of this kind is complicated by the following factors.

Firstly, it is extremely difficult to collect a fraction of crystals with a specified size. Secondly, the mutual diffusion coefficient (D_{AB}) of the exchanging ions varies during the process as the ratio of the mole fractions of the cations participating in the exchange (X_A and X_B) is varied:

$$\frac{1}{D_{AB}} = \frac{X_A}{D_A} + \frac{X_B}{D_B},$$

where D_A and D_B are the diffusion coefficients of the corresponding cations in the individual phases.⁴² Thirdly, there is a possibility of a change in the diffusion conditions in the solid matrix as a consequence of its transformation in the course of the exchange (for example, for layered phosphates as a consequence of the change in the interplanar spacings and in the degree of hydration).⁸ Fourthly, there is a possibility of a change in the size of the sorbent particles during the exchange process.^{43–45} The vast majority of studies have therefore been devoted to a qualitative description of the ion exchange kinetics.

The rate-limiting stage of the diffusion of cations in the solid phase is their passage through the common face of two coordination polyhedra within the crystal. As a result of the consecutive fusion of occupied and unoccupied polyhedra, conductivity channels appear and may extend in the structure along one, two, or three directions and hence ensure one-, two-, or three-dimensional diffusion. The size of the cross-section of such a channel is determined by the number of anion atoms constituting it and their nature. The required size may be estimated on the hypothesis of the close packing of the anions and of the formation by the latter of regular planar polygons in the cross-section (Fig. 3). The results of the calculation of the cross-sections formed by oxygen ions ($R = 1.40 \text{ \AA}$) are presented in Table 2. The size of the cross-sections of the channels may increase somewhat when account is taken of the radius of the polyvalent cations binding the oxygen atoms.

Cation	Li ⁺	Na ⁺	K ⁺	Rb ⁺	Cs ⁺
Radius †	$\frac{0.59}{0.62}$	$\frac{0.99}{1.02}$	$\frac{1.37}{1.38}$	$\frac{—}{1.52}$	$\frac{—}{1.67}$

Furthermore, all the figures considered, starting with the tetragon, are nonrigid and the displacement of some of the ions from the plane of the channel cross-section leads to a decrease in their size.

Analysis of the data presented in Table 2 with allowance for the radii of the alkali metal cations makes it possible to conclude that the channels with a triangular cross-section are difficult to pass through by virtually all cations, while the channels with a tetragonal cross-section are difficult to pass through by all cations other than the lithium cation. The diffusion of the remaining cations requires at least pentagonal channels. However, it is known that lithium ions are capable of passing also through channels with a triangular cross-section made up of oxygen atoms.^{48,49} This ability is due to the activation energy for the given process.

In individual instances (for example, in polyphosphates of polyvalent elements), channels with a comparatively large cross-section are formed between oxygen atoms belonging to neighbouring planes, which facilitates the diffusion of cations. In order to ensure the diffusion of cations in $\alpha\text{-M}^{\text{IV}}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, it is necessary that they should pass through the face of a coordination polyhedron with a radius of $1.3 \text{ \AA}$ made up of oxygen atoms.⁵⁰ Small cations (Li^+ , Na^+) permeate through it comparatively readily. For larger cations — with a radius $> 1.3 \text{ \AA}$ (K , Rb^+ , or

† The number above the line is the radius of a cation with a coordination number of 4, while the number under the line is the radius of a cation with a coordination number of 6.⁴⁷

^a E = polyvalent cation.

Cs^+ for titanium phosphate and Rb^+ or Cs^+ for zirconium phosphate) — a considerable energy barrier must be overcome. In this case, for the implementation of the ion-exchange process it is necessary to maintain a high pH of the solution. The low activity of hydrogen ions is responsible for the possibility of the release of an additional number of protons from the ion-exchange material matrix. The latter acquires a negative charge and an electrostatic potential difference is created between the ion exchanger and the solution and is responsible for the diffusion of bulky cations into the cation exchanger. For this reason the exchange with lithium and sodium ions on $\alpha\text{-M}^{\text{IV}}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ takes place in acid solutions, while the exchange with caesium occurs only in alkaline solutions.^{33,50} In the case of $\gamma\text{-M}^{\text{IV}}(\text{HPO}_4)_2 \cdot 2\text{H}_2\text{O}$ with a significantly greater interplanar spacing, the energy barrier is virtually absent and the exchange of all the cations occurs readily in acid solutions.³³ Strictly speaking, the determination of the equilibrium thermodynamic parameters of H^+/K^+ , H^+/Rb^+ , and H^+/Cs^+ exchange processes for the α -phosphates of tetravalent elements is difficult and the characteristics presented in Table 1 refer to the 'pseudo-equilibrium' state.

Alberti *et al.*⁵⁰ and Troup and Clearfield⁵¹ carried out the sorption of caesium ions on zirconium hydrogenphosphate in the presence of traces of sodium (Fig. 4). The cations of the latter substitute some of the protons on the surface of the crystals, as a result of which the interplanar spacing in the latter increase from 7.6 to $11.8 \text{ \AA}$. The gap between the planes for $[\text{M}^{\text{IV}}(\text{HPO}_4)_2]_n$ then expands and caesium cations enter freely into the lattice already at a pH close to 4.

In order to estimate the kinetic parameters of the ion-exchange processes, Barrer's method is used.^{52–54} The diffusion coefficients are calculated by means of the following equation:

$$F = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp \frac{-D t \pi^2 n^2}{R^2}, \quad (13)$$

where F is the degree of completion of the exchange process, n an integer, D the diffusion coefficient, t the time, and R the radius of the ion-exchanger particles. The series in the equation quoted above converges comparatively rapidly for large values of F .

The diffusion coefficients calculated from the results of the ion-exchange experiments are presented in Table 3.

The above method has been used also to investigate ion-exchange processes on layered hydrogenphosphates of tetravalent elements. The diffusion coefficients and the activation energies for diffusion presented in Table 3 for these compounds differ markedly. The differences are due to the fact that the size of intergrown crystals and not the crystals themselves was used in a number of studies. In this case, an average diffusion coefficient was determined, since the rate of diffusion can be significantly different in the intergranular space and in the grain itself. On this basis, Larsen and Cilley³⁸ concluded that the values obtained are too high and they were unable to convert kinetic curves into diffusion coefficients.

Another problem is that Eqn (13) was derived by Barrer for a homogeneous isotropic spherical grain with a continuous series of solid solutions of the type $\text{A}_y\text{H}_{1-y}\text{X}$. On the other hand, none of the above conditions holds for many materials, among which one

may identify also the layered hydrogenphosphates of tetravalent elements. The exchange in these substances takes place as a result

of the drift of the interface between the AX and HX phases with extremely narrow regions of homogeneity. The rate-limiting stage is then two-dimensional diffusion of A^+ and H^+ ions through the AX layer. In the latter case, one can therefore consider, as an alternative method for the study of ion exchange kinetics, the method of stationary concentrations where the pH of the solution is kept constant by adding an excess of alkali. The latter procedure is analogous to the method widely used in the description of topochemical solid-phase processes and is based on a simplified solution of the stationary diffusion equation

$$l^2 = Dt, \quad (14)$$

where l is the thickness of the substituted layer. The main disadvantages of this approach are the impossibility of taking into account the free energy of the exchange reaction, which determines the driving force of the diffusion process, and the probability of entering the region of nonstationary diffusion. Furthermore, the physical significance of the concept of 'the driving force of the diffusion process', believed as a rule to be the concentration gradient within the substance, is also lost. In compounds with a narrow region of homogeneity the concentration gradient is comparatively small.

The solution of the 'diffusion problem' for an ion exchange process occurring as a result of the migration of the interface between two phases, based on the consideration of the model of a species moving within the crystal in a field with a periodic potential and the chemical potential superimposed on it, has been examined by Yaroslavl'tsev and Khrulev.¹⁸ The chemical potential difference ($\Delta\mu$) between the solution and the interface in the crystal was chosen as the driving force of the process. The resulting kinetic equations for one-, two-, and three-dimensional diffusion through a plane, a hollow cylinder, and a hollow sphere assume the following forms respectively:

$$\frac{dQ}{dt} = Dc_0\Delta\mu \frac{S/l}{RT}, \quad (15)$$

$$\frac{dQ}{dt} = \frac{2\pi Dc_0 h \Delta\mu}{RT \ln(r_0/r)}, \quad (16)$$

$$\frac{dQ}{dt} = \frac{4\pi Dc_0 \Delta\mu [rr_0/(r_0 - r)]}{RT}, \quad (17)$$

where dQ/dt is the flux of diffusing ions, c_0 is the concentration of the migrating ions in the layer where diffusion takes place, S and l are respectively the area and thickness of the plate, h is the height of the cylinder, and r_0 and r are the outer and inner radii of the cylinder or sphere. The quantities l and r are variable and are determined by the thickness of the layer of the growing phase. In the course of the experiment, they can be determined from the amount of reagent added and its current concentration. The chemical potential difference between the interfaces can be found from the relation

$$\Delta\mu = RT \ln \frac{c_M c'_H}{c_H c'_M}, \quad (18)$$

where c and c' are respectively the equilibrium and current concentrations of the cations. The relations presented are valid also in the exchange for the large potassium, rubidium, and caesium cations. For these species, the passage of the interface between solid phases requires an additional chemical potential difference.¹⁸

IV. The main types of inorganic ion-exchange substances

Among inorganic ion-exchange compounds, it is possible to identify the following classes: complex oxides, globular hydrates, and salts of polyvalent elements.

1. Complex oxides

Complex oxides are most widely represented among inorganic ion-exchange compounds. They include all natural ion exchangers — clay minerals and zeolites. The advantages of complex oxides is their availability and thermal and (partially) chemical stability. However, in view of the tendency of oxides to be close-packed, most of them have channels with small cross-sectional areas which must be passed by cations in order to migrate in the lattice. Furthermore, the high energy of the crystal lattices of the oxides is responsible also for the high energy of formation of defects in the latter (ΔH_f). As a consequence of this, the cationic diffusion coefficient is low and at room temperature does not as a rule exceed $10^{-10} \text{ cm}^2 \text{ s}^{-1}$.⁶⁰ The diffusion coefficient is defined by the relation

$$D = \frac{1}{6} f c a^2 v_0 \exp\left(\frac{\Delta S_f}{2R}\right) \exp\left(-\frac{E + \Delta H_f/2}{RT}\right), \quad (19)$$

where f is the correlation factor, which varies for the majority of substances from 0.33 to 0.78 as the coordination number of the cation increases, c is the concentration of the cations of the given type, a is the length of the elementary transfer step, v_0 is the pre-exponential factor for the transfer frequency in the range $10^{12} - 10^{14} \text{ s}^{-1}$, ΔS_f and ΔH_f are the entropy and enthalpy of the defect formation process, and E is the activation energy for the mobility of defects.

Calculations by Eqn (13) have shown that between three days and one year is required to achieve 95% completion of the exchange process for 0.1–1 mm oxide particles.⁶⁰ Such duration is characteristic of geological processes, but it cannot satisfy experimenters. A simple solution to this problem has been found: since the activation energy for diffusion in oxides is 80–100 kJ mol⁻¹, an increase in temperature by 100 °C leads, in conformity with Eqn (19), to an increase in the diffusion coefficient and hence in the rate of the process by 3–4 orders of magnitude. Bearing this in mind, the ion exchange, which occurs slowly at room temperature, is carried out either under hydrothermal conditions or in a melt.^{61,62} If this is insufficient and also if the thermal stability of the ion exchanger is low, experimenters attempt to reduce the enthalpy of formation of defects, for example by heterovalent doping. In particular, doping of $\text{Li}_2\text{Y}^{\text{IV}}\text{O}_3$ by a compound of a pentavalent element having the composition $\text{Li}_2\text{Z}^{\text{V}}\text{O}_3$ leads to formation of lithium vacancies in the structure:

On the other hand, doping with the compound $\text{Li}_3\text{Z}^{\text{III}}\text{O}_3$ leads to the appearance of interstitial lithium ions:

In materials of this kind, the energy of formation of defects is reduced to zero and the diffusion coefficient is defined by the relation

$$D = \frac{1}{12} f c x a^2 v_0 \exp\left(-\frac{E}{RT}\right). \quad (22)$$

Even for $x = 0.01$, the diffusion coefficient increases significantly and may prove to be fully acceptable for ion exchange at a comparatively low temperature.

a. Zeolites and clay minerals

Typical representatives of complex oxides with ion-exchange properties are zeolites and clay minerals. The structural base of these compounds consists of alternating layers of SiO_4 and AlO_4 tetrahedra or AlO_6 octahedra. The general formula of such compounds can be expressed in the form $\text{M}_{x/2}[(\text{AlO}_2)_x \cdot (\text{SiO}_2)_y] \cdot m\text{H}_2\text{O}$. All clay minerals have a layered structure and the blocks, approximately corresponding to the composition $\text{Si}_8\text{Al}_4\text{O}_{24}^{4-}$, are arranged at right angles to the crystallographic c

Figure 5. Schematic illustration of the structure of clay materials. (1) and (2) blocks of the layered structure; M^+ = alkali metal cation.

axis (Fig. 5). The surface of the blocks is made up of oxygen atoms carrying a non-compensated negative charge. The electroneutrality of the compound is ensured overall by the incorporation in the interstitial space of alkali or alkaline earth metal cations or protons,⁶ forming coordinate or valence bonds with the oxygen atoms of the $\text{Si}_8\text{Al}_4\text{O}_{24}^{4-}$ blocks. Some of these cations are capable of exchanging with the cations of the surrounding solution. The overall ion-exchange capacity of such materials ranges from hundredths to 1.5 mequiv g⁻¹ and for compounds with compositions close to $\text{H}_4\text{Si}_8\text{Al}_4\text{O}_{24} \cdot n\text{H}_2\text{O}$ the ion-exchange capacities with respect to cations and anions are approximately the same.⁶ A characteristic feature of such materials is their ability to swell in aqueous solutions or in water.

The silicon at tetrahedral sites can be partly substituted by aluminium cations, while aluminium at the octahedral sites can be substituted by a whole series of cations (divalent and trivalent iron, magnesium, and certain others with similar radii). Substitution by an ion with a smaller radius ($\text{Si}^{4+}/\text{Al}^{3+}$, $\text{Al}^{3+}/\text{Fe}^{2+}$, $\text{Al}^{3+}/\text{Mg}^{2+}$) increases the ion-exchange capacity with respect to cations. Therefore, for the majority of zeolites and clay minerals, the cation-exchange capacity exceeds the anion-exchange capacity. Clay minerals are distinguished by selectivity with respect to the sorption of large cations (Table 1). In the series of alkali metals, the selectivity increases from lithium to caesium.^{21,22,63,64}

In zeolites, the joining of the AlO_4 and SiO_4 tetrahedra *via* vertices, edges, or faces leads to the formation of diverse structures — fibrous, layered, or structures with a three-dimensional framework. The chemical and ion-exchange properties of zeolites with fibrous and layered structures are close to those of clay minerals, while those of zeolites having a rigid framework in the structure may differ significantly. The crystal lattices of the latter can be regarded to a first approximation as a $(\text{SiO}_2)_n$ matrix with three-dimensional connections, some of the silicon ions in which have been substituted by aluminium ions. The excess negative charge is compensated by the insertion into the lattice of cations with a smaller charge or by the substitution of some of the oxygen atoms by anions of monobasic acids. All these 'defective' cations and ions and also a certain number of water molecules are located within channels having different cross-sections (Table 2). If the size of the ions is smaller than the size of the channels, they can migrate in the structure and can participate in ion exchange. In contrast to clay minerals, the volume of such substances hardly changes during exchange and their ion-exchange capacity is determined by the chemical composition and may be fairly high. Thus, for certain minerals of the type of feldspar, it approaches 10 mequiv g⁻¹ (sodalite, ultramarine) or can actually exceed this

value (cancrinite).⁶⁵ Alkali metal cations are partly exchanged even on contact with water:

As a result of this, many zeolites in the initial form contain a certain number of protons.⁶⁶ In order to attain a more complete conversion into the hydrogen-form, zeolites are treated with solutions of ammonium salts at elevated temperatures, the ammonia formed being removed during annealing.^{67, 68}

Zeolites with a three-dimensional structure and a fixed size of the channels are used as 'ionic sieves'. Indeed, cations with a radius close to the radius of the cross-section of the channels are weakly sorbed, whilst still larger ones altogether fail to be sorbed. Thus ultramarine sorb effectively lithium, sodium, and silver ions and poorly rubidium and ammonium ions, while caesium does not participate in the exchange process.⁶⁵ Zeolites with a large size of the channels sorb weakly various alkylammonium cations,⁶ but certain zeolites are capable of sorbing even bulky complex cations.⁶⁹

The specific sorption properties of zeolites, their availability, low cost, and stability have led to their extensive practical application. For example, zeolites are used to extract heavy elements (including radioactive ones) such as caesium, thorium, and uranium from solutions.^{25, 63, 70–73} Zeolites modified with the aid of ion exchange by copper, nickel, platinum, ruthenium, and certain other cations are promising as catalysts in reactions involved in organic synthesis and for the conversion of nitrogen oxides and carbon monoxide in exhaust and industrial gases.^{74–82}

b. Complex oxides with a trivalent metal

Many complex oxides incorporating polyvalent elements have structures similar to those of the compounds examined above. The simplest representatives of complex oxides with a trivalent metal are alkali metal aluminates, chromates, and ferrites. The best known are the β -aluminates, also known as β -alumina having the composition $\text{M}_{1+x}\text{Al}_{11}\text{O}_{17+x/2}$ ($\text{M}^+ = \text{Li}^+, \text{Na}^+, \text{K}^+, \text{Rb}^+, \text{Cs}^+, \text{H}_3\text{O}^+, \text{NH}_4^+, \text{Ag}^+, \text{Ti}^+, \text{etc.}$). These compounds are distinguished by a high ionic conductivity involving alkali metal cations or protons.^{83–85}

The structure of β -aluminates is made up of $\text{Al}_{11}\text{O}_{16}$ spinel blocks containing four layers with close packing of oxygen, each fifth layer containing only a quarter of the oxygen atoms retaining these blocks next to one another in crystals (Fig. 6). Alkali metal cations are located in the same layer, five cavities of different types corresponding to each. The population of cavities of each type depends not only on the nature of the singly charged cations but also on the stoichiometry of the compound and even on temperature.^{85, 86–90} β -Gallates also have a similar structure.^{91, 92} The extremely low energy barriers to jumps between the cavities (the

Figure 6. Schematic illustration of the structure of the oxygen sublattice of sodium β -aluminate with accommodation of the alkali metal cations in the conducting plane. The oxygen atoms in the conducting plane pass through the later.

minimum values correspond to silver and sodium ions) give rise to the possibility of rapid ion transfer. It is remarkable that, contrary to the generally accepted view, the similar energies for the localisation of singly-charged cations at different crystallographic sites, for example $(\text{NH}_4)_{1+x}\text{Al}_{11}\text{O}_{17+x/2}$, lead to a decrease in the population of the principal Beaver–Ross sites and to an anomalously rapid increase in the concentration of ammonia in the interstices with increase in the nonstoichiometry index x .⁹³ This fact can be explained by the displacement of ammonia from the main sites by the cations located in close proximity in the interstices.⁹⁴ Within the framework of the theory developed by Bruce and Abrahams,⁹⁵ such displacement leads to the formation of alternating structural blocks with populated sites and interstices and to the cooperative transport of ions. accordingly, nonstoichiometric compounds with a large value of $x^\ddagger$ are characterised by a high cationic mobility.^{96–100}

The first communication about the occurrence of ion exchange in sodium β -aluminates for alkaline earth metals is that of Toporov and Stukalova.¹⁰¹ Exchange of this kind occurs comparatively slowly at room temperature, but is significantly accelerated on raising it. It is therefore most suitable to carry out this process in nitrate melts at 300–350 °C.¹⁰² Under such conditions, the diffusion coefficient of even caesium β -aluminate reaches $10^{-7} \text{ cm}^2 \text{ s}^{-1}$ and the tendency of the structure to sorb cations increases in the sequence $\text{Ag}^+ > \text{Ti}^+ > \text{K}^+ > \text{Na}^+ > \text{Rb}^+ > \text{Li}^+ > \text{Cs}^+$.^{62, 102} The ammonium-forms of the β -aluminate^{62, 85, 99, 103} and β -gallate,^{98, 104, 105} as well as ammonium β -ferrite¹⁰⁶ can be obtained by exchange from the melt. In order to accelerate the removal of the alkali metal, the ammonium nitrate melt is electrolysed with a rubidium β -aluminate anode.¹⁰⁷ For the preparation of the oxonium forms of the β -aluminates, the exchange was carried out in inorganic acids at an elevated temperature^{105, 108–110} or the silver form of the β -aluminates was reduced with hydrogen.^{62, 111}

β -Aluminates are capable of sorbing multicharged cations, in particular the lanthanide cations.^{112–116} The latter are also localised in the conducting plane^{112, 113, 116} and are characterised by a comparatively high mobility.¹¹⁶

The α - NaCrO_2 -type structures of lithium and sodium ferrites and chromites consist of close-packed oxygen atoms, among which the alkali metal and chromium ions occupy alternately octahedral cavities in the direction of the (111) crystallographic planes.¹¹⁷ Interaction of these compounds with lithium and silver nitrate and copper(I) chloride melts leads to the formation of the compositions ABO_2 ($\text{A} = \text{Li}^+, \text{Ag}^+, \text{Cu}^+$; $\text{B} = \text{Fe}^{3+}, \text{Cr}^{3+}$).^{60, 118} When the corresponding process is carried out using a stoichiometric mixture of metallic palladium and palladium(II) chloride, the A sites may be occupied by palladium ions.¹¹⁸ Analogous reactions have been described also for a series of aluminates of monovalent and divalent metals.^{119, 120} When sodium chromite is treated with a 300-fold excess of 25% nitric acid for 12 h, it is possible to achieve virtually complete substitution of the sodium ions by protons.⁶⁰ It is noteworthy that not all the compounds obtained retain the crystal structure of the initial substance.

c. Complex oxides with tetravalent, pentavalent, and hexavalent cations

The layered titanates $\text{M}_2\text{Ti}_n\text{O}_{2n+1}$ and $\text{M}_4\text{Ti}_n\text{O}_{2n+2}$, the structures of which are made up of $\text{Ti}_n\text{O}_{2n+1}^-$ or $\text{Ti}_n\text{O}_{2n+2}^{2-}$ layers, are inorganic ion-exchange materials. On being combined *via* common edges or vertices, the TiO_6 octahedra form infinite cavities between which alkali or alkaline earth metal cations are located.^{121–130} Since the latter possess a fairly high mobility, they can be substituted in solutions or melts by M^+ and M^{2+} cations or protons. A certain number of water molecules, can also

[‡] Such compounds are frequently referred to as β'' -aluminates (gallates, ferrites).

permeate into the interlayer space.^{60, 126, 128, 130, 131} The exchange reactions in these compounds may prove to be hindered kinetically. Thus treatment of lithium titanate with a zinc chloride melt leads to only partial exchange.⁶⁰ This phenomenon can be explained by postulating that the cationic sites are nonequivalent: only some of them are capable of being substituted by zinc cations, as in lithium germanates described by Joubert and Durif.¹³² A series of new titanates have also been synthesised in recent years, among which one may differentiate fibrous materials containing hydrogen or alkali metal cations within $\text{Ti}_8\text{O}_{18}^{4-}$ layers and octahedral $\text{Ti}_8\text{O}_{17}^-$ tunnels. The cations within the layers tend to exchange rapidly, while those located within the tunnels are inert.¹³³

One of the few representatives of hydrated oxides of polyvalent cations, capable of stoichiometric ion exchange, is polyantimonic acid $(\text{H}_3\text{O})_2\text{Sb}_2\text{O}_6 \cdot \text{H}_2\text{O}$. Together with the method usually employed for the synthesis of hydroxides, namely deposition from solution, this acid can be obtained with the aid of the ion-exchange reaction occurring on treatment of potassium antimonate with nitric acid.¹³⁴ The compound formed has the pyrochlore structure with oxonium ions in the octahedral cavities.^{134, 135} The protons of polyantimonic acid are capable of being quantitatively substituted by alkali metal cations. The selectivity series then assumes the following form: $\text{Na}^+ > \text{K}^+ > \text{Rb}^+ > \text{Cs}^+ > \text{Li}^+$, while the overall ion-exchange capacity reaches $5.1 \text{ mequiv g}^{-1}$.^{136–139}

Alkali metal niobates and tantalates (pyrochlore structural type) are also capable of undergoing stoichiometric substitution of all the cations by hydrogen. The ion-exchange capacities of these compounds reach $2\text{--}3.3 \text{ mequiv g}^{-1}$. This is due to the appreciable polarisation of the oxygen ions, leading to the formation of weak bonds between the lattice and the exchanging cation and to the presence of comparatively large channels. The hydrogen-forms of these ion exchangers may be obtained as a result of the hydrolysis of the pentachlorides⁸ or by the acid treatment of thallium,^{134, 140} lithium,^{141–145} or potassium¹⁴⁶ niobates at an elevated temperature. In contrast to antimononic acid, only half of the $(\text{H}_3\text{O})\text{HM}_2\text{O}_6$ protons are hydrated in niobium and tantalum hydroxides. NMR data have also confirmed the presence of protons and oxonium ions in these substances.¹³⁴ Many investigators have concentrated particular attention on the study of the phases formed at intermediate stages of the exchange process.^{142, 143, 145}

In order to obtain ion-exchange materials with a high capacity and high rates of exchange, it appears attractive to synthesise compounds with heterovalent substitution of the atoms in the ion-exchanger matrix. A considerable number of studies have been devoted to the preparation of mixed titanates, niobates, and tantalates with a layered or tunnel structure. The best known are the compounds $\text{MTi}_n\text{NbO}_{2n+3}$, and $\text{M}_3\text{Ti}_n\text{NbO}_{2n+4}$.^{147–153} The monovalent cations in these substances ensure a charge balance in the structure, remaining weakly bound to the framework. The alternating TiO_6 and NbO_6 octahedra, joined together by common edges or vertices, form double layers between which singly charged cations, capable of being substituted, are located.¹⁵² The reactivities of mixed titanates - niobates differ significantly. Thus the substitution of the alkali metal cation for a proton in MTiNbO_5 takes place comparatively easily, while the analogous process involving $\text{CsTi}_2\text{NbO}_7$ requires treatment with concentrated acid and the reaction product is the hydrate $\text{HTi}_2\text{NbO}_7 \cdot 2\text{H}_2\text{O}$. In the case of $\text{K}_3\text{Ti}_5\text{NbO}_{14}$, the maximum degree of substitution of potassium by hydrogen reaches only 80%.^{148, 152}

Variable-composition compounds, incorporating singly, doubly, triply, and quintuply charged cations together with titanium, may be differentiated as a separate group. The formulae of such compounds can be written as $\text{A}_x^I\text{B}_x^{II}\text{Ti}_{2-x}\text{O}_4$, $\text{A}_x^I\text{B}_x^{III}\text{Ti}_{2-x}\text{O}_4$, and $\text{A}_{1-x}\text{Ti}_{1-x}\text{Nb}_{1+x}\text{O}_5$.^{148, 151, 154, 155} In the compounds of the first two types, the substitution of part of the titanium by atoms B with a lower valence leads to a deficiency of cations, which is compensated when the corresponding number of ions A^+ are inserted into

the interstices. On the other hand, in compounds of the third type the compensation of the charge on substitution of titanium by niobium leads to the formation of vacancies in the cationic sublattice. Such a defective structure is distinguished by an increased cationic mobility, which helps to accelerate ion-exchange processes. On the other hand, the ion exchange of caesium for lithium, sodium, or potassium in $\text{Cs}_{0.7}\text{Mg}_{0.35}\text{Ti}_{1.65}\text{O}_4$ proceeds comparatively rapidly in melts at $300\text{--}400^\circ\text{C}$. However, the completion of the exchange of caesium for sodium in an aqueous solution requires four days.¹⁵⁵

Heterovalent substitution is possible in niobates and tantalates. The layered niobates and tantalates containing calcium or lanthanum were investigated vigorously in the 1980s–1990s.^{156–162} Treatment of these compounds with concentrated acids at 60°C leads to fairly rapid ion exchange.^{157, 159} The proton conductivity of the hydrogen-form of a series of such materials reaches $10^{-3} \text{ S cm}^{-1}$ at 400°C .¹⁶² Certain compounds containing niobium or tantalum together with tungsten or molybdenum also possess similar properties.^{163–165} The complete substitution of potassium by hydrogen on treatment with concentrated hydrochloric acid even of the stoichiometric compound KTaWO_6 occurs at room temperature. The hydrate $\text{HTaWO}_6 \cdot \text{H}_2\text{O}$ formed exhibits an appreciable proton conductivity of $2 \times 10^{-7} \text{ S cm}^{-1}$ at 25°C .¹⁶⁵

d. Oxides with variable-valence cations

An effect analogous to heterovalent doping may be obtained on partial oxidation or reduction of the ions of the framework. A typical representative of sorbents with a variable valence of the lattice cations is manganese dioxide. It has long been noted that the freshly precipitated compound contains an appreciable amount of impurity ions which can be readily exchanged for cations present in the solution surrounding it.^{166, 167} This is due to the fact that manganese dioxide contains divalent and trivalent manganese. Its composition may be represented by the formulae $\text{Mn}_n^{II}\text{Mn}_y^{III}\text{Mn}_{1-x-y}\text{O}_{2-2x-y}(\text{OH})_{2x+y} \cdot m\text{H}_2\text{O}$ or $\text{MnO}_{2-x}(\text{OH})_x \cdot n\text{H}_2\text{O}$ (the charge is compensated as a result of the insertion of protons, which form OH groups with oxygen). It was initially postulated that only hydroxy groups located on the surface of the particles of the test substance, may participate in the exchange process. However, it was later shown that the ion-exchange capacity of manganese dioxide may reach 4 mequiv g^{-1} ,^{168, 169} which in no way agrees with this hypothesis. All the known modifications of manganese dioxide are made up of MnO_6 octahedra joined together in such a way that long channels are formed between them.⁸ Singly and doubly charged cations are in fact located within these channels and readily migrate along them, ensuring the possibility of exchange processes.

Among other compounds with distinct ion-exchange properties, one may identify the tungsten and molybdenum blues and bronzes A_x^IBO_3 , which possess both electronic and ionic conductivity. They can be readily obtained by the electro-chemical reduction of molybdenum or tungsten oxides and also by the interaction of the latter with the corresponding metal or hydrogen at an elevated temperature. Vanadium and niobium bronzes possess similar properties. In the simplest case, small cations are intercalated in the octahedral cavities of the tungsten or molybdenum oxide lattice. The formation of tunnel or layered structures is an alternative.¹⁷⁰ All these compounds have been thoroughly described in the literature, but they are not often used for ion-exchange processes. Therefore, without dealing in detail with their properties, we shall note only some of the latest studies where these compounds were examined.^{171–173}

2. Globular hydrates

Globular hydrates are widely distributed compounds, typical representatives of which are loose deposits of hydrated oxides of polyvalent elements of the type $\text{Al}_2\text{O}_3 \cdot n\text{H}_2\text{O}$ and $\text{ZrO}_2 \cdot n\text{H}_2\text{O}$. Since such compounds are sparingly soluble, their formation reactions occur at a high degree of supersaturation of the solutions

where the rate of nucleation is very high and fully comparable to the rate of growth of the particles. The precipitated deposits represent a large number of very small and poorly formed (amorphous or weakly crystallised) particles. The geometry of small particles is in many respects determined by the requirement that the surface tension energy be minimised.⁹⁴ The formation of particles in the form of spheres (globules), the core of which usually has a composition close to that of the corresponding oxides is the most favourable. The extensive surface of the globules contains a multiplicity of uncompensated bonds, which may be stabilised as a result of the sorption of protons H^+ and OH^- groups from the solution,¹³⁶ as well as other ions and water molecules (Fig. 7a). The bonds between the sorbed particles and the core are comparatively weak, so that dissociation of the $\equiv E-O-H$ groups *via* an acid or base mechanism and the transfer of the resulting ions into the intergranular space are possible.¹³⁶

The most significant difference between the globular hydrates and the substances described above is the variable and comparatively low ion-exchange capacity determined in the first place by their surface area. After prolonged storage or heating, particularly under hydrothermal conditions, olation, oxolation, and crystallisation processes involving the substances take place,¹⁷⁴ as a result of which the ion-exchange capacity may decrease by several orders of magnitude. Furthermore, we may recall that the ion-exchange capacity depends significantly on the pH of the solution in contact with the hydroxides^{12,13} and even the nature of the process occurring on raising the pH changes from anion-

exchange to cation-exchange reactions. Since the nature of the active centres on the surfaces of globular hydrates depends on the method of their preparation, the position of the equivalence point is not a fundamental characteristic of the substance but depends on its previous history. Nevertheless the relation between cation- and anion-exchange properties of hydrated oxides is determined primarily by the electronegativity of the polyvalent cation. Thus the distinctly acid hydrated antimony(V) oxide, mentioned above, may participate only in cation exchange.¹³⁶ On the other hand, the hydrated yttrium oxide, dissociating preferentially *via* a basic mechanism, is an anion exchanger.²⁰

The presence of ion-exchange properties in globular hydrates may lead to their contamination and hence to an ambiguous treatment of the experimental results. For example, the hydroxides of trivalent elements are most often obtained by deposition with ammonia from solutions of salts of the corresponding metals. The deposition product is characterised by an appreciable content of the anions of the initial salts. This is due to the fact that the resulting solution is a buffer containing the $NH_4X + NH_4OH$ mixture.²⁰ The concentration of hydroxide ions in it in the presence of a 10% excess of the precipitant reaches only 2×10^{-6} and is several orders of magnitude lower than the concentration of the anions X^- . For this reason, the surface of the globules actively sorbs the anions. The content of nitrate ions in the yttrium hydroxide $Y(OH)_{3-x}(NO_3)_x \cdot 0.7H_2O$ ($0 < x < 0.5$), obtained by deposition from a nitrate solution, corresponds to the fraction of the cations localised on the surface of the particles.²⁰ For the complete conversion of the compounds thus obtained into the hydroxide, it is necessary to wash them with solutions of alkalis containing OH^- ions. Similar ion-exchange processes may occur also on much better formed deposits, for example on hydrated aluminium oxide.^{173,176}

Materials with distinct anion-exchange properties may be obtained by doping hydrated oxides having basic properties with an admixture containing a high-valence cation. It has been postulated^{6,177} that the excess positive charge is compensated as a result of the sorption of anions from the $Zn_{1-y}Al_y(OH)_2X_y$ solution. However, this interpretation appears doubtful, since the initial hydroxide already possesses similar properties and is characterised by a significant degree of disorder, which should abolish the effect of heterovalent doping.

Among globular hydrates, hydrated oxides of tetravalent elements (silicon, tin, titanium, and zirconium) are most often employed as ion-exchange materials. Their principal advantage is very low solubility in both acid and alkaline solutions. In the series of compounds quoted, the acid properties are somewhat weakened:¹³⁶ whereas silicon hydroxide can participate only in cation exchange, for the zirconium compound the zero-charge point is attained at a pH close to 7.^{12,13,176,178,179} Dichromate and molybdate ions are sorbed in the anionic form, the latter being involved in octahedral coordination, which does not rule out the possibility of the condensation of polyanions on the surface of the hydroxides.¹⁷⁹ Hydrated vanadium(V) oxide also has properties close to those of the compounds listed above.^{136,180}

A series of specific properties of hydrated oxides are determined by the characteristics of their structure. In the first place, such properties are determined by the nature of the highly mobile 'solution' in the interlayer space, which contains water molecules and ions formed on dissociation of the groups localised on the surface. In view of the extremely small size of the micropores ($< 100 \text{ \AA}$ ¹⁸¹) containing the intergranular solution and also as a consequence of the lack of order in the system of hydrogen bonds formed within it and on the surface of the globule, such a solution has a very high mobility. The latter vanishes only on cooling the specimen to temperatures close to the boiling point of nitrogen.^{178,181-183} The presence of proton defects (H_3O^+ or HO^-) in the solution is responsible for a fairly high proton conductivity of globular hydrates, the magnitude of which reaches $10^{-2} \text{ S cm}^{-1}$ for the series of compounds (Table 4). The proton conductivity and the mobility of the proton-containing groups decrease sig-

Figure 7. Schematic illustration of the structures of the globular hydrates $SnO_2 \cdot nH_2O$ (a), $Tl_{3-x}H_x(PW_{12}O_{40}) \cdot nH_2O$ (b), and $H_3PW_{12}O_{40} \cdot 29H_2O$ (c).

nificantly during the dehydration of the hydrated oxides.^{136, 182, 184} The kinetics of the exchange processes depend on the relative permittivity of the solvent, since ion-exchange processes take place on the surface of the particles of the globular hydrates and in the intergranular solution. The rate of exchange and the capacity of the ion exchanger may therefore change, for example in the presence of alcohols.¹⁹⁴

Alkali metal and thallium tungstophosphates, the ion-exchange properties of which have been examined by Yaroslavtsev *et al.*,^{195, 196} are constructed similarly. The X-ray diffraction patterns of these compounds are identical with those of the anhydrous salts of the heteropolyacids constituting the cores of the globules, but differ by the broadening of the reflections corresponding to the formation of 80–200 Å particles. Water molecules are localised in the inter-granular space (Fig. 7b), their number varying from 7 to 12 per formula unit. In the interaction of solutions of heteropolyacids and alkali metal chlorides, a high concentration of hydrogen ions is maintained. For this reason, not only alkali metal cations but also protons are sorbed on the particles deposited from the solution. In the presence of an excess of the chloride, the trisubstituted salts M₃PW₁₂O₄₀·*n*H₂O are deposited, their formation being thermodynamically most favourable. In the presence of a deficiency of the chloride, their surface sorbs heteropolyanions and protons, which is equivalent to the deposition of acid salts in which the content of hydrogen ions may reach 1.05 per formula unit (for example, Cs_{1.95}H_{1.05}PW₁₂O₄₀·*n*H₂O characterised by a minimal solubility product and a minimal crystal size).¹⁹⁵

It has been established by ²⁰⁵Tl NMR that a significant proportion of the thallium ions in Tl₃PW₁₂O₄₀·11.5H₂O are in a mobile state.¹⁹⁶ Prolonged washing of the above compound with water leads to the disappearance of the line due to mobile thallium, which indicates its removal from the surface of the globules as a result of the reaction

The process described above leads to an increase in the ionic conductivity from 2.7 × 10⁻⁴ to 5 × 10⁻⁴ S cm⁻¹ in view of the greater mobility of protons compared with Tl⁺ ions.¹⁹⁶ The increase in ionic conductivity on passing from neutral to acid salts of heteropolyacids has been noted also for other cations.^{195, 197}

From the standpoint of thermodynamics, the formation of particles smaller than 100 Å is difficult owing to the considerable expenditure of energy on the formation of the interface. There is therefore probably a limiting minimum size of the hydrate globules. However, the series of compounds examined is aptly supplemented by the hydrates of heteropolyacids with a high water content (H₃PX₁₂O₄₀·29H₂O, where X = Mo, W), the anion of which, with a radius of ~12 Å, can be regarded as a micro-globule (Fig. 7c).¹⁹⁸ The high mobility of the 'intergranular' 3H⁺·29H₂O solution disappears at very low temperatures.⁵⁹ The proton conductivity of these compounds is a maximum among all those measured at room temperature,¹⁹⁰ its magnitude decreasing significantly in the course of dehydration (Table 4). Similar properties are characteristic of numerous heteropolyacid solvates.¹⁹³ The conductivity of such solvates diminishes with increase in the volume of the solvent molecule (in conformity with the decrease in its rotational mobility, which is required for the transfer of a proton).

It is difficult to observe ion exchange for heteropolyacid hydrates because their crystal lattice is unstable and readily disintegrates on contact with the solvent. Nevertheless, an ion-exchange process was achieved when H₃PW₁₂O₄₀·29H₂O and Cu_{3/2}PW₁₂O₄₀·28H₂O single crystals came into contact.⁵⁹ The mutual diffusion of copper and hydrogen ions can be observed readily in this case from the change in the colour of the crystals. The coefficient of the mutual diffusion of H⁺ and Cu²⁺ is (3–7) × 10⁻⁸ cm² s⁻¹.

There are no fundamental differences between the structure of globular hydrates and that of the hydrated antimony and manganese oxides described above. However, the microstructures of the cores of the globules and the chemical individuality of the polyvalent cation in the latter determine the possibility of the occurrence of exchange processes throughout the bulk of the particles, which in fact serves as the basis for their assignment to the class of complex oxides. On the other hand, from the standpoint of the interpretation of the nature of the proton conductivity, all these compounds can be assigned to globular hydrates, because the conductivity within the grain is negligible compared with the surface component. The use of fractal geometry appears extremely productive in the treatment of the properties of compounds with a high surface area and porosity.¹⁹⁹

3. Salts of polyvalent elements

a. The layered hydrogenphosphates and arsenates H₃B(XO₄)₂

Among the salts of polyvalent elements, the sparingly soluble phosphates and arsenates H₃B(XO₄)₂ are most widely used as inorganic ion-exchange materials. Zirconium hydrogenphosphate Zr(HPO₄)₂·*n*H₂O has been undoubtedly most thoroughly investigated. Investigators have shown particular interest in this compound after a communication had been published in 1943 concerning the possibility of separating with its aid uranium and plutonium from their fission products.²⁰⁰ The communication of Clearfield and Stynes⁵ about the synthesis of crystalline zirconium hydrogenphosphate stimulated the development of research into the nature of ion exchange on inorganic phosphates.

Zirconium hydrogenphosphate may be obtained after prolonged heating of a mixture of zirconium oxychloride with an excess of phosphoric acid or by evaporating the corresponding solution with added hydrofluoric acid. In this case, the slow disintegration of zirconium fluoride complexes results in the deposition of well formed Zr(HPO₄)₂·H₂O crystals. The latter consist of long [Zr(HPO₄)₂]_n layers, in which zirconium ions are in an octahedral environment consisting of the oxygen atoms of the anions (Fig. 8). Only three oxygen atoms of the anion participate in the formation of the P–O–Zr linkages, while the fourth is oriented towards the interplanar space and is linked to hydrogen *via* a valence bond. The layers are retained next to one another *via* hydrogen bonds with water molecules (O₃PO–H–OH₂) 2.77 and 2.81 Å long.^{50, 201} The acid nature of the HPO₄²⁻ groups and the nearly optimum lengths of the hydrogen bonds²⁰² create precon-

Figure 8. A fragment of the structure of acid zirconium phosphate with an indication of the preferred site where the cation is located in the distorted octahedron made up of oxygen atoms.

ditions for the appearance of proton conductivity in $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ and, together with the possible cationic diffusion in the interlayer space, for the appearance of ion-exchange properties.

A considerable number of hydrogenphosphates of polyvalent elements are isostructural with the above compound, but, in view of the difficulty of obtaining large crystals, structural data are available only for a few of them.^{203, 204} The main characteristics of these materials are the interlayer distance and the ion-exchange capacity (Table 5).

A new phase — $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot 0.5\text{H}_2\text{O}$ with an interlayer distance of 7.42 Å — has been described and characterised

Table 5. Interlayer distances and calculated ion-exchange capacities of certain acid phosphates and arsenates of tetravalent elements.

structurally comparatively recently.²¹³ It differs from the monohydrate by the system of hydrogen bonds. The authors²¹³ note the stability of this phase — they did not observe its conversion into a mixture of the monohydrate and the anhydrous compound.

The interlayer distance in the γ -modifications of the acid phosphates $\gamma\text{-M}(\text{HPO}_4)_2 \cdot 2\text{H}_2\text{O}$ is significantly greater^{208–210} than in the α -modification, which facilitates the occurrence of ion-exchange processes. The study of the structure of compounds of this type is complicated because only finely disperse specimens are obtained in the course of synthesis. For this reason, none of the information concerning their structure can be regarded as fully reliable. However, it has been established reliably with the aid of ³¹P NMR that two nonequivalent PO_4 polyhedra, coordinated twice and four times to the multicharged cation, are present in the

structure.²¹⁴ As a result of this, the H_2PO_4^- anions are displaced into the interlayer space, which in fact leads to the layers moving apart (Table 5).

Tantalum hydrogenphosphate has a structure similar to that of the α -phosphates of tetravalent elements.^{211, 212} However, the number of hydrogen ions in this compound is smaller by a factor of 2 and the negative charge of the basic layers is therefore smaller, the interaction between them is weaker, and the interlayer distance is greater.²¹² Furthermore, the polarisation of the phosphate anion by the pentavalent cation decreases the proton-accepting capacity of the oxygen atoms and leads to the dissociation of the HPO_4^- groups giving rise to diaquahydrogen ions H_5O_2^+ .²¹²

In the course of ion exchange on α -phosphates, alkali metal cations permeate into the interlayer space and are disposed in the vicinity of the centre of the octahedron made up of the oxygen atoms of the anion (Fig. 8) not coordinated to the tetravalent cation. A type $\text{AB}(\text{XO}_4)_2$ lattice with the structure of an anhydrous alum is obtained. Numerous double antimony and tantalum phosphates with alkali metals are constructed in this way.^{215–218} The coordination sphere of potassium in zirconium phosphate with a degree of substitution of 50% [$\text{ZrKH}(\text{PO}_4)_2$] is formed similarly.²¹⁹ The real radius of the octahedral cavities in such structures is equal to 4.7–5.3 Å and the radius of the cation in it should be 3.3–3.9 Å, which exceeds significantly the size of any alkali metal cation. The above octahedra therefore contract along the threefold axis and the interlayer distance diminishes. However, this contraction is insufficient and the excess space is filled with water molecules. The cation then shifts from the highly symmetrical position and the interlayer distance increases as a rule relative to that in the initial acid phosphate.³⁹

The number of highly symmetrical sites at the centre of the octahedron is smaller by a factor of 2 than the number of monovalent cations in the structure of the products of the complete substitution of tetravalent elements in acid phosphates. As a result of this, the coordination sphere of the metal is formed in a specific manner — with partial involvement of the oxygen atoms of the anion and water molecules. Thus there are four nonequivalent cationic sites in $\text{Na}_2\text{Zr}(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$ with coordination numbers of 7, 7, 6, and 4. Between one and four water molecules and between two and five oxygen atoms of the anion enter into the immediate environment of sodium. Among the oxygen atoms, there are also those involved in the formation of P–O–Zr linkages.²²⁰ In $(\text{NH}_4)_2\text{Zr}(\text{PO}_4)_2 \cdot \text{H}_2\text{O}$, two nonequivalent types of ammonium ions are surrounded by respectively four and five oxygen atoms of the anion and are linked to a water molecule *via* a bridging hydrogen bond: $\text{NH}_4^+ - \text{HOH} - \text{NH}_4^+$.²²¹

During ion exchange on acid phosphates, the structure of the $[\text{M}(\text{PO}_4)_2]_n$ layers is kept almost constant. Therefore, when the unit cell parameters a and b are similar, the interlayer distance changes significantly (usually increases), which is a sign of the occurrence of ion-exchange processes for the compounds $\text{M}(\text{HXO}_4)_2 \cdot \text{H}_2\text{O}$. The typical interlayer distances in certain products of ion exchange on acid phosphates with the ratio $\text{M}:\text{XO}_4 = 1:2$ are presented in Table 6 and their dependences on the degree of hydration and the radius of the cation in the monosubstituted sodium salts of zirconium α -phosphate and titanium γ -phosphate are shown in Fig. 9. The interlayer distance increases with increase in the radius of the sorbed cation and with the degree of hydration of the compound.

As a consequence of the structural nonequivalence of the hydrogen atoms in the hydrogenphosphates of tetravalent elements and the steric hindrance to the accommodation of a second cation, the exchange process on α -phosphates usually occurs in two stages. There is therefore a possibility of the formation of two substitution products — $\alpha\text{-AHM}(\text{HXO}_4)_2 \cdot n\text{H}_2\text{O}$ and $\alpha\text{-A}_2\text{M} \cdot (\text{HXO}_4)_2 \cdot n\text{H}_2\text{O}$, where A is an alkali metal cation. The formation of only the product of the complete substitution of protons has been noted for large cations. It has been shown^{18, 50} for potassium, rubidium, and caesium ions that this is caused by the kinetic inhibition of the exchange process. After the substitution of the

first cation, the $[\text{M}(\text{XO}_4)_2]_n$ layers move apart and the insertion of a second cation between them becomes preferred to the migration of the singly substituted phase front into the bulk of the specimen. In particular, this conclusion has been confirmed by the possibility of obtaining $\alpha\text{-KHZr}(\text{PO}_4)_2$ by other methods.²¹⁹ The removal of this limitation and the weakening of the interaction forces between the layers, for example for $\gamma\text{-Zr}(\text{HPO}_4)_2$, leads to the formation of two intermediate phases with degrees of substitution of 25% and 50%, in the course of the exchange.³³ In the case of tantalum hydrogenphosphate with an even weaker interaction between the layers, the solid solutions $\text{M}_x\text{H}_{1-x}\text{Ta}(\text{PO}_4)_2 \cdot n\text{H}_2\text{O}$ are formed.³⁹

The proton/alkali metal cation ion-exchange processes in acid phosphates of polyvalent elements are due to the high mobility of the hydrogen ions and the incoming cations, which increases with increase in the degree of hydration and diminishes with increase in the radius and content of the alkali metal.^{39, 224} The attempt to

achieve the exchange of the protons of acid tin phosphate for Cu^{2+} cations showed that the ion exchange occurs only on the surface.²²⁴ This is caused by the fact that the diffusion of doubly charged cations is kinetically hindered and that the double tin copper phosphate with a low mobility of the cations is formed on the surface. The nuclei of the new phase produced cover the conductivity channels and prevent further exchange.²²⁴ However, it was possible to obtain the product $\text{MgZr}(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$ by refluxing titanium hydrogenphosphate with magnesium acetate.²²⁵ This method makes it possible to increase the diffusion coefficient by carrying out the process at an elevated temperature and by working in the region of comparatively low pH values, which are determined by the ratio of the concentrations of acetate ions and acetic acid in solution. An alternative method of synthesis of compounds with doubly and triply charged cations involves their preparation from the sodium-form of zirconium α -phosphate in accordance with the mechanism proposed by Scou *et al.*²²⁶

Magnesium zirconium hydrogenphosphate $\alpha\text{-Mg}_{0.5}\text{HZr}(\text{PO}_4)_2 \cdot 3\text{H}_2\text{O}$ and chromium zirconium hydrogenphosphate $\alpha\text{-Cr}_{0.5}\text{H}_{0.5}\text{Zr}(\text{HPO}_4)_2 \cdot 5\text{H}_2\text{O}$ were thus synthesised at room temperature. The sorption of the ions $[\text{Ru}(\text{NH}_3)_6]^{2+}$ from the corresponding aqueous solution has been achieved similarly (with the intermediate formation of the ammonium analogue).²²⁷

The hydrated acid phosphates can be obtained from the potassium salts $\text{K}_x\text{Sb}_x\text{P}_{2-x}\text{O}_{3x+5}$ by ion exchange with inorganic acids at an elevated temperature,²²⁸ but this process is slow. The substitution of potassium in $\text{KTa}(\text{PO}_4)_2$ takes place more simply.²¹¹ Chernorukov *et al.*²²³ obtained double tantalum alkali metal phosphates by solid-phase synthesis from finely disperse tantalum hydrogenphosphate and the corresponding chlorides and hydroxides at 200–400 °C.

The corresponding process cannot be carried out in solution owing to the hydrolysis of the tantalum hydrogenphosphate. However, the synthesis of the coarsely crystalline compound using the method proposed by Yaroslavtsev and Nikolaev²¹¹ made it possible to achieve proton/alkali metal cation ion-exchange in aqueous solutions.^{17, 39}

A multiplicity of other materials with ion-exchange and catalytic properties as well as proton conductivity have been obtained from hydrogenphosphates of polyvalent elements. Among them, mention should be made of a mixed zirconium hydrogenphosphate-arsenate²¹⁹ and numerous phosphonates and mixed phosphate-phosphites, which have been extensively investigated in recent years as promising ion exchangers with a high selectivity.^{31, 230–235} The products of the intercalation of amines, alcohols, and other organic derivatives, containing functional groups and capable of forming bonds with a proton in the structure of acid zirconium phosphate, have also been studied intensely.^{44, 236–245}

b. Structures of the NASICON type

Hydrogenphosphates of tetravalent elements with the ratio $\text{M}^{\text{IV}} : \text{XO}_4 = 2 : 3$ belong to the NASICON structural type. They have become widely known by virtue of the high cationic conductivity⁸ of a series of solid solutions $\text{Na}_{1+x}\text{Zr}_2\text{Si}_x\text{P}_{3-x}\text{O}_{12}$.^{246, 247} A series of compounds $\text{A}^{\text{I}}\text{B}_2^{\text{IV}}(\text{PO}_4)_3$, where A^{I} is an alkali metal cation, while B^{IV} is the cation of a tetravalent metal, which is usually zirconium, have been synthesised. Solid-

§ Their name 'Na super-ion conductor' (NASICON) is due precisely to this property.

phase or hydrothermal synthesis as well as synthesis from the melt are normally employed.^{248–255}

The joining together of BO_6 octahedra and PO_4 tetrahedra is characteristic of the NASICON type crystal structure, but, in contrast to the layered phosphates examined above, all the oxygen atoms of the anion participate in the formation of the $\text{P}–\text{O}–\text{B}$ linkages. Channels extending along the crystallographic c axis are formed in the three-dimensional lattice. However, whereas 75% of the cavities remain unoccupied in $\text{NaZr}_2(\text{PO}_4)_3$,^{247, 249} they are all occupied in $\text{Na}_4\text{Zr}_2(\text{SiO}_4)_3$.^{256, 257} All the oxygen atoms in the structure described are simultaneously coordinated to quadruply and quintuply charged cations and they therefore possess comparatively weak electron-donating properties. Together with the partial occupation of the cavities, this ensures a high mobility of the cation and the possibility of the occurrence of ion-exchange reactions.

The cation exchange in the compounds $\text{A}^{\text{I}}\text{B}_2^{\text{IV}}(\text{PO}_4)_3$ is most often carried out by treating the initial phase with salt melts. The lithium, potassium, and silver derivatives can be obtained in this way from the sodium phase.^{8, 258–260} The attempts to obtain the hydrogen-form of zirconium phosphate by treating the sodium or ammonium compound with an acid under hydrothermal conditions were unsuccessful.²⁵⁴ $(\text{H}_3\text{O})\text{B}_2^{\text{IV}}(\text{PO}_4)_3$ was obtained by the interaction of $\text{LiZr}_2(\text{PO}_4)_3$ or $\text{LiTi}_2(\text{PO}_4)_3$ with an acid⁷ and also as a result of the heat treatment of $\text{NH}_4\text{Zr}_2(\text{PO}_4)_3$ with subsequent maintenance of $\text{HZr}_2(\text{PO}_4)_3$ in water.²⁶¹ The substance obtained can serve in its turn as the initial basis for the synthesis of derivatives with other monovalent ions. Thus the preparation of $\text{LiTi}_x\text{Zr}_{2-x}(\text{PO}_4)_3$ by ion exchange with lithium hydroxide under hydrothermal conditions has been described.²⁶²

In contrast to layered phosphates, the three-dimensional lattice of compounds with a NASICON type structure changes little when the cations are varied. However, there are structures of this type differing in symmetry. The assignment of a substance to a particular structural type is determined primarily by the number of singly charged cations per formula unit. The compounds $\text{A}_3\text{B}_2^{\text{III}}(\text{PO}_4)_3$, where $\text{B}^{\text{III}} = \text{Sc}, \text{B}, \text{or Fe}$,^{263–266} exhibiting ion-exchange properties and cationic conductivity, have been obtained. As in the $\text{NaZr}_2(\text{PO}_4)_3$ structure, the number of singly charged cations (A^{I}) is found to be smaller than the number of sites available for their accommodation. Sodium and lithium ions are then found to be statistically distributed between a pair of possible sites with nonequivalent populations, forming the so called statistical dipoles.^{263, 264, 267}

c. Compounds based on the structure of NbOPO_4 and its derivatives

The oxide phosphates BOXO_4 (where B is, for example, V, Nb, or Mo and X = P or As) are characterised by one of the simplest types of isostructure, formed by the joining together of BO_6 octahedra and XO_4 tetrahedra. The crystal lattice of the oxyphosphates of pentavalent vanadium, niobium, and molybdenum is made up of planes of tetrahedra of phosphate anions and metal octahedra joined together by four vertices (Fig. 10a).

The two remaining vertices of the octahedron are in the *trans*-position relative to one another and are combined with the analogous vertices of adjacent layers, ensuring bonding between them as a result of the formation of the $–\text{O}–\text{B}–\text{O}–\text{B}–\text{O}–$ bridges.^{268–270} The BOXO_4 structures are distinguished by a significant nonequivalence of the metal–oxygen bonds: one of the bonds formed is close to being a double bond, whilst the other is close to a very weak coordinate bond (Table 7).

By virtue of the features listed above, the intercalation of water molecules in compounds of this kind is possible.^{278–281} This process proceeds particularly readily in vanadium oxyphosphate, the cation of which tends to form multiple bonds. Here it is assumed that, on dissociation of the $–\text{O}–\text{V}–\text{O}–$ chain of bonds, $\text{H}_2\text{O}–\text{V}=\text{O}$ fragments are formed and the planes $(\text{H}_2\text{VO}_2\text{PO}_4)_n$ move apart in space, forming a layered structure (Fig. 10b).^{271, 272} The positions of protons and of the second water molecule in $\text{VOPO}_4 \cdot 2\text{H}_2\text{O}$ have not been determined. The formation of

Figure 10. Fragments of the VOPO_4 (a) and $\text{VOPO}_4 \cdot 2\text{H}_2\text{O}$ (b) structures.

Table 7. The metal–oxygen bond lengths in certain compounds based on the NbOPO_4 structure.

Compound	The length of B–O bonds in octahedron /Å			Ref.
	B–O–(X)	B–O–(B)	B=O	
NbOPO_4	1.97	1.78	2.32	269
MoOPO_4	1.97	1.66	2.63	268
VOPO_4	1.87	1.58	2.87	270
$\text{VOPO}_4 \cdot 2\text{H}_2\text{O}$	1.92	1.43	2.49	271, 272
$\text{NH}_4(\text{VO}_2)(\text{HPO}_4)$	1.92	1.57	1.69	273
$\text{HUO}_2\text{PO}_4 \cdot 4\text{H}_2\text{O}$	2.31	1.75	1.78	274
KMnO_2PO_4	1.98, 2.19	1.69	1.69	275
KTiOPO_4	1.99	1.72	1.98	276, 277

compounds with a higher degree of hydration is also possible. Analogous transformations under the influence of a hydrochloric acid solution occur in niobium oxide phosphate, where the metal–oxygen bonds differ less.²⁸¹ It has been established by NMR that the monohydrate and trihydrate contain two hydroxy groups, not bound to the phosphorus, per cation, (*i.e.* these substances are niobium hydroxophosphates $\text{Nb}(\text{OH}_2)\text{PO}_4$ and $\text{Nb}(\text{OH})_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$).²⁸¹

The compounds formed may split off protons, which can migrate in the interlayer space. This follows, in particular, from the evident analogy between the structure of the hydrated oxyphosphates and uranyl phosphate — one of the best proton conductors at room temperature ($1.8 \times 10^{-3} \text{ S cm}^{-1}$).^{274, 282} The conductivity of niobium oxyphosphate trihydrate is lower almost by an order of magnitude ($3 \times 10^{-4} \text{ S cm}^{-1}$), probably as a consequence of the less-developed system of hydrogen bonds, while the activation energies for this process are virtually identical in the two compounds.²⁸¹ The conditions in the interlayer space are favourable for the migration of cations. Thus, conditions for ion-exchange processes are created in a series of compounds

$\text{BOX}_4 \cdot n\text{H}_2\text{O}$, $\text{H}_3\text{OMoO}_2\text{PO}_4$ and its potassium analogues have similar structures, although the metal–oxygen bonds are then in the *cis*-position in the molybdenum coordination polyhedron.^{275, 283}

Hydrated vanadium and niobium oxyphosphates exhibit ion-exchange properties on interaction with solutions of alkalis, substituting one of the protons by a cation *via* the reaction^{284–287}

where $\text{M} = \text{Li}, \text{Na}, \text{K}, \text{Rb}, \text{Cs}$, or NH_4 .^{284–287} The lengths of the metal–oxygen bonds are then significantly equalised even in the vanadium derivatives $\text{NH}_4(\text{VO}_2)(\text{HPO}_4)$ ²⁷³ and there is a simultaneous rearrangement of the structure with migration of the proton to the anion and the formation of a vanadium coordination polyhedron in the form of a square pyramid.²⁸⁸ The compound $\text{LiHBO}_2\text{PO}_4$ with a high lithium conductivity has been obtained by the heat treatment (500 °C) of the products of the interaction of niobium oxyphosphate with lithium hydroxide.²⁸⁷

In uranyl phosphate, the oxygen atoms of the anion are coordinated to the metal and the remaining two participate in the formation of the uranyl ion. The ‘anionic part of the framework’ therefore manifests weak proton-accepting properties and the proton is transferred to the proton hydrate sub-lattice $\text{H}^+ \cdot 4\text{H}_2\text{O}$ localised in the interlayer space.²⁷⁴ This is responsible for the high ionic conductivity and the distinct ion-exchange properties. Oxonium ions are readily substituted by an alkali or alkaline earth metal ion.²⁸⁹ Uranyl phosphate readily sorbs cations even from dilute aqueous systems with formation of solid solutions. All the compounds formed have a fairly high ionic conductivity.^{192, 291–293}

Another type of ion-exchange processes, occurring in hydrated vanadium oxyphosphate, is the reductive intercalation of hydrogen and singly or doubly charged cations with partial reduction of vanadium *via* the reaction^{278, 293–298}

An intermediate degree of oxidation of vanadium in the range $4 < z < 5$ was most frequently attained, but in the case of the reductive intercalation of lithium and hydrogen the limiting case with $x = 1$ occurred. The compounds $\text{AVOPO}_4 \cdot n\text{H}_2\text{O}$ can then be considered as the reduction products.²⁹⁸ These substances may give rise to several crystal structures, differing in the type of binding of the octahedra and in the number of molecules of the water of hydration. A characteristic feature of these substances is the presence of the vanadyl ion with a shortened metal–oxygen distance (~ 1.5 Å). Three sites in the equatorial plane are occupied by the oxygen atoms of the anion and one site is occupied by the oxygen of water or the vanadyl ion ($R_{\text{V}-\text{O}} \approx 2.0$ Å). Weakly coordinated water molecules or the oxygen of a neighbouring vanadyl cation ($R_{\text{V}-\text{O}} \approx 2.3$ Å) are located in the *trans*-position relative to the oxygen of the $\text{V}=\text{O}$ group.^{298–301}

In compounds of the type $\text{VOHPO}_4 \cdot n\text{H}_2\text{O}$ the hydrogen phosphate anions are highly polarised and may dissociate with elimination of the proton. The substance formed on substitution of such a proton by an alkali metal cation retains the ability to exchange the latter for other cations (Na^+ , K^+ , Rb^+ , NH_4^+ , Ag^+ , Ti^+).^{303–306} The substitution products AVOPO_4 are constructed from distorted VO_6 octahedra, combined into chains *via* a pair of common vertices, and from PO_4 tetrahedra bound to them.³⁰⁶ Such compounds belong to the KTiOPO_4 structural type characterised by the presence of channels along the crystallographic *c* axis,^{276, 277} which are responsible for the ionic mobility and the ion-exchange properties.²⁶⁵

V. Conclusion

The data presented in the review show that inorganic sorbents are promising materials for the separation and extensive purification

of various ions, including alkali metal cations, which are difficult to separate by other methods. Such ion exchangers are characterised by a high radiation stability and by the ability to sorb heavy metal cations. They are therefore actively employed in the atomic industry. The ability to extract selectively a series of cations from a large number of competing ions of the main substance is quite important. Inorganic sorbents are widely employed for the creation of different kinds of materials with an extensive specific surface, catalytic properties, and ionic conductivity. Furthermore, with the aid of ion exchange it is possible to obtain a series of substances, the synthesis of which by other methods is impossible owing to the thermodynamic instability of the initial compounds or the kinetic inhibition of their reactions.⁸¹ All this provides grounds for the hypothesis that the use of inorganic sorbents will expand.

We believe that the employment of ion-exchange processes as model reactions for the comprehensive study of the thermodynamic and kinetic characteristics of certain phenomena occurring in solids (for example, the diffusion of ions, solid-phase reactions, *etc.*) is also promising. The possibility of selecting substances with different sizes of cavities, conductivity channels, and interplanar spacings makes it possible to trace in detail the influence of these parameters on the dynamics of the processes considered and to investigate the dependence of the affinity of the structure for particular ions on the geometry and nature of their potential environment, rigidly specified by the structure of the ion-exchange matrix. The simplicity and high accuracy whereby the changes in the concentrations of the reactants in solution may be monitored permit the modelling of many processes in solids.

This review has been written with the support of the Russian Fundamental Research Fund (project No. 97-03-33736).

Oxo-acidity in ionic melts

V L Cherginets

IV. The reactions of melts with gaseous acid and basic reagents	606
V. Conclusion	609

Abstract. The current state of research into the oxo-acidity in alkali metal nitrate, sulfate, and halide melts is analysed on the basis of the proposed classification of oxo-acidity reactions (Lux–Flood acid–base interactions). It is established that a considerable proportion of literature data on homogeneous acid–base equilibria are incorrect, since no account is taken in them of either the levelling of the acid (basic) properties by the solvent or of the error in the determination of the reaction stoichiometries. An explanation is proposed for the considerable scatter of data on the solubilities of oxides in ionic melts, which has been the principal inhibiting factor in the development of this field. The reactions of melts with gaseous acid and basic reagents are examined. The bibliography includes 171 references.

I. Introduction

Ionic melts are widely used in science and engineering as media for various processes such as electrolysis, electrochemical synthesis, the growing of single crystals, *etc.* The virtually complete dissociation of the solvents into constituent ions makes it possible to generate high current densities in electrolysis. In the absence of oxidants, for example H^+ , it is possible to obtain in ionic melts products which cannot be isolated from aqueous solutions (alkali and alkaline earth metals, subions, *etc.*). From the standpoint of the protection of the environment, the application of fused salts as technological solvents is specially attractive, because their use does not entail the accumulation of liquid industrial waste.

The processes in solvent melts are appreciably influenced by the impurities present in the initial salt starting material or formed during the fusion of the solvents as a consequence of high-temperature hydrolysis or the interaction of the melt with the material of the container and the corrosive components of the atmosphere. Such impurities include impurity metal cations and various oxygen-containing anions (sulfates, carbonates, hydroxides). The strength of the effect of the anions on the processes in ionic melts depends mainly on the degree of their dissociation with formation of the oxide ion O^{2-} as one of the products.

Uspekhi Khimii 66 (7) 661–676 (1997); translated by A R Grzybowski

Reactions involving the transfer of oxide ions in ionic melts are usually regarded as acid–base interactions (oxo-acidity); their treatment is then based on the ideas proposed by Lux¹ and developed in the studies of Flood and coworkers:^{2–4}

where A is an acid and B a base. The oxygen index pO, analogous to pOH in aqueous solutions, serves as a quantitative measure of the basicity (acidity) of fused media:

$$pO \equiv -\lg a_{O^{2-}} \sim -\lg m_{O^{2-}},$$

where $a_{O^{2-}}$ and $m_{O^{2-}}$ are the activity and molality of the oxide ions in the melt respectively.

Although studies on oxo-acidity have been carried out since 1939,¹ hitherto no attempt has been made to survey or treat systematically the results obtained and the available information about oxo-acidity in ionic melts consists of a set of scattered and frequently incorrect data. The present review is intended to fill the existing gap. It is possible to identify the following main trends in studies on oxo-acidity in ionic melts:

- homogeneous (intrinsic acid–base) reactions;
- dissolution and dissociation of oxides in melts;
- interaction of melts with gaseous reagents, including high-temperature hydrolysis of the melts, elimination of oxygen-containing impurities, and dissociation of Lux–Flood bases (CO_3^{2-} , OH^- , *etc.*).

II. Homogeneous acid–base equilibria

1. Specific features of ionic melts as media for acid–base interactions

Ionic melts as media in which Lux–Flood acid–base interactions take place may be divided into two classes depending on the presence in them of constitutional oxygen ions (*i.e.* ions entering into the composition of the main components of the melts): oxygen-free and oxygen-containing. We shall consider the characteristic features of the acid–base interactions in melts of the types indicated.⁵

Oxygen-free melts do not contain constitutional oxygen and the ‘pure’ melt cannot therefore serve as a O^{2-} donor. However, as a consequence of the inevitable contamination of the melt by oxygen-containing impurities such as SO_4^{2-} , CO_3^{2-} , and OH^- , in practice oxygen-free melts nevertheless always contain a certain amount of oxide ions. The concentration of oxide ions in the ‘pure’ solvent melt is not constant but depends on the content of impurities and the degree of their dissociation with formation of O^{2-} , which increases in the sequence $SO_4^{2-} < CO_3^{2-} < OH^-$.

In the 'pure' oxygen-free melts, the pO is usually in the range 3–4.5. The use of even the strongest halogenating agents does not permit a significant decrease in the O^{2-} concentration and this is the 'inevitable fault' leading to errors in potentiometric measurements especially when small amounts of the test substances are added. However, in a number of instances the pO of the 'pure' halide melt is used as the 'internal standard' of the melts for the construction of acidity scales.^{6–9}

In oxygen-containing melts, the acid–base reactions are more complex, since in this case a competing equilibrium acid–base autodissociation of the solvent-melt takes place. A characteristic feature of the oxygen-containing melts is the presence in the latter of not only the base but also of the solvent-acid. This renders oxygen-containing melts similar to low-temperature solvents with an intrinsic acid–base equilibrium.¹⁰

However, oxygen-containing melts also possess a series of characteristic features due to the relatively high temperature of the liquid state. Very often, the solvent-acid is volatile or unstable^{1,11} and is gradually removed from the acid melt as a consequence of decomposition or evaporation, while the pO in such a solution gradually approaches the corresponding value for a neutral melt. For this reason, very frequently not only are the acid properties levelled off in oxygen-containing melts but an upper acidity limit is also established.

Thus it has been observed that the highest chromium and molybdenum oxides decompose a nitrate melt with evolution of NO_2 and with increase in temperature the e.m.f. of a cell with an oxygen electrode is appreciably reduced.¹² It has been suggested that the nitrogen(V) oxide and the corresponding anions are formed in the interaction of the oxides with the melt. Since the acids indicated are very strong, one may postulate that the process

is fully displaced to the right and that the acid strength is determined by the acid properties of the nitronium cation NO_2^+ . The stability of the latter is low and, after the attainment of certain concentration, its reaction with the melt anions becomes fairly intense:

The kinetic methods for the determination of the acidity of the melt are based on this reaction. As reaction (2) occurs, the concentration of the nitronium cation diminishes and the rate of the process falls. Ultimately it becomes so low that a constant e.m.f. is observed in a series of consecutive measurements. This is in fact the upper acidity limit in the melt, which is independent of the type of acid. The above considerations make it possible to explain readily the temperature dependence observed by Shams El Din and El Hosary:¹² an increase in temperature leads not only to a decrease in the stability of the nitronium cation but also to an increase in the rate of process (2).

The presence of an upper acidity limit is also characteristic of sulfate melts, which is apparently associated with the limited solubility of SO_3 in the latter. This is indicated by the drift of the e.m.f. (pO) in the acid-containing melt towards the neutral point.¹

2. Methods of investigation

Most diverse methods are used to investigate oxo-acidity and to estimate the acid properties of melts. The simplest is the indicator method, the essential feature of which has been described by Brough *et al.*¹³ The behaviour of 11 acid–base indicators used in aqueous solutions has been investigated in the melts KNO_3 – $LiNO_3$ at 210 °C and KSCN at 200 °C. The colour transitions of the indicators (Ind), associated with the change in the acidity of the medium on titration of an alkali or sodium peroxide with potassium pyrosulfate were examined:

In the nitrate melt, only the colour of phenolphthalein changed (yellow → purple), whilst the remaining indicators were apparently oxidised. In the KSCN melt, which has no oxidative properties, colour transitions were observed for all the indicators investigated (Methyl Red, thymolphthalein, *etc.*).

The use of indicators for the investigation of acidity is limited primarily by their thermal instability and by their ready oxidisability at high temperatures. Since ionic melts do not as a rule contain water, the transition of the indicator to the protonated form [reaction (3)] is hardly possible (the yellowing of the solution in the reverse transition of phenolphthalein has been noted¹³). The indicator method can therefore be used only in the study of relatively low-temperature melts (< 250 °C).

The application of spectroscopic methods for the study of the basicity of melts has been described.^{14,15} Duffy *et al.*¹⁴ constructed an 'optical' basicity scale for metallurgical slags relative to CaO adopted as the standard. The optical basicity was determined by estimating the changes in the frequencies of the spectral lines (the $^1S_0 \rightarrow ^3P_1$ transition) of the Tl^+ , Pb^{2+} , and Bi^{3+} cations in a basic medium. X-Ray fluorescent spectroscopic study of the Na_2O – B_2O_3 – Al_2O_3 , Na_2O – B_2O_3 – SiO_2 , and Na_2O – SiO_2 – Al_2O_3 melts showed that the relative acidity of the oxides diminishes in the sequence $B_2O_3 > SiO_2 > Al_2O_3$.¹⁵ The spectroscopic methods require as a rule the use of cooled (quenched) specimens, which may affect the validity of the results obtained in view of the discrepancy between the temperature of the melt investigated and the temperature at which the acid (basic) properties are estimated.

There are data obtained in the study of the basicity of melts by measuring the solubility in the latter of acid gases.^{16,17} The solubility of sulfur(VI) oxide in sodium phosphates has been determined by a gravimetric method and a correlation has been established between the basicity of the melt and the solubility of the acid gas in the latter.¹⁶ Iwamoto¹⁷ used CO_2 and H_2O in order to determine the basicity. However, such methods are applicable only to basic melts, because the acids present in stable acid melts displace the indicator acid gas. Furthermore, the products of the interaction of the acid gas with basic melts are stable, which leads to an irreversible change in the properties of the latter.

The so called 'kinetic' method has been proposed for the estimation of the acidity of alkali metal nitrate melts. The interaction of nitrate melts with pyrosulfate ions^{18,19}

leads to the formation of the nitronium cation, which subsequently interacts with nitrate ions in accordance with Eqn (2). The latter reaction is the slowest and the overall acidity of the medium can be inferred from its rate:

$$T_A = [S_2O_7^{2-}] + [NO_2^+].$$

The interaction of dichromate ions with chlorate ions in the KNO_3 – $NaNO_3$ melt involves the occurrence of two reactions:^{20,21}

Reaction (4) is rate-limiting. The rate of evolution of chlorine is proportional to the quantity

$$T_A = [Cr_2O_7^{2-}] + [ClO_2^+].$$

The interaction of bromate ions with dichromate in a nitrate melt has been studied.²² The cations investigated can be arranged in the sequence $BrO_2^+ < ClO_2^+ < NO_2^+$ in terms of their acidity. We suggest that the introduction of the overall quantity T_A by the above investigators^{18–24} unjustifiably complicates the analysis of the results, because the acidity of nitrate melts is determined solely by the concentration (activity) of NO_2^+ ions and the rates of the rate-limiting reactions (2) and (4) depend only on the concentrations of the cations NO_2^+ and ClO_2^+ respectively.

The kinetic method has been used also to investigate the acidity of the Cu^{2+} and Co^{2+} cations in the $\text{KNO}_3\text{--NaNO}_3$ melt at temperatures in the range 325–375 °C.^{23,24} The acidity was determined from the rate of reaction (2). The nitronium cation was formed in solution *via* the reaction

The acidity of the cations of these metals was found to be close to that of the dichromate ion and the cations investigated by Duke and coworkers.^{18–22} Evidently Slama^{23,24} made a definite error in the estimation of the acidity of the cations, because the degree of binding of the oxide ions O^{2-} by the latter is determined not only by their active properties but also by the formation of a new phase — the corresponding oxides, which are virtually insoluble in the test melt.

The deficiencies of the methods described prevent their wide-scale employment for the investigation of the oxo-acidity of metals over a wide temperature range.

The method based on the e.m.f. of cells with transport in which an oxygen indicator electrode, reversible with respect to O^{2-} ions, is employed is the most promising. The electrochemical cells can be represented as follows in a general form:

In the familiar potentiometric studies, it has been postulated that the diffusion potential is zero. Either a metallic electrode (*i.e.* a metal immersed in a solution of the salt of the corresponding cation at a definite concentration) or an oxygen electrode immersed in a solution with a known or constant concentration of oxide ions (concentration cells) have been used as reference electrodes.

3. Nitrate melts

Since a large number of publications have been devoted to studies of the oxo-acidity of nitrate melts, these systems are traditionally regarded as most thoroughly investigated. The relatively low melting points of both individual alkali metal nitrates and of their mixtures permit the employment of comparatively simple experimental apparatus. Potentiometric studies in nitrate melts reduce mainly to the determination of the acid–base equilibrium constants.

The greatest number of publications concern the studies of the oxo-acidity of the KNO_3 melt at 350 °C.^{12,25–49} The results of the determination of the constants for the addition of the oxide ion to higher oxides and anions of Group V elements (P, As, V) have been published.^{25–30} All the oxides investigated react with the nitrate melt to form the salts of the corresponding meta-acids:

Reaction (2) displaces the equilibrium to the right. Nitrogen(IV) oxide is evolved until the e.m.f. decreases to ~ 0.5 V, which, judging from the results of other studies, corresponds to the upper limit of acidity in the KNO_3 melt.^{25–30} According to these data,^{25–30} the acid–base product for the solvent is $\sim 10^{-16}$. As the titrant Na_2O_2 is added, the following reactions take place consecutively in the melt:

$\text{R} = \text{P, As, V}.$

The acid properties of the oxide intensify in the sequence $\text{V}_2\text{O}_5 < \text{P}_2\text{O}_5 < \text{As}_2\text{O}_5$.

Apart from these reactions, the equilibria which according to Shams El Din *et al.*^{25–27} are established when the ions HPO_4^{2-} , H_2PO_4^- , HAsO_4^{2-} , and H_2AsO_4^- , added to the melt are titrated

have also been investigated. The equilibrium constants of the reactions

were determined. However, even pure salts, incorporating the corresponding anions, decompose at temperatures very appreciably below 350 °C, forming the corresponding meta- and pyro-salts.⁵⁰ In the absence of water vapour, equilibria (5) and (6) cannot therefore occur.

The study of the acid properties of the highest oxides of Group VIB,^{12,31,32} showed that chromium(VI) and molybdenum(VI) oxides react with the nitrate melt, forming the dichromate and trimolybdate ions respectively. After the cessation of the evolution of NO_2 , the e.m.f. is close to 0.5 V, which agrees with the values obtained for the oxides of Group V elements.^{25–30} The products of the interaction of chromium and molybdenum oxides with the melt are titrated in one stage and the final products of the neutralisation reactions are the chromate and the molybdate respectively. Tungsten(VI) oxide is a weaker acid and does not decompose the pure melt. Its titration takes place in one stage and the product is tungstate ions. The acidity of the oxides investigated increases in the sequence $\text{WO}_3 < \text{MoO}_3 < \text{CrO}_3$.

The published equilibrium constants K ^{12,25–40} cannot be called correct because the calculated values vary during titration within the limits of several orders of magnitude of $\text{p}K$. This occurs either owing to the incorrect selection of the participants in the equilibrium (the stoichiometry) or because the authors did not calibrate in an ‘acid’ medium the oxygen electrode $\text{Pt}(\text{O}_2)$ employed.

It has been established by the method involving the titration of the corresponding carbonates by dichromate³⁴ and metaphosphate³⁵ ions, *i.e.*

that the acidity of the cations increases in the sequence $\text{K}^+ < \text{Na}^+ < \text{Li}^+$, $\text{Ba}^{2+} < \text{Sr}^{2+} < \text{Ca}^{2+} < \text{Pb}^{2+}$. Although this sequence agrees satisfactorily with the electronegativity series of the metals, nevertheless this method for the examination of acidity must be regarded as unsuccessful because the acids employed by the investigators for the titration not only eliminate oxide ions from the carbonates but can also form insoluble chromates and phosphates with the majority of the cations. The formation of complexes or precipitates is demonstrated by the position of barium in this series, the acidity of which is comparable to the acidity of potassium and sodium and is appreciably lower than the acidity of lithium. This might have influenced also the positions of a number of other alkaline earth metals in the series considered.

The relative Lux–Flood base strengths in nitrate melts have been investigated.^{36,37} The bases investigated were separated into two groups: the oxide ions (OH^- , O^{2-} , and O_2^{2-}) and the carbonate ions [CO_3^{2-} , HCO_3^- , $(\text{COO})_2^{2-}$, CH_3COO^- , HCOO^-]. The first group includes the bases, which, according to the authors, dissociate fully in the melt with formation of oxide ions. The second group is made up of weak bases. Since they all decompose at the experimental temperature (350 °C) with formation of the carbonate ion, the differences between separate representatives of this group are confined to their reducing properties: by reducing nitrate ions, organic acid salts promote the accumulation in the melt of excess amounts of oxide and carbonate ions compared with the stoichiometric concentrations. The majority of the bases investigated are therefore unsuitable for quantitative studies.

There exists the view³⁷ that oxide ions are present in nitrate melts in the form of pyronitrate ions, which are strong bases with strengths comparable to that of carbonate ions. From the contemporary point of view, the existence of the pyronitrate ion is doubtful, because the coordination number of nitrogen with respect to oxygen cannot exceed 3, whilst in the hypothetical

pyronitrate it is 4. It has been shown³³ that the pyronitrate ion is not formed in basic melts. Oxide ions can be stabilised in the melt solely by virtue of the formation of silicate ions in the reaction with the material of the container (Pyrex).

The communications of Shams El Din and Gerges^{39,40} also contain data on the behaviour of oxygen electrodes in nitrate melts. The 'anomalous' behaviour of the platinum oxygen electrode has been attributed to the 'peroxide' function of oxygen gas electrodes. On the other hand, a satisfactory reversibility is characteristic of metal oxide electrodes (of the second kind).

Experimental study of the acid–base equilibria involving phosphates and molybdates led to the conclusion that heteropolyacids are formed in nitrate melts.^{41,42} This has been confirmed by the results of cryoscopic studies.⁴³ Certain characteristic features of the potentiometric titration method in melts have been described.^{44,45} The automatic titration method consists of the following features:⁴⁴ a rod of the solidified solution of $K_2Cr_2O_7$ in the test melt is lowered at a uniform rate, by means of a special device, into the melt containing the base and the pen recorder measures the e.m.f.'s. This method makes it possible to estimate only the concentration of the acid in the test melt (to within 3.5% according to the authors). The thermodynamic characteristics could not be determined because the measured e.m.f. does not correspond to equilibrium.

With increase in the acidity of the oxide, the decomposition temperature of the nitrate melt falls.⁴⁶ This has been explained by the decrease in the activation energy for the decomposition reaction as a result of the binding of the oxide ions formed by acids. However, the observed phenomenon can be explained also, without resorting to kinetic ideas, by the shift of the decomposition equilibrium towards the formation of oxide ions and nitrogen oxides in accordance with the Le Chatelier rule. The affinity of the oxide decreases in the sequence $SiO_2 > TiO_2 > ZrO_2 > Al_2O_3 > MgO$.

A study of the possibility of using a series of metal oxide oxygen electrodes ($Nb|Nb_2O_5$, $Ta|Ta_2O_5$, $Zr|ZrO_2$) in potentiometric studies^{47–49} made it possible to construct the following acidity series in the potassium nitrate melt at 350 °C: $NH_4VO_3 > NaPO_3 > NaH_2PO_4 > K_2Cr_2O_7 > K_2HPO_4 > Na_4P_2O_7 > NaH_2AsO_4 > K_2CO_3 > Na_2O_2$.

The presence in this series of certain acids, the existence of which is doubtful, shows that the authors did not always take into account the real processes occurring in the melt. Thus it is quite clear that ammonium metavanadate should decompose to the oxide V_2O_5 , which is partly reduced by ammonia, whilst acid salts decompose to the corresponding pyro- and meta-salts. The above acidity series cannot therefore be regarded as uncontroversial.

4. Sulfate melts

The intrinsic acid–base dissociation equilibrium is established in sulfate melts:

Such systems have been investigated to a much smaller extent than the nitrate melts, which can be explained by the relatively high melting points of both the individual sulfates and their eutectic mixtures. Another possible cause is the very low stability of the acid solutions in such melts. Indeed, reaction (7) should lead to the formation in the melt of SO_3 , which is a gas at the melting points of the known eutectic mixtures of alkali metal sulfates. The sulfate melts may contain SO_3 as a result of the formation of polysulfates, for example the pyrosulfate $SO_3 \cdot SO_4^{2-}$. According to reference data,^{50,51} the decomposition temperatures of pure pyrosulfates do not exceed 460 °C and in solution they should be even lower. Under the conditions of continuous renewal of the atmosphere over the melt, *i.e.* in an argon or nitrogen stream, the process involving the evaporation of the acid SO_3 from the sulfate melt, *i.e.*

should be displaced fully to the right according to the Le Chatelier rule and equilibrium cannot be attained in acid solutions. From the standpoint of the study of oxo-acidity, the eutectic mixture of potassium, lithium, and sodium sulfates (0.135 : 0.78 : 0.085) with a melting point of 512 °C may prove to be the most promising.⁵² In this case, studies may be carried out at lower temperatures than in the classical study¹ and hence acid and basic solutions will be more stable.

The oxygen electrode $Pt(O_2)$ has been calibrated and an acidity scale has been constructed¹ in the K_2SO_4 – Na_2SO_4 melt at 800 °C. The study of the thermal stability of the pyrosulfate showed that the enhancement of the acidity of the cations of the melt lowers the decomposition temperature of the latter.³

Measurements of the acidity of centimolar solutions of sodium pyrosulfate and peroxide showed that the extent of the acidity scale in the K_2SO_4 – Li_2SO_4 – Na_2SO_4 melt at 550 °C amounts to 10 pO units.^{53,54} Hence it is easy to determine the acid–base product for the solvent: it is 10^{-14} . The range of stability of the VO^{2+} ion is $pO = 8.5$ – 10.6 .

In conclusion of the topic of oxo-acidity in sulfate melts, one should mention the study⁵⁵ in which the potentiometric titration of MoO_3 , $Cr_2O_7^{2-}$, PO_3^{3-} , $P_2O_7^{4-}$, and V_2O_5 with sodium carbonate in the K_2SO_4 – Li_2SO_4 – Na_2SO_4 melt was achieved at 625 °C. The e.m.f. jump was observed at an acid : carbonate molar ratio of 1 : 1. In the case of vanadium oxide, the ratio was 1 : 3. There is no information about the equilibrium constant.

5. Silicate melts

The studies of silicate melts are as a rule of applied importance and these systems are widely used in industry (slags, glasses, *etc.*).

A number of studies^{56–58} have been devoted to the dependence of the acidity of silicate melts on their composition. Together with SiO_4^{4-} , the polyanions $(SiO_3)_3^{6-}$ and $(SiO_{2.5})_6^{6-}$ exist in the PbO – SiO_2 system ($N_{SiO_2} = 0$ – 0.6) at 1100–1200 °C.⁵⁶ A decrease in the ratio Na_2O/SiO_2 in fused glasses diminishes the basicity, whereas magnesium oxide hardly affects the basicity of the melt.⁵⁷ The study was carried out with the aid of the $Ag(O_2)$ oxygen electrode in concentration cells.

The platinum oxygen electrode is satisfactorily reversible in the PbO – SiO_2 , Na_2O – CaO – SiO_2 , and MO – PbO – SiO_2 silicate melts, where M is an alkali earth metal cation.⁵⁹

The application of the membrane oxygen electrode for the monitoring of the acidity of fused silicates during glass making has been described.⁶⁰ The study of the basicity of Na_2O – Al_2O_3 – SiO_2 melts by an e.m.f. method showed that Al_2O_3 exhibits weaker acid properties than SiO_2 .⁶¹

Under the conditions of the corrosion of the glasses $Na_2O \cdot x \cdot Al_2O_3 \cdot 2SiO_2$ ($x = 0$ – 0.4) in alkaline earth metal nitrate melts, the degree of interaction of the melt with the silicate increases with decrease in the radius of the alkaline earth metal cation, *i.e.* with intensification of its acidity.⁶²

The influence of the charge and radius of the cation in the oxides Tl_2O , PbO , CdO , ZnO , and Bi_2O_3 on the basicity of the lead metasilicate melt has been investigated potentiometrically at 800, 850, and 900 °C.⁶³

6. The equimolar KCl–NaCl mixture

The reversibility of the oxygen gas electrode $Pt(O_2)$ in chloride melts has been investigated and the constants for the acid–base equilibria involving chromium(VI), molybdenum(VI), and tungsten(VI) oxides and anions have been determined at 700 °C.^{64–69} The constants for the addition of the oxide ion to chromium oxide and sodium metaphosphate have been found.^{64–66} It has been established that the titration of CrO_3 proceeds in accordance with the scheme

and the equilibrium constant is 2.88×10^3 for the first stage and 1.4×10^{-1} for the second.

The metaphosphate ions are also titrated in two stages:

The equilibrium constants for the first and second stages are $(2.88 \pm 1.2) \times 10^3$ and $(2.5 \pm 1.4) \times 10$ respectively.

An excess of the titrant (O^{2-}) leads to the formation of basic phosphates, to which the authors attribute the composition $\text{PO}_3^- \cdot 2\text{O}^{2-}$. When sodium carbonate is used as the titrant, basic products are not formed. The Ba^{2+} and Li^+ cations exhibit appreciable acid properties in a chloride melt; the equilibrium constants for the addition of the oxide ion are 8.1×10^3 and 3.53×10^2 respectively.

The study of the acid properties of MoO_3 and the corresponding anions showed that the equilibrium constants for the addition of the oxide ion, *i.e.*

are 5×10^4 and 880 ± 880 respectively.⁶⁷

Two studies^{68,69} were devoted to the determination of the constants of the acid–base equilibria involving a tungsten(VI) oxo-compound. The titration of tungsten oxide in the melt is also a two-stage process:

with the equilibrium constants 1460 ± 390 and 880 ± 880 respectively. The platinum oxygen electrode exhibits a satisfactory reversibility with respect to oxide ions in a chloride melt.⁶⁹ The slope of the E – $p\text{O}$ relation is close to $2.3RT/2F$ (F is the Faraday), which corresponds to the electrode process

The above results served as the basis for further electrochemical studies on electrochemical reduction reactions of Group VI metals.^{70–72} The theoretical foundations and principles of controlling electrochemical processes involving the isolation of metals and their compounds with nonmetals (carbides, borides, silicides) from ionic melts have been developed.⁷³

In a study of the acid–base equilibria in CaWO_4 solutions, the solubility of CaO in the KCl – NaCl melts at 1000 K was found to be ~ 0.084 mol.%.⁷⁴ The solubility of scheelite in a chloride melt at 1000 K is $10^{-3.5}$ mol kg^{-1} . The equilibrium constant for the reaction

is ~ 10 .

According to Combes and Tremillon,⁷⁴ the polyanion $\text{W}_3\text{O}_{10}^{2-}$ ($pK = 12.7$) is formed on reverse titration. Thus the titration curve is not reversible. The results may be accounted for by the elimination of WO_3 from acid chloride melts in the form of the oxide chloride. Under the conditions of reverse titration, the substance used as the titrant is lost in an uncontrolled manner. These considerations apply also to other studies in which titration involving the transition from a base to an acid was resorted to in the investigation of the acid properties of the oxo-compounds of Group VI elements.

The acid–base equilibria in solutions of phosphorus(V) oxo-compounds have been investigated at 700 °C with the aid of the membrane oxygen electrode $\text{Pt}(\text{O}_2)|\text{ZrO}_2(\text{Y}_2\text{O}_3)$.⁷⁵ In the melt with the ratio $\text{Na}_2\text{O}:\text{P}_2\text{O}_5 = 1.67-3$, the polyphosphate ions are formed:

The corresponding equilibrium constants have been determined. The solubilities of the polyphosphates formed have been found by the cryoscopic method.

The titration of V_2O_5 takes place in two stages:⁷⁶

The pK for the first and second stages are -9.3 ± 0.3 and -8.3 ± 0.3 respectively.

The acid–base properties of certain higher oxides and oxo-anions in chloride melts at 700 °C have been investigated in a series of studies.^{77–81} The results, presented in Table 1, agree satisfactorily with the analogous data obtained with the aid of the membrane oxygen electrode $\text{Pt}(\text{O}_2)|\text{ZrO}_2$. The application of the platinum oxygen electrode leads to pK values which are lower by approximately 3–4 orders of magnitude. In chloride melts, the $\text{Cr}_2\text{O}_7^{2-}$ ion is unstable and decomposes with formation of equimolar amounts of CrO_3 and CrO_4^{2-} .⁷⁹

Table 1. The constants of certain acid–base equilibria in KCl – NaCl and NaI melts.^{77–81}

Equilibrium	– pK		
	m^a	N^b	mol. %
KCl–NaCl melt, 700 °C			
$2\text{PO}_3^- + \text{O}^{2-} \rightleftharpoons \text{P}_2\text{O}_7^{4-}$	8.01 ± 0.1	10.67	6.67

7. Other alkali metal halide melts

Empirical acidity series in KCl and CsI melts at 700 °C have been quoted.^{6,7} The practical value of these studies is that the $\text{SO}_4^{2-}/\text{S}_2\text{O}_8^{2-}$, $\text{WO}_4^{2-}/\text{W}_2\text{O}_7^{2-}$, and $\text{PO}_4^{3-}/\text{P}_2\text{O}_7^{4-}$ buffer solutions proposed by the authors, which have satisfactorily reproducible $p\text{O}$ values, may be used as standard solutions for the calibration of oxygen electrodes in alkali metal halide melts.

The acidity series in the sodium iodide melt at 700 °C have been constructed by Rybkin and Banik.⁸ The authors conclusion that the carbonate and hydroxide ions are bases of equal strength cannot be regarded as correct, since the acidity scales were constructed using solutions in which the contents of the test reagents were the same (0.01 mol kg^{-1}), whereas it follows from the equations

that the amount of hydroxide should be twice as great. One mole of O^{2-} may be formed from 1 mol of CO_3^{2-} , whereas only 0.5 mol of O^{2-} may be obtained from 1 mol of OH^- . Indeed, in another study by the same workers it was shown that the hydroxide ion is a stronger base than the carbonate.⁸²

Certain results of the study of the acid properties of boron(III) and vanadium(V) oxo-compounds in the NaI melt at 700 °C, carried out by Cherginets,⁸¹ are presented in Table 1.

The comparative Lux–Flood base strengths (OH^- , CO_3^{2-} , SO_4^{2-} in the NaI melt at 700 °C have been established by titration with sodium pyrophosphate.^{82,83} The first of these bases reacts with the acid in proportions of 2:1, whilst the others are neutralised in proportions of 1:1. Depending on the e.m.f. jump at the point of equivalence, the bases investigated can be arranged in the sequence $\text{OH}^- > \text{CO}_3^{2-} > \text{SO}_4^{2-}$ in terms of the decrease in basicity. The equilibrium constants have not been quoted.

In a number of instances, the substances introduced into the melt actually exist in the latter in another form. For example, potassium nitrate and nitrite decompose to the oxides at the experimental temperature.^{6,7}

This applies also to pyro- and per-sulfates^{6,7} and also to acid phosphates.⁸ The acidity of the pyrophosphate in an iodide melt is much higher than that of the metaphosphate ion according to the data of Rybkin and Banik.⁸ However, the titration of phosphorus oxo-compounds proceeds in accordance with the scheme

and the acidity of the pyrophosphate should therefore be lower, because in the conjugate pair ‘metaphosphate–pyrophosphate’ the latter is the base. The frequently observed lack of correlation between the pH of aqueous solutions of salts and the pO of the analogous solutions in the melt (this usually applies to phosphorus oxo-compounds) is due to the difference between the processes occurring during neutralisation. The neutralisation of phosphoric acid in aqueous solutions proceeds in stages in accordance with the scheme

The analogous sequence in melts assumes the form

A correlation should therefore be sought between the acidities of an aqueous solution of the anion and a solution of the corresponding anhydro-acid in the melt. The salts NaPO_3 and $\text{Na}_4\text{P}_2\text{O}_7$ can be readily obtained by pyrolysing the corresponding acid salts, but the reverse processes hardly occur in aqueous solutions and the above substances exist as the salts of the independent acids HPO_3 and $\text{H}_4\text{P}_2\text{O}_7$. On the other hand, in the case of meta- and pyro-arsenates, which exhibit a greater tendency to hydrolyse, a correlation between the pH of the aqueous solutions of these anhydro-compounds and the pO of the solutions in the melt should be observed. Thus the breakdown of the correlation in the case of phosphorus oxo-compounds is only apparent, because it is induced solely by kinetic limitations.

Analysis of literature data makes it possible to discover also a fundamental inaccuracy which has arisen in the studies of oxo-acidity in nitrate melts, in particular in KNO_3 . As a constituent of this melt, the NO_3^- ion is capable of dissociating with formation of O^{2-} in accordance with the equation

which is thus the equation of the intrinsic acid–base dissociation of the solvent.⁸⁴ In the potassium nitrate melt, there is a possibility of the levelling off of both acid properties,^{84 i.e.}

and basic properties (as has been observed by De Andrade *et al.*),^{85 i.e.}

This implies that acids stronger than NO_2^+ and bases stronger than K_2O cannot exist. According to Eqn (11), the acid–base titration curves for solutions of strong acids of equal concentration should be identical. This permits a fresh look at the results obtained in earlier studies.^{39–42}

We shall consider the potentiometric titration data for solutions of oxo-acids (Fig. 1). The curves presented virtually coincide (despite some difference between the initial concentrations of the acid). This means that the process

occurred in all cases, whereas the above investigators^{39–42} performed their calculations on the basis of reaction equations with other stoichiometric coefficients, which in fact led to an appreciable drift in the calculated equilibrium constants.

Figure 1. Potentiometric titration curves for solutions of the oxo-acids CrO_3 (1), MoO_3 (2), WO_3 (3), and PO_3 (4) at concentrations of $\sim 0.1 \text{ mol kg}^{-1}$ in the KNO_3 melt at 350 °C (according to data in Refs 39–42). The arrow indicates the error in the measurement of the e.m.f.

The levelling of the acid strengths in oxygen-containing melts makes the latter an unsuitable medium for the determination of the equilibrium constants for processes involving strong acids. The melts of alkali metal halides, in which this phenomenon is not observed, are more suitable for this purpose. Since the physicochemical properties of ionic melts (ionic densities, charges, and radii)[†] are usually similar, the application of the acidity scale obtained for one melt in order to characterise another melt is more justified than, for example, the use of different low-temperature molecular solvents, the physicochemical properties of which (relative permittivity, donor–acceptor properties) differ extremely significantly.

[†] The radii of the NO_3^- and Cl^- ions are 0.165 and 0.167 nm respectively.¹⁰

III. The solubilities of oxides in alkali metal halide melts

The dissolution of oxides in alkali metal halide melts is accompanied by the interaction of the ions of the oxides with those of the melt (solvation). These interactions are superimposed on the oxide dissociation process and lead to the formation of halo-complexes and oxides of the alkali metals. Furthermore, part of the molecular oxide also dissolves. Thus the following equilibria are established in a saturated solution of the oxide:

where Kt^+ is the cation of the melt (Cs^+ , K^+ , and Na^+).

Since the formation of complexes between the anions of the melt and various cations proceeds to approximately the same extent, one may postulate that the dependence of the solubility of the oxide on the nature of its constituent metal is determined primarily by the degree of interaction of the metal cation and the oxide ions in the melt, which is an acid–base process as defined by Lux and Flood.

According to Lux and Flood, the equilibrium constant of reaction (1) may serve as a quantitative measure of the acidity of the chemical compound or ion. If all the participants of this reaction are in the dissolved state, then the equilibrium established in the homogeneous system may be regarded as of the acid–base type. However, the solubility of the majority of oxides in melts is limited (the excess oxide precipitates). Thus, the oxide ions are eliminated from the melt not only as a result of the reaction with the cationic acid but also as a result of the formation of another phase (*i.e.* a deposit of the oxide). In the study of the solubilities of oxides in melts by potentiometric titration, one must therefore take into account equilibrium (13). It follows from Eqns (13)–(16) that the binding of the oxide ions by the metal cations is in general a heterogeneous process, as a result of which a new phase (the metal oxide) is formed. In this case, the affinity of the cation M^{2+} cannot be unambiguously related to the completion of the $\text{M}^{2+} + \text{O}^{2-}$ interaction in the melts. The solubility of the oxide (Σs_{MO}) in the melt can be determined, taking into account its incomplete dissociation, as the sum of the activities (concentrations) of the metal cations and the undissociated oxide:

$$\Sigma s_{\text{MO}} = a_{\text{M}^{2+}} + a_{\text{MO}}, \quad (17)$$

where $a_{\text{M}^{2+}}$ and a_{MO} are respectively the activity of the metal cation and of the undissociated oxide in the saturated solution.

Since the concentration of the undissociated oxide in the saturated solution is as a rule extremely difficult to determine, in practice the solubility product P_{MO} is used as the characteristic of the solubility of the oxide:

$$P_{\text{MO}} = a_{\text{M}^{2+}} a_{\text{O}^{2-}}. \quad (18)$$

According to the Law of Mass Action, in the region of saturation of the solution the dissociation constant of the oxide can be expressed in the form

$$K_{\text{MO}} = \frac{a_{\text{M}^{2+}} a_{\text{O}^{2-}}}{a_{\text{MO}}}. \quad (19)$$

Comparison of Eqns (18) and (19) leads to the expression

$$K_{\text{MO}} = \frac{P_{\text{MO}}}{a_{\text{MO}}}. \quad (20)$$

The complete set of the constants characterising the equilibria in the saturated solution of the oxide can be obtained, provided that two parameters of Eqn (20) out of three have been found.

Owing to the lack of well developed and generally accepted methods for the determination of activity coefficients and their dependence on the concentrations of the corresponding species in fused salts, in practice the calculation of concentration parameters is usually resorted to.

1. Methods for the investigation of the solubilities of oxides in melts

In the study of the solubilities of oxides in oxygen-containing and halide melts, different versions of the isothermal saturation and potentiometric titration methods are usually employed.

The isothermal saturation method consists in the successive addition of the test oxide to the solvent melt until the formation of a saturated solution. The instant of saturation is established both with the aid of potentiometric measurements^{85,86} and by a titrimetric procedure (by determining the concentration of the metal forming the oxide in a sample of the melt).⁸⁷ The final result is the determination of the ‘total’ solubility in accordance with Eqn (17), which, when account is taken of Eqns (18) and (20), may be expressed in the form

$$\Sigma s_{\text{MO}} = P_{\text{MO}}^{1/2} + \frac{P_{\text{MO}}}{K_{\text{MO}}}. \quad (21)$$

Naturally, if the potentiometric method with a precalibrated electrode system is used to monitor the degree of saturation, then, knowing the amount of added oxide and the equilibrium molality of the oxide ion in the melt, the parameters of its dissociation can be determined separately. However, this case is more of an exception. Furthermore, in order to obtain a representative selection it is necessary to carry out a series of experiments, which requires much time and a considerable expenditure of reagents.

The method involving the analysis of melt samples⁸⁷ is used fairly widely, but it may lead to distortion of the results as a consequence of the contamination of the sample by suspended oxide particles. It is therefore necessary to take measures to prevent the formation of suspensions in the melt, which greatly complicates the technique of the measurement.

The isothermal saturation method is very convenient in studies over a range of temperatures, but it can hardly be used to determine the solubilities of oxides of the type MgO , NiO , Al_2O_3 , *etc.*, which are extremely sparingly soluble in nitrate and halide melts. As a rule, the data obtained in such investigations do not permit the simultaneous estimation of the solubility product of the oxide and its dissociation constant with the exception of limiting cases where the oxide is either fully dissociated or, conversely, is hardly dissociated. Since the ‘pure’ melt itself contains oxide ions, in the determination of the solubility errors may arise which become especially pronounced if the solubility is comparable to the concentrations of the oxide ion in the ‘pure’ solvent melt.

The potentiometric titration method is applicable over a much wider range. It makes it possible to determine the solubility product and in many instances (when an unsaturated solution region is present on the titration curve) also to calculate the dissociation constants of oxides in melts. Potentiometric studies are as a rule carried out in cells with transport, but this does not lead to significant experimental errors, because the potentials of liquid compounds in melts are insignificant.⁸⁸

2. The KCl–LiCl melt (0.405 : 0.595)

The solubility of the Fe(II, III) oxides in the KCl–LiCl (0.405 : 0.595) melt has been investigated.^{89,90} Potentiometric and diffractometric studies showed that, on precipitation by the donor of oxide ions (CO_3^{2-} , pure FeO is formed, whereas trivalent iron is deposited as the LiFeO_2 – $\text{Li}_y\text{Fe}_{1-y}\text{O}$ solid solution. The solubility products of the iron oxides FeO, Fe_3O_4 , and Fe_2O_3 are $10^{-5.4}$, $10^{-36.3}$, and $10^{-29.16}$ respectively. The Fe^{3+} cations oxidise the chloride melt with liberation of chlorine. An evident disadvantage of these studies is the use of sodium carbonate,

known *a priori* to be incompletely dissociated, as the base, which undoubtedly influenced the calculated solubility products. Furthermore, it is not comprehensible how it was possible to obtain Fe_2O_3 by deposition if the corresponding cation is unstable in the chloride melt.

The qualitative study of the solubilities of oxides in the KCl – LiCl melt at $\sim 500^\circ\text{C}$ was based on the visual monitoring of the solubility.^{91,92} KOH was added to a solution of the chloride of the test metal in the melt. If the oxide was not then precipitated, it was regarded as soluble (CdO , PbO , BaO , CaO , Ag_2O). Otherwise the oxide was regarded as sparingly soluble (CoO , NiO , ZnO) or insoluble (MgO , BeO , Al_2O_3). Copper(II) oxide proved to be unstable in chloride melts and its dissolution was accompanied by the reduction of Cu^{2+} ions to Cu^+ . The chlorides of certain other metals in the highest oxidation states, for example TiCl_3 , FeCl_3 , and AuCl_3 , behave similarly. The addition of the corresponding metal chlorides to a melt containing other oxides led to the dissolution of the latter as a result of the occurrence of reactions of the type

A significant difference between the solubilities of the oxide in 'the powder form' or prepared *in situ*, i.e. by adding KOH to a solution of the corresponding chloride, has been noted. The solubilities of CaO and CdO obtained by the latter method are much higher.

Saturated solutions of various oxides have been investigated polarographically.^{93,94} The degree of interaction of the oxide with the melt was inferred from the potential, the shift of the polarogram, and the change in its form compared with theoretical data. It has been established that, in the electrochemical reduction of a cation, the stage involving the acid–base dissociation of the corresponding oxide is rate-limiting. The stability constants of the oxides were found to have the following values (in mol.%): $\text{CoO} - (9.9 \pm 1.9) \times 10^3$, $\text{NiO} - (6.8 \pm 0.8) \times 10^3$, $\text{PbO} - (3.4 \pm 1.3) \times 10^3$, and $\text{Bi}_2\text{O}_3 - (8.7 \pm 3.5) \times 10^3$. The equilibrium constant for the formation of the plumbate ion from PbO is $(2.0 \pm 1.6) \times 10^2$. Cadmium, copper, and silver oxides were fully dissociated under the experimental conditions, which agrees with other data.^{91,92}

The estimation of the solubilities of a series of oxides was undertaken in order to elucidate the possibility of using the corresponding metal oxide electrodes (electrodes of the second kind) as indicator oxygen electrodes.⁹⁵ The solubilities of the oxides at 500°C were found to have the following values (in mol kg^{-1}): $\text{NiO} - 3.3 \times 10^{-4}$, $\text{BiOCl} - 6.8 \times 10^{-4}$, $\text{PdO} - 9.4 \times 10^{-3}$, $\text{PtO} - 3.32 \times 10^{-2}$, and $\text{Cu}_2\text{O} - 3.8 \times 10^{-2}$.

3. The KCl – NaCl melt (0.50 : 0.50)

The study of the solubilities of CaO , SrO , and BaO over the range of temperatures from T_m to 900°C was carried out by an isotopic method.⁹⁶ Together with the KCl – NaCl melt, the pure individual potassium and sodium chlorides were also used as the solvent. The solubilities of the oxides increased in the sequence $\text{CaO} < \text{SrO} < \text{BaO}$. The solubility products of the oxides in the KCl and KCl – NaCl melts were found to be similar and somewhat lower than in the NaCl melt. Comparison of the experimental data with the results of thermodynamic calculations showed that the solution contains simultaneously both the molecular oxide MO and the M^{2+} and O^{2-} ions formed on its dissociation.

In an analogous investigation,⁸⁷ the solubilities of the oxides in the temperature range 700 – 810°C were determined by measuring the concentrations of the metal cations in the solidified melt specimen using the complexometric titration method. Comparison of the observed solubility products with theoretical estimates made it possible to calculate the activity coefficients of the oxide ions in the saturated solutions studied. The quantities obtained can hardly be regarded as correct, because they are influenced significantly by the incomplete dissociation of the oxides in the melt and by the deviations from ideality of the solution induced by

the presence of doubly charged alkaline earth metal cations and O^{2-} . The contribution of each of these components was not estimated separately.

The acid properties of the Ca^{2+} , Li^+ , and Ba^{2+} cations have been investigated⁹⁷ at 700°C and the constants for the acid–base equilibria

were found as 353 mol.% and 81 mol.% respectively. It follows from these data that all the cations investigated are appreciably acid.

The acidity of the cations of the main subgroup elements weakens with increase in the atomic number of the element, whereas in the Group B elements and in transition series such behaviour is not observed.⁹ Careful analysis of the data of Ovsyannikova and Rybkin⁹ showed, however, that the weakening of the acid properties occurs also in the Zn – Cd diad. Although the above study can in fact be regarded as systematic, it is difficult to extract from it any quantitative data for the estimation of the solubilities of the oxides, since the additional equilibrium (7) is superimposed on the main acid–base equilibrium (14) in the KCl – NaCl melt, because all the cations investigated were added to the melt in the form of sulfates and the influence of this equilibrium was not estimated quantitatively. The use of sulfates should evidently lead to the formation of a deposit and the evolution of SO_3 from the solutions containing the most acid cations.

Furthermore, the results of the above workers⁹ are in direct conflict with the phenomenon of the levelling of basic properties described in the preceding section. According to potentiometric data, the content of O^{2-} at equilibrium in the BaSO_4 solution is ten times higher than in the K_2SO_4 and Na_2SO_4 solutions at the same concentration. The concentrations were found to be higher to a somewhat lesser extent in solutions containing Cs^+ (by a factor of 3.2), Sr^{2+} (by a factor of 2), and Rb^+ (by a factor of 1.2). It follows from the equation

that, when the metal cation in the melt based on sodium salts is a weaker acid than Na^+ , the equilibrium should be displaced to the right and the basicity of O^{2-} is limited by the basicity of Na_2O in the corresponding melt. The addition to the melt of a small amount of a compound with cations less acid than Na^+ should therefore induce the same effect as the addition of an equivalent amount of the corresponding sodium salt (since the authors investigated solutions at a concentration of 0.01 mol kg^{-1} , $\text{M}^{n+}/\text{Na} = 0.0026/n$). However, the results obtained in the above study⁹ conflict with this conclusion.

The solubilities of ZnO , HgO , NiO , and SrO have been investigated by the potentiometric titration method, with the initial transition from the acid to the base and then from the base to the acid.⁹⁸ The characteristics corresponding to the solubility product and the dissociation constant were calculated from the experimental data. Unfortunately the average values of the calculated parameters of the equilibria are not quoted in the above study⁹⁸ (the averaging was carried out by Combes *et al.*⁹⁹). It was found that the calculated values of K_{MO} and P_{MO} for the forward and reverse titrations differ significantly. This constitutes yet another piece of evidence in support of the need to apply a single research technique in the search for correlations. In the sequence $\text{MgO} < \text{NiO} < \text{ZnO} < \text{SrO}$, the solubility increases. In a later study,⁹ a somewhat different series of cations was found. However, preference should be given to the results obtained by the potentiometric titration method.

The solubilities of a series of oxides in the KCl – NaCl melt at 1000 K have been investigated also in other studies.^{85,99–101} Two steps were observed on the Mg^{2+} titration curve: the first corresponded to the formation of Mg_2O^{2+} and the second to the

formation of MgO.⁹⁹ Although the potentiometric studies of the solubilities of MgO in this and analogous chloride melts have been frequently performed, no one else observed a similar phenomenon. There is usually only one e.m.f. jump, corresponding to the reaction

The use of BaO for the titration of alkaline earth metal cations cannot be regarded as correct either, because in this case the substances precipitated are not the individual oxides but their solid solutions with BaO, the solubility of which differs from that of the pure oxide. The principal result of the studies quoted is the conclusion that the solubilities of the oxides increase in the series of alkaline earth metals $\text{MgO} < \text{CaO} < \text{BaO}$ (the solubility of MgO was measured by the potentiometric method and those of the remaining two oxides were found by the isothermal saturation method). The temperature dependence of the solubility of zirconium(IV) oxide in the KCl–NaCl melt assumes the form¹⁰²

$$N_{\text{ZrO}_2} = (-5.7 \pm 3.1) \times 10^{-6} + (7 \pm 3) \times 10^{-9} T.$$

The solubility of ZrO_2 at 700 °C is insignificant even in an acid medium, so that the use of membrane electrodes based on stabilised ZrO_2 should not lead to an appreciable contamination of the test melt by zirconium(IV) compounds.

The solubilities of 11 oxides of s^2 and $3d$ metals at 700 °C have been investigated (Table 2)^{103, 104} The existence of a correlation between the solubilities of the oxides and the crystal-chemical radii of the cations r was established:

$$\text{p}P_{\text{MO}} = \text{p}P_{r \rightarrow \infty} + \frac{k}{r^2}. \quad (22)$$

In a number of instances, the results obtained by different workers^{98–101, 103, 104} agree well with one another, which can be accounted for by the virtually identical experimental conditions (the method for the determination of the solubility, the titrant, the molality of the cation, *etc.*). However, the discrepancies are usually fairly considerable. Such a scatter of the results has not so far been accounted for and the impossibility of a systematic treatment of the results naturally did not promote the development of studies on the solubilities of oxides in alkali metal halide melts.

Solubility data can be divided into two groups depending on the method for their determination (Fig. 2); within each group, the solubilities of one oxide have similar values. A fairly unexpected result of the comparison of the available literature data is the conclusion that the solubilities of oxides found by the isothermal saturation method are as a rule several orders of magnitude lower than the values calculated from potentiometric data, although in the former case one determines Σs_{MO} and in the latter only s_{M}^{2+} .

Figure 2. The solubilities of alkaline earth metal oxides in the KCl–NaCl melt measured by the isothermal saturation (open squares) and potentiometric titration (filled squares) methods: (1) according to the data of Combes and coworkers;^{85, 99–101} (2) according to the data of Delimarskii *et al.*;⁹⁸ (3) according to the data of Shapoval and Tsiklauri;⁹⁷ (4) according to Volkovich's data;⁸⁷ (5) according to the data of Cherginets and coworkers^{104, 110} (at 700 °C).

The higher solubility in melts of oxides prepared *in situ* was first noted by Delarue,^{91, 92} although no explanation of the results was given.

The solubility of any substance depends on the size of its crystals in contact with the solution. For substances dissolving in the form of molecules, this dependence is expressed by the Ostwald–Freundlich formula:¹⁰⁵

$$\frac{RT}{M} \ln \frac{S_1}{S_2} = \frac{2\sigma}{d} \left(\frac{1}{r_2} - \frac{1}{r_1} \right),$$

where S_1 and S_2 are the solubilities of the crystals with the radii r_1 and r_2 respectively, M is the molecular weight, d the density, and σ the surface energy.

For dissociating substances, the analogous equation assumes the form

$$\frac{RT}{M} \ln \frac{P_1}{P_2} = \frac{2\sigma}{d} \left(\frac{1}{r_2} - \frac{1}{r_1} \right),$$

where P_1 and P_2 are the corresponding solubility products.

In particular, it follows from the equations presented that an increase in crystal size leads to a diminution of solubility. For this reason, larger particles should be deposited from concentrated solutions than from dilute solutions. The increase in the size of crystals in a concentrated solution of the cation can be explained

Table 2. The values of $\text{p}P_{\text{MO}}$ and $\text{p}K_{\text{MO}}$ for certain oxides in alkali metal halide melts (on the mole fraction scale).^{103, 104}

Oxide	KCl–NaCl (700 °C)		CsCl–KCl–NaCl (600 °C)		CsCl–KCl–NaCl (700 °C)		CsBr–KBr (700 °C)		CsI (700 °C)
	pP	pK	pP	pK	pP	pK	pP	pK	pP
BaO	4.66		4.75		~4.5		5.16		4.98
SrO	5.44	2.30	5.81	2.71	5.54	2.14	6.82	2.45	6.28
CaO	6.72		7.73	3.71	6.86	2.99	9.93	3.76	7.50

MnO	9.13		9.73		9.49		10.70		
CoO	10.24		10.92		10.50		11.33		
NiO	11.38		12.60		11.42		12.71		
Cu ₂ O	6.53		6.95	3.29	6.35	2.59			
ZnO	9.28		8.80		8.15		11.03		
CdO	7.35		7.54		7.09		9.35		8.00
PbO	7.47	4.47	8.21	5.08	7.04	4.03	8.52	5.81	7.80

by the ageing of the oxide — recrystallisation, which is faster when the concentrations of the reactants increase.

Under the conditions of oxidative titration, a finely dispersed metal oxide is formed and begins to 'age' as a consequence of the occurrence of recrystallisation, *i.e.* of the increase in the size of the crystals and the decrease in the surface energy σS , which leads to a decrease in solubility (solubility products). The recrystallisation is promoted by prolonged maintenance at a high temperature and for a high concentration of the corresponding ions in solution. The first case obtains, in particular, when studies are performed by the isothermal saturation method, where the oxide is subjected to preliminary heat treatment or sintering and the pellets obtained are kept in the melt for several hours. In the second case, the transfer of the substance from small to large crystals is evidently accelerated.

We may note that the solubilities of the oxides quoted by Delimarskii *et al.*⁹⁸ are somewhat higher than those obtained by the present author. This can apparently be accounted for by the fact that the study of Delimarskii *et al.*⁹⁸ was carried out in more dilute solutions (0.01 mol kg⁻¹), where ageing is somewhat slower. A significant disadvantage of dilute solutions is the very marked change in the concentration of the cation during the period of the investigation and hence the poor reproducibility of the results. The measurement of the solubility of NiO in the KCl–NaCl melt may serve as an example. Titration of a solution at a concentration of 0.01 mol kg⁻¹ yields $pP_{\text{NiO}} = 7.95 \pm 0.20$ (Delimarskii *et al.*⁹⁸ obtained 8.32), whereas at a concentration of 0.05 mol kg⁻¹ we have $pP_{\text{NiO}} = 9.03 \pm 0.06$. However, in this case too the values of pP differ by an order of magnitude. The results quoted^{98, 101, 103, 104} for magnesium and barium oxides were obtained by titrating solutions at a concentration of 0.05 mol kg⁻¹ and they agree very well with our data. In the vicinity of the equivalence point, the values of pP_{MO} frequently decrease slightly. This is apparently also caused by the difference between the dimensions of the crystals deposited from the melt.

4. The solubilities of the oxides in other alkali metal halide melts

The solubilities of the oxides of s^2 and $3d$ metals in the CsCl–KCl–NaCl (0.455:0.245:0.30, eutectic) melt have been investigated at 600 and 700 °C (Table 2).^{106–111} A method for the separation of the regions of existence of unsaturated and saturated solutions of the oxides, ensuring that the calculated dissociation constants and solubility products of the oxides respectively are correct, has been proposed and justified. The solubilities of the oxides in lithium-free chloride melts at the same temperature are identical (in mole fractions) and the temperature variation agrees with the Schroeder equation.

The solubilities of the oxides in the 2CsBr·KBr melt at 700 °C are lower than in the analogous system with the Cl⁻ ion.^{112–114} Thus, SrO which is moderately soluble in chloride melts, becomes sparingly soluble in the bromide melt, whilst the sparingly soluble calcium and cadmium oxides become virtually insoluble. The range of oxides the solubilities of which can be investigated in the CsI melt¹¹⁵ is still narrower than in the case where systems with other halide ions are employed (Table 2). The results of the investigations have shown that the iodide melt occupies an intermediate position between the chloride and bromide melts as regards the solubilities of the oxides in it.

The linear dependence of pP on r^{-2} holds for all the alkali metal melts investigated.^{106–115} This makes it possible to employ the relations indicated (Table 3) for the estimation of the solubility products of the oxides from the cationic radii. Furthermore, on the basis of the results quoted,^{110, 111} it is possible to calculate the solubilities of the oxides also at other temperatures by means of the Schroeder equation. When one halide anion of the melt is replaced by another, the degree of association of the melt ions changes, which exerts a decisive influence on the solubilities of the oxides.

Table 3. The coefficients of Eqn (22) for alkali metal halide melts (95% confidence limits).

Melt	$T/^\circ\text{C}$	$pP_{r \rightarrow \infty}$	k
KCl–NaCl	700	1.8 ± 0.9	0.053 ± 0.01
CsCl–KCl–NaCl	600	1.7 ± 2.0	0.057 ± 0.01
CsCl–KCl–NaCl	700	1.7 ± 0.3	0.054 ± 0.02
CsBr–KBr	700	3.2 ± 1.8	0.053 ± 0.01
CsI	700	2.65 ± 0.58	0.052 ± 0.01

The study of the solubility of ZrO₂ in the potassium metaphosphate melt and in KCl–KPO₃ mixtures at 800 °C showed that the solubility of zirconium oxide reaches 1.34 mass % in pure KPO₃ and 3.25 mass % in the equimolar KCl–KPO₃ mixture.¹¹⁶ The increase in the solubility of ZrO₂ with decrease in the KPO₃ concentration is caused, according to the authors, by the depolymerisation of the latter and by the enhancement of the acid properties of the melt. At a KCl concentration above 60 mol.%, the solubility of ZrO₂ falls sharply, apparently owing to the decrease in the acidity of the melt because the intensification of the dissociation of the metaphosphate under these conditions is no longer compensated by the decrease in the concentration of the acid.

The solubilities of nickel and thorium(IV) oxides in the KF–LiF melt at 550 °C have been studied potentiometrically using a membrane oxygen electrode.^{117, 118} The solubility product of NiO is 1.3×10^{-6} , which is appreciably higher than in the chloride melt. The solubility of NiO apparently increases as a result of the formation of stable fluoride complexes of Ni²⁺.

The solubility products (in mole fractions) of Co₃O₄, NiO, and Y₂O₃ at 1100 K in the NaCl melt are $(0.99–3.3) \times 10^{-11}$, $(1.9–4.9) \times 10^{-12}$, and $(1.4–2.2) \times 10^{-36}$, while those in the Na₂SO₄ melt are $(0.8–2.2) \times 10^{-10}$, $(1.6–8) \times 10^{-11}$, and $(4.5–6.4) \times 10^{-31}$ respectively.^{119, 120} The excess titrant leads to the formation of the anionic oxo-complexes NiO₂⁻, CoO₂⁻, and YO₂⁻ in the melt.

The solubility products of zinc oxide and K₂ZnO₂ in the potassium chloride melt at 800 °C are 2.3×10^{-8} and 3.2×10^{-12} respectively.¹²¹

A number of studies have been devoted to oxo-acidity in alkali metal chloride melts to which cations with a high acidity have been added: MgO–BaCl₂–CaCl₂–NaCl,¹²² CaO–CaCl₂–KCl–NaCl,¹²³ CeCl₃–KCl–NaCl,¹²⁴ and ZnO–NaCl–ZnCl₂.^{125, 126} The cationic acids influence significantly the acid–base processes in ionic melts as a result of the binding of the oxide ions. This increases the solubilities of the oxides in such melts (see, for example, Refs 122 and 123).

IV. The reactions of melts with gaseous acid and basic reagents

The gases present in the atmosphere over the melt can react both with its principal components and with impurities. In reactions of the first kind, which include, in particular, hydrolysis, the gas (H₂O) behaves as a Lux–Flood base, supplying O²⁻ ions to the melt. In reactions of the second type (purification of melts by halogenating agents, dissociation of bases), the gaseous reagent is an acid.

1. High-temperature hydrolysis of melts

Reactions of this type have been investigated mainly in relation to individual alkali metal halides and their mixtures. The hydrolysis of the solid and fused sodium chloride in the temperature range 600–950 °C has been investigated by a 'dynamic method',¹²⁷ which consists in passing nitrogen, containing water vapour, through a layer of solid or fused sodium chloride:

The HCl evolved was determined titrimetrically.

The rate of evolution of HCl can be described by the following equation:

$$\frac{dn}{d\tau} = \frac{v p_{\text{HCl}}}{p}, \quad (24)$$

where p is the overall pressure, p_{HCl} the 'equilibrium' partial pressure of HCl, and v the rate of supply of the moist gas.

The equilibrium constant of reaction (23) is

$$K = \frac{\gamma^n p_{\text{HCl}}}{N p_{\text{H}_2\text{O}}}, \quad (25)$$

where γ is the activity coefficient of NaOH in NaCl. Integration of Eqn (24) taking into account Eqn (25) leads to the expression

$$n = \left[\frac{2v N p_{\text{H}_2\text{O}} K}{p\gamma} \right]^{1/2} \tau^{1/2},$$

which is linear in terms of the $n-\tau^{1/2}$ variables. Evidently this relation should pass through the origin of coordinates ($\tau = 0$, $n = 0$). However, it was found that reaction (23) is complicated by the diffusion of NaOH in NaCl and the authors¹²⁷ therefore improved the model by introducing into the latter a correction λ , which is in essence the time required to reduce the diffusional limitations to a minimum:

$$n = \left[\frac{2v N p_{\text{H}_2\text{O}} K}{p\gamma} \right]^{1/2} \left\{ \tau + \lambda \left[\exp\left(-\frac{\tau}{\lambda}\right) - 1 \right] \right\}^{1/2}.$$

The hydrolysis of sodium chloride occurs to a slight extent, although the rate of evolution of HCl exceeded the expected value as a result of hydrolysis on dissolution of NaOH in NaCl.

An evident disadvantage of the above method is the use in it of the hypothesis that the partial pressure of HCl in the gas phase is equal to the equilibrium partial pressure. Judging from the experimental method, it should in fact be much lower, because NaCl is hydrolysed albeit at a low rate.

The same method has been used to investigate the high-temperature hydrolytic and oxidation reactions of sodium iodide.^{128, 129} According to the estimates made, the heats of the reactions

are 32.8 ± 2 and 13.9 ± 1 kJ mol⁻¹ for solid sodium iodide and 30.6 ± 2 and 9.3 ± 2 kJ mol⁻¹ for fused sodium iodide. Hence it follows that the latter shows a greater tendency to oxidise than to hydrolyse. In contrast to NaOH, sodium peroxide is almost insoluble in crystalline sodium iodide. The conclusions reached cannot be adopted without stipulation, because they are based on the values of ΔH and not ΔG for the reactions indicated above.

A simple but unquestionable method has been used to investigate high-temperature hydrolysis in the KCl–NaCl melt.¹⁰¹ A mixture of HCl and H₂O, obtained by passing an inert gas through aqueous HCl solutions at a definite concentration, was passed into the melt. Measurements of the equilibrium O²⁻ concentration by the potentiometric method made it possible to calculate the equilibrium constants for the process

($\text{p}K = 55.3 \times 10^3 T^{-1} - 40.2$). At 1000 K, $\text{p}K \approx 15.1$ and equilibrium (28) is therefore displaced to the left.

A similar method has been used to investigate the hydrolysis of the KCl–LiCl melt at 500 °C ($\text{p}K = 9.77 \pm 0.4$).¹³⁰ The hydroly-

sis of the chloride melt is thermodynamically unfavourable and is fully suppressed in the presence of bases (at a concentration of $\sim 10^{-3}$ mol kg⁻¹).

The cells

where the symbols M and X designate the alkali metal and the halogen respectively, have been used to investigate the hydrolysis of individual alkali metal halide melts (with the exception of lithium salts).¹³¹

The e.m.f. of cell (29) is related to the concentrations of the reactants by the expression

$$E = E^0 + \frac{RT}{F} \ln \frac{P_{\text{H}_2}^{1/2} P_{\text{X}_2}^{1/2}}{P_{\text{H}_2\text{O}}} a_{\text{MOH}},$$

where P_{H_2} and P_{X_2} are the partial pressures of hydrogen and the halogen over the melt respectively.

The logarithms of the equilibrium constants

$$\ln K = \frac{F}{RT} E - \frac{\Delta G_{\text{HX}}^0}{RT} + \ln \frac{P_{\text{H}_2}^{1/2} P_{\text{X}_2}^{1/2}}{P_{\text{H}_2\text{O}}} a_{\text{MOH}}$$

are negative, which indicates that the hydrolysis of alkali metal halide melts is thermodynamically unfavourable. The tendency towards hydrolysis of melts of individual alkali metal halides diminishes with increase in the radii of both the cation and the anion. According to the results of Smirnov *et al.*,¹³¹ the solutions of alkali metal hydroxides in the corresponding individual chlorides are close to ideality.

2. Elimination of oxygen-containing impurities from alkali metal halides

The studies of the elimination of oxygen-containing impurities from melts are as a rule of an applied character and are performed in melts having industrial applications. Various halogenating agents, usually hydrogen halides or the halogens themselves, are used to eliminate the impurities.^{132–138}

where X is the halogen. However, the water formed in reaction (30) exhibits the properties of a Lux–Flood acid, *i.e.*

and this retards the purification process. The cessation of the effect of XH may lead to partial hydrolysis, because, as can be seen from the previous section, the type (30) reactions are reversible. The shift of process (30) to the left is also promoted by the thermal instability of HBr and HI.

The effectiveness of the purification of melts based on lithium salts by hydrogen halides is much lower. Water dissolves in the KCl–LiCl melt in appreciable amounts and is firmly retained at temperatures up to 400 °C.¹³⁹ When dry HCl is passed for 1 h, H₂O is not fully removed.

The effectiveness of the purification by the halogens depends on their oxidation-reduction potentials and decreases from chlorine to iodine. In addition, the latter can disproportionate:

The iodate ions formed are stable in the melts and oxygen-containing impurities are thus not removed from the iodide melt.

The effect of ammonium halides NH₄X involves the formation of the corresponding hydrogen halide as a result of thermal dissociation.^{140–142}

However, the addition of NH₄X is recommended only for the drying and heat treatment of the initial components and its use for

the industrial purification of the fused salts is undesirable because it is much easier to ensure the continuous supply of the corresponding hydrogen halide into the melt being purified. Ammonium halides constitute a very convenient means for the removal of oxygen-containing impurities from melts before the investigation: the addition of these crystalline salts lowers the equilibrium concentration of oxide ions to 10^{-5} – 10^{-6} mol kg $^{-1}$.¹⁰⁹

It is believed that the most convenient method for the elimination of oxygen-containing impurities from alkali metal halide melts is carbohalogenation.^{143–150}

The effectiveness of CCl₄, COCl₂, Cl₂, and the C + Cl₂ mixture (C is acetylenic carbon black) can be explained by the occurrence of the reactions¹⁴³

Thermodynamic analysis of reactions (32)–(34) showed that the effectiveness of the purification is in all cases approximately the same,¹⁴⁴ but reaction (32) has the advantage that highly toxic reagents such as chlorine and phosgene are not used in it. For this reason, CCl₄ has been used in virtually all the subsequent studies involving the carbochlorination of melts.^{145–149}

It has been suggested that CHBr₃, CBr₄,¹⁵⁰ C₂H₅Br, and CH₃I¹⁴² be used for the removal of oxygen-containing impurities from bromide and iodide melts. A significant advantage of carbohalogenation is the fact that this process leads to an appreciable decrease in the concentration of transition metal cations in the melts being purified. However, in the purification of melts by halogen-substituted compounds with a low halogen content, carbon (carbon black) accumulates in the melt and is displaced by the crystallisation front when single crystals are grown.¹⁴³ The presence of a suspension of carbon in alkali metal halide melts is not always desirable and this method cannot therefore be recognised as universal.

The carbohalogenation of the melt leads to the formation of CO₂, which reacts with oxide ions and lowers the equilibrium concentration of O²⁻ and induces the accumulation of the fairly stable carbonate ions CO₃²⁻. The latter are the main form in which oxygen-containing impurities exist in melts purified in this way.

The use of halo-derivatives of silicon for the purification of iodide melts¹⁵¹ is based on the reaction

the product of which is silicon dioxide, which is separated from the melt as a consequence of the differences between the densities. Thermodynamic analysis showed¹⁵² that the effectiveness of the purification of iodide melts diminishes in the sequence SiH₄ > -HI > I₂.

The use of silicon halides for the purification of the melts used in the growing of single crystals does not lead to the appearance of additional impurities, because the processes are carried out in quartz (*i.e.* containing silicon) containers.

Although the methods of purification described are fairly effective in most cases, some kind of oxygen-containing and cationic impurities characteristic of each method always remain in the melt. The method of purification must therefore be selected depending on the aims of the subsequent application of the melt.

3. Dissociation of Lux – Flood bases

The problems of the dissociation of oxide ion donors (Lux – Flood bases) in ionic melts is important both for experimental studies of oxo-acidity and for technological purposes.

Investigators have paid particular attention to strong bases: hydroxide, carbonate, and peroxide ions and barium oxide. The dissociation of the last two bases proceeds in accordance with the equations

The dissociation of barium oxide (see Section III) leads to the accumulation of ‘foreign ions’ Ba²⁺ in the melt. Furthermore, BaO exhibits a limited solubility in ionic melts. This imposes a series of limitations on the practical use of this compound. It should not be used for the investigation of the solubility of alkaline earth metal oxides with which BaO forms solid solutions, for the investigation of acid–base equilibria in solutions of anions in which Ba²⁺ forms insoluble compounds [Ba₃(PO₄)₂, BaCrO₄, *etc.*], and for the investigation of bromide and iodide melts, in which incomplete dissociation takes place.

As regards the remaining three bases mentioned above, their behaviour in ionic melts requires separate consideration. The point is that alkali metal hydroxides distill without decomposition at temperatures above 1300 °C, while sodium and potassium carbonates melt without decomposition at 854 and 890 °C respectively and the CO₂ pressure over their melts is low even at 1000 °C. The thermal dissociation of sodium peroxides begins at 460 °C, whilst K₂O₂ melts without decomposition at 490 °C.⁵¹ Thus the above bases should be sufficiently stable under the conditions of the majority of investigations (200–800 °C).

On the other hand, their dissolution in melts in the absence of conjugate acid gases (H₂O, CO₂, O₂) in an inert atmosphere should lead, according to the Le Chatelier rule, to complete dissociation with formation of O²⁻, which is bound by the melt cations. The degree of decomposition of the base is determined by the concentration and acidity of the cations, the association of the melt ions, temperature, the solubility in the melt of the conjugate acid gas, and its content in the form of impurities in the inert atmosphere. Owing to the diversity and complexity of these factors, the estimation of the strength of the bases from the results of thermodynamic calculations is frequently incorrect. It is therefore difficult to overestimate the contribution of experimental studies to the solution of this problem.

Potentiometric studies of the dissociation of O₂²⁻ in nitrate melts have shown^{153–156} that at temperatures in the range 200–350 °C the main form in which oxygen ions exist in basic media is O₂²⁻, because oxide ions are oxidised in accordance with the reaction

Naturally, the use of a gaseous oxygen electrode in potentiometric studies leads to the appearance in the atmosphere above the melt of gaseous oxygen, which also oxidises the O²⁻ ions. The decrease in the basicity of the melt both owing to the enhancement of the acid properties of the cations constituting the melt¹⁵⁶ and as a result of the decrease in the concentration of oxygen ions^{157, 158} lowers the stability of O₂²⁻. Under these conditions, the main form in which oxygen anions exist in the melt becomes O²⁻.

Studies of the stability of the O₂²⁻ ions in higher-temperature chloride and sulfate melts^{69, 117, 118, 159} have shown that the peroxide ions may be formed in appreciable amounts only in the presence of gaseous oxygen, whilst in an inert atmosphere they are decomposed fully to O²⁻. The constants of equilibrium (35) at 1100 K in NaCl and Na₂SO₄ melts are 0.05–0.07 and 0.03–0.05 respectively.

The behaviour of carbonate ions in nitrate melts has been investigated.^{160, 161} The experimental results show that CO₃²⁻ dissociates fully in these melts and the oxide ions formed are stabilised as a result of the formation of pyronitrate. On the other hand, it has been shown¹⁶² on the basis of potentiometric studies that carbonate ions are not fully dissociated in fused nitrates. In order to establish the truth, cooled specimens of carbonate solutions in nitrate melts were subjected to titrimetric analysis¹⁶³ by standard methods.¹⁶⁴ It was found that the consumption of the acid on each of the two titration steps is the same and carbonate ions are therefore fully stable in nitrate melts.

The temperature dependence of the dissociation constant for the carbonate ion in KCl–NaCl melts is given by the following equation:¹⁶⁵

$$pK_{\text{CO}_3^{2-}} = 1.32 \times 10^4 T^{-1} - 8.4.$$

At 1000 K, $pK = 4.8$. According to Combes *et al.*,¹⁶⁵ the carbonate ion can be used as the reference base at temperatures above 1000 K, because it should be fully dissociated at low partial pressures of CO_2 .

The use of sodium carbonate as a strong base and in the determination of the solubility products of CaO and MgO in the BaCl_2 – CaCl_2 –NaCl eutectic melt at 600 °C has been described.¹²² The study was performed on the assumption that the base employed is fully dissociated without testing it. The correctness of the results obtained is therefore doubtful.

Potentiometric study of the dissociation of the carbonate ion in the KCl–NaCl melt at 700 °C showed⁶⁶ that the carbonate does not dissociate fully even in the absence of CO_2 in the atmosphere over the melt. The ‘formal’ stability constant of CO_3^{2-} , which was understood as the ratio $[\text{CO}_3^{2-}]/[\text{O}^{2-}]$, was 2.5 ± 0.5 (the concentrations were expressed in mol.%). It was postulated that the partial pressure of CO_2 over the melt is constant. It was found that, even at concentrations of the order of 10^{-3} mol kg^{-1} , the degree of dissociation of CO_3^{2-} in the KCl–LiCl melts at 500 °C and in KCl–NaCl at 700 °C does not exceed 70%.¹³⁰ Thus the hypothesis¹⁶⁵ of the complete dissociation of the carbonate ion at temperatures of ~ 1000 K has not been confirmed.

Only a few quantitative studies on the dissociation of OH^- in melts are known. It has been established potentiometrically^{166, 167} that the constant for equilibrium (9) in the KNO_3 – NaNO_3 melt at 500 K is 10^{-18} . This indicates the stability of OH^- ions. There are no data in the studies quoted on the stability of the hydroxide under a dry atmosphere.

The hydroxide ions do not decompose fully in the KCl–LiCl melt at 400 °C.¹⁶⁸ It may be that this is associated with the fact that the above melt retains water fairly strongly.¹³⁹ According to polarographic^{91, 92} and potentiometric¹³⁰ data, an increase in temperature to 500 °C leads to the complete decomposition of the hydroxide.

In order to investigate equilibrium (9), an O^{2-} donor was added to the KCl–NaCl melt, after which the equilibrium e.m.f.’s were measured at water vapour pressures from 1 to 8 mm Hg.^{101, 169} The calculation of the constant for equilibrium (9), based on the e.m.f.’s obtained, showed that the temperature dependence of the pK in the range 737–817 °C is expressed by the equation

$$pK = 8.15 \times 10^3 T^{-1} - 6.75.$$

It has been shown^{130, 170} that the dissociation of hydroxide ions in alkali metal halides does not correspond to Eqn (9) and that the decomposition of OH^- proceeds in accordance with the scheme

The pK values for reaction (36) in the KCl–LiCl melt at 500 °C and the KCl–NaCl melt at 700 °C are 2.76 ± 0.15 and 2.22 ± 0.06 respectively. In the absence of water vapour in the atmosphere over the melt, equilibrium (36) is fully displaced to the right in both systems. The main form of the existence of hydroxide ions in the melts is dimers, while OH^- ions may be present only in trace amounts and do not exert an appreciable influence on the equilibria investigated. A possible cause of the formation of the dimers $(\text{OH})_2^{2-}$ in the melts is the formation of a hydrogen bond. The existence of such bonds in the OH^- –containing NaCl melt has been indicated.^{102, 171}

Thus, among the bases examined, only Na_2O_2 and NaOH dissociate fully at temperatures above 500 °C and may be recommended for investigation. The application of BaO and CO_3^{2-} is

less desirable, because their solubility is limited and they do not dissociate fully even in high-temperature melts.

V. Conclusion

The above analysis of literature data made it possible to discover a series of causes which prevent the development of studies on oxo-acidity in ionic melts. Evidently the existing view that the properties of ionic and molecular liquids are fundamentally different precludes the application of the approaches and rules developed for molecular solvents to the study and treatment of data on oxo-acidity in ionic melts. This state of affairs led to the isolation of studies on oxo-acidity in melts from the investigation of acid–base equilibria in other media. This resulted not only in a low scientific level of the studies carried out (for example, in nitrate melts) but also in the absence of any qualitative development of the field under consideration. Ultimately, studies on homogeneous equilibria virtually ceased completely and the rate of accumulation of data on the solubilities of oxides diminished sharply.

The results of the investigation of acid–base reactions in nitrate melts require a significant revision. It is essential to alter the very approach to further studies on oxo-acidity: the acid–base solubility products should be determined in oxygen-containing melts, while the acid–base equilibrium constants should be determined in oxygen-free melts, having made sure beforehand that the proposed mechanism of the acid–base process corresponds to reality.

The lack of an explanation of the scatter of data on the solubilities of oxides has still remained the main reason retarding the development of this field of study. Such an explanation has now been given on the basis of the Ostwald–Freundlich equation. In order to establish the general rules governing the solubility of oxides in ionic melts, it has been suggested that a single technique be used for the measurements (the same electrodes, identical initial concentrations of reactants). However, the solubilities obtained should nevertheless be treated with a certain degree of caution because the method of preparation of the initial oxide may exert a fairly considerable influence on them (Fig. 2). Studies on the interaction of melts with gaseous reagents have begun to develop, which may be accounted for by the great applied importance of the results.

Overall, the study of the acid–base interactions in melts is far from being completed. After the boom in the development of this field observed in the 1960s–1970s, which did not, however, yield significant results, the time has come to proceed to serious systematic investigations.

VI. On the mechanism of α -metallogenylalkylation reactions	631
VII. Conclusion	633

Abstract. Experimental data on α -metallogenylalkylation reactions are generalised and systematised. These reactions are widely used for the synthesis of different metallocene derivatives, many of which may be of practical importance. Advantages and limitations of different variants of these reactions under homogeneous and heterogeneous conditions are discussed, new approaches to their efficient realisation are offered. The bibliography includes 160 references.

I. Introduction

Dicyclopentadienyl complexes of subgroup VIIIA transition metals (metallocenes) as well as their derivatives played an important role in the progress of the chemistry of π -complexes of transition metals.^{1–4} Reactions with the participation of α -metallogenylcarbocations (MCC) the enhanced stability of which is due to the presence of the electron-donating metallocene fragment in the α -position to the cationic centre are of considerable interest.⁵ With the help of these reactions that we have named ' α -metallogenylalkylation', different α -metallogenylalkylated compounds, especially those that could not be synthesised by other methods, may be obtained.^{6,7}

The early stage in the development of this field of chemistry of organometallic compounds (OMC) has been associated with the elaboration of methods of α -ferrocenylalkylation by trialkyl(ferrocenylmethyl)ammonium salts, chloromethylferrocene, and stable salts of α -ferrocenylcarbocations that allowed one to introduce the FcCH_2^+ group into the molecules of different organic and inorganic nucleophilic derivatives.³ Each of these methods, however, has fundamental limitations in the choice of both the ferrocene-containing derivative and the nucleophilic substrate.

† Mc is $\text{C}_5\text{H}_5\text{MC}_5\text{H}_4$, Fc is $\text{C}_5\text{H}_5\text{FcC}_5\text{H}_4$, Rc is $\text{C}_5\text{H}_5\text{RuC}_5\text{H}_4$, and Oc is $\text{C}_5\text{H}_5\text{OsC}_5\text{H}_4$.

More suitable and diverse ferrocene-containing reagents in these reactions are α -hydroxyalkylferrocenes which readily generate on treatment with mineral or strong carboxylic acids, the corresponding metallocene cations that react further with nucleophiles. Surprisingly, these ferrocene derivatives have not until recently found extensive application in α -ferrocenylalkylation reactions apart from a few special cases.^{8–11}

Annual reviews on ferrocene by Rockett and Marr that have been published over 20 years (the first review was published in 1972, and the last one was published in 1991) in the *Journal of Organometallic Chemistry* usually quoted 5–10 papers on ferrocenylalkyl compounds.¹² There are separate sections concerning the α -metallogenylalkylation reactions in a monograph³ and Gmelin Handbook¹³ containing extensive experimental data accumulated before 1979, however, there is no specialised review covering this subject. The interest in these studies at present does not decline which is associated with the development of the theoretical aspects of structure and reactivity of MCC¹⁴ as well as with the search for convenient methods for the synthesis of valuable ferrocene-containing compounds.¹⁵ The present report is devoted to the analysis and generalisation of the studies of α -metallogenylalkylation reactions performed during the last 15 years.

II. α -Ferrocenylalkylation with ferrocenylalkylammonium salts and other onium compounds

Among the reagents for the introduction of the ferrocenylmethyl group in nucleophilic substrates, most attention was paid to quaternary ammonium salts of *N,N*-dimethylaminomethylferrocene^{3,13} which is due to their availability and high reactivity.^{16,17} In particular, new reactions of *N*-, *C*-, *S*-, and *P*-ferrocenylmethylation of different compounds were performed with the help of *N,N,N*-trimethyl(ferrocenylmethyl)ammonium iodide (**1**).^{18–23} In the presence of alkali or sodium carbonate in all the cases elimination of trimethylamine and the corresponding salt of the hydriodic acid occurs.^{18–20} Thus, new ferrocenylalkyl derivatives of nitrogen bases were synthesised:

Nu = NHNH₂, NHNHPh, NHC(O)NH₂, NHC(S)NH₂,

NHNHC(O)NH₂, NHNHC(S)NH₂, NHNHC(S)NPh,

An 8–10-fold excess of hydrazine hydrate is necessary for the preparation of ferrocenylmethylhydrazine,¹⁸ as the action of a 4-fold excess of the nucleophilic agent on the salt **1** gives the product of complete ferrocenylmethylation of hydrazine, tetrakis(ferrocenylmethyl)hydrazine, with a yield of higher than 80%. Condensation of the salt **1** with AcNHCH(COOEt)₂ in ethanol in the presence of EtONa gives the ethyl ester of *N*-acetyl-3-ferrocenyl- α -alanine, which was separated into enantiomers by column chromatography on solid chiral carriers such as *N*-*tert*-butylamides of L-amino acids.²¹

The condensation of 2-*R*-aziridines with the methiodide **1** in aqueous solution in the presence of potassium carbonate gives 2-*R*-1-(ferrocenylmethyl)aziridines in 70%–75% yields.²⁴

R = H, Me, Et.

In reactions of the methiodide **1** with sodium diethyldithiocarbamate in aqueous medium,¹⁸ or with thiols (RSH) in the presence of EtONa in ethanol,²² or with 2,3,4,6-tetra-*O*-acetyl-1-thio- β -D-glucopyranose in acetonitrile in the presence of sodium carbonate,¹⁹ the corresponding products of *S*-ferrocenylmethylation are formed in 50%–90% yield:

When a mixture of equimolar amounts of methiodide **1** and sodium diethyl phosphite was refluxed for 17 h in anhydrous xylene, the product of *P*-ferrocenylmethylation, *O,O*-diethyl ferrocenylmethylphosphonate (**3**), was formed in 45% yield.¹⁸ The phosphonate **3** was prepared similarly from ferrocenylmethylpyridinium tosylate (**2**), however, the reaction conditions were milder (refluxing of the reagents for 2 h).¹⁸ The product **3** was also synthesised by the reaction of the salt **1** with triethyl phosphite (the Arbuzov rearrangement) in aqueous medium.¹⁸

Other salts of *N,N*-dimethylaminomethylferrocene can also enter into the ferrocenylmethylation reaction. Thus, upon reaction of different alcohols with the salt **4** in alkaline medium, *O*-ferrocenylmethylation occurs to give ethers **5** in 75%–92% yield.²⁵

R = Et, Bu, C₈H₁₇, CH₂CH=CH₂, CH₂CH₂OCH₂Fc.

It has been found²⁶ that the ferrocenylmethylation of alcohols by the salts of *N,N*-dimethylaminomethylferrocene does not require the isolation of the ammonium salts in the pure state; it is quite sufficient to add the salt-forming reagent such as dichloroethane or *p*-toluenesulfonylchloride to the mixture of ferrocenylmethylamine, the corresponding alcohol, and alkali. This does not result in a decrease in the yields of the ethers **5**.

The betaine, dimethyl-3-sulfopropyl(ferrocenylmethyl)-ammonium (**6**), is yet another rather efficient ferrocenylalkylating reagent.²⁷ This compound reacts readily with different nucleophilic reagents in aqueous medium to form the products of *O*-, *N*-, *S*-, and *C*-ferrocenylmethylation in 92%–97% yield.²⁷

As is evident from the scheme, the second reaction product is sodium *N,N*-dimethylaminopropyl-3-sulfonate, which can be readily separated from the ferrocenylmethyl derivatives due to its high solubility in water.

The activity of the betaine **6** is 10 times higher than that of the salt **1**, which allowed one to perform with its help direct ferrocenylmethylation of ammonia in aqueous solution.²⁷ This resulted in a mixture of products of *N*- and *O*-ferrocenylmethylation, which could be separated by chromatography on alumina.

The salts **1** and **2** under analogous conditions practically do not react with aqueous ammonia.²⁷

The pyridinium derivatives may be successfully used as the ferrocenylalkylation agents. In particular, the interaction of ferrocenylmethylpyridinium tosylate (**2**) with carbamide in methanol results in the formation of ferrocenylmethylcarbamide, while thiocarbamide under the same conditions formed only *S*-ferrocenylmethylthiuronium tosylate.²³

The reactions of the salt **7** with the salts of hydrazoic acid MN₃ in aqueous methanol gives a mixture of the products of *N*- and *O*-ferrocenylalkylation.²³

Not only ammonium (compounds **1**, **2**, **4**, and **6**), but also sulfonium salts **8** proved to be rather efficient ferrocenylmethylation reagents.²⁸ In reactions with sodium cyanide and azide, they gave the corresponding ferrocenylmethylation products in 90% to 95% yield.²⁸

R = Me, Et, CH₂Ph; X = BF₄, ClO₄; Y = CN, N₃.

It is noteworthy that most of the salts, homologues of *N,N*-dimethylaminomethylferrocene of the FcCH(R)N⁺Me₃X[−] (R = Alk) type, are thermally unstable and not easily accessible compounds.^{29,30} Therefore, they did not find extensive application as ferrocenylalkylating reagents. Only the use of the methyl iodide **9** in reactions of α -ferrocenylalkylation of sodium azide and thioctic acid, has been reported.³¹

R = N₃, SCH₂COOH.

The salts of *N,N*-dimethylaminoethylferrocene also turned out to be unstable and could not be isolated in the pure state. For instance, the interaction of amines **10** with MeI in acetone results in the formation of the corresponding substituted vinylferrocenes rather than ammonium salts.^{32,33}

R = H, Ph; R' = Alk, PPh₂, SiMe₃.

The study of the reactivity of different trialkyl(ferrocenylmethyl)ammonium salts in reactions with water in alkaline, neutral, and acidic media has revealed¹⁷ that hydrolysis follows the S_N1 mechanism with the intermediate formation of ferrocenylmethyl cation **11** at the rate-determining stage.

The kinetic isotope effect of the solvolysis of ferrocenyl-1,1-dideuteromethyltrimethylammonium iodide in aqueous medium is not more than 10% at 80 °C ($K_{\text{H}}/K_{\text{D}} = 1.06 \pm 0.04$), while the activation parameters of the reaction at 70–90 °C are close to those for the salt **1** ($\Delta H^\ddagger = 132.6 \pm 3.8$ kJ mol^{−1}, $\Delta S^\ddagger = 54.0 \pm 2.1$ kJ mol^{−1}). These data led to the conclusion³⁴ that in the transition state the α -carbon atom in the carbocation **11** is

bound both with the carbon atom of the five-membered ring of the ferrocene system and with the iron atom; a transition state of the fulvene type is not realised.

Thus, the method of α -ferrocenylalkylation by ferrocenylammonium salts is widely used for the synthesis of numerous derivatives of the ferrocene series, however, it cannot be considered general, as only ferrocenylmethyl compounds may be thus obtained with high yields.

III. Reactions of α -haloalkyl derivatives of ferrocene with nucleophiles

α -Halogen-containing derivatives of ferrocene are unstable at room temperature, they cannot be isolated in the pure state. Tidwell and Traylor³⁵ described the preparation of chloromethylferrocene (**12**) which involved bubbling of HCl through an ethereal solution of ferrocenylmethanol (**13**) in the presence of anhydrous calcium chloride, however neither the isolation procedure nor the constants of the isolated product were reported. When anhydrous hydrogen halides passed either through the solution of vinylferrocene in pentane or through the solution of α -hydroxyethylferrocene in diethyl ether in the presence of Al₂O₃ at −78 °C, α -chloro- and α -bromoethylferrocenes were obtained, and the reaction of bromine with vinylferrocene under the same conditions resulted in the formation of α,β -dibromoethylferrocene.³⁶

X = Cl, Br.

However, all the isolated compounds are extremely unstable and can be stored for several days at low temperature *in vacuo*; they readily undergo hydrolysis in the presence of moisture.³⁶

Chloromethyl- and 1,1'-bis(chloromethyl)ferrocene (**14**) are also formed in the reaction of PCl₃ with the corresponding hydroxyl derivatives of ferrocene **13** and **15** in anhydrous acetone in the presence of pyridine at 0 °C.^{37,38} However, due to their instability, they were used in the α -ferrocenylmethylation reactions of such nucleophilic compounds as sodium azide,²³ carbamide,³⁹ sodium salts of 1,2,4-triazoles^{37,38} and tetrazoles without preliminary isolation. In the latter case, a mixture of 1- and 2-isomers was formed.^{37,38}

The reactions of ferrocene α -hydroxymethyl derivatives **15**–**17** with PCl₃ in the presence of pyridine in anhydrous THF are reported.^{40,41} The chloromethyl derivatives thus formed **14**, **18**, **19** were used without isolation in the α -ferrocenylalkylation reactions of different nucleophilic substrates such as formamidomalonate, phenol, thiophenol, *N*-methylaniline, and acetylacetone.

R = C(NHCHO)(COOEt)₂, OPh, SPh, N(Me)Ph, CH(COMe)₂.

In the reactions of dichlorides **14** with 4,4'-bipyridine in DMF, the corresponding pyridinium salts were synthesised with yields of 80% and 39%.⁴²

M = Fe, Ru.

The reaction of relatively stable α -chlorovinylferrocene with lithium triphenylstannane in a mixture of anhydrous THF and diethyl ether results in the formation of 1-ferrocenyl-1-triphenylstannylethylene in 72% yield.⁴³

α -Ferrocenylalkylation by haloalkyl derivatives of ferrocene did not find extensive application because of the low stability of α -haloalkylferrocenes.

IV. Application of α -hydroxyalkyl- and α -alkenylmetallocene derivatives in α -metallocenylalkylation reactions

The synthetic potentialities of α -metallocenylalkylation of nucleophilic derivatives are primarily determined by the availability of the corresponding organometallic component. α -Hydroxyalkylmetallocenes of the VIIIA subgroup are the most convenient and promising alkylation reagents. They are synthetically accessible and demonstrate high stability at room temperature, while under certain conditions the hydroxy group can easily undergo nucleophilic substitution. α -Alkenyl derivatives of metallocenes have also found application as alkylating reagents. Metallocenylalkylation by α -hydroxyalkylmetallocenes can be subdivided into O-, S-, C-, N-, P- and other types of α -metallocenylalkylation depending on the element that forms a new bond as a result of the substitution of the hydroxy group.

At present, a few methods for the preparation of α -hydroxyalkylmetallocenes are known.^{1-3,7,44-71} Although their consideration is beyond the scope of the present review, the stereoselective reduction of metallocenylketones by lithium aluminium hydride in the presence of optically active com-

pounds⁴⁸⁻⁵⁰ is however worth mention. The enantiomeric metallocenyl-containing alcohols thus prepared on dissolution in acid, form optically active metallocenylcarbocations⁴⁹ that may be used for the synthesis of chiral derivatives of subgroup VIIIA metallocenes by α -metallocenylalkylation. A method of preparation of chiral ferrocenyl alcohols, which allows one to synthesise FcCH(OH)R with an optical purity of higher than 95% and the yields of 80%–89%, deserves special attention.⁷²

Two methodologies of α -metallocenylalkylation^{3,6,7} by alcohols and alkenes, namely, reactions in homogeneous (HS) and two-phase (TS) systems, may be distinguished.

1. Reactions in homogeneous systems

A general method for α -ferrocenylalkylation in a homogeneous system involves the action of triphenylcarbenium salts at room temperature on an equimolar mixture of α -hydroxyalkylferrocene derivative and a nucleophile in a polar solvent, (anhydrous dichloromethane).^{6,73,74} This method proved especially useful for the synthesis of different onium salts, as they may be easily separated from triphenylmethanol, which is a nonpolar side product of the reaction.^{73,74} In the case of non-ionic α -ferrocenylalkyl compounds chromatographic separation of the reaction products is necessary.⁶

In the reaction of the diol **15** with triphenylphosphine under identical conditions different reaction products are formed depending on the reagent ratio.⁶ The bistrisphenylphosphonium salt **20** was obtained in quantitative yield when the ratio of **15**, triphenylphosphine, and triphenylcarbenium tetrafluoroborate was 1 : 2 : 2, while the monotriphenylphosphonium salt **21** was formed in 62% yield when the reagent ratio is 1:1:1.^{6,73} Due to the presence of the hydroxymethyl group, the latter was successfully used in the synthesis of heteroannular disubstituted ferrocene derivatives in a two-phase liquid–liquid system (see Section VI).

In contrast to ferrocenemethanols **13** and **15**, α -hydroxyalkyl derivatives of ruthenocene and osmocene do not react with nucleophilic reagents under the action of triphenylcarbenium salts under the same conditions.⁶ In this case, only the known products of nucleophilic substitution of the triphenylmethyl series are formed.

a. O-Alkylation

Numerous examples of α -ferrocenylalkylation of alcohols and phenols at the oxygen atom by α -hydroxyalkylferrocenes are known.³ These reactions readily proceed in the presence of catalytic amounts of organic (acetic, trifluoroacetic) or Lewis acids in an organic solvent (alcohols, CH_2Cl_2). For instance, re-esterification of butyl vinyl ether by ferrocenemethanol **13** in the presence of mercuric acetate gives ferrocenylmethyl vinyl ether **22**, which readily polymerises under the action of cationic catalysts.⁷⁵

b. S-Alkylation

The reactions of α -hydroxyalkylferrocenes with sulfur-containing nucleophilic reagents have been studied rather thoroughly. For instance, the interaction of the diol **15** or 1,1'-bis(α -hydroxyethyl)ferrocene **23** with dithiols $\text{HSCH}(\text{R})\text{CH}(\text{R})\text{SH}$ or $\text{HS}(\text{CH}_2)_n\text{SH}$ in CH_2Cl_2 in the presence of trifluoroacetic acid leads to the formation of ferrocenophanes with the bridging sulfur atoms,⁷⁶ which are of interest as complex forming ligands.

R = H, Me, Ph; $n = 2, 3$.

The analogous reactions of the diol **15** with mercapto derivatives $(4\text{-RC}_6\text{H}_4)_2\text{X}$, where R = SH, CH_2SH , and X = CH_2 , O under similar conditions give the corresponding paracyclophanes.⁷⁷

X = CH_2 , O.

In reactions of the alcohol **13** with the same mercapto derivatives at a reagent ratio of 2:1, linear products of S-ferrocenylmethylation are formed.⁷⁷

The interaction of the diols **15**, and **23** with bis-mercaptoethers $\text{HS}(\text{CH}_2\text{CH}_2\text{O})_n\text{CH}_2\text{CH}_2\text{SH}$ ($n = 2, 3$) in a mixture of benzene and CH_2Cl_2 in the presence of CF_3COOH under high-dilution conditions, results in mononuclear ferrocenophanes in high yields.^{78, 79}

In solutions with higher concentrations the binuclear products may also be obtained; however, their yields are low (5%–7%).⁷⁹

A binuclear ferrocenophane was synthesised in 87% yield by reaction of the homoannular diol **16** with H_2S in acetic acid.⁸⁰

1,1'-Bis[(α -carboxymethylthio)alkyl]ferrocenes were synthesised in 75%–90% yields in reactions of heteroannular ferrocenyldiols **24** with thioglycolic acid in CH_2Cl_2 in the presence of CF_3COOH . They are formed as a mixture of stereoisomers that could not be separated into enantiomers by TLC.⁸¹

R = Me, Et, Prⁱ.

The reaction of the α -hydroxyferrocenyl derivatives **25** with thiophenol,⁸² $\text{HSCH}_2\text{CH}(\text{OH})\text{CH}_2(\text{OH})$ ⁸³ and thioacetic acid⁸⁴ under the same conditions results in a high yield of the corresponding products of S- α -ferrocenylalkylation.

R = H, R' = H, Me, Et, Prⁱ, Ph; R = Me, R' = Me, Ph;
R'' = SPh, $\text{CH}_2\text{CH}(\text{OH})\text{CH}_2(\text{OH})$, Ac.

The resulting thioacetates $\text{FcC}(\text{RR}')\text{SAc}$ readily undergo hydrolysis and alcoholysis, which allows one to obtain the corresponding thiols and thioethers in high yields.⁸⁴

R'' = Me, Et.

The study of the kinetics of S- α -ferrocenylalkylation of thioglycolic acid under the action of FcCH(Me)OH in CH₂Cl₂ in the presence of CF₃COOH demonstrated that the process has an activation energy of 83.04 kJ mol⁻¹ (see Ref. 85); it is completed in 20 min at 20 °C and results in the formation of the acid FcCH(Me)SCH₂COOH. The authors discovered the intermediate formation of vinylferrocene FcCH=CH₂. Its quantity is minimised in the temperature range of 20–30 °C.

c. N-Alkylation

The synthesis of ferrocenylalkylazide in the reaction of hydrazoic acid with the alcohol **26** (R = Ph) in benzene in the presence of trichloroacetic acid is one of the first examples of N- α -ferrocenylalkylation.⁸⁶

Later, this reaction was extended to a wide range of nitrogen-containing nucleophiles.⁸⁷ Thus the interaction of aniline with alcohols **27** in aqueous medium gives products of N-ferrocenylalkylation in poor yields.^{87,88} Benzylamine and piperidine⁸⁸ under these conditions proved to be non-reactive, which is evidently due to their high basicity in comparison with aniline.

R = H, I, CH₂NHPh.

Heating of equimolar amounts of ferrocenemethanolcarbinol **13** with aniline in AcOH at 130 °C leads to the products of C-ferrocenylmethylation at the aromatic nucleus, which is explained by the possibility of migration of the ferrocenylmethyl group from the nitrogen atom towards the aromatic nucleus at high temperature.⁸⁹

Indeed, heating of N-ferrocenylmethylaniline up to 130 °C results in rearrangement with the formation of the above-mentioned products of C-alkylation with the ratio of *ortho*- and *para*-isomers 1.6:1. However, if the ratio of the starting reagents, the alcohol **13** and aniline, is 2:1, only the products of di- and mono-N-ferrocenylmethylation, PhN(CH₂Fc)₂ and PhNHCH₂Fc, are formed under the same conditions.⁸⁹

The study of the effect of the acidity of the medium on the reaction of the alcohol **13** with different amines has demonstrated that in the case of aliphatic amines the highest yields (up to 97%) are achieved in acetic acid at pH = 5.2–4.9, while in the case of aromatic amines yields of 70%–95% are achieved in aqueous methanol at pH = 7.9–9.7.^{10,90}

R = Bu^t, CH₂Ph, Ph, 4-NO₂C₆H₄, 2,4-(NO₂)₂C₆H₃, C(O)NH₂,

N- α -Ferrocenylalkylation of urea and its derivatives is also performed in high yields (70%–90%) by alcohols **26** in acetic

acid. Usually, alkylation proceeds at the unsubstituted amino-group, however in the case of N,N'-dimethylurea the product of substitution at the N-methylaminogroup has also been isolated. An excess of alcohols **26** results in the formation of the products of the double N,N'-di- α -ferrocenylalkylation in low yields.⁹¹

R = H, Me, Ph; R' = Me, Ph.

A method for the conversion of α -hydroxyalkylferrocenes into amines^{92–94} by substitution of the hydroxyl group under the action of dimethylamine or tetramethyldiaminomethane in the presence of acetic acid or Me₂NH·AlCl₃ in CH₂Cl₂ has been developed.

R = H, Me, Et.

However, the amines formed (R = Me, Et) undergo the Hoffmann degradation on heating in AcOH with the formation of α -substituted vinylferrocenes, which readily polymerise under the reaction conditions.⁹²

Another method for the preparation of α -ferrocenylalkylamines^{95,96} is based on the generation of the corresponding α -ferrocenylcarbocations from α -ferrocenylalkanols in strong acids and their further reaction with amines. It is sometimes possible to isolate the carbenium salts. Thus, the alcohols **26** (R = Me, Ph) under the action of HBF₄ in a mixture of diethyl ether and acetic anhydride are converted into carbenium salts **28**, which have been isolated in the pure state.⁹⁵ They readily react with amines in CH₂Cl₂ to form α -ferrocenylalkylamines.^{95,96}

R = Me, Ph; R' = Me, Et.

Hermann and Ugi^{66,70} synthesised a large series of α -ferrocenylalkylamines by a 'three component' reaction of ferrocene with a carbonyl compound and an amine in a mixture of CCl₃COOH and AcOH in the presence of fluorosulfonic acid.

R, R' = H, Alk, Ph; R'', R''' = H, Alk.

Taking into account the availability of the initial reagents, this reaction may be considered as a simple preparative method for the synthesis of α -ferrocenylalkylamines despite the low yields. Ugi *et al.*⁹⁷ extended this method for the preparation of chiral α -ferrocenylalkylamines which were used for the stereospecific synthesis of peptides.

Successive interaction of α -hydroxyethylferrocene with gaseous HBr in benzene and then with amines results in the corresponding α -aminoethylferrocenes which were synthesised in 60%–85% yields.⁹⁸

R = Me, Prⁱ,

Reactions with ammonia lead to a mixture of mono-, bis-, and tris- α -ferrocenylethylamines.⁹⁸

The reaction of 1,1'-bis(α -hydroxy- β -phenylethyl)ferrocene with the excess of R_2NH under analogous conditions results in a mixture of products, viz., 1,1'-bis(α -amino- β -phenylethyl)ferrocenes (yield 50%–70%) and 1-(α -hydroxy- β -phenylethyl)-1'-(α -amino- β -phenylethyl)ferrocenes (yield 15%–30%).⁹⁹

$R = \text{Me, Et.}$

It is interesting to note that the reaction of 1,1'-bis(α -hydroxyethyl)ferrocene **23** with HBr and then with dimethylamine leads to a more complicated mixture of products, which contains 1,1'-bis(α -dimethylaminoethyl)ferrocene, 1-(α -dimethylaminoethyl)-1'-vinylferrocene, and 1,1'-divinylferrocene in the yields of 35%, 45%, and 15% respectively.⁹⁹ Butler *et al.*^{98,99} suggest that under the specified conditions the alcohols are first converted into α -bromo-, or α,α' -dibromoalkylferrocenes, and then nucleophilic substitution of bromine by the amino group occurs.

Besides amines, the nitrogen-containing heterocyclic compounds, such as 1,2,4-triazole¹⁰⁰ and tetrazole^{100–102} derivatives also readily enter into the reaction of N- α -ferrocenylalkylation. The interaction of the alcohols **26** with 3-nitro- and 3,5-dinitro-1,2,4-triazoles in AcOH results in the formation of the corresponding 1-substituted triazoles whose yields vary considerably (12%–57%).¹⁰⁰

$R = \text{H, Me, Ph; } R' = \text{H, NO}_2.$

The products of the reactions of the alcohols **26** with the substituted triazoles **29** are mixtures of isomeric 1- and 2- α -ferrocenylalkyltetrazoles,¹⁰⁰ the ratio thereof depending on the nature of both the substituent R' in the heterocycle and on the substituent R in the alcohols. In particular, increase in the size of the substituent R results in a decrease in the yield of the 1-isomer.

$R' = \text{H, Me, NO}_2.$

The following results were obtained in the alkylation of the derivatives of tetrazole **29** and 1,2,4-triazole by the diols **15**, and **23** in AcOH.¹⁰⁰ A mixture of all three possible isomers (1,1'-, 2,2'-, 1,2'-) is formed from tetrazole; 5-methyltetrazole gives two isomers (2,2'- and 1,2'-), while only the 2,2'-substituted isomer is obtained from 5-nitrotetrazole. In the reaction of 3-nitro- and 3,5-

dinitro-1,2,4-triazoles only 1,1'-disubstituted products of α -ferrocenylalkylation have been isolated.

The detailed study of the alkylation of tetrazole by α -hydroxyethylferrocene in carboxylic acids¹⁰¹ has demonstrated that in CF_3COOH , 1- and 2-isomers are formed in the ratio of 2.4:1, while in AcOH the ratio between these isomers is close to 1:1. These differences in the isomeric composition are due to the formation of the protonated tetrazole in CF_3COOH , and as a consequence ferrocenylalkylation proceeds *via* a different mechanism.¹⁰¹

The α -ferrocenylalkylation of 5-aryltetrazoles in AcOH, independent of the structure of alcohols **26** and the electronic properties of the substituents in the heterocyclic nucleus, results only in 2-(α -ferrocenylalkyl)-5-aryltetrazoles in 80%–85% yield.¹⁰²

$R = \text{H, Me, Ph; } R' = \text{H, 3-Me, 4-Me, 4-Br, 4-OMe, 3-NO}_2.$

According to Shirobokov *et al.*,¹⁰² tetrazolate-anions and α -ferrocenylcarbocations are the reactive species in this reaction, and the selectivity of the process is determined by steric factors in the substrate and alkylation agent.

In the alkylation of 5-aryltetrazoles by the diols **15**, and **23** under the same conditions, ferrocene compounds containing two tetrazole rings with the C–N bond in position 2 are formed.¹⁰²

$R = \text{H, Me.}$

d. C-Alkylation

There are only few examples of the reactions of α -hydroxyalkylferrocenes with CH-acids performed in homogeneous systems.¹⁰³ The CH-acids with activated methylene and methine groups have been most studied. Thus heating of alcohol **13** with the C-substituted diethyl malonates in DMF gave the corresponding ferrocenylmethyl derivatives in 40%–50% yield.¹⁰³

$R = \text{H, Me, Ph.}$

α -Hydroxyalkylferrocenes react with organomagnesium compounds¹⁰⁴ to form a multicomponent mixture. It should be noted that under these conditions neither diphenyl- nor triphenylmethanols react with MeMgI .¹⁰⁴

$R = R' = \text{Me, Ph; } R = \text{H, } R' = \text{CH=CHPh; } R = \text{H, } R' = \text{Ph; } R'' = \text{Me, Et, X = Br, I.}$

e. Se-Alkylation

The interaction of the diol **15** with hydrogen selenide in AcOH in the presence of CF_3COOH , resulting in the formation of 2-seleno-[3]-1,1'-ferrocenophane in 51% yield, has been reported.¹⁰⁵

2. Reactions in two-component systems

Reactions of α -hydroxyalkylmetallocenes with different nucleophilic compounds proceed most efficiently in two-component systems, such as liquid-liquid (system *A*)¹⁰⁶ and liquid-solid (system *B*).^{73, 107} In the former case, the reaction of equimolar amounts of α -hydroxyalkylmetallocenes and nucleophilic substrates is carried out at room temperature with vigorous stirring in a two-phase system consisting of an organic solvent (CH_2Cl_2 , $\text{C}_2\text{H}_4\text{Cl}_2$, CHCl_3 , CCl_4 , or benzene) and aqueous solution (45%–70%) of an acid HX ($\text{X} = \text{BF}_4$, ClO_4 , or I).^{106, 108} Under these conditions reactions proceed predominantly at the organic-inorganic interface: the organic phase contains the hydrophobic metallocene-containing compound (initial and/or reaction product), and the aqueous phase contains acid HX and/or water-soluble reaction products (NaX , KX , BrMgX , etc.). The polar hydroxy group of the organometallic substrate is probably exposed to the aqueous phase and is thus available for protonation, while the metallocene nucleus, on the contrary remains in the organic phase and is not subjected to protonation and oxidation. The procedure of α -ferrocenylalkylation in the system *A*, allows one on the one hand, to attain high acidity at the interface ($H_0 = -7$ to -9),¹⁰⁹ which facilitates the formation under mild conditions of thermodynamically stable MCC,⁵ and, on the other hand, to reduce the possibility of oxidation of the metallocene-containing substrates, which readily occurs in acidic media.¹¹⁰ This is obviously due to the small probability for the contact (except for the interface) of the metallocene-containing component in the organic phase with the acid HX in the aqueous phase. The carbenium reaction centre and the non-polar part of the MCC formed are in different phases. Therefore, the efficient interaction of the carbenium centre with the corresponding nucleophilic reagent may occur, other side reactions (rearrangement, dimerisation, polymerisation, formation of ethers, etc.) which are characteristic of the MCC are practically excluded.^{1–4}

When system *B* is used,^{73, 107, 111} the interaction of the equimolar amounts of α -hydroxyalkylmetallocenes with the nucleophilic reagents occurs under vigorous stirring of an organic solvent (CH_2Cl_2 , $\text{C}_2\text{H}_4\text{Cl}_2$, CHCl_3 , benzene, or xylene) and solid (cation-exchange resins or zeolites in the H-form). In this case, the formation of the corresponding MCC occurs only in the adsorption layer on the surface of the solid phase, they react further with the nucleophilic substrate. As in the case of system *A*, side transformations of MCC are minimal.

The above-mentioned advantages and peculiarities of the α -metallocenylalkylation in the two-phase systems *A* and *B* allow one to extend considerably the range of both metallocenyl and nucleophilic reagents and to increase the yields and purity of the products isolated. Moreover, reactions of organometallic compounds can be thus performed in aqueous-organic media in air rather than in anhydrous solvents and in an inert atmosphere.

For the sake of completeness and for better systematisation of the synthetic data, and convenience of their use, the information of this section is presented largely in the form of tables containing the detailed information concerning the initial compounds and reagents, reaction conditions, yields, and the structure of the products of α -metallocenylalkylation.

a. C- α -Metallocenylalkylation

Weak CH-acids, activated aromatic, organomagnesium and organomercury derivatives, and alkyl derivatives of ferrocene may be used as nucleophilic reagents when reactions are performed in the two-phase systems *A* and *B*. Various α -hydroxymetallocenyl derivatives of the subgroup VIIIA elements were used in these reactions (Table 1), however, their structural peculiarities in most cases only slightly affected the character of the products formed. The choice of the nucleophilic reagents was mostly determined by both their reactivity and the stability of the functional groups of the molecule under the reaction conditions.

In the system *A*, α -hydroxymetallocenyl derivatives (Table 1) react¹⁰⁸ only with CH-acids with pK_a 's in the range of 9–13.¹¹⁷

Compounds with lower mobility of the hydrogen atoms ($pK_a = 16$ –21),¹¹⁷ such as phenylbenzoylmethane, acetophenone, acetone, and fluorene, do not react under these conditions.¹⁰⁸ It is interesting that phenol and α -naphthol react neither in the system *A*, nor *B*.^{108, 112}

The interaction of α -hydroxyalkylmetallocenes with highly nucleophilic aromatic compounds (Table 1) in the systems *A* and *B* occurs¹¹² chemoselectively in accordance with the general features¹¹⁸ of electrophilic substitution. In this case, it is possible to introduce sequentially several similar or different metallocenylalkyl groups into the molecules of nucleophilic compounds.

Under the conditions described, organomercury or organomagnesium compounds may enter into the metallocenylalkylation reaction. The direction of the reaction in this case sometimes greatly depends on the peculiarities of the nucleophile structure. Thus, the reaction of 1-bromomagnesiumindole with the alcohols **13** or $\text{CpRuC}_5\text{H}_4\text{CH(R)OH}$ in the system *A* gives only products of N- α -metallocenylalkylation (Table 2) rather than C-alkylation.¹¹² In the system *A*, the organomagnesium derivatives RMgBr with alkyl radicals ($\text{R} = \text{Me}$, Et , CH_2Ph , $\text{CH}_2\text{CH}=\text{CH}_2$) decompose with the elimination of the corresponding hydrocarbons RH , the decomposition is too fast to allow reactions with alcohols.¹¹² Reactions of these alcohols with organomagnesium compounds, containing aryl radicals or with Iotsich reagents gives the products of decomposition of initial reagents (benzene, naphthalene, phenylacetylene) in 10%–25% yields together with the products of α -metallocenylalkylation (Table 1).¹¹² Also, the reaction of Grignard reagents with the alcohol **13** gives 2%–3% of 1,2-diferrocenylethane, while in the reaction with $\text{CpRuC}_5\text{H}_4\text{CH(Me)OH}$, 3%–5% of polymeric substances are formed.¹¹²

The interaction of α -hydroxyalkylmetallocenes with the organomercury compounds R'HgBr in the system *A* containing different types of protic acids HX , in most cases results in the products of α -metallocenylalkyldemercuration with considerably variable yields (see Table 1).¹¹⁶ In this case, side products are also formed: R'H , polymeric compounds, and mercury-containing metallocenes. Obviously, the formation of R'H occurs as a result of the competitive protodemercuration of the initial mercury-containing derivatives, which in many cases is the main direction of the reaction. It has been found,¹¹⁶ that the activity of the mercury-containing substrates in α -metallocenylalkyldemercuration reactions decreases with the decrease in the electron accepting character of the R' radicals in the series: $\text{CH}_2\text{CHO} > \text{CH}_2\text{C(O)Ph} > \text{CH}_2\text{C(O)Me} > \text{CH}_2\text{COOMe} > \text{Ph} > \text{Alk}$.

The maximum yields of the products of α -metallocenylalkyldemercuration were achieved when 56% HI was used, while the minimum yields were observed with HCl , HClO_4 , and HBF_4 .¹¹⁶ This can probably be explained by the specific role of the iodide ion: because of its high nucleophilicity iodide is readily coordinated by the mercury atom, thus polarising the $\text{C}-\text{Hg}$ bond of the initial complex.¹²⁰ As a result, the reactivity of R'HgBr is enhanced at the final stage of α -metallocenylalkyldemercuration.

Comparison of the yields in bromomercurioacetaldehyde reactions with different α -hydroxyalkylmetallocenes in the two-phase system $\text{CH}_2\text{Cl}_2 - \text{HI}$ testifies¹¹⁶ that their activity changes in the series: $\text{FcCH}_2\text{OH} > [\text{FcCH(Me)OH}; \text{RcCH(Me)OH}] > \text{FcCH(Ph)OH} > \text{OcCH(Ph)OH}$. This regularity is presumably determined by the increase in the steric hindrance of the hydroxy group. The nature of the metal atom in this case practically does not affect the yields of the products of α -ferrocenylalkyldemercuration.¹¹⁶

In contrast to α -hydroxyalkylferrocenes,¹¹⁵ the analogous ruthenocene and osmocene compounds do not give the corresponding derivatives of 1,2-dimetallocenylethane in reactions with powdered copper in system *A*.⁶

In system *A*, it is possible to perform the alkylation of ferrocene and its homologues, sym-octamethyl- and 1,1'-diethylferrocene; the corresponding binuclear diferrocenylalkanes were

^a Reagent ratio is 2 : 1.

thus formed in high yields.¹¹⁴ In this system, the 1,1'-diethylferrocenium salt can also be alkylated:⁷

It is difficult to interpret this result without additional data, however, it may be suggested that this process occurs as a result of reduction of the ferrocenium cation and further alkylation of diethylferrocene formed according to the usual scheme. Another possible interpretation of this reaction may be intramolecular electron transfer in the methylferrocenylcarbenium cation followed by free radical substitution in the 1,1'-diethylferrocenium cation.

b. N- α -Metalloce nylalkylation

Many reactions of α -hydroxymetalloce nyl derivatives with different nitrogen-containing nucleophilic agents were performed in the systems *A* and *B*.^{6, 28, 46, 51, 73, 108, 112, 119, 121–124} Both non-ionic (Table 2) and onium (Table 3) organometallic derivatives were synthesised in high yields. In most cases, no special purification techniques were necessary.

Unlike urea (Table 2), thiourea gives only thiouronium salt $\text{FcCH}_2\text{S}^+ = \text{C}(\text{NH}_2)_2\text{BF}_4^-$ in reaction with alcohol **13** in the system *A*.¹⁰⁸

The interaction of aromatic bis-amines (Table 2) with two equivalents of the alcohol **13** and acid HX (system *A*) gave the products of N,N'- α -ferrocenylmethylation, which were isolated in the form of the corresponding salts (Table 2). Under the action of alkali on these salts the elimination of the acid HX and the formation of free bases occurred.¹⁰⁸

Under analogous conditions, the action of two equivalents of the alcohol **13** on urea¹⁰⁸ and the sodium salt of benzotriazole¹¹⁹ the products of N,N'-di- α -ferrocenylmethylation are formed. The same compounds were synthesised in higher yields by the action of the alcohol **13** on the corresponding mono- α -ferrocenylmethylated derivatives under the conditions of system *A* (Tables 2, 3). When the alcohols **26** were used in these reactions, asymmetric products of N,N'-di- α -ferrocenylalkylation of urea, $\text{FcCH}_2\text{NH} \cdot \text{C}(\text{O})\text{NHCH}(\text{R})\text{Fc}$ (R = Me, Ph), were synthesised.⁶ However, the formation of urea derivatives di-substituted at one nitrogen atom, has not been observed, which is presumably due to steric hindrance.

Comparison of the yields (Tables 2, 3) of the structurally similar reaction products reveals that in system *A* they depend only slightly on the nature of the metallocene nucleus, while with increase of the bulk of the substituent at the α -carbon atom (from H to Ph) the yields decrease monotonically.

The correlation between the basicity of the nitrogen-containing derivatives and their capacity to undergo α -metalloce nylalkylation in systems *A* and *B* has been analysed.^{6, 7} In the presence of acid HX or a cation-exchange resin KU-2, the metalloce nylalkylation of the nitrogen-containing nucleophilic compound at the nitrogen atom may also be accompanied by protonation.¹¹⁸ Therefore, the basicity of the nucleophilic substrate is one of the main factors determining the direction and the extent of metalloce nylalkylation.

It is quite clear from the analysis of the results^{6, 7} that nitrogenous bases with $\text{p}K_a > 7$ (ammonia, aliphatic amines) cannot be alkylated in system *A*. Only their protonation at the nitrogen atom

with formation of the corresponding salts occurs with quantitative yields. Compounds with $\text{p}K_a$ between 6 and 4 give the products of N- α -metalloce nylalkylation in poor yields, while the yield of the salts amounts to 80%–85%. The nitrogen-containing substrates with $\text{p}K_a$ value in the range from 4 to –6 react readily with α -hydroxyalkylmetallocenes in system *A* to give high, frequently quantitative, yields (Tables 2, 3) of the corresponding N- α -metalloce nylalkylation products. The formation of salts in this case is not observed. Finally, the extremely weak nitrogen-containing bases with the $\text{p}K_a < -6$ (trinitroaniline, pentachloropyridine) do not enter into the reaction of metalloce nylalkylation in system *A*.⁶

The important role of the solvent is to be emphasised. The use of CH_2Cl_2 and the like allows on the one hand, the synthesis of α -metalloce nylcarbocations in the active form *in situ*, which is due to the low donor activity of CH_2Cl_2 . On the other hand, because of the low solubility of CH_2Cl_2 in water, a two-phase system may be formed, which prevents oxidation of the products of metalloce nylalkylation, which are usually present in the organic phase.

In system *B*, with a 3–5-fold excess of the cation-exchange resin KU-2, compounds with high basicity, such as piperidine and, diethylamine (Table 2), as well as those with low basicity, *e.g.*, 4-bromoaniline or acetamide, readily undergo N- α -ferrocenylalkylation.¹⁰⁴ In this case, the excess of the cation-exchange resin KU-2, ensures the protonation of the highly active nitrogenous compounds and generation of the corresponding electrophilic intermediates from α -hydroxyalkylferrocenes; these intermediates further react with the nitrogen-containing substrates. The shift of the equilibrium of this reaction towards the formation of the alkylation products occurs presumably as a result of efficient desorption of the more hydrophobic N- α -ferrocenylalkylamines from the surface of the cation-exchange resin into the organic phase, dichloromethane.

Thus, the use of the two-phase systems *A* and *B* allows one to perform N- α -ferrocenylalkylation of a variety (Tables 2, 3) of nitrogen-containing nucleophilic compounds with $\text{p}K_a$ spanning a range of more than 15 units.

For the synthesis of biologically active compounds, α -ferrocenylalkylation of nucleotide bases, nucleosides, and DNA has been recently performed under the conditions of system *A*.¹²⁵ α -Hydroxyethylferrocene was used as the alkylating agent; it was possible to introduce α -ferrocenylethyl groups into the molecules of the above-mentioned substrates. According to the analysis of the products, the reaction may follow different routes. The IR and NMR data allow one to suggest that N- α -ferrocenylalkylation occurs at different nitrogen atoms of heterocyclic bases of nucleotide bases, nucleosides and DNA.¹²⁵

c. P- α -Metalloce nylalkylation

Reactions of α -hydroxyalkylmetallocenes with different types of organophosphorus compounds in the two-phase systems *A* and *B* have been studied.^{6, 28, 46, 51, 73, 124, 126} It was found⁶ that in reactions of equimolar amounts of the metallocene alcohols **30** with diphenylphosphine ($\text{p}K_a = -0.20$)¹²⁷ in the system *A*, trisubstituted phosphines **31** were formed as a result of α -metalloce nylalkylation at the phosphorus atom (72%–92%).

Mc = Fc, Rc, Oc; R = H, Me, Ph, CH=CHFc, C $\equiv$ CFc;
X = BF₄, ClO₄.

Unlike diphenylphosphine, diethyl phosphite does not react with the alcohols **30** in system *A*,⁶ however its sodium salt readily reacts with ferrocenemethanol **13** in the two-phase system benzene–aqueous HX⁶ with the formation of the phosphonate **3**, the product of P-ferrocenylmethylation.⁶

It should be noted that the triphenylphosphonium salts **33**–**38** and phosphonate **3** may be used as reagents in the Wittig and Horner¹²⁷ reactions for the synthesis of unsaturated compounds of the subgroup VIIIA metallocenes.^{46, 124, 126}

d. S- α -Metallocenylalkylation

In contrast to CH-acids and nitrogen-containing compounds with an N–H bond, compounds containing SH groups do not react with α -hydroxyalkylmetallocenes in the two-phase systems *A* and *B*.⁶ However the interaction of alcohols **30** with sodium thiocyanate, sulfide, methanethiolate, *N,N*-diethyldithiocarbamate, thiophenoxide, and arenesulfonate in the systems *A* and *B* gives S- α -metallocenyl compounds (**40**–**43**) in 60%–90% yields.^{73, 108, 112}

R = H, Me, Ph, CH=CHFc; R' = Me, Ph, C(S)NEt₂; R'' = H, Me.

It was estimated by IR-spectroscopy that in the course of reactions with sodium thiocyanate rearrangement products, the corresponding isothiocyanates **40**, are not formed.⁶

The reactions of α -ferrocenylalkylation of the bifunctional nucleophiles **44**–**46** containing both nitrogen and sulfur atoms as two reaction centres with the alcohols **26** in systems *A* and *B* yield the products of both N- and S- alkylation.¹²² Ferrocenylalkylation of 2-mercaptobenzothiazole (**44**) and 2-mercaptobenzimidazole under the action of equimolar amounts of alcohols **26** and HBF₄ occurs at the sulfur atoms in 80%–90% yields.^{7, 122}

R = H, Me, Ph.

The analogous reaction of *S*- α -ferrocenylalkylation occurs also under the action of ferrocenemethanol **13** on 2-methyl-6-(5-mercapto-1-tetrazolyl)-benzothiazole, **45** but under more rigorous conditions.¹²²

In reactions of equimolar amounts of sodium 2-methylquinoline-8-thiolate **46**, the alcohol **13**, and HBF₄, a mixture of products of ferrocenylmethylation at both sulfur **48** and nitrogen **49** atoms is formed.¹²²

The interaction of sulfides with the alcohols **30** in system *A* leads to *S*- α -metallophenylalkylsulfonium salts **50** in 50%–100% yields.^{28, 51, 124}

R' = Me, Et, CH₂Ph; X = BF₄, ClO₄.

It has already been mentioned above that, like trialkylferrocenylmethanilium salts, the salts **50** also proved to be efficient α -metallophenylalkylating reagents.^{28, 124}

e. *Sb*- α -metallophenylalkylation

The α -metallophenylalkylation by alcohols **30** of triphenylantimony in the two-phase system *A* has been described.⁶ The triphenylstibonium salts **51** are formed in this reaction.

Mc = Fc, Rc, Oc; R = H, Me.

It turned out that the yields of the salts **51**, in contrast to the triphenylphosphonium salts, depend to a considerable extent on both the size of the substituents R at the α -carbon atom and on the size of the metal atom in the metallocene core. Increase in the steric hindrance lowers the yields from 74% to 17%;⁶ in the case of hydroxy derivatives of ruthenocene and osmocene and R = Ph the triphenylstibonium salts are not formed at all.⁶

f. α -Metallophenylalkylation by vinylmetallocenes

Similarly to the α -hydroxyalkylmetallocenes, vinyl derivatives of ferrocene, ruthenocene, and osmocene **52** may be also successfully used in α -metallophenylalkylation reactions^{6, 115, 124} for the synthesis of the same products. For instance, in systems *A* and *B*^{6, 115} 2,3-diferrocenylbutane was obtained in the presence of powdered copper in 70%–72% yields (see Table 1), while the interaction of alkenes **52** with triphenylphosphine in the system *A* leads to the

corresponding triphenylphosphonium salts **53** with 80%–95% yields.^{6, 124}

X = BF₄, ClO₄.

V. α -Hydrogen-containing metallocenes in α -metallophenylalkylation reactions

New methods of α -metallophenylalkylation of nucleophilic substrates with the use of α -hydrogen-containing metallocene derivatives as alkylation agents have been proposed.^{6, 74, 128} For instance, the action of triphenylcarbenium salts on an equimolar mixture of α -hydrogen-containing derivatives of ferrocene and nucleophile in anhydrous dichloromethane gives the corresponding products of α -ferrocenylalkylation and triphenylmethane in high yields.^{6, 128}

However, the α -hydrogen-containing ruthenocene and osmocene derivatives turned out to be unreactive.⁶

A more general method of α -metallophenylalkylation of nucleophilic compounds by α -hydrogen-containing metallocene derivatives of subgroup VIIIA was proposed by Boev.⁷⁴ The essence of this method is as follows: at first, α -hydrogen-containing derivatives of metallocenes are treated with oxidizing agents (AgClO₄, AgBF₄, FeCl₃) in dichloromethane, then an equimolar mixture of a free radical (triphenylmethyl or Fremy's salt¹²⁹) and a nucleophilic substrate is added to the oxidation products. As a result, the products of substitution of the α -hydrogen atom by a nucleophile are formed with high yields. In the case of the use of Fremy's salt (KSO₃)₂N–O• and anionic nucleophiles (NaNu), the second step of the process is performed in a two-phase system CH₂Cl₂–H₂O with intense stirring at room temperature.^{6, 74}

Mc = Fc, Rc, Oc; R = R' = H; R = H, R' = Me; R = H, R' = Ph;

Nu[−] = CN[−], N₃[−], PhS[−], PhO₂S[−]; X = BF₄, ClO₄.

Along with the target products, triphenylmethane (in 86% to 94% yield) or potassium hydroxylamine disulphonate (in 80% to 90% yield) were isolated.

VI. On the mechanism of α -metallophenylalkylation reactions

The analysis of literature data^{3–11} reveals that all reactions of α -metallophenylalkylation proceed *via* the formation of thermally stable ^{3,5} α -metallophenylcarbocations (MCC), the mechanism of their formation depending on both the nature of the initial

substrates and on the reaction conditions. The MCC then react quite rapidly with the nucleophilic reagents to yield the products of α -metallocenylalkylation. Some researchers^{3,8,10,17} believe that the mechanism of these reactions may be classified as S_N1 .

$X = \text{NMe}_3^+, \text{SMe}_2^+, \text{Hal}, \text{OH}; \text{Mc} = \text{Fc}, \text{Rc}, \text{Os}.$

Unfortunately, no special kinetic studies that would confirm the formation of MCC as a kinetically independent species corresponding to a definite point on the reaction coordinate have been performed so far, but a series of indirect experimental data support an S_N1 mechanism.

In particular, it has been shown by numerous experiments,^{6,7} that α -metallocenylalkylation in the two-phase systems *A* and *B* may proceed only at the interface of phases with high acidity ($H_0 \approx -7$ to -9).¹⁰⁹ It is under these conditions that the generation^{3,5} of metallocenylcarbocations from α -hydroxyalkyl- and α -alkenylmetallocenes readily occurs. In this case, the proton is thought to attack the oxygen atom of the hydroxyl group or the double bond as centres with the highest nucleophilicity in the substrates.

Attack of the proton at the metallocene fragment is also possible, as it is known¹⁻³ that ferrocene, ruthenocene, and osmocene, under certain conditions, can be protonated. It has however been established by Boev,⁶ that these metallocenes practically do not undergo any changes under the action of aqueous acids HX ($X = \text{BF}_4, \text{ClO}_4$) or a cation-exchange resin KU-2 in systems *A* and *B* (according to UV and NMR data), while in the presence of nucleophilic reagents only the salts of the latter are formed. Besides, as has been mentioned above, the metallocene nucleus in the two-phase systems is in the organic phase and therefore it is inaccessible to protons. Therefore, initial attack of the proton at the metal atom, as the potential basic centre in organometallic substrates in the two-phase systems *A* and *B*, may be excluded.

On the other hand, the action of aqueous acids HX on α -hydroxyalkylmetallocene derivatives^{6,108} and vinylferrocene⁶ in dichloromethane in the absence of the nucleophilic substrates results in the quantitative formation of MCC (according to UV-spectral data), identified by comparison with the authentic^{95,124} species. Therefore, high acidity of the medium, that arises at the interface in the system *A* guarantees the efficient formation of the corresponding MCC from vinylferrocene and ferrocenyl-alkanols. The study of the reactions of the authentic MCC with different nucleophiles has shown that they lead to formation of the corresponding derivatives of FcCHRNu type with quantitative yields.⁶

All these data indicate that MCC correspond to a definite point on the reaction coordinate of metallocenylalkylation.

In the two-phase system *B* (liquid–solid phase), the formation of MCC may occur only at the surface of KU-2 in the H-form. This is indirectly confirmed by the fact that the rate and the yield of the reaction of α -metallocenylalkylation in the system *B* are directly affected by the intensity of mixing of the reaction system, that is by the efficiency of the contact of the reacting substrates with the surface of the cation-exchange resin KU-2, where the MCC is generated.^{6,73}

The observation⁷³ (both visual and microscopic) of the resin surface during the reaction leads also to the conclusion of possible generation of MCC at its surface. At first, the resin grains change their colour from light-brown to dark-red or dark-blue, which is characteristic of MCC,³ and then as the MCC formed react with nucleophiles, the initial light-brown colour is restored.

The comparison of the rate of reactions of the ferrocene-containing alcohols of different structural types with aqueous solutions of HX and triphenylphosphine (system *A*) by the

method of competing reactions¹²⁴ demonstrates that the activity of alcohols in alkylation reactions decreases with the increase in the steric hindrance at the α -carbon atom independently of the thermodynamic stability (pK_{R^+}) values of the corresponding carbocations.³

$pK_{R^+} \quad -1.75 \quad -3.20 \quad -0.92 \quad -0.15 \quad +4.18$

The activity of the structurally similar alcohols of ferrocene, ruthenocene, and osmocene decreases with decrease in the pK_{R^+} of the corresponding carboxylic acids in the following series:¹²⁴ $\text{OcCH(Me)OH} (+1.75) > \text{RcCH(Me)OH} (+1.20) > \text{FcCH(Me)OH} (-0.92).$

The generation of MCC from α -hydrogen-containing metallocene derivatives in reactions of α -metallocenylalkylation of nucleophiles presumably proceeds in a different way. In this case, MCC are formed as a result of the oxidative dehydration of α -hydrogen-containing metallocene derivatives subjected to the action of the triphenylcarbocation salts.¹³⁰

An analogous mechanism is presumably realised in the reaction of the α -hydrogen-containing metallocene derivatives first with an oxidant and then with a mixture of the stable radical with a nucleophile.⁷⁴

$(\text{R}')^\cdot = \text{Ph}_3\text{C}^\cdot, (\text{KSO}_3)_2\text{NO}^\cdot.$

Thus, the reactions of α -metallocenylalkylation of nucleophilic reagents may proceed according to two alternative mechanisms depending on the nature of the initial reagents and the reaction conditions.

One of them, the S_N1 mechanism, is realised in reactions of ammonium,³ and sulfonium¹²⁴ salts, or of α -halogen derivatives³ of metallocenes with the nucleophilic reagents, or in reactions of α -hydroxy or α -alkenyl derivatives of metallocenes with acids HX or a cation-exchange resin in the two-phase systems *A* and *B*.^{6,7}

Another mechanism, $S_{RN}2$,^{4,6} is involved in the consecutive interaction of α -hydrogen-containing metallocene derivatives with one-⁷⁴ or two-electron¹²⁸ oxidizing agents, and then with nucleophiles as the reducing agents.

While discussing the mechanism of reactions of α -ferrocenylalkylation, one should not neglect the possible contribution of free-radical and redox processes, if only because of easy oxidizability of the ferrocene nucleus in acidic media in the presence of oxygen. These processes can in general be initiated in at least two ways, either through protonation and further oxidation of the central atom or by migration of an electron from the central metal atom to the carbenium centre.

As has been mentioned earlier in connection with the reactions proceeding in system *A*, the first way seems improbable, because the reaction centre (in this case the iron atom), located in the organic phase, is shielded from proton attack by the interface. Such shielding occurs in systems of *B* type, the difference, however, is that the carbenium centre is located in the adsorption layer of the cation-exchange resin. However, in those cases the reaction proceeds in a single-phase system, especially in the presence of strong acids, the contribution of protonation at the main metal centre may become significant.

As to the second reaction pathway, the general possibility of the migration of an electron from iron to the carbenium α -carbon with the formation of a paramagnetic compound has been unambiguously demonstrated in the example of the diamagnetic nonamethylferrocenylcarbenium salt.¹³¹ It has also been demonstrated that the biradicals thus formed may recombine, to give the corresponding binuclear dications.¹³¹ It has also been found that phenylferrocenylcarbenium tetrafluoroborate undergoes the analogous transformations. In this case as well, the dication is formed, which may be reduced to 1,2-diphenyl-1,2-diferrocenylthene.[‡] The doublet states E_{2g} and A_{1g} are close in energy, thus ensuring the possibility of the thermal occupation of the d_{z^2} iron orbital and facilitating electron transfer from iron to the carbon atom without disturbance of the orbital symmetry.¹³² Taking these facts into account, formation of ferrocenium salts and diferrocenylalkanes in reactions of α -ferrocenylalkylation may be regarded as indirect evidence for realisation of the pathway initiated by electron transfer from iron to carbon atoms.

In the two-phase systems, where reactions usually proceed with quantitative yields, the contribution of the reaction following this pathway is rather small. Nevertheless, it becomes noticeable when reactions are performed under more drastic conditions, which is in agreement with the increase of the yield of the side products of dimerisation and polymerisation.

Some ferrocenium salts may oxidise some nucleophiles, especially anions (*e.g.*, azole anions).¹³³ It cannot be excluded that the final products of ferrocenylalkylation in certain situations may be formed according to the free-radical scheme with initiation by single-electron transfer:

In this case, realisation of the redox mechanism results not only in dimerisation and polymerisation products, but also leads to the target products.

On the other hand, in Ru and Os compounds, the formation of direct metal- α -carbon contact and the corresponding onium derivatives, which has been demonstrated recently,¹³⁴ should most likely result in blocking of the reaction centre and decrease

in the reactivity in α -metallophenylalkylation. In these systems the contribution of redox processes seems highly improbable.

VII. Conclusion

The data of the present review demonstrate, that during recent years many studies aimed at both the extension of known and the search for the new methods of α -metallophenylalkylation of different nucleophilic reagents have been carried out. At present a vast variety of different ferrocenylalkylating reagents is used, *viz.*, ferrocenylalkylammonium salts and the like (especially, the corresponding pyridinium salts), ferrocenylsulfonium salts, α -haloalkyl ferrocene derivatives, α -hydroxyalkyl-, as well as α -alkenyl derivatives of metallocenes. It allows one to perform reaction at quite different reactivity centres (N-, C-, O-, S-, P-). The use of various additives (oxidative, acid-base, radical) offers further possibilities.

The synthetic potential is considerably extended by metallophenylalkylation in liquid-liquid or liquid-solid two-phase systems. In these systems most reactions proceed under mild conditions with high yields of the final products, which often do not require special purification. This allows one to overcome the limitations associated with the acid-base characteristic of the nucleophilic reagents. Besides, the use in these systems of the ferrocene-containing alcohols allows one not only to work with stable initial reagents, but also to vary considerably the substituents at the α -carbenium centre. The advantages of the two-phase systems are illustrated in Table 4, in which the possibilities and conditions of α -ferrocenylalkylation reactions are compared.

The variety of methods of ferrocenylalkylation allows one to perform the synthesis of different functionally substituted derivatives of ferrocene and other α -metallophenyl compounds of subgroup VIIIA metals.

The practical use of these compounds is rather extensive.³ Many of the newly synthesised α -ferrocenylalkyl compounds may be of interest as medicinals with antimicrobial,^{136–142} antiinflammatory,^{143, 144} antitumor,^{6, 7, 145–149} activity as well as chemical means of plant protection.¹⁵⁰ Photosensitive materials with α -ferrocenylalkyl compounds as electron-donating components^{151–155} or organic photoconductors¹⁵⁶ have been developed. A series of ferrocene derivatives of this class found application as stabilisers of rubbers,¹⁵⁷ latent image centres in high-resolution photographic materials,¹⁵⁸ regulators of burning

processes,¹⁵⁹ macroenergetic compounds,¹⁶⁰ and indicators of radioactivity.⁶

Taking into account the dynamics of the development of the synthetic and applied studies in this field of organometallic chemistry, one may anticipate the elaboration of technological aspects of ferrocenylalkylation reactions, new investigations leading to α -metallocenylalkyl compounds of various structures that may find extensive applications in different fields of science, technology, medicine, and agriculture.

V. Conclusion	644

Abstract. The use of analytical reagents immobilised on the surface of sorbents in sorption-spectroscopic methods of analysis is surveyed. The bibliography includes 131 references.

I. Introduction

At present, analytical methods which can be used not only under stationary laboratory conditions, but also at the site of sampling are attracting more and more attention of researchers.^{1,2} These methods should be highly sensitive and selective and also permit quick, easy and cheap analysis. Determination of traces of substances is preceded, as a rule, by their extractive concentration, ion-exchange separation,^{3,4} etc. It is known³ that efficient extraction of traces of elements by a small volume of an organic solvent from a large volume of the aqueous phase is hampered by the mutual solubility of these phases and by the difficulty of their separation. Ion-exchange materials are used most frequently for separation rather than for concentration of substances,⁵ because, prior to the analysis, the absorbed ions must be eluted, and this implies dilution and, hence, decreases the sensitivity of the analysis. Better results can be achieved by measuring an analytical signal of the analyte directly on the surface of an ion-exchanger or another sorbent.⁶

There is a linear correlation between the absorption of light by a solid sorbent and the concentration of a substance adsorbed on its surface.⁷ The method based on this correlation, which is referred to as solid-phase spectrophotometry, permits the sensitivity of analysis to be increased substantially compared to that achieved when the light absorption of the analyte is measured after its elution to a solution. Currently, sorption-photometric, sorption-luminescence and sorption-X-ray fluorescence techniques are being successfully developed; the procedures include concentration of the component to be determined from the liquid or gaseous phase onto a solid matrix, which is accomplished by its reaction with a reagent fixed on the surface, and subsequent measurement of spectral characteristics of the solid phase, in particular, of its reflection coefficient. Equations relating the

diffuse reflection coefficient of a matrix to the concentration of a substance adsorbed on its surface for thick layers of finely dispersed weakly absorbing samples (Kubelka–Munk function) and for a thin adsorbent layer (for example, for paper chromatography) have been proposed.^{8–10} The measurements can be carried out directly on the surface of the sorbent.

Sorption concentration in combination with measurement of an analytical signal on the surface makes it possible to decrease the limits of detection of elements by several orders of magnitude,^{5,8–11} while the use of sorbents modified by specific analytical reagents increases the selectivity of analysis.

Sorbents modified with chromophoric reagents are used in visual test methods which are indispensable for quick analysis of environmental objects, especially, for tentative (rough) analysis.^{1,2}

To transfer an analyte to the sorbent phase, various procedures are used: (a) the ion to be determined is first absorbed by an ion-exchange resin and then ‘visualised’ by a reagent that forms a coloured compound with the sorbate; (b) the analyte is converted initially into a complex by interaction with an organic or inorganic reagent or into an ion associate in solution, and then it is sorbed by an ion exchanger or by a non-modified sorbent; (c) the analyte is extracted from solution by a sorbent modified with an appropriate organic or inorganic analytical reagent. The latter method is the most promising, especially for the environmental control, for two main reasons. Firstly, the formation of a coloured compound in the sorbent phase is less dependent on the ionic strength of the solution than that in the solution bulk. Secondly, the reagent, which has an influence on the chemical equilibrium in the system under analysis, virtually does not pass from the sorbent surface to the aqueous phase.

In recent years,¹² it has been shown that chemical and analytical properties of immobilised reagents, especially the complex-forming ability, often differ markedly from those in solution. The chemical interactions in a two-phase system ‘an analyte in solution—an analytical reagent fixed on the surface of a solid support’ have not been adequately investigated.

Thus, the use of organic reagents fixed on a solid matrix is a new line in modern analytical chemistry that develops at the boundary between the analytical chemistry and surface chemistry.

II. Classification of modified sorbents

Sorbents modified with various reagents and meant for analytical purposes can be classified according to the type of either the support or the modifying agent used. Various sorbents are used as supports: ion-exchange resins, cellulose, poly(vinyl chloride)

membranes, fibres and, most frequently, highly dispersed silicas.^{3, 13} Chelate-forming organic reagents,^{15–41} metal salts,^{42–46} natural compounds^{47–50} and some micro-organisms^{51, 52} have found the widest application as modifiers.

The possibilities of the target-directed variation of the chemical and analytical properties of sorbents by modifying them with various reagents are almost limitless. A number of techniques can be used to fix an analytical reagent on a matrix. One of them is a synthetic method involving the so-called covalent grafting of a modifying reagent.⁵³ Another method is impregnation of a matrix with a solution of a modifier.⁵⁴ The most convenient way consists in immobilisation (or fixing) of a modifying reagent on the surface of a support using adsorption, electrostatic interaction, hydrogen bond formation or other types of interaction.^{12, 55}

The main advantage of modified sorbents prepared *via* covalent grafting is their chemical and mechanical stability. Difficulty and complexity of modification and regeneration of systems of this type should be regarded as their drawbacks.

Impregnation of sorbents with analytical reagents is much less labour-consuming. However, the resulting sorbents are not very suitable for operation under dynamic conditions and are relatively unstable; therefore, they do not ensure sufficient reproducibility of analytical results.

At present, there exists a broad range of sorbents with analytical reagents immobilised on their surface. They are chemically and mechanically stable and are easily modified and regenerated. Sorbents of this type are best suited to the requirements for visual test systems.

III. Methods for the immobilisation of analytical reagents

1. Sorption of organic reagents from polar aprotic and protic solvents

This method is used most frequently for immobilisation of reagents under both static and dynamic conditions. Water, acetone, dimethylformamide, alcohols and their mixtures with water are used as solvents. Some examples of modification of sorbents by this method are presented below.

Silica gel has been modified with 8-hydroxyquinoline (HQ) by stirring the sorbent, first, with formaldehyde and acetic acid for 1 h and then with a solution of HQ in anhydrous ethanol for 2 h at 60 °C.^{24, 56}

Immobilisation of 1-(2-pyridylazo)-2-naphthol (PAN) on silica gel has been carried out under static conditions by stirring an ethanolic solution of the reagent with a weighed portion of the sorbent for 4 h.⁴⁰ The modified sorbent was washed with water and dried for 12 h at 80–100 °C and then for several hours at 80 °C under reduced pressure. The content of PAN in silica gel obtained in this way was $4 \mu\text{mol g}^{-1}$. When silica gel was modified under dynamic conditions,⁵⁷ a solution of PAN in a 2 : 8 ethanol–water mixture was passed through a column with the sorbent using a peristaltic pump or a syringe.⁵⁷ The excess of the reagent was removed by elution with a solution of HNO_3 .

Immobilisation of PAN on the surface of a styrene-divinylbenzene copolymer has been carried out in static and dynamic regimes from a methanolic solution.⁵⁸

To modify silica gel with Eriochrome Black T, an ethanolic solution of a modifier was poured over a weighed portion of the sorbent, and the mixture was stirred with a magnetic stirrer for 30 min, and then filtered, washed with water and dried.⁵⁹ Modification of silica gel with polyhydroxyflavones has been carried out in a similar way.⁶⁰

4-(2-Thiazolylazo)resorcinol (TAR) has been applied on the surface of Silochrome C-120 from acetone solutions.⁶¹ The Silochrome was treated with 1 M solution of sulfuric acid and washed with water to create a weakly acidic medium. After that, a solution of TAR was introduced, and the system was allowed to stand for 1 day with occasional stirring. The sorbent was washed with water and dried in air.

Organic reagents have also been applied from aqueous solutions. For example, to modify the AB-17 $\times 8$ anion exchanger with 1-(2-thiazolylazo)-2-naphthol-3,6-disulfonic acid (TAN-3,6-S), a weighed portion of the sorbent was shaken for 30 min in an aqueous solution of the reagent at pH 5.7. The modified ion exchanger was washed with water and dried in air.^{62, 63}

Membrane ultrafilters have been modified by immersing them in a mixture of water with a solution of the corresponding organic reagent in dimethylformamide (DMF).⁶⁴ The optimum time needed for the modification of the poly(vinyl chloride) film 'Vladipor' with 4,4'-bis(dimethylamino)thiobenzophenone from a 50% DMF solution was only 10–15 min.⁶⁵ The modified films were thoroughly washed and stored in the dark in twice distilled water.

Sorption of a chemiluminescent reagent lucigenin on the surface of various silicas has been carried out from aqueous solutions.^{55, 66} The maximum uptake was achieved on non-functionalised silicas, silica gel ($1.6 \times 10^{-5} \text{ mol g}^{-1}$) and Silpearl ($3.4 \times 10^{-5} \text{ mol g}^{-1}$), over a period of 5 min.

2. Sorption of organic reagents from non-polar aprotic solvents and their mixtures

Modification of silica gel with quaternary ammonium salts has been carried out as follows. Silica gel was stirred with a solution of a reagent in hexane for 1 h and then dried for 2 h at 60 °C.^{67, 68}

Static modification of silica gel with di(2-ethylhexyl) phosphate (DEHPA) has been carried out by stirring the sorbent, dried preliminarily for 2 h at 160 °C, with a solution of DEHPA in a chloroform–heptane mixture (70 : 30).³⁷ Then the sorbent was dried in air until the solvent was completely removed.

A similar procedure was used to modify silica gel with the azanalogue of dibenzo-18-crown-6; for this purpose, a solution of the crown compound in a heptane–chloroform mixture (1 : 1) was employed.⁶⁹

3. Immobilisation of organic reagents from the gas phase

A method for the modification of sorbents by treating them in a high-frequency low-temperature plasma in the presence of vapours of organic reagents has also been proposed.⁷⁰ Polysorb-1 was used as the sorbent and propargyl alcohol, allylamine and acrylic acid were used as modifiers. The sorbents were treated for 30 min, and after that, they were washed twice with methanol by decantation and dried in air.

4. Immobilisation of inorganic reagents

Modification of sorbents with inorganic reagents is mostly carried out by sorption or precipitation of metal hydroxides, oxides or salts on their surface.

Immobilisation of calcium phosphate on silica gel has been performed by treatment of the sorbent with a solution of calcium hydroxide and, after drying, with a solution of sodium dihydrogen phosphate.⁷¹ Then the material was dried once again.

Aluminium and iron hydroxides have been applied to the surface of activated carbon by precipitating them from a solution of the corresponding sulfate in the presence of coagulating agents based on polyacrylamide.⁷²

To apply titanium and zirconium hydroxides on carbon, it has been preliminarily impregnated with solutions of salts of these metals; then the hydroxides have been precipitated with ammonia, and the sorbent dried in air at 105–115 °C.^{73, 74}

The modification of acetylcellulose by manganese oxide has been accomplished by treating the sorbent with a solution of potassium permanganate at 60 °C and pH 2.⁷⁵

5. Composite materials based on modified sorbents

Modified sorbents serve as the basis for a number of composite materials.⁷⁶ For example, a composite material based on polyacrylonitrile fibre has been filled during moulding with a selective chelate-forming sorbent containing grafted heterocyclic amines⁷⁷ or with a strongly basic anion-exchange resin.⁷⁸ Discs of a

polyacrylonitrile fibre filled with finely dispersed ion exchanger have been additionally modified by immersing them into a solution of PAN in aqueous acetone⁷⁹ or into aqueous solutions of Xylylene Orange (XO),⁸⁰ arsenazo I⁸¹ or *p*-nitrosodiethylaniline.⁸² The resulting materials were stored wet.

Immobilisation of 4-phenylazo-3-aminorhodanine (PAAR) to a disc-shaped polyacrylic fibre filled with a finely dispersed KU-2 ion-exchange resin has been carried out in the following way.⁸³ Wet discs weighing 40–50 mg were washed with 50 ml of 0.1 M HNO₃ and with 10 ml of acetone, immersed into 10 ml of a 5×10^{-5} M solution of PAAR for 15 min and washed with 50 ml of 0.1 M H₂SO₄. The material was stored wet. The capacity of the sorbent with respect to PAAR was 5×10^{-6} mol g⁻¹.

IV. Analytical applications of modified sorbents

1. Organic reagents

a. Nitrogen-containing reagents

Sorption of gaseous compounds — hydrogen sulfide, carbon disulfide, methanethiol and sulfur dioxide — on silica gel impregnated with diethanol- and monoethanolamine has been studied.⁸⁴ The capacity of the sorbent with respect to diethanolamine amounted to 1.51–2.06 mmol g⁻¹. The sorption of gases is due to their chemical interaction with amines. Unlike acidic gases, CH₃SH is inert towards monoethanolamine and diethanolamine; therefore, it is adsorbed on modified silica gel much less efficiently than on the pure support.

A procedure for the determination of traces of Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and Pb(II) in river water and in industrial sewage has been developed.²³ The method involves preliminary sorption of the metal cations on silica gel impregnated with *N,N,N',N'*-tetrakis(2-aminophenyl)ethylenediamine and their subsequent desorption with a 0.13 M solution of tartaric acid at pH 3. The contents of metals are determined by spectrophotometry. The calibration plots are straight lines for concentrations of the metal ions ranging from 1×10^{-8} to 3×10^{-6} mol litre⁻¹.

It has been proposed to use *p*-nitrosodiethylaniline immobilised on discs of a polyacrylonitrile fibre filled with the strongly acidic KU-2 cation-exchange resin as a unit sensitive to the presence of Pd(II) ions.⁸² Palladium ions are sorbed from solutions in a dynamic regime, and diffuse reflection spectroscopy is used for their determination. The response of the sensing element is formed over a period of 2–10 min at a palladium(II) concentration of 1×10^{-6} mol litre⁻¹, and the detection limit is 5×10^{-9} mol litre⁻¹. The use of immobilised *p*-nitrosodiethylaniline makes it possible to improve the selectivity and enhance the sensitivity of the determination of palladium and to extend the range of concentrations suitable for determination compared to that in the case of conventional photometric analysis.

The possibility of concentrating and determining Zn(II) and Cd(II) ions with the aid of an ion exchanger modified with phenylsulfonfylaminoquinoline, which is fairly sensitive and relatively selective with respect to these metals, has been studied.⁸⁵ The contents of metal ions were determined by fluorometry.

A new solid-phase chemiluminescence reagent for the determination of V(IV) and Fe(II) ions has been obtained based on lucigenin (*N,N*-dimethyldiacridylum nitrate) immobilised on a silica gel or Silpearl surface.^{55, 66} The limit of detection of V(IV) is 0.7 and that for Fe(II) is 0.8 mg litre⁻¹. One portion of the reagent makes it possible to carry out more than 200 analyses in a flow regime without additional regeneration.

An extraction and chromatographic procedure involving the use of silica gel modified with Aliquat 336S has been proposed for the determination of bismuth at pH 3 in a 0.01 M solution of citric acid.⁸⁶ At the final stage, bismuth is determined by spectrophotometry as an iodide complex. The procedure is suitable for the determination of bismuth in low-melting alloys containing also lead, zinc, antimony and tin.

A simple and rapid method for concentrating zinc ions as a complex with 4-(2-pyridylazo)resorcinol (PAR) using methyl-

triocetylammmonium chloride and bromide immobilised on the surface of biphenyl with PAR has been proposed.⁸⁷ The content of zinc was determined by the atomic absorption method.

Sorption of high-molecular-weight quaternary ammonium bases on highly dispersed silica can be used for preparing solid-phase reagents possessing anion-exchange properties. The sorption of (didecylaminoethyl)tridecylammmonium iodide (DDATD), *N*-methyl-*N,N,N',N',N'*-pentadecylethylenediammonium diiodide (PDEDA) and *N,N,N,N',N',N'*-hexadecylhexamethylenediammonium diiodide (HDHMDA) on silica gel Chemapol L 40/100 has been studied.^{88, 89} The maximum amount of DDATD adsorbed is 0.4 mmol g⁻¹, while those of PDEDA and HDHMDA are 0.12 mmol g⁻¹. It was proposed to use DDATD on silica gel for the concentration and determination of Co(II), Cu(II), Zn(II), Bi(III) and Mn(II) as acido-complexes.^{90, 91} This material is also suitable for the chemiluminescent and visual-test quantification of cobalt(II) in natural water (the detection limit is 2 mg litre⁻¹).

Visual tests for the analysis of cobalt and bismuth ions in drinking water at their contents close to the maximum permissible concentration have been developed.^{36, 91} The tests are based on the formation of coloured ion associates by bismuth tetrathiocyanocobaltate and bismuth tetraiodide on a silica gel surface. The sorption can be carried out in both static and dynamic regimes. Macro- and micro-components of natural water do not interfere with the determination.

The DDATD–silica gel system modified with chromophoric and luminescence reagents (indicators) of the anionic type: Methyl Orange, Methyl Red, picric acid and fluorescein, is also of interest.^{88, 89} In this case, ion associates of the composition DDATD:indicator = 1:1 are formed on the surface of the solid phase. Inorganic and low-molecular-weight organic anions do not displace the immobilised reagents from the surface. However, the indicators enter into exchange reactions with anionic surfactants and thus pass into solution. This provides the basis for a procedure for determining micro-quantities of sodium dodecyl sulfate in natural and waste waters. The indicator displaced to the solution from the sorbent surface is quantified by spectrophotometry or luminescence or by visual test methods.

To determine formaldehyde in air by high performance liquid chromatography, the air is pumped through a glass cartridge filled with silica gel impregnated with 2,4-dinitrophenylhydrazine.⁹² As a result, hydrazone is formed on the sorbent surface; then it is eluted with methanol and determined by UV spectroscopy at a wavelength of 365 nm.

b. Macrocyclic ligands

Sorption under dynamic conditions of Cd(II), Co(II), Mg(II), Ni(II), Pb(II) and Zn(II) ions on silica gel modified with macrocyclic ligands, diaza-18-crown-6, octaethylporphyrin and 8,9,17,18-dibenzo-1,7-dioxa-4,10,13,16-tetraazacyclooctadecane, has been studied.^{33, 69} At pH 6.7, Cd, Co and Mg are eluted from silica gel modified with diaza-18-crown-6 in the order Cd > Co > Mg, and at pH 4, Zn, Pb and Ni are eluted in the order Zn > Pb > Ni. In the case of modification by octaethylporphyrin and by 8,9,17,18-dibenzo-1,7-dioxa-4,10,13,16-tetraazacyclooctadecane, elution occurs in the order Mg > Co > Cd (pH 6.7) or Ni > Pb > Zn (pH 4). When two reagents are immobilised simultaneously on the silica gel, the sequences of retention of metal ions change: Co and Pb ions are eluted first.

Immobilisation of tetraphenylporphyrin and its complexes with Sn(IV), In(III) and Zn(II) on aminopropyl-silica gel (with a particle size of 10 µm) afforded sorbents for high performance liquid chromatography.⁹³ These sorbents ensure virtually complete chromatographic separation of the above metals in normal, reversed-phase and anion-exchange variants. Examples of anion-exchange separation of aromatic carboxylic acids and sulfonic acids have also been reported.

c. N,O-Reagents

8-Hydroxyquinoline (HQ) is among the most efficient extractants used for the determination of metal ions.⁹⁴ Since at present, there is a constant tendency to decrease the toxicity of the chemicals used in analytical procedures and the labour content of the procedures, it is no wonder that numerous studies devoted to the immobilisation of HQ on the surface of various sorbents and to their analytical applications have been published. Sorption of Al(III), Fe(III), Cd(II), Co(II), Cu(II) and Mg(II) from aqueous solutions by silica gel modified with HQ (HQ-SS) has been reported.⁹⁵ The kinetics of sorption of various metal ions are dissimilar. Thus at pH 6, quantitative sorption of Cu(II) is achieved over a period of 10 min, while Zn(II) is sorbed quantitatively over a period of 30 min. The HQ-SS sorbent is used to concentrate rare earth elements from natural waters and to separate them from barium.³¹ The possibility of using this sorbent for the extraction of traces of metals from sea water⁹⁶ has also been shown. The extracted metals were detected by various modifications of mass spectrometry,^{17, 25, 28, 32, 37} by atomic absorption spectroscopy in the on-line regime^{28, 37} and by inversion voltammetry.⁹⁷ HQ-SS is used successfully in the analysis of organic compounds, in particular, nitrophenol and chlorophenol present in water at levels higher than their maximum permissible concentrations.²⁹

To determine iron(III) ions in sea water in a flow regime, a sorbent based on HQ immobilised on the surface of a chelate resin has been proposed.⁹⁶ The iron ions were then desorbed and detected by the luminescence method.

It has been suggested to detect aluminium(III) and manganese(II) in the presence of iron(III) using C₁₆-silica gel modified with a mixture of octaethylporphyrin and 5-phenylazo-8-hydroxyquinoline taken in a ratio of 5 : 1.⁹⁸ The metal ions are quantified in the eluate by spectrophotometry in the presence of Xylylene Orange.

β -Hydroxynaphthylidene-*o*-aminophenol immobilised on the APA-8n anion-exchange resin has been used as a sensing element in an optical sensor for detecting Al(III) ions.⁹⁹ The chemical and analytical properties of this solid reagent and of the fluorescent complex with aluminium formed on the surface of the sorbent were studied. The advantages of using this solid reagent for the analysis of aluminium were shown.

The use of silica gel modified with 1-(2-pyridylazo)-2-naphthol (PAN) for the concentration and separation of Cu(II), Co(II) and Ni(II) ions, the contents of which in a solution are several mg per litre has been described.⁴⁰ The concentration factor exceeds 100. It has been shown²⁰ that copper(II) ions are sorbed at pH 5–7 under dynamic or static conditions with a concentration factor of 200. Copper(II) is determined after its desorption with a 0.1 M solution of thiourea or 0.03 M hydrochloric acid flowed at a rate of 0.3–0.4 cm³ min⁻¹. The presence of less than 0.1 mg of Cr(VI), 2 mg of Zn, 0.2 mg of Mn(II), 3 mg of Ca(II) and 3 mg of Mg(II) does not interfere with the determination of copper. The optimum conditions for the sorption of cobalt(II) ions with PAN–silica gel and for its subsequent quantification by diffuse reflection spectroscopy and by the visual test method have been established.³⁴

A linear colorimetric method for the determination of Fe(III) and Cu(II) using PAN–silica gel has been proposed.⁵⁷ One millilitre of a solution of a sample with pH 3.0 (Fe) or pH 2.5 (Cu) is injected with a syringe into a tube with modified silica gel. The quantity of the metal is found from the length of the coloured zone using a calibrating plot. Sorption of Pb(II) ions by the same sorbent was also studied.⁹⁹

Foamed polyurethane and ion-exchange resins modified with PAN are used for concentration of uranium(VI) prior to its determination by diffuse reflection spectroscopy.³⁵ It has been proposed to use an ion exchanger based on a copolymer of styrene with divinylbenzene modified with PAN to analyse river water for Cu(II), Zn(II), Fe(III), Cd(II), Ni(II) and Pd(II).⁵⁸

A procedure for the concentration of zirconium and its subsequent determination by spectrophotometry in the solid phase using the AB-17×8 sorbent modified by Eriochrome Black T (ECB T) has been developed.⁵⁹ The capacity of the sorbent with respect to zirconium under static conditions is 18.2 mg g⁻¹, and the detection limit is 9.6 mg litre⁻¹.

Silica gel treated with a mixture of ECB T with liquid anion-exchange reagent Aliquat 336 is capable of concentrating traces of transition and alkaline earth metals from water.⁹⁵ Neither alkali metal ions nor ammonium ions are sorbed on this anion exchanger. The sorbed metals are eluted with dilute perchloric acid and determined by atomic absorption spectroscopy. The modified sorbent makes it possible to concentrate these metals by a factor of 250. This served as the basis of a procedure developed for concentrating Fe(II), Cu(II), Pb(II), Ca(II) and Mg(II) ions from water and from solutions of sodium, potassium and ammonium salts by column chromatography.

An optical-fibre fluorescence sensor for simultaneous determination of Al(III) and Ga(III) or Al(III) and In(III) has been developed. The method involves the use of the Bio-Rad AG1-X4 anion-exchange resin modified with lumogallion.¹⁰⁰ The analysis is carried out in a dynamic regime. The minimum concentrations of Al, In and Ga that can be determined in this way are 0.02×10^{-6} , 3.0×10^{-6} and 0.2×10^{-6} mol litre⁻¹, respectively.

The optimum conditions for the sorption of U(VI) on the Silochrome C-120 silica gel with immobilised 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol were found.¹⁰¹ A new test form for the determination of uranium in the sorbate phase by diffuse reflection spectroscopy was proposed. The detection limit is 35 ng in a 10-ml sample.

Xylylene Orange (XO) immobilised on the surface of a polyacrylonitrile fibre filled with a finely dispersed anion-exchange resin has been proposed as the sensing element of an optical sensor for detection of Pb(II) and Th(IV) ions.⁸⁰ The response of the sensing element is formed over a period of 1–10 min at lead(II) and thorium(IV) concentrations of 1×10^{-8} – 3×10^{-6} mol litre⁻¹.

Discs of a fibrous material filled with a weakly basic anion exchanger with immobilised arsenazo I have been used to determine U(VI) ions.⁸¹ The discs with arsenazo I are suitable for rapid quantification of uranium(VI), which is sorbed in the dynamic regime and then determined by diffuse reflection spectroscopy. The detection limit for uranium is equal to 3×10^{-8} mol litre⁻¹. As in the majority of cases, the immobilised reagent increases the sensitivity and selectivity of the analysis. In addition, the use of this method extends the range of concentrations that can be determined relative to that in the method involving the formation of complexes with arsenazo I in aqueous solutions.

Cellulose materials have been modified with ethylenediaminetetraacetic acid and used to determine Cr(III), Fe(II) and Pb(II) ions by atomic absorption spectroscopy.¹⁰² The quantity of metal ions that pass from a solution to the surface of the sorbent depends on the duration of the contact between the phases and on the concentration of the metal in the solution. Lead ions are sorbed most efficiently.

Traces of vanadium(IV) and vanadium(V) in water are determined by atomic absorption spectroscopy after concentration and separation on columns filled with silica gel containing immobilised fluorinated β -diketones — benzoyltrifluoroacetone and thenoyltrifluoroacetone — and *N*-(2-aminoethyl)- γ -aminopropyltrimethoxysilane.²⁰ To determine the overall amount of vanadium(V) and (IV), a sample in an acetate buffer solution (pH 6) was passed at a rate of 10 cm³ min⁻¹ through a column filled with 1.5 g of modified silica gel. Then the sorbed material was eluted with 6 M hydrochloric acid, a $(1-10) \times 10^{-6}$ M solution of cobalt(II) serving as the internal standard. The separate determination of vanadium(V) and vanadium(IV) is based on the fact that they are sorbed differently at various pH. For the adsorption of V(V) ions, a solution with pH 3 was passed through a column with modified silica gel, and to extract V(IV) from the liquid phase, a

solution that had passed through the column was neutralised to pH 6 and then passed through a second column filled with the same sorbent. The detection limit for vanadium is $0.06 \mu\text{g litre}^{-1}$. Iron(III) and copper(II) ions as well as ions of other metals present in high concentrations can be masked by complexone III. This procedure was used to determine $1-2 \mu\text{g litre}^{-1}$ of vanadium in river water.

It has been shown that silica gel modified with reagents containing ethylenediamine and ethylenediaminetriacetate functional groups can be used for the separation and concentration of vanadium(V) and vanadium(IV).²² The separation is carried out using two columns filled with modified silica gel. The first column contains silica gel modified with a compound incorporating ethylenediamine functional groups, while the second column is filled with the sorbent modified with a compound with ethylenediaminetriacetate functional groups. At pH 2.5–3.0, only vanadium(V) is sorbed in the first column. When inductively coupled plasma atomic adsorption spectroscopy is used for quantification of vanadium(V), the detection limit amounts to 60 pg cm^{-3} .

The use of silica gel modified with zincon for concentrating Na, K, Mg, Ca, Al, Zn(II), Cd(II), Pb(II), Mo(II), Fe(III), Co(II), Ni(II) and Cr(III) ions from aqueous solutions of their salts at pH 1–9 has been proposed.¹⁰³ A procedure for the atomic-absorption determination of these ions was developed. Prior to the determination, the ions were eluted from the surface of the modified sorbent with solutions of hydrochloric or perchloric acid. Zincon is used both for the separation of these elements and for purification of solutions of some salts from Zn(II), Pb(II), Cd(II) and Cu(II) ions present as impurities.

A procedure for the anion-exchange concentration of Cu(II), Zn(II), Pb(II) and Cd(II) ions using an anion-exchange resin modified with sulfonate azo-dyes has been developed.¹⁰⁴

According to a known sorption-photometric method for the determination of palladium, the AB-17 $\times$ 8 anion exchange resin modified with nitroxaminazo (NOA) is used as the sorbent.¹⁰⁵ The limit of detection of microquantities of palladium is of the order of $10^{-4} \mu\text{g cm}^{-3}$.

A procedure for the on-line separation of Pb(II), Cu(II), Cd(II), Co(II), Zn(II), Ni(II) and Mn(II) ions has been developed.¹⁰⁶ The ions are sorbed on cartridges filled with sorbents based on silica gel ($40 \mu\text{m}$) with immobilised hydroxamic acid. The calibrating plots are linear over a wide range of concentrations ($0.01-5.0 \text{ mg litre}^{-1}$). The detection limits for Cu(II), Co(II), Zn(II) and Ni(II) ions are $5-10 \mu\text{g litre}^{-1}$, and those for Pb(II) and Cd(II) ions are 20 and $30 \mu\text{g litre}^{-1}$, respectively. This modified sorbent was used for analysis of tap water.

Sorbents based on ODS C18 silica gel or XAD-4 resin containing immobilised *p*-tert-butylcalyx[4]arenetetrahydroxamic acid have been used for the pre-concentration of traces of transition metal ions.¹⁵ The conditions for the sorption of Fe(III), Co(II), Pb(II), Cd(II), Mn(II), Ni(II), Zn(II) and Cu(II) ions in the pH range of 2–7 were studied. A procedure for chromatographic determination of copper(II), zinc(II) and manganese(II) in natural and other waters was elaborated.

d. S₃N- and S-containing reagents

A method for the spectrophotometric determination of micro-quantities of Ag(I) and Pd(II) in water involving the use of a poly(vinyl chloride) film modified with 4,4'-bis(dimethyl-amino)-thiobenzophenone has been proposed.⁶⁵ In aqueous solutions of metal salts, the colour of the modified films changes due to the formation of complexes on the solid surface. The intensity of the colour depends on the pH, duration of shaking, the temperature of the solution and the concentration of the metal. The largest factor of concentration (1000) is achieved under optimum conditions, namely, a 500-ml sample, a surface area of the modified film of 12 cm^2 , a shaking time of 60 min and a temperature of the solution under analysis of $40-60^\circ\text{C}$. The limit of detection of silver is $0.5 \mu\text{g litre}^{-1}$ and that of palladium is $0.2 \mu\text{g litre}^{-1}$.

A sensing element for the determination of Hg(II) has been produced by immobilisation of 4-phenylazo-3-aminorhodanine (PAAR) on discs of polyacrylonitrile fibre filled with finely dispersed KU-2 ion-exchange resin.⁸³ The colour of the complex with mercury develops over a period of 3–5 min (for an initial volume of 10 ml). The method makes it possible to determine mercury directly in a solution, the detection limit being $0.02 \mu\text{g cm}^{-3}$. Ions of many transition metals that usually accompany mercury do not interfere with its determination. The use of PAAR applied on the solid phase increases the selectivity of the analysis by an order of magnitude with respect to that achieved when mercury is determined using PAAR in solution.

A sorbent based on the AB-17 $\times$ 8 anion-exchange resin modified with 1-(2-thiazolylazo)-2-naphthol-3,6-disulfonic acid (TAN-3,6-S) has been proposed for the determination of copper.^{62,63} To extract micro-quantities of copper from aqueous solutions and from water–organic mixtures, sorbents with coverages of 43% and 8%, respectively, are used.¹⁰⁷ The sorption-photometric method for the determination of low concentrations of copper is more sensitive and selective than the known photometric method for the determination of copper with TAN-3,6-S in solution.

The optimum conditions for the absorption of Pd(II) by this sorbent were also elucidated.^{108,109} The amount sorbed depends on the nature and concentration of mineral acids as well as on the coverage of the sorbent with the modifier and on the presence of organic solvents. The detection limit for palladium(II) is $1.25 \mu\text{g cm}^{-3}$.

Sorption of Fe(III) ions on the AB-17 $\times$ 8 ion exchange resin in the chloride form modified with TAN-3,6-S has been studied.¹¹⁰ The formation of complexes of Fe(III) ions with TAN-3,6-S immobilised on the sorbent surface was studied by spectrophotometry. It was found that the ratios of the components in the complexes formed in solution and in the phase of the sorbent are identical.^{62,108}

Conditions for sorption of Ni(II) ions with this sorbent were studied over a wide pH range.⁶² The composition and the stability constant of the nickel complex formed in the resin phase were determined by spectrophotometry. The influence of the stoichiometry of the nickel complex with the modifying agent on the kinetic properties of the sorbent was considered.

Group concentration of Cu(II), Ni(II), Zn(II) and Cd(II) ions on the AB-17 $\times$ 8-Cl anion exchanger modified with TAN-3,6-S creates conditions for the subsequent X-ray fluorescence determination of these elements in the concentrate.^{111,112} A sorption-X-ray fluorescence procedure for the determination of micro-concentrations of these metals present simultaneously was developed. The detection limit is $0.35-1.2 \mu\text{g}$, and the concentration factor is 200.

The protolytic and optical properties of Silochrome C-120 with 4-(2-thiazolylazo)resorcinol immobilised on its surface have been studied. Chemical and analytical conditions for the interaction of this material with U(VI), Cu(II), Ni(II), Zn(II), Co(II), Pd(II) and Fe(II, III) ions were identified.⁶¹ The sorbent is used for the test determination of Co(II), Pd(II) and U(VI) ions present in concentrations of $0.005-0.03 \mu\text{g cm}^{-3}$ by diffuse reflection spectroscopy and also for determination of palladium and uranium in real objects.

The AB-17 $\times$ 8 anion-exchange in the chloride form modified with 2-(2-thiazolylazo)-5-diethylaminophenol (TADEAP) has been proposed as the sorbent for the determination of U(VI) present in a concentration of about $10^{-5}\%$ by solid-phase spectrophotometry.¹¹³ The analysis is carried out for alkaline solutions of complex compositions without preliminary separation of uranium from the accompanying elements.

A method for detecting traces of cadmium and copper in salt sediments of sodium chloride has been reported.²⁶ The method includes ion-exchange pre-concentration of the elements to be analysed on silica gel modified with a thiol and atomic absorption spectroscopy.

Reagents with xanthate and dithiocarbamate functional groups immobilised on a silica gel surface have been used to concentrate traces of noble metals.¹¹⁴ The Pd(II), Ag(I), and Pt(IV) ions are sorbed quantitatively on this material at pH 4–5 and 2–5. The ions are detected by the atomic absorption method after desorption.

e. O-Containing reagents

Silica gel modified with dodecylbenzenesulfonic acid has been used under dynamic conditions for ion-chromatographic separation of transition metal ions.¹¹⁵ Solutions of strontium salts containing citric, tartaric, oxalic, pyrophosphoric and dipicric acids added for complex formation were used as the eluents. The optimum conditions for the selective determination of Cu(II), Ni(II), Pb(II), Co(II), Cd(II), Fe(II) and Mn(II) cations were chosen. The analysis requires 25 min.

Eriochromocyanine immobilised on the XAD-2 support can serve as an optical sensor for the determination of Al(III).¹¹⁶ The content of this metal is found by diffuse reflection spectroscopy.

Extraction chromatography on columns filled with silica gel containing a mixture of high-molecular-weight and isomeric tertiary C₁₀ carboxylic acids 'Versatic 10' immobilised on its surface is used to separate indium(III) from accompanying elements.¹¹⁷ Indium(III) is sorbed quantitatively from acetate buffer solutions with pH 4.5–6.0 and is desorbed with solutions of mineral acids. Neither Fe(III), Ni(II), Co(II), Zn(II) and Cu(II) ions nor U(VI), Cr(III), Al(III), Tl(III), Ga(III), lanthanide, Zr(IV) and Th(IV) ions are sorbed under these conditions; they can be separated by choosing an appropriate mobile phase.¹¹⁷ The researchers cited presented examples of the separation of Al(III)–In(III)–Ga(III)–Th(III), UO₂(II)–In(III)–Zr(IV) and La(III)–In(III)–Th(IV) mixtures.

To analyse environmental objects, a procedure has been proposed in which traces of Cd(II), Cu(II), Mn(II), Zn(II) and Fe(III) are concentrated by sorption from aqueous solutions with pH > 6 on silica gel modified with 3-methyl-1-phenyl-4-stearoyl-5-pyrazolone (with a coverage of 4.2%).¹¹⁸ Desorption of metal ions is accomplished using 1 M hydrochloric acid, and the contents of metals in the eluate are determined by atomic absorption spectroscopy. This procedure was used to determine traces of Cu(II), Mn(II) and Zn(II) in tap water.

The analytical potentialities of morin immobilised on the KU-2 cation-exchange resin and on a dextran type sorbent, Sephadex G-25, have been studied.⁶⁰ These sorbents are suitable for selective determination of zirconium and tin in wastewater. The minimum concentration of Zr detected in this way is 1.0 µg cm⁻³ and that for Sn(II) is 0.5 µg cm⁻³.

f. Algae

Sorption of toxic metal ions (Co, Ni, Pb, Cd, etc.) from aqueous solutions by silica gel modified with an alga *Chlorella vulgaris* has been studied.⁵¹ The sorbent was used to concentrate metals, which were then quantified by atomic absorption spectroscopy.

A method for the immobilisation of marine algae cells on silica gel has been proposed.⁵² The material thus obtained was used to extract lead from aqueous solutions by column chromatography. The lead is determined after its desorption with a mixture of nitric and hydrochloric acids. The adsorption capacity of the modified sorbent with respect to lead decreases by 15% after 20 adsorption–elution cycles. This sorbent also extracts almost completely micro-quantities of cesium from strongly saline solutions.

2. Inorganic reagents

Methods for the preparation and applications of inorganic sorption materials based on various supports — carbon, zeolites, sand, wood cellulose, etc. — have been considered in a review.⁷¹ The accessibility of many of these supports, the ease of synthesis of sorbents based on oxides, hydroxides, ferrocyanides and other solid phases, their mechanical strength and high kinetic characteristics make these materials highly promising sorbents for process-

ing of natural and waste waters, liquid radioactive wastes and various solutions.

a. Metal salts

A separate group of sorbents comprises materials modified with inorganic salts; they are meant for the analysis of compounds capable of being involved in complex-formation, precipitation or redox reactions with the salts fixed on the surface.

Chromatographic behaviour of a large number of inorganic anions on silica gel modified with 0.1% aqueous solutions of CuSO₄, ZnSO₄, [Co(NH₃)₆]Cl₃ and NiCl₂ has been studied.⁴⁴ Desorption is carried out using water–organic mixtures containing mineral acids, and detection is accomplished using thin-layer chromatography and various visualising reagents.

A method for the separation of Tl(III) from Cd(II), Al(III), Ni(II), Fe(III), Ag(I) and Pb(II) using silica gel modified with sodium molybdate dissolved in a formic acid–butanol mixture has been reported.⁴³

A procedure has been proposed for the determination of aromatic sulfur-containing heterocyclic compounds in slate pitch. The method includes chromatography on columns filled with silica gel containing palladium(IV) chloride adsorbed on its surface.⁴² The analysis is performed by UV spectroscopy or flame photometry.

Sorption of cesium ions on silica gel with immobilised potassium tetracyanocuprate has been studied under static conditions.¹¹⁹ The rate of ion exchange between potassium and cesium increases as the capacity of the sorbent with respect to the above copper(I) complex decreases. The sorbent can also be used under dynamic conditions.

A method for preparing a sorbent based on iron(III) hexacyanoferrate(II) has been described.¹²⁰ Cellulose was treated with a mixture of solutions of potassium hexacyanoferrate(III) and iron(III) nitrate in a special mixing reactor. The capacity of the sorbent with respect to the modifying reagent was 300 to 600 mg cm⁻³.

Inorganic sorbents based on potassium hexacyanoferrate(III) have been obtained using precipitation reactions.¹²¹ The compositions and physicochemical and sorption properties of the materials depend on the conditions of their synthesis.

Oxidative and indicator systems based on modified silica gel have been used to determine nitrogen oxides in air.⁴⁶ The oxidative tube contained silica gel impregnated with an acid solution of potassium permanganate, while the indicator tube was filled with silica gel impregnated with potassium iodide, starch, sodium chloride and sodium thiosulfate.

Tin(IV), zinc(II) and aluminium(III) iodides applied on activated carbon are used to extract radioactive iodine from solutions.⁷¹

A number of sorbents based on potassium hexacyanoferrate(II) applied on a zeolite, an acrylic fibre or silica gel are used for treatment of radioactive wastewaters.⁷¹

Amorphous calcium phosphate applied on an acid-resistant porous support with an extensive surface is used as a sorbent for the concentration of heavy metal ions.

A sorbent possessing high selectivity with respect to strontium in calcium-containing solutions is prepared by treatment of coal with a solution of potassium permanganate containing 1.0 to 1.2 g litre⁻¹ of ammonia.⁷¹

b. Metal oxides and hydroxides

Oxide and hydroxide films immobilised on various inert matrices (sand, cellulose, activated carbon, various copolymers, etc.) constitute a large group of inorganic sorbents.

A sorbent based on manganese dioxide applied on a support is used for the sorption of Cu(II), Zn(II) and Pb(II) ions under dynamic conditions.⁷⁵

To purify water from iron, it is filtered through the so-called 'black sand',¹²² which is prepared by the successive treatment of sand with solutions of manganese chloride and potassium per-

^a DRS is diffuse reflection spectroscopy, CL is a chemiluminescence method, AAS is atomic absorption spectroscopy, MS is mass spectrometry, SPSP is solid-phase spectrophotometry, PL is photoluminescence, CC is column chromatography and GC is gas chromatography. ^b Capacity of the sorbent is expressed in mg g⁻¹.

manganate. This yields a sorbing layer of manganese dioxide. Sulfonated coal can be used instead of sand.

A flow injection procedure for the determination of organic reducing agents in water samples using lead(IV) oxide immobilised on a silica surface has been suggested.⁴⁵ The concentration of organic compounds in water is found from the quantity of Pb(II) resulting from the reaction of Pb(IV) with reducing reagents. The concentration of Pb(II) is determined by spectrophotometry using 4-(2-pyridylazo)resorcinol or by atomic absorption spectroscopy.

The sorbent obtained by precipitation of aluminium and iron(III) hydroxides from solutions of metal sulfates on activated carbon in the presence of coagulating agents based on polyacrylamide is also suitable for the extraction of heavy metal ions from water.⁷² The $\text{Al}(\text{OH})_3 : \text{Fe}(\text{OH})_3$: carbon ratio in this material is 1 : 4 : 5 by weight. The capacity of the sorbent with respect to uranium amounts to 266 mg g⁻¹.

Sorbents consisting of aluminium(III), iron(III) and manganese(II) hydroxides applied on copolymers of styrene with divinylbenzene with various degrees of cross-linking are used to concentrate microelements from sea water.¹²³ The factors of concentration of metals depend on the thickness of the hydroxide layer and on the degree of porosity of the support. The material is suitable for sorption under dynamic conditions.

The sorption on iron(III) hydroxide applied on various supports is used to purify solutions from water-soluble compounds of arsenic.^{71, 124} This procedure ensures extraction of traces of arsenic and arsenous acids, organic arsenic-containing acids and their derivatives.⁷¹

Composite sorbents prepared by deposition of titanium(IV) and zirconium(IV) hydroxides on the activated carbon BAU are selective with respect to phosphate and fluoride anions.^{73, 74} A sorbent of this type absorbs 2.4 times as much phosphate ions per gram as granulated titanium hydroxide, all other factors being the same. The high capacity of these materials with respect to phosphate ions is retained in neutral and weakly alkaline media.⁷¹

A sorbent consisting of a thin layer of iron oxide applied on sand has been proposed for the extraction of copper ions from washings containing ammonia.¹²⁵

To concentrate metal ions from sea water and industrial sewage, a sorbent has been proposed,¹²⁶ which consists of dispersed metal hydroxides, oxides or sulfides or of these compounds precipitated on or embedded into an organic or inorganic porous support (organic polymers, zeolites, molecular sieves). The synthesis of a sorbent based on zinc hydroxide and an organic support is described in the patent cited¹²⁶ as an example. Methods for preparing a composite sorbent for the extraction of heavy metal ions from sea water or wastewater have been developed.^{127, 128} This material is based on a porous support, for example, an organic polymeric gel in which finely dispersed aluminium, iron, manganese, titanium or other metal oxides and hydroxides are introduced. The quantity of the inorganic compound introduced is more than 0.1 mole per litre of the gel. The preparation of composite sorbents based on polyacrylamide and hydroxides of the above metals is described as an example. The exchange capacities of the sorbents with respect to copper(II), nickel(II), mercury(II), chromium(III) and some other heavy metal ions were determined. Characteristic features of the composite adsorbents are their high stabilities, good adsorption properties and easy separation from water.

A procedure for modification of inorganic sorbents consisting of hydroxides or insoluble salts of multi-charged metal ions applied on porous supports such as carbon, active sludge and sawdust has been reported.¹²⁸ These sorbents can be used to remove non-ferrous metal ions from wastewater of electrochemical plants.

Extraction of heavy metal ions from sea water can be carried out using adsorbents based on activated carbon, poly(vinyl acetate) or a fibrous non-woven material modified by treatment with a hydrosol of titanate acid (with a concentration of 5% – 10 % and a size of colloidal particles of 1 – 100 µm).⁷¹

The sorption properties and stability of titanium-containing sorbents on a sawdust support have been considered.^{129, 130} The kinetics of peptisation of a wood-supported titanium hydroxide layer in water were studied and some assumptions as to the nature of the bond between the sorption material and the support were made.¹³⁰

The main chemical and analytical characteristics of the immobilised reagents described above are summarised in the general Table 1.

V. Conclusion

Analysis of the published data indicates that the new line of research associated with the use in chemical analysis of reagents immobilised on the surface of various supports is quite promising. These reagents increase the sensitivity and selectivity of determination of many elements.

The decrease in the detection limits is achieved due to the concentration of the components to be analysed from a relatively large volume of a solution into the phase of a sorbent. Unlike extractive concentration, the sorption methods do not require the use of organic solvents and, hence, they cause no health hazard. The sorbents themselves are non-toxic and are readily separated from solutions by filtration, which makes the analysis quicker.

The better selectivity of these methods results from the fact that in some cases, owing to some geometrical features of fixing of organic reagents on a support surface, their complex-forming properties, for example, dentate number, change upon immobilisation. It can be assumed that modified sorbents extract most efficiently those metal ions that react with the immobilised reagent to give ion associates or complexes with a metal : ligand ratio of 1 : 1. In this case, steric restrictions caused by fixing of the ligand on the surface of the sorbent are minimised.

The subsequent development of this branch of analytical chemistry requires that the chemical nature of immobilisation of reagents on the surface of solid supports be elucidated.^{67, 131} At present, the reagents are mostly fixed on the surface of a matrix by ion – ion interaction; other types of interaction are used much more seldom. In the latter cases, the chemical nature of the interaction of reagents with the sorbent surface is usually ignored, and the way of immobilisation is selected empirically by changing the solvents. Study of the chemical nature of the interaction of various classes of reagents with the surfaces of supports and elucidation of the regularities of the complex-formation involving supported ligands would markedly extend the analytical potential of the sorption methods. It is also necessary to work out scientifically justified criteria that would permit 'solid-phase reagents' to be regarded either as organic reagents modified with a surface or as sorbents modified with analytical reagents; at the current stage of investigation, this consideration is sometimes difficult.

Abstract. The current state of investigations of the relationship between electronic transitions and molecular topology of linear conjugated systems, *viz.* polymethine dyes and α,ω -disubstituted polyenes, is considered. The effect of parity of methine groups in a polymethine chain, of filling of the electronic shell, molecular symmetry, and the topology of terminal groups on the electronic structure of polymethines and polyenes are described. Spectral effects arising upon changes in the structures of chromophores, and the nature of the first and higher transitions in linear conjugated compounds containing several chromophores are discussed. The localisation of transitions in molecular fragments and the conditions for the inversion of the polymethine and local electronic transitions in polyenes and polymethines are considered. The bibliography includes 242 references.

I. Introduction

According to current theoretical concepts on the electronic structure of conjugated systems, in particular, the triad theory being developed by Daehne,^{1–4} the conjugated compounds with a stable closed electronic shell can be classed into three basic types: aromatic compounds, polymethines, and polyenes. Aromatic compounds have a cyclic structure, the CC bond lengths are equalised and the carbon atoms bear no noticeable charge. The linear conjugated systems (LCS) under consideration always have the *trans*-conformation. Polymethines are distinguished by the alternation of significant positive and negative charges on the carbon atoms and by maximum equalised CC bonds. On the contrary, polyenes are characterised by a significant alternation of the CC bond lengths and the lack of charges.

Linear conjugated systems contain, as a rule, terminal groups (TG) conjugated with the polymethine chain (PC). In the general case, LCS with a non-branched PC and one π -system can be represented as follows:

where G_1 and G_2 are TG, m is the number of the methine groups, z is the charge ($z = 0; \pm 1; \pm 2$). Individual atoms, simple groups of atoms, and complex carbo- and heterocyclic residues with a branched π -system can serve as TG.

Traditionally, LCS with an odd number of polymethine groups in the PC are termed polymethine dyes (PMD); systems with an even number of π -centres in PC are termed α,ω -hetero-substituted polyenes or heterylpolyenes (HP).^{5–13} Symmetric PMD and HP differ substantially in several chemical and spectral properties, therefore, these two types of conjugated compounds are usually studied separately (it is especially true for experimental studies).^{6, 9, 14–16} If LCS have an asymmetric structure, the difference between PMD and HP decreases.

Linear conjugated systems are suitable and favourite objects for the studies of problems of the colour theory. A chromophore in these systems has a relatively simple structure that can be easily varied; their absorption and fluorescence spectra manifest relatively narrow and intense bands, especially in the case of PMD. It permits a reliable identification of electronic transitions and successful application of methods of quantum chemistry to studies of the relationship between structure and colour.

Due to unique spectral characteristics of LCS, they have found widespread practical application connected with the transformation of light energy. For example, LCS are used as optical sensitizers,^{13, 17–19} active media and passive modulators of the duration of lasers,^{20–24} initiators for polymerisation reactions,^{25–28} organic photoconductive materials,^{29–32} systems with a high polarisability for non-linear optics,^{33–37} and fluorescent markers.^{33, 39}

The creation of novel promising compounds with a given range of absorption and a number of other properties usually presumes preliminary estimation of the most important of their characteristics. This estimation is based on the well-developed colour theory or more precisely, on the theory of electronic transitions. The present review is devoted to the consideration of the current status of investigations of the relationship between molecular topology of LCS and the nature of their electronic transitions.

II. Specific features of electronic structure

1. Boundary molecular orbitals and classification of linear conjugated systems

Boundary molecular orbitals (BMO), *viz.*, the highest occupied (HOMO), and the lowest unoccupied (LUMO) orbitals, and the

orbitals close to them in energy are the most interesting for the theory of electronic transitions in LCS.

Symmetrical LCS (see 1, where $G_1 = G_2 = \text{TG}$) can be subdivided into four groups according to the symmetry of BMO and the parity of the number of the methine groups in PC.⁴⁰

1. Polymethines of class A in which m is odd, the HOMO is symmetric, and the LUMO is antisymmetric relative to the central atom;

2. Polymethines of class B in which m is odd, the HOMO is antisymmetric, and the LUMO is symmetric relative to the central atom;

3. Polyenes of class A in which m is even, the HOMO is symmetric, and the LUMO is antisymmetric relative to the midpoint of the central bond;

4. Polyenes of class B in which m is even, and the symmetry of the HOMO and LUMO is opposite to that of LCS of group 3.

Lengthening of the chain of PMD or HP by one vinylene group is accompanied by a change in the class of the compound. The class of LCS depends also on the number of the HOMO: the addition or removal of a pair of π -electrons changes the class to the opposite one.

The linear conjugated systems can exist in several forms depending on the ratio between the number of π -electrons and p-centres. Thus for non-substituted polymethines or PMD with alternant hydrocarbons as the TG, two forms are possible, namely, the electron-excess or $(N + 1)$ form (polymethine cation) and the electron-deficient or $(N - 1)$ form (polymethine anion), where N is the number of π -centres. In the case of non-substituted polyenes or HP with alternant TG, three forms are possible: the electron-excess $(N + 2)$ form, the electron-balanced N -form, and the electron-deficient $(N - 2)$ -form.⁴¹

2. Electron donor ability and topological indices of terminal groups

In the Hückel approximation, occupied and vacant levels in unsubstituted polyenes are symmetric relative to the level of the non-bonded π -electron (the Fermi level of π -electrons), whereas non-substituted polymethines contain a non-bonding level that is occupied in anions and vacant in cations. The distance between the Fermi level and neighbouring levels decreases with a lengthening of PC, however, the relative position of the energy gap between the highest occupied and the lowest vacant levels remains the same. The introduction of a TG results, as a rule, in the change in the relative position of the energy gap in LCS.

A φ_0 parameter was proposed⁴⁰ for quantitative characterisation of the relative position of boundary levels

$$\varphi_0 = 90^\circ \frac{\varepsilon_e - \alpha}{\varepsilon_e - \varepsilon_0}, \quad (1)$$

where ε_e is the energy of the LUMO, ε_0 is the energy of the HOMO, and α is the energy of the Fermi level.

Another form of the representation of the φ_0 parameter is

$$\varphi_0 = 90^\circ \frac{x_i}{x_e - x_0},$$

where x_i is the energy of an i th MO expressed in the β units and referred to the Fermi level α , $x_i = (\varepsilon_i - \alpha)/\beta$; ε_i is the energy of any i th MO, and β is the resonance integral of the CC bond in PC.

It is seen from formula (1) that an increase in the φ_0 parameter should correspond to an increase in the polarographic reduction potential and the electron affinity and to a decrease in potentials of oxidation and ionisation. The φ_0 parameter reflects the electron donating properties of LCS and is therefore termed as the electron donor ability.⁴⁰

For molecules with stable, closed electronic shell, the φ_0 value is usually positive and falls within the interval

$$0 \leq \varphi_0 \leq 90^\circ. \quad (2)$$

A model of LCS with a rather long PC appeared to be useful for a quantitative account of the influence of the topology of TG.^{12,42–46} In the context of this model, the energies of the boundary and close molecular orbitals (ε_l) can be represented as a function of parameters of individual molecular fragments.

$$\varepsilon_l = \alpha + \frac{2(\Phi_{01} + \Phi_{02} - \pi l/2)}{m + L_1 + L_2} \beta, \quad (3)$$

where m is the number of methine groups in PC, Φ_{01} , Φ_{02} , L_1 , and L_2 are topological indices of both TG, l is the number of the MO.

The topological parameter of the zero order Φ_0 corresponds to a displacement of the nodes of BMOs from the positions that they occupy in non-substituted LCS. This parameter characterises the ability of TG to donate the π -electron density to the atoms of PC.⁴⁷ It can be compared with the value of additional stabilisation of double bonds (ASDB)⁴⁸ introduced by Brooker and with experimental estimations of the properties of TG as bases, for instance, with the parameter b ('basicity') proposed by Platt⁴⁹ or 'electron donor ability' D proposed by Il'chenko.⁵⁰

The topological index L reflects quantitatively the effective lengthening of a chromophore at the expense of the π -system of TG and can be expressed by the equivalent number of methine and vinylene groups.

The parameters Φ_0 and L are calculated *via* junior coefficients of the polynomial for TG ($Q = q_0 + q_1x + \dots$) and its minor ($R = r_0 + rx_1 + \dots$) with no regard to the atom bound to the PC.^{44,46}

$$\text{tg } \Phi_0 = -\frac{q_0}{r_0}, \quad (4)$$

$$L = \frac{2q_1r_0 - 2q_0r_1 + q_0^2}{q_0^2 + r_0^2}. \quad (5)$$

In the framework of the model of long LCS, the additive parameters of TG of higher order were also obtained,^{51–53} however, only two topological indices Φ_0 and L are used in practice.

It was shown⁴⁰ that the topological parameter of the zero order Φ_0 is directly connected with the electron donor ability φ_0 by the following relations:

for PMD

$$\Phi_0 = \lim_{m \rightarrow \infty} \varphi_0, \quad (6)$$

for HP

$$\Phi_0 = \lim_{m \rightarrow \infty} \varphi_0 \pm 45^\circ. \quad (7)$$

The sign in formula (7) depends on the form in which the HP exists.

The parameter φ_0 characterises the relative position of the boundary levels, *i.e.* it has a distinct physical meaning and can therefore be measured experimentally. For example, linear relationships between redox potentials, the transition energy, or the ionisation potential, on the one hand and calculated energies of MO, on the other hand, can be used for this purpose.⁵⁴

The parameters φ_0 and Φ_0 appeared to be useful for the analysis of the relative stability of LCS, which is understood as the stability of π -systems with the same values of the energy gap, *i.e.* of those absorbing in the same spectral range.⁴¹ The π -system is supposed to be stable if all the bonding levels are mutually filled and antibonding levels are vacant; in this case condition (2) is fulfilled. Molecules with a medium electron donor ability ($\varphi_0 = 45^\circ$) in which the energy gap is symmetrical relative to the Fermi level, appear to be the most stable.

According to formula (1), a change in the number of the HOMO by a unity, *i.e.* the passage from one group of LCS to another, corresponds to a change in the parameter φ_0 by 90° .

Hence, with regard to condition (2), only one form should be stable within the limits of the model with equivalent bonds. In fact, symmetric PMD that are characterised by equalising of bond lengths in PC exist, as a rule, in one form. Non-substituted polymethines or PMD with alternant TG having the boundary values of the φ_0 and Φ_0 parameters are the exceptions, when two unstable forms are possible.^{5, 7–12} It is seen from the ratio (6) that the maximum relative stability of PMD is ensured by TG with medium electron donor ability (with $\Phi_0 = 45^\circ$).

In the case of HP, the essential alternation of bond lengths in PC leads to an additional increase in the energy gap, larger displacement being experienced by the boundary level that is located closer to the Fermi level.⁴¹ The relationship between the φ_0 and Φ_0 parameters [see formula (7)] is complicated due to the alternation of bonds, therefore the electron donor ability changes less ($\Delta\varphi < 90^\circ$) on going from one form to another. Thus in the case of polyenes two forms are stable, as a rule (see, for example, a review⁶). Polyenes containing TG with the limiting values of the index Φ_0 equal to 0 or 90° appear to be the most stable. In this case, even three forms are able to exist: a stable, electron equalised and two less stable, an electron excess and electron deficient ones.⁴¹

3. Distribution of the electron density on atoms and bonds

a. Atomic charges

Non-substituted polymethines with a closed electronic shell are charged. The values of charges on the carbon atoms are defined as squares of coefficients of non-bonding MO (NBMO). The NBMO has nodes in the even positions. The nodal atoms bear no charges. In the odd positions, the charge value Δz depends on the number of π -centres in the chain (N), and the sign depends on the form of polymethine.

$$\Delta z \simeq \pm \frac{1}{N+1}. \quad (8)$$

The introduction of a TG is accompanied by a change in absolute values of charges in the odd positions and by induction of charges in the even positions. Formulae of the perturbation theory⁵⁵ can be used for the analysis of changes in the π -electron density q_μ .

$$q_\mu = q_\mu^0 + \pi_{1,\mu} h, \quad (9)$$

where q_μ^0 is the electron density on the μ th atom in non-substituted LCS, $\pi_{1,\mu}$ is atom-atomic polarisability, h is the magnitude of perturbation on the terminal atom of the chain.

For the middle of the chain we have

$$\pi_{1,\mu} \simeq \frac{1}{N+1} \left[\frac{2}{\pi} + (-1)^\mu \right] \text{ at } \mu \rightarrow \frac{N}{2} \text{ or } \frac{N+1}{2}. \quad (10)$$

It follows from formulae (9) and (10) that the sign of a change in the electron density depends on the sign of the term $(-1)^\mu$, i.e. on the parity of the position of TG. Consequently, the effects of TG in neighbouring positions are inverse. If a molecule of PMD contains two TG, their influence is synchronous because the parities of any position relative to both ends of the chain coincide.

According to the rule of 'topological charge stabilisation',^{56–58} the significant alternation of the electron density on atoms causes the relatively high stability of odd conjugated systems. *ab initio* Calculations have shown that polymethines are stabilised largely at the expense of a lowering of the potential energy of the π -electrons, while aromatic systems are stabilised due to their low kinetic energy.^{57, 58}

Hückel, PPP, CNDO/2, and MINDO/3 calculations have shown that the ratio between the absolute values of positive and negative charges on the carbon atoms in neighbouring positions in PMD depends unambiguously on the topological index Φ_0 (Fig. 1).^{12, 59–61}

Figure 1. Charges on atoms of PC in the ground state. Charge: (1) is positive, (2) is negative. Φ_0 /grad: (a) 76, (b) 45, (c) 27.

In contrast to polymethines, the π -electron density in non-substituted polyenes in the stable *N*-form, is uniformly distributed over all the carbon atoms, and the π -charges are lacking. The introduction of one TG induces the alternation of positive and negative charges as in the case for polymethines with one TG. However, in the case of symmetrical HP, the overall influence of two TG differs from that for symmetrical PMD, since for polyenes the parities of any position of carbon atoms in the chain relative to each end are opposite. This results in the annihilation of alternating charges in the middle of the chain in symmetrical HP.^{60, 61}

The regularities found for the charge distribution in the ground state of PMD and HP are confirmed by experimental observations, in particular, of the changes in chemical shifts in ^{13}C NMR spectra as the molecular topology of LCS varies.^{5, 62–66, 69}

A change in the π -electron density on going to the excited state Δq_v can be written in the analytical form:^{12, 60, 61} for PMD

$$\Delta q_v = a(-1)^{n+v+1} \cos\left(v\frac{\pi}{2}\right) \cos\left[va\left(\frac{\pi}{2} - \Phi_0\right)\right], \quad (11)$$

for HP

$$\Delta q_v = a(-1)^{n+v} \sin\left(v\frac{\pi}{2}\right) \cos\left[va\left(\frac{\pi}{2} - \Phi_0\right)\right], \quad (12)$$

where $a = 1/(n+L)$, n is the number of vinylenes groups in PC, v is the number of the atom counted from the midpoint of PC.

Changes in populations on neighbouring atoms are opposite in sign due to the first multiplier which is confirmed by calculations using more rigorous approximations.^{56–61}

An analysis of formulae (8)–(12) and of the results of quantum-chemical calculations shows that the excitation of the atoms of PC in symmetrical PMD results in recharge, i.e. the signs of the charges in the ground and excited states are opposite. In the case of symmetrical polyenes, the signs of the charges remain the same upon the transition of the molecule to the excited state.

b. Bond orders

The π -electron density on atoms of PC in PMD alternates strongly, whereas in HP it is equalised. As far as populations of bonds are concerned, the situation is opposite: populations alternate in polyenes and equalise in polymethines.^{1–4}

Calculations of symmetrical PMD predict nevertheless some alternation of the CC bond orders if the topological index Φ_0 (and therefore the electron donor ability φ_0) has an increased or decreased value; the amplitude of alternation is minimum in the midpoint of the chain and increases towards its ends.^{61, 67} Not

only the p_{uv} value of bond populations, but also the order of sequence of the bonds with larger or lesser population change with the change in the parameter Φ_0 . The absolute value of p_{uv} depends on the extent to which the parameter Φ_0 differs from the average value of 45° .

Non-equivalence of the CC bonds in PC of symmetrical PMD is confirmed by X-ray spectroscopy^{68,69} and by direct coupling constants in the NMR spectra.^{70–72}

Using analytic expressions for coefficients of MOs and, respectively, for bond orders in unsubstituted LCS,^{55,73–75} the amplitude[†] of the alternation of bonds can be calculated.

$$\Delta_\mu = p_{\mu,\mu+1} - p_{\mu+1,\mu+2}.$$

It has been shown that at the beginning of the chain of rather long polymethines and polyenes, the Δ_μ value approaches to the same limiting value of $1/\pi$, however, in the middle of the chain, the amplitude of the alternation of bonds differs significantly for different types of LCS: for PMD

$$\Delta_\mu \simeq \frac{(-1)^{\mu+1}}{(N+1)^2}; \quad (13)$$

for HP

$$\Delta_\mu \simeq \frac{(-1)^{\mu+1}}{N+1}. \quad (14)$$

Significant alternation of orders and, respectively, of bond lengths in polyenes is predicted by calculations within the more rigorous, *viz.*, semiempirical^{15,16} and *ab initio*,¹⁵ approximations. In the majority of cases, the difference between the lengths of neighbouring bonds is close to 0.08 Å. The degree of the alternation changes little upon introduction of donor and acceptor substituents.^{76–80}

On going from one form of polyenes to another, the order of sequence of the bonds with larger or lesser population, *i.e.* the sign of the parameter Δ_μ changes to the opposite. In the excited state, the alternation of bond orders decreases though for polyenes and the difference in the orders of neighbouring bonds still remains significantly larger than that for polymethines, the order of sequence of the bonds with increased and decreased population being opposite to that in the ground state.

c. Ideal electronic states

Daehne^{1–4} has introduced the concepts of ideal polymethine and ideal polyene states. In the general case, for LCS with an arbitrary TG, the conditions for the realisation of the ideal electronic states can be pointed out using the electron donor ability φ_0 and topological indices of the TG.^{40,61} Thus the ideal polymethine state is achieved in symmetrical PMD with the TG for which $\Phi_0 = 45^\circ$. In this case, $\varphi_0 = 45^\circ$ and the boundary levels are located symmetrically relative to the Fermi level, bond orders are equalised in both the ground and excited states, and the charges alternate to the maximum extent. The excitation of ideal polymethines leads to the maximum change in the electron density and to the minimum change in bond orders.

The opposite situation in the distribution of the π -electron density corresponds to the ideal state of polyenes in symmetrical HP. The boundary levels are also located symmetrically and $\varphi_0 = 45^\circ$, however, it is provided by the terminal residues with $\Phi_0 = 0$. The charges on the atoms in the ground and excited states are absent, but the difference in populations of neighbouring bonds is a maximum; the change in bond orders in the excitation is also a maximum.

Hence, both ideal states are achieved at $\varphi_0 = 45^\circ$, however, ideal polymethines contain a TG with $\Phi_0 = 45^\circ$ and ideal polyenes contain a TG with $\Phi_0 = 0^\circ$.

d. Asymmetric LCS

The violation of symmetry in molecules of LCS leads to the shift of nodes of MOs towards one TG. It is convenient to characterise the degree of asymmetry by the difference in the topological indices of the terminal residues

$$\Delta\Phi_{12} = \Phi_{01} - \Phi_{02},$$

the numbers of TG are denoted by subscripts 1 and 2.

It follows from calculations of asymmetrical PMD that the charges decrease in the middle of PC as the parameter $\Delta\Phi_{12}$ increases (see Ref. 47). At the ends of the chain of asymmetrical PMD, 'the behaviour' of charges is determined by the nature of the neighbouring TG, and the effect of the second TG decreases inversely with the length of PC.

Bond orders in asymmetrical PMD depend on two major factors, namely, the difference in the topological indices of the terminal groups $\Delta\Phi_{12}$ and the electron donor ability, which is connected with the topological indices by the relationship

$$\varphi_0 = \frac{\Phi_{01} + \Phi_{02}}{2}.$$

The latter factor causes an alternation of bonds from the centre of PC to its ends, as in symmetrical polymethines, which is proportional to the absolute value of the difference $|45^\circ - \varphi_0|$. The maximum alternation, uniform along all the chain, is achieved if $\Phi_{01} > 45^\circ$ and $\Phi_{02} < 45^\circ$.

In contrast to polymethines, the violation of symmetry in HP leads to an increase in the alternation of charges on neighbouring atoms and to a decrease in the alternation of bond orders in proportion to $\Delta\Phi_{12}$.

It was found that in the excited state the amplitude of the alternation of bond orders in asymmetrical PMD and HP is substantially less than that in the ground state.⁴⁷ Note that in solutions the polarity of a medium can also influence the degree of alternation of bonds.⁷²

III. Topology of polymethine chromophore

1. Electronic levels and transitions

The colour of LCS is known^{1–3} to be determined by intense $\pi \rightarrow \pi^*$ electronic transitions. The intensity of possible $n \rightarrow \pi^*$ transitions is negligibly small, therefore, they will not be considered in the present paper.

In non-substituted conjugated molecules, the π -orbitals are completely delocalised. However, if LCS contain complex TG with a developed π -system, orbitals localised largely on the terminal residues can appear. For the sake of convenience, the orbitals delocalised over all the molecule were suggested to be termed as polymethine MOs and those localised mainly in TG local or more precisely, quasi-local MOs.^{81–83}

Thus, in the general case, two major types of $\pi \rightarrow \pi^*$ transitions are possible in LCS, *viz.*, transitions between the polymethine MO (levels), the so-called polymethine electronic transitions (PET) and transitions with the participation of local levels, *i.e.* quasi-local and local transitions (LET).

Polymethine and local electronic transitions differ substantially in several characteristics: in the value of dipole moment, in the sensitivity to the length of PC and topology of TG, to the effect of substituents. As a rule, LET is accompanied by a significant intramolecular charge transfer from one fragment to another in which the MOs that take part in the given transition are localised.^{39,82,83} In this case, the dipole moment of the molecule increases strongly, these transitions are therefore sensitive to the polarity of a solvent.^{82–85} The corresponding absorption bands differ also in intensity and contour.⁸¹

[†] The difference between two values for neighbouring atoms or bonds and for two states, the ground and excited one, is denoted as amplitude.

Calculations show that in symmetrical PMD with equalised bonds, electronic levels in the vicinity of the Fermi level are arranged uniformly, and the first excited state is mainly described by the χ_1 configuration (Fig. 2). If the function of the p th excited state Ψ_p^* is represented as the expansion within the basis of χ_i electronic configurations

$$\Psi_p^* = \sum_i T_{ip} \chi_i,$$

it turns out that $T_{pp} > 0.9$. This allows the use of a one-configurational approximation often to a sufficient accuracy.^{5, 7, 12, 47, 61, 67}

Since the boundary MOs of symmetrical LCS have opposite symmetries, the first transition is antisymmetrical, $A_1 \rightarrow B_1$ and the moment μ_1 is directed along the polymethine chain. The next two transitions are symmetrical and are described by a superposition of χ_2 and χ_3 configurations (Fig. 2a); their moments are polarised perpendicular to PC. In the approximation of long LCS, the χ_2 and χ_3 configurations have the same energies E_2^0 equal to double the energy of the χ_1 configuration (Fig. 2b). The interaction of the configurations leads to two excited states with energies

$$E^+ = E_2^0 + h$$

and

$$E^- = E_2^0 - h,$$

where $h = \langle \chi_2 | \hat{H} | \chi_3 \rangle$ is the interaction energy, $|\hat{H}|$ is the Hamiltonian.

In the case of PMD, the splitting value h is relatively small and the energies of the second and the third electronic transitions exceed significantly the energy of the first PET (see Fig. 2b).

For polyenes, the distance between the boundary levels increases due to the alternation of bond lengths, whereas the

Figure 2. Electronic levels, single-excited configurations χ_i (a), and electronic states and transitions (b) in polymethines.

Figure 3. Electronic levels, single-excited configurations χ_i (a), and electronic states and transitions (b) in polyenes.

next vacant and occupied levels are located closer to the corresponding boundary level (Fig. 3); at a sufficient lengthening of the chain, the levels form zones.^{15, 16, 86, 87} As a consequence, the energy of the transition between the boundary levels ($A_1 \rightarrow B_1$) is always larger for polyenes than that for polymethines containing even shorter PC (see Fig. 3), which is confirmed experimentally (for instance, a large body of spectral data are reported⁸⁸ for PMD and HP).

In polyenes, the energies of χ_2 and χ_3 configurations differ from that of χ_1 configuration significantly less than in polymethines (see Fig. 3a). If the distance within the zones is relatively small and the interaction of the configurations is significant, the energy of one of the split states of the A_1 symmetry can appear to be even lower than that of the antisymmetrical B_1 state (see Fig. 3b).^{15, 16, 89–100} The symmetry forbidden A_1 state was really found experimentally (by two-photon spectroscopy) in non-substituted polyenes as the state with the lowest energy.^{15, 93, 101} Note that the excitation of polyenes is accompanied by equalising of the bonds; it can lead to the inversion of excited states of different symmetries. Thus in α,ω -diphenylbutadiene, photoemission occurs from the B_u state whereas absorption corresponds to the transition to the A_g state.¹⁰² In longer polyenes, the A_g state is emitting.

The introduction of a TG and the transition of one form to another lead, as a rule, to an increase in the distance between the levels within the zones and, therefore, to an increase in the difference between the energies of the χ_1 and the higher χ_2 and χ_3 configurations. That is why in these polyenes, the lowest excited state is still described by the χ_1 antisymmetrical configuration; it is the $A_1 \rightarrow B_1$ transition having a larger moment that is responsible for the colour of HP.

2. The length of polymethine chain

Koenig¹⁰³ has discovered experimentally that the lengthening of PC in symmetrical PMD shifts regularly the maximum of the absorption band to the long wavelength range. The value of this

shift upon the introduction of one vinylene group was termed as the vinylene shift

$$V = \lambda_{n+1} - \lambda_n,$$

the V value appeared to remain approximately constant in vinyl-ogous series of PMD and is equal to ~ 100 nm.^{5, 48, 49, 88, 104} Therefore, the vinylene shift can be considered as an additive contribution of one vinylene group (topological unit of PC) to this integral characteristic of the molecule as the absorption wavelength λ_n .

In vinylogous series of HP and asymmetrical PMD, the vinylene shift decreases regularly; Brooker called these series convergent unlike non-convergent series in the case of symmetrical PMD with a constant vinylene shift.⁴⁸

Naturally, similar shifts of the bands with the lengthening of PC is also observed in fluorescence spectra. It was shown that the V values in the fluorescence and absorption spectra of symmetrical PMD are nearly the same.^{12, 23, 24, 105–107}

PPP and CNDO/C calculations of the vinylene shift for vinylogous series of LCS show that the value of the parameter V depends, first, on the degree of equalisation of bonds in PC; alternation of bonds leads to an increase in the energy of PET in proportion to the number of bonds thus resulting in a decrease in vinylene shifts.^{5, 12, 104} It was shown above that bond orders in PC are 'sensitive' to the electron donor ability ϕ_0 , the type and shape of LCS, symmetry, and topological indices of TG. These factors should also influence the additive contribution of PC into the wavelength of PET.

a. Vinylogous series of polymethine dyes

Since PMD are characterised by equalising of bonds, significant vinylene shifts are observed in their spectra that change little with the lengthening of PC. Figure 4 shows the spectral data for the following vinylogous series of the most known polymethines:

The vinylene shift changes somewhat with the change in the polarity of a solvent.^{85, 108, 109}

In some species of PMD, the first vinylene shift deviates from an average value of 100 nm due to the interaction between TG in

Figure 4. The dependence of wavelengths of the maxima of absorption bands $\lambda_{\max}$ of PMD 2–9 on the chain length.

monomethine dyes ($n = 0$), which disappears as the PC lengthens. Thus for quino-2-monomethinecyanines 3, ($n = 0$), steric hindrances are accompanied by a bathochromic effect and V is equal to 82 nm, whereas the second and the third vinylene shifts are equal to 98 and 100 nm.¹⁰⁴ In the case of dyes 2 and 9, the V value is influenced by the resonance interaction of valent non-bonded sulfur atoms, and the spectral effect depends on the class of compound: if the monomethine dye belongs to class A (2), the first vinylene shift is increased ($V = 182$ nm); if the first member of the series belongs to class B (9, $n = 0$), the V parameter decreases and is equal to 65 nm.¹¹⁰

The vinylene shift is 'sensitive' to the topology of TG.^{104, 111–113} If the Φ_0 index differs significantly from the average value of 45° , as, for example, in PMD 4 ($\Phi_0 = 0^\circ$), the alternation of bonds from the centre to the ends appears in PC and the value of the V parameter decreases to 60 nm.¹⁰⁴

b. Vinylogous series of heterylpolyenes

For polyenes, the dependence of the energy of PET on the PC length and the Φ_0 topological index is even more complicated due to both significant bond alternation and the possibility for the existence of several stable forms. It should be also noticed that the absorption bands for HP are relatively broad, their maxima are poorly resolved (see, for example, Refs 114–117).

The fact that the difference in the lengths of neighbouring bonds is a maximum in non-substituted polyenes causes very small vinylene shifts and their gradual damping as the PC length increases.^{15, 88, 104} An increase in Φ_0 with the introduction of TG is accompanied by some increase in the parameter V . Thus for non-substituted polyenes $V = 33–18$ nm at $n = 1–6$, for conjugated α,ω -diketones ($\Phi_0 = 63^\circ$) $V = 50; 50; 33; 29; 26$ nm at $n = 1–6$.¹¹⁸

The amplitude of alternation of bond lengths depends also on the shape of a polyene which should also influence the magnitude of the vinylene shift. Thus, for the electron-equalised N -form of α,ω -diphenylpolyenes, $V = 28–17$ nm at $n = 1–6$; for the electron-excess ($N + 2$) form, $V = 50$ and 57 nm at $n = 4; 5; 6$.^{88, 104}

It appeared that in the cases when two forms of HP are possible, the more stable form as a system with a larger amplitude of bond alternation has a more shortwave colouration and smaller vinylene shifts; stronger absorption and somewhat larger values of the parameter V are characteristic of the less stable form. Table 1 lists the band maxima of vinylogous series of polyenes 10–12 with TG of various electron donor ability for which two forms are known.

Table 1. The maxima of the absorption bands for different forms of polyenes **10–12** (nm).^{73, 75}

PC	Φ_0 /deg.	n	$(N + 2)$ -form, $z = 0$		N -form, $z = 2 +$		$\Delta\lambda^a$

	27	4	410	25	575	40	–165
	27	5	423	13	613	38	–190

^a $\Delta\lambda = \lambda_{\max}[(N + 2)\text{-form}] - \lambda_{\max}[N\text{-form}]$.

**10****11****12**

As seen from Table 1, it is stable dications of polyenes **10** with strongly electron donating benzimidazole residues that are more highly coloured and for polyenes **12** with low electron donating β -indole nuclei, it is neutral molecules that are more highly coloured. The difference between the maxima of the absorption bands of different forms increases as PC lengthens and the number of alternating bonds increases.

3. Lengthening of chromophore at the expense of terminal groups

The energy of PET is known to be significantly affected by, both the length of PC and the topology of TG.^{5, 12, 48, 49, 88, 104, 112, 113} Thus, carbocyanines **1** absorb in the range of 500–600 nm,⁸⁸ and dyes **14** with the same length of PC absorb in the range of 600–800 nm (Scheme 1).¹¹⁹

In the framework of the colour theory, it is convenient to consider this effect of TG as an effective lengthening of the polymethine chromophore.¹⁰ Various empirical increments were proposed for its quantitative estimation.^{49, 120–125} They appeared

Scheme 1

**13****14**

Se	795

to remain approximately constant for the entire vinylogous series. However, they can be used only for the analysis of novel members of vinylogous series of LCS; empirical increments are hardly suitable for prediction of energies of transitions in compounds that have not been synthesised yet. The topological index of the first order L coined in the approximation of long polymethines^{42–47} appeared to be more convenient for the theoretical determination of the effect of TG on spectral characteristics of LCS. In this case, the wavelength of PET can be written as

$$\lambda_n = V(n + L). \quad (15)$$

This formula allows the understanding of the physical meaning of the parameter L : this is an effective length of TG expressed as an equivalent number of vinylene groups.

In the case of TG with the linear non-branched π -electron system, the effective length L is proportional to the actual dimensions of the molecule. For complex cyclic systems, it can be less than the real range of delocalisation of electron as it is, for example, in dyes **15** ($L = 2.7$) or exceed it significantly as in dyes **16** ($L = 12$).

**15****16**

The effective length L shows how many vinylene groups the model LCS with equalised bonds should contain for its first absorption band to fall in the same spectral range as the band of a dye with the given TG. Since the index L is calculated from formula (5), it reflects mathematically correctly such topological factors of TG as linearity or branching of the π -system; the presence, the number, position and size of the rings; the position of attachment of PC, the location and characteristics of heteroatoms and heterobonds.^{12, 42–46}

The concept of effective length of TG appeared to be useful for both the interpretation of the regularities observed in the spectra of LCS and for the search for novel compounds with the required spectral properties, in particular, dyes absorbing in the near IR range. A deep colour can be ensured mainly by two routes: by lengthening of the polymethine chromophore due to the introduction of additional vinylene groups into PC and by the introduction of TG with a large effective length.

The second route is more promising since dyes with a long open chain are not stable as the possibility of rotation about CC bonds increases, which leads to a sharp decrease in the efficiency of sensitisation and quantum yield of fluorescence. The combination of both approaches, *viz.*, the use of a long PC fixed rigidly by polymethylene bridges, and the use of pyrylium residues and its

heteroanalogues or benzo[*c,d*]indolium with a relatively large effective length, allows the absorption range of 1300–1500 nm to be achieved.^{5, 23, 24, 113, 126–133}

Systematic theoretical studies of the effect of the topology of TG on transition energies in LCS, in particular, the effect of cyclization of a part of PC,^{12, 45, 134} annelation of TG^{135–138} can be performed using the parameter *L*. In many cases, expressions for the indices Φ_0 and *L* can be written in the convenient analytical form.

4. Asymmetrical systems

The violation of the symmetry of LCS influences significantly the electronic transitions, spectral effects depending markedly on the type of compound.

Asymmetrical LCS are usually considered as derivatives of the corresponding symmetrical compounds, which are usually referred to the as parent compounds (see, for example,^{5, 9, 48–50, 139}). In the construction of asymmetrical systems, a half of the molecule is taken from one symmetrical parent compound, the other half is taken from another parent compound. If the initial systems, PMD and HP, belong to the same class, an asymmetrical system of the same class is obtained, *viz.*, polymethine or polyene, respectively; if the classes do not coincide, this gives a system of the opposite type. However, in the case of asymmetrical HP, the ambiguity arises because at least two forms of polyenes differing by a pair of π -electrons have a stable electronic shell.

In order to estimate quantitatively the degree of asymmetry, deviations *D* are traditionally used, which can be calculated in the following way:^{9, 48}

$$D = \frac{\lambda_1 + \lambda_2}{2} - \lambda_a, \quad (16)$$

where λ_1 and λ_2 are absorption maxima of the corresponding symmetrical parent systems, λ_a is the absorption maximum of the asymmetrical molecule.

Kiprianov and Pilyugin¹⁴⁰ and independently Brooker⁴⁸ have observed that for polymethine dyes $D > 0$, *i.e.* the position of the maximum for an asymmetrical dye λ_a is shifted towards short wavelengths as compared to the arithmetic mean value from the maxima of the mother dyes λ_1 and λ_2 . Thus can be rationalised by the fact that if TG are non-equivalent, the alternation of longer and shorter bonds arises in PC.

Energies of transitions and deviations in asymmetrical LCS can be determined from both absorption and fluorescence spectra; the difference consists in the structure of the initial state.

a. Absorption spectra

Specific features of absorption spectra of asymmetrical LCS are determined by the specific features of populations of bonds in a polymethine chromophore in the ground state.

As was shown above, the bonds with a larger or smaller order alternate in PC of asymmetrical PMD; the amplitude of the alternation of π -populations of neighbouring bonds (bond orders) is proportional to the difference in basicities of TG or the difference $\Delta\Phi_{12}$. Accordingly, deviations of absorption bands also increase.^{9, 48–50} In asymmetrical chromophore, however, the alternation of populations of bonds from the centre to the ends can additionally arise if the electron donor ability φ_0 differs from the average value of 45°. That is why deviations are sensitive not only to the difference in the topological indices $\Delta\Phi_{12}$, but also to the parameter φ_0 , which relates to indices of TG in the case of asymmetrical PMD in the following way:

$$\varphi_0 = \frac{\Phi_{01} + \Phi_{02}}{2}.$$

Deviations appear to be a maximum if $\Phi_{01} > 45^\circ$ and $\Phi_{02} < 45^\circ$. In this case the alternation of bonds in the vicinity of nuclei is

synchronous with that along the chain, and its amplitude is maximum at a given $\Delta\Phi_{12}$ difference. If both TGs have either increased ($\Phi_{01} > 45^\circ$, $\Phi_{02} > 45^\circ$) or decreased ($\Phi_{01} < 45^\circ$, $\Phi_{02} < 45^\circ$) basicity, the alternation is weakened, and the deviations in these PMD are practically lacking (or insignificant), though they still grow somewhat as the $\Delta\Phi_{12}$ difference grows.^{9, 48, 141, 142}

The violation of symmetry in polyenes leads to the opposite change in bond orders as compared to that in PMD: bonds in asymmetrical HP are more equalised than in the corresponding parent compounds. For this reason, the deviations calculated from formula (16) should be negative, which was proved by experimental studies of vinylogous series of asymmetrical polyenes (17) with one constant nucleus and variable residues.^{143, 144} The spectral characteristics are listed in Table 2.

As is seen from the presented data, the deviations are really negative, *i.e.* the absorption maximum of an asymmetrical poly-

Table 2. Spectral characteristics of asymmetrical polyenes 17.¹⁴⁴

ene is shifted to the long wavelength range as compared to the arithmetic mean from the maxima of the corresponding symmetrical parent HP. The absolute value *D* increases regularly with an increase in the topological index Φ_0 of the variable residue in the series indolenine–benzothiazol–2-quinoline.

b. Emission spectra.

Specific features of the structure of the excited state should influence the energies of transitions determined from fluorescence spectra. As was mentioned above, in the case of asymmetrical LCS, bond orders equalise substantially on excitation. For this reason, emission spectra are remarkably less sensitive to the violation of symmetry, and the additive formula should be true for them

$$\lambda_n^{\text{fl}} = V^{\text{fl}} \left(n + \frac{L_1 + L_2}{2} \right). \quad (17)$$

An analysis of the spectra has shown that deviations of the maxima of fluorescence are 1–2 orders of magnitude less than those of absorption maxima.^{23, 24, 106, 107} Thus, for dye 18 with a rather long PC, the deviation calculated from the absorption spectra is 176 nm whereas that of the fluorescence maximum is only 3 nm.¹⁰⁶

The studies of vinylogous series of asymmetric of dyes **19** and **20**

have shown that the contribution of PC also appears to be additive.^{24, 106, 107, 145–147} As is seen from the data of Table 3, the V^{fl} parameter is virtually equal to 100 nm and changes little with the lengthening of PC while V is significantly smaller and decreases on going to higher vinylogues.

The alternation of bonds in polyenes and asymmetrical polymethines leads to the formation of photoisomers in the excited

state, which can appear in fluorescence spectra, especially when measured by flash spectrometry.^{148–151} Calculations show that the height of the conformational barrier depends on the nature of TG.^{148, 149, 152–154}

Substantial difference in the energies of transitions observed in the absorption and emission spectra is used in practice for the creation of dyes with large Stokes shifts. These dyes are applied in quantum electronics (see, for example, review²⁴).

5. Branching of a chromophore

Symmetrical branching of a chromophore observed in the so-called tri-nuclear dyes (TPMD) is of special interest. The effect of this change in molecular topology manifests itself most clearly (**21**).

Simultaneous lengthening of each branch of PC yields homologous series of TPMD. A stable closed electronic shell is characteristic of TPMD in the form of monocations (monoanions) or dications (dianions), as for example,

If all three TGs have identical structures, the ion of TPMD in the ground state has the C_3 symmetry, which is confirmed by the ¹³C NMR spectra.^{155, 156} In the crystalline state, the C_3 symmetry is maintained only for single-charged dyes having one counterion; in the case of TPMD with two counterions, this symmetry is violated.¹⁵⁶ The C_3 symmetry of the chromophore leads to the degeneracy of the antisymmetrical MO. For TPMD with an even number of methine groups m , the LUMO is degenerate in each branch, for those with an odd m , the HOMO is degenerate.

Note that branching of a chromophore is also possible if a central cycle, three-^{158, 159} or four-membered¹⁶⁰ one, is introduced.

a. Trimethine shifts

The degeneracy of one of the boundary orbitals leads to the degeneracy of PET; therefore, two transitions are responsible for the observed longwave band.^{161, 162} The violation of the equivalence of bonds in branched PC causes broadening of absorption bands (to 1300–1500 cm^{−1})¹⁶² as compared to PMD with two TGs (~ 900 cm^{−1}).¹⁶³

The contribution of PC into the wavelength of PET in the case of TPMD is evaluated as the so-called trimethine shift T

$$T = \lambda_m - \lambda_{m-1}. \quad (18)$$

It has been shown¹⁶⁴ that the parameter T depends on the parity of the number of the methine groups the topological index m and Φ_0

$$T = V + (-1)^m \Delta \left(\frac{\pi}{2} - 2\Phi_0 \right), \quad (19)$$

where $\Delta = V/3\pi \approx 10$ nm.

Due to the $(-1)^m$ multiple the trimethine shift alternately exceeds or is less than as the vinylene shift V , which is in accordance with the experimental data for TPMD **22** with indolenine residues (Table 4).

The data presented in Table 4 also confirm that the trimethine shift depends on the Φ_0 index.

b. Asymmetrical trinuclear polymethine dyes

The violation of the C_3 symmetry lowers the degeneracy of MO and, hence, the degeneracy of electronic transitions; the splitting of the levels is proportional to the difference between the effective lengths of TG. When the topological indices differ sufficiently, two transitions in asymmetrical TPMD can manifest themselves in the spectra as separate maxima, which was observed for asymmetrical [2.2.2]heptamethinecyanines **24** containing two identical TGs and one differing in structure.^{161, 162}

If effective lengths of the nuclei differ insignificantly (for 2-quinoline, benzothiazole, benzimidazole, $L = 3.0-3.5$), the absorption band has one maximum. The introduction of residues with a relatively high L value such as pyrylium (6.06), thiopyrylium (7.26), benzo[*c,d*]indole (6.50), causes splitting of the absorption band (Fig. 5).

**Figure 5.** Absorption spectra of asymmetrical trinuclear dyes **24a-c**.**c. Excited states**

Population of the degenerate excited state of symmetrical TPMD should be accompanied, according to the Jahn–Teller rule, by a significant change in the molecular geometry. If lifetime of the excited state is sufficiently long, one of the branches of TPMD

deviates from the plane, and the symmetry of the chromophore lowers. It was pointed in a number of publications^{156, 157, 165–167} that in the excited state one of the branches is located perpendicular to the plane of the rest of the molecule. Similar situation seems to occur in asymmetrical TPMD with symmetrical branching of PC at a small splitting of the energies of the states.

If TPMD contains one nucleus differing from the others, two conformers are possible: one corresponds to symmetrical binuclear dye with a substituent in the meso position, the other corresponds to the meso-substituted asymmetrical dye. A substantial change in geometry upon excitation leads also to significant Stokes shifts $\Delta\nu_C$. Table 5 lists the luminescence spectral data for asymmetrical TPMD **25**. The Stokes shifts are in fact greater than those for binuclear dyes for which $\Delta\nu_C$ is 400–500 cm^{-1} . In the case of TPMD **25c** and **25h** bearing TG with significantly different basicities (indolenine, benzimidazole), two conformers with different fluorescence maxima were observed.^{162, 168}

**Table 5.** Spectral characteristics of TPMD **25**.^{162, 168}

IV. Changes in the structure of the polymethine chromophore

In addition to the basic topological factors that were comprehensively considered above, the energy of PET is appreciably influenced by such changes in the structure of polymethine chromophore as substitution of the methine groups by heteroatoms, introduction of substituents and the acetylene-cumulene bond, steric hindrances, cyclization of a part of PC, etc. These effects can be interpreted relatively reasonably within the framework of perturbation theory.^{169–174} The final expressions resemble the well-known Hammett relationship

$$\Delta\lambda_{\max} = \rho\sigma, \quad (20)$$

where $\Delta\lambda_{\max}$ is the spectral effect of perturbation, ρ is the change in the electronic structure of the chromophore upon excitation, and σ is the magnitude of perturbation.

Let us consider the most important types of perturbations of the structure of chromophore.

1. Replacement of methine groups by heteroatoms.

Within the framework of perturbation theory, this change in the structure can be simulated by varying the electronegativity of the μ th atom or more precisely, the h_μ Coulomb integral. A change in

the wavelength of PET appear to be proportional to a change in the electron density (Δ_μ) upon excitation.^{170–172}

$$\Delta\lambda = a\Delta_\mu h_\mu, \quad (21)$$

where

$$a = \frac{V(n+L)^2}{\pi}.$$

It was shown above that PMD are characterised by a remarkable changes in atomic populations during electronic transitions, whereas in HP chromophore Δ_μ values are substantially smaller. As a result, the heterosubstitution in polyenes affects the spectra much less. Thus the spectral effect of the replacement of the methine group by the nitrogen atom in PMD can exceed 100–120 nm, especially for the middle of the chain; on approaching the nuclei, the maximum is less shifted.^{5, 9, 10, 170–172, 175} The changes in the spectra of polyenes are much less. Moreover, it should be taken into account that for HP the influence of the change in the degree of conjugation of the heterobond relative to the CC bond can overlap the effect of changes in electronegativity of the atom. It is the case, for example, for α,ω -diketones **26** in comparison to polyenes **27**.

n	$\lambda_{\text{max}}/\text{nm}$	$\Delta\lambda/\text{nm}$	
	26 ¹¹⁸	27 ¹⁰⁴	
1	228	256	−28
2	278	289	−11
3	328	317	+11
4	351	343	+8
5	380	366	+14
6	406	384	+22

2. Conjugated substituents

Heteroatom X with a lone electron pair can be an example of the simplest conjugated substituent.

X = F, Cl, Br, OR, SR, NR₂ ...

If the distance between the levels of a substituent and the boundary levels of the polymethine chromophore is significantly less than the energy gap, the formula for the displacement of the $\Delta\lambda$ maximum resembles formula (21). In the general case, with $\lambda = V(n+L)$, the formula can be written for the middle of the chain

$$\Delta\lambda = (-1)^{n+\mu+1} \left(\frac{\lambda_{\text{max}}^0}{\pi} \right) \delta_X;$$

$$\delta_X = \frac{C_{vj}^2}{\varepsilon_j} \beta_{CX}, \quad (22)$$

where atoms are numbered from the midpoint of PC, so that $\mu = 0$ for the meso position. The parameter δ_X characterises numerically the effect of the substituent: β_{CX} is the resonance integral between substituent X and the chromophore, C_{vj} is a coefficient of the j th MO of the substituent at the v th atom bound to the μ th atom of the chromophore, and ε_j is the energy of the level of substituent.

Formula (22) reflexes qualitatively the known Förster–Dewar–Nott rule^{172–174} concerning the direction of the shift of the longwave absorption band depending on the nature and the place of perturbation: the introduction of donor substituents ($\delta_X > 0$) or replacement of the methine groups by more electronegative atoms ($h_\mu > 0$) in the meso- and vinylogous positions (*i.e.* in the positions with the same parity, μ is even) in dyes A lead to bathochromic effects; on the contrary, the introduction of acceptor substituents ($\delta_X < 0$) or heterosubstitution by less electronegative atoms ($h_\mu < 0$) is accompanied under the same conditions by a shift of the maximum of the absorption band towards the shortwave region. For neighbouring positions and upon changing the class (*i.e.* the change in the number of vinylyne groups n in PC), the sign of the effect changes to the opposite, which is confirmed by a large body of experimental observations.^{88, 170, 176, 177}

Note that for a more rigorous quantitative estimate, the inductive effect of substituents should be also taken into account. Thus the following correlational equation connecting the absorption frequency for thiocarbocyanines with the constants of resonance δ_{res} and inductive δ_{ind} interactions was found:^{176, 178}

$$\Delta\nu = 67 - 1170(\delta_{\text{ind}} + 5.28\delta_{\text{res}}). \quad (23)$$

3. Rules of sensitivity

Spectral effects are rather sensitive to electron donor ability of LCS for the effect of conjugated substituents depends clearly on the distance between the interacting levels. A study of the influence of polar groups in thiazole and benzthiazole dyes¹⁷⁹ has shown that the spectral effect of electron donor groups decreases with an increase in the basicity of the dyes, and vice versa, the effect of electron-withdrawing substituents decreases under identical conditions.

Indeed, in PMD with high electron donor ability for which Φ_0 , $\varphi_0 > 45^\circ$, the boundary levels are up-shifted and located nearer to the vacant level of the electron-accepting substituent (for instance, cyano or nitro group). And on the contrary, the boundary levels appear to be distant from the occupied level of the donor substituent. Since the interaction between the levels is inversely proportional to the distance between them, these dyes, other conditions being identical, are more sensitive to acceptor substituents; on the contrary, donor substituents cause smaller shifts of the absorption band.

In dyes with a decreased electron donor ability (Φ_0 , $\varphi_0 < 45^\circ$), the boundary levels are located nearer to the level of the donor substituent. For this reason, these dyes are more sensitive to similar substituents. Acceptor substituents should cause lesser effect, for their levels are more remote from the boundary levels responsible for the electronic transition. PMD, derivatives of benzo[*c,d*]indole with a decreased electron donor ability can provide the experimental evidence;¹⁸⁰ the introduction of donor groups leads to a larger shift of the maximum of the absorption band than the introduction of the electron-withdrawing nitro group.

Another rule concerns the magnitude of hypsochromic and bathochromic effects. An analysis of energies of transitions and mutual location of a chromophore and a substituent shows that the bathochromic shifts of the band of PET result from the interaction between the level of the substituent (both donor and acceptor) and the boundary level that is located closer to it, and hypsochromic shifts result from the interaction with the substituent having the more distant level. Bearing in mind that the levels usually repel and the shift of levels is inversely related to the distance between them, the following rule can be formulated: the introduction of conjugated substituents should cause larger, other conditions being identical, bathochromic shifts of absorption bands in the spectra, the difference between the values of the bathochromic and hypsochromic shifts being the larger, the greater is the energy gap.

Table 6. Spectral data for chromophore-substituted PMD **28–31**.

Dye	R	R ¹	$\lambda_{\max}$ /nm	$\Delta\lambda$ /nm
The data of Ref. 176				
28	H	H	556	—
	CN	H	610	+ 54
	H	CN	529	–33
29	H	—	636	—
	CN	—	613	–23
The data of Ref. 181				
30	H	—	758	—
	CN	—	810	+ 52
31	H	—	766	—
	CN	—	884	+ 118

This can be illustrated by the spectral data for cyano-substituted thiacyanines (BT is the benzothiazole residue) presented in Table 6.

In the case of heterosubstitution, the absolute values of the hypsochromic shifts appear to be bigger than those of the bathochromic shifts due to the alternation of bonds arising in the chromophore.^{171, 175}

4. Cyclisation of a part of the chain

Let us consider a fragment of the chromophore in which the bridge Q can be an ordinary bond, an atom (O, S), or a group of atoms (NR, (CH₂)_m, CH = CH, *o*-C₆H₄, etc.).

Spectral effects of symmetrical cyclization can be predicted.¹⁸² The influence of cyclization with involvement of a single bond can be simulated within the framework of perturbation theory by increasing the resonance integral from zero to some finite value. Spectral effects may be rather significant (of the order of 100–200 nm).^{10, 182}

The formation of cycles *via* bridges resembles the introduction of conjugated substituents with the only difference that two bonds are used instead of one. However, it is an increase in the number of bonds formed between the reacting systems (the chromophore and the bridge) that determines the principal difference on cyclization.

The change in the energy of MO upon cyclization is described by the general formula:

$$\varepsilon_i = \sum_j \frac{1}{\varepsilon_i - \varepsilon_j} \left(\sum_{\mu} \sum_{\nu} C_{i\mu} C_{j\nu} \beta_{\mu\nu} \right)^2, \quad (24)$$

where ε_i and $C_{i\mu}$ are energy and coefficients of MO of the chromophore, respectively, ε_j is energy, and $C_{j\nu}$ are coefficients of the MO of the bridge Q; $\beta_{\mu\nu}$ are resonance integrals of the bonds formed upon cyclization.

Analysis of the formula (24) shows that the effect of cyclization differs from the sum of effects of two conjugated substituents by a factor that includes the composition of the coefficients of four atoms μ , μ' and ν , ν' involved in the formation of two bonds between the chromophore and the bridge: $2C_{i\mu}C_{i\mu'}C_{j\nu}C_{j\nu'}$. Hence, not only the signs of populations of orbitals on atoms determined by squares of coefficients are clearly taken into account, as in the case of substituents, but also the signs of the coefficients of MO. With regard to whether the signs of the coefficients coincide or not, the effect of cyclization can either exceed the overall effect of substituents or be practically absent as is proved experimentally using the cyclization *via o*-phenylene,^{183–186} vinylene,^{187, 188} and polymethylene^{64, 126, 181, 187, 188} bridges as examples.

Polyphenylenes and polyphenylenevinylene can be considered as polyenes with the vinylene bridges.¹⁸⁹ This change in the topology of PC leads to an increase in the energy gap. Analogous cyclization *via* the sulfur atoms is followed by a shift of zones of the levels.^{190, 191} This case, local levels of substituents appear between the zones, and the electronic transition is accompanied by the electron transfer through the conjugation chain. This phenomenon finds wide application in molecular electronics.^{191–193}

The above-formulated rule about a bigger absolute value of the bathochromic shifts of the absorption band is true for spectral effects of cyclization. To illustrate this, below are given formulae of thiacyanines¹⁸⁴ **32**, **33** and malocyanines¹⁸³ **34**, **35** with the *o*-phenylene bridge in PC that obey this rule.

$$\lambda_{\max} = 755, \Delta\lambda = +100 \text{ nm}$$

$$\lambda_{\max} = 615, \Delta\lambda = -40 \text{ nm}$$

$$\lambda_{\max} = 630, \Delta\lambda = +290 \text{ nm}$$

$$\lambda_{\max} = 534, \Delta\lambda = -30 \text{ nm}$$

5. Change in the resonance interaction

A change in the conjugation takes place in the case of steric hindrances, with the introduction of acetylene/cumulene bonds and heterobonds, for example, $-\text{N}=\text{N}-$, $-\text{P}=\text{P}-$, etc. These perturbations can be conveniently simulated by varying the resonance integral $\delta\beta_{\mu\nu}$. Then the change in the energies of MO ($\delta\varepsilon_i$) and the wavelength of PET ($\delta\lambda$) will be written in the form^{10, 12, 170, 171}

$$\delta\varepsilon_i = 2 \sum_{\mu\nu} C_{i\mu} C_{i\nu} \delta\beta_{\mu\nu}, \quad (25)$$

$$\Delta\lambda = -b \sum_{\mu\nu} \Delta_{\mu\nu} \delta\beta_{\mu\nu}, \quad (26)$$

where $b = 2(V/\pi)(n + L)^2$, and $\Delta_{\mu\nu} = \rho_{\mu\nu}^* - \rho_{\mu\nu}^0$ is the change in the order of the bond being varied in the excitation.

Since in polymethines the nodes of the boundary orbitals are located in the vicinity of atoms and in polyenes they are located near the middle of the bonds, the influence of the change in the resonance interaction between neighbouring atoms ($\nu = \mu \pm 1$) should be substantially less for PMD than for HP.

Spectral effects arising in PMD with steric hindrances and upon the introduction of an acetylene bond have been comprehensively studied.^{5, 9, 171, 194–198} The shift of the absorption maximum was found to depend on the basicity of TG (especially strongly in the perturbations at the ends of PC). However, for polymethines with a medium electron donor ability, the sign of the effect in the middle of the chain depends only on the nature of perturbation.^{171, 194}

Changes in the spectra of HP differ in principle. The analysis of formulae (25) and (26) and the signs of the boundary MO allow one to formulate the following rule: an increase in the resonance interaction along the formally double bond of PC in HP is accompanied by a hypsochromic shift, and that along the formally ordinary bond causes a bathochromic shift of the absorption band; a decrease in the resonance interaction along the formally double bond leads to bathochromic shifts, that along the ordinary bond results in a hypsochromic shift of the maximum.

Spectral data for acetylenes and cumulenes serve as the best experimental evidence. The introduction of additional π -bonds perpendicular to the major π -system in these compounds leads to a change in the CC bond lengths; in this case electronegativity of the atoms changes: for acetylenes the hypsochromic shifts, and for cumulenes the bathochromic shifts are observed.⁸⁸

If in PC of symmetrical polyenes only the central bond is substituted, the sign of the effect depends on the class of the compound. It can be illustrated by the data of Table 7 for indopolyenes **36** the longwave band of which is reliably assigned to the polymethine band.

As is seen from the data presented, the sign of the effect changes every time in accordance with the above-formulated rule, when the class of HP is somehow changed: either by change in the chain length or by change in the number of the HOMO.

Table 7. Spectral data for HP **36** (nm)^{115–117}

<i>m</i>	X	<i>(N + 2)</i> -form, <i>z</i> = 0			<i>N</i> -form, <i>z</i> = 2 +

2	CH	B	435	—	A	454	—
2	N	B	387	– 48	A	492	+ 38

V. Systems with several polymethine chromophores

In some cases, LCS can contain several π -systems. In addition in order to give more spectacular interpretation it is more convenient sometimes to split the common chromophore into constituents

that are responsible for individual bands. However, the spectra of molecules with several chromophores or aggregates of molecules with one chromophore differ from those of the initial systems due to the so-called interaction of chromophores.^{199, 200} The theoretical interpretation of this phenomenon is given²⁰¹ in terms of the dipole-dipole approximation. It was shown that the interaction of chromophores leads to an extension of the absorption maxima against the position of the corresponding maxima in parent chromophores. The nature of this extension can be explained using a model proposed for the analysis of the excited states of molecular crystals.²⁰²

If the system contains two chromophores having the transition energies E_a and E_b ($E_a < E_b$) and the energy of the interaction H_{ab} is small, the energies of two new transitions E_- and E_+ are determined as follows:

$$\begin{aligned} E_- &\simeq E_a - \frac{H_{ab}}{E_a - E_b}, \\ E_+ &\simeq E_b + \frac{H_{ab}}{E_a - E_b}. \end{aligned} \quad (27)$$

It is seen from these formulae that the interaction should result in the movement apart of the absorption maxima, the effect being the larger the closer the maxima are located. If the energies of the parent chromophores coincide, the formulae change somewhat

$$E_{\pm} = \frac{1}{2} \left(E_0 \pm \sqrt{E_0^2 + 4H_{ab}^2} \right). \quad (28)$$

It is impossible to say which of the bands belongs to the excitation of one chromophore and which belongs to the other. Both bands are associated with the excitation of both chromophores, but during one transition the chromophores are excited in phase, and during the other they are excited in antiphase.

In the dipole approximation, the energy of the interaction H_{ab} is calculated using the moments of transitions of the parent chromophores M_a and M_b

$$H_{ab} = \frac{e^2}{R^3} [(M_a M_b) \mathbf{R}_{ab}^2 - 2(M_a \mathbf{R}_{ab})(M_b \mathbf{R}_{ab})], \quad (29)$$

where R is the length of the $\mathbf{R}_{ab}$ vector directed from the chromophore a to the chromophore b .

If two chromophores are arranged linearly, the longwave transition appears to be more intense, if they are located in a parallel way, the shortwave transition is more intense. If the dipoles are oriented arbitrarily with a ϑ angle between them, the ratio of intensities of the longwave I_- and shortwave I_+ transitions is

$$\frac{I_-}{I_+} = \operatorname{tg}^2 \frac{\vartheta}{2}. \quad (30)$$

This approximation gives good results if the distance between chromophores exceeds their own dimensions.^{200, 201, 203}

1. Bisdyes

Widely studied bisdyes are the simplest and most convenient systems in which two PET manifest themselves in the visible and near-IR ranges of the spectrum.

37

Here M is the bonding bridge that can be both conjugated and non-conjugated. In the spectra of bisdyes of symmetric structure ($G_1 = G_4$, $G_2 = G_3$, $k = l$), the absorption band corresponding to the parent PMD splits into two bands. The distance between the split bands and the ratio of their intensities depend on the degree

Figure 6. Absorption spectra of bisdyes 38–40.

of conjugation, the distance and the angle between chromophores.^{200, 203–206}

An experimental study of cyanine dyes bound by a non-conjugated polymethylene bridge, $-(CH_2)_m-$, has shown that the distance between the first and the second maxima decreases with an increase in the number of the methylene groups.²⁰⁷ If the non-conjugated chromophores are arranged in the strictly parallel manner as in bisdyes 38, the longwave transition is symmetry forbidden ($I_- = 0$) and all the intensity is concentrated in the shortwave band (Fig. 6).²⁰⁸

Note that the spectrum of the bisdye 38 was assigned to the erroneously observed conformation *a* of the dye in which any overlap of the π -orbitals and, hence, their interaction are lacking.²⁰⁸ In fact the spectrum is in accordance with the conformation *b* with a dihedral angle between the π -systems of the chromophores of $\sim 40^\circ$ and a minimum distance of ~ 2.5 Å between the π -centres of both chromophores, which is sufficient for the effective interaction of the π -systems.

The interaction of the chromophores is more substantial in bis-dyes with conjugated bridges,^{209–212} for example, in compounds 39 and 40.

If in PMD 39 the chromophores are arranged linearly, practically all the intensity is concentrated in the longwave band (see Fig. 6). In the case of the dye 40 with a fixed acute angle between the chromophores, two bands are observed, however, according to formula (30), the band in the shortwave region is more intense.^{211, 212}

2. Aggregation of polymethine dyes

There are many publications concerning the structure and application of molecular aggregates of PMD.^{213–217}

The phenomenon of aggregation in dyes has been discovered by Scheibe²¹⁸ and Jelly.²¹⁹ PMD were found to form molecular aggregates both in solution and on the surface of certain crystals. It was shown that in aggregates the molecules of a dye are bound owing to the non-valent resonance interaction. Depending on the conditions and the molecular structure, dyes can form two main types of aggregates (*J* and *H*) that differ distinctly in the spectral properties. The maxima of the absorption bands of *J*-aggregates (*J*-bands) show a bathochromic shift whereas the maxima of the absorption bands of *H*-aggregates (*H*-bands) show a hypsochromic shift relative to the band maxima of isolated molecules (*M*-bands).

It was found that *J*- and *H*-aggregates differ in the value of the angle between the long axis of the chromophore and the axis of the molecular aggregate.^{218, 220, 221} In accordance with the theory of interaction of chromophores, different orientation of molecules in the corresponding aggregates leads to the appearance of very intense and very narrow longwave bands in the spectra of *J*-aggregates, unlike the spectra of *H*-aggregates.

It should be noted that the nature of a solvent, the type of the surface of the ionic crystal and some other factors can affect appreciably the aggregation of dyes.^{17, 213–215}

VI. Terminal groups as local chromophores

If LCS contain complex conjugated TG with their own strong absorption in addition to the band corresponding to the polymethine chromophore, the bands resulted from the transitions from the orbitals localised predominantly in the terminal nuclei appear in the spectra; therefore, TG can be conventionally considered as local chromophores.

Within the orbital approximation, the simplest type of local transitions is described by the local level and one of polymethine levels delocalised over the whole molecule of LCS (Fig. 7 *a–d*). As a result, LET and PET should interact strongly. The assignment of the band to polymethine chromophores depends on which transition, PET or LET, has the lowest energy.

Figure 7. The position of polymethine (PL) and local (LL) levels in LCS with local chromophores (*a–d*) and in bis-dyes (*e*); (1) PET, (2) LET.

1. Local transitions in PMD

In the case of typical PMD, delocalised polymethine levels are usually arranged nearer to the Fermi level than the local level (see Fig. 7 *a, b*). The first transition has the polymethine character, the

second is mainly localised in TG. Asymmetrical cyanines, derivatives of thiazolopyridinium,^{222–224} thiazolopyrimidinium,^{225–227} 2,6-diphenylpyrylium and its heteroanalogues^{228, 229} are compounds with this arrangement of the levels. If both residues have relatively intense absorption of their own as, for instance, in dye **41**, both nuclei can be regarded as local chromophores.²³⁰

$\lambda_{\max} = 784; 500; 384 \text{ nm}$

$\lambda_{\max} = 543 \text{ nm}$

$\lambda_{\max} = 410 \text{ nm}$

Calculations have shown that the first transition is delocalised over the whole molecule, the atoms of the pyrroloanthracene moiety participate predominantly in the second, and atoms of the thiapyrylium nucleus take part in the third.

Lengthening of PC little affects the localised levels, however, the polymethine level regularly approaches the Fermi level. For this reason, the band responsible for LET undergoes a bathochromic shift as well as the band corresponding to PET, but the magnitude of this shift is less than that of the vinylene shift of the polymethine band.^{81, 222–227, 231}

Symmetrical PMD contain two identical local chromophores. If they do not interact as, for example, in α, ω -di(1-azulenyl)polymethines, the second band observed experimentally is responsible for two practically degenerate LETs.⁸¹ If local chromophores do interact, the bands split, as was observed for symmetrical cyanine dyes, derivatives of thiazolopyridinium.²³¹

2. Inversion of local and polymethine electronic transitions

If local levels appear nearer to the Fermi level than in polymethines (Fig. 7 c,d), the local transition has the lowest energy, *i.e.* the inversion of the transitions takes place. The following conditions are necessary for the inversion of PET and LET: TG should have a level located near the Fermi level (it is usually the case when the initial heterocycle is deeply coloured); a relatively big distance between the polymethine levels; a shift of polymethine levels towards the local level (it occurs if PMD contains either strongly basic or weakly basic nuclei, *i.e.* when the Φ_0 index takes the values close to the limiting, 0 or 90°).

These conditions are realised, for example, in α, ω -di(2-azulenyl)polymethines **42** ($\Phi_0 = 0^\circ$) or **43** with residues of isoquinoline ($\Phi_0 = 80^\circ$).

42

43

It has been shown that two first transitions are mainly localised on the atoms of the terminal group (though the atoms in the odd positions also participate in them), which can be conventionally considered as conjugated substituent of the local chromophore. These transitions are characterised by smaller vinylene shifts as compared to the third transition localised in the polymethine chromophore.⁸¹ The polymethine levels come closer together regularly with an increase in the number of vinylene groups, while the position of the local level changes little. Consequently, lengthening of the chain can be accompanied by a change in the nature of transitions.⁸¹

44

The inversion of PET and LET was observed experimentally in triazotriazine dyes **44**.²²⁴ As is seen from Fig. 8, the contour of the shortwave band is close to those of the longwave bands corresponding to PET in typical PMD. Obviously, the long wavelength band in the case of dyes **44** can be assigned to the local transition in the residues of triazotriazinium.

Figure 8. The absorption spectra of PMD **44**.
n: (1) 0, (2) 1, (3) 2.

3. Local transitions in heteropolymethines

A change in the type of LCS, the passage from PMD to HP, influences little the position of local levels, but affects significantly the position of polymethine levels. First, they are shifted by approximately half of the gap due to an additional π -level, up-shifted in the case of the reduced form and down-shifted in the case of the oxidised form, in accordance with formula (7). Second, the distance between the highest occupied and the lowest unoccupied polymethine levels and, therefore, the energy of PET increases additionally due to the strong alternation of bonds in PC. As a result, the inversion of electronic transitions is more probable in HP than in PMD with the same TG, especially for a small number of vinylene groups in the chain. As the length of the polymethine chromophore is increased, its levels approach the Fermi level but significantly more slowly than the polymethine levels do in PMD. Since for polyenes $\varphi_0 = \Phi_0 \pm 45^\circ$, the maximum shift of the polymethine levels is achieved when TG has a medium electron donor ability ($\Phi_0 = 45^\circ$), in contrast to PMD. α, ω -Di(1-azulenyl)polymethines and their isomers having PC in another position can serve as examples. In the spectra of these compounds in the visible and near-IR regions, two typical absorption bands were observed: a broad longwave and a more narrow, shortwave band.^{232, 233} Calculations show that the two first transitions result from excitations in local azylene chromophores, and the third is

delocalised along the whole molecule of the polyene.⁸¹ Lengthening of the chain by one vinylene group practically does not change the energies of the first and the second transitions, further introduction of vinylene groups can result even in the negative vinylene shift (-8 nm). It is probably associated with the weakening of the interaction between local chromophores. The vinylene shift of the third (polymethine) transition is $30-35$ nm, which falls within the interval of values typical of PET in polyenes.

4. Local transitions in asymmetric donor-acceptor polyenes

Of especial interest is the case when both boundary levels appear to be local (Fig. 7e) and are localised in different TG as, for example, in donor-acceptor polyenes of the general formula

45

In these systems, the photoexcitation is accompanied by a significant intramolecular charge transfer, the so-called photoinduced charge transfer.²³⁴⁻²³⁷ In the first approximation, the energy of the electronic transition between the localised HOMO and LUMO is determined by the difference between the ionisation potential of the donor group P_D and the electron affinity of acceptor E_A .^{39, 238-240}

$$E = P_D - E_A + C, \quad (31)$$

where C is correction for the Coulomb and resonance interactions of electrons.

Localisation of both boundary MO results, as a rule, in a lower intensity of charge transfer transitions. At the same time, the dipole moment of the molecule in the excited state increases significantly, and therefore, asymmetrical donor-acceptor systems 45 exhibit high polarisability. This property determines their wide application in non-linear optics.^{33-37, 189-193}

Due to considerable changes in the dipole moment, these local transitions are very sensitive to the polarity of the solvent.^{236-238, 241, 242} A decrease in the energy of charge transfer transitions can originate from the rotation of fragments of the molecule in the excited state with the violation of conjugation, for example, of dimethylamino group. In this case, in very polar solvents, fluorescence with an anomalously high Stokes shift and low quantum yield is observed.^{39, 236-238}

Hence, local transitions can influence substantially the spectra of LCS changing even the nature of the longwave band, which usually determines the colour of the compound.

Abstract. Data concerning the most important aspects of the use in the colour photoprocess with diffusional transfer of the image of coordination compounds of *d* elements with nitrogen-, oxygen-, and sulfur-containing chelate and macrocyclic ligands as the 'working material' or the creation of nonsilver photographic images on silver halide light-sensitive materials by means of their additional treatment and also as the active principle of nonsilver light-sensitive systems are treated systematically and discussed. The bibliography includes 235 references.

I. Introduction

A current characteristic feature of modern coordination chemistry is a tendency, together with the constant expansion of the range of compounds investigated, to expand also the regions of their practical application. During the last 10–15 years, the tendency to employ coordination compounds as components of nonsilver photographic systems has arisen. This will promote the replacement of silver by other less expensive readily available chemical compounds.¹

In principle, economies can be achieved in the use of silver in two ways: by employing coordination compounds either as 'carriers' of photographic images on traditional silver halide light-sensitive materials or as components of nonsilver photographic systems sensitive to radiation. It is noteworthy that the first procedure has nowadays become quite common in silver recovery processes, during which dyes, intensely absorbing in the visible region of the spectrum, arise on the silver halide materials together with silver compounds. After the removal of silver-containing compounds from the photographic emulsion, these dyes form nonsilver photographic images.² The best known dyes of this type are organic dyes containing both nitrogen and oxygen.^{2,3} However, the resistance of these dyes to the action of light and corrosive agents in the environment is low, as a result of which the nonsilver photographic images containing them are decolorised comparatively rapidly.⁴ Dyes based on metal chelates and especially on the metallomacrocycles of 3*d* elements with

nitrogen-, nitrogen and oxygen-, and nitrogen and sulfur-containing ligands are free of this disadvantage. There are grounds for the hypothesis that the latter are extremely promising carriers of nonsilver photographic images regardless of whether they have been formed on nonsilver or even on silver halide light-sensitive materials.

Towards the end of the 1980s, extensive data accumulated on the use of metal chelates and metallomacrocycles of *d* elements as carriers of nonsilver photographic images on AgHal photographic materials and as intrinsic light-sensitive components of photographic emulsions. These results have been surveyed by Mikhailov and Polovnyak.⁵ However, during the time elapsed since the publication of this review (almost ten years), quite a few new investigations have been published. Among them, one must differentiate studies devoted to the use of metal chelate and macrocyclic coordination compounds as the 'working material' for the formation of nonsilver images on AgHal photographic materials, as coloured components in silver halide photographic processes with diffusional transfer of the image, and as the 'active principle' of photographic systems.

II. Chelate and macrocyclic coordination compounds as carriers of nonsilver images formed on 'traditional' AgHal photographic materials

It is known^{1,2,4} that up to 30% of the silver contained initially in the given photographic material remains in the silver images produced on AgHal photographic materials after their exposure and subsequent chemical-photographic treatment in accordance with the standard scheme (development plus fixation). Thus the replacement of a silver image by a nonsilver one can afford fairly appreciable additional economies in the use of silver in the chemical-photographic industry and it follows therefore that this problem cannot be ignored. The process involving the transformation of a silver image into a nonsilver one using carriers based on azo- and azomethine dyes has long been known. In principle, this process actually makes it possible to extract silver fully from the treated AgHal photographic material, but the nonsilver images thus obtained are extremely unstable during storage and are readily 'decolorised' by both light and by corrosive agents in the environment.² On the other hand, chelate and macrocyclic coordination compounds of *d* elements are very inert in relation to the action of the above factors⁶ and one may therefore expect that their employment as carriers of nonsilver photographic images would make it possible to store the image for

a longer time. This factor stimulated the search for technologies involving the transformation of silver images on AgHal photographic materials which could actually lead to the formation of metal complex nonsilver images. Their essential feature reduces to the following. The elemental silver contained in the initial image is transformed into a mixture of compounds of silver(I) (in particular AgHal) and of some other d element on treatment with a specific solution. Next the photographic emulsion containing this kind of 'mixed' image is treated with a solution which converts the silver(I) compound into a water-soluble one, but does not interact with the other component of the 'mixed' image. This results in the formation of a nonsilver photographic image, the carrier of which is the inorganic compound formed previously in the photographic emulsion together with the silver(I) compound. On treatment of the latter with the appropriate solution, specific complex-formation reactions result in the formation of the final metal chelate nonsilver image. The process described usually involves three stages.^{5,7}

1. The bleaching of the silver image formed initially on the AgHal photographic material as a result of the standard chemical-photographic treatment (development plus fixation) accompanied by the deposition in the photographic emulsion of the hexacyanoferrate(II) complex of some kind of $3d$ element. These two processes can usually be combined. For this purpose, the photographic emulsion with the silver image is kept in an aqueous solution containing potassium hexacyanoferrate(III), some kind of hydroxy acid (usually citric, oxalic, or tartaric) and (or) its salt, and a soluble salt of the $3d$ ion (usually chloride or sulfate). However, in certain cases such combination is impossible and the bleaching and deposition of the corresponding hexacyanoferrate(II) have to be carried out in two different solutions — this happens, for example, in the case of $\text{Co}_2[\text{Fe}(\text{CN})_6]$.

2. The fixation of the bleached image, which results in the elimination from the photographic emulsion of the silver(I) compounds formed in the latter after the bleaching stage. This stage is carried out by maintaining the photographic emulsion with the bleached image in an aqueous solution of sodium thiosulfate ($\text{Na}_2\text{S}_2\text{O}_3$).

3. The toning of the image which has passed the above two stages, which results in the formation of the metal chelate nonsilver photographic image. This stage is achieved by maintaining the photographic material in a solution containing some kind of chelating organic compounds and alkaline reagents (usually NaOH, KOH, or Na_2CO_3).

The processes occurring in the first two stages are noncatalytic.³ As a consequence of this, when they are carried out exhaustively the amount of the hexacyanoferrate(II) of the $3d$ element formed in the photographic emulsion is determined exclusively by the content of silver in the initial photographic image. The third stage is none other than the complex formation reaction in $3d$ metal hexacyanoferrate gelatin-immobilised matrix systems.^{8,9} The amount of chelate complex formed depends primarily on the concentration of the hexacyanoferrate(II) of the corresponding metal ion in the photographic emulsion and the concentration of the chelating compounds in the 'toning' solution in contact with it. It is therefore natural to expect that the third stage is in fact decisive in the formation of the nonsilver image with carriers comprising chelate and macrocyclic coordination compounds. A factor such as the solubility of the complex formed in the toning stage then becomes important: if it exceeds a certain critical level, the leaching of this complex from the photographic emulsion comprising the treated material becomes possible, which leads to some decomposition of the metal chelate nonsilver image itself.

The process involving the formation of images in the third stage can be described quantitatively in terms of the following relations: $D' = f(\lg H)$, $D' = f(D^{\text{Ag}})$ or $D' = f(c_{\text{F}}, c_{\text{L}}^0, t)$, where D' is the optical density of the metal chelate image obtained after treatment from the initial silver image with an optical density D^{Ag} , H is the level of exposure ensuring, after carrying out the standard

chemical-photographic treatment, the formation of a silver image with a density D^{Ag} , c_{F} is the concentration of the hexacyanoferrate(II) of the corresponding ion of the $3d$ element in the photographic emulsion attained after bleaching and fixation of the silver image, c_{L}^0 is the concentration of the ligand in the solution used in the toning stage, and t is the duration of toning.

The theory of the kinetics of the processes occurring under these conditions and the procedure for the mathematical treatment of the experimental $D' = f(c_{\text{F}}, c_{\text{L}}^0, t)$ relations in order to determine the stoichiometric coefficients of the complex formation reactions and their rate constants have been described by the present author.¹⁰

More than 30 different Fe(II), Fe(III), Co(II), Co(III), Ni(II), and Cu(II) coordination compounds with N,O-, N,S-, and N,O,S-chelate and macrocyclic ligands have now been tested for the production of nonsilver photographic images on AgHal photographic materials.^{11–81} The increased attention devoted precisely to the chelates of the above metal ions is linked directly to factors such as the ease of their formation in gelatin emulsions of the AgHal photographic materials, the considerable absorption intensity in the visible part of the spectrum, and a fairly high thermodynamic stability.¹² The carriers for metal chelate nonsilver images mentioned most frequently are Ni(II) chelates,^{13–42} to a lesser extent Cu(II) chelates,^{43–64} and to a still lesser extent Co(II) and Co(III)^{65–75} as well as Fe(II) and Fe(III)^{76–81} chelates. In most cases the formation of metal chelate photographic images proceeds in a very complex manner and the composition of the nonsilver image depends on the concentration-time regime (*i.e.* on the specific values of the parameters c_{F} , c_{L}^0 and t).^{29, 30, 58, 74} However, one should note that in a number of instances, for example in the Ni(II)–8-mercaptoquinoline (or its 5-substituted derivatives),^{31, 39, 40} Ni(II)–*N,N'*-diphenyldithiooxamide,^{19, 29, 30} Fe(II)–isonitrosoacetone,⁷⁷ and Fe(II)–8-mercaptoquinoline⁷⁸ systems, the formation of only one complex species with metal ion:ligand ratios of 1:2, 1:2, 1:2, and 1:3 respectively was recorded.

The formation of nonsilver images from chelate and macrocyclic Ni(II) coordination compounds is preceded by the stage involving the bleaching of the silver image with deposition of $\text{Ni}_2[\text{Fe}(\text{CN})_6]$. In all the cases described in the literature, this stage is carried out using the following composition: 15.0 g $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ + 88.0 g Na_3HCT (or K_3HCT) + 14.0 g $\text{K}_3[\text{Fe}(\text{CN})_6] + \text{H}_2\text{O}$ (up to 1 litre) [HCT^{3-} is the citrate trianion $-\text{O}_2\text{CCH}(\text{OH})\text{CH}(\text{CO}_2^-)\text{CO}_2^-$].

The bleaching stage is usually carried out for 20–25 min at 20–25 °C. Nickel hexacyanoferrate is formed by the reaction

After the 'bleaching' of the image

only nickel hexacyanoferrate remains in the photographic emulsion imparting a pale yellow-green colour to the latter. By varying further the composition of the toning solution under toning conditions, it is possible to obtain diverse nickel-containing nonsilver photographic images.^{11, 12}

The most familiar coordination compound which may be used to form a nonsilver photographic image on AgHal light-sensitive materials is bis(dimethylglyoximate)nickel(II).⁸²

The generation of images with this type of carrier has been described.^{11, 12, 15, 16} It was noted that the optical density relations $D' = f(\lg H)$, $D' = f(D^{Ag})$, and $D' = f(c_F, c_L^0, t)$ put forward above are monotonic, lack extrema, and tend to a limiting value with increase in c_L^0 and t for a fixed value of D^{Ag} (and hence c_F). The nonsilver pink or pink-red images obtained are of particular practical interest because, when they are examined under green light (to which the eye is known to be most sensitive), there is an appreciable increment in the optical densities D compared with the optical densities of the initial silver image D^{Ag} .^{15, 16}

The formation of nonsilver images based on Ni(II) chelates comprising dithiooxamide has been investigated in detail because of the extremely interesting colour transitions occurring in this instance and the wide variety of coordination compounds produced.^{8, 11, 12, 14, 21, 22, 29, 30, 32–34} On interaction of nickel(II) hexacyanoferrate, formed in the photographic emulsion after the occurrence of stages 1 and 2, solutions of dithiooxamide (pH 12.0) give rise to five different complexes **2–6**.^{8, 29, 30, 32–34}

Compounds **2–5** are insoluble in water and impart a greenish-blue colour to the photographic emulsion with a grey tint ($\lambda_{\text{max}} = 590\text{--}610$ nm), a pink-violet colour ($\lambda_{\text{max}} = 580$ nm), a violet colour ($\lambda_{\text{max}} = 570$ nm), and a dark-blue colour ($\lambda_{\text{max}} = 640$ nm) respectively, while compound **6**, being insoluble in water, readily diffuses from the photographic emulsion into the toning solution in contact with the latter. A unique and from the practical point of view an extremely valuable property is actually associated with the formation of compound **6**: the process involving the generation of non silver images from nickel(II) chelate complexes of dithiooxamide at fairly high concentrations of the

above organic reagent in the toning solution (8.0×10^{-3} M) is not only unaccompanied by an increase in fogging compared with that for the initial silver image but actually entails its diminution. (At dithiooxamide concentration in the toning solution $c_L^0 > 0.1$ M, the nonsilver image is not formed at all.²⁹) This factor has been used at one time to increase the sensitivity of direct positive photographic materials.²⁶ In an early study,¹⁴ it was noted that the process involving the generation of such images may be applied successfully to prepare the so-called blue slides, which have been recently used increasingly for presenting illustrations at conferences, symposia, *etc.* The preparation of 'blue slides' with carriers consisting of nickel(II) chelate complexes of dithiooxamide has been investigated in detail.^{21, 22, 29} It has been noted that this process is less laborious and, which is particularly important, its sensitivity to external conditions is much less critical compared with the traditional technology for the preparation of 'blue slides' on the basis of organic dyes, one of the versions of which has been described by Filin *et al.*⁸³ The fact that the sky-blue or blue metal chelate images obtained in our case have a higher purity of their light lines and a better contrast than those described by Filin *et al.*⁸³ merits attention in this connection. It is remarkable that none of the processes (1)–(3) in the nickel(II)–dithiooxamide system has been recorded hitherto for complex formation in solution.^{32, 33}

Bearing in mind the set of formation reactions of compounds **2–6**, it is easy to explain the unusual time variation of the optical densities of the nonsilver image in the third stage: for $c_L^0 > 8.0 \times 10^{-1}$ M, the values of D' initially increase with t , reach a maximum, and then fall.^{11, 12, 29, 30} According to Eqn (4), the transition **4** $\rightarrow$ **5**, entailing a change in the colour of the photographic emulsion from violet to dark-blue, is possible in an acid medium. The concluding stage of the technological process for the preparation of 'blue slides' is associated with this transition.^{14, 26, 29, 30} A similar type of $D' = f(D^{Ag})$ and $D' = f(c_F, c_L^0, t)$ relations has also been noted for the processes involving the generation of nonsilver photographic images with carriers consisting of nickel(II) chelate complexes of quinoxaline-2,3-dithiol **7** and *N,N'*-diphenylthiooxamide **8**.^{19, 28, 35}

Incidentally, here too the transition from chelates with complete deprotonation of the ligands to chelates with partial deprotonation of the latter is also observed, which is accompanied by a sharp alteration in the colour of the metal chelate photographic image (from pink to blue-green in the case of quinoxaline-2,3-dithiol and from bright-yellow to brown in the case of *N,N'*-diphenylthiooxamide).^{29, 35, 37} It is remarkable that, in contrast to the process in which a dark-blue nonsilver image is generated from the nickel(II) chelate complex of dithiooxamide (the transition **4** $\rightarrow$ **5**), the analogous processes involving the generation of blue-green and brown images from quinoxaline-2,3-dithiol and *N,N'*-diphenylthiooxamide are reversible and, when they are treated with alkaline solutions at pH > 9.0 , their initial colour (pink and bright-yellow respectively) is immediately restored^{35–37} and a very appreciable decrease (to the extent of 50%–55%) in the optical densities of both the pink and bright-yellow metal chelate images is then observed. Whereas complex **5** is a coordination polymer, the nickel(II) complexes of quinoxaline-2,3-dithiol and *N,N'*-diphenylthiooxamide are coordination monomers because steric hindrance in the quinoxaline-2,3-dithiol and *N,N'*-diphenylthiooxamide molecules precludes the formation of polymeric compounds. The processes involving the generation of metal chelate images can therefore be described by reactions (6) and (7) in the case of quinoxaline-2,3-dithiol and *N,N'*-diphenylthiooxamide.

Reactions (1)–(7) do not occur on formation of nonsilver metal chelate images from nickel(II) coordination compounds with a ligand close to dithiooxamide and *N,N'*-diphenylthiooxamide — *N,N'*-diphenyldithiooxamide PhNHC(S)C(S)NPh ; in this case, this process is described by Eqn (8):³⁵

The cause of this difference should be sought both in the influence of diffusion factors and in the poor proton-donating properties and the sparing solubility of *N,N'*-diphenyldithiooxamide compared with dithiooxamide and *N,N'*-diphenylthiooxamide.

The technology for the generation of nonsilver photographic images from nickel(II) chelate complexes of 8-mercaptoquinoline and a series of 5-substituted derivatives having the general formula **14** has been described.^{23, 24, 32, 38–40}

R = H, SH, SMe, Cl, Br.

In this case, the nonsilver image is generated in accordance with Eqn (9):

The colour of the images thus obtained varies from pink-red to dark-brown. A very steep slope of the $D' = f(D^{\text{Ag}})$ curves in the range of low optical densities of the initial silver image is

characteristic of the nickel(II) complexes of unsubstituted 8-mercaptoquinoline. It has been suggested that this factor be used to intensify very weak photographic images on radiographic materials.^{31, 39} A very considerable increase in D' compared with D^{Ag} has been noted also for nonsilver metal chelate images based on nickel(II) compounds of 5-chloro-8-mercaptoquinoline.^{38, 40}

The nonsilver images derived from copper(II) chelate complexes with N,O-, N,S-, N,O,S-, and S,S-donor ligands are also of interest. Their absorption in the visible region of the spectrum exceeds in most cases the absorption of the analogous nickel(II) chelates. Formally this fact renders copper(II) coordination preferable for the generation of nonsilver metal chelate photographic images compared with those based on nickel(II). This probably accounts for the greater range of copper(II) chelate complexes compared with the nickel(II) complexes.¹²

The formation of metal chelate images is also preceded by the stage in which the initial silver images is bleached and fixed. The bleaching is carried out either in the 7 g $\text{CuSO}_4 \cdot 5\text{H}_2\text{O} + 90$ g Na_3HCT (or K_3HCT) + 6 g $\text{K}_3\text{Fe}(\text{CN})_6 + \text{H}_2\text{O}$ (up to 1 litre) solution (see Mikhailov and Polovnyak⁵³) or the 7 g $\text{CuSO}_4 \cdot 5\text{H}_2\text{O} + 50$ g $\text{K}_2\text{C}_2\text{O}_4 + 4$ g $\text{K}_3\text{Fe}(\text{CN})_6 + \text{H}_2\text{O}$ (up to 1 litre) solution (see Mikhailov *et al.*⁶²).

In both cases, the bleaching process occurs at 20–25 °C for 20 min. The nonsilver image generation processes are described by Eqns (10) and (11):

In order to fix the 'bleached' image, the treatment of the latter in aqueous $\text{Na}_2\text{S}_2\text{O}_3$ solutions for 3–5 min is used as in the case of $\text{Ni}_2[\text{Fe}(\text{CN})_6]$; the process occurring under these conditions is described by the equation

After bleaching and fixation, copper(II) hexacyanoferrate remains in the photographic emulsion, imparting a red or red-brown colour to the photographic image. The optical densities of this intermediate nonsilver image are fairly high and, when it is observed through a blue light filter, they actually exceed the densities of the initial silver image.^{11, 12} There are data showing that the bleaching with the 'copper hexacyanoferrate oxalate' bleaching agent affords higher optical densities of the intermediate metal hexacyanoferrate image than bleaching with the 'copper hexacyanoferrate citrate' bleaching agent.⁸⁴ The reason for this difference has not so far been elucidated, but it is undoubtedly not in any way related to the difference between the covering powers of the $\text{Cu}_2[\text{Fe}(\text{CN})_6]$ constituting this image because subsequently, during toning under identical conditions, the optical densities of the metal chelate nonsilver images obtained are found to be different. Presumably, in the case of the 'copper hexacyanoferrate citrate' bleaching agent the $\text{Cu}_2[\text{Fe}(\text{CN})_6]$ formed during bleaching dissolves to a slight extent, whereas in the case of the 'copper hexacyanoferrate oxalate' bleaching agent the dissolution does not occur at all or its extent is much smaller because the citrate anion forms more stable coordination compounds with copper(II) than does oxalate.⁸⁵

The formation of nonsilver images from copper(II) coordination compounds of dithiooxamide has been most thoroughly investigated.^{44, 53, 60, 61} According to the results of a number of investigations^{44, 53, 60, 61}, when the photographic emulsion containing $\text{Cu}_2[\text{Fe}(\text{CN})_6]$ comes into contact with an alkaline ($\text{pH} \approx 12$) solution of dithiooxamide, the water-insoluble coordination polymers

are formed. They are structurally analogous to polymers **4** and **5** and the polymeric copper(II) hydroxide. The last compound arises as a result of the alkaline degradation of $\text{Cu}_2[\text{Fe}(\text{CN})_6]$:

It is noteworthy that copper hydroxide accumulates in appreciable amounts in the gelatin emulsion of the treated photographic material only at extremely low ($<10^{-5}$ M) concentrations of dithiooxamide in the toning solution in contact with this material.⁶¹ The optical densities D' of the nonsilver images based on the copper(II) complex of dithiooxamide are appreciably higher than the optical densities of the images based on nickel(II) chelates (cf the studies described in Refs 29 and 30, on the one hand, and that in Ref. 53, on the other). However, the image based on copper(II) chelate complexes of dithiooxamide also decomposes readily at fairly high ligand concentrations in the toning solution ($\sim 1.5 \times 10^{-2}$ M), like the image based on nickel(II) chelates, as a consequence of the formation of soluble 1:3 complex **18**, to which the following structure has been attributed:

This factor should lead to the appearance of maxima on the $D' = f(c_F, c_L^0, t)$ curves.^{60,61} The difference between the shapes of the kinetic curves in the nickel(II)–dithiooxamide and copper(II)–dithiooxamide systems consists only in the fact that the degradation of the copper(II) chelate image begins at higher ligand concentrations in the toning solution than the degradation of the nickel(II) chelate complex of dithiooxamide.

Complexes with analogous compositions and structures are formed also in the course of the generation of nonsilver images from copper(II) chelate complexes of quinoxaline-2,3-dithiol.^{45,60} According to the present author's data,⁶⁰ dimeric copper(II) chelate complexes with the above ligand have the 2:2 and 2:4 compositions (depending on the degree of deprotonation of the ligand). Nonsilver images based on copper(II) chelate complexes of α -benzoin oxime **19**, distinguished by a very high resolving capacity, not inferior to that of the initial silver image, have also been described in the literature.^{46,86} Judging from all the available evidence, in this case the dimeric bright-green chelate **20** is formed in the photographic emulsion.

The copper(II) complexes of 8-hydroxyquinoline (the bright-green complex **21**),⁴⁸ 8-mercaptoquinoline, bis(thiocarbamoyl)hydrazine (the black complex **22**), and 1-carbamoyl-2-thiocarbamoylhydrazine (the black-brown complex **23**) have also been described.^{50,60,62}

In the last two cases, nonsilver photographic images are obtained, the colour and optical characteristics of which are extremely close to those of the initial silver image. Several studies have been devoted to the nonsilver images based on copper(II) chelate complexes of various 3-benzoylthioureas $\text{RHN}-\text{C}(\text{S})-\text{NH}-\text{C}(\text{O})\text{Ph}$, where R is an aryl group with bulky substituents.^{55–59} In most cases, the photographic images have colours with 'warm' tones, the tints of which are determined both by the nature of the chelating agent and the concentration-time regime in the toning stage.^{7,8,60}

Only two cobalt(II) coordination compounds used as carriers of nonsilver photographic images are known at present, namely the chelate complexes of 2-nitroso-1-naphthol **24**^{65,71,73} and the isomeric 1-nitroso-2-naphthol **25**.⁷³

According to the literature,^{65,71,73} these images are formed in four stages: bleaching [4% aqueous $\text{K}_3\text{Fe}(\text{CN})_6$ solution, 10–12 min, 20–25 °C]; intermediate toning (5% aqueous CoCl_2 solution, 10 min, 20 °C); fixation (25% aqueous $\text{Na}_2\text{S}_2\text{O}_3$ solution, 3–5 min, 20–25 °C); generation of the nonsilver image (1–10 min, 20 °C). The first three stages correspond to the generation of the intermediate image. The process occurring under these conditions are described by Eqns (14)–(17) respectively:

The intermediate image obtained on $\text{Co}_2[\text{Fe}(\text{CN})_6]$ has a pale-green colour, whereas the images based on the chelates **26** and **27** have dark-red and brick-red colours respectively^{65, 71, 73} with extremely high optical densities in green and blue light. With increase in the duration of the fourth stage (toning) and also with increase in the concentrations of both isomeric nitrosonaphthols in the toning solution, the densities D' increase monotonically, tending to certain limiting values.⁷³

Despite the fact that cobalt(III) forms a much greater number of coordination compounds with chelating and macrocyclic N,O-, N,S-, and N,O,S-donor ligands compared with cobalt(II), only very few of them have been used as carriers of photographic nonsilver images.^{66–70, 72, 74} The synthesis of nonsilver images based on cobalt(III) chelates from initial silver images can be achieved in three stages. The first two correspond to the formation in the photographic emulsion of an intermediate image from cobalt(III) hexacyanoferrate, whilst the third corresponds to the formation of the target metal chelate image. Bleaching is carried out in the course of 20–25 min at 20–25 °C in the 10 g $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ + 50 g Na_3HCT (or K_3HCT) + 4 g H_4Ct + 4 g $\text{K}_3\text{Fe}(\text{CN})_6$ + 0.2 g L-methionine + H_2O (up to 1 litre) solution. Fixation is carried out in 25% $\text{Na}_2\text{S}_2\text{O}_3$ solution at 20–25 °C for 3–5 min. According to literature data,^{66, 70, 74} the processes occurring under these conditions can be described by Eqns (18) and (16) respectively:

The optical densities of the intermediate nonsilver image thus obtained, measured through blue, green, and yellow light filters, greatly exceed the optical densities of the initial silver image.⁸⁴ It is interesting to note that the $D' = f(D^{\text{Ag}})$ relations for such images on negative phototechnical films have a distinct maximum,^{84, 87} whereas on radiographic films there is no such maximum. This difference was attributed⁸⁷ to the different degrees of graininess of the photographic emulsions comprising the materials indicated.

The processes leading to the formation of nonsilver images from cobalt(III) chelates have been analysed in greatest detail in a study by the present author,⁷⁴ who noted, in particular, extremely complex $D' = f(D^{\text{Ag}})$ relations on formation of images with carriers comprising cobalt(III) chelate complexes with ligands such as dithiooxamide, N,N' -diphenyldithiooxamide, and N,N' -diphenylthiooxamide. According to the present author,⁷⁴ this form of the curves may be fairly adequately interpreted in terms of the concept of stepwise complex formation in accordance with Eqns (19)–(21):

It is noteworthy that, in contrast to the nickel(II) and copper(II) chelates, in the generation of nonsilver images from cobalt(III) chelate complexes of dithiooxamide a dependence of the nature of the $D' = f(\lg H)$ and $D' = f(D^{\text{Ag}})$ curves on the type of photographic material in which the initial silver image had been formed is observed. Thus, in the case of radiographic or direct positive films, these curves have a single maximum,^{66, 74} whilst in the case of negative phototechnical films there are two maxima,^{66, 70} the first of which corresponds to the maximum observed on these photographic materials for intermediate cobalt(III) hexacyanoferrate images, while the second is located in the region of lower values of $D^{\text{Ag}}(\lg H)$. It is even more remarkable that the second maximum is observed only in measurements through a blue light filter.⁶⁶ Another characteristic feature is that, immediately after the attainment of the second maximum, there is a sharp alteration of the colour of the image from amber-yellow to brick-red, which is linked directly to processes (20) and (21).^{66, 70, 74} This type of $D' = f(D^{\text{Ag}})$ relations is entirely unique and has no analogues whatever among other nonsilver photographic image generation processes. It must be specially emphasised that the nonsilver images considered exhibit a very high absorption in the visible part of the spectrum, as a result of which the photographic sensitivity of the treated AgHal material may increase during their formation by a factor of 30–50 and more compared with that for the initial silver image,^{72, 74} which is of undoubted practical interest. Nonsilver photographic images based on cobalt(III) chelate complexes of 8-mercaptoquinoline, which, like the images based on cobalt(III) chelate complexes of dithiooxamide and its analogues, have a dark-brown colour, have been described;⁶⁹ however, these images have not so far been investigated.

Iron(II) or iron(III) chelate complexes should be of greatest interest as 'working materials' for nonsilver images based on coordination compounds of 3d elements because iron and its compounds are cheapest and most readily available. Unfortunately, the majority of iron(II) and iron(III) complexes are relatively unsuitable for the generation of nonsilver photographic images because of their weak absorption in the visible part of the spectrum and appreciable solubility in water. For this reason, the list of iron coordination compounds used as carriers for nonsilver images is extremely limited. Only images based on iron(II) chelate complexes of 8-hydroxyquinoline^{76, 79, 81} and isonitrosoacetone⁷⁷ [the 'iron(II) ion:singly deprotonated form of ligand' ratio is 1:20] and iron(III) chelate complexes of 8-mercaptoquinoline (the above ratio is 1:3)⁷⁸ have been described in the literature. Such images are obtained in three stages: (1) bleaching in the 5 g NH_4FeCt + 2.0 g H_4Tr (H_4Tr = tartaric acid) + 4.5 g $\text{K}_3\text{Fe}(\text{CN})_6$ + 2.5 g $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ + H_2O (up to 1 litre) solution (see Mikhailov and Budnikov⁷⁸) or the 5 g NH_4FeCt + 1.8 g H_4Tr + 4.0 g $\text{K}_3\text{Fe}(\text{CN})_6$ + 0.1 g $\text{K}_2\text{Cr}_2\text{O}_7$ + H_2O (up to 1 litre) solution (see Mikhailov and Polovnyak⁷⁷); (2) fixation in 25% aqueous $\text{Na}_2\text{S}_2\text{O}_3$ solutions; (3) transformation of the intermediate image arising in the bleaching stage into the metal chelate image. The intermediate image is coloured sky-blue or blue and has an extremely high optical density in red light.⁸⁴ It could have full independent practical importance were it not for its low resistance to photodegradation by UV and visible light and also by alkaline agents. The generation of this image can be described by Eqns (12) and (22):

The most promising ligand for the generation of photographic iron chelate images is 8-hydroxyquinoline, which forms the dark-brown compound **31** with iron(II). It imparts to the gelatin emulsion of the photographic material a colour which is very close to that of the initial silver image but with higher optical densities.⁷⁹ In the course of the formation of nonsilver images with such a carrier, compound **32** is formed simultaneously (in a small amount).^{76, 79}

This reaction was not detected in the formation of nonsilver images from iron(II) chelate complexes of isonitrosoacetone (which are coloured blue).⁷⁷ However, the oxidation-reduction reaction (23) is decisive in the formation of nonsilver images from the iron chelate complexes of 8-mercaptoquinoline (coloured orange). According to Mikhailov and Budnikov,⁷⁸ the emulsions contain exclusively tris(8-mercaptoquinolinato)iron(III) **33**, while bis(8-mercaptoquinolinato)iron(II) was not detected in the photographic emulsion in appreciable amounts of any kind.

Summarising, one should note that the concrete result of the transformation of the silver image into the metal chelate nonsilver image — intensification or attenuation compared with the initial silver image — depends significantly not only on the nature of the chelate complex constituting the image and the concentration — time regime in the toning process but also on the type of photographic material. It has been noted that intensification of the image is usually observed on the photographic emulsions of radiographic AgHal materials, whereas the image is actually attenuated in the photographic emulsions of negative phototechnical and direct positive films.^{13–20, 43–51, 65–67} This factor has been attributed to the greater 'covering power' (the ratio of the optical density of the image and the concentration of the carrier present in it) of silver in images on the last two types of photographic materials, as a consequence of which lower concentrations of silver in the initial image correspond to the same optical density in the case of phototechnical and direct positive films compared with the concentration in the case of radiographic films, as a result of which smaller amounts of the hexacyanoferrate(II) of the corresponding metal are deposited together with the silver(I) compounds in the course of bleaching.

It is noteworthy that in a number of instances the nonsilver images on AgHal photographic materials may be obtained by means of a short procedure: for this purpose, the initially exposed photographic material is developed and is then immediately treated without fixation (the fixation stages have been used in some studies^{11–81}) by the procedure described above involving the transformation of the silver image into a metal chelate nonsilver image. Despite the shortening of the overall duration of the treatment, it is then possible to accelerate and render more complete the bleaching of the silver formed in the photographic emulsion after the development stage. However, this possibility has been indicated only in patent publications.^{88–92}

Mikhailov and Polovnyak⁸⁶ measured certain quantitative structural characteristics of metal chelate nonsilver images and in particular their resolving power. These measurements demonstrated that in most cases the given parameters differ extremely little from the analogous parameters for the initial silver image.

This indicates the possibility of employing such images even for defectoscopic purposes, in particular in medical radiography. The data on the resolving power of nonsilver images based on copper(II) chelate complexes of α -benzoin oxime⁸⁶ give grounds for the hope that the carriers entering into their composition may be recommended for the generation of images on holographic materials, where the most severe requirements must be met by the resolving capacity of photographic materials.¹ It is striking that the decrease in the resolving power of nonsilver metal chelate images compared with that of the initial silver image has been noted predominantly in those cases where the chelate constituting the image undergoes partial degradation during complex formation as a consequence of its deprotonation or the attachment of additional ligand molecules, which is accompanied by the formation of soluble complexes.⁸⁶

Data have recently appeared in the literature concerning the possibility of obtaining nonsilver photographic images consisting of coordination compounds of *d* elements with macrocyclic ligands during their so called mild template synthesis in metal hexacyanoferrate gelatin-immobilised matrix systems.^{41, 42, 63, 64, 93–95} The carriers for such nonsilver images are cobalt(III), nickel(II), and copper(II) coordination compounds of 2,8-dithiono-3,7-diaza-5-oxanonane-1,9-dithioamide and 2,7-dithiono-3,6-diazaocta-3,5-diene-1,8-dithioamide (complexes **34–37**), arising when photographic emulsions containing cobalt, nickel, and copper hexacyanoferrates come into contact with dithiooxamide — formaldehyde or dithiooxamide — glyoxal toning solutions. According to the literature,^{41, 42, 63, 64, 93–95} the following reactions occur in this case:

The generation on AgHal photographic materials of nonsilver images with carriers of this kind makes it possible to achieve an appreciable increase in photographic sensitivity (almost by two orders of magnitude) compared with that for the initial silver image.^{64, 93–95} Judging from the literature data,^{41, 42, 63, 64, 93–95} the use of template synthesis reactions gives rise to new possibilities for the synthesis of metal chelate nonsilver images and large scale studies are clearly necessary in this field.

There are indications of the possibility of obtaining polychromic metal chelate nonsilver images in which the nickel(II) coordination compounds of *N,N'*-diphenylthioxamide, dimethylglyoxime, and dithioxamide, already mentioned, serve as the yellow, purple, and sky-blue components, although unfortunately this possibility has not so far been realised in practice.⁹⁶

III. Metal chelates and metallomacrocycles in the colour photographic process with diffusional transfer of the image

In the photographic processes examined in Section II, the nonsilver photographic images with metal chelate carriers arose in the photographic emulsion of the initial AgHal photographic material as a result of the transformation of the silver image produced on it initially into the nonsilver target image via a series of specific chemical reactions. The individual stages of the process leading to the transformation of the silver image into the nonsilver one were then separated both in space and in time. However, it is possible to imagine a AgHal photographic system in which these metal chelates or their derivatives are already present initially in a 'pure form' whereupon the nonsilver image is formed in one stage. This version of the single-step AgHal process, in which exposure and the chemical-photographic treatment take place simultaneously, was proposed in 1947 by the American inventor E Land.⁹⁷ In the process which he proposed, the light-sensitive emulsion of the exposed photographic material immediately came into contact with photographic paper containing a special layer of varnish. In the course of the chemical-photographic treatment, particles of the metal chelate dye, creating a negative image in the photographic material, remained on the exposed sections, whereas the particles of the dye remaining on the unexposed sites of the photographic material diffused into the receiving layer of the photographic material on an opaque support (usually photographic paper), where the positive coloured image was in fact created.

In the photographic process with diffusional transfer of the image, photographic materials consisting of three layers are usually employed.

Each of them is in its turn divided into two sublayers: the upper light-sensitive layer containing AgHal and reacting selectively to red, green, or blue light and the lower layer with an intensely coloured metal chelate, the colour of which is 'complementary' to that of the zonal sensitivity of the upper sublayer (namely sky-blue, purple, and yellow). The nonsilver image consists of a mixture of the above dyes, the ratio of which in the ultimate image depends primarily on the level of exposure and the spectral composition of the exposing radiation, so that the image is almost always polychromic. The carriers of these images are

usually none other than intensely coloured coordination compounds of 3d elements with N-, N,O-, or N,S-containing chelating or macrocyclic ligands.^{98–137} This type of AgHal photographic process has been called a colour diffusion photographic process; several reviews have been devoted to it.^{106, 110, 138–140}

At the present time the most popular is the AgHal photographic process where the purple and yellow colouring components are chromium(III) coordination compounds of azomethine dyes or azo-dyes, while the sky-blue component is a copper(II) chelate complex of the macrocyclic phthalocyanine formed in the course of template synthesis.^{98–109} Thus the chelates **38–40** have been used.¹⁰¹ The SX-70 Polaroid photographic material with diffusional transfer of the photographic image (USA) is widely known. Dyes of the above or similar composition are used in it as the colour components.¹⁰⁵ Judging from all the available evidence, the combination of the chelate complexes **38–40** is altogether one of the most successful.

Other chromium(III) coordination compounds have also been proposed as reagents for the generation of nonsilver metal chelate images, but, so far as we are aware, they have not found any kind of appreciable practical use.

The nonsilver image formation processes in the colour diffusion photographic process have been described in detail.^{106, 110} For chemical photographic treatment of photographic materials with diffusional transfer of the photographic image, use is made of compositions an obligatory element and active principle of which is NaOH, KOH, or another alkaline agent. Diffusing in the course of the photographic treatment in the light-sensitive layer, the alkaline agent ionises the developing substance present in the photographic emulsion (this is usually methylphenylhydroquinone, which performs the same function in this instance as in the standard AgHal photographic process) and the colouring components. An example of the ionisation of a yellow dye is presented below:

On the exposed regions, sodium (or potassium) methylphenylhydroquinonate reduces AgHal [Eqn (30)], being converted at the same time into the corresponding radical-ion:

By subtracting an electron from the ionised form of the dye, the radical-ion transforms it into the semiquinone form. A scheme illustrating the formation of semiquinones for a yellow dye is presented below:

The semiquinones are fairly readily converted into insoluble dyes, incapable of diffusion and not coming into contact with the reception layer. On the unexposed sections of the photographic material, where the semiquinones are not formed, the soluble forms of the colouring components (the ionised forms) permeate into the reception layer and come into contact with the photographic paper, being at the same time reconverted into the insoluble forms. A nonsilver metal chelate image is formed on the photographic paper as a result.

Apart from the coordination compounds **38–40**, there is of course a possibility of using also other representatives of complexes of the given class. Thus it has been suggested that cobalt(II) and nickel(II) complexes of phthalocyanines¹¹⁹ and the chelate β -ketoacetamidoimidazoquinoline complexes of a series of *d* elements,¹²⁰ which exhibit a very high resistance to the action of radiation and corrosive agents in the environment, be employed. In a series of studies carried out in recent years, the possibility of using the coordination compounds of nickel(II),^{121–125, 131, 133, 135} cobalt(III),¹²⁸ and also platinum group metal ions, in particular those of rhodium(III)¹²⁹ and palladium(II),^{123, 125, 131, 137} in the colour diffusion photographic process has been considered. Judging from all the available evidence, a very large number of coordination compounds with structurally cumbersome N,N'-N,O-, and N,S-chelating and especially macrocyclic ligands having high extinction coefficients in the visible part of the spectrum are suitable for effecting the colour photographic process with diffusional transfer of the image.^{129, 131} The use of compounds **38–40** is associated primarily with their availability and low cost.^{110, 138, 139}

IV. Chelate and macrocyclic complexes as the 'active principle' of nonsilver photographic systems

Several decades before the silver halide photographic process saw the light of day, namely in 1831, Döbereiner already observed that potassium tris(oxalato) ferrate(III) $\text{K}_3[\text{Fe}(\text{C}_2\text{O}_4)_3]$ exhibits an extremely high sensitivity to ultraviolet and blue radiation. Döbereiner's observation for a long time failed to attract the attention of investigators even despite the fact that in 1842 J Herschel created on its basis a fundamentally new, for the time, method of recording information — the so called cyanotype method. Its essential feature reduced to the fact that the photolytic redox process

occurred on the sections of the paper impregnated with $\text{K}_3[\text{Fe}(\text{C}_2\text{O}_4)_3]$ solution subjected to illumination by quanta in the ultraviolet and visible (blue zone) regions of electromagnetic radiation.

The 'working material' for the generation of the visible image was in this case the hexacyanoferrate $\text{KFe}[\text{Fe}(\text{CN})_6]$, which was formed on the exposed sections of the photomaterial, treated with an aqueous solution of potassium hexacyanoferrate, in accordance with the following reaction:

The unexposed sites remained unchanged after treatment of the exposed photomaterial with $\text{K}_3[\text{Fe}(\text{CN})_6]$ solution. This resulted in the formation of a blue image on a white background. This process was used in practice (mainly for copying work) up to the 1960s; nowadays it has been displaced by improved methods (in the first place xerox copying) and it is therefore of only historical interest. However, the problem of the search for systems which are not inferior to silver halides as regards their sensitivity to visible radiation remains of current interest.¹ In this connection, the attention of investigators has been attracted by the coordination compounds of *d* elements with chelating and macrocyclic ligands; one cannot rule out the possibility that in the future photographic materials based on them will prove capable of offering serious competition to AgHal light-sensitive systems.^{141–145}

Coordination compounds with N,O- and N,S-ligands, in particular with the azomethines **43** and azo-dyes **44**,^{146–150} 8-hydroxyquinoline, anthra-quinone and its derivatives,¹⁵¹ various substituted derivatives of dithione and dithiocarbamic acid (compounds **45** and **46**),^{152–154} and the structurally similar compound **47**¹⁵⁵ have been proposed as reagents suitable for recording UV and visible radiation.

M = ion of 3d element; R¹, R² = Alk, Ar;

R¹, R², R³ = H, Alk, NO₂, Hal, NR'₂.

Also proposed have been a series of coordination compounds with dithiolate ligands (in particular complexes **48–50**),^{156–161} *i.e.*

R¹–R⁵ = Alk, Ar;

M = V, Ni, Cu, Pt; R = Ph, Ar, AlkO

and with N,N-donor ligands,^{162–189} among which special mention should be made of the zinc(II), cobalt(II), and mercury(II) coordination compounds of benzindolinospiropyrans,¹⁶² the copper(II) complexes of 1,2-ethylenediamine and its analogues [CuL_n](BR₄)₂ (n = 2–4, R = Ar),^{163,164} and compound **51**.¹⁶⁹

M = Mn, Co, Ni, Cu, Pd, Pt;

R¹–R³ = H, Hal, OH, COOH, Alk, AlkO, Ar.

However, coordination compounds with various phthalocyanine ligands, the simplest of which is complex **52**, aroused the greatest interest. Initially complexes of this type were used as carriers of the nonsilver photographic image;¹⁷⁰ however, the role of the light-sensitive compounds was assumed by coordination compounds of the type [PdL_mX_n]_kY_l [L = sterically hindered polydentate ligand of the type of 1,1,7,7-tetraethyldiethylenetriamine; X = Cl, Br, N₃, SCN; Y = Cl, Br, N₃, SCN, B(OR)₄; m, n = 1,2; k, l = 1–4] while the leuco-forms of the phthalocyanine

complexes served as a kind of 'developing substances'. However, studies have been published recently^{171–186} where macrocyclic coordination compounds of this kind were used this time as radiation receptors. Thus Mn(III) and V(IV)O alkylphthalocyanines have been proposed for the recording of information with the aid of a semiconductor laser,¹⁷¹ 1,2-benzophthalocyanines **53** have been proposed as optical recording materials,^{172,176} and fluoroalkylated phthalocyanines have been suggested for the recording of laser radiation.¹⁷⁷
