The use of coordination compounds of 3d elements with related phthalocyanine ligands, in particular the cobalt(II), nickel(II), and copper(II) complexes of substituted tetrapyrizinoporphyryns^{187,188} and the gold(II) and palladium(II) complexes of hydroxyphlorins (complexes **54**)¹⁸⁹ as light-sensitive reagents has also been described.

Quite a few instances of the successful employment of coordination compounds of metals with hydroxyacids (the photochromic properties of such compounds have been known for a long time) as well as other O,O-ligands (in particular β-diketones and crown-ethers^{190–200}) are known.

M = Co, Ni, Cu.

There are also literature data concerning the fairly high sensitivity of carbonyl and cyanide complexes to UV and visible light quanta,^{200–205} in particular their practical application as the active principle in a series of photochromic systems.^{206,207} The use of ferrocene and its derivatives,^{208–215} for example the products of its interaction with the salts of quaternary heterocyclic bases,²⁰⁸ for this purpose is extremely instructive. Thus photographic emulsions recording radiation as far as the blue-green region of the visible spectrum have been prepared on the basis of complex **55**.

X, Y = CO(CH=CH)_nAr (n = 1, 2)

In certain nonsilver systems based on the titanium(IV) chelate complex of 8-hydroxyquinoline,¹⁵² it was possible to achieve a comparatively high sensitivity of the photographic emulsions to light quanta over the entire visible range (400–700 nm), but the level of sensitivity of the AgHal photographic materials in the same range has not so far been attained. In most cases, the coordination compounds with chelate and macrocyclic ligands are sensitive only to radiation in the UV and blue-violet (< 430 nm) spectral regions furthermore, the lower limit of the level of radiation per unit surface of the photographic emulsion which they are still capable of detecting (it can be regarded as a kind of characteristic equivalent to photographic sensitivity) is $\sim 10^{-3}$ J cm², whereas for modern silver halide photographic systems it is close to 10^{-7} J cm².²¹⁴ Data concerning the possibility of using the coordination compounds of metals with chelate and macrocyclic ligands for the recording of streams of fast electrons, X-rays, γ -rays, and other types of high-energy radiation are more promising in this connection.^{216–229} In particular, the ferrocenyl complexes **55** as well as the analogous nickel(II) cobalt(II), chromium(III), and titanium(IV) complexes, already mentioned above, have been used for this purpose, as a result of which it proved possible to record electron streams and X-rays with energies up to 20 keV.

Even more interesting data have been obtained on cobalt(II) chelate complexes with 1-(2-pyridazo)-2-naphthol ligands (complex **56**), *i.e.*

which in terms of sensitivity to ionising radiation in general and to X-rays in particular are superior to silver halides. The copper analogue of complex **56** with a metal ion : ligand ratio of 1 : 2 also exhibits a fairly high sensitivity to electron streams.²²³ The coordination compounds of cobalt(III) with other tridentate ligands, in particular with 1-(2-pyridyl)-, 1-(2-thiazolyl)-, and 1-(2-oxazolyl)-formazans, and also with 1-(2-pyridyl)-1-(2-quinolyl)-dithiooxamide may also serve as the active principle in light-sensitive systems.²²⁰ A comparatively high sensitivity to X-rays has been noted also in the iron(III) chelate complex of acetylacetone **57**.²¹⁹

The same complex can be used for the reception and brief fixation of information under the influence of high-intensity radiation, in particular laser radiation. There is no doubt that the list of coordination compounds of *d* elements with chelating and macrocyclic ligands may increase appreciably in the future. Bearing in mind that silver halide photographic materials with extremely high AgHal concentrations per unit surface are used for the recording of hard ionising radiation in medical and especially industrial radiography,²³⁰ the interest of investigators in these materials becomes understandable.

Unfortunately at the present time there have been few detailed studies of the mechanisms of the formation of nonsilver images in light-sensitive systems comprising coordination compounds with chelating and macrocyclic ligands.^{175, 195, 231–233} The mechanism of the formation of images in photographic emulsions containing organopolysilanes and titanil(IV) phthalocyanine as a result of their exposure to UV radiation has been examined.¹⁷⁵ The photo-colouring process and the photodecolorisation of titanium(IV) coordination compounds of hydroxy-acids under the influence of UV and visible radiation has been investigated; the authors¹⁷⁵ believe that the photochromism observed in this case is associated with the redox process

This hypothesis is supported if only by the fact that the colour of the photochromic solution vanishes not only in the dark but also on oxidation, for example by atmospheric oxygen.¹⁷⁵

A short but extremely interesting paper²³² in which the mechanism of the absorption of radiation by the chromium(III), iron(III), cobalt(II), nickel(II), and copper(II) coordination compounds of azo-dyes, in particular 2-hydroxyphenylazo-2-naphthol and 2-carboxy-4-methylphenylazo-4,5-diphenyltriazole also merits attention. A relation has been established between the ability of these compounds to record radiation and the formation in their presence of singlet oxygen. The image formation process in photographic emulsions based on ferrocene has been examined^{212, 215} and the effect involving the reversal of the image under the influence of a small amount of reagents capable of forming stable coordination compounds with iron(II) and iron(III) was noted. In this connection, the hypothesis was put forward²¹² that such reagents bind iron(II) and (or) iron(III) and eliminate them from the autocatalytic process involving the reduction of ferrocene and actually play the role of a kind of inhibitors (the virtually complete inhibition of the development process is observed even at extremely low concentrations of these substances, namely ~ 0.003 M).

An attempt has been made to interpret the light-sensitive properties of tris(2,2-bipyridyl)ruthenium in photoinduced film stencils made from organic pigments,²³³ whilst in another study²³¹ photographic systems with an 'active principle' comprising copper(I) and cobalt(III) coordination compounds were considered; mechanisms of the formation images on the corresponding photographic materials have been proposed in individual instances.

Overall, it is essential to note that, despite the existence of a fairly considerable set of review articles and monographs (see, for example, Refs 138–145, 234, and 235), the studies on the mechanisms of the formation of photographic images on nonsilver light-sensitive materials are narrowly specific and scattered. Furthermore, the sensitisation possibilities remain completely undiscovered for nonsilver photographic systems based on coordination compounds of *d* elements with chelating and macrocyclic ligands (as is the case for AgHal photographic materials), so that the true potential possibilities of such light-sensitive systems remain in essence completely unknown. The sensitometric characteristics of the nonsilver photographic materials which might be realised in practice by varying the processes involved in their chemical-photographic treatment also still remain obscure. The mechanisms of the formation of catalytic centres in nonsilver light-sensitive systems based on coordination compounds with chelating and macrocyclic ligands have also been inadequately investigated. (In the vicinity of these centres, the development reaction, accompanied by the formation of a carrier of the nonsilver image in the photographic emulsion, is known to occur first of all.^{2, 3}) The coordination of the efforts of specialists in two extremely remote fields of science — the photochemistry of the information recording processes and coordination chemistry — is essential for the successful solution of the problem. Unfortunately one has to conclude that in recent years interest in the search for and study of nonsilver photographic systems based on chelate and macrocyclic coordination compounds has appreciably diminished despite the fact that there has been no real increment in the extraction of silver throughout the world and, judging from all the available evidence, cannot be expected in the foreseeable future.

V. Conclusion

The nonsilver photographic systems and photographic images examined in this review, the carriers of which are coordination compounds of *d* elements with chelating and macrocyclic ligands, are of considerable interest both for photographic science and for the chemistry of coordination compounds. The generation of metal chelate photographic images can increase in many instances the information content in light-sensitive materials. Furthermore,

one may expect in the future also the creation of a colour photographic process analogous to current silver halide colour photography, in which the image carriers will be coordination compounds of *d* elements with chelating and macrocyclic ligands. They will ensure the highest resistance of photographic materials to the action of light and corrosive agents in the environment. There are all possible grounds for the assumption that, as new experimental data accumulate, this global problem in modern photography will be successfully solved.

As regards the chemistry of coordination compounds, the synthesis of complexes of 3*d* elements with chelating and macrocyclic ligands marks the appearance of an independent scientific discipline — the study of the reactivities of polymer-immobilised coordination compounds with fixation of the substance by intermolecular forces and the discovery of the rules governing complex formation involving such compounds.⁹

This review has been written with the financial support by the Russian Foundation for Basic Research (grant No. 96–03–32112).

Abstract. The essential data on the immobilisation of nanoscale and cluster metal particles in polymeric matrices are considered and systematised for both macroligands and the matrices formed *in situ*. Special attention is paid to the controlled chemical passivation (stabilisation) of extremely active particles of colloidal size using high-molecular-weight compounds. The routes of formation of polymer-immobilised nanoparticles directly in the polymer medium are analysed. This allows the preparation of compositions characterised not only by the most regular distribution of these particles over the bulk of polymer but also by a strong chemical interaction between the components. Studies in the field of polymer-analogous transformations, which offer a promising approach to the binding of mono- and heterometallic clusters as a new direction in the physicochemistry of nanoparticles, are discussed in detail. The peculiarities of the immobilisation of clusters, polynuclear structures, and nanoparticles by synthetic polymers, on the one hand, and by biopolymers, on the other hand, are considered. The basic fields of the application of the products obtained and the prospects of the development of this direction are outlined. The bibliography includes 394 references.

I. Introduction

The possibility of combining the physicochemical properties of metals and polymers in a single material and of regulating these properties through concentrational changes has long been under discussion.^{1,2} The progress in this direction is stimulated by the ever-growing interest in this problem shown in many fields of chemistry, physics, and materials science. Numerous materials have been already produced, that are unique with regard to their mechanical, electrophysical, magnetic, optical, catalytic, and often biological properties. Two major stages may be differentiated in the development of this direction. At the beginning, major attention has been given to the development of convenient and reproducible techniques for the synthesis of ultrasmall metal

particles of nanometre size (with parameters not exceeding 100 nm in at least one dimension), their improvement, and bringing into practical usage. The second stage of studies in this field focused on the development of effective methods for the stabilisation of metal nanoparticles with the help of polymers.

These studies were largely advanced by the development of metal–polymer (metal-filled) composite materials (nearly single-phase, sufficiently homogeneous, and relatively stable systems) possessing specific physicochemical and mechanical properties: increased heat and electric conductivity, high magnetic susceptibility, and the ability to shield from ionising radiation. Specifically, these materials meet the major requirement for protective screens by providing the predetermined degree of decrease in radiation at minimum weight. Metal-polymer composite materials are most widely used in the electronics and radio engineering for producing electroconductive pastes and glues (in particular, printed circuit boards), special coatings (paint and varnish), photo- and X-ray-resistors, X-ray-contrast polymers, rheomagnetic fluids, as well as in instrument building, aviation, and space technology. The spectrum of practical uses of these materials has been much expanded by the discovery of their specific catalytic properties,³ which display close similarity to those of polymer-immobilised catalysts,^{4–5} by their application in chemisorptional and photographic processes (including the production of magnetic developers for xerography and photorecording media) and in the synthesis of antifrictional polymeric coatings, *etc.* Investigation of the interactions in the macroligand–nanoparticle systems may provide additional information on both the principal structural elements of the latter and the peculiarities of the surface of polymers. Finally, it is well known that the nanoparticles of certain metals are endowed with biological activity: they are used as effective drugs in medicine and plant protectors in agriculture.⁶ Many polynuclear enzymes are known to contain clusters of metals (*i.e.*, essentially ultrafinely dispersed particles) bound to biopolymers.^{7,8} Thus, there are certain common characters in the behaviour of metal nanoparticles in synthetic polymers, polymer-immobilised clusters, and metal clusters (polynuclear structures) in biopolymers.

To date, especially over the last 10–15 years, a large body of diverse information has been accumulated on basic techniques for the preparation and investigation of the structure and properties of polymer-immobilised nanoparticles; nonetheless, all these data stand in need of adequate systematisation. Some of the relevant

problems have been considered recently in the example of nanoparticles and clusters of the platinum group metals in polymers.⁹

II. General characterisation, methods of preparation and some properties of the metal nanoparticles

Small n -nuclear particles, which are structural elements of ultra-finely dispersed powders, occupy the intermediate position between clusters and massive metals. On transition from a single atom in the zero valence state (M) to a metal particle endowed with all of the compact metal properties, the system passes through a number of intermediate stages,

among which the principal is the formation of clusters and nanoparticles characterised by small sizes of their morphological elements. This is followed by the formation of large stable particles of a new phase. The process of collectivisation of electrons in the core that is formed occurs spontaneously and is in essence similar to the formation of molecules from individual atoms. The attribute 'metallic' reflects solely the composition rather than the nature of these particles, which are regarded as transient species between the bulk metal and its individual atoms. Clusters are figuratively called metal embryos.¹⁰ The extent of dispersion has a crucial influence on their chemical activity, and as a metal particle grows larger its properties change substantially. With regard to their size, such particles may be divided into three following types:¹¹ nanometric (ultradispersed) (from 1 to 30–50 nm),¹² highly dispersed (from 30–50 to 100–500 nm), and micrometric (from 100–500 to 1000 nm). The latter are as a rule composed of individual particles and their aggregates, being mono- and polycrystals of the fractal type. The particles of the first two types are called colloidal, while those of the third type are known as coarse-dispersion particles. When prepared under normal conditions, the aerosol metal particles with a mean size of ~50 nm have the spherical or a close to spherical shape owing to their high surface energy.¹³

The terms 'ultrasmall particles', 'nanocrystals' (for designating the metal nanoparticles whose size ranges from 2–5 to 50 nm),^{14, 15} and 'colloidal crystallites'⁶ are also frequently used. The requirements for the size of nanocrystals of semiconductors in polymeric matrices boil down to the following:¹⁷ the upper limit of their size should allow the optical homogeneity of a composite material (light is not scattered by the media composed of particles with the size below 1/4 of the light wavelength), whereas the lower limit is determined by the very fact of the existence of crystalline particles (the boundary of transition from the crystalline to the quasi-molecular phase). The notions of 'molecular aggregation' and 'crystalline clusters' are used less frequently.¹⁸

Naturally, a process occurring according to the Eqn (1) is not reduced to a trivial mechanical build-up of metal atoms involved in the formation of n -nuclear constructions. It is common practice to differentiate two types of nanoparticles: clusters, *i.e.*, the particles with ordered structures (their size ranging from 1 to 10 nm) composed as a rule of 38–40 (sometimes more) metal atoms, and the nanoparticles proper (disordered structures), having a size of 10–50 nm and including in most cases 10^5 – 10^6 atoms.

It is known that the cluster formations are characterised by a non-monotonic dependence of their properties (*e.g.*, ionisation potential and bond energy per metal atom, interatomic distances, optical and magnetic properties, electron conductivity, electron–substrate interactions, *etc.*) on the cluster size, *i.e.*, on the number of metal atoms incorporated. It is these criteria that determine the existence of the so-called 'magic numbers': a discrete set of numbers of atoms (N) corresponding to the formation of the energetically most favourable clusters.¹⁹ These

numbers equal to 13, 55, 147, 309, 561, 923 ... are calculated by the formula²⁰

$$N = \frac{1}{3}(10n^3 + 15n^2 + 11n + 3).$$

The structure of small and medium-size homometallic clusters (3, 4, 5, 6, 10, 20, and 38 atoms) has been established by X-ray diffraction analysis.²¹ Their metallic framework consists mainly of cycles, carcasses, and polyhedra. On going from clusters to nanoparticles, the non-monotonic character of structures becomes less pronounced. Still, the symmetry in the distribution of acting forces is violated because of the non-compensated character of bonds at atoms localised in the subsurface layers, *i.e.*, having neighbours mostly on one side (they amount a substantial proportion of the total number of atoms in a particle). As regards their properties, these 'ligand-deficient' atoms are to a certain extent similar to the superficial atoms of crystals. The disposition of atoms at the interface, their interaction with neighbours and motions near the crystal facets predetermine disturbance in the translational symmetry, strong anisotropy, a pronounced anharmonic character of oscillations, *etc.*^{10, 13, 22–25} This results in the enhanced adsorption potential of such atoms, larger possibilities of ion and atom exchange, contact interactions of structural elements, *etc.* However, there appear difficulties in the interpretation of their behaviour due to the impossibility of distinguishing between the bulk and surface properties of these particles. Furthermore, if the parameters of their structural elements are commensurate at least in one direction with the correlation radius of a definite chemical or physical phenomenon (*e.g.*, with the length of free path of electrons, phonons, the coherence length in a superconductor, the size of a magnetic domain or a nucleus of a new phase, *etc.*) or are less than this radius, such systems or the reactions involving them manifest the so-called dimensional effects.

Thus, the nanoparticles with highly developed interfacial surfaces possess excess energy in comparison with homogeneous materials, and they are often called energy-saturated systems. Their investigation is the subject of a new rapidly expanding branch of science, physicochemistry of nanoparticles (also known as nanotechnology and physics of clusters). Since the progress in this field is closely associated with the development of methods for the synthesis of nanoparticles, we shall briefly dwell on the main of them.

The spectrum of techniques used for the preparation of nanoparticles is rather broad and is based on two major approaches: physical and chemical. The former is largely based on condensation techniques consisting in the 'assembly' of nanoparticles from individual atoms of metals. By way of their gradual association and on reaching a definite size with the appearance of a clear-cut physical interface, these atomic aggregates become nuclei (embryos) of a new phase. The condensation methods include direct evaporation of metals, in particular with the use of Knudsen cells, induction heating, low-temperature condensation technology, spray and electron bombardment, condensation in electric arc discharges and by plasma techniques, explosion of conductors, *etc.* In most cases, these techniques prove to be mutually complementary rather than competitive. Less widespread are the techniques for preparing nanoparticles by dispersion of coarse particles (colloidal mills, shakers, sonication, high-frequency, and electric arc fragmentation, *etc.*).

Of the chemical methods, the most popular is the reduction of metals in solutions in the presence of different stabilisers dating back to the 19th century. Metal aluminium hydrides, borohydrides, amino boranes, hydrazine and its derivatives, hypophosphites, formalin, salts of oxalic and tartaric acids, hydroquinone, dextrin, a number of other compounds (H_2O_2 , H_2S , CO , CS_2 , NO , $SnCl_2$), and most often hydrogen serve as the reducing agents. The chemical methods also include diverse pyrolysis techniques of moderately stable metal compounds (carbonyls, formates, oxalates, organometallic compounds), various modifications of cryochemical synthesis, and plasmochemical techniques. As a rule,

the common disadvantage of chemical methods is the formation of polydisperse colloids with a wide particle size distribution.

A new direction in the physicochemistry of nanoparticles known as chemistry of 'giant' clusters deserves special mention. The most recent years witnessed the development of techniques for the synthesis of compounds with metal–metal bonds whose nuclearity may be as high as a few hundred units,[†] *e.g.*, Pd₅₆₁Phen₆₀(OAc)₁₈₀ or Pd₅₆₁Phen₆₀(PF₆)₆₀O₆₀,^{26,27} and even the compounds containing up to 1415 Pd atoms.¹⁰ In fact, these huge clusters are nanoparticles coated with a ligand envelope protecting them from environmental impacts.

The extremal conditions of the synthesis and a large specific surface of the nanoparticles characterised by a small size of morphological elements may induce changes in their physicochemical properties and even lead to the distortion of their atomic structure.²² Very high (or very low) temperatures, high rates of processes, various external impacts (*e.g.*, rapid condensation, annealing) favour the formation of non-equilibrium 'frozen' states in the growing *n*-nuclear particles.

A highly developed interface surface, excessive energy of superfacial atoms, and decreased activation energies of different reactions determine the extremely high reactivity of nanoparticles. Therefore, the energy-saturated nanoparticles produced under strongly non-equilibrium conditions are highly reactive towards the components of the medium they are formed in.[‡] When placed into an inert atmosphere, they usually undergo spontaneous aggregation leading to the eventual formation of powders with normal dispersity. In some instances, the exceptionally high chemical reactivity of nanoparticles is useful, though more frequently it poses a number of problems related to the necessity of their stabilisation for transportation and storage purposes. In this context, the search for effective ways of the controlled chemical passivation of nanoparticles is a topical problem. The solution of this problem is largely facilitated by a high adsorption capacity of these particles towards high-molecular-weight compounds.

III. Basic principles and mechanisms of the stabilisation of nanoscale metal particles by polymers

The interaction between nanoparticles and adsorbed macromolecules is the most important field in the modern science of polymeric colloids studying the regularities of the formation of the dispersion systems with highly developed interfacial surface, their kinetic and aggregative stability, diverse surface phenomena at the interface, and the adsorption of macromolecules on solid surfaces from liquid media.²⁸ The adhesion between polymers and metals is determined by a number of factors, among which the most essential are the nature of the molecular forces, surface defects, internal strain, and electrical charges. These factors influence the mechanism underlying the polymer–metal interaction.^{28–30} They are best described within the framework of the theory of 'molecular solder' (the term used for strong adhesive interactions between components),³¹ based on the concept of structural–mechanical factors of the stability of dispersion systems and spatial networks of the coagulation structure type.

[†] Strictly speaking, such huge clusters are not individual compounds but rather include particles of different size and composition within a narrow distribution range (similar to the molecular mass distribution of polymers). The idealised formulae used to describe them are averaged over a statistical ensemble.

[‡] The free energy variation during the dispersion of a homogeneous metal of volume *V* to particles with radius *r* is equal to

$$\Delta F(r) = \frac{\sigma V}{r},$$

where σ is the increment of free energy of a system during formation of a unit of new interfacial surface.

A colloidal system is formally composed of a continuous phase, dispersive medium (polymer), containing distributed nanoparticles representing the dispersed phase. A colloidal system is regarded as stable, when the dispersed phase exists in the form of individual isolated particles for a sufficiently long period of time (a few months or even years).[§] Sometimes, the sedimentation resistance is estimated from the quantity of pellet formed by centrifugation (*e.g.*, after a 20-min centrifugation of a Pt–polyvinyl acetate (PVA) system at 6000 *g*). The size of colloidal particles in the system Pt–PVA may be controlled by varying *g* and the centrifugation time.³⁷

There are two types of polymer-stabilised colloids: lyophobic and lyophilic. In the former, the interaction between the dispersive medium and the dispersed phase is so weak that such colloids prove to be unstable (in the thermodynamic sense) and the attractive forces lead to the aggregation of particles. Nonetheless, the existence of a noticeable repulsive barrier and the remoteness of particles from each other can slow down this process so that the system remains virtually unlimitedly stable (the kinetic stability). Sometimes, these colloids are called thermodynamically metastable. A typical way of achieving the kinetic stability of lyophobic particles is electrostatic stabilisation. On the contrary, the lyophilic systems are thermodynamically stable, *i.e.*, their total free energy of mixing is negative, and the dispersed state may be characterised as a low-energy state. The prime cause of the aggregational resistance of such particles is their solvation.

The aggregation of such systems is called coagulation, when densely packed aggregates are formed, or flocculation, when the particles remain separated from each other by a polymer. The coagulation of nanoparticles on polymeric surfaces is sometimes called heteroadagulation. The non-charged particles coagulate rapidly owing to the dispersional attraction (the London forces). This process is described by the rate constants of fast coagulation according to Smoluchowski: $k_c = 4kT/\eta$, where *k* is the Boltzmann constant, *T* is temperature, and η is the dispersive medium viscosity. The constant k_c characterises the long-range attraction between colloidal particles. The van der Waals attraction between individual atoms or molecules extends only over the distance of a few decimal fractions of a nanometre. However, in the systems under discussion, a polynuclear (multicentre) interaction takes place: each atom or molecule of an individual nanoparticle attracts each atom of another particle containing 10^6 – 10^{10} atoms. The interaction force of the particles in the dispersed phase in coagulation structures is estimated, on the average, as 10^{-10} N per one contact. Summation of a huge number of all possible interatomic interactions between nanoparticles results in a considerable attraction.

The potential attraction energy U_r between two spherical particles with radius *r* at the minimal distance between their surfaces l_0 may be described by the following simplified equation:

$$U_r \approx \frac{Ar}{12l_0} \text{ at } r \gg l_0,$$

where *A* is the effective Hamaker constant having the energy dimensions. In its order of magnitude, the constant *A* is close to *kT* for latex particles, though in the case of metal dispersions it may also have higher values. For example, for poly(methyl methacrylate) (PMMA), polystyrene (PS), Ag, and Al₂O₃, the values of $10^{20} A$ are 6.3, 6.15, 40.0, and 15.5 J, respectively.³⁸ Note for comparison that the attraction energy of two latex particles, each being 120 nm in size, is $\sim 10 kT$ at the distance of 1 nm and $2 kT$ at 5 nm. In the absence of repulsion between particles, this would be quite sufficient for coagulation, since by its absolute value, the energy of attraction is greater than the thermal energy of particles, equal to $\sim \frac{3}{2} kT$ for the three translational degrees of freedom.

[§] The theory of stabilisation of colloidal particles by polymers is considered in sufficient detail in Refs 32–36. We discuss here only the problems that are directly relevant to polymer-immobilised nanoparticles.

Hence, it may be assumed that in the systems under consideration the region of van der Waals attraction extends to the distance of 5 nm. The magnitude of London attraction and its action radius are the crucial factors in the choice of ways for the stabilisation of such particles.³² A long action radius of attractive forces restricts considerably the possibilities of stabilisation. It follows that the stability condition of nanoparticles requires the occurrence of repulsion between particles at the distances at least commensurate with the action radius of attraction. Coagulation takes place at isoelectric points (when the particle charge becomes zero).

In order to stabilise the 'ligand-free' clusters, use is made of matrices of inert gases, low temperatures, and surfactants. The hydrophobic nanoparticles are homogeneously dispersed inside the core of micelles at surfactant concentrations above the critical micelle concentration (CMC). At lower concentrations, the stabilisation is achieved by adsorption of surfactants on the surface of nanoparticles.

The most important are the electrostatic and polymeric methods of stabilisation (also known as charge and steric stabilisation). The latter is brought about by the adsorptional coating of the nanoparticle surface with macromolecules.

It is known that the size of gold nanoparticles is increased in the presence of poly-4-vinylpyridine (P4-VPy) that is indicative of the chemisorption of macrocations on them and the formation of a 'soluble complex'.³⁹ The mean hydrodynamic radius of such stabilised particles (21 ± 0.5 nm) is larger than that of nanoparticles in water (13 ± 0.5 nm) (Fig. 1). According to Kiwi and Gratzel,³⁷ the mean hydrodynamic radius of Pt particles stabilised with PVA with a molecular mass of 60 kDa is 10.5 nm, the size of metal particles being small compared with the thickness of the protective environment.

The possibility of polymeric stabilisation is determined by the condition that the spatial dimensions of even relatively low-molecular-weight compounds are comparable with, or larger than, the action range of the forces of London attraction of particles. Assuming the 'diameter' of a linear polymeric macromolecule to coincide with the root mean-square distance between its ends, the ratio of the particle radius to the molecular weight of a polymer (M_r) may be calculated by the expression³²

$$\langle r^2 \rangle^{0.5} \approx 0.06 M_r^{0.5}.$$

For the polymers with $M_r = 10^4$, $\langle r^2 \rangle^{0.5} = 6$ nm, whereas for $M_r = 10^5$, $\langle r^2 \rangle^{0.5} = 20$ nm.

Thus, the polymeric molecules with $M_r > 10^4$ have precisely the size range required for the stabilisation of colloidal particles (clearly, it is also necessary that the macromolecules induce repulsion of particles). Another necessary condition of the stabilisation is the ability of polymer to wet the nanoparticle surface,

Figure 1. Structure of the 'soluble polyelectrolyte complex' formed by a gold particle and a polycation macromolecule.³⁹

and this in turn is dependent on the character of the interaction of the polymeric medium with the active centres of the surface.

The steric stabilisation of particles can follow two different mechanisms. The first mechanism assumes the attachment of macromolecules to the surface of particles, for example, by grafting or physical adsorption. In this situation, irrespective of the form of the molecules (unfolded or globular) localised on the surface of nanoparticles, their interaction is determined by the number of polar groups in the adsorbed polymer per unit surface. According to the second mechanism, stabilisation is performed by macromolecules from solution. A combined method of electrosteric stabilisation based on the use of the superficial charges on the particle or on the polymer, *e.g.*, on a polyelectrolyte, is frequently used (especially in biopolymeric systems, see Section VI).

The mechanisms of the stabilisation have not been totally clarified yet because of their complexity. Simultaneous occurrence and mutual influence of processes of particle enlargement and adsorption of macromolecules on the surface of both initial and formed particles is to be noted. Here, the aggregative stability depends on the ratio of coagulation and adsorption rate constants. By analogy with the sorption processes, the quantity of sol coagulated per unit surface within a definite time interval is calculated by the equation⁴⁰

$$q = \frac{(c_0 - c_e)V_1S_1}{m_2S_2},$$

where c_0 and c_e are the initial and equilibrium weight concentrations of a metal sol, respectively; V_1 is its volume; m_2 is the weight of the polymer; S_1 and S_2 are the specific surfaces of metal sol and polymer, respectively. In most cases, the 'sorption equilibrium' is reached within a few hours, while the calculated sorption isotherms have an S-like shape and are approximated by the Langmuir equation in its linearised form in the region of low concentrations of nanoparticles. This implies that the superficial layers of metal particles are formed on polymers following the pattern of molecular sorption.

Simulation of the adsorption-coagulation processes is a rather difficult task. Let us confine ourselves to a mere listing of the most significant effects.³² The case with attached macromolecules involves elastic homosteric and enhanced steric stabilisation, flocculation (phase partitions, substitutive coagulation, crystallisational coagulation), and heterosteric stabilisation (selective flocculation, heteroflocculation, phase separation). In the case of free macromolecules, there occur substitutive stabilisation, flocculation, and phase separation. The efficiency of the sorption processes, to which the coagulation of nanoparticles is also referred, is determined by the overall balance of surface forces in the course of interaction of phases of different nature.⁴¹ Thus, the stabilising effect of polymers, often called shielding with a protective colloid,⁴² is the consequence of the adsorption of macromolecules on the surface of nanoparticles. By enveloping the nanoparticles, the macromolecules make them less sensitive to the action of electrolytes.

The attempts aimed at the quantitative estimation of the stabilising capacity of polymers date back to the times of Faraday (1857) who studied the effect of gelatin on the variation of the gold sol colour from red to blue upon addition of NaCl.

This phenomenon called subsequently protective action is associated with the ability of soluble polymers to prevent the coagulation of sol by electrolytes. To characterise various biopolymeric stabilisers, the notion of 'golden number' was introduced as the quantity of polymer (mg) capable of averting the flocculation of 10 ml of gold sol upon addition of 1 ml of 10% NaCl solution. The lower is the 'golden number' the more effective is the polymer in preventing the coagulation of the dispersed phase. Despite a sceptical attitude of some investigators¹ to such empirically established 'numbers', we believe that they are definitively useful for comparative analysis. For example, the 'golden numbers' for gelatin, albumin, gum arabic, and dextrin are 0.005–0.01, 0.1–0.2, 0.15–0.25, and 6–20, respectively.

The protective capacity of a polymer, *i.e.* its ability to stabilise colloids, is sometimes estimated as the weight of gold (g), which is stabilised by 1 g of polymer added to 1% aqueous solution of NaCl.⁴³ The protective capacities of gelatin, polyvinylpyrrolidone (PVP) with the mean degree of polymerisation $P = 3250$, polyvinyl alcohol (PVAI, $P = 500$), polyacrylic acid (PAA), and polyethylenimine (PEI) are 90, 50, 0.07, and 0.04, respectively. The ability of polymers to stabilise dispersions increases as their protective capacity increases. The critical concentration of KCl ($10^3 c_{\text{KCl}}$) required for the change of the colour of gold sol from red to blue in the presence of a definite concentration of polymer (1.0 g litre⁻¹) is also used for the evaluation of the stabilising capacity of polymers. It is significant that c_{KCl} is also sensitive to the molecular mass of polymers. For example, the value of $10^3 c_{\text{KCl}}$ varies from 12.5 (in the absence of polymers) to 18, 22, 47, and 480 in the presence of polyethylene oxides with molecular masses of 600, 4000, 6000, and 9000 Da, respectively.

A number of classical studies have established the physico-chemical base of the existence of gold sols, their morphology, and structure.[¶]

The strength and rigidity of protective layers, their spatial extent, as well as the mode of polymer adhesion to the particles are the most important characteristics of the stabilising effect. Polyelectrolytes or relatively rigid non-ionic macromolecules may be attached by adsorption either by their one end ('tails') or both ends ('loops'). The adsorption in the form of loops is most characteristic of homopolymers. As a rule, homopolymers are rarely used as steric stabilisers because they are driven out of the interaction zone in the process of Brownian collisions of particles. However, their efficiency is substantially enhanced when there are centres of specific interaction in the homopolymers themselves or on the surface of the particles to be stabilised. Most often this concerns the protective action of polynucleotides possessing in their native state a complex architecture (secondary, tertiary, and even quaternary). Therefore, they bring about simultaneously both electrostatic and polymeric stabilisation.⁴⁵

Here, the polymeric chain itself may undergo various conformational transformations. In this connection, it seems appropriate to mention the problem of 'blue silver': the radiation-chemical reduction of Ag^+ ions in slightly alkaline aqueous solutions is accompanied by the appearance of bright-blue colouration in the presence of PAA.^{46,47} The reduced 'blue silver' possesses high stability even when exposed to air and may be isolated in the pure form by evaporation of water. This phenomenon is due to the stabilisation of silver by PAA. In alkaline solution, the PAA molecules become unfolded owing to the repulsion of groups COO^- , providing Ag^+ ions with the possibility to interact with groups COO^- . Further Ag^+ reduction leads to cluster formation.

Another example is the stabilisation of $\text{Fe}(\text{OH})_3$ particles containing up to 120 iron atoms[†] in the presence of PVAI or polyvinyl esters with different degrees of polymerisation (Fig. 2).

Figure 2. The 'inclusion' complexes consisting of PVAI and $\text{Fe}(\text{OH})_3$ -like clusters with hydrophobic bonding.

The optimum synthetic stabilisers are amphiphilic polymers, block- or graft-copolymers, which have one fragment ('anchor') in the form of a polymer insoluble in the dispersive medium, whereas the second part of the macromolecule is, on the contrary, soluble in this medium. A characteristic example may be polystyrene-block-polybutadiene subjected to epoxidation with subsequent modification by different nucleophiles.⁴⁸ The micelles of these copolymers in toluene dissolve salts of noble metals, as well as Zn and Cu, which are insoluble in pure toluene. The polymer-stabilised particles formed have the size of ~ 10 nm and are characterised by low polydispersity. Statistical copolymers are less effective.

As a rule, the anchor fragments are attached to the particles as a result of either physical adsorption (which is interpreted in a simplified approach as including processes determined by the van der Waals forces, dipolar interaction, or weak hydrogen bonding which is easy to break), or chemisorption (caused by strong specific bonding of the electrostatic or covalent nature, or by the acid-base interaction). The stabilising fragments ensure the steric protection owing to their mutual repulsion. This occurs in the following manner. When particles come close to each other in the course of the Brownian motion, the fragments are subjected to a stress generated by the compression of adsorption polymeric layers (in the collision of particles, the mutual penetration of polymeric chains is either weak or absent). The release of macromolecules from the region of strong compression requires either their desorption or displacement over the surface out of the stress zone, which demand a significant energy expenditure.

Naturally, in real systems the extreme adsorption of polymeric chains is often not achieved and there are superficial sites unsaturated with macromolecules. In addition, when the compression stress is sufficient for the desorption of macromolecules, the displacement of chains leads to their concentration at particular sites of the overall surface, and this process is accompanied by a decrease in the surface entropy. Furthermore, it is necessary to take into account the presence of defects in any metal surface, in particular, an almost unavoidable existence of an oxide film whose properties strongly depend on the nature of the metal. This leads to an enhanced adhesion due both to formation of hydrogen bonds between certain units of the macrochain and the oxide film and to 'infiltration' of polymers into surface defects or into a relatively porous oxide layer. Moreover, if a polymer contains hydroxyl, carbonyl, and other functional groups, there appears a possibility of heterogeneous chemical interactions. Preliminary treatment (lyophilisation) of the surface of nanoparticles or polymers with specific reagents may lead to the appearance of sites with increased electron densities. They play the role of preferential centres for the formation of nanoparticle primers

¶ There are two basic approaches to the preparation of stable monodisperse sols of colloidal gold:⁴² (a) disintegration of metallic Au by an electrical arc in a liquid medium and (b) reduction of gold halides (most often, HAuCl_4) by sodium citrate at 100 °C or by sonication under conditions of pulse or laser radiolysis. In a standard citrate sol, the gold particles are charged negatively, which is due to strong adsorption of citrate ions the charge of which is equilibrated by weakly bound sodium ions. The charge of gold particles may be positive, if the citrate is removed by filtration through an ion-exchange column with subsequent treatment of solution with *N*-hexylpyridinium polyethylene bromide. The positively charged polymer is strongly adsorbed on gold (the size of sol particles is 10–20 nm), while the bromide acts as the counterion.

† Hydrolysis of Fe^{3+} in aqueous solutions leads to the precipitation of particles $\text{Fe}_x(\text{OH})_{3-x} \cdot n\text{H}_2\text{O}$ in which the values of x and n depend on the reaction conditions; in some cases $\alpha\text{-FeO}(\text{OH})$ with a mean particle size of 2 nm is formed instead of $\text{Fe}(\text{OH})_3$.³⁵

(embryos). For example, treatment of gelatin with bromine facilitates its subsequent decoration with gold.⁴⁹

One should also take into account that ionomers manifest a clear-cut trend toward the association of ionic groups, which form ionic regions as a separate microphase in hydrophobic polymers. For instance, perfluoroalkylsulfonic acid (trade name 'Nafion') revealed morphological formations with ionic regions 3–4 nm in diameter generated by the sulfonate groups. These domains are connected by hydrophilic channels about 1 nm in diameter surrounded by fluorocarbon matrix (Fig. 3). These areas become the sites of concentration of ionic centres for the preferential formation of metaloclusters.⁵¹ In matrices of this type, a restricted diffusion of nanoparticles is observed. In pores of solvated polymeric networks, the coefficient of restricted diffusion of iron hydroxide particles (3–9 nm) exceeds $2 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$.⁵²

In conclusion of the brief discussion of the modes of stabilisa-

Figure 3. Schematic diagram of ionic domains in the Nafion ion-exchange resin.

tion of nanoparticles, let us dwell on the following points.

Although the basic theoretical concepts of the formation and stabilisation of colloidal dispersions refer primarily to polymeric emulsions (latex polymerisation of vinylic and diene monomers, the directed choice of emulsion paints and surface coatings, *etc.*), they also seem to be well applicable to the problem of nanoparticle stabilisation. The differences would most likely be of a quantitative rather than qualitative character. Specifically, as noted above, the attractive forces between particles of dispersed organic polymers are considerably weaker than between particles of metals, their oxides, and salts (cf. the above-mentioned values of Hamaker constants).

The quantitative theory of stabilisation of colloidal particles is based on the analysis of dilute colloids, one of their principal properties being the kinetic (sedimentation) stability. In the case of concentrated, and particularly highly concentrated (containing up to 80% of metal powder) systems, the involvement of the dispersed phase particles in the Brownian motion does not play any critical role. According to the expert view of P A Rebinder, their distinctive features such as strongly developed interfacial surface and high concentration of the dispersed phase in a liquid dispersive medium result in a major consequence: within the concentrated systems, thermodynamically stable spatial structures appear spontaneously as a result of mutual cohesion of particles inside the dispersed phase.³¹ The participation in the Brownian motion of nanoparticles, which are fixed in a spatial network owing to the atomic or coagulative contacts between the particles, is limited to oscillations around the equilibrium position. Indeed, the energy of thermal motion ($3/2 kT$) is much lower than the total energy of the interaction of neighbouring particles, which is determined by the nature of the elementary contacts, their number, and the distribution pattern in structures. Therefore, the

protective high-molecular-weight compounds and dry compositions of dispersed phases of sols are used in the preparation of concentrated hydrosols.

The protected sols acquire the properties of reversible colloids: the dry dispersed phase remaining after the evaporation of the dispersive medium can reform a stable sol upon repeated contact with this medium. In these systems, the lyophobic nanoparticles appear to be in a cobweb of the protective polymer. Such materials find diverse applications, because the practically valuable changes in their properties (higher thermal and electrical conductivity, heat capacity, ability to screen radiation, *etc.*) are realised only at large concentrations of nanoparticles (most frequently, above 50 vol.%, or 90 mass %). However, high viscosity of the molten polymeric matrix does not allow one to achieve regular distribution of nanoparticles, and this degrades the dielectric and mechanical parameters of the materials produced. Thus, the distribution character of nanoparticles in polymers is also significant from the practical viewpoint. For numerous purposes, it is important to achieve the formation of fractal clusters (fractal aggregates) *via* definite physical processes of growth in polymeric media.[‡] The fractal cluster is close to the percolational one⁵⁴ that makes it possible to realise transfer processes (in particular, the system conductance).

The above-discussed concepts refer to the bulk stabilisation (in solutions, gels, swollen polymers). Though, stabilisation often takes place on the surface (*e.g.*, in thin films or a thin subsurface layer of a polymer powder). Furthermore, natural 'cavities' are nearly always present in real polymers with a high degree of crystallinity, *e.g.* in polyethylene (PE) or polytetrafluoroethylene (PTFE) in which this index is 60%–85% and 75%–80%, respectively. Their existence is due to the peculiarities of polymeric chain packing upon transition from the amorphous to the crystalline phase. The amorphous regions are looser and include considerably more cavities, since here the cross-linking of macrochains is weaker than in the crystalline blocks. In these cavities, nanoparticles may be localised and stabilised. For example, the 'ligand-free' iron clusters (up to 35 mass %) are stabilised in the PE or PTFE matrices with a fairly narrow range of their sizes (the distribution maxima were observed for the particles measuring 1.48 and 1.81 nm, respectively).

A crucial role is also played by the pore size, which is one of the basic factors determining the stabilising capacity of matrices. The pores act as transport arteries for the penetration of nanoparticles or their precursors into the bulk of polymers. The incorporation of nanoparticles can also distort considerably the polymeric structure itself. The porosity is estimated from the specific surface (S_s), total volume (V_0), and radius (r) of pores and depends on many parameters, the most essential being the cross-linking density. With regard to their size, all pores are arbitrarily divided into three groups: micropores ($r < 1.5 \text{ nm}$, $V_0 < 0.5 \text{ cm}^3 \text{ g}^{-1}$, the magnitude of S_s is meaningless in this case), mesopores or transient pores ($r = 1.5\text{--}30 \text{ nm}$, $V_t \approx 0.8 \text{ cm}^3 \text{ g}^{-1}$, $S_s = 700\text{--}900 \text{ m}^2 \text{ g}^{-1}$), and macropores ($r > 30\text{--}6500 \text{ nm}$).

There are two basically different modes of the matrix isolation of nanoparticles. The first one is the most usual and consists in mere addition of a suspended or solubilised polymeric stabiliser to a prepared dispersion of particles (a modification of microencapsulation). There are other versions of this technique including mixing of metal powders with latexes. Latex is mixed with the metal phase particles having a size smaller than that of latex particles (100 and 700 nm, respectively) and, after the stabilisation of the resultant mixture (which is often accompanied by coagulation), the dispersive medium is removed. Then the coagulates are heated and moulded to produce samples of metal polymers.

‡ It is assumed that in most of the colloidal dispersions, the aggregation of particles leads to the formation of fractal clusters regarded as geometric objects possessing a self-similar structure in different spatial scales.⁵³

The second approach is based on the preparation of dispersions in the presence of a stabiliser or in the production of a stabiliser from its precursor in the presence of a prepared dispersion of nanoparticles. A widespread version of this method is the formation of nanoparticles in a polymeric medium. This makes it possible to prepare compositions in which the mixing occurs prior to the resin solidification.⁸ The materials produced are remarkable not only for the most uniform distribution of metal particles over the polymer bulk but also for strong chemical interaction of the metal with the polymer. On rare occasions, both components, *viz.* polymeric stabiliser and nanoparticles, are prepared *in situ*.

The complete stabilisation of nanoparticles by polymers is achieved when the adsorption–solvation layers are structured and form a structural–mechanical barrier for coagulation. The strength of these structures and their ability to recover rapidly after damage determine basically the aggregative stability of nanoparticles.

Now let us consider the most interesting techniques for the preparation of polymer-immobilised nanoparticles.

IV. Typical formation processes and the structure of nanometric metal particles in polymers

The difficulties of preparation and practical uses of polymer-immobilised nanoparticles are due, on the one hand, to a rather poor reproducibility of many synthetic procedures and, on the other hand, to rapid oxidation of particles of non-noble metals by potential oxidants at the stage of colloid formation. Virtually all of the known methods for producing polymer-immobilised nanoparticles are at least two-stage processes: they include molecular dispersion (atomisation or reduction) and subsequent condensation of atomic metal into nanoparticles. These stages occur in a rapid succession and virtually form an integral complex process of the appearance of nuclei and growth of a solid metallic phase. The very notion of 'solid phase nucleus' is somewhat equivocal. A cluster containing 25 Pt atoms corresponds in its adsorptional properties to a bulk metal.⁵⁶ On the other hand, in the course of gold chloride reduction, the collectivised ionic groups start to display properties characteristic of the metal nucleus (embryo) only after the accumulation of 300 and more Au atoms.⁴⁶

The heteroadagulation of polymer-immobilised nanoparticles on polymeric powders, films, or fibres could be the simplest method for their preparation. These studies have been carried out mostly on mineral supports, though there are also reports on heteroadagulation of non-stabilised hydrosols (8–12 nm) and organosols (4–11 nm) of Fe, Zn, and Cu on the surface of Dacron (lavsan) and polycaprolactam (capron) fibres.⁴⁰ On the lavsan fibres, the heteroadagulation rate is higher, which is explained by the specific interaction and the formation of the surface M–O bonds. The lowest adagulation rate is characteristic of the iron sol. However, the materials thus obtained are heterogeneous: the nanoparticles are localised only on the surface of polymers.

1. Technique of the atomic metal evaporation

The most attractive, from the technological viewpoint, are the methods of cryochemical deposition (most frequently, vacuum deposition at pressures of 10^{-1} – 10^{-4} Pa) of atomic (gaseous) metal on thin (~ 1000 nm) polymeric supports. The latter are usually high-molecular-weight paraffins, polyesters, oligo- and polyolefins, polydienes, vinyl- and phenyl-siloxane polymers. The metal atoms are first deposited at temperatures of 77 K and above (the so-called technique of 'bare' atoms).^{57–64} Then, the stabilisation of small clusters stable at low temperatures is carried out. In

Scheme 1

these systems, both homo- and heterocluster particles are formed and stabilised at an evaporation rate of 10^{-8} mol min⁻¹. As shown in Scheme 1, first a single metal atom forms bonds with two functional groups (arene rings, or oxygen atoms) (stage I). This is followed by the stage of metal–polymer chain 'growth' (II), and finally the stabilisation of clusters by ligands takes place (III). The stabilisation may also result from the inclusion of clusters into a trap of highly viscous metal–polymer network (IV) and the enlargement of cluster particles (V).

As a rule, the deposition results in the formation of mini-clusters, the size of which depends on the conditions of process and the nature of the metal (in most cases, transition metals are used). Cr clusters contain 2–3 metal atoms, those of Mo contain 2–5 metal atoms, and clusters of other metals include not more than 10 atoms.[¶]

In principle, the kinetics of metal vapour condensation is analogous to the coagulation kinetics of an ideal suspension, which is in an absolutely unstable state, and which can be described by the Smoluchowski equation of fast coagulation.

Some spectral techniques have been elaborated for the identification of polymer-immobilised clusters. For example, mono-, di-, and tri-mers of molybdenum immobilised on poly(methylphenylsiloxane) absorb at $\lambda_{\max} = 318, 418,$ and 502 nm, respectively, whereas the four- and five-nuclear formations absorb at $\lambda_{\max} = 598$ and 640 nm, respectively. This makes it possible to follow the growth of cluster particles. According to Scheme 1, this process comprises a number of consecutive irreversible bimolecular reactions:

¶ These formations are thermally stable only below 290 K and disintegrate rapidly under the action of oxygen (even under a pressure of 1 mm Hg). Note for comparison that the energy of Cr–Cr and Mo–Mo bonds are 150 and 400 kJ mol⁻¹, respectively.

§ An interesting variant consists in the vulcanisation of rubber mixtures containing ferrite dust.⁵⁵

where M is a metal and L is a ligand.

The formation of clusters may be regarded as a continuous deposition of metal atoms on a polymeric film over the time t at the rate W ; then the corresponding rate equations are

$$\frac{d[\text{M}]}{dt} = W - \sum_{j=0}^p k_m[\text{M}][\text{M}_j\text{L}_2],$$

$$\frac{d[\text{M}_n\text{L}_2]}{dt} = k_m[\text{M}]\{[\text{M}_{n-1}\text{L}_2] - [\text{M}_n\text{L}_2]\}.$$

The concentration of cluster nuclei M_nL_2 of various nuclearity on the polymer may be expressed in general form as

$$\frac{[\text{M}_n\text{L}_2]}{[\text{ML}_2]} = [\text{M}_0]^{n-1} \frac{2^{n-1}}{n[\text{L}_0]^{n-1}} = k[\text{M}_0]^{n-1},$$

where M_0 is the total mass of metal atoms deposited on the polymeric film over the time t .

Generally speaking, the cryochemical condensation of metals on cooled matrices leads to the formation of a variety of 'cluster series', which are interpreted⁶⁵ as a set of clusters with the monotonically increasing nuclearity with the same composition of ligands (M_nL_m , where $n = qx$, x is the nuclearity of the simplest member of this series, q is an integer). In these series, the basic structural elements (the simplest building blocks) are individual metal atoms, whereas the series *per se* are models of the atom-by-atom growth of metal particles. One can follow the course of their formation *via* the addition of individual 'bricks', which are elements of the nucleus formation.

It is significant that the cryochemical method allows the preparation of both homo- and hetero-metallic polymer-immobilised cluster particles. Thus the consecutive or simultaneous deposition of vapour of different metals, *e.g.*, Mo and Ti or Ti and Cr, especially at high concentrations, yields the non-solvated bimetallic clusters M_x^1M_y^2 , which are close in size to the colloidal particles (Cr_xTi_y) (Scheme 2) or to small clusters (the cluster Mo_xTi_y includes 13 atoms).

Scheme 2

The particles formed are chemically bound with the polymer and possibly bring about the cross-linking of its chains.

Control of the conditions of metal evaporation also allows the preparation of polymer-immobilised nanoparticles. For example, colloidal silver was obtained with the particle size of 1.0–20 nm (the colloidal Ag particles less than 40 nm in diameter absorb light at ~ 400 nm).⁶⁶ The dispersion of gold nanoparticles (mean particle size ~ 2 nm) in poly(diphenylbutadiyne) has been obtained by cocondensation of vapour of Au and diacetylene monomer on a support at 77 K.⁶⁷

Different versions of cryochemical synthesis have been developed using the protective properties of polymers. To this end, for example, an oscillatory contour is applied for the electrical condensational dispersion of metals.⁶⁹ In non-polar media, dispersions of Ag, Al, Bi, Cd, Cu, Co, Mo, Fe, Ni, Zr, Pt, Sn, and W with the particle size of 1–10 nm are stable only in the

presence of stabilisers (the synthetic rubbers SKD, SKB-35) that can form three-dimensional structures in solution. In their absence, immediate coagulation takes place.

The evaporation of solid polymeric particles (accompanied by considerable pyrolysis) and the co-deposition of volatile products (mostly radicals) with the metal vapour are used less often. This technique is employed, *e.g.*, for the formation of copper islets of ~ 10 nm in diameter in a polyethylene matrix.⁷⁰ The explosive evaporation of a metal wire coated with a polymer, when a short-circuit causes an instantaneous evaporation of metal and the fragmentation of polymer,⁷¹ processes of pulsed mechanochemical interaction (of the Bridgman anvil type),⁷² *etc.* are the modifications of this method. Over the recent years, a keen interest has been shown in the ionic spray of metals on polymeric surfaces. In this context, it seems appropriate to mention the studies into the vacuum deposition of Au and Zn on PE and PTFE.⁷³

The low-temperature condensation of Cr vapour with macromolecular matrices containing aromatic rings (oligobenzyl, oligoarylene, benzene-*m*-xylene copolymer) was used for the preparation of macromolecular sandwich-type Cr complexes.⁷⁴ The direct interaction of atomic metal with the matrix is prevented by the joint condensation of the metal vapour and the solvent (*e.g.*, chromium and diglyme).⁷⁵ This interesting technique makes it possible to replace the direct metal–matrix interaction by the process of exchange of one stabilising ligand for another high-molecular-weight ligand (this procedure is called resolution). Non-ionogenic surfactants are sometimes used for the replacement of dispersive medium. Thus the organosols of silver with particles 3–12 nm in diameter obtained by the cryochemical method in acetone are subsequently stabilised with 0.2% Triton X-100 solution in water and incorporated into a cross-linked polyacrylamide gel.⁷⁶ The nature of the solvent⁶⁴ and the polymer used for the cryochemical synthesis substantially affects both the reaction direction and the stability of products.

Resolution may precede the preparation of polymer-immobilised nanoparticles. For example, the cryochemical synthesis of colloidal Ag particles is performed in acetone, which is then replaced by formamide. Such a dispersion remains stable for a few days. The system Ag (2–5 nm)–formamide is used as a solvent in the preparation of cross-linked polyacrylamide gel.⁷⁷ Three different resolution variants for the synthetic purpose are documented.⁷⁸ In the first version, a Co–nonadecane system obtained by the cryochemical method was mixed with a solution of a polymer in nonadecane with subsequent sonication. In the second version, the nanoparticles of Co or Ni in toluene were added to a solution of low-pressure polyethylene (LPPE) in toluene at 363 K. Finally, according to the third variant, a toluene solution of a polymer was cooled from 383 to 185 K, and the gel-like system was mixed with nanoparticles obtained cryochemically and subjected to sonication. The above techniques make it possible to virtually preclude the aggregation of particles at all intermediate stages. However, along with the peptisation and resolution, more complex physicochemical interactions of nanoparticles with the solvent may also take place.

In the preparation of polymer-immobilised nanoparticles, the matrix, as a rule, does not remain indifferent to the fixation of metal atoms. This is often accompanied by a sharp decrease in the molecular weight of polymers (in particular, in the case of oligoarylenes)⁷⁵ or by the matrix structuring leading to the loss of solubility. In some instances, the ester and other bonds are cleaved, while the interaction of the functional groups of the polymer with metal atoms yields new products (*e.g.*, the splitting of the terminal chlorine atoms in the oligobenzyl matrix synthesised from benzyl chloride in the presence of Cr results in the formation of CrCl_3). The interaction of atomic zinc with the polymer surface is accompanied by a profound destruction of the polymeric subsurface layers and the interaction of zinc with the degradation products.⁷³

Figure 4. Electron micrographs of composite plasmopolymer–Ag films. The degree of filling decreases upon moving from *a* to *h*.

2. Preparation of polymer-immobilised nanoparticles by polymerisation in plasma

Polymerisation in a plasma (in a glow discharge) is initiated by ions, excited molecules, and photons with sufficiently high energy. The vapour pressure of a monomer (its concentration) during polymerisation in plasma is too low (10^{-3} – 10 mm Hg) to allow the production of polymers by the conventional technique. The role of polymer-forming substances is played by relatively simple compounds (CH_4 , CF_4 , benzene, chlorobenzene, perfluoropropane); less often, by more complex compounds. For example, homogeneous coatings enriched in beryllium are prepared by the thermal evaporation of Be with the concomitant deposition of a plasmopolymer of *trans*-but-2-ene.⁷⁹ In this method, mixtures of gaseous monomers with argon are often used. The chain mechanism of the polymer growth does not play a substantial role in the deposition of polymers from the gas phase. The chain propagation occurs basically according to a rapid stepwise mechanism with the predominance of reactions between active particles, which are often called reactions of polyrecombination. Although the products formed are regarded as polymers, they have however little in common with the usual materials of this type because of their structural peculiarities. As a rule, they are three-dimensional products with a high degree of cross-linking, especially when produced by extended (5–10 min) treatments with plasma. In the course of plasma-induced polymerisation, two competitive processes take place: the formation of a polymer by deposition from the gas phase and the etching (destruction) leading to its removal. The relationship between these processes at each specific site is determined by the energy of excited particles, their concentration, and the surface temperature, as well as by the nature of the monomer (*e.g.*, polymerisation predominates in the case of C_3F_8).⁸⁰

A substantial distinction of the plasma polymerisation from the traditional ways of polymer formation consists in the possibility of forming thin (50–100 nm), virtually defect-free films on most varied supports. It is also significant that the polymerisation

in plasma, is not restricted by the choice of material and the support shape. Therefore, this technique is well-suited for the preparation of microencapsulated nanoparticles (the so-called metal-doped polymeric films).⁸¹

Thin composite films are formed under the conditions of simultaneous polymerisation of corresponding compounds and vacuum evaporation of metals. Various modifications of this method[†] have been reported that differ basically in the mode of preparation and introduction of nanoparticles. One version of this method includes simultaneous evaporation of a monomer and metal from different sources,⁸⁵ while another relies on the combination of plasma polymerisation and metal evaporation.^{81,86} There is an original variant, according to which the plasma-induced graft polymerisation of monomers of traditional type (*e.g.*, vinylimidazole on a capron film)⁸⁷ occurs concomitantly with the metal evaporation. Of special interest is the plasma polymerisation of organometallic compounds.⁸⁸ The plasma-induced polymerisation of diethylberyllium is remarkable for the simplicity of the equipment required.

The preparation of polymer-immobilised nanoparticles most often involves combined targets including a metal and a polymer.⁸⁹ The target material is sprayed by plasma, and the sprayed product is deposited, as a rule, outside the plasma zone. It is very convenient to use the cathode material (Mo, Cu, Au) as the source of the metal. In trifluoropropane–metal systems thus obtained the content of the metal in the thin-film material amounts to 18 mass %–26 mass %. Metallopolymers with the formal composition $(\text{C}_3\text{F}_4\text{O}_{0.6}\text{Mo}_{0.3})_n$ and $(\text{C}_3\text{F}_3.9\text{O}_{0.3}\text{Cu}_{0.3})_m$ have been prepared and characterised.⁸² An aluminium-containing material with enhanced adhesion properties is produced by the spray and polymerisation of CH_4 in plasma using aluminium as the electrode

[†] The conditions of low-temperature plasma generation and the technology of plasmachemical processes are described.^{82–84}

material. Even at a relatively low frequency (10 kHz), the electrode surface is bombarded so strongly that the physical spraying of Al takes place with its inclusion into the growing macromolecule, the metal atoms being uniformly distributed over the bulk of the deposited material.

The volume portion (or the filling factor) of the metal embedded into the metallopolymeric material is calculated by the equation⁹⁰

$$r = \frac{S_f - C_f}{S_m - C_f},$$

where S_f is the density of the metal-containing film, C_f and S_m are the densities of the 'metal-free film' and the metal, respectively. Depending on the conditions, the parameter r may vary from 0.1 to 1.0 reflecting the structure of the polymer-immobilised nanoparticles. Thus at low r values and short plasma treatments, the plasma polymerisation of benzene with silver yields quasi-two-dimensional particles.⁹¹ Their distribution pattern in the polymer depends on both the conditions of plasma polymerisation and the filling factor. For example, the transmission electron microscopy has shown⁹² that the composite plasmopolymer–silver films include three different structural regions with different r values (Fig. 4): the metallic region (a, b) composed basically of the metal particles with polymer inclusions, the percolational region (c) in which there are no aggregated metal particles and the formation of interacting cluster particles is initiated, and finally the region of the cluster particles completely isolated by the polymer ($d-h$), i.e., microencapsulated polycrystalline silver particles. Similar structure is characteristic of the Cu, Au, and Ag particles of colloidal size encapsulated with thin shells.^{93,94} This group also includes the particles of Au,^{80,81,95–97} Co, Al, and Mo⁹⁸ in fluoropolymers, Cu in polyethylene,⁸⁵ Ag in a polymer obtained from chlorobenzene⁸⁶ and benzene,⁹¹ etc. The distribution of gold nanoparticles in a polymer resulting from the plasma treatment of the C_3F_8 –Au mixture has been studied in detail.^{80,90} The mean size of gold particles is 5.5 nm ($r = 0.15$). The size of silver crystallites in thin composite films formed upon polymerisation of chlorobenzene and vacuum evaporation of Ag ranges from 5 to 10 nm⁸⁶ and from 100 to 200 nm at high Ag levels. Special studies have shown that neither AgCl nor silver carbide are formed.

Thus, the polymerisation in a glow discharge makes it possible to produce thin polymeric films of controlled size on the surface of nanoparticles prepared *in situ*. The complexity of this technique resides in the fact that it is difficult to control the rate of metal spray and its incorporation into the polymer formed.

3. Preparation of metal sols in polymers by the thermal decomposition of precursor compounds

Heating of volatile metal compounds (primarily, carbonyls, π -allylic complexes, formates, acetates, and organometallic compounds) in organic media or in the gas phase leads to their degradation with the liberation of metals or their oxides in the form of dispersed phase. An example is the decomposition of iron pentacarbonyl:

If these reactions are carried out in the presence of polymers, it is the simplest and apparently the most widespread method for the introduction of large (sometimes up to 90 mass %) quantities of colloidal particles of pure metals into polymeric compositions. This method underlies numerous processes intended for the preparation of polymer-immobilised ferromagnetic nanoparticles *via* the chemisorption of macromolecules on metal particles formed *in situ*. In the first place, this is pertinent to the thermolysis of metal carbonyls.

The stable homogeneous polymer-immobilised dispersions of colloidal particles of Fe, Co, Cr, Mo, W, Mn, Re, Ni, Pd, Pt, Ru, Rh, Os, and Ir can be produced using two modifications of the thermal decomposition of their precursor compounds.^{99,100} The first version is based on the use of solution of 'active' polymer

(containing amino, amide, imine, nitrile, hydroxyl, and other functional groups) in an inert solvent to which labile metal compound is added gradually. In this case, favourable conditions are created for the chemisorptional polymer–metal interaction. After this, the thermal decomposition is performed (mostly, at 100–170 °C). Sometimes the solution or suspension is subjected to different types of irradiation. The second modification relies on a 'passive' polymer that can react with the initial metal complex after the loss by the latter of at least one ligand (the CO group in the variant under discussion). The gradual addition to the solution of such polymers (*e.g.*, polystyrene, polybutadiene, co-polymers of styrene and butadiene, *etc.*) in an inert solvent of the initial complex at a definite temperature is accompanied by the dissociation of a ligand and the binding of the anionic complex with the passive polymer. Then the thermal degradation is performed.

Certain stages of this multistage process (especially the particle growth) have much in common with the above-discussed transformations taking place during the condensation of metal vapour on polymeric matrices. One of the best studied processes is the thermolysis of cobalt carbonyl^{101,102} and iron carbonyl^{99,102–104} in the presence of polymers. For instance, the thermolysis of $Fe(CO)_5$ in a xylene solution of *cis*-polybutadiene or a block-copolymer of styrene and butadiene (408 K, 24 h, under argon) involving a number of consecutive stages leads to the formation of $[C_8H_{12}Fe(CO)_3]$ units:

$n = 1, 2, 3.$

The initial stage involves the formation of a highly reactive anion $Fe(CO)_4^-$, which interacts with isolated double bonds, and then the isomerisation of double bonds occurs accompanied by the formation of π -complexes with the iron tricarbonyl residues. The final product is composed of the η^4 -(butadienyl)irontricarbonyl units with the *trans-trans*- and *cis-trans*-tetramethylene groups. Since the iron tricarbonyl complexes with two non-conjugated double bonds are unstable, no intermolecular products are formed. The reaction of iron carbonyls with low-molecular-weight non-conjugated dienes is accompanied by the double bond migration (Scheme 3).¹⁰⁵

Scheme 3

Three resonance structure are formed on the reaction of iron carbonyl with vinylallenes:¹⁰⁶

A characteristic feature is that the carbonyl complexes of the same type bound with the allyl fragments of the polymeric chain were also detected upon immobilisation of $Co_2(CO)_8$ or $Fe_3(CO)_{12}$ by the polystyrene–polydiene block-copolymers.^{107,108} The thermal decomposition of these polymer-immobilised π -allyl complexes

results in nanoparticles. In the case of polystyrene, the $\text{Cr}(\text{CO})_3$ fragments are bound to π -complexes with the benzene ring.¹⁰⁹

The size of nanoparticles depends on numerous factors, of which the major are the nature of the polymer-disperser, its molecular weight ($M \approx 100\,000$ is the optimum value), the nature of the functional groups (L), and the solvent. Thus under the conditions of annealing in vacuum at 493 K for 2 h, the cobalt-containing polystyrene–polybutadiene copolymer forms a non-magnetic phase of cobalt clusters ~ 1 nm in diameter, whereas the thermolysis at 473–573 K leads to the formation of particles with the size of 3–10 nm. Further increase in the thermolysis temperature up to 623 K leads to the enlargement of cobalt nanoparticles to the size of 50 nm and the appearance of the ferromagnetic properties in the materials formed.

The nature of the solvent plays a very important role. Metal carbonyls disproportionate in basic solvents (e.g., in DMF) to form complexes of ionic type in which metal atoms have the formal charge 2+. The composition of products identified by IR spectroscopy was found to depend on the ratio of the components (the extent of the substitution of carbonyl groups) (Scheme 4).

Scheme 4

In the general case:

where Nu is a nucleophile (Py, *N*-methylpyrrolidone, etc.), $x = 2-6$; $n = 2, m = 8$, or $n = 3, m = 11$, or $n = 4, m = 13$. Under these conditions, dicobalt octacarbonyl is transformed according to the scheme

Basic solvents and high temperatures favour the binding of metal carbonyls by polymers. Stable colloidal dispersions are formed (e.g., iron dispersion with 5–10-nm particles) upon the thermolysis of carbonyls in dilute polymeric solutions. The nanoparticles of this type are very reactive, the particles with the size less than 10 nm are superparamagnetic, while the magnetic hysteresis is observed for the particle size of 10–20 nm.¹⁰⁴

The size of Co particles may be controlled within the range from 2 to 30 nm with a narrow interval of size distribution by varying the reaction temperature, the concentration of reagents, and the polymer composition (e.g., ter-copolymer of methyl methacrylate–ethyl acrylate–vinylpyrrolidone)¹⁰² in a solvent medium with low dielectric constant (e.g., in toluene). It is also noteworthy that the polymers containing larger number of polar groups can form particles of a smaller size. The same result is achieved by the decrease in the metal carbonyl concentration in the polymer.

The nucleophilic fragments of macroligands (in particular, those in the copolymer of styrene with *N*-vinylpyrrolidone) catalyse the degradation of metal carbonyls according to the scheme⁹⁹

The first stage involves the ligand functional groups to form a soluble macromolecular complex, which by releasing CO is transformed into a polymer-immobilised cluster particle M^0 . The subsequent growth of this particle leads to the formation of a nanoparticle. As the matter of fact, there are stages of initiation, growth of particles, and the reaction termination, which may be regarded as a simple disproportionation of metal carbonyl on the particle surface.

The major requirement for the functionalised polymer consists in that the reaction rate on the polymer should be higher than the metal carbonyl decomposition rate in solution, i.e.

$$k_1 + k_2 - k_{-1} - k_{-2} > k_4,$$

$$k_3 > k_4.$$

Thus, in the thermolysis of metal carbonyls in polar media, as a rule, two major reaction routes are realised. First, the disproportionation products react with the polymeric chain and initiate the side reactions of cross-linking, destruction, and isomerisation of the chain, as well as the immobilisation of mononuclear carbonyl complexes. For example, the polybutadiene containing 92% of *cis*-1,4-; 4% of *trans*-1,4-; and 4% of 1,2- units ($M_r = 246$ kDa) if reacted with $\text{Fe}_3(\text{CO})_{12}$ for 2 h at 350 K undergoes isomerisation resulting in an increase in the content of *trans*-1,4 units up to 76%.^{103,110} Second, in parallel, there occurs major process of particle growth (enlargement) from the 'hot' metal atoms and the formation of nanoparticles with a size of 1–10 nm:

The binding of small, insufficiently grown particles (M_n) by the polymer

(in fact, the chain termination) leads, as a rule, to the formation of non-magnetic materials. Introduction of large (compared to the interchain distances and the size of crystalline blocks and cross-links) metal particles results in the perturbation of the polymer structure and deterioration of its physicomechanical properties. The reactions occur spontaneously along both routes, while the competition between them determines the ratio between the rates of thermolysis and diffusion towards the 'hot' metal centres in the solid polymeric matrix, depending on the nature of the reacting particles and the reaction conditions. In addition, these processes are considerably influenced by the character of the medium (oxidative or reductive).

The conditions of thermolysis of metal carbonyls in polymeric matrices and the size of nanoparticles thus formed are given in Table 1.

There is an original method for the formation of metallopolymers by localisation of particles resulting from the rapid unimolecular degradation of solutions of metal compounds in molten polymers, in natural cavities of polymeric matrices of polyethylene, polypropylene, polytetrafluoroethylene, etc. These materials were given a collective name of Claspol.^{112–115} In this process, the melt temperature should considerably exceed the temperature inducing the degradation of carbonyls. Carbonyls are used as dilute solutions under conditions providing for the most rapid and complete removal of ligand from the reaction system. This technique offers a number of advantages. On the one hand, higher temperatures increase the extent of carbonyl decomposition and reduce the yield of by-products, on the other hand. In addition, in contrast to solutions, the melts preserve the close order of the initial polymer structure, while the cavities may host the particles formed. The polymer-immobilised particles thus obtained are characterised by a relatively high dispersity and homogeneous distribution over the polymer volume, while macromolecules are irreversibly sorbed on their surface. The metal particles are

Table 1. Thermal decomposition of metal carbonyls in polymeric matrices.

$M_a(\text{CO})_b$	Polymeric matrix	Conditions of thermolysis	Content of nanoparticles (mass %)	Size of nanoparticles /nm	Ref.

primarily localised in the amorphous, less compact matrix regions. This renders difficult the segmental displacement of the amorphous phase resulting from both the reduced free volume and its possible cross-linking. The polymeric materials formed display enhanced thermal resistance (*e.g.*, in the case of atactic polypropylene modified with metal clusters, T_m is increased by 50–80 °C) and the product acquires a monolithic pseudocrystalline structure. The recurrent spacing of the distribution of metal clusters in it is concentration-dependent and in the case of iron, for example, is 9–12 nm at high concentration (20 mass %–30 mass %) and 20–22 nm at low concentration (2 mass %–3 mass %) with a narrow size distribution of particles (half-width ~1 nm). It is significant that the presence of the metal phase does not affect either chemical or physicochemical properties of such materials as the strong interaction of nanoparticles with the polymer leads to the formation of pseudocrystalline materials. In other words, at definite ratios of ingredients, these products are one-phase metal-polymers.

Of particular interest is the thermolysis of metal carbonyls in the halogen-containing matrices, which apparently should be

regarded as ‘passive’ in terms of the above-discussed classification. The modification of PTFE by Fe^{3+} or Mn^{4+} oxides is brought about by the sorption of the corresponding carbonyls and their subsequent decomposition under the action of KMnO_4 or H_2O_2 .^{116–118} The oxides formed are incorporated into the amorphous regions of PTFE.

In most cases, nanoparticles are prepared in polar solvents that form intermediate complexes with the carbonyls (see Scheme 4), which react with the fluorinated polymers. The main factors influencing the selectivity of the $\text{Fe}(\text{CO})_5$ or $\text{Co}_2(\text{CO})_8$ reaction with polyvinylidene fluoride (PVF) in the course of their thermolysis have been discussed.^{119–121} The results of IR spectroscopy indicate that the adsorption leads to the formation of complexes $[\text{Fe}^{2+}(\text{DMF})_6][\text{Fe}_3(\text{CO})_{11}]^{2-}$ – PVF and $[\text{Co}^{2+}(\text{DMF})_6][\text{Co}(\text{CO})_4]^-$ – PVF, and made it possible to carry out kinetic studies and to elucidate the mechanism of their degradation. The thermolysis of both intermediates follows the mechanism of first-order reactions; however, the rate constant and the activation energies of these processes are substantially different (Table 2). The thermolysis rate constant of polymer-

Table 2. Reaction rate constants and activation energy of decomposition of different products in systems $M_x(\text{CO})_y$ -PVF (140 °C, DMF).¹²⁰

System	$10^{-5} k / \text{s}^{-1}$	$E_a / \text{kJ mol}^{-1}$
PVF-Fe(CO) ₅	8.41	142.59
PVF-Fe ₃ (CO) ₁₁ ²⁻	12.2	51.62
PVF-Co(CO) ₄ ⁻	104	45.80

immobilised cobalt carbonyl is one order of magnitude higher than that of iron carbonyl. This is consistent with the fact that the cobalt carbonyl anion is more reactive than the iron carbonyl anion. A very high activation energy of the decomposition of neutral Fe(CO)₅ in PVF compared with E_a for the immobilised carbonyl reflects differences in the mechanisms of these reactions. The thermolysis of Fe and Co carbonyls in PVF *in situ* leads to the formation of heterophase metallic domains in the polymeric matrix. When the same carbonyls are bound with the polymer, the homogeneously distributed ferromagnetic particles of 5–10 nm in diameter are produced. The mean surface area per particle varies from 80 to 700 nm². The electron diffraction analysis of these systems has revealed the formation of γ -Fe₂O₃ and FeF₂ particles from Fe(CO)₅, and of Co, Co₂O₃, and CoF₂ from Co₂(CO)₈.¹²⁰ The appearance of metal fluorides is associated with the involvement in this reaction of the polymeric chain with the cleavage of C–F bonds.

Hence, two parallel processes occur in these systems: the major process leading to the formation of nanoparticles upon the thermolysis and the side process, which consists in the attack of the polymer chain by metal ions and is accompanied by various transformations of the polymer itself (destruction, cross-linking, binding of metallocomplexes). Besides, the secondary carbenium ions formed from PVF (the formation of carbenium salts was also observed in the interaction of halides of transition metals with halogen-containing polymers)¹²² are highly reactive and take part in various reactions. Recently, the formation of ZnF₂ was reported⁷³ as a result of the reaction of atomic zinc with the PTFE surface.

The character of bonding the clusters and nanoparticles with the polymeric matrix and their topography have not been totally clarified to date; nonetheless, it is obvious that the reactivity of the metal centres formed in the course of decomposition is a critical factor controlling the character of interaction between the polymer and the metal particle.

In the thermal degradation (especially, in the oxidative atmosphere), immobilised polynuclear complexes[‡] with volatile ligands may form nanoparticles of metals and their oxides, and sometimes also with admixtures of metal carbides. Thus heating of poly(η^6 -phenyl methacrylate)-Cr(CO)₃ films at 423 K resulted in the formation of a mixture of chromium oxides enclosed in the matrix of a cross-linked polymer:¹²⁴

In a similar way, the thermolysis of copolymers of acrylonitrile or styrene with (η^4 -hexa-2,4-dienyl acrylate)iron tricarbonyl in air at 473 K leads to the formation of nanoparticles of Fe₂O₃.¹⁰⁹

‡ The fixation of mononuclear metal carbonyls on polymers⁴ and the synthesis of organometallic polymers¹²³ are reviewed.

The distinctive feature of nearly all polymers of this type is that they decompose without melting, apparently owing to the formation of cross-linked structures. Since the metal oxides are the final products of the oxidative decomposition of any metal-containing polymer, the possibility of the replacement of toxic Fe(CO)₅ by polyvinylferrocene¹²⁵ has long been debated.

Less often, the carbonyls, which act as metal-forming substances in the preparation of polymer-immobilised nanoparticles by thermolysis, are replaced by other precursor compounds, usually by metal formates, acetates, and oxalates,^{126–129} and by organometallic compounds. Recently, a metal–polymer composition of the ‘Claspol’ type was obtained by the thermolysis of a triethylenediamine complex of copper formate [Cu(En)₃]. (HCOO)₂ in PS using dimethylformamide as the common solvent.¹³⁰ This complex disintegrates at 170 °C to form metallic copper in a highly dispersed state. It is noteworthy that this temperature is 20 °C lower than that of the thermolysis of the initial copper formate, which is explained by the catalytic effect of the polymer on the thermal degradation of this complex. The point is that the reactive centres of the polymer favour the formation of metal particle nuclei, which are precisely the centres of aggregation. This is followed by the thermolysis and redistribution of the copper complex. The maximum quantity of copper that can be incorporated into PS is 10%.

PTFE increases the decomposition temperature of cadmium oxalate trihydrate,¹²⁶ while the products of degradation of the latter, in turn, increase the temperature at which an intensive degradation of PTFE begins. The thermal decomposition of the highly dispersed copper formate leads to the formation of a metal–polymer composition (20%–34% Cu); the maximum on the granulometric curve of nanoparticles corresponds to ~4 nm. No chemical interaction between the components was observed. The decomposition of a fine dispersion of palladium hydroxide in polyvinyl chloride (PVC) results in spatial structures with highly dispersed Pd particles ($S_s = 26 \text{ m}^2 \text{ g}^{-1}$) in the nodes.¹³¹ It is significant that this process results in the increase in the temperature of complete dehydrochlorination of PVC. The thermolysis of cobalt acetate in the presence of PS, PAA, and poly(methyl vinyl ketone) proceeds at a much higher temperature and leads to the formation of metal clusters that catalyse the electroreduction of oxygen.¹³²

The preparation of a highly dispersed Cd phase regularly distributed in the PS bulk by mixing PS with dibenzylcadmium in THF followed by removal of the solvent and decomposition of the organometallic compound at 130 °C has been reported.¹³³ Materials containing 1.4%–4.3% of metal were obtained from the bisarene complexes (C₆H₅CH₃)₂M, where M = Ni, Co, synthesised by the cryochemical method, by their rapid degradation in LPPE at temperatures higher than the complex decomposition temperature.⁷⁸ Cobalt nanoparticles (with the mean particle size of ~1.6 nm and narrow particle distribution) were prepared¹³⁴ by hydrogenation of the organometallic compound Co(η^3 -C₈H₁₃)(η^4 -C₈H₁₂) in the presence of PVPy at 273–333 K. An original method of impregnation of organometallic compounds into the amorphous regions of PS, high-pressure polyethylene (HPPE), PTFE, and polyacrylates followed by their structural modification and formation of clusters has been exemplified with cymanthrene (η^5 -C₅H₅)Mn(CO)₃.¹³⁵ To this end, fluids are used in their supercritical state (CO₂ under a pressure of 8–25 MPa at 30–40 °C).[§] According to another protocol,¹³⁹ a precursor, dimethyl(cyclooctadiene)platinum(II) is dissolved in CO₂, and the solution obtained is used to impregnate thin films of poly(4-methylpent-1-ene) or PTFE. The reduction of this system by thermolysis or hydrogenolysis yields polymer-immobilised nanocomposites with the Pt particle size of 15–100 nm.

§ The interest in the processes occurring in supercritical fluids has sharply increased over the recent years,^{136,137} especially in the reactions in supercritical CO₂.¹³⁸

Despite the abundance of studies of this sort, the relevant literature does not carry any information on the thermolysis in polymer-immobilised carbonyl-hydrides, substituted (mixed) carbonyls, and mixed metal carbonyls (such as $\text{Co}_2\text{Ir}_2(\text{CO})_{12}$, $\text{H}_3\text{FeRu}_3(\text{CO})_{15}$, $\text{Fe}_2\text{Ru}(\text{CO})_{12}$, or $\text{MM}'(\text{CO})_n$, where $\text{M} = \text{Mn}$, Re ; $\text{M}' = \text{Cr}$, Mo , W), *etc.* The data on the thermolysis of metal carbonyls in reactoplasts are also very meagre. The only thing known is that the heating of the degradable metal carbonyls introduced into an epoxy resin leads to the deposition of nanoparticles on the surface of the polymer formed.¹ Possibly, in this process the highly reactive metal particles initiate the opening of the epoxy ring with the formation of three-dimensional structures.

4. Reductive methods in the synthesis of polymer-immobilised nanoparticles

The reductive methods appear to be the most common techniques for the preparation of polymer-immobilised nanoparticles. They may be divided into two types different in principle. The first type, or the 'impregnation' method consists in the chemical reduction of metals from solutions or suspensions of their salts (to this end, ammoniacal solutions of Cu , Cr , and Ag hydroxides are often used) or in the electrochemical or radiation-chemical reduction in the presence of macroligands. The second type resides on the reduction of mononuclear metal complexes chemically bound with polymers. The first method is more widely applied because it meets better the needs of catalysis. In particular, metal blacks, ultradispersed powders, *etc.* are prepared thereby. For example, Raney nickel is stabilised by incorporating it into the silicone rubber¹⁴⁰ with the subsequent polymer vulcanisation at room temperature.[¶]

Sols of Au , Fe , and Cr were prepared by the reduction of their hydroxides by hydrazine hydrate in a matrix of water-soluble polymers, and dispersions of particles of Pd (1–2 nm) and Au (1–13 nm) were obtained in synthetic rubber films.¹⁴³ The treatment of polymeric films prepared from aqueous solutions of PVA and AgNO_3 with photographic reducing agents (hydroquinone, *p*-phenylenediamine, pyrogallol, *etc.*) yields the corresponding metallocomposite materials.¹⁴⁴ Monodispersed hyperfine powders of gold^{145, 146} and platinum^{147–149} were prepared by the reduction of their salts in the presence of protective colloids.

Natural polymers (gelatin, gum arabic, agar, proteins and products of their hydrolysis, sodium protalbuminate, starch, cellulose and its derivatives) and polymeric compounds soluble in organic media (synthetic rubbers, naphthenic acids) are often used as protective high-molecular-weight compounds in the production of sols of silver, mercury, bismuth, copper, and platinum group metals by the reduction of corresponding ions. β -Cyclodextrin may also be employed as a stabilising agent for colloidal particles of Rh , Pt , and Pd (1–100 nm).¹⁵⁰ Ultrafine particles of Ni (5–20 nm) were prepared by reduction with hydrogen of $\text{Ni}(\text{NO}_3)_2$ following the diffusion into gel membranes of cellulose acetate.¹⁵¹ It is significant that the adsorption of ions by protective polymers (see Section III) creates favourable conditions for the concomitant appearance of a large number of embryos (nuclei) of colloidal metal particles. The metal that is reduced is mostly consumed to form these embryos, while only small quantity remains for their growth. As a result, only small nanoparticles are formed, and this is also favoured by the high aggregative resistance of sols.

The radiation-chemical and photo-induced reduction is preferred to the reduction by hydrogen when it is necessary to prepare small particles with a narrow size distribution.¹⁵² A characteristic example is the preparation of 'blue silver' in the process of

γ -irradiation of slightly alkaline aqueous solutions of AgClO_4 containing 2-propanol and PAA.⁴⁵ The 'blue silver' is a linear Ag cluster stabilised on a polymer molecule. In the course of radiation-chemical reduction, the Ag clusters are transformed through a number of successive stages into a polymer-immobilised colloidal silver.

The interaction of H_2 with colloidal Pd obtained by the radiation-chemical reduction of Pd^{2+} in an aqueous solution of PAA does not increase the particle size and is accompanied solely by hydrogen sorption on the surface of nanoparticles.¹⁵³

It is noteworthy that the 'impregnation' method does not rule out the chemical interaction between the compound to be reduced and the polymeric matrix. The absence of chemical interaction between the metal and the polymer is rather an exception than the rule. For example, in the systems based on polymers devoid of functional groups (polyacetylene and MX_n) the macromolecule plays the role of a specific ligand; this hampers the multicentre association of complexes and prevents their enlargement.¹⁵⁴ Most probably, the condensation of a metal in a liquid phase occurs at the moment when its ion undergoes reduction and not after the formation of a supersaturated solution of metal atoms. The formation of nanoparticle nuclei occurs spontaneously, basically at the sites of largest concentration of metal ions, whereas their growth results from the reduction of ions adsorbed on the surface. Apparently, this process has much in common with the growth of particles in the course of cryochemical synthesis.

The mechanism underlying the reduction of metal ions chemically bound with polymers is rather complex. It has been elucidated in detail using the formation of clusters of zero-valent Pd , Ru , Rh , Ag , Os , Ir , Pt , Au , and Ni as the examples.^{155–158} When solutions of salts of these metals in proton-donating solvents are boiled in the presence of polymers (*e.g.*, a solution of RhCl_3 in aqueous methanol mixture in the presence of PVA), several chemical transformations take place (Scheme 5).

Scheme 5

At the first stage of this complex process, RhCl_3 coordinates with PVA, then an oxonium product is formed, which is further transformed *via* alkoxide into a polymer-bound hydride complex. These reactions lead to a homogeneous colloid resulting from the disproportionation of rhodium hydrides and subsequent growth of particles (Scheme 6).

Scheme 6

The 13-nuclear clusters formed have the structure of a face-centred cubic lattice with a rhodium atom coordination number equal to 12. The clusters are 4 nm in diameter. They interact with the protective polymer owing to electrostatic attraction or to physical adsorption, and possibly to the formation of coordination bonds.

By changing the reaction conditions, the nature of the medium, (ethanol, butanol, toluene–butanol), by introducing additional ligands (*e.g.*, PPh_3), or using various polymers (*e.g.*,

¶ Synthetic rubbers may also be vulcanised by salts of unsaturated acids; this results in the formation of vulcanised metallopolymeric structures.¹⁴¹ Metal–polymer compositions are prepared by introducing dispersed metal (Al , Fe , Cr , Ta , W) powders into oligomers, for example, into trioxoethylenedimethacrylate with subsequent solidification induced by a flux of accelerated electrons.¹⁴²

PVPr, copolymer of MMA with *N*-vinyl-2-pyrrolidone, polyacrylamide gel, *etc.*), one can prepare metallopolymers with cluster particles of different size (0.9–4 nm for Rh⁰ and 1.8 nm for Pd⁰). These particles are stable in the protective colloid, they have a narrow size distribution and high stability (they remain in the gel upon variation of pH from 2 to 12). Thus, the water-soluble polymers act in these systems as protective colloids, while alcohols play the role of reducing agent.

The reduction of NiCl₂ by NaBH₄ in ethanol in the presence of PVPr may be used for the preparation of nickel boride sol, it is still more suitable for the preparation of organosols of noble metals. It proved to be very useful in the synthesis of colloidal dispersions of polymer-protected bimetallic Pd–Pt or Pd–Au clusters.^{159–161} They were produced by the joint reduction of PdCl₂ and H₂PtCl₆ or HAuCl₄ in the presence of PVPr (by boiling in methanol or illumination with visible light). The products remained stable for a few months at room temperature. The size of Pd–Pt and Pd–Au clusters was ~1.5 and 3.4 nm, respectively. This method was also used to prepare the polymer-protected bimetallic Pt–Co colloids with Pt:Co ratios of 3:1 and 1:1.¹⁶²

The obstacle to the synthesis of metal colloids based on insoluble polymers is the diffusion of ions to be reduced into the polymeric matrix. For example, reduction of Ni²⁺ with NaBH₄ in aqueous methanolic solution in porous isotropic isotactic polypropylene (PP) has been carried out using the method of counter-current diffusion.¹⁶³ The process comprises the following consecutive stages: penetration of metal ions and the reducing agent into the polymeric matrix, in-depth diffusion of reagents described by the Fick's first law, and finally, the chemical reaction itself. The size of the nanoparticles formed depends on the reaction conditions and the parameters of the porous polymeric structure. This technique allows the microencapsulation, in the polymer pores, of metal crystallites (3–10 nm in diameter) assembled in polycrystalline aggregates with the controllable size of narrow distribution. Nickel particles prepared by the reduction in the polymeric matrix resisted oxidation in water for over two weeks, whereas when dried, it remained unoxidised for half a year.¹⁶⁴ At the same time, the nickel obtained in the absence of polymers rapidly oxidised in water and air. A mixture of reduced Ni with a polymer solution proved also to be unstable. Apparently, the shielding with polymers prevents not only further growth of particles but also provides their high resistance to oxidation. It is assumed that the macromolecules can trap and stabilise the nuclei of metallic phase owing to the cooperative interaction of chain segments according to the mechanism of matrix 'recognition' by the growing chain during the matrix polymerisation.¹⁶⁵

Under the action of different reducing agents, the immobilised complexes (including the mononuclear ones) may undergo different transformations leading to the increased nuclearity. For example, compounds of Rh, Ru, and Pt fixed by ion exchange on the completely fluorinated resin Nafion (Fig. 3) undergo reduction in a flow of H₂ at 473 K with formation of metallic clusters with sizes of 2.8, 3.3, and 3.4 nm, respectively.^{50,51,166} Cations of Ag, Cu, Rh, Ru, Pt, and Ir bound to perfluoroethylenesulfonic acid or to a partially sulfated PS oxidise CO, NO, NH₃, N₂H₂, and C₂H₂ at 373–473 K, and this process leads to the formation of metal particles 2.5–4.0 nm in diameter.¹⁶⁷

Generally speaking, the formation of polymer-immobilised metalclusters in the course of catalytic reactions is a rather common phenomenon, especially in complex organometallic catalysts deposited on polymers.^{4,168} This phenomenon may be the reason for both the activation of these catalysts (*e.g.*, in hydrogenation reactions) and their inactivation (in particular, in reactions of ionic-coordination polymerisation). Significant data on the transformations of immobilised Ni²⁺ in the course of ethylene dimerisation¹⁶⁹ were provided by measurements of magnetic susceptibility in strong magnetic fields (up to 70 kG) and low temperature (4.2 K).¹⁷⁰ Under these conditions, the susceptibility of different spin states depends non-linearly on the

magnetic field strength (described by the Brillouin's function), which made it possible to establish the distribution of nickel states over the magnetic moment values. Evidence has been provided for the formation of one-nm microparticles containing 10–30 Ni atoms that display no ferromagnetic (supermagnetic) properties and are polymer-immobilised clusters with ferromagnetic exchange. In the polymer-immobilised cobalt systems (the catalysts of butadiene polymerisation) a considerable proportion of Co²⁺ ions are reduced to the metallic state in the absence of polymerised monomer. In any case, 90% of total ferromagnetic cobalt is localised in the relatively large particles 10 nm in diameter.¹⁷¹

There are other numerous methods for the chemical reduction of metal salts in the presence of polymers yielding polymer-immobilised nanoparticles.

5. Electrochemical methods for the preparation of polymer-immobilised nanoparticles

The electrochemical and electroflotation methods are widespread techniques for the preparation of chemisorbed macromolecules bound to colloidal metal particles generated *in situ*. Reactions of electrochemical polymerisation are heterogeneous: they are initiated on the electrode surface, while other stages (chain growth or termination) occur, as a rule, in the liquid phase.¹⁷² The yield of a polymer depends on the chemical and physical nature of the electrodes and their surface, electrode overvoltage, potential under which the reaction occurs, and electrical current density. The nature of the electrode material (metals or alloys, thin metallic coats, *etc.*) determines the characteristics of electron transfer reactions (initiation) and polymerisation. Such types of electrode processes as direct electron transfer between the electrode and monomer, cathodic deposition and anodic solubilisation of metals are optimum for the electrochemical polymerisation. Metal salts, which are the precursors of nanoparticles, may act as specific electrochemical activators influencing the process through direct chemical binding to the monomer and by virtue of transfer, decomposition, or catalytic effect. Nonetheless, the method of electrochemical polymerisation has found only limited use in the preparation of polymer-immobilised nanoparticles.

A procedure for the preparation of metal organosols by electrolysis in a two-layer bath proved to be more suitable.^{1,2} The upper organic layer of the electrolytic bath is a dilute solution of a polymer in an organic solvent (sometimes, supplemented with a minor quantity of surfactant), which interacts near the interface with the nascent colloidal metal particles.

Less often, nanoparticles are formed on polymers by means of electrophoretic and electrochemical deposition of metals from solutions onto polymeric suspension that is used as an additive in the electrolysis.¹⁷³ The metallopolymer formation results from the polarisational interaction of polymer and metal particles during deposition on the electrode and the chemisorptional interaction of macromolecules with the surface of metal at the moment of its reduction. This process includes several stages, such as discharge of Mⁿ⁺ ions, crystallisation of deposited metal, a number of parallel electrochemical reactions, *etc.* The contributions from different stages depend on the concentration of the dispersed phase and electrolyte, and the particle charge. The ratio between these contributions determines the transition from polymer-immobilised nanoparticles to electrochemical plating with high metal content.

Owing to the shielding properties of polymeric particles, the surface of the electrode and metal particles is blocked, and a specific type of polarisation known as electrophoretic polarisation appears, which has an appreciable effect on the process of metal electrocrystallisation. The polymer is often deposited as a separate phase (liquid or solid) on the electrode surface. Therefore, the transfer of ions, electrons, or neutral particles through the layer of the new phase may face noticeable kinetic restrictions depending on the permeability of polymeric coating. Coating the anode with an insulating polymer layer reduces the electrode activity and the

current amplitude. This inconvenience can be partly eliminated by the use of liquid electrodes, *e.g.*, the dropping mercury electrode.

Let us consider some characteristic examples. Colloidal Pd particles are obtained by the electrolysis of aqueous solutions of palladium chloride at pH 1 in a two-layer bath in the presence of a hydrocarbon solvent and epoxy dianic resin or PVA.¹⁷⁴ Electrolysis results in the formation of organosols of colloidal palladium stabilised by the chemisorptional bonds of the polymer. The products remaining after the removal of solvent and residual electrolyte are metallopolymers containing up to 90%–95% of Pd. They are formed under high cathode polarisation with abundant concomitant elimination of hydrogen adsorbed on the nanoparticles (5.5–7.8 nm in diameter).

The combined deposition of Ni nanoparticles and PTFE suspension from the sulfamic-acid electrolyte for nickel-coating at room temperature leads to polymer inclusion into the Ni deposit (up to 20 mass %). The process is controlled by varying the cathode current density and the concentration of suspension introduced.¹⁷⁵ The relationship between the homo- and hetero-coagulation interactions of metal particles and polymer is determined by the rates of electrochemical deposition and isolation of metal in the Ni–PTFE systems.¹⁷⁶

In turn, the electrode material may become the precursor of nanoparticles of noble metals; polypyrrole films containing functional groups such as 4,4'-dipyridyl, alkylammonium, and others may serve as protectors in this case.^{177–180} Bimetallic Pd–Pt or Pd–Rh nanoparticles incorporated into such films are also used for the electrocatalytic hydrogenation.¹⁸¹ Fine dispersions of iron powders (~200 nm) formed electrochemically may be used as modifying coats of various materials.¹⁸²

Thus, the effect of polymeric dispersions on the reduction of metal ions depends on the concentration and composition of the electrolyte and the dispersed phase, charge and size of polymeric particles, and the mode of electrodeposition.

The thermal techniques have substantial advantages over the electrochemical ones because the latter occur with considerable degradation of the dispersive medium, noticeable oxidation of the colloidal particles formed, *etc.*

6. Preparation of polymer-immobilised nanoparticles at the polymerisation (polycondensation) stage

Of special interest are the methods including simultaneous formation of the matrix and nanoparticles. This large group of techniques is reported mostly in the patent literature. The early studies^{183, 184} have already demonstrated the ample possibility of initiating the polymerisation of vinylic monomers by intensive mechanical dispersion of certain inorganic substances, including metals (Fe, Al, Mg, Cr, W). The degree of polymerisation of monomers (styrene, vinyl acetate, acrylonitrile, MMA) depends on the dispersion intensity. The role of catalyst and initiator is played by freshly formed metal surfaces: they are the sites of electron transfer from the superficial metal atoms to the monomers to form initiating particles of ion-radical type. Colloidal particles of Au, Ti, and Pt were found to influence substantially the bulk and solution polymerisation of styrene.¹⁸⁵

Sometimes, organometallic compounds are used instead of compact metals in the preparation of polymer-immobilised nanoparticles. The addition of relatively small quantities of organocadmium compounds has virtually no effect on the initial rate of radical polymerisation of MMA.^{186–189} In this case, nanoparticles may be obtained by two routes: from organometallic compounds (*e.g.*, from bis(triethylgermyl)cadmium) that decompose at a temperature close to that of polymerisation or by heating the composition formed including a component whose decomposition temperature is higher than that of MMA polymerisation (*e.g.*, alkyl derivatives of cadmium). Interestingly, the organocadmium compounds of this type diminish considerably the molecular weight (M_n) of the PMMA formed. For example, its M_n decreases from 800 to 60 kDa in the presence of 2.5 mass % of these compounds. Chain transfer on the organometallic compound

may be probable reason. The formation of nanoparticles in the monomer–polymer mixture may be schematically represented as follows (Scheme 7).

Scheme 7

The size of Cd nanoparticles formed at the polymerisation stage increases as the content of the initial component in the monomeric mixture increases: from 6.3 nm at 8 mass % to 300 nm at 40 mass %. Compositions formed upon heating contain larger nanoparticles that have a regular hexagonal structure characteristic of Cd crystals.

In the processes under consideration, the critical parameters are the ratio of the rates of decomposition of the organometallic component and the polymerisation of the corresponding monomer, and the sedimentational resistance of metal dispersions formed in the monomer. Apparently, this also holds true for solidifying systems, for example, for the thermally generated epoxy-thiocol resin, into which colloidal Pb is incorporated at the moment of its formation by thermolysis.¹⁹⁰ In this case, however, one should also take into account the internal stresses existing in solidified systems.⁵³

High stability is characteristic of nanoparticles prepared *in situ* by combining photopolymerisation (acrylamide and *N,N'*-methylene-bis-acrylamide, non-filtered light from a DRSh-250 mercury lamp), and photoreduction of highly stable Ag^+ ions.⁷⁶ In the presence of atmospheric oxygen, the nascent specimens remain stable for a few weeks, and films formed remain unaltered for a few months. The size of Ag particles (≤ 20 nm) is comparable with that of nanoparticles prepared by the method of combined low-temperature condensation of vaporised metals. A modification of this method was reported recently.¹⁹¹ It consists in the combined condensation, on a support refrigerated with liquid nitrogen, of the vapour of metals (Ag, Pb, Cd, or Mg) and monomers capable of low-temperature polymerisation (specifically, *n*-xylylene), which yields poly-*n*-xylylene films with regularly distributed nanoparticles more or less homogeneous in size. The formation of these films was induced by UV irradiation at 80 K or heating to 130–160 K.

Other modifications of this method for the preparation of nanoparticles in polymers have also been reported. Let us note here only one of them, in which the catalysts containing highly dispersed particles of transition metals immobilised in polymeric films were obtained by the electrolytic oxidative polymerisation of a monomer derived from mercaptohydroquinone containing metals of platinum group incorporated by electrochemical deposition.¹⁹²

Not all of the approaches considered in this section are equally developed. The priority is given to the reduction techniques. The role of the dispersive phase is mostly played by carbon-chain polymers and less often, by condensation-type polymers. The immobilisation of nanoparticles is nearly always accompanied by interaction of the particles formed with the matrix, in contrast to mechanical mixtures of metals with polymers.

V. Polymer-analogous transformations in the immobilisation of metal clusters

Although the polymer-immobilised systems considered above are characterised, as a rule, by high dispersity, by homogeneous distribution of nanoparticles over the polymer bulk, and sometimes by the irreversible sorption of macromolecules on the surface of colloidal particles, which remain in the gel state over a

The features of polymer-immobilised clusters formation may be reduced in the most general form to the following statements.^{213–218} If the concentration of phosphine groups in the macroligand is low (*i.e.*, less than 2% of benzene rings are phosphorylated, see Scheme 8) or the PPh_2 groups are randomly distributed, then polymer-immobilised clusters are formed in which the metal cluster, particularly, of Ir, is bound with one PPh_2 group of the polymer. In the case of higher concentration of PPh_2 groups (with over 3% of functionalised benzene rings), a mixture of clusters is formed that are bound with one or two groups of the polymer. The product with two bonds is virtually the only one formed in the case of the styrene–divinylbenzene–vinylidiphenylphosphine block copolymer containing 8%–15% of PPh_2 groups.

The ligand exchange of the functional groups carrying equivalent numbers of electrons is a typical mode of immobilisation of clusters that undergo fast dissociation, which is especially characteristic of clusters of the $\text{H}_4\text{Ru}_4(\text{CO})_{12}$ type. The exchange between the phosphine ligands of clusters and the phosphorus-containing groups in the polymer occurs under milder conditions than that involving the carbonyl ligands. Thus, an attempt to bind the carbonyl $\text{Ir}_4(\text{CO})_{12}$ with a phosphorus-containing polymer has failed. Therefore, use is commonly made of mixed phosphine- and carbonyl-containing clusters as the precursors of polymer-immobilised nanoparticles (see Scheme 9).

In some cases, the immobilisation process leads to the appearance of small aggregates with indefinite structure. These polymer-bound particles can in principle be carbonylated or decarbonylated with the formation of clusters of definite structure. The

reaction conditions markedly affect the binding of clusters and the polymers. When $\text{Rh}_4(\text{CO})_{12}$ reacts with P-PPh_2 in hexane at 50°C , binuclear clusters are formed.²¹⁶ When this reaction is carried out in benzene containing $\text{Rh}_6(\text{CO})_{16}$, the reactor walls become covered with black spots of deposited atomic rhodium $2.5\text{--}4.0\text{ nm}$ in diameter (*i.e.*, about 100 Rh atoms in each spot).²¹⁷ The decrease in the reaction temperature and the use of CO lead to the immobilisation of $\text{Rh}_6(\text{CO})_{13}(\text{PPh}_3)_3$ clusters. The increase in the temperature affects noticeably the behaviour of immobilised Ru clusters: they dissociate at $100\text{--}150^\circ\text{C}$ to form crystalline ruthenium. Interestingly, the cluster anion $\text{Ru}_5\text{Cl}_7^{2-}$ cannot penetrate inside the polymeric matrix for steric reasons, and an attempted binding to the PPh_2 group resulted in the dissociation of this anion with eventual formation of immobilised mono- and bi-nuclear complexes. Along with the immobilisation, decarbonylation may occur, which is particularly characteristic of the Fe and Co clusters, apparently because of similar energies of M-M and M-CO bonds (about 113 kJ mol^{-1}). The addition of $\text{Fe}_3(\text{CO})_{12}$ to P-PPh_2 leads to the fragmentation and formation of a monosubstituted complex $\text{P-PPh}_2\text{Fe}(\text{CO})_4$ and traces of $\text{P-(PPh}_2)_2\text{Fe}(\text{CO})_3$.¹⁹⁵ It is noteworthy that the homogeneous reaction of $\text{Fe}_3(\text{CO})_{12}$ with the excess of PPh_3 yields nearly equal quantities of mono- and di-substituted products. Thus, the polymeric ligand brings about definite steric control. Subsequent thermal or photochemical impacts result in the decomposition of mononuclear carbonyl complexes with the formation of 'ligand-free' clusters dispersed in the polymer.

Of other phosphorus-containing polymers used for the immobilisation purposes, the most interesting seems to be the macro-ligand modified by optically active groups of 2,3-isopropylenedioxy-1,4-bis(diphenylphosphino)butane on which the cluster fragments of $\text{Ir}_4(\text{CO})_{12}$ may be immobilised.²¹⁹

The distribution of functional groups and clusters that are formed over the bulk of the polymer is of principal significance, since the homogeneity of dispersion is a sign of the isotropy of the polymeric material. In this context, scanning electron microscopy was used to study the distribution of P and Pd along the diameter of the spherical granules of immobilised three-nuclear Pd clusters (Fig. 6).²²⁰ The immobilisation may be performed in such a way so as to allow either uniform distribution of metal clusters along the diameter of the granule (2% of cross-links) or their preferential localisation in a thin subsuperficial layer (20% of cross-links) 0.2 mm thick, the diameter of the granule being 1 mm . The phosphorus-containing groups are distributed uniformly over the entire thickness of granules. The structure of the polymer-

Figure 6. Distribution of palladium (1) and phosphorus (2) as a function of granule diameter in the palladium-immobilised phosphorylated polystyrene with the cross-linking degree of 2% (a) and 20% (b).

immobilised clusters depends on the $[\text{P}]:[\text{Pd}]$ ratio. In the case of polymers with 2% of cross-links and $[\text{P}]:[\text{Pd}] < 1$, the structure may be schematically presented in the following form:

However, one can hardly imagine, at least for steric reasons, the structures that would be formed at $[\text{P}]:[\text{Pd}] > 1$:

Data on the immobilisation of clusters by polymers with other functional groups, *e.g.*, nitrogen-containing (aminated PS, P4-VPy, amino-containing ion-exchange resins of Amberlyst A-21 type, *etc.*) are more scarce. Carbonyls $\text{Rh}_6(\text{CO})_{16}$, $\text{Rh}_4(\text{CO})_{12}$, and $\text{Rh}_2(\text{CO})_4\text{Cl}_2$ interact with aminated PS resulting in $\text{P-CH}_2\text{NMe}_2\text{HRh}_x(\text{CO})_y$ compounds.²²¹ The product of the Os_3 cluster binding by this ligand has the composition $\text{HOs}_3(\text{CO})_{11}\text{N}^+\text{Et}_2\text{CH}_2\text{CH}_2\text{-P}$.²²² Similarly $\text{Ru}_3(\text{CO})_{12}$ is bound to macroporous chelating polymers functionalised with dipyriddy, 2-aminopropyl, 2-aminophenyl, and other groups. An anionic trinuclear iron cluster is immobilised through the NR_4^+ group on a $10\text{ }\mu\text{m}$ -thick ion-exchange membrane. $[\text{Pt}_{15}(\text{CO})_{30}]^{2-}$ cluster is bound by the hydrophilic polymer QAE-Sephadex containing diethyl(2-hydroxypropyl)aminoethyl groups.²²³

The interaction of metal clusters with the amino-containing macroligands, contrary to that with the phosphorus-containing macroligands, yields a large number of by-products, especially when the polymer carries the primary and secondary amino groups. For example, the reactions involving carbonyl clusters of ruthenium and osmium lead to the activation of α - and β -C-H bonds, *trans*-alkylation (at $25\text{--}45^\circ\text{C}$), and even the cleavage of C-N bonds (at $125\text{--}143^\circ\text{C}$). The latter refers also to the interaction of tertiary amines with Os_3 clusters.

The mechanism underlying the binding of $\text{Rh}_4(\text{CO})_{12}$ clusters by the 4-VPy macromolecules is not completely clear. The interaction of $\text{Os}_3(\text{CO})_{12}$ with 4-VPy is carried out in DMF under CO for 3 h at 110°C .²¹⁰ The structure of the product is difficult to interpret: the IR spectrum reveals two intense absorption bands with maxima at 2040 and 1940 cm^{-1} . These data in combination with those from ^1H NMR (Table 3) allowed an inference that the cluster fixation involves two pyridine rings of the polymer of which one is chelating. This mode of binding becomes possible owing to the flexibility of the polymeric chain.

Note also that the preservation of the polynuclear structure or its disintegration depend also on the nature of the proper ligand groups of the cluster. As a rule, the contribution to the cluster energetics from the ligand environment is rather large and diminishes as the nuclearity increases.²¹ In the binding of the acetate complex $[\text{Rh}_2(\text{OCOCH}_3)_4]$ by polymers containing 3(5)-methylpyrazole or imidazole groups,²²⁴ the binuclear structure is preserved and the rhodium retains its oxidation state $2+$, whereas

in its binuclear complexes with acetonitrile, sulfate, and hexafluoroacetylacetonate the cleavage of the Rh–Rh bond occurs with the increase in Rh oxidation state. Thus, the cleavage of the Rh–Rh bond is favoured by the labile ligands which can be substituted by the amino groups, while in the case of binuclear Rh^{2+} complex the contracting action of bridging acetate groups favours the preservation of the initial structure.

The O- and S-containing matrices, including polymeric alcohols and ketones, are less often used for the immobilisation of clusters. The binding of an Os_3 cluster to polymeric alcohols follows, as in the case of inorganic oxides, the mechanism of oxidative addition:²²⁵

High stability is characteristic of di- and tri-nuclear Ru complexes of the type $\text{Ru}^{3+}-\text{O}-\text{Ru}^{4+}-\text{O}-\text{Ru}^{3+}$, that are readily bound by the ion-exchange resin CR-10 containing iminodiacetate groups.²²⁶

Metal clusters can also be immobilised on natural cyclodextrins.²²⁷ The cavity of γ -cyclodextrin, in contrast to that α - and β -cyclodextrins, is large enough to accommodate not only metal ions but also bi-, tri-, and even tetra-nuclear clusters (Fig. 7). It is significant that the incorporation of clusters into the γ -cyclodextrin cavities increases considerably their stability. For instance, the tetranuclear Co cluster dissociates at 393 K, whereas the product of its interaction with γ -cyclodextrin disintegrates only above 473 K.

Formally polynuclear formations, such as 12-heteropolyacid of Keggin type $\text{H}_n[\text{XM}_{12}\text{O}_{40}]$, where X stands for heteroatom and $\text{M} = \text{Mo}$ or W , can also be immobilised on polymers. When they are stirred with 4-VPy at 30–35 °C, a product is formed in which,

Figure 7. Supposed structure of an inclusion compound formed by a cluster complex of Co and γ -cyclodextrin.

according to IR spectroscopy and chemical analysis data, one $\text{H}_4[\text{SiMo}_{12}\text{O}_{40}] \cdot 13\text{H}_2\text{O}$ molecule binds four protonated vinylpyridine units, and $\text{H}_3[\text{PMo}_{12}\text{O}_{40}]$ binds three such units.²²⁸ The repeating units in the structures formed have the formulae $(\text{H}_4\text{-VPy})_4[\text{SiMo}_{12}\text{O}_{40}]$ and $(\text{H}_4\text{-VPy})_3[\text{PMo}_{12}\text{O}_{40}]$. The same type of binding is observed in the immobilisation of 12-heteropoly acids on water-soluble polyelectrolytes, viz., alkylated poly-(2-methylvinylpyridine), and poly(dimethyldiallylammonium) chloride:²²⁰ the negative charge of the heteropolyanion is compensated by positive charges of the polymeric chain.

2. Polymer-immobilised heteropolymetallic compounds

It is known that the heterometallic polynuclear centre is preferred to the monometallic one in the solution of numerous problems, in particular, in the field of catalysis. Immobilised particles of this type may be regarded as models of bimetallic catalysts that find industrial use for the reforming of petroleum fractions. However, in contrast to the industrial alloy-based catalysts, the bimetallic clusters are structurally homogeneous.

The binding of heterometallic clusters and the identification of the products may be based, as a rule, on much the same approaches as those used for the immobilisation of monometallic clusters. Usually, they are assembled from monometallic complexes or clusters (for example, through the joint decomposition of $\text{H}_2\text{PtCl}_6 - \text{Fe}(\text{NO}_3)_2$ or $\text{Rh}_4(\text{CO})_{12} - \text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ mixtures in polymers). There are strong grounds for stating that bimetallic clusters are formed in colloidal dispersions of Pt and Pd stabilised by PVPr^{159–161} at the initial molar ratio $[\text{Pd}]:[\text{Pt}] = 4:1$. In some instances, the preparation of required products is based not on the monomeric clusters but rather on the cluster compounds with different metals. Thus ion-exchange resins were brought into reaction with mixtures of $\text{Rh}_4(\text{CO})_{12}$ and $\text{Co}_4(\text{CO})_{12}$ in the molar ratio from 3:1 to 1:1.²¹⁹

In the immobilisation, the preference is given to the heterometallic clusters with identified structures.[‡] In most cases, the matrix is formed by $\textcircled{\text{P}}-\text{PPh}_2$, and the immobilisation is performed by means of ligand or ion exchange. A reliable technique for the identification of the structure of the polymer-bound products is comparison of the IR spectra of their carbonyl groups

[‡] The number of known compounds in which one molecule contains several metal species exceeds 100. The common principle of their synthesis consists in the substitution of one metal by another in high-symmetry metallopolyhedrons with the preservation of the total number of cluster valent electrons and the type of ligands. The most common are the heterodi-, heterotri-, and heterotetra-metallic clusters obtained by addition, substitution, elimination, and restructuring. Their stability is enhanced by centring with μ_3 -bridges consisting of elements of the main subgroups (specifically, C, S, P). The common aspects of the synthesis of these compounds, their structure, and classification based on the topology–geometry principle have been reviewed.²²⁹

Scheme 10

with the spectra of low-molecular-weight models. Typical examples of the immobilisation of intact heterometallic clusters on P-PPh_2 are shown in Scheme 10.^{3, 207, 214, 230, 231}

Also worthy of note is the binding of $\text{H}_2\text{FeOs}_3(\text{CO})_{13}$ by cross-linked macroporous chelating polymers.²³² There are reports of the immobilisation of $\text{Co}_2\text{Rh}_2(\text{CO})_{12}$ on Dowex-1 ion-exchange resin,²³³ as well as of $\text{H}_2\text{FeRu}_3(\text{CO})_{13}$, $[\text{FeRh}_4(\text{CO})_{15}](\text{NMe}_4)_2$, and $\text{Rh}_{4-x}\text{Co}_x(\text{CO})_{12}$ ($x = 2, 3$) on different macroligands. The mechanisms of these reactions remain obscure.

The binding of bimetallic Keggin heteropolyacids, *e.g.*, $\text{H}_6[\text{CoW}_{12}\text{O}_{40}]$,²²⁸ to P4-VPy is analogous to that of monometallic ones. The repeating units have the composition $(\text{H}_4\text{-VPy})_4\text{H}_2[\text{CoW}_{12}\text{O}_{40}]$. In principle, similar processes can occur with polyoxoanions of niobium-containing polytungstates, such as $[(\text{CO})_2\text{Rh}]_5[\text{Nb}_2\text{W}_4\text{O}_{19}]_2^{3-}$, $[(\text{CO})_2\text{Ir}]_2\text{H}[\text{Nb}_2\text{W}_4\text{O}_{19}]_2^{5-}$ and others.²³⁴

The compounds mentioned above are formally of the trimetallic type. The trimetallic clusters bound with P-PPh_2 are obtained by the assembly method, *i.e.*, through the interaction of a polymer with MPPH_3Cl ($\text{M} = \text{Cu}$ or Au) and subsequent treatment of the product with the tetranuclear bimetallic cluster $\text{FeCo}_3(\text{CO})_{12}$.²⁰⁸ The cluster thus obtained has the following structure:

The general strategy for the preparation of heterometallic clusters possessing high nuclearity may be described by Scheme 11.

Scheme 11

Most probably, the reaction involves the formation of heterometallic rings. The trimetallic units of type A serve as building blocks in the chemistry of clusters.²³⁵

The polymer-immobilised clusters of polymetallic type are more stable than the initial ones: the decomposition temperature of the cluster $(\text{PPh}_3)\text{CuFeCo}_3(\text{CO})_{12}$ is 170–178 °C, while its polymeric analogue dissociates at 186–193 °C. The clusters based on gold are always less stable than the copper-containing ones (the dissociation temperatures of the initial and fixed gold clusters are 163–165 and 171–176 °C, respectively). In general, the immobilisation increases the thermal stability of both the cluster and the binding polymer. Heterometallic clusters are also often immobilised on the surface of inorganic polymers. For instance, worthy of note is the fixation of $[\text{Fe}_6\text{C}(\text{CO})_{16}](\text{Et}_4\text{N})_2\text{HFeCo}_3(\text{CO})_{12}$, $[\text{Rh}_5\text{Fe}(\text{CO})_{16}](\text{Et}_4\text{N})$, $[\text{RhFe}_5\text{C}(\text{CO})_{16}](\text{Et}_4\text{N})$ and other clusters on SiO_2 .²³⁶ According to the data from IR spectroscopy, the clusters do not undergo any changes in this case, except for the cluster based on RhFe_5 that reacts vigorously with SiO_2 . The attempts to bind the clusters $\text{H}_2\text{FeRu}_3(\text{CO})_3$ and $\text{Fe}_2\text{Pt}(\text{CO})_8(\text{PPh}_3)$ with phosphorylated silica gel were unsuccessful.²³¹ A number of bimetallic clusters were encapsulated in channels of zeolites, while the clusters $\text{Rh}_{4-x}\text{Co}_x(\text{CO})_{12}$ ($x = 2, 3$) were immobilised by deposition on carbon.^{237–239}

The method of ‘layering’ was used for the binding of Prussian blue and its analogues with polyvinylamine hydrochloride: salts of the type MCl_2 ($\text{M} = \text{Fe}, \text{Co},$ and Cu) bound with ions $[\text{Fe}(\text{CN})_6]^{n-}$ ($n = 3$ or 4) were fixed on a polymer in aqueous solutions.²⁴⁰ The logarithms of the formation constants of binuclear complexes from mononuclear immobilised complexes of Fe, Co, and Cu are 9.8, 7.7, and 10.4 in litre mol^{-1} units, respectively. Although the degrees of freedom of the polymeric chain and the cluster decrease upon formation of polynuclear complexes, the ΔS value remains positive, which is indicative of the entropy increase, apparently due to the release of several molecules of water bound initially to M^{2+} and $[\text{Fe}(\text{CN})_6]^{n-}$.

One can conclude that the studies on the immobilisation of heterometallic clusters are making rapid progress, although this research area has still numerous problems related mainly to the mechanism underlying the interaction of clusters and functional groups of polymers, transformations of immobilised reactants, and the structure of final products.

3. Polymerisation and copolymerisation of cluster-containing monomers as a route to the production of polymer-immobilised metaloclusters

By analogy with the formation of nanoparticles by means of polymerisation of appropriate monomeric mixtures (simultaneous formation of the matrix and nanoparticles, see Section IV), it could be expected that the polymerisation and copolymerisation of cluster-containing monomers are very simple one-step methods for the preparation of cluster-containing polymers. It was presumed that the major problem would be the synthesis of the appropriate monomers.

Recently, two promising approaches have been developed for the synthesis of cluster-containing monomers.^{241, 242} According to the first approach, the groups capable of polymerisation are introduced as ligands into the known clusters. To this end, recourse is made to the replacement of the intrinsic ligands of clusters by their analogues carrying multiple bonds, oxidative binding, addition of new groups on multiple $\text{M}-\text{M}$ bonds under mild conditions, *etc.* These reactions may lead to a higher or lower nuclearity of clusters. The reaction of $\text{Ru}_3(\text{CO})_{12}$ with dimethyl fumarate in boiling heptane results in the formation of complexes with different nuclearity, their relative yields being dependent on the ratio of reagents and the duration of the reaction.²⁴³

The second approach consisting in the build-up of conventional monomers with clusters is not as popular as the former. A characteristic example of this approach is the preparation of cluster monomers based on methyl *p*-vinylthiobenzoate (Scheme 12).^{244, 245}

Scheme 12

Although these reactions are complicated by a number of side processes (desulfurisation, formation of metal sulfides and products of ortho-metallation, *etc.*) not allowing the achievement of yields of target products above 40%, it is essential that the cluster skeletons are preserved, and the monomers formed can undergo polymerisation.

Scheme 13

An example of a more convenient route to the synthesis of this class of potential monomers is the reaction of tricobaltalkylidene complexes $\text{Co}_3(\mu_3\text{-CR})(\text{CO})_9$ with vinylphosphine ligands in heptane at 308 K. This allowed the isolation and characterisation of $\text{Co}_3(\mu_3\text{-CR})(\text{CO})_{9-x}(\text{PPh}_2\text{CH}=\text{CH}_2)_x$ ($x = 1, 2, 3$).²⁴⁶ When the product with $x = 1$ is heated to 343 K, it eliminates CO groups (Scheme 13), and an additional coordination of vinyl groups with Co atom occurs.

High yields of cluster-containing monomers were obtained from trinuclear clusters $\text{M}_3(\text{CO})_{12}$ ($\text{M} = \text{Os}, \text{Ru}$), $\text{Os}_3(\text{CO})_{11}(\text{-MeCN})$, $\text{Os}_3(\text{CO})_{10}(\text{MeCN})_2$, and $(\mu\text{-H})\text{Os}_3(\text{CO})_{10}$. $(\mu\text{-OR})$ ($\text{R} = \text{H}, \text{Rh}$), and conventional monomers (4-VPy, acrylic acid (AA), allylamine (AAM), allyl sulfide (AS), *etc.*):²⁰⁹

Interestingly, like in the above-considered system obtained by the immobilisation of $\text{Os}_3(\text{CO})_{12}$ on P-4-VPy , the pyridine ring in the monomer based on 4-VPy was chelated. The complex $\text{Os}_3(\text{CO})_{10}(\text{MeCN})_2$ reacts rapidly with 2VPy to form a trinuclear cluster $\text{HOs}_3(\text{CO})_9\text{L}(2\text{VPy})$ ($\text{L} = \text{CO}$ or PMe_2Ph). The preparation of a triosmium alkylidene cluster $\text{H}_2\text{Os}_3(\text{CO})_9[\mu_3\text{-(2VPy)}]$, which may be used as the starting material for the preparation of planar hexaosmium carbonyl cluster with an open structure, has been described.²⁴⁷

The reaction of 4-VPy with $\text{Rh}_6(\text{CO})_{16}$ in the presence of acetonitrile or trimethylamine *N*-oxide occurs under mild conditions and yields a monosubstituted derivative $\text{Rh}_6(\text{CO})_{15}(4\text{-VPy})$ as the major product and a small amount of $\text{Rh}_6(\text{CO})_{14}(4\text{-VPy})_2$, which can be easily isolated in a pure state by chromatography.²¹¹ Contrary to the osmium derivative, the monomer $\text{Rh}_6(\text{CO})_{15}(4\text{-VPy})$ is an octahedral cluster with 11 terminal and 4 μ_3 -bridging carbonyl ligands, and the vinylpyridine moiety is linked with the rhodium atom only through the nitrogen atom and

occupies the coordination position of the twelfth terminal CO. The mean length of the Rh–Rh bond is 0.2762 nm, which is close to that in other Rh clusters. Apparently, this mechanism also operates in the reaction of Rh clusters with the allylic ligand $\text{Ph}_2\text{PCHCH}=\text{CH}_2$.²⁴⁸

The metallomonomers considered above incorporate only carbonyl clusters, though the solution of numerous problems requires monomers and polymers that contain other type of clusters, *e.g.*, halogenated ones.

Mo(II) halides, which readily form polynuclear complexes (of $\text{Mo}_6\text{Cl}_{12}$ type) owing to a strong trend of divalent molybdenum to association, are highly promising.²⁴⁹ Of special interest are the complexes with a stable group $[\text{Mo}_6\text{Cl}_8]^{4+}$, which is named a staphylonuclear group (Fig. 8). This group includes an octahedron with six molybdenum atoms surrounded by eight chlorine atoms localised in the apices of a slightly distorted cube. The octahedron is inscribed into the cube so that the Mo(II) atoms are localised at the centres of facets. It is this circumstance that provides for the existence of six equivalent directions (normals) along which the effect of shielding of molybdenum atoms by chlorine atoms is minimal. The diameter of this cluster may be estimated at ~ 1 nm (as the sum of a cube diagonal Cl–Cl equal to 0.6 nm and the radii of two chlorine atoms, each being 0.18 nm). The stable staphylogroup plays the crucial role in the complexation reactions.^{250, 251} It can bind up to six axial ligands, negative ions or polar molecules, including those containing multiple bonds thus making possible polymerisation of monomers. For the first time, vinylimidazole and vinylpyrrolidone were used as ligands.^{252, 253} In principle, conventional vinylic monomers, *e.g.*, 4-VPy, acrylonitrile, acrylamide, *etc.*, can serve as these ligands.²⁵⁴

Figure 8. Structure of the staphylonuclear group $[\text{Mo}_6\text{Cl}_8]^{4+}$.

The methods of the synthesis and polymerisation of cluster-containing monomers are still in their infancy, though a breakthrough in this direction may be expected in the near future. For example, there are no essential restrictions on the application of the above-considered method of vaporisation of atomic metals to this end (see Section IV).

Recently, cryosynthesis involving atomic chromium and phenylacetylene as reagents has yielded Cr-containing polymeric products along with cyclotrimers of phenylacetylene.²⁵⁵ The condensation of vapour of gold with large excess of a diacetylene monomer has been recently accomplished.⁶⁷

These methods apply equally to the creation of monomers based on heteropolynuclear clusters. One possible way consists in the introduction of groups with multiple bonds into heterometallic complexes. For example, treatment of the iron–ruthenium complex $[\text{FeRu}(\text{CO})_4(\eta^5\text{-C}_5\text{H}_5)_2]$ with olefins yields μ -vinylic complexes ($\text{R} = \text{H}, \text{Ph}$) with Fe–Ru bonds.²⁵⁶

In these complexes, the atoms of Fe and Ru are linked with alkenes through the σ - and π -bonds, respectively. The reactivity of bimetallic complexes as regards transformations of unsaturated hydrocarbons is close to that of homonuclear ones and decreases in the series $\text{FeRu} > \text{Fe}_2 > \text{Ru}_2$. The group of potential heterometallic monomers may be extended to include $\text{FeCo}(\text{CO})_7$, $(\mu\text{-CH}=\text{CHR})$,²⁵⁷ bimetallic η^2 -complexes of Mo, V, or Fe with formaldehyde bridging,²⁵⁸ and a number of other compounds (for example, AuPt_2 -based clusters).²⁵⁹ The acetylenide cluster of Pt_2Cu_4 (**2**) was prepared by treatment of 1,1'-[chloro(η^4 -cyclooctadiene)platino]ferrocene (**1**) with an excess of phenylacetylene and CuI (Scheme 14). The same product is obtained from [phenylethynyl(η^4 -cyclooctadiene)platino]ferrocene (**5**). The bis-substituted ferrocene **3** gives the cluster **4** (Scheme 14, Fig. 9). The Pt–Cu bond length is 0.2845–0.2975 nm.

Figure 9. Molecular structure of the complex **4** (the hydrogen atoms are not shown).

One may also consider the monomers comprising atoms of the same metal in different valent states, *e.g.*, FeCl_2 , $(\text{FeCl}_3)_2(\text{CH}_2=\text{CHCN})_6$, as heterometallic ones.²⁶¹

Numerous attempts to polymerise cluster monomers²⁶² have always faced insurmountable problems associated with the presence of such bulky substituents as cluster fragments possessing specific electronic structures, with the reaction of the initiating radicals or ions with cluster-containing monomers leading to their degradation, *etc.* These complications rule virtually out the possibility of homopolymerisation of these exotic metallomonomers. The most successful proved to be the attempt to copolymerise monomers derived from dicobalt octacarbonyl or diiron nonacarbonyl and dithioesters (Scheme 12) or thioamides with styrene or *N*-[tris(hydroxymethyl)methyl]acrylamide. This copolymerisation has led to the products containing up to 1 mol.%–2 mol.% of units with intact cluster framework (Table 4). The copolymers produced possessed large molecular weights.

Scheme 14

Special studies on styrene polymerisation in the presence of $\text{Os}_3(\text{CO})_{12}$ and $(\mu\text{-H})\text{Os}_3(\mu\text{-4-VPy})(\text{CO})_{10}$ have shown²⁶³ that the starting cluster $\text{Os}_3(\text{CO})_{12}$ has no influence on either the rates of the initiator degradation and styrene polymerisation or the molecular-weight parameters of the PS produced. The homopolymerisation of $(\mu\text{-H})\text{Os}_3(\mu\text{-4-VPy})(\text{CO})_{10}$ proceeded with difficulty: an oligomer with 5–6 units in the chain was obtained with a yield of 1%–2% in benzene at 70 °C in the presence of 2,2'-azobis(isobutyronitrile) as an initiator. The copolymerisation of $(\mu\text{-H})\text{Os}_3(\mu\text{-4-VPy})(\text{CO})_{10}$ with styrene or acrylonitrile under the same conditions resulted in the incorporation of up to 3% of cluster units into the polymeric chain without noticeable changes in the structure of these clusters. The IR spectra of the cluster

carbonyls are virtually indistinguishable from the spectra of the corresponding initial monomers (Table 3), though some minor changes in the intensity and widening of individual absorption bands may still be revealed. Apparently, the conjugation of the double bond in $(\mu\text{-H})\text{Os}_3(\mu\text{-4-VPy})(\text{CO})_{10}$ leads to the redistribution of the electron density in the Os–Os bonds and the decrease in their length. In the polymer, this conjugation disappears, and the photoelectron spectra of the framework become close to those of the unsubstituted cluster $\text{Os}_3(\text{CO})_{12}$. Kinetic studies showed that each polymeric chain ($\overline{M}_n = 5\text{--}37$ kDa) contained, on the average, one cluster unit and one terminal double bond.²⁶³ This implies that the binding of the Os_3 -containing monomer to the growing macroradical inhibits the chain growth (Scheme 15). This

Scheme 15

does not however lead to the decrease in the concentration of active species owing to the fast transfer in the chain.

The role of chain transmitters may be played by both styrene and comonomer containing Os_3 ; however, as in the case of homopolymerisation, the steric hindrances impose certain restrictions on the chain transfer reaction onto the cluster monomer. Therefore, the role of this reaction is insignificant. It is most probably that the chain transfer is realised only *via* styrene. The analysis of the molecular mass characteristics allowed the estimation of the constant of the growing radical interaction with the double bond of the cluster monomer.²⁶⁴ The lower limit of this parameter is within the range of 40 to 300 litre $\text{mol}^{-1} \text{s}^{-1}$. Similar features were revealed for the copolymerisation of Os_3 -containing monomer with acrylonitrile.

The copolymerisation of $\text{Rh}_6(\text{CO})_{15}(4\text{-VPy})$ with styrene in toluene occurs much easier,²⁶⁵ and the content of the cluster monomer may be as high as 10%. This seems to be due to the fact that 4-VPy is linked to the cluster framework only by a donor-acceptor bond.

It may be assumed that the size of the metal-containing cluster particles is not much larger than that of the initial clusters, especially at their low levels in copolymers since the polymeric segment formed from the comonomer is a stabilising factor preventing associative processes. This view is supported by the direct evidence provided recently from a study²⁵³ of the radical block copolymerisation of staphylnuclear monomers in solubilising monomeric media with $[\text{Mo}_6\text{Cl}_6(\text{N-VI})_6](\text{CF}_3\text{COO})_4$, where N-VI is *N*-vinylimidazole. *N*-Vinylimidazole acts simultaneously as a solvent for the cluster monomer (at 0.1 and 0.5 M) and as a comonomer. At 70 °C, fast homogeneous copolymerisation took place with subsequent cross-linking and thickening of the reaction medium, which contained the chemically bound monodispersed clusters at a relatively high concentration. The sizes of the polymer-immobilised staphylnuclear and the initial clusters were close and amounted ~ 1 nm. Apparently, one should agree with the view of Golden *et al.*^{252,253} who believe that the use of monomers as solvents may become a common practice in the preparation of polymer-immobilised monodispersed metaloclusters.

The incorporation even of small quantities of cluster monomers into a copolymeric chain improves the parameters characterising the resistance to destruction of both the metalocluster itself and the polymer. For example, the Os_3 -copolymers manifest mutual stabilisation of PS and PS-bound clusters.²⁶⁶ The decarbonylation of clusters begins at ~ 200 °C, while the decarbonylation temperature of copolymers is higher by ca. 150 °C. The thermal resistance of clusters is increased only when they are bound with a polymeric chain, while in mechanical mixtures this effect is absent. One of the major reasons for this phenomenon may be the transfer of energy at increased temperatures from the rotational-vibrational degrees of freedom of the cluster to the translational degree of freedom of the polymeric chain segments. The decomposition temperature of the polymers comprising metaloclusters is in turn increased by 50–60 °C, while the effective activation energy of thermal destruction is increased by 40–60 kJ mol^{-1} . The vitrification temperatures of polyvinylimidazole and of its copolymers with an imidazole staphylnuclear cluster at concentrations of 0.1 and 0.5 M are 164, 220, and 257 °C, respectively.²⁵³

Despite the sparse character of the data on the polymer-immobilised clusters prepared *in situ*, the recent progress in this direction promises the obtaining of new data and their systematisation.

The above statements referred to the preparation of polymer-immobilised clusters by polymerisation. There are no principal obstacles preventing the use of polycondensation reactions for this purpose. In all cases, the principal difficulty resides in the synthesis of appropriate metallomonomers with bi- or poly-functional ligands. The role of such ligands may be played by the groups capable of binding active hydrogen from diols, diamines, and other compounds.

The high diversity of reactions of substitution or exchange between the functional groups of reagents makes this approach rather promising. The synthesis of these polymer-immobilised clusters may also rely on the use of cluster-containing compounds with the ligands comprising epoxy or other (*e.g.*, ethyleneimine) cycles, isocyanate groups (*p*-phenylenediisocyanate, 2,4-toluylene-diisocyanate), *etc.*⁸ This method allows the preparation of cluster-containing polyurethanes, polyamides, polyesters, and polyepoxy compounds.

Naturally, the controlled pyrolysis of polymer-immobilised clusters yields highly dispersed metal powders, while the pyrolysis of heteronuclear polymer-immobilised clusters may potentially be a suitable technique for producing nanometre-sized powder alloys (similarly to the pyrolysis of initial $\text{HFeCo}_3(\text{CO})_{12}$, $[\text{Co}(\text{MeCO-Me})_6][\text{FeCo}_3(\text{CO})_{12}]$,²⁶⁸ *etc.*). One should not rule out that this approach may be beneficial in the development of the solid-phase method for reducing metal oxides (it is known²⁶⁹ that if the contact between reagents is close, the reduction of Ag_2O in graphite is realised at temperatures as low as 100–200 °C). The incorporation of Pt clusters into a glass-carbon matrix was carried out by immobilisation of mononuclear complexes of (ethylene)-bis(triphenylphosphine)platinum(0) on the triple bonds on poly(phenylenediacetylene) oligomer.²⁷⁰ On heating to 600 °C, the toluene-soluble complex of composition 1:4 or 1:2 yields a Pt-enriched glass-carbon in the form of thin films with a narrow distribution of Pt clusters with a mean diameter of 1.6 nm. The structure of these clusters is shown in Fig. 10. Interestingly, the non-immobilised complexes form large Pt particles 600 nm in diameter. The ceramics of general formula $\text{M}_x\text{Si}_y\text{C}_z$ ($\text{M} = \text{Fe}, \text{Co}$) are produced by the pyrolysis of cluster-containing diacetylene oligomers at 1350 °C.²⁷¹

VI. Nanometre-sized particles, clusters, and polynuclear structures immobilised in biopolymers and their analogues

The interaction of metal ions and nanoparticles with biopolymers and cells plays a highly significant role in the enzymatic catalysis, geobiotechnology, and bihydrometallurgy. Of practical interest for the geomicrobiological transformation of heavy metals are natural and genetic-engineering microorganisms the vital activity of which occurs under extreme conditions (high temperature and pressure, highly acidic or basic media, strong salinity, the presence of metals at levels toxic for common microorganisms). By analogy with thermophiles, halophiles, acidophiles, *etc.*, a group of microorganisms is named metallophiles.^{272–276}

§ Recently, platinum – gold phosphine clusters with isonitrile ligands of the type $[\text{Pt}(\text{RNC})(\text{AuPPh}_3)_8]^{2+}$, $[\text{Pt}(\text{CO})(\text{AuRNC})(\text{AuPPh}_3)_7]^{2+}$ have been synthesised.²⁶⁷

It is believed²⁷² that the extent of selective metallophilicity of microorganisms is determined by a number of factors: the selective direction of motion of the colloidal particles relative to microorganisms, the nature of chemical fixation of particles on the surface and its strength, *etc.* Among the bonds formed, the covalent ones are predominant.

A consequence of selective metallophilicity is a genetically predetermined specialisation of microorganisms for the interaction with definite metals. This results in the appearance under natural conditions of a rigorously determined system including a cell of definite species and a metal (or a group of related metals).²⁷² Flocculation of cells by colloidal metal particles leads to the formation of rather large (up to 50–60 μm) bioskeletal aggregates undergoing sedimentation in aqueous media. Specific NADH oxidase, the protein capable of incorporation of gold into the active centre, has been isolated and characterised recently. Its molecular weight is 600 000, and it contains three metal atoms per mol of protein.

In addition to bacteria, the binding of metals is effected by yeasts, fungi, numerous algae, and some Protozoa, and this largely extends the potential of biochemical transformation and transfer of metals under natural conditions.

One of the manifestations of the colloidal-chemical binding is the coagulation of metal sols (in particular, the best studied is the gold sol that is characterised by the simplicity of its preparation and a relatively high stability, see above). The heterocoagulation of these sols results in the formation of biopolymer-immobilised nanoparticles or, in other words, mixed aggregates of living microorganisms and nanoparticles. Many of them possess specific properties that are apparently determined by the processes occurring in the diffusion layers of cells and are associated with the electrical heterogeneity of their surface.²⁷⁷ These processes induce the binding of sol particles and simultaneously decrease the threshold of their coagulation due to the increased concentration of counterions. These highly dispersed biogenic aggregates are widely distributed in nature as economically important metal ores, the sole of sedimentogenesis facies,²⁷⁸ *etc.* Furthermore, the very idea of immobilisation of metal complexes on polymers is largely borrowed from natural systems.

1. The pathways of formation of metallobiopolymeric systems

The peculiarities of the interaction of microorganisms with metal sols, as a rule, largely depend on the nature of the metal. In this respect, the best studied systems are the colloids of gold,²⁷⁶ the colloids of other noble metals, as well as those of iron, copper, and manganese have been investigated to a lesser extent. Biosorption is the novel approach to the metal recovery from the dilute solutions. It was shown that microorganisms and algae allow the extraction of up to 100% of lead, mercury, zinc, nickel, cobalt, manganese, chromium, uranium, and some other elements, up to 96%–98% of gold and silver, up to 84% of platinum, 93% of selenium from dilute solutions. It is shown also that bacterial polysaccharides are effective in the recovery of radioactive elements, as well as of copper and cadmium, from solution (Table 5).²⁷⁹

The bacterial concentration of metals is preceded by their adsorption on the cell surface with subsequent assimilation.²⁸⁰ This can be accompanied by enlargement of sol particles (flocculation) and the adsorption and deposition of a coarse metal-bacterial mass (heterocoagulation). Like in the systems based on synthetic polymers, the sol with particle size of ~ 10 nm proves to be the most stable.

An important distinctive feature of the colloid-bacterial interaction is the diversity of the forces involved with mechanisms of electrostatic, molecular, and chemical origin. The preferential adhesion between colloidal particles and associations of bacterial cells is observed at sites of their contact. For example, the coccal bacteria *M. luteus* with the mean size of 2000 nm isolated from an auriferous placer form packages of 4–8 cells that sorb effectively the gold particles (up to 10 mg of Au per 1 g wet biomass),²⁷⁶ but

Table 5. Sorption of metals by microorganisms.²⁷⁹

Metal sorbed	Microorganisms	Metal content (mg) per 1 g dry cells mass
U, Th	Denitrifying bacteria	140
	<i>Rhizopus arrhizus</i>	180
U	<i>Pseudomonas aeruginosa</i>	≤ 560
	<i>Saccharomyces cerevisiae</i> ,	100–150
	<i>Pseudomonas aeruginosa</i>	
	Biosorbent M (<i>Penicillium chrysogenum</i>)	80–120 (purification of waters containing < 0.05 mg litre ⁻¹ of elements)
Ag	Bacterial community of <i>Ps. maltophilia</i> , <i>Staphylococcus aureus</i> and unidentified forms	≤ 300

do not induce heterocoagulation; in this situation, one cell binds, on the average, 10^4 colloidal gold particles.

At least in the initial stages, the interaction is reduced to the electrostatic binding, and it is this fact that explains the reversibility of heterocoagulation:²⁸⁰ after the introduction of the protonophore into the incubation medium, the dispersed metal particles are released from the cell surface. In general, there are two routes for the realisation of this process. In cell associates, further concentration of particles occurs at the sites of their contact, which is accompanied by their enlargement. In single cells, the increase in the particle size is not preceded by aggregation: the particles formed in the process of concentration are gradually rejected by the cell surface.

Most probably, the electrostatic and chemisorptional attachment of colloidal particles of metals and their compounds to the cell surface occurs mainly due to the products of its metabolism including such functional groups as $-\text{S}-$, $-\text{COO}^-$, $\text{PO}(\text{OH})\text{O}^-$, $-\text{NH}_3^+$. It is significant that, in contrast to positively charged proteins (trypsin, papain, lysozyme, RNase),²⁸¹ the negatively charged proteins (human serum albumin, soybean trypsin inhibitor) do not cause flocculation of gold particles. Lysozyme manifests special properties: the flocculation of sol on it occurs in a narrow range of enzyme concentrations ($1-10$ $\mu\text{g ml}^{-1}$), while its higher levels stabilise the sol and enhance the aggregational stability of the system, on the whole. The occurrence of consecutive stages of flocculation and stabilisation of metal colloids with the increasing concentration is also characteristic of certain synthetic polymers, such as polyethyleneimine and non-ionogenic polyethyleneoxide.

Let us note some differences in the behaviour of proteins and synthetic polymers. First, proteins differ in their selectivity towards different dispersed phases in the course of flocculation which is determined not only by electrostatic factors but also by specific binding of these phases by functional groups of amino acid residues, especially by the sulfhydryl and amino groups.²⁸² In particular, the addition of *p*-chloromercuribenzoate, which specifically blocks the SH groups of proteins, was found to decrease their flocculating activity. Second, the native structure of the biopolymer is of prime importance for the sorptional processes to occur. For example, partial destruction of the polysaccharide skeleton of bacterial cell walls (by lysozyme) reduces considerably their sorptional ability.

The cells of monoculture tissues (*Pseudomonas sp.*, *Bacillus cereus*, *Bacillus sp.*, *Bacillus subtilis*) grown under similar conditions differ significantly in their ability to accumulate metal particles on their surface. The accumulative ability of cells was observed to correlate with the flocculating capacity of preparations isolated from them (Fig. 11).²⁸³

Figure 11. The cell of associate tissue culture in the presence of colloidal gold particles ($\times 35\,000$).²⁸³

There is experimental evidence for the binding of metal particles on the surface of cells by their carbohydrate or glycoprotein structures. A glycoprotein with a molecular weight of ~ 50 kDa providing for the binding of colloidal gold was isolated from different cells (including *B. subtilis*) by extraction with butanol. The specificity of binding of different compounds by this protein decreases in the series $\text{Au} \gg \text{Pt} > \text{MnO}_2 > \text{Al}_2\text{O}_3$.

The liposomes (which are the closest models of biomembranes having no effect on the aggregative stability of gold) modified by this glycoprotein sorb actively particles of metals. Apparently, the glycoprotein is bound with lipids in the bacterial cell wall. As a matter of fact, it is the increased level of glycopospholipids in them and the extended branching of fatty acid residues that determine the ability of the above-mentioned *M. luteus* cells to survive under extreme conditions (at high Au concentration).²⁸⁴

Following the adsorption and heterocoagulation of colloids in biopolymers, the recrystallisation and enlargement of dispersed metal particles occurs on the surface of living cells. These processes result from the occurrence of intense oxidation–reduction of metals. In case of gold, at the first stage, the colloidal gold particles are oxidised possibly by hydrogen peroxide generated by cytochrome C, while the second stage involves the endogenous reduction of gold ions with the participation of the plasma membrane.²⁷⁶ This may occur only at a sufficiently intense ion flux. The cationic $-\text{NH}_3^+$ groups are believed to be responsible for the solubilisation (oxidation) of gold by the *Bacillus subtilis* cells, whereas the anionic carboxyl and phosphoryl groups are responsible for the reduction of complexes of gold with metabolic products.²⁸⁵

Thus, in the system ‘biopolymer–colloidal gold particles’, the latter are redissolved to eventually form larger particles.

The mould fungi are known to reduce gold to its metallic state.²⁸⁶ Sometimes, these transformations also involve humic and fulvic acids. As a result, a specific ‘depot’ of bioelements is formed.²⁸⁷

The surface of bacteria may contain several independent metal binding sites (M). This process is described by the equilibrium

The symbol L designates the binding site on the bacterial surface, while ML stands for the ‘bacterium–sol particle’ complex. The total number of binding sites (n), the quantity of bound metal particles (v), and the association constant $K = [\text{ML}]/[\text{M}][\text{L}]$ may be calculated by the Scatchard equation:²⁸⁸

$$\frac{v}{[L]} = nK - vK.$$

For example, the *M. luteus* cells have two types of independent gold-binding sites:²⁷⁶ in the first type of sites (hydrophilic), the binding occurs as a result of electrostatic interaction ($K_1 = 3.85 \times 10^9$ litre mol⁻¹, $v_1 = 4.7 \times 10^3$), in the second type of

binding sites it goes occurs *via* an oxidative process of the formation of gold complexes ($K_2 = 4.6 \times 10^8$ litre mol⁻¹, $v_2 = 4.3 \times 10^3$).

The model of bacterial concentration and crystallisation is rather complicated. The process may proceed *via* fusion (assimilation) of small (10–20 μm) needle-like crystalline polygons, which bind to each other to form visible gold grains extracted by the gravimetric method. In addition, the colloidal particles may play the role of crystallisation centres as nuclei of a new phase under conditions of continuous cooperative oxidation and reduction of the metal ions formed. Apparently, the transformation of endogenous gold under conditions of placers formation follows the same mechanism.[¶]

The processes of accumulation of heavy metals by cells occupy a special place. It is known that the most important cell components are the low-molecular-weight (5–10 kDa) metal-binding proteins thioneins, rich in SH groups, which accumulate both the metals essential for the cell (Cu, Mn, Fe, Co, Cr, Mo) and unessential ones.[†] The macromolecules of these proteins consist of two separate subunits. Each of them binds metal ions into a polynuclear metal-thiol cluster surrounded by cysteine residues. For example, Cd- and Zn-thioneins contain 7 metal atoms each, of which four are bound with 11 cysteine residues ($\text{M}_4\text{Cys}_{11}$) in a C-terminal A-cluster, while 3 metal atoms are bound with 9 cysteine residues (M_3Cys_9) in the N-terminal B-cluster.²⁹¹ At the same time, Ag and Cu form M_{12} metallothioneins containing 6 metal atoms in each domain.

The biological function of thioneins is, most likely, the storage and detoxification of heavy metals and possibly in the provision of the resistance of microorganisms to them.²⁹² Apparently, the accumulation of metals is associated with intense reduction, localisation, and adhesion on the outer membrane of metal particles formed. During the period of adaptation, the cells can acquire a plasmid of resistance to the metal, and this capacity is realised through the intensification of the reduction of metal ions. Thus, natural selection may result in the formation of metal-tolerant microbial strains.

The analysis of the immobilisation of nanoparticles on biopolymers allows one to note two aspects. First, most of the heavy metals bind simultaneously to several protein macroligands with a specific spatial environment and conformation. Triple complexes may also form, *e.g.*, protein–M–nucleic acid ($\text{M} = \text{Au}, \text{Pt}, \text{Pd}$).²⁹³ Possibly, it is the presence of these formations that provides the anticarcinogenic effect achieved upon introduction of these metals into organisms. Second, heavy metals, *e.g.*, Au(I) react with mixed-metal thioneins (with native Zn-, Cd-, and Co-thioneins) by replacing selectively Zn and even Cd when added in excess. This process is characterised only by minimal changes in the protein conformation.

Metalloclusters play a very important role in the processes of bacterial mineralisation,^{294–296} and their investigation is the subject of a new branch of science called bioinorganic solid-state chemistry. Its topic is the study of the formation and structure of nanoscale materials in biological environment. A characteristic example is the formation of nanoparticles on the base of ferritin (Fig. 12).²⁹⁷ A nanoparticle of Fe_3S_4 is deposited in the inner part of the protein shell as a result of chemical transformations under mild conditions. The process is still more simplified when a ‘metal-free’ apoferritin is used for this purpose. For example, the biopolymer-immobilised Mn^{3+} oxides 8 nm in diameter are obtained upon oxidation Mn^{2+} to Mn^{3+} . This route is also effective for the preparation of nanoscale biomaterials based on Ag_2O and especially of calcium phosphates ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, $\text{Ca}_8\text{H}_2(\text{PO}_4)_6$, *etc.*) which are important components of osseous

¶ The solubilisation, deposition, and formation of new layers of gold on the surface of initial grains is characteristic of the entire history of hypergenic native gold.²⁸⁹

† Deposits of iron and manganese, which are highly important for functions of living organisms are mostly of biogenic origin.

Figure 12. Synthesis of nanophase materials based on ferritin: (a) Fe_3S_4 ; (b) Mn_2O_3 ; (c) Fe_3O_4 .

tissues. Special attention should be given to the intraferritin formation of *in situ* deposits of Fe_3O_4 with definite crystallochemical characteristics.²⁹⁸ This leads to the formation of ferromagnetic proteins,[‡] which are used to prepare magnetic images for clinical purposes. The complexity and precision of such bioinorganic reactions require strict ordering of the particles formed with regard to their size and morphology which are difficult to achieve under laboratory conditions.

Some heterometallic clusters of ferredoxin with the composition $[\text{MFe}_3\text{S}_4]$, where $\text{M} = \text{Zn}, \text{Co}, \text{Mn}$, are known. They are present, in particular, in the *Pyrococcus furiosus* cells. It is believed²⁹⁵ that bacterial methods may be effective in the preparation of finely dispersed precursors of superconducting high-temperature ceramics and other materials.

Metalloprotein preparations are quite often used in medicine to regulate the enzyme activity and to devise new drugs of narrow targeted action.³⁰⁰ Colloidal compounds of calcium and magnesium with plant proteins are employed for the regulation of gastric juice acidity, a finely dispersed Fe_3O_4 complex with serum albumin is administered intravenously as a contrasting compound for X-ray studies, *etc.* Colloidal gold and its biopreparations have been used since ancient times as medicaments, many of them are known to be effective antiarthritis drugs. Colloidal gold is widely used in immunochemical studies as an electron-dense cytochemical marker in electron microscopy. The hydrophobic character of gold particles and the existence of electrostatic charge on their surface have allowed the development of specific markers with numerous macromolecules, such as antibodies, lectins, enzymes, various proteins, glycoproteins, and polysaccharides.³⁰¹

‡ This is clearly seen in electron micrographs of bacterial magnetite,²⁹⁹ an intracellular product composed of Fe_3O_4 crystals arranged in a chain parallel to the longitudinal axis of *Coccus* and *Spirillum* bacteria (Fig. 13). Such magnetically ordered (magneto-tactical) bacteria may orient themselves (move) even in weak (0.25–0.5 G) magnetic terrestrial fields by performing the 'navigational' functions in living organisms.

Figure 13. Electron micrographs of *Coccus* bacteria with a chain of nine intracellular magnetic crystals (a) and *Spirillum* cells with a chain of cubic-octahedral crystals (b). The cell length is 3 μm , the size of each crystal is $\sim 50 \times 50 \text{ nm}$.

Special attention should be paid to the microbial geotechnology, *i.e.*, to the extraction of metals from their ores, concentrates, embedding rocks, and solutions by means of microorganisms and their metabolites.²⁷⁹ The bacterial leaching of copper and uranium has long been used in the industrial scale. This process includes fragmentation of ores and preparation of pulp, bacterial leaching of the target metal, filtration, neutralisation of solid residues, and cyanation. The colloidal-biochemical basis has been elaborated recently for the detoxification of cyanide-containing wastes.³⁰²

2. Polynuclear metalloenzymes

All metal-containing protein systems important for biocatalysis and metabolism are divided into four main groups:³⁰³ enzymes (containing Mn, Fe, Co, Cu, Mo), redox proteins, transport, and storage systems (which regulate the concentration of metal(s) at specific sites of the organisms). Kidney proteins, which bind and withdraw heavy metals from living organisms, are also sometimes classified in these groups. The biological functions of these proteins and the types of interactions in them have been reviewed.³⁰⁰

The most typical representative of storage proteins is ferritin. This iron-storing protein contains 24 identical subunits with an inorganic core composed of 4500 iron atoms in the form of basic hydrophosphate $(\text{FeOOH})_8(\text{FeO}-\text{OPO}_3\text{H}_2)$ and having a diameter of 7.3 nm (such a structure is similar to that of synthetic polymers considered above) (Fig. 2).³⁰⁴

The distinctive feature of this large group of redox biocatalysts is the presence of several interacting atoms of transition metals in one protein molecule. Nowadays, over 100 enzymes are known that include several atoms of iron, copper, molybdenum, or manganese, and in many of them the arrangement of atoms in polynuclear ensembles has been established. This refers especially to the metalloproteins containing non-hem iron complexes linked by oxy-, hydroxy-, and alkoxy-bridges.^{7,8,305} Binuclear iron complexes (with the $\text{Fe}_2\text{O}(\text{OCOR})_2$ core) were found in hemerythrin, ribonucleotide reductase, and acid phosphatase. Polynuclear $\text{Fe}^{2+}\text{Fe}^{3+}$ complexes are supposed to exist in numerous enzymes; the Fe_2S_2 groups, in ferredoxin; the high-nuclearity oxo-centres of iron, in the iron-storage proteins of ferritin and hemosiderin type, and in the magneto-tactic microorganisms mentioned above.

In the processes of biological nitrogen fixation, the active enzyme form is produced with the involvement of two components, iron- and iron-molybdenum-containing proteins (including 32–34 Fe and 2 Mo atoms), under the action of natural electron donors (ferredoxins, flavodoxins) in the presence of ATP. The molybdenum nitrogenase cofactor may possibly have the structure $\text{MoFe}_6(\text{SR})_6\text{L}_3$; the MoFe- and VFe-proteins (nitrogenases) were isolated from *Azotobacter vinelandii* and *A. chroococcum*.⁸

Enzymic photosystems that are employed for the liberation of oxygen from water comprise polynuclear complexes containing a cubane-like manganese core Mn_4O_2 ³⁰⁶ immobilised on the protein complex by means of carboxyl groups. Of other bimetallic systems, the Cu^{2+} – Zn^{2+} -containing superoxide dismutases, Cu_2Co_2 -superoxide dismutases, and some others deserve mention. The advantages of these structures with shared nuclear frameworks have been analysed in detail.^{7,8} Biopolymers including clusters with nuclei of Rh_6 ,³⁰⁷ Ru_3 ,³⁰⁸ Fe_4 ,³⁰⁹ and other are described.

Extensive studies of synthetic oligopeptide models of complexes may provide additional information on the mechanisms of action and routes of electron transport in native proteins.

VII. Major fields of the application of polymer-immobilised metal nanoparticles and metal clusters

As noted above, these species have found applications in diverse, sometimes unexpected fields of chemistry, physics, and biology, which largely stimulates their further studies.

The interaction of nanoparticles or clusters with traditional polymers improve their physicochemical properties and performance. This is explained by the ability of these particles to form ionic and coordination cross-links, restricting the mobility of molecular chains or their segments, by cohesive and adhesive interactions, and by other reasons.

The incorporation of metal nanoparticles into a polymer (polymeric shell) may lead to changes in the properties primarily of the polymer matrix itself and also of immobilised nanoparticles or clusters (in particular, to their passivation). An in-depth analysis of these changes goes beyond the scope of this review, and we shall dwell here only on the most essential ones.

1. The modifying effect of nanoparticles on polymer matrices

Virtually all of the methods used to prepare polymer-immobilised nanoparticles are associated with the metal–matrix interaction, especially at the interface. The incorporation of even such a small species as a nanoparticle perturbs substantially the polymer structure.³¹⁰ The extent of structural changes depends on the concentration of nanoparticles, which are the knots of the emerging structural network. The presence of as little as 1% of highly dispersed $\text{Fe} + \text{FeO}$ mixture resulting from the decomposition of iron oxalate in HPPE alters the sizes of the structural element of the polymer, increases the density of the fluctuational network of molecular anchoring and the proportion of oriented polymeric chains.³¹¹ This results in a considerable increase in the impact elasticity of the material, its tensile strength, and resistance to cracking. The processes of structuring in the polymer phase in the presence of nanoparticles occur in different ways. The interaction of nanoparticles with each other (especially at their high concentrations) leads to the formation of coagulation structures. At low levels of nanoparticles, when the formation of coagulation structures is impossible, the polymer matrix itself undergoes structure changes. These processes are accompanied by changes in the temperatures of vitrification, fluidity, thermal destruction, and in the thermomechanical parameters (as a rule, towards their enhancement), which is connected, as noted above, with the restricted mobility of macromolecules due to their interaction with the surface of nanoparticles, and also with the formation of secondary structures.

Thus in the Claspols (see Section IV) obtained by the thermal decomposition of metal salts and carbonyls in polymers melts (PE, PTFE, *etc.*) particles appear that reduce the mobility of molecular chains and increase thereby the thermal resistance of polymeric compositions.³¹² As noted above, the decomposition of a fine dispersion of palladium hydroxide in PVC leads to the formation of network structures containing in their knots the highly dispersed metal thereby raising the temperature of the complete dehydrochlorination of the polymer.¹³¹ The nanoparticles produced by the thermal degradation of copper oxalate increase the

size of the polyamide crystallites, the interaction energy between the structural elements, and strength, but they reduce the overall degree of the polymer crystallinity.¹²⁶ The water of crystallisation released during the decomposition of cadmium oxalate trihydrate accelerates the crystallisation of structural elements, decreases the cohesion energy, and leads to a looser polymer matrix. The π -complexes of iron tricarbonyl with polystyrene-butadiene block-copolymers influence, in the temperature range of their softening, the segmental mobility of the polybutadiene microphase and even when present at levels below 2 mass % Fe they manifest an ordering effect, which increases the macromolecule rigidity.³¹³ At higher metal concentrations, this effect is enhanced owing to the development of a physical network. The dispersed metals formed *in situ* appear to be promising modifiers of the polymer fluidity.¹⁸⁸ Of special interest is the method of ‘non-chain’ inhibition of the thermo-oxidative destruction of temperature-resistant polymers³¹⁴ based on the binding of oxygen by highly effective acceptors, metal nanoparticles formed directly in the polymer matrix.

There are numerous examples of the improvement of adhesive properties of the systems under discussion.³¹⁵ The tribological coatings (of Ni–PTFE type) are characterised by the homocoagulation interaction between the polymer and nanoparticles at the moment of their isolation on the electrode.¹⁷⁶

2. Electrical and magnetic properties

Various atomic and electronic processes that occur at the interface in polymer–nanoparticle composites largely determine their unique properties. These materials become electrical conductors only at definite ratios of the components when conducting chain-type coagulation structures and not matrix systems are formed. In other words, the role of current-conducting channels is played by the fractal clusters⁵⁴ formed upon cohesion of nanoparticles. The highest conductivity is attained when the metallopolymeric material is permeated by interconnected chains of contacting conducting particles, *i.e.*, when it has a percolational structure. As a rule, this is achieved at a content of nanoparticles of ~50 vol. %.

These materials find extensive uses in microelectronics (in the production of connecting circuit boards, flexible cables, *etc.*), in the production of highly dispersed conducting coatings, and in the film and membrane technology. They are also applied as precursors in the preparation of superconducting ceramics. Materials with the superconductivity transition temperature of 90 K were obtained on the basis of Y-, Ba-, and Cu-chelates of polycondensation type.³¹⁶ This temperature is still higher (110 K) in the polymers with components of bismuth ceramics.³¹⁷

To prepare ultradispersed metal particles in polymeric matrices, nearly all of the methods described in Section IV are used, including the vacuum metallisation of polymers. The properties of these magnetic materials, ferroplastics or ferroelastics, namely, their magnetisation curve, magnetic permeability, coercive force, magnetic hysteresis loop, magnetostriction, *etc.*, depend on their prehistory, the nature of the polymer and the nanoparticles, concentration and structural state of particles and can vary over very wide ranges. For instance, the magnetic behaviour of the systems Ni–HPPE and Co–HPPE depends on the conditions of cryosynthesis.⁷⁸ At temperatures above 370 K, the irreversible interaction of Ni clusters with the matrix takes place in the Ni–HPPE system. In the Co–HPPE system, at 470 K the form of the thermomagnetic curve is completely changed due to the enlargement of Co particles.

The peculiarities of the magnetic behaviour of systems obtained by the reduction of metal salts in the medium of a swollen interpolymeric complex of polyacrylic acid with an urea–formaldehyde oligomer¹⁶⁴ and by the thermolysis of cationic complexes of iron arenecyclopentadienyl and arylencarborane oligomers^{72, 318} have been considered. Studies along the same lines were carried out with composites obtained by the thermal and oxidative decomposition of Co and Fe carbonyls in PVF

matrices,¹²⁰ and the hydrogen reduction of organocobalt precursors¹³⁴ and Ni carbonyl in epoxy resin films in different solidification conditions.³¹⁹ Interestingly, the conductivity and the percolation parameters of the latter system depend on the internal stresses arising during solidification.⁵³ Magnetic particles are rather often introduced in different gels: silicone,³²⁰ polyacrylamide,³²¹ polyethyleneoxide,³²² and other gels.⁷² The conducting Ag-containing films are produced by the reduction of AgNO₃ in PVAI.¹⁴⁴ Sometimes, ferroplastics are formed in magnetic fields (for example, neodymium ferrites, in 3–30 G fields), and then are subjected to mechanical (pressing,³²¹ processing on Bridgeman anvils⁷²), thermal,^{323, 324} and other³²⁵ impacts. In recent years, these studies are being developed extensively.

Of interest is the preparation of thin (3–7 nm) modifying magnetic coatings (that can be obtained, *e.g.*, by electrochemical deposition) on the surface of self-assembling thin films of the Langmuir–Blodgett type. Thus, the coatings including α -Fe (70 at.% Fe), magnetite Fe₃O₄, and admixtures of Fe₂O₃, may be formed on organosilanes.¹⁸² Polymer-immobilised particles are formed *in statu nascendi* in magnetic fields. These materials seem to be rather promising as drug carriers, for magnetic recording of information, magnetic separation, as materials possessing the magnetic-optical properties, and as magnetic fluids,³²⁶ the latter being colloidal solutions with strong magnetic properties. The role of carriers operating under extreme conditions (wide temperature range, vacuum, aggressive and biologically active media) may also be played by polymers, *e.g.*, oligoorganosiloxanes.

3. Polymer-immobilised nanoparticles as optical materials and semiconductors

The composite materials that comprise polymeric optical media and nanoparticles possess a unique set of the optical (in the visible light range) and semiconductor properties. The ease of mechanical processing and the film-forming properties of these materials make possible their use for the preparation of dispersive optical elements, band light filters, *etc.* To this end, the products of joint condensation of Au with a large excess of a diacetylene monomer, diphenylbutadiyne, or its polymer are most often used.⁶⁷ The metallopolymers produced contain 7%–16% of metal with a mean particle size of ~ 2 nm. The composite material is characterised by a 200-fold increase in the third-order optical coefficient. Thin films of Au- and Ag-plasmapolyfluorocarbon possess good optical properties.^{86, 90}

Homogeneous composite materials with high absorption and refraction indices suitable for the production of optical elements are prepared on the basis of polymeric glasses with sulfoselenides of transition metals, photochromic glasses with Ag and Cu halides, holographic emulsions of Ag halide nanoparticles in gelatin,³²⁷ *etc.* As a rule, the semiconductor component concentration in a polymeric binder (4-VPy, PVAI, *etc.*) does not exceed 0.1%, *i.e.*, ‘dilute solutions’ are used.

As in the synthesis of metal nanoparticles, the methods of the assembly of semiconductor components directly in polymeric matrices have found extensive applications. For example, nanocrystals of CdS and ZnS are obtained from their salts and H₂S in polymeric solutions. The content of cadmium sulfide (in the form of ~ 50 -nm particles) in these materials may be as high as 50%.¹⁷ It is known that the optical characteristics of gelatin films depend on the particle size of incorporated PbCrO₄.³²⁸ In this connection, it is noteworthy that the effective control of the particle size may be realised by varying the composition of copolymers and thereby the size of domains (Fig. 3) in ionomers.^{329, 330} Thus, the mean size of CdS particles in toluene solutions of the block-copolymer of styrene with acrylic acid increases from 1.8–2.3 nm to 3–5 nm as the number of acrylic units in the ionic block increases from 4 to 32. Note also good promises for the application of materials of this type in the systems for solar energy accumulation and transformation.^{331, 332}

4. The specific nature of catalysis with polymer-immobilised nanoparticles and clusters

The Group VIII metals in the colloidal state were among the first known catalysts of hydrogenation of organic compounds. As early as in the 1940s, PVAI, PVA, and PMMA were used to protect these colloids.³³³ Later, silk fibroin, nylon, PETF, *etc.* were used to this end.

Catalysts of this type are of prime theoretical interest since they allow modelling of the size effects on the catalytic activity. They may be used to exemplify many concepts of basic theories of the catalysis: A A Balandin multiplet theory, N K Kobozev theory of active ensembles, and D V Sokolskii theory of skeletal catalysis. Multiple attempts were undertaken to assess the influence of the catalyst particle size on its activity. For example, the size of nickel particles was varied from that of individual atom to the bulk metal.³³⁴ Quantitative estimates were made for the effect of the size of Ni_n/SiO₂ and Ni_nCu_m/SiO₂ on the course of hydrogenation.³³⁵ Similar studies were performed with regard to the behaviour of deposited polynuclear complexes in the processes of hydrogenation and isomerisation of alkenes.^{217, 336}

The application of polymer-immobilised cluster and nanoscale particles provides an additional possibility to shed light on the relationship between homogeneous, heterogeneous, and enzymic catalysis.⁴ According to some features, these particles are close to homogenous catalysts: they are obtained from ordinary, soluble metal compounds by increase in their nuclearity, the polymer often performs the functions of macroligand and stereochemical environment, they can function under mild conditions, *e.g.*, at temperatures below 100 °C. At the same time, these contacts also inherit major properties of heterogeneous systems: reactions occur at the interface, the activation of the substrate results from adsorption on the surface, the catalyst is easily separated from the reaction products and may be regenerated. The peculiarities of enzymic catalysis (substrate enrichment, structural correspondence, favourable orientation of reacting molecules, additional activation of the substrate by the multi-centre catalytic system, *etc.*) are also easily simulated using polymer-immobilised clusters and nanoparticles. For example, additional introduction of neodymium ions into ultradispersed Pd particles immobilised in water-soluble polymers exerts a promoting effect on these catalysts of acrylic acid hydrogenation.³³⁷ The reason for this effect consists in the substrate concentration resulting from the additional coordinational interaction with neodymium ions.

The above-discussed cryochemical technique for combining different elements, *e.g.*, Ag, Pd, or Pt with liquid oligo- and polyesters, and polydienes makes it possible to achieve the ‘critical loading’ of polymer (when the concentrations of metals exceed the coordination possibilities of polymers). Subsequent deposition of such polymer-immobilised nanoparticles on carbon powder may lead to the formation of Ag_n⁰/C, Pd_n⁰/C, and Pt_n⁰/C systems, which are traditional catalysts of numerous processes. Nanoparticles of Pt incorporated in glass-carbon matrices (Fig. 10) may also be referred to this type of catalyst.

In many cases, the polymer-immobilised nanoparticles manifest high activity and selectivity. This may be exemplified by the processes of ionic-coordinational polymerisation, hydrogenation, and oxidative transformations.⁵ The activity of these catalysts essentially depends on the nature of the polymer and the size of nanoparticles. After the removal of heavy Pt particles by centrifugation (20 000 rpm), the transparent supernatant containing about 20% of the initial Pt in a finely dispersed form manifests much higher activity in the catalytic reaction of hydrogen liberation from water.³⁷ The size of the remaining Pt particles is critical for their catalytic activity to be manifested irrespective of the nature of the protecting colloid.

Of special interest is the regioselectivity observed in the hydrogenation of undecenoic and oleic acids on clusters stabilised by surfactants or polymers.¹⁴⁸ The surfactant micelles surrounding a cluster not only stabilise it but also orient appropriately the

Figure 14. A supposed mechanism of the hydration of unsaturated fatty acids in micellar (a) and polymeric (b) systems.

unsaturated fatty acids (Fig. 14). In the case of a linear polymer, the double bond of substrate is more accessible to nanoparticles since the macromolecules are in a chaotic molecular motion.

The polymer-immobilised bimetallic Pt–Co colloids exhibit high selectivity (up to 99.8%) in the reaction of hydrogenation of cinnamaldehyde to the corresponding alcohol.²⁴⁷ The application of polymer-protected nanoparticles is expected to lead to the discovery of new specific effects in catalysis. The cluster $[\text{Pt}_{15}(\text{CO})_{30}]^{2-}$ fixed on Sephadex is used as the catalyst of the hydrogenation of selective redox-active cofactors.²²³

VIII. Conclusion

Among theoretical problems of the formation of clusters and nanoparticles in polymeric matrices, the most topical seem to be the questions of structural-morphological and spatial organisation of these systems at the local, molecular, and supramolecular levels, including thermodynamic peculiarities of their formation. Such an analysis has recently been performed using macrochelates as an example.³³⁸ The most important problem seems to be the stabilisation of nanoparticles by monolayers of polymers and Langmuir–Blodgett films. The number of studies carried out in this direction is clearly insufficient. Thus, the nature of the adhesion at the interfaces formed still remains obscure.

The passivation of nanoparticles formed should be realised within reasonable limits allowing preservation of their energy-rich state. A highly significant theoretical and practical problem is to learn to control the processes that occur on the surface or in a thin subsurface layer of polymer granules, films, or fibres. In this context, of interest is the preparation of self-assembling colloidal layers of Au, Ag, and Ag–Au on the surface of compounds of different origin (including the plasma-purified PTFE) premodified by hydrolysed alkoxy silanes containing functional groups.³³⁹ On such surfaces brought into contact with dilute solutions of monodisperse colloids, the assembly of nanoparticles takes place only as a monomolecular layer, which is 5–70 nm thick in the case of Ag and 5–20 nm thick in the case of Au and Au–Ag.

One may expect further progress in the development of novel methods for the preparation of polymer-immobilised clusters and nanoparticles. A promising direct synthesis of these products appears to be the dissolution of zero-valent metals in solutions of polymers that function as macroligands (like the solubilisation of metals in the presence of organic low-molecular-weight ligands)³⁴⁰ with subsequent recrystallisation of particles, as it occurs in biological systems (Section VI). The technique of stabilisation of nanoparticles and clusters in the course of polymerisation of micelle-forming monomers is likely to become practically significant. These methods have been devised using Pt clusters as models resulting from the photodecomposition of H_2PtCl_6 in the presence of monomers of the type of $\text{CH}_2=\text{CH}(\text{CH}_2)_8\text{COO}(\text{CH}_2\text{CH}_2\text{O})_n\text{CH}_3$.³⁴¹

It is only recently that studies of the formation of nanoparticles with polymer–polymer compositions have begun.¹ Hybrid PMMA–epoxy resin compositions and clusters of noble

metals have been prepared,³⁴² which are currently used as functional light-sensitive solid solutions and non-linear optical materials.

Formation of an inorganic phase $\text{Ti}(\text{OR})_4$ or $\text{Zr}(\text{OR})_4$ in copolymers of styrene and 4-vinylphenol (with the particle size ranging from 20 to 250 nm),³⁴³ preparation of nanoparticles by pyrolysis of metal carbonyls and mesogenic petroleum pitch,³⁴⁴ production of drug carriers composed of nanoscale particles,³⁴⁵ *etc.*, have been described.

Undoubtedly, the progress of research into such small particles requires further development and the application of modern physicochemical methods, including the visualisation of the surface structure at the atomic level by means of scanning tunnel microscopy, transmission electron microscopy, ferromagnetic resonance, small-angle X-ray scattering, X-ray photoelectron spectroscopy, *etc.*

The polymer-immobilised nanoparticles are already used to solve specific technological problems associated with the surface modification: its metallisation, the imparting of antistatic and magnetic properties to it, design of new materials for photo- and cinematography, design of efficient fibrous filtering materials allowing isolation and concentration of precious metals, *etc.* Specifically, the surface metallisation is required to decorate plastics,^{49, 310, 346} to modify polymeric films,³⁴⁷ to make tribological coatings, and other purposes. The coatings made of polymer-immobilised nanoparticles on the basis of Be and plasmopolymers have found unexpected applications in the reactions of thermonuclear synthesis.⁷⁹

It should be noted that clusters of metals can also be formed in such specific ‘polymers’ as fullerenes. In this case, both inclusion compounds of the type of endohedral complexes $\text{M}@\text{C}_{60}$, which are localised in the inner cavities of the spheroidal molecule C_{60} , and organometallic polymers of the type C_{60}Pd_n ,^{348, 349} or oligomers containing manganese carbonyls³⁵⁰ are formed.

Nanocomposite materials are also formed upon evaporation of metals in carbon nanotubes. The clusters of metals (Cr, Ni, *etc.*) are localised both inside these tubes and on their ends and surface.^{351, 352} On the other hand, the evaporation of metals in the oxidised nanotubes leads solely to the decoration of nanotube surface with nanoparticles (Fig. 15). An analogous pattern is also characteristic of lipid structures;³⁵³ their electrochemical polymerisation and metallisation result in metal-coated polymers having the shape of hollow cylinders several tens of microns long, $\sim 0.5 \mu\text{m}$ in inner diameter, and $\sim 50 \text{ nm}$ thick walls. Of interest is the similarity of such materials with the metallophilic microorganisms (Fig. 11).

Figure 15. Electron micrograph of oxidised nanotubes decorated with silver.

Under mild conditions, biological systems bring about a controllable growth of iron oxide crystals (including magnetite) of definite size and morphology with strictly defined crystallochemical characteristics, which are so far difficult to achieve under laboratory conditions. Extensive studies of these processes (bio-inorganic solid-phase chemistry) will allow one to establish the basic principles of targeted synthesis of the products classed as 'crystal engineered'. The discovery of the phenomenon of selective aggregation of microorganisms with dispersed metals and their compounds has already laid the foundation for the methods of biotechnological enrichment used in metallurgy and for the environment protection. Many of these principles are employed in the rapidly developing field known as nanotechnology³⁵⁴ and are likely to form the basis of a new branch of science which may be defined as chemistry of highly organised compounds, including supramolecular chemistry and chemistry of hypermolecular compounds.³⁵⁵

* * *

Several publications related to the problems surveyed in this article have appeared since its submission. Of special note are an A.C.S. publication,³⁵⁶ a special issue of 'Chemical Materials' Journal,³⁵⁷ and a conference on electronic materials.³⁵⁸ The theoretical problems of stabilisation of nanoparticles by polymers have been discussed.^{359–366} Further development of the methods for preparation of polymer-immobilised nanoparticles^{367–378} and clusters^{379–382} has been documented. The research in traditional and novel fields of application of polymer-immobilised nanoparticles and clusters is in progress.^{371, 375, 383–394}

The author is indebted to Prof. S P Gubin for helpful discussion and attention to this review and thankful to Dr. G I Dzhardimalieva for assistance in preparing the manuscript.

Exogenous nitric oxide donors and inhibitors of its formation (the chemical aspects)

V G Granik, S Yu Ryabova, N B Grigoriev

Contents

I. Introduction	717
II. General aspects	717
III. Exogenous donors of nitric oxide	719
IV. Inhibitors of NO-synthase	727
V. Conclusion	728

Abstract. The published data on the biological role of nitric oxide formed *in vivo* by enzymic oxidation of L-arginine are generalised. Special attention is given to exogenous nitric oxide donors, which can release NO *in vitro* and *in vivo* in oxidation, reduction, or hydrolytic cleavage. Also considered are the data on the chemical nature of inhibitors of NO-synthase responsible for nitric oxide formation from L-arginine. The bibliography includes 161 references.

I. Introduction

The discovery and verification of the mediator role of nitric oxide in living organisms have stimulated the search for drugs new in principle. Publications have appeared that were concerned primarily with the biological role of nitric oxide, problems of its insufficient or excessive release *in vivo*, and, correspondingly, the ways of increase or decrease in its content in organs and tissues.^{1–10}

The present review generalises and considers the data on NO release from chemical compounds of different structure that can be combined under the common name of donors (or generators) of nitric oxide. In addition, the results of studies on inhibitors of isoforms of NO-synthase (NO-S) responsible for nitric oxide formation from L-arginine *in vivo* are discussed.

II. General aspects

Nitric oxide plays a crucial role in the functioning of the vascular system as an endogenous relaxant. The release of nitric oxide from endothelial cells of blood vessels results from an increase in the intracellular Ca^{2+} level, which initiates NO biosynthesis. Nitric oxide penetrates into neighbouring cells and activates soluble guanylate cyclase (SGC). The latter favours the transformation of

guanosine triphosphate (GTP) into cyclic guanosine monophosphate (cGMP). The increase in the cGMP level in cells causes the relaxation of vessels, eventually resulting in the lowering of arterial pressure. Other important biological functions of nitric oxide are: inhibition of platelet aggregation and effects on the immune system as well as on the central and peripheral nervous systems. Hence, NO plays the key role in the control of vascular tonicity and neuromediator mechanisms and exerts a cytotoxic and cytostatic action. A wide variety of pathological states (*e.g.*, cardiovascular, infectious, and inflammatory diseases, brain injuries resulting from insults, *etc.*) may largely be due to the elevated or lowered content of nitric oxide.

Biosynthesis of NO in the organism occurs *via* the oxidation of L-arginine and is catalysed by NO-synthase (NO-S) (for NO-S isoforms see below) with the participation of reduced nicotinamide adenine dinucleotide (NADPH) as an electron donor. NO-S contains one mole each of (6*R*)-5,6,7,8-tetrahydrobiopterin (BH_4), flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), and heme per monomeric subunit as the cofactors. A general scheme of L-arginine oxidation is given below:⁶

The oxidation occurs stereospecifically, L-arginine (but not its D-isomer) is the only source of nitric oxide.¹¹ L-N-Hydroxyarginine (**1**) is an intermediate product of L-arginine oxidation.^{12–20} Compound **1** was synthesised¹³ from the α,ω -diamino acid ester (**2**) *via* the N-cyano derivative, which was further converted into

the *N*-hydroxyguanidine intermediate (**3**). Deprotection of the carboxyl and α -amino groups resulted in *N*-hydroxyarginine **1**.

Like L-arginine, *N*-hydroxyarginine **1** causes the relaxation of vessels, which can be prevented by the NO-synthase inhibitors, *N*^ω-methyl- and *N*^ω-nitroarginines.¹³ These data agree well with the finding that *N*-hydroxyarginine **1** is the intermediate in the syntheses of NO and L-citrulline (L-Cit) from L-arginine.¹³ Special experiments^{16,17} have shown that L-arginine oxidation by NO-synthase occurs in at least two stages. At the first stage, which requires the presence of NADPH and oxygen, *N*-hydroxyarginine **1** is formed; the second stage, which requires B-H₄, oxygen, and 0.5 equiv. of NADPH, gives L-citrulline and nitric oxide. The same authors have established that *N*-hydroxyarginine **1** is a good substrate for inducible NO-synthase (i-NO-S). It is necessary to note that the oxidation of *N*-hydroxyarginine **1** with a labelled ¹⁵NOH-group results in ¹⁵NO₂⁻ and ¹⁵NO₃⁻ (the products of NO transformation), whereas the compound with a labelled ¹⁵NH-group of the imidoxime fragment gives nonlabelled NO₂⁻ and NO₃⁻ anions. Consequently, i-NO-S utilises only the *N*-hydroxylated fragment for its oxidation. Using H₂¹⁸O, it has been shown that L-citrulline formed upon the oxidation contains no label, *i.e.*, it is formed with the participation of O₂ rather than water. The idea that *N*-hydroxyarginine **1** is the intermediate in NO biosynthesis *in vivo* is in good accord with data on the pharmacological activity of this compound in comparison with the activity of arginine (including the experiments with NO-S inhibitors).¹⁸ There is evidence²⁰ of the ability of compound **1** to undergo oxidation in cells to nitric oxide and nitrites also in the absence of NO-S, apparently *via* catalysis mediated by cytochrome P-450. Nevertheless, the main pathway of nitric oxide formation in the organism is the NO-S-catalysed oxidation of L-arginine. Two major isoforms of NO-S have been described in the literature, namely, the constitutive NO-synthase (c-NO-S) found in vascular endothelium and brain and inducible NO-synthase (i-NO-S) present in activated macrophages. The constitutive isoform requires Ca²⁺/calmodulin for its activation and can be subclassified into endothelial and neuronal isoforms. The former generates NO that influences the lowering of arterial pressure and inhibits the aggregation of platelets; the latter (the neuronal enzyme) functions as a neurotransmitter. The main function of i-NO-S is the immune protection of the organism, *i.e.*, the synthesis of NO, a cytotoxic and antiinflammatory agent. Unlike c-NO-S, i-NO-S does not require regulation by Ca²⁺ (see Refs 10, 21).

Of great importance is the further fate of nitric oxide in living organisms, namely, its involvement in various biochemical processes and the mode of its deposition in cells. Although in many studies the role of a vasodilating agent has been ascribed to nitric oxide, the identity of NO with the so-called endothelium-derived relaxation factor (EDRF) is very doubtful due to the high reactivity of nitric oxide and, correspondingly, the high probability of its rapid biotransformation in living organisms. The fact that, unlike EDRF and *S*-nitrosothiols, NO enters into reaction with hemoglobin (Hb) to give a HbNO complex (data from the tracer technique, EPR spectroscopy), allowed one to conclude that EDRF is not free nitric oxide but rather is an *S*-nitrosothio compound of the *S*-nitrosocysteine type.²² *S*-Nitrosothiols have been proposed as candidates for EDRF in a number of other investigations.^{2,23–25} However, there exists an alternative view-

point,^{26–31} according to which EDRF is represented by dinitrosyl complexes of non-heme iron (DNCI) with low-molecular-weight thiol ligands. Both types of compounds (nitrosothiols and DNCI) have been detected in cells and tissues that generate nitric oxide from L-arginine under catalysis by NO-S.^{29,30} The same authors have demonstrated that these compounds can undergo interconversions, *i.e.*, the deposition of nitric oxide according to both these mechanisms is not mutually exclusive. Protein ligands seem to have greater affinity for Fe(NO)-groups; however, in the interaction with thiols, such as cysteine and acetylcysteine, the following equilibrium is established:²⁹

According to Vanin *et al.*,²⁹ protein DNCI provide stable storage of nitric oxide, whereas low-molecular-weight DNCI act as carriers. In endothelial cells, EDRF is largely represented by DNCI, whereas in the intercellular medium, by *S*-nitrosocysteine.³⁰ Since DNCI are much more stable than *S*-nitrosothiols, in animal organisms the equilibrium is markedly shifted to the left and the viewpoint, according to which EDRF is predominantly represented by iron complexes, appears to be rather convincing.³¹

The binding of nitric oxide by iron seems to determine also the activation of soluble guanylate cyclase (SGC) responsible for GTP transformation into cGMP and the biochemical and biological effects produced thereby. It has been found³² that the UV spectrum of SGC changes under the influence of NO. Simulation of this system has revealed that after addition of nitric oxide protoheme-CO complexes transform into the pentacoordinated Fe(II)-NO complexes that apparently mimic the behaviour of SGC. It is assumed³³ that NO nitrosylates heme-SGC to give a nitrosyl-heme complex, in which iron is out of the plane of the porphyrin ring. The structure of the complex becomes similar to that of the SGC activator, protoporphyrin IX, and SGC activation takes place. The NO influence on SGC having been established, the activation of this enzyme by several nitric oxide complexes with transition metals has been studied.³⁴ Three types of nitroso complexes have been examined: sodium nitroprusside, Na₂[FeNO⁺(CN)₅], in which the NO group bears a positive charge (nitrosonium cation), K₃[CrNO(CN)₅] and [CoN(O)(NH₃)₅]SO₄ (where NO is the neutral group), and K₃[CoN(O⁻(CN)₅], where NO is coordinated as the anion. The most effective activator of SGC is sodium nitroprusside whose activating effect is determined by the interaction of NO⁺ with the heme of the enzyme. Nitroso complexes with cobalt and chromium, in which NO is a neutral group, activate SGC insignificantly, whereas the complexes with the NO⁻ anion inhibit the enzyme. In contrast to nitroprusside, other nitroso complexes have no hypotensive effect mediated by a heme-dependent mechanism.

Before we come to the consideration of the material concerning the analysis of various types of structures that are responsible for the release of exogenous nitric oxide or inhibit its formation in living organisms, it seems expedient to consider in this section the analytical methods allowing the identification of NO.

The main techniques (chemiluminescent, electrochemical, EPR, spectrophotometrical, chromatographic, electrophoretic, and fluorimetric) used to determine nitric oxide have been described in detail in a recent review.⁸ Here it seems appropriate to cite some papers not mentioned in this review. Thus NO has been determined colorimetrically as nitrite anion and by EPR spectroscopy as the nitrosyl-ferrohemoglobin paramagnetic

complex obtained by decomposition of thionitrites in the presence of oxyhemoglobin.³⁵ Analysis of NO has been performed by EPR spectroscopy of an iron–mononitrosyl–dithiocarbamate complex.^{15, 28, 36} A chemiluminescent method has also been used.^{37, 40} Special reference should be made to an indirect electrochemical method recently developed for the determination of nitric oxide.^{41–45} It turned out that NO can be identified polarographically, since it is reduced on a mercury dropping electrode (MDE) in acidic media (pH < 3) to give an irreversible five-electron wave.⁴¹

The wave appears at -0.77 V (relative to SCE, saturated calomel electrode) and rapidly disappears when nitrogen is passed through. This does not allow one to consider this method as an analytically applicable one. It is more appropriate to detect NO from the reduction current of NO_2 that is formed upon the interaction of NO with dissolved atmospheric oxygen. In this case, the determination is carried out at a pH close to the physiological one.

In weakly acidic solutions (pH 3–4) a non-dissociated HNO_2 is formed, which is discharged on the MDE via a one-electron mechanism ($E_{1/2} = -1.0$ V vs SCE).

The appearance of this wave is an indirect marker of the presence and concentration of NO in the solution. Yet, another possible method for the determination of nitric oxide is the introduction into the solution of polyvalent cations (La^{3+} , Ce^{3+} , and Nd^{3+}).⁴¹ In this case, a wave with $E_{1/2} = -1.2$ V is observed.

To further improve this method, a polarographic procedure^{42–45} has been developed for the determination of NO in the form of the nitroprusside anion, which is formed upon the reduction of the compound under study with potassium ferrocyanide or upon its oxidation with potassium ferricyanide. For example, in the reaction of well-known NO generators, such as nitrites, with the ferrocyanide anion the following processes take place:

This interaction gives a polarographically active nitroprusside anion, and, in the appropriate selection of optimum conditions, this process can be used for reliable quantitation of nitric oxide.^{42–44} Another analytical procedure^{42, 45} is based on a time-dependent decline of the anodic wave of cysteine in the presence of a nitric oxide source.

The data presented above point to the expediency of a search for compounds that can increase or decrease the nitric oxide content in organs and tissues, while the existence of reliable analytical methods for the determination of NO makes it possible to select the most promising NO donors *in vitro*. Below we consider methods of synthesis of NO donors and provide ample data on nitric oxide generators and inhibitors of its NO-S-catalysed *in vivo* synthesis and discuss some biological and toxicological problems arising from the effect of exogenous compounds on various biological systems.

III. Exogenous donors of nitric oxide

1. Guanidines and related compounds

As indicated above, it is the guanidine fragment of L-arginine, the target for NO-S, that undergoes oxidation to the *N*-hydroxy derivative **1** and further to citrulline and nitric oxide. It is supposed that the binding of substrates with NO-S occurs also *via* the amino-acid part, but largely it is due to the guanidine fragment (with the heme of the enzyme and a special site of ‘guanidine binding’).⁶ It could therefore be expected that some compounds having guanidine or guanidine-like groups can act as substrates for NO-S and can be transformed *via* the oxidative NO-synthase mechanism (including NO-S catalysis) with the evolution of NO. First of all, this applies to the main endogenous substrate, L-arginine, since enzymic processes are mostly highly specific. Of the investigations concerning arginine itself, special mention should be made of a study that has demonstrated that this amino acid and the ethyl ester of *N*^ω-benzoyl-L-arginine can lower intra-ocular pressure *in vivo*.⁴⁶ In addition, L-arginine and its derivatives with lipophilic substituents can be used in the treatment of ischemia retinae.⁴⁷ The authors of these two papers believe that these phenomena are due to the ability of L-arginine and its derivatives to undergo oxidation with the liberation of nitric oxide and, correspondingly, cause the relaxation of blood vessels resulting in the lowering of blood pressure. The vasodilating effect of *N*-hydroxyarginine **1** is enhanced during its interaction with nitric oxide. It was shown that the reaction of compound **1** with NO, HNO_2 , and other nitrosating agents gives an adduct able to cause the relaxation of vessels.¹⁹ The reaction of certain cyanamides, carbodiimides, and other compounds with hydroxylamine resulted in a series of the corresponding *N*-hydroxyguanidines **4–7**.¹⁹ These compounds also give adducts with nitrosating agents that liberate nitric oxide in aqueous solutions (data from chemiluminescent analysis).¹⁹

The structure of these adducts has not been established; however, it has been shown that they are stable prior to dissolution. In aqueous solutions, they decompose at different rates, the decomposition being irreversible at low pH (1.0–1.5). In organic solvents, the degradation occurs rapidly but the yield of NO is small. Using labelled nitrosating agents, it has been demonstrated that ^{15}NO incorporates into the adduct and it is this nitrogen (^{15}N) that is lost upon decomposition. Pharmacological tests have revealed the relaxation of vessels under the influence of these compounds. In this case, more labile adducts give a short-term and sharp relaxation, whereas slowly decomposing adducts elicit a more prolonged (on a time scale) response of lower intensity. It is self-evident that apart from the NO formed by degradation of its adducts with hydroxyarginine **1** and some other hydroxyguanidines, the NO formed by the oxidation of the guanidine fragment of arginine is also released. The β -aminoethylisothiuronium salt **8**, which readily rearranges into β -mercaptoethylguanidine **9** at pH 7.0, has been studied.^{48, 49}

The equilibrium ratio **8**:**9** has been quantitatively estimated by the polarographic method.⁴⁹ It has been found that the amine **8** is completely converted into the thiol **9** at pH 7.0. This finding has led the authors to assume the probability of the same transition *in vivo*. It was conjectured that the oxidation of **9** with the formation of NO is accompanied by the capture of NO by the thiol group to give the *S*-nitrosothiol **10**, and thus the deposition of the released nitric oxide takes place.

To test this hypothesis, β -methylthioethylguanidine **11** has been synthesised.

It turned out that the guanidine **11** activates SGC far less efficiently than thiol **9** and produces a less pronounced hypotensive effect, which probably confirms the expediency for a search for systems containing 'traps' capable of retaining and preserving nitric oxide for some time along with fragments responsible for NO release. This question will further be discussed in the consideration of other NO generators. It is worth special note that the oxidation of the thiol **9** seems to occur *via* the same mechanism as that of L-arginine, *i.e.*, with the participation of NO-S. Evidence in favour of this conclusion can be derived from the fact that SGC is not activated when the thiol **9** is used in combination with the NO-S inhibitor, *N*^ω-methylarginine.

Yet, another new type of NO-donor is represented by dienediamines of the indolinone series **12**.^{50, 51}

Compounds **12** form nitric oxide upon oxidation and, depending on the substituent at the nitrogen atom, manifest a more or less pronounced ability to activate SGC and exert hypotensive activity *in vivo*.

The chemical oxidation of *N*-hydroxyguanidines, such as **1**, **13**, and **14**, which is accompanied by NO release, has been studied.¹⁵ Of the oxidants tested only two, *viz.*, lead tetraacetate and potassium ferricyanide/hydrogen peroxide, have been found to direct the process along the desired pathway.

N-Cyanopiperidine **15** has been isolated and identified as one of the oxidation products of compound **13**. A scheme of the process that differs basically from the enzymic oxidation of L-arginine and *N*-hydroxyarginine has been proposed:¹⁵

Interestingly, chemical oxidation does not result in ureas, *i.e.*, products similar to citrulline formed upon arginine oxidation. This fact provides additional evidence in favour of the enzymic pathway of the *in vivo* oxidation of guanidine derivatives. It is noteworthy that oxidation by other reagents results in HNO which dimerises to give HON=NOH. The decomposition of the latter gives N₂O and H₂O.

2. Nitrates

For the derivatives containing the guanidine or modified guanidine fragment, oxidation is the main pathway of NO generation. On the contrary, the formation of nitric oxide from nitrate vasodilators (drugs of the nitroglycerin type that have been used for many years) and related compounds requires reduction. It is now obvious that the coronarodilator effect of nitrates is associated with enhanced release of nitric oxide by these donors.^{37, 38, 52–58} Nitrates are traditionally used in the treatment of stenocardia but their clinical applications can further be extended to diabetes mellitus, atherosclerosis, and vasospasm. In addition to the well-known nitrates,^{37, 38, 52} some authors offer novel compounds, such as nitroxyalkyl coumarins.⁵³ The activity of some representatives of this series exceeds that of nitroglycerin 2- to 10-fold. A recent report⁵⁴ on a novel drug, the benzoxazine derivative **16**, points to an improved action on coronary vessels. This drug is undergoing the second stage of clinical trials. Some novel oxazine, thiazine, and pyrimidine derivatives **17** manifest antiischemic activity.⁵⁴

Data have been given⁵⁵ on the vasodilating and antiaggregating activity of NO donors, such as *S*- and *N*-nitroso compounds, relative to nitroglycerin. The vasodilating action of nitroglycerin is at a sufficiently high level; however, with regard to the inhibition of platelet aggregation this drug is strongly inferior to *S*- and *N*-nitroso compounds. Nitrofenac (diclofenac δ -nitroxybutyl ester, **18**)⁵⁷ belongs to novel NO donor compounds.

With regard to antiinflammatory and antipyretic action, nitrofenac is similar to diclofenac sodium (voltaren, orthofen) but its antithrombotic activity (which is characteristic of NO donors) is much higher. However, the main advantage of **18** in comparison with diclofenac sodium is its ability to markedly reduce gastrototoxicity without any detriment to its ability to inhibit prostaglandin synthesis. This important property is ascribed to the presence of a nitrate fragment in compound **18**.

Direct evidence in favour of NO formation from nitrates in the presence of thiols has been obtained using the polarographic method.⁴⁵ The course of the reaction of nitroglycerin with thiols was followed by the decline of the anodic waves of thiol and nitrate. Thus, the polarographic wave reflecting cysteine oxidation gradually declines with time according to the equation:

It has been established that nitroglycerin reduction with cysteine or unithiol (sodium 2,3-dimercaptopropane sulfonate) occurs in two steps, *i.e.*, reductive hydrolysis of the nitrate with thiol and reduction of the NO₂⁻ formed to NO. Disproportionation of HNO₂ is also possible:

The rate of the nitroglycerin reaction with thiols is rather low, being essentially less than the manifestation of the therapeutic effect of this drug, which suggests the enzymic formation of nitric oxide from nitroglycerin *in vivo*.⁴⁵ One of the most important problems in the clinical application of nitrates is the development of a tolerance effect, which is believed to be associated with different mechanisms of blockade or metabolism of nitroglycerin and/or with the effect of its active metabolite, nitric oxide.⁵⁸ In this case tolerance is not eliminated with an increase in the nitroglycerin dose. A proposal has been put forward⁵⁹ that tolerance is caused by rapid depletion of intracellular depots of cysteine or, in more general terms, by the deficiency of SH-containing compounds. This hypothesis has given rise to a noticeable trend in the synthesis of SH-containing NO donors. In this case 'intramolecular assistance' is possible (as in the case of β-mercaptoethylguanidine) consisting in intramolecular trapping of the released NO to give rather unstable S-nitrosothiols, which serve as a source of NO in the organism. Synthetic compounds based on this principle are highly effective vasodilators, potent nitric oxide donors, and SGC activators. Among them, compound **19** exerts the highest activity.⁵⁹

Apparently, compound **19** and its analogues do not produce the effect of development of tolerance. Synthesis of the ethyl ester of [N-(3-nitroxypivaloyl)-N-(N'-acetyl-DL-alanyl)-L-cysteine (SPM-5185, **20**), a coronarodilator drug comparable in activity with nitroglycerol, has been described.⁶⁰⁻⁶³

To check the idea that the presence of a thiol group in the molecule of nitrate is necessary to exclude the development of tolerance, a comparative study of the biological effects of compounds **20** and **21** has been carried out. It has turned out that the activity of the former markedly exceeded that of the latter, which was devoid of the thiol group; however, neither of these compounds induces any noticeable tolerance. This finding made it possible to assume⁶¹ that the cysteine fragment of compound **20** is not necessary and the reduction of the number of thiol groups can hardly be the reason for tolerance. The fact that tolerance did not develop with ester **20** has been specially examined and confirmed.⁶⁴ However, in another recent study⁶⁵ it has been demonstrated again that it is particularly the depletion of thiol groups that is the true reason for the development of tolerance to nitrates. Bron *et al.*⁶⁵ have synthesised compounds containing ONO₂⁻ groups together with a thiazolidine fragment whose hydrolysis gives free thiol compounds. Pharmacological studies of these compounds have made it possible to conclude that the presence of the released nitric oxide together with the liberated thiol groups in the system prevents nitrate tolerance. In conclusion, let us return to the reaction of nitrates with thiols which, as can be evidenced from the above data, is the most important mechanism of their biological action. The reaction of thiols with nitrates has been analysed⁹ and it has been established that the thiol structure is the crucial factor. All thiols decompose nitrates to the nitrite anion, but only some of them (cysteine, N-acetylcysteine) convert them into nitric oxide. If NO is formed (even together with NO₂⁻), the activation of SGC occurs; if only NO₂⁻ is formed, no activation of SGC takes place. These differences in the behaviour of thiols were rationalised in terms of a possible intramolecular rearrangement (thionitrate → sulphenyl nitrite).

Obviously, the validity of the concepts concerning nitrate metabolism needs further verification and analysis.

3. Other nitro-, nitroso-, and related compounds

Like O-nitro, N-nitro derivatives can also be generators of nitric oxide, which can be exemplified by the study of nitropyrroles (PzNO₂, **22**).⁶⁶

Both electrochemical and chemical reduction of these compounds with potassium ferrocyanide or cysteine gives nitric oxide. Compounds **22** activate SGC. The putative mechanism of this transformation is given below, using the reaction with potassium ferrocyanide as an example:

With thiol compounds (cysteine), pyrazoles **22** react according to the scheme:

A number of investigations have been dedicated to the analysis of compounds containing an *N*-nitroso group. A series of *N*-methyl-*N*-nitrosoanilines **23**, which, as it turned out, were able to *S*-nitrosate cysteine-containing compounds (*e.g.*, papain) and thus form stable NO-depots, have been investigated.⁶⁷

N-Nitroso compounds **24** and **25**, which exhibit a pronounced mutagenic effect, manifest vasodilating properties; the vascular response can be prevented by hemoglobin that binds NO or by Methylene Blue that inhibits guanylate cyclase.⁶⁸

Interestingly, compounds **24** and **25** can deaminate DNA bases. It is assumed⁶⁸ that the above effects are due to the release of nitric oxide. A group of *N*-nitroso compounds **26**–**28** acting as nitric oxide donors have been studied.³⁶

For *N*-nitroso-*N*-hydroxylaniline **26**, an oxidation reaction with involvement of oxyhemoglobin **29** has been suggested.

The scheme of oxidation of compound **26** without the involvement of hemoglobin is given below:⁶⁹

For compounds of the type **26**, a peroxidase-catalysed enzymic oxidation is observed. The oxidation can also be modelled electrochemically.⁷⁰

In both cases nitric oxide is formed.

Some studies have dealt with the analysis of derivatives of *N*-nitroso-*N*-alkoxy compounds.^{69–71} Thus compounds $\text{RN}(\text{NO})\text{OR}'$ (**30**: $\text{R} = \text{R}' = \text{Me}$; **31**: $\text{R} = \text{R}' = \text{Et}$) can effectively generate nitric oxide, which may be the reason for their far greater cancerogenic activity⁷¹ in comparison with, *e.g.*, *N*-nitrosodimethylamine.

These studies are close to those on the oxidation of compounds with the N–O bond.^{72–76} This group includes nitrones giving nitric oxide upon photolysis⁷³ and activating SGC, nitroxyl (HNO) producing biological effects similar to those of NO,⁷⁴ peroxynitrite (ONOO^-), which gives NO upon interaction with glucose and causes the relaxation of vessels inhibited by oxyhemoglobin,⁷⁵ and *N*-hydroxybenzenesulfamide **32**,⁷⁶ Piloti's acid, which upon oxidation releases NO (presumably this process occurs *via* an enzymic route).⁷⁶ Oximes (*e.g.*, **33**–**35** derived from quinuclidone-3) have turned out to be interesting objects for the study of nitric oxide generation.

Using an indirect electrochemical method [$\text{K}_3\text{Fe}(\text{CN})_6$ and $\text{K}_4\text{Fe}(\text{CN})_6$, see above], it has been established that the majority of these compounds generate NO upon oxidation.^{44, 77} The highest yield of nitric oxide has been observed for compounds **34** and **35** (in both cases, Ar is *o*-hydroxyphenyl); *i.e.*, the proximity of the oxime fragment and the phenolic hydroxyl favours the formation of NO. It is essential that these compounds are oxidised to NO even by atmospheric oxygen. These oximes activate SGC and have hypotensive action. A conclusion has been made⁴⁴ about the possible role of the phenolic *ortho*-hydroxyl group as nitric oxide carrier, which stabilises NO in the form of *O*-nitrites or *O*-nitrates. The interaction of NO with phenolic antioxidants and phenoxyl radicals that can be regarded as nitric oxide carriers in biological systems is documented.⁷⁸ The oxidation of compound **36** containing both the oxime fragment and the nitro group has been studied.⁷⁹

At pH 7.5, compound **36** rapidly transforms into the diketone (**37**) with the release of NO. The latter has been identified by EPR spectroscopy, colorimetric titration, and using a procedure based on the interaction with the tyrosyl residue of ribonucleotide reductase. Compound **36** is a potent vasodilating agent, it activates SGC and increases the level of intracellular cGMP. This study provides no direct data as to which of the groups (nitro group, oxime group, or both) make the main contribution to NO production.

There is experimental evidence that 5-nitrofurans and 5-nitroimidazoles form nitrosyl complexes of hemoglobin in the presence of ascorbic acid as reducing agent, *i.e.*, they released nitric oxide.⁸⁰ In conclusion, it is appropriate to mention that NO is formed in the photolysis of 2-methyl-2-nitrosopropane.⁸¹ Upon irradiation, this compound induces the relaxation of vessels, activates SGC, and, correspondingly, increases the cGMP level in biological solutions.

4. S-Nitrosothiols

Since *S*-nitrosothiols represent, perhaps, the most abundant and especially well-studied group of exogenous generators of nitric

oxide, it seems expedient to isolate them as a separate class of NO donors. Roy *et al.*³⁵ have proposed the main requirements for nitric oxide generators that confirm the expediency of a search for new drugs particularly in the *S*-nitrosothiol series. The reasons for this are: (i) simplicity of synthesis and the possibility of isolation of pure compounds in a stable (predominantly solid) form and (ii) capability for relatively fast degradation in aqueous solutions at physiological pH resulting in the release of NO without any redox activation. This decomposition occurs with quantitative liberation of NO and is not accompanied by the formation of toxic side products. A large group of *S*-nitroso compounds of the general formula **38** have been synthesised.³⁵

The stability of these compounds in solution has been studied, and their ability to generate nitric oxide was confirmed by several known methods. Quantitative determination of the half-life of *S*-nitrosothiols **38** in a phosphate buffer at pH 7.0 has been carried out: they vary from several minutes to tens of hours depending on the structure. It is believed that the formation of NO is based on homolytic cleavage of the S–N bond.

The production of NO is accompanied by the formation of the RS[•] radical, which is so unstable that it cannot be detected by EPR spectroscopy. If 5,5-dimethylpyrroline *N*-oxide is used as a trap, its reaction with the thiyl radicals yields stable paramagnetic species that can be detected by EPR spectroscopy.³⁵

The effect of structure on the stability of nitrosothiols has been ascribed to the contribution of the resonance structure **A** stabilising the molecule with respect to the homolytic cleavage of the S–N bond. The contribution of this structure increases with an enhancement of the electron-donor properties of the radical R (in these cases the stability of *S*-nitrosothiols increases also).

Thiyl radicals have been discussed by Feelish,⁹ who has demonstrated potential hazardous properties of these highly reactive compounds. They can not only undergo dimerisation, but also enter into other reactions, thereby giving compounds with unknown biological activity. Another potential danger from the use of *S*-nitrosothiols is the reaction of transnitrosation of SH groups of proteins. This reaction may cause irreversible modification of SH groups of enzymes and result in the formation of mixed disulfides with a partial or complete loss of enzymic activity. The problem of transnitrosation has been discussed in detail by Butler *et al.*,⁸² who have analysed the properties of *S*-nitroso-*N*-acetylpenicillamine **39** and *S*-nitrosoglutathione **40**.

Compounds **39** and **40** differ essentially in their chemical properties. The former is unstable; its decomposition to the corresponding disulfide and NO is catalysed by Cu²⁺. The latter is stable in solutions over many hours and are not affected by copper cations. Dicks⁸³ has pointed to the long induction period preceding the decomposition of compound **40** rather than its complete stability under these conditions. Nevertheless, *S*-nitrosoglutathione **40** is comparable in activity towards vascular relaxation with compound **39** and is more active as a platelet aggregation inhibitor. Compound **40** rapidly reacts with cysteine to give *S*-nitrosocysteine, an unstable compound, which rapidly generates nitric oxide.⁸² Thus, *S*-nitrosoglutathione **40**, which is relatively stable in solution, can produce NO at a high rate in the presence of cysteine. An alternative (and, seemingly, also fast) pathway of NO release from compound **40** is the enzymic pathway mediated by γ -glutamyl transpeptidase.

According to Park,⁸⁴ transnitrosation is the primary mechanism of the hypotensive effect of *S*-nitrosothiols. This viewpoint can be validated by the much lower rate of their hydrolysis relative to the development of the pharmacological effect. As for transnitrosation, it is a rather fast process. The same conclusion has been made by Mathews and Kerr.⁸⁵ Neuroprotective effects of *S*-nitrosothiols are caused by transnitrosation and, as stated by Arnelle and Stamler,⁸⁶ these processes occur with the participation of NMDA receptors (NMDA — *N*-methyl-D-asparagine). At the same time, neurodestructive effects of NO are probably due to its interaction with the superoxide anion (O₂^{•-}) resulting in peroxynitrite. It is conjectured⁸⁶ that the vasodilating, antiaggregating, and antimicrobial effects of *S*-nitrosothiols do not depend on the rate of NO release. Arnelle and Stamler⁸⁶ have considered the possibility of formation of such species as NO, NO⁺, and NO⁻. The amount of nitric oxide released from *S*-nitrosothiols has been determined by the rate of hemoglobin oxidation to methemoglobin. The high rate of transnitrosation has been attributed to the ability of nitrosothiols to act as NO⁺ donors, the rate of NO⁺ formation being higher than that of NO release. To study the NO⁻ release, the following model system has been used:

The fast formation of disulfides is accompanied by the release of hydroxylamine and N₂O, which is indicative of NO⁻ release. A conclusion is drawn from the experimental data that under physiological conditions *S*-nitrosothiols can act as NO⁺, NO, and NO⁻ donors. The authors advocate that the activity of these compounds is due not only to homolytic but also to heterolytic cleavage of the S–N bond. The papers dedicated to the synthesis of new, and analysis of the already known *S*-nitrosothiols are rather numerous.^{55, 87–92} Special mention should be made of the synthesis of *S*-nitrosocaptopril **41**.⁸⁸ This compound, which structurally represents a hybrid molecule, can influence both vital systems that maintain arterial pressure in living organisms

and can induce vasodilatation both through activation of SGC and inhibition of the angiotensin-converting enzyme (ACE).⁹³

Indeed, it has been shown experimentally that compound **41** possesses vasodilating properties and inhibits ACE and platelet aggregation. According to the authors, compound **41** can be used in the treatment of hypertension and various cardiovascular diseases; however, in our opinion, the clinical application of this compound is hardly possible because of its low stability.

5. NO Complexes with nucleophiles

One more group of compounds that can act as nitric oxide donors is represented by the so-called nonoates **42**, in which the ON–NO dimer is formally bound to the nucleophile through the nitrogen atom.^{94,95}

X = Et₂N, PrⁱNH;
Y = Na, NH₄, RR'NH₂.

These compounds are very stable as such, however, in solutions at pH 7.4 they are readily hydrolysed to give nitric oxide. In this case, like nitrosothiols, they do not require either reducing or oxidising agents for their hydrolysis. The rate of degradation is determined by the structure of the compounds and varies within a very broad range. Biological assays of this type of compounds have revealed that they are active vasodilating agents, platelet aggregation inhibitors, and regulators of cytochrome P-450 activity.^{39,96,97}

To localise the NO release in definite organs and tissues, the above system has been incorporated into a polymeric matrix. Various types of polymers have been synthesised, *e.g.*, by incorporation of Et₂N[N(O)NO][−]Na⁺ into polyethylene glycol, fusion of H₂NCH₂CH₂N[N(O)NO][−]CH₂CH₂NH₃⁺ with polycaprolactam, and polymerisation of H₂N(CH₂)₃N.[N(O)NO][−](CH₂)₃NH₃⁺ with dextran.³⁹ It has been established that the polymers containing the [N(O)NO][−] fragment and stored *in vivo* as localised sources of nitric oxide can slowly release NO at pH 7.0 and 30 °C. These polymers prevent platelet aggregation and inhibit cell proliferation *in vitro*.

Another pathway of NO release in the vicinity of a biological target is the creation of prodrugs incapable of releasing nitric oxide without preliminary metabolic transformation into the nonoate by enzymes specific for this particular cell target. To this end, the following alkyl derivatives have been synthesised:

These compounds can release nitric oxide in solution and exhibit hypotensive activity *in vivo*.⁹⁸

6. Heterocyclic derivatives

a. 1,2-Diazete-1,2-dioxides

This class of compounds has been studied relatively recently.^{41,99,100} Compounds of the **43** type are known to decompose in aqueous solutions on moderate heating at physiological pH values to give nitric oxide. These data have been obtained using polarography⁴¹ and EPR spectroscopy.¹⁰⁰

Electrochemical studies of a series of 1,2-diazete-1,2-dioxides **43** have revealed that the rate of NO release depends on the structure of the radicals and varies within a rather broad range. Compounds **43** are potent activators of SGC, manifest a noticeable spasmolytic effect *in vitro*, and effectively lower arterial pressure *in vivo*. In all cases studied (rate of NO generation, SGC activation, as well as spasmolytic and antihypertensive effects) there was a convincing correlation between the experimentally determined series of activities. The rate of NO formation is the determining factor in the manifestation of the above biological effects. The highest activity was observed with compound **43** [R¹ = Br, R²–R³ = (CH₂)₄, R⁴ = Me] and the lowest activity, with compound **43** [R¹ = R⁴ = H, R²–R³ = (CH₂)₅].

b. Furoxanes

A number of investigations have been dedicated to the study of the NO donor properties of furoxanes. It has been shown¹⁰¹ that the release of nitric oxide takes place in the reaction of furoxanes with thiols (Scheme 1).

Furoxanes activate SGC and enhance the coronary blood flow. According to Feelisch *et al.*,¹⁰¹ furoxanes can be regarded as prodrugs that exert their action *via* the NO/cGMP pathway. The thiol-dependent release of nitric oxide from furoxanes has been studied in detail with the interaction of 4-phenyl-furoxane-3-carboxynitrile **44** with cysteine and thiophenol as an example. Compound **44** activates SGC, produces strong vasodilating action, and demonstrates high antiaggregating activity. The yield of NO₂ formed upon oxidation of NO in the presence of 5 mmoles of cysteine is 14±2% (after 1 min), 29±1% (after 5 min), and 40±2% (after 1 hour), and in the presence of 0.5 mmoles of thiophenol it is 64±2% within 1 hour. The reaction of **44** with thiophenol has been studied in detail¹⁰² and is summarised in Scheme 2.

Compound **46** has been isolated in 20% yield, whereas isoxazole **47** formed from the intermediates **45a** ⇌ **45b**, in 60% yield. The experimental data provide an idea about the plausible

scheme of furoxane transformations leading to NO. A large series of biologically active furoxanes have been synthesised.^{103–105} No tolerance to 4-hydroxymethylfuroxane-3-carboxamide **48** has been noted.¹⁰⁴

In contrast with the above findings, Hecker *et al.*¹⁰⁵ have shown that the release of nitric oxide is not thiol-dependent. The lack of tolerance makes it possible to use furoxane derivatives in the treatment of cardiovascular diseases.¹⁰⁵ One more study¹⁰⁶ is dedicated to the synthesis of hybrid molecules, furoxane analogues of the known drug prazosin **49**, in which the furyl fragment has been substituted by the furoxanyl one (compound **50**).

Compounds **50** act primarily as antagonists of α_1 -adreno-receptors. Although their action is weaker than that of prazosin. However, at higher concentrations the ability of these compounds to release NO also has a part in the vasodilating effect. And, finally, worth noting is the study,¹⁰⁷ in which the cleavage of the furoxane ring upon electron impact mass spectrometry has been studied. The proposed fragmentation rationalises the formation of nitric oxide:

c. Sydnonimines

Another important class of heterocycles, for which the release of nitric oxide is characteristic under certain conditions, is represented by sydnonimines. Molsidomine **51**, one of the most potent antihypertensive drugs, belongs to this series.¹⁰⁸ Data on the high activity of this mesoionic heterocycle appear regularly in current literature (see, *e.g.*, Refs 55, 92, 109–113). Among compounds of this class, special mention should be made of the highly active nitric oxide donor, pirsidomine **52**, the biological activity of which is similar to that of isosorbide mononitrate, and the major metabolite of pirsidomine **53**.¹⁰⁹

Unlike isosorbide mononitrate, compounds **52** and **53** do not induce tolerance, which is consistent with the hypothesis on the difference in the action mechanisms of sydnonimines and nitrates. In contrast to nitrates and, presumably, furoxanes, the generation of NO by sydnonimines does not require thiols.¹⁰⁹

The high antithrombotic activity has been observed for sydnonimines with different substituents, *viz.*, *N*-*exo*-nitroso derivatives **54**¹¹⁰ and compounds having thiazine residues at position 3 **55**, **56**.^{111,113} It is noteworthy that the activity of compound **56** is somewhat lower than that of its morpholine analogue, molsidomine **51**.¹¹³

It is stated¹¹² that sydnonimines are prodrugs and that their antianginal effects are due to the release of nitrogen oxide: the first stage of formation of type **57** metabolites from molsidomine occurs fast in neutral media. The formation of compound **58** and NO is accompanied by oxygen uptake.

As expected, in the presence of oxyhemoglobin (the NO 'trap') or Methylene Blue (the SGC inhibitor) the biological activity of **63** and **64** drops drastically.

Most of the data presented herein concerning exogenous nitric oxide donors can be summarised in the Scheme 3.

Scheme 3

This scheme illustrates the possibilities of control of the nitric oxide level in the organism through the introduction of NO generators having specific action mechanisms. Another approach to the regulation of the nitric oxide level in organs and tissues is the inhibition of NO-S responsible for NO production.

IV. Inhibitors of NO-synthase

The foregoing sections dealt with the ways of the increasing the level of nitric oxide in organs and tissues under conditions of its insufficient production in living organisms. However, a number of pathological states, including cardiovascular diseases, infections, brain injuries, *etc.*, are accompanied by excessive release of NO. The undesirable toxicological effects of NO overproduction include extremal hypotension and/or cardiovascular collapse, cell injuries, and septic shock.¹⁰ Therefore, in some cases the necessity to inhibit NO-S has been mentioned. As above, the synthesis of nitric oxide is performed by NO-S isoforms.¹²⁴ Both c-NO-S and i-NO-S produce nitric oxide through the oxidation of the guanidine fragment of L-arginine by utilising molecular oxygen and NADPH as a cosubstrate. All the isoforms contain FAD, FMN, and heme iron as prosthetic groups and require BH₄ as a cofactor. Correspondingly, flavoprotein inhibitors can suppress the activity of NO-S. Thus the iodonium salts **65** and **66** and ebselenium (**67**), the selenium analogue of isothiazole, are potent inhibitors of NO-S.¹⁰

Ar = Ph, 2-thienyl

Arginine derivatives and related compounds are most commonly used as NO-S inhibitors. Since several reviews concerning approaches to the synthesis of NO-S inhibitors have been published recently,^{4,6,10} here we shall dwell only on some of the most

important and recent studies in this field. It should be mentioned, however, that the most important NO-S inhibitors are *N*^ω-methyl-**68** and *N*^ω-nitro-L-arginines **69**¹⁰ whose properties are still the subject of most intensive studies.^{125–129}

Thus compound **68**, the inhibitor of macrophage and i-NO-S, manifests its activity particularly through the alkylation of the enzyme.¹²⁵ It has been established that methylarginine **68**, similarly to aminoguanidine, inhibits NO-S and thus prevents the development of diabetic vascular functions.¹²⁶ Interestingly, methyl esters of the amino acids **68** and **69** manifest an analgesic effect that is ascribed to their influence on the central nervous system.¹²⁷ Inhibitors **68** and **69** potentiate the hypertensive effect of adrenaline.¹²⁸ Essentially, nitroarginine **69** induces strong arterial hypertension that can partly be prevented by administration of L-arginine, but not of D-arginine.¹²⁹ It was assumed¹³⁰ that compound **68**, being an irreversible inhibitor of macrophage i-NO-S, is subject to NO-S action according to the following two schemes:

Olken and Marletta¹³¹ and Feldman¹³² have synthesised two novel i-NO-S inhibitors, *viz.*, *N*^ω-allyl- **70** and *N*^ω-cyclopropyl-L-arginines **71**. It is interesting that whereas the former is an irreversible inhibitor, the latter is reversible, *i.e.*, the effect of compound **70** is similar to that of nitroarginine **69**. The reasons for such a difference in the effect of compounds **70** and **71** are unclear. A series of structural analogues of arginine as NO-S inhibitors have been described.^{21, 133–135} Thus i-NO-S inhibitors (substituted arginines and homoarginines) have been used in the treatment of systemic hypotension caused by pathological 'overproduction' of nitric oxide.¹³⁴ As i-NO-S inhibitors, *N*⁶-(1-iminoethyl)-L-lysine **72**, *N*⁵-(1-iminoethyl)-L-ornithine **73**, and *N*⁶-(1-iminoethyl)-D,L-homolysine (**74**) have also been examined. It has been found²¹ that compound **72** is a strong selective inhibitor of i-NO-S, whereas the ornithine **73**, which is also an active inhibitor of i-NO-S, does not possess any selectivity and affects c-NO-S with equal strength.

The synthesis of L-thiocitrulline **75**, L-homothiocitrulline **76**, and S-methylthiocitrulline **77** has been performed.¹³⁶ These analogues and derivatives of L-citrulline, the product of L-arginine oxidation in living organisms, are potent inhibitors of neuronal c-NO-S and i-NO-S. It is noteworthy that compound **77** is much more active in comparison with methylarginine **68**. The stereoselectivity of its interaction with the enzyme has been stressed again, and the activity of only L-enantiomers has been noted. D-isomers are fully devoid of the inhibitory activity.

Compounds **75** and **77** are potent pressor agents *in vivo*. The basic idea of the synthesis of this novel class of inhibitors was that the presence of a sulfur atom might result in their strong binding to the active centre of the enzyme in the vicinity of the heme iron, *i.e.*, this might enhance the interaction of the inhibitor with the enzyme. The experimental data seem to confirm this hypothesis.¹³⁶ One of the molecular fragments of arginine and related compounds responsible for the binding to NO-S is, undoubtedly, the guanidine moiety. Clearly, simple derivatives of guanidine and various amidines have also been tested as NO-S inhibitors.^{137–142} It has been shown that aminoguanidine is an NO-S inhibitor,^{126, 137} like N-arylguanidines¹³⁸ and cyclic guanidines or amidines of the general structure **78**.¹³⁹

Compounds **78** preferentially inhibit i-NO-S.¹³⁹ Isothioureas and cyclic guanidines of the type **79**, cyclic amidines (**80**), and related compounds^{140–142} are active inhibitors of NO-S.

X = O, S, NH; $n = 0–4$.

Some of the above-mentioned compounds can inhibit i-NO-S *in vivo*. Despite the great number of novel NO-S inhibitors having guanidine and amidine groups, the amino acid inhibitors **68**, **69**, and **73** are still most frequently used.^{143–146}

Novel inhibitors have been detected in the series of various heterocycles. They include 7-nitroindazole **81**,^{147–149} coumarin derivatives **82**,¹⁵⁰ and benzoxazole derivatives **83**.¹⁵¹ Compound **81**, possessing high analgesic activity, may be used as the 'starting material' in the elaboration of selective NO-S inhibitors acting on the CNS without any cardiovascular effect.

The data on inhibition of NO-S by compounds of various types considered in the above sections have been summarised in Scheme 4.

For the sake of completeness, it is necessary to stress once again that iron-heme-containing proteins and, correspondingly, heme-binding agents are inhibitors of NO-S. Thus carbon

monoxide is a good ligand for Fe^{2+} and a potent inhibitor of NO-S. Other heme-ligands of the cyanide type and even nitric oxide itself can play the role of inhibitors.^{10, 152}

V. Conclusion

Despite the fact that the enzymic formation of nitric oxide in vascular endothelial cells was discovered only in 1987, it follows from the above data that this biological mediator has aroused considerable interest among investigators, and the number of publications in this particular field of chemistry, biology, and medicine is steadily increasing. It can be emphasised once again that the present review deals primarily with the chemical and structural problems connected with the possibility of creating novel types of compounds able to generate or, contrariwise, inhibit NO production in the organism. Hence, a vast number of purely medical and biological problems, which are irrelevant to the subject of our discussion, have fallen outside the scope of this review. Also, the review gives relatively little information about such important problems as nitrate therapy; little attention is given to the well-known drug, sodium nitroprusside. Biological and clinical applications of the drug molsidomine have been described in less detail than they deserve. Problems of carcinogenicity and mutagenicity of N-nitroso compounds (*e.g.*, N-nitroso-N-methylurea and related compounds, such as N-methyl-N-nitroso-N'-nitroguanidine) have been described in only little detail. These problems have been considered in a number of the above-cited and other reviews^{1, 153–155} and the references cited therein.

In the contemplation of the above data, quite a large number of problems still remain unsolved, and even experimental data are often at variance with one another. This refers to differences in the pathways of chemical and enzymic oxidation of guanidine fragments; to the problems pertaining to the tolerance of nitrates that can be thiol-dependent or independent of the content of thiol compounds; to the demand for thiols upon NO release from furoxanes (for reference, see one of the most recent publications¹⁵⁶ in which it has been shown that some furoxanes can release NO in the absence of thiols, whereas for structurally related furoxane derivatives thiols are necessary); to the simultaneous release of nitric oxide and the superoxide anion; to the 'indirect' NO-generating effect of sodium nitroprusside, and so on.

Unquestionably, it is important to establish (although it is currently difficult to evaluate), to what extent the high reactivity of nitric oxide can influence some particular biochemical processes. For example, it has recently been established that NO oxidises dihydropyridines to pyridines.¹⁵⁷ When dihydropyridine

systems in the organism, such as NADH and NADPH, are considered, it is clear that this phenomenon needs special analysis.

After this review had been prepared for publication, a paper was published¹⁵⁸ that may have a great impact on the approach to problems related to NO formation from arginine and NO donors. It describes the discovery of 1*H*-[1,2,4]-oxadiazolo[4,3-*a*]quin-oxalinone-1 (SGC), which is the first direct inhibitor of NO-induced activation of SGC. The use of this compound presents indisputable interest, although it is still unclear what new avenues in the understanding of the role of NO it will open.

All these problems still await their solution. However, even now it can be predicted with certainty that the efforts aimed at creating novel generators of nitric oxide and specific inhibitors of NO-S isoforms hold much promise and represent a perspective trend in the search for novel effective drugs that has already turned out to be highly profitable in the theoretical sense. Further developments in this field may culminate in impressive achievements, including practical ones, even in the nearest future.

Abstract. The results of the studies of the structure and properties of non-crystalline (liquid and amorphous) oxide systems obtained using computer simulation methods are summarised. The models of simple oxides, homologous series of non-crystalline oxides and of binary and multi-component oxide systems are considered. The results of the simulation of the ion transfer are discussed. The ionic theory of oxides allows one to predict adequately the structural and thermodynamic properties of oxide systems except for the phosphate oxides and some other systems. The bibliography includes 222 references.

I. Introduction

Studies of the structure and properties of non-crystalline (liquid and amorphous) oxide systems obtained by powerful computer simulation methods, such as molecular dynamic (MD), static relaxation (SR), Monte Carlo (MC), and Reverse Monte Carlo are reviewed in this paper. General aspects of computer simulation have been discussed in detail in a number of reviews (see, for example, Refs 1–8) and will not be considered here. We confine ourselves to the analysis of specific applications of the above-mentioned methods to oxide systems.

The results of numerous experimental studies of oxide systems indicate a substantial contribution of ionic bonding to interatomic interactions. This is caused by the high electronegativity of the oxygen atoms. Nevertheless, the account of a covalent component is important in the simulation of structure and properties of the oxides. The covalent interaction is described in terms of three-particle potentials, which significantly increases the computational time required. Since ionic contribution cannot be neglected for oxide systems, the Coulomb interactions have to be considered as well. Construction of a model for an oxide with mixed ion and covalent bonding requires too many force parameters that are extremely difficult to calculate *ab initio*. Therefore, the models

have to be simplified. The choice of a model based only on the ionic interactions has significant advantages. Any doubts in the applicability of the ionic scheme were eliminated in a study, in which a purely ionic model of non-crystalline SiO₂ (charge of ions 4+ and 2–) was successfully built.⁹ The structure and energy of the oxide within this model were in good agreement with the experimental data.

Recently, the ionic model of non-crystalline oxides has found broad applications. Simulation of the properties of many simple and complex oxides as well as of related systems (in particular, oxyfluorides) has been performed. The aim of the present review is to discuss and analyse the results obtained in these studies.

II. Construction of models of oxide systems

1. Interparticle potentials in oxides

The applicability of the ionic theory for the construction of models of oxide systems is determined by a significant difference in the electronegativities of oxygen (3.5 according to Pauling) and the majority of metals (0.9 for Na, 1.0 for Ca, 1.5 for Al, *etc.*). For example, in CaO the difference in the electronegativities is ~2.5 and the ionicity of Ca–O bond is close to 76%. For SiO₂, the ionicity is ~51%. Somewhat simplifying the situation, one may therefore assign a formal charge of $-2e$ (where e is the electronic charge) to oxygen atoms, and $+2e$, $+3e$, $+4e$ to Ca, Al, and Si, respectively. In the case of an ionic bond, the interparticle potential is paired, and it is usually written in the form of the Born–Meyer potential or the Pauling potential (see, for example, Ref. 10). The Born–Meyer potential is written as:

$$u_{ij}(r) = Z_i Z_j \frac{e^2}{r} + B_{ij} \exp\left(-\frac{r}{R_{ij}}\right) - \frac{C_{ij}}{r^6} - \frac{D_{ij}}{r^8}, \quad (1)$$

where r is a distance between the centres of ions i and j , Z_i , Z_j are the charges of i th and j th ions, respectively (expressed in elementary charge units e), B_{ij} and R_{ij} are parameters accounting for the repulsion of the ionic shells, C_{ij} and D_{ij} are parameters accounting for the dipole-dipole and dipole-quadrupole interactions, respectively. A special form of the potential (1) is the Born–Meyer–Higgins potential (BMH)¹⁰ in which B_{ij} and R_{ij} are expressed through the ion radii r_i and r_j :

$$B_{ij} = b \left(1 + \frac{Z_i}{n_i} + \frac{Z_j}{n_j}\right) \exp\left(\frac{r_i + r_j}{R_{ij}}\right), \quad (2)$$

D K Belashchenko Moscow State Institute of Steel and Alloys (Technological University), Leninskii prosp. 4, 117936 Moscow, Russian Federation. Fax (7-095) 237 80 07, Tel. (7-095) 230 46 67
E-mail dkbel@misa.ac.ru

Received 12 March 1996

Uspekhi Khimii 66 (9) 811–844 (1997); translated by Ya Zubavichus

where $b = 0.211$ eV, n_i and n_j are numbers of electrons in the outer filled electron shells of the i th and j th ions, respectively (2 for Li, 8 for O, *etc.*). One of the important properties of the potential (1) is that it decreases at small distances for oppositely charged ion pairs. When $r \rightarrow 0$, the second term in the expression (2) approaches B_{ij} and the first term approaches $-\infty$. These potentials should be applied with care to prevent a probable collapse of the system (unlimited approach of ions) in the simulations. It was shown¹¹ that the collapse can occur when B_{ij} is less than a certain critical value ($B_{ij} < B_{ij}^{\text{cr}}$). This critical value for a M_mO_n oxide is defined by formula

$$B_{ij}^{\text{cr}} = -\frac{Z_i Z_j e^2}{0.5413 R_{ij}}. \quad (3)$$

Usually it is assumed that $R_{ij} = 29$ pm.⁹

However, the collapse may occur even for $B_{ij} > B_{ij}^{\text{cr}}$ in the simulations of strongly compressed systems, if the distance between oppositely charged ions becomes less than r_* , which is the position of the maximum of the potential (1) defined as

$$r_*^2 \exp\left(-\frac{r_*}{R_{ij}}\right) = -Z_i Z_j e^2 \frac{R_{ij}}{B_{ij}}. \quad (4)$$

The Pauling potential is written as:

$$u_{ij}(r) = \frac{Z_i Z_j e^2}{r} + \frac{B_{ij}}{r^n} - \frac{C_{ij}}{r^6} - \frac{D_{ij}}{r^8}. \quad (5)$$

Here n is a parameter ranging, as a rule, from 8 to 10. The Pauling potential approaches infinity when $r \rightarrow 0$, and hence collapse is impossible.

The values of the BMH and Pauling potentials for systems close to oxides (alkali metal halides) were first determined by Fumi and Tosi.^{10,12} The refinement of these parameters was performed according to the known experimental characteristics of the crystalline compounds, such as density, compressibility, and the energy of the system. The precision of the simulations with the BMH potential appeared to be higher than with the Pauling potential. Generally the terms that take into account the dipole-dipole and dipole-quadrupole interactions play a minor role in (1). For instance, the total energy for liquid KCl at 1045 K is -730.2 kJ mol⁻¹, and the contributions of the corresponding interactions are -26.5 kJ mol⁻¹ and -4.1 kJ mol⁻¹ (see Ref. 13). In oxide systems, these terms are even less important and therefore they are often neglected.

The parameters of the Born–Meyer potentials for crystalline MO oxides ($M = \text{Mg, Ca, Sr, Ba}$) were calculated from the values of cell parameters and dielectric constants.¹⁴ Pair potentials for these oxides and for SiO_2 , UO_2 , TiO_2 , Nb_2O_5 , and silicates were considered.¹⁵ The parameters of the interactions in $M\text{--O}$ pairs ($M = \text{Mn, Fe, Co, and Ni}$) were also estimated.¹⁶

Despite their simplicity, the potentials (1) or analogous potentials with the additional terms of the Morse type may be used for a description of crystal structures of quartz, cristobalite, boron oxide, as well as the structures of liquid oxides in systems like $\text{Na}_2\text{O--B}_2\text{O}_3$ and $\text{CaAlSi}_2\text{O}_8$ (anorthite).¹⁷

If the simulation does not require calculations of the energy of the system and related characteristics, then the knowledge of the force functions $F(r) = -du/dr$ is sufficient. In a series of studies (see, for example, Ref. 18) Pauling type force functions were applied:

$$F_{ij}(r) = \frac{Z_i Z_j e^2}{r^2} \left[1 + \text{sgn}(Z_i Z_j) \left(\frac{r_i + r_j}{r} \right)^n \right], \quad (6)$$

here the sgn is equal to $+1$ or -1 depending on the sign of the argument ($Z_i Z_j$) and the parameter n varies in the range from 8 to 10.

More complicated pair potentials similar to the Born–Meyer potentials were proposed for silica.¹⁹ Potential parameters were adjusted to give agreement with the experimental data on the stability of α -quartz, α -cristobalite, coesite, and stishovite crystals.

The interaction potentials for $M\text{--O}$ pairs ($M = \text{Ca, B, Al, Si, V}$) were calculated²⁰ using the ‘magic’ Mulliken formula,²¹ which takes into account the mixed ion-covalent character of bonding. The calculated dependences of the potentials on r were approximated by the Pauling expression:

$$U_{ij}(r) = \frac{Z_i Z_j e^2}{r} \left[1 + \text{sgn}(Z_i Z_j) \left(\frac{r_i + r_j}{r} \right)^n (n+1)^{-1} \right]. \quad (7)$$

For all oxides n was taken to be equal to 10. The calculated formal charges did not agree with the normal oxidation states of the metals:

Oxide	Z_1	Z_2	r_1/pm	r_2/pm
CaO	1.46	−1.46	102.0	133.0
B ₂ O ₃	2.34	−1.56	10.0	140.0
Al ₂ O ₃	2.55	−1.70	42.5	140.0
SiO ₂	2.30	−1.15	30.1	120.4
V ₂ O ₅	3.65	−1.46	40.1	133.0

where 1 refers to M and 2 refers to O.

The optimisation of Z_i and r_i according to results of quantum-chemical calculations of ternary systems including Ca, B, Al, Si, V, and O was also performed.²⁰ In particular, the values of $Z_{\text{O}} = -1.46$, $Z_{\text{Si}} = 2.92$, and $Z_{\text{V}} = 3.65$ were obtained. Further, the MNDO quantum-chemical method was applied for calculation of ion-covalent pairwise and three-particle interaction profiles in oxides of silicon, aluminium, phosphorus, *etc.*^{22–26} In a number of other studies, the selection of effective ion charges smaller than the standard oxidation state also allowed one to obtain reasonable agreement between the calculated and experimental structural data for non-crystalline oxides in the framework of the pair interaction model, which indirectly takes into account the mixed ion-covalent character of bonding. However, the use of this model of the interpretation of ‘intermediate’ bonding may prevent calculations of the thermodynamic properties.

The Born–Meyer potentials were used in a simulation of the structure and properties of LiNbO_3 and KNbO_3 (see Ref. 27). For all ion pairs it was taken that $B_{ij} = 1822$ eV and $R_{ij} = (r_i + r_j)/12.36$. Ionic charges and radii were adjusted to give the best agreement with the experimental phonon spectra. For oxygen atoms in KNbO_3 , it was necessary to take two r_i values in two different sites in the unit cell. The formal charges Z_{O} strongly deviate from the common value of -2 . For $\text{Li}_2\text{O--B}_2\text{O}_3$ system, the BMH-type pair potentials were used. Ionic radii were chosen equal to 93 (Li^+), 74 (B^{3+}), and 142 pm (O^{2-}); the charges were equal to 1, 3, and -2 , respectively.²⁸

Interparticle interactions in the covalent bonding model are usually described on the basis of three-particle potentials. The energy of the system is written as

$$U = U_0 + C_2 \sum_i \sum_j u(r_i, r_j) + C_3 \sum_i \sum_j \sum_k v(r_i, r_j, r_k), \quad (8)$$

where U_0 is the energy of the ideal crystal,[†] C_2 and C_3 are coefficients, $u(r_i, r_j)$ and $v(r_i, r_j, r_k)$ are bond stretch and angle distortion terms, respectively. The C_2 and C_3 coefficients were chosen to give the best agreement of the simulated and the experimental characteristics of the oxide (vibrational spectra and internuclear distances). The simplest form for $u(r_i, r_j)$ and $v(r_i, r_j, r_k)$ functions was suggested by Keating,²⁹ *viz.*,

$$u(r_1, r_2) = |\mathbf{r}_1 - \mathbf{r}_2|^2 - d_0^2,$$

where $\mathbf{r}_1$ and $\mathbf{r}_2$ are the radii-vectors of neighbouring ions, and d_0 is the equilibrium bond length, and

[†] The ideal crystal means the crystal with the equilibrium values for all bond lengths and angles; the equilibrium bond angle depends on the type of the crystal lattice.

$$v(r_i, r_j, r_k) = [\cos\theta(ijk) - \cos\theta_0(ijk)]^2, \quad (9)$$

where $\theta(ijk)$ is the angle between $i-j$ and $j-k$ bonds, and $\theta_0(ijk)$ is the corresponding equilibrium angle. The summation in (8) is over the nearest neighbours of the central particle. The three-particle potential is especially often used for silicon (see, for example, Ref. 30). In ionic bonding model, the choice of the initial state for a model is of little importance (it could be either a crystal lattice or a random ionic system), but in the 'covalent version', special initial state should be chosen with fixed coordination numbers (for instance, 4 for Si and 2 for O). This selection of the initial state is usually required in simulation of loose systems by the Reverse Monte Carlo method.

For silica³¹ the pairwise Mie potential was used.³²

$$u = ar^{-n} - br^{-m},$$

where $10 \leq n \leq 12$ and $4 \leq m \leq 6$; and for a three-particle contribution, the Axilrod–Teller potential was applied, which describes the interaction of three dipoles:³³

$$v = c(3\cos\alpha\cos\beta\cos\gamma + 1)(r_1r_2r_3)^{-3},$$

where r_1, r_2, r_3 are the sides of a triangle formed by dipoles, α, β, γ are its angles, and c is a fitting parameter. The coefficients for low- and high-temperature modifications of cristobalite and quartz were adjusted according to the experimental data for SiO_2 . For the Si–Si pairs, the data for pure Si were used and the $u(r)$ potential was chosen in the Lennard–Jones form. A model of pure silicon, which is stable in the diamond lattice, was obtained as a result. For the O–O pairs, the properties of O_2 and O_3 molecules (Lennard–Jones potential) were used. Within this scheme, the dissociation energy of oxygen molecule obtained was in agreement with the experimental data, but the stable configuration for O_3 appeared to be linear rather than triangular. For the Si–O pairs, the Lennard–Jones potential was also used. Other parameters of the model were refined to achieve agreement between the calculated and the experimental results for the properties of the crystalline silica. *Ab initio* potentials were used³⁴ to describe the lattice parameters and melting points of the MgO , Mg_2SiO_4 , and MgSiO_3 oxides.

In a number of studies, combined potentials were used that take into account both ionic and covalent contributions in oxides. A combination of the Keating potential (9) for the triatomic combination that included Si and O, and the Lennard–Jones potential for Na–Si and Na–O pairs were used to simulate Na_2O – SiO_2 glasses.³⁵ A similar approach was utilised to simulate glasses of the Na_2O – B_2O_3 type (see Ref. 36). For O–B–O and O–B–B triatomic combinations, the three-particle potential was selected, and for pairs including Na atoms the pairwise Born–Meyer potential (1) was chosen.

Data discussed above show that the choice of the interparticle potential is arbitrary to some extent. After this choice, the values of parameters of the potential can be determined quite accurately from the properties of a crystal or liquid. The more complicated the form of the potential, the more difficult the determination procedure of its parameters and the more specific the potential itself.

2. Specific features of model construction for oxides

If a bulk phase rather than a small cluster is under consideration, the models are placed in the basic cube with periodic boundary conditions, the calculations of the Coulomb terms of the energy and interaction forces is to be done by summing according to Ewald, taking into account all particle pairs in the cube (see, for example, Refs 6, 13, 37, and 38). The procedure of Ewald summation gives high accuracy, but it is time consuming. Thus, some approximations were proposed which described not only spherically symmetrical terms, but also cubic symmetry corrections. For example, the Hansen approximation³⁹ represents the interaction energy in the form of exponential-polynomial series giving an error of about 0.1%. Attempts to restrict the Ewald sums by spherically symmetrical part of the potential generally

lead to substantial losses in accuracy,^{40,41} though to more rapid calculations.

For construction of models at temperatures $T > 0$, MD and MC methods are used. Models of amorphous phases at $T = 0$ K can be adequately built with the algorithm of Continuous Static Relaxation (CSR).⁴² In this algorithm, the particles are shifted along the overall force by a certain value on each step. The magnitude of the shift is chosen so as to provide an efficient system relaxation. Initial shift may be large (for instance, 50 pm), but as the equilibrium state is approached it gradually decreases to ~ 0.1 – 1 pm. The shift should be decreased in the case when the monotonic decrease in the potential energy of the system ceases. The CSR method has the same disadvantages as MD: it does not guarantee that the global energy minimum is reached, however at low temperatures it allows one to reach substantially more stable states than the MD method.⁴²

III. Main structural characteristics of non-crystalline systems

The main structural characteristics of non-crystalline multicomponent systems are partial pair correlation functions (PPCF) $g_{ij}(r)$, which give the probability of occurrence of a pair of i and j particles at a distance r . They are normalised to give $g_{ij}(r) \rightarrow 1$ when $r \rightarrow \infty$. These functions are directly calculated in MD and CSR methods. The distribution of azimuthal $\theta(\text{BAC})$ angles for B–A–C three-atomic systems in which B and C atoms are the closest neighbours of the central A atom can be also calculated. These distributions are especially informative for loose systems with chain or network structures. Construction of Voronoi polyhedra^{43,44} for loose systems is of little interest due to their high diversity; none of the polyhedra type is more abundant in these systems.

Analysis of polymerisation processes is performed by building up bound groups, which allows one to reveal complex ions such as SiO_4^{4-} , $\text{Si}_2\text{O}_7^{6-}$, etc., which are formed in silicates as time-stable moieties. In the search for the bound groups, the Si–O distance (r_c) should be defined. This distance determines the closest neighbours of the central particle and usually coincides with the first minimum position of the corresponding PPCF. The cyclic part of the structure can be found and the distribution of rings along the overall structure can be calculated in a similar way. The cycle included only neighbouring particles at distances not longer than r_c .

Topological looseness of a system can be characterised by two parameters, viz., ρ_1 and s .⁴⁵ The parameter ρ_1 is defined as the mean height of the first peaks in the PPCF.

$$\rho_1 = \frac{\sum X_i X_j r_1(ij)}{d_0}, \quad (10)$$

where X_i and X_j are the ionic parts for the i th and j th particles, respectively, $r_1(ij)$ is the position of the first maximum in the PPCF of the ij pairs, summation is done over all pairs of particles, and $d_0 = (V/N)^{1/3}$, N is a number of particles in the volume V . Topologically dense systems (simple liquids, liquid and amorphous metals, non-crystalline alkali metal halides, etc.) have $\rho_1 = 1.08 \pm 0.02$ and loose systems have $\rho_1 < 1.05$. For the loosest systems, such as amorphous carbon, the ρ_1 value is 0.608.⁴⁶

The second parameter is defined by ratio $s = g_1/g_{1d}$, where g_1 is a mean value of the first maxima heights of the PPCF and g_{1d} is the corresponding value for a dense system calculated according to the widths of the first maxima of the PPCF.⁴⁵ Topologically dense systems have $s \approx 1$, while for loose systems $s > 1$.

There are a number of other physicochemical characteristics of the systems considered, which are often studied by computer simulations. They include self-diffusion coefficients of particles, viscosity, autocorrelation functions of velocities, flows, etc., which allow calculations of vibrational spectra and their comparison with the experimental data on elastic and inelastic scattering of

radiation. Studies of this kind for oxide systems are relatively rare (see, for example, Refs 1–6).

The role of Coulomb interactions in the structure formation and its influence on some properties of non-crystalline ionic systems were investigated.^{47,48} LiCl–KCl eutectics were analysed⁴⁷ with Coulomb interactions ‘switched on’ and ‘switched off’ (the BMH potentials were used). It was demonstrated that for a neutral system the positions of the first maxima of the PPCF for all pairs depend on the particle size and increase on going from Li to K. Taking account of the Coulomb interactions (for the same volume) results in a drop of pressure and a decrease in self-diffusion coefficients by a factor of 2–5 and an increase in lifetime of the first coordination spheres of Li and K by a factor of 1.5–3.

Gradual changes in the structure and the thermodynamic properties of a liquid on going from the ideal gas state to the ionic model state of an MO oxide were considered.⁴⁸ The density of a system corresponded to that of liquid MgO. Particle interactions were described by Eqn (1) with the variables $B_{ij} = B$ and $Z_1 = -Z_2 = Z$. The influence of these parameters on the shape of PPCF, coordination numbers (CN), topological characteristics, and thermodynamic properties was considered. It was established that the growth of B leads to a monotonic increase in the PPCF peak heights. If $B < 600$ eV and $Z = 0$, the structure of the liquid appeared to be loose ($\rho_1 < 1.01$). On going from the ideal gas state to an MO system with neutral particles at constant volume and temperature, the entropy decreased by $3.43Nk$ (where N is the number of particles in the model, k is the Boltzmann constant). On further transition to the ionic system with $Z = 2$, it decreases additionally by $1.76Nk$. Therefore, the Coulomb interactions give a somewhat smaller contribution to the entropy of a liquid than the repulsion of ionic shells.

IV. Models of simple non-crystalline oxides

M₂O and MO oxides do not form glasses on ordinary cooling of liquids. Diffraction studies (hereinafter, X-ray and neutron diffraction methods are meant) of these liquid oxides, to our knowledge, have not been performed. Oxides of M₂O₃ (B₂O₃, Al₂O₃), MO₂ (SiO₂, GeO₂), M₂O₅ (P₂O₅, Nb₂O₅, Ta₂O₅), and MO₃ (WO₃) types have been intensely studied by the methods mentioned. The number of studies of silica and boron oxide is especially large.

1. Models of silica

According to diffraction data,^{49–51} liquid and amorphous SiO₂ have the structure of a tetrahedral network with the coordination number for Si–O pairs $z(\text{Si–O}) = 4$. The structural element of the network is a nearly tetrahedral complex SiO_4^{4-} , the adjacent tetrahedra are attached to each other through the shared vertices so that oxygen atoms have coordination numbers $z(\text{O–Si}) = 2$. The most serious defects in this structure are silicon atoms with coordination number $z(\text{Si–O}) = 3$.⁵²

The first ionic model of SiO₂ that used the Born–Meyer pair potentials was constructed in 1976.⁹ The charges of Si and O were equal to 4 and –2, respectively. The model contained 162 ions in the basic cube with periodic boundary conditions. The MD method with Ewald’s account for the Coulomb interaction was applied. The B_{ij} parameters of the potential (1) for Si–Si, Si–O, and O–O pairs were equal to 2055.4, 1729.5, and 906.5 eV, respectively. First, heating of the system up to 6000 K was simulated in order to accelerate the diffusion of particles. After relaxation, cooling of the system to 300 K was simulated. In this way, a model of glass-like silica was obtained. The PPCF for a model of SiO₂ obtained with similar potentials⁵³ are shown in Fig. 1. The position of the first peak for Si–O pairs is ~ 162 pm, which is in accordance with the experimental data.^{49–51} It is noteworthy, that the energy[‡] of the model ($-12\,240$ kJ mol^{–1}

Figure 1. Partial pair correlation functions for the models of amorphous silica at 0 K (CSR method).

The curves are shifted along the ordinate axis; numbers denote pairs of ions (1 states for Si, 2 for O).

relative to ions at infinite distance) is very close to the real value ($-13\,300$ kJ mol^{–1}). This means that the ionic model describes the real situation adequately.

Ion models containing 375 and 3000 ions in the basic cube were constructed.^{54,55} Simple force functions in the form (6) were applied. Values of $Z_1 = +2.272$ and $Z_2 = -1.136$ had to be chosen to achieve agreement with the diffraction data. First, relaxation of liquid SiO₂ at 3000–7000 K was simulated by the MD method. Subsequent cooling to ~ 1500 K resulted in a glass-like state with the structure of a tetrahedral network. Model PPCF were in good agreement with the X-ray data on the peak positions. It was demonstrated that at 300 K the distribution of O–Si–O azimuthal angles has a maximum at $109.5 \pm 10^\circ$ and that of Si–O–Si at $151 \pm 18^\circ$. The structure of SiO₂ is loose and contains cavities (pores) with a mean radius of 93 pm. Jumps in heat capacity, pressure, and self-diffusion coefficient observed for the model at ~ 1500 K were attributed to a glass transition.

An autocorrelation function of velocities and, from this function, density of vibrational states, were calculated for amorphous silica.⁵⁵ However, no agreement with the experimental data on neutron scattering was achieved. It was found⁵⁶ that the Keating potential (9) matches best to a reconstruction of the vibrational spectrum. Good agreement with the experimental data was also obtained for a model with 750 particles.⁵⁷ The calculated vibrational spectra for Si⁴⁺ and O^{2–} ions⁵⁸ differ somewhat from the measured ones.

The statistics of pore distribution and the character of their aggregation into the bigger cavities (‘trees’) in amorphous silica were investigated on a model composed of 648 atoms.^{59,60} Pore radii appeared to be in the range of 18–183 pm. A series of overlapping pores was considered to be a tree. It was demonstrated that the number of ‘trees’ decreases rapidly with the increase in a pore number (N) in a ‘tree’ ($N = 3–20$). The longest trees have approximately linear shape.

The presence of pores in the structure of silica plays an essential role. Ionic admixtures occupying these pores may enlarge their sizes and affect density fluctuation of the silicon-oxygen network. The appearance of a first sharp diffraction peak in structural factor of silica at magnitude of the scattering vector of $K \approx 15$ nm^{–1} was explained by the presence of pores.⁶¹ This assumption was examined⁶² by the MD simulation of (MO)_x(–SiO₂)_{1–x} (M = Li, Na) solutions with $x = 0.18–0.67$. Each model contained 216 Si particles. Admixture atoms occupied the pores of the silicon-oxygen network. The intensity of the first sharp diffraction peak increased linearly as the Li atoms concentration increased and decreased on addition of sodium. This

‡ Hereinafter the following notations will be used in the discussion: E , E_{coul} , E_{kin} , E_{sh} , which stand for the total, Coulomb, and kinetic (thermal) energies and energy of repulsion of electron shells, respectively.

behaviour is due to the ratio of neutron scattering lengths on pores and impurity atoms.

A model of amorphous SiO₂ (246 ions) was also constructed by the CSR method.⁶³ Later, models of liquid and amorphous silica containing 498 ions each in the basic cube were constructed.^{53, 64–66} The pair potentials (1) were used (without the two last terms) with the values of $B_{11} = 0$, $B_{12} = 1729.5$, $B_{22} = 1500$ eV, and $R_{ij} = 29$ pm. Coulomb interactions were taken into account by the Ewald–Hansen method. First, a heating of the system up to 6000–9000 K was simulated to reach the equilibrium structure and then the temperature was lowered to 2000 K. The length of MD-sweeps was 500–1000 time steps (one time step is 2.04 fs). The values of the total energy for models of SiO₂ with different numbers of particles (n) at $T = 0$ K obtained in different studies (scaled for equal B_{ij} coefficients) are compared below.

$-E/\text{kJ mol}^{-1}$	n	Ref.
12245	162	9
12487	246	63
12414	498	53

For the two last models, the energy differs by only 0.58%, which exceeds insignificantly the computational error. In another study,⁹ the energy is higher by ~ 200 kJ mol⁻¹, i.e. this model is less stable. The differences may be caused not only by the different number of particles, but also by a different degree of approach of the system to the equilibrium.

Table 1 shows the characteristics of silica calculated at 0 K and 2000 K and those found experimentally at 300 K. It is clearly seen that the ionic model of SiO₂ with the potentials (1) and (2) allows one to obtain altogether reasonably good agreement with the experimental results. Coordination numbers of Si⁴⁺ ions are distributed as follows:

$z(\text{Si}-\text{O})$	3	4	5
Number of Si ⁴⁺ ions	7	152	7

Thus, $\sim 8.4\%$ of silicon atoms have a coordination number (CN) equal to 3 or 5, but the majority of Si atoms are surrounded by four oxygen atoms. In the real non-crystalline silica the number of 'defective' silicon ions is much less. Coordination numbers of 4 and 2 were determined by Della Valle and Andersen.⁶⁷ The mean value of O–Si–O angle in the models is close to the tetrahedral (109.5°). Therefore, the structure of silica is a tetrahedral network. According to the values of the topological parameters ρ_1 and s , this structure is rather loose. If a volume of silica is contracted by a factor of ~ 2.5 , then the ρ_1 value becomes equal to 1.08 and the structure turns dense, similar to the structure of metal glasses.¹¹

Models of liquid silica at temperatures of 2100 K and 6000 K and densities 2.2–4.0 g cm⁻³ were constructed.⁶⁸ Coulomb interactions were taken into account by the Ewald summation. The p – V isotherms, structural characteristics, self-diffusion coefficients of ions, density of vibrational states, and IR absorption spectra were calculated. A study of SiO₂ structure at 6000 K and pressures up to 35 GPa by the MD method indicated⁶⁹ an increase in ordering of the melt structure and in the coordination

numbers with the increase in pressure. It was demonstrated that compression of the glass noticeably changes the ring statistics.⁷⁰

The existence of a close correlation between ρ_1 and s parameters and the trend of the system to glass formation was proposed.^{11, 53} Indeed, the looser the system, the more difficult the crystallisation process (even merely for geometrical reasons). The factors governing the glass transition are evidently kinetic ones. There is also a thermodynamic aspect associated with the driving force of the crystallisation (difference in the Gibbs energies of non-crystalline and crystalline phases). However, for a number of loose structures with $\rho_1 < 1.0$ there is a regularity, which states that a decrease in ρ_1 results in easier glass formation. In particular, low value of ρ_1 (~ 0.9) is the reason for easy glass formation by silica on ordinary cooling in air.

In order to investigate the size effects, big models of amorphous silica with numbers of ions 648, 5184, and 41 472 and density of 2.2 g cm⁻³ were constructed using the MD method.⁷¹ Pair potentials of the Pauling type, but with shielded Coulomb interactions and including ion polarisability, were used. In addition, the three-particle interactions were introduced by the method of Stillinger and Weber.⁷² As a result, 19 potential parameters had to be adjusted. Heating of β -cristobalite up to 12 000 K and its gradual cooling to 300 K were simulated. The calculated structural factor (SF) of the model was in very good agreement with the data on neutron scattering. The agreement for PCF was also good. It was demonstrated that the size of the system does not affect the PPCF shape of the model, although structural factors differ slightly in the region of the scattering vectors of 15–55 nm⁻¹. The height of the first distinct peak of SF at the scattering vector $K = 15$ nm⁻¹ increases slightly with increase in the size of the system (from 1.25 to 1.48) and for $N = 41$ 472 it is in excellent agreement with the experimental value. The density of vibrational states in SiO₂ was calculated⁷¹ by diagonalisation of the dynamic matrix.⁷³

Destruction of amorphous and crystalline silica have been simulated.⁷⁴ Models of porous silica with different densities were also investigated.⁷⁵

2. Models of boron oxide

According to diffraction analysis data,^{49, 51, 76, 77} amorphous B₂O₃ has a layered structure with average CN of B–O pairs equal to 3. The first peak of the total PCF (TPCF) for X-ray radiation, which corresponds to B–O pairs, is located at 137–138 pm. The second peak corresponds to O–O pairs (237 pm). An isosceles triangle with sides of 138, 138, and 237 pm contains the obtuse angle of *ca.* 120°. Therefore, BO₃ groups have to be almost planar triangles. These triangles are fused by shared vertices (oxygen atoms). In the glass-like boron oxide, the presence of boroxol B₃O₃ rings with angles inside the ring of $\sim 120^\circ$ was proposed.⁵⁰ Addition of Na₂O to B₂O₃ leads to an increase in coordination number of boron from 3 to 4 and to a decomposition of the initial structure.⁴⁹

The structure of the B₂O₃ glass was also investigated by NMR method using ¹¹B isotope (see Ref. 78). Boron sites of two types with ratio 2:1 were observed. The first type was assigned to boroxol rings and the second one to BO₃ groups; and these structural elements are present in equal ratios. O–B–O angles for these two configurations are similar. However, the chemical shifts for the sites of two types are different due to the longer B–O bonds in the rings as compared to BO₃ groups.

Basing on NMR data and model calculations of the correlation functions, it was shown^{79, 80} that the B₂O₃ glass can contain more extended elements of local ordering than the BO₃ groups and boroxol rings, in particular, B₃O₇, B₃O₈, B₄O₉, B₅O₁₀, B₅O₁₁, and B₅O₁₂ in which the boron atoms may have CN of 3 and 4. In this case, simulations give a glass density close to the experimental value which could not be achieved using purely boroxol model.

It should be taken into account that nanometer-scaled structural inhomogeneities revealed in real glasses or melts by, for example, small angle scattering cannot be reproduced on relatively small models with the basic cube edge of ~ 2 nm. Using this

Table 1. Calculated and experimental parameters for ionic models of silica.

method, structures of B_2O_3 (200–270 °C) and of a series of alkali borates and silicates systems were studied.^{81,82} In the case of B_2O_3 , domains with an average size of ~ 1.5 nm and with densities lower than in the surrounding matrix, were found. In alkali borate glasses the inhomogeneities are due to several reasons, viz., thermal density fluctuations, structural inhomogeneities, supercritical concentration fluctuations, and peculiarities of the fusion of high-alkali structural complexes.

Models of amorphous boron oxide were constructed.^{18,83–86} Force functions (6) were introduced for the boron oxide description.^{18,83,84} The parameters were adjusted to obtain the structure with planar triangular BO_3 fragments. The models composed of 320 ions were relaxed during 1000 steps at 6000 K. The diffusion processes in the system occurred very slowly. This could be accelerated by decreasing the ion charges. Two experiments with the models composed of 192 and 1920 ions were carried out. For both models, the temperature was gradually decreased from 2000 to 300 K at constant volume. The energy and pressure decreased during the cooling, and the temperature dependencies of both characteristics could be represented in the form of two linear regions. If the intersection point is identified as the glass transition point and its actual value (~ 540 K) is taken into account, the estimates for the effective charges are $Z_1 = +1.125$ and $Z_2 = -0.75$.

Analysis of the models demonstrated that the values of the azimuthal O–B–O angle lie in the range $119 \pm 6^\circ$ and of the B–O–B angle, in the range $154 \pm 20^\circ$. The rings composed of six and more B atoms predominated in the structure and the boroxol rings B_3O_3 were absent. Almost ideal, centred BO_3 triangles linked through the vertices form an infinite system of layered elements and twisted ribbons.

An attempt to decrease the width of the B–O–B angle distribution in the model of B_2O_3 using a special algorithm was undertaken.⁸⁷ To this end, the values of B–O and B–B bond lengths were fixed at 138 and 239 pm ($239 = 138\sqrt{3}$), respectively. The model comprised 1680 ions. A decrease in temperature from 6000 to 300 K was performed in 5000 steps, 1 fs each. At 300 K, the energy was equal to -2950 kJ (g-at.)⁻¹ instead of -2975 kJ (g-at.)⁻¹ without fixing the bond lengths. The heat capacity of the model with the fixed bond lengths was equal to 10.3 J (g-ion K)⁻¹ instead of 24.5 J (g-ion K)⁻¹ with the usual algorithm. The final structure of the glass did not contain the six-membered boroxol rings. Therefore, the mere fixation of B–O–B angles (120°) does not lead to the formation of these rings. The structure of boron oxide is a result of a fusion of BO_3 triangles by shared vertices. The planes of neighbouring triangles are non-coplanar, and the most probable angle between them is 90° . It was shown⁸⁵ that a decrease in the rate of cooling in the simulation by six orders of magnitude leads to an increase in the glass density, but it hardly affects the ordering of the structure.

Models of liquid and amorphous B_2O_3 were also constructed.^{64,88} The models comprised 500 ions in the basic cube. The potentials (1) with the account for the Coulomb interactions according to Ewald–Hansen³⁹ were applied. The potential parameters were as follows: $Z_1 = +3$, $Z_2 = -2$, $B_{11} = 0$, $B_{12} = 800$ eV, $B_{22} = 1500$ eV, and $R_{ij} = 29$ pm. Characteristics of B_2O_3 calculated for 0 K and 2000 K and the experimental values are shown in Table 2.

Partial pair correlation functions for the model of liquid B_2O_3 at 1473 K are depicted in Fig. 2. Simulated $r_1(ij)$ distances are in very good agreement with the experimental data. Coordination numbers were the same as in Ref. 18: $z(B-O) = 3$ and $z(O-B) = 2$ (with the closest neighbour sphere radius of 200 pm). The distributions of the O–B–O and B–O–B azimuthal angles are Gaussian ($116 \pm 10.3^\circ$ and $154.2 \pm 12.2^\circ$) and are similar to those found earlier.¹⁸ Structural characteristics of the liquid oxide at 2000 K differ only slightly from those calculated at 0 K (see Ref. 64). Topological characteristics of the models indicate the looseness of the structures of both liquid and amorphous boron oxide. It is less dense than the structure of silica. The basic

Table 2. Calculated and experimental parameters of B_2O_3 .

structural elements are almost planar BO_3 groups fused through shared vertices. In the model of liquid B_2O_3 four four-membered, five six-membered, and seven eight-membered rings were found.

The molar volume for the model of amorphous B_2O_3 is close to its actual value. However, the calculated atomisation energy for the model is 1383.1 kJ mol⁻¹, while the experimental value⁸⁹ for B_2O_3 crystals is 2737.1 kJ mol⁻¹. The difference between these values is 7.8% of the total energy and can not be attributed to the amorphisation energy of crystal. Probably, it indicates the greater contribution of covalent bonding in boron oxide. The value of energy at 300 K ($-14\,875$ kJ mol⁻¹)⁸⁷ is substantially higher than that found in other studies.^{64,88}

New interparticle potentials for boron oxide were proposed;⁹⁰ their parameters were adjusted using the method of linear programming. For better description of the properties of various crystal phases, terms depending on CN were included. This method allowed one to predict new stable polymorphous forms of crystalline B_2O_3 with a high content of the boroxol rings (up to 100%). These potentials were applied for the construction of a B_2O_3 glass model with an increased concentration of these rings.⁹¹ Seven different potentials (including three-particle ones) were used⁹² for construction of an MD model of B_2O_3 (424 particles). Structures of the models proposed appeared to be similar to each other and were close to the real one. Nevertheless, the dynamic properties of the system (vibrational modes) were reproduced correctly only in the case when the three-particle contributions were taken into account.

A process of glass formation in boron oxide and some borates on cooling from a liquid state was investigated using MD method.⁹³ The properties of the phase were described with Prigogine–Defay parameter (γ), which establishes the correlation between the glass transition point and the ordering parameters.⁹⁴ For the system studied $\gamma > 1$. It was shown, that the formation of B_2O_6 groups results in a decrease of γ , and the formation of groups

Figure 2. Partial pair correlation functions for the model of liquid B_2O_3 at 1473 K.

The curves are shifted along the ordinate axis; numbers denote pairs of ions (1 states for B, 2 for O).

with terminal oxygen ions (which have only one neighbouring boron atom) results in an increase of γ .

3. Models of non-crystalline Al_2O_3

The structure of liquid Al_2O_3 has not been studied experimentally due to its high melting point. In the bulk, alumina does not form glass. Amorphous oxide is formed only as thin films (for example, in anodic oxidation of the aluminium). Data by different authors on the structure of Al_2O_3 are only in partial agreement. An electronographic study of films obtained by anodic oxidation in boric acid-containing electrolyte was reported.⁹⁵ Peak positions in the total PCF (TPCF) were equal to 175, 275, and 320 pm. The first peak corresponds to Al–O pairs, the second one to O–O, and the third one to Al–Al pairs. Similar films with a thickness of 5 nm were studied⁹⁶ at the maximum scattering vector $K = 185 \text{ nm}^{-1}$. Peak positions in the TPCF were 182, 310, and 420 pm. The mean CN were as follows: $z(\text{Al–O}) = 6$ and $z(\text{O–Al}) = 4$. Therefore, virtually all aluminium atoms were in an octahedral environment.

For a film with thickness of 150 nm (after separation),⁹⁷ the peak positions were at 180 and 320 pm, and $z(\text{Al–O}) = 5.5$. Such an arrangement of particles is typical of γ' - Al_2O_3 crystal modification. An approximate interpretation gave the following results:

Pair	Al–Al	Al–O	O–O	Al–O(2)
$r(ij) / \text{pm}$	315	180	261	345
CN	10.3 ± 0.2	5.4 ± 0.1	12.0 ± 0.1	9.1 ± 0.2

The notation Al–O(2) relates to the second peak of the Al–O pairs. These data are close to the results of another study.⁹⁵

The following groups: AlO_4 , AlO_5 , and AlO_6 were found in a transitional amorphous phase α - Al_2O_3 using NMR ^{27}Al (see Ref. 98).

A model of amorphous Al_2O_3 incorporating the structural data⁹⁶ has been constructed.⁹⁹ The model contained 150 particles in a sphere with a diameter of $\sim 150 \text{ pm}$. First, the particles were arranged in a quasirandom order with limitations on the minimum interparticle distance, CN, azimuthal angles, and the type of neighbours. Further relaxation of the model was performed by the Reverse Monte Carlo method. In the structure obtained, the distribution of the Al–O–Al angles had maxima at 60, 80–100°, and 120–130°, and the maxima of distribution of the O–Al–O angles were at 80–100°, 130–140°, and 150–160°. Taking into account the small size of the model, the authors concluded that its structure was similar to that of α - Al_2O_3 . A model of amorphous oxide composed of 120 particles was constructed analogously¹⁰⁰ revealing a layered structure and the formation of clusters of 5- or 6-membered spatial rings in the layers.

An MD model of liquid oxide at $T = 2560 \text{ K}$ with ion charges $Z_1 = +2.55$ and $Z_2 = -1.70$ was constructed.¹⁰¹ The Al–O and O–O distances appeared equal to 185 and 273 pm, *i.e.* slightly longer than the actual values, with $z(\text{Al–O}) = 5.2$.

In a simulation (500 particles) of liquid (overcooled) oxide at 2000 K and of amorphous oxide at 0 K by MD and CSR methods the potentials (1) were applied.⁸⁸ The following parameters were chosen: $Z_1 = +3$, $Z_2 = -2$, $B_{11} = 0$, $B_{22} = 1500 \text{ eV}$ (the same as for models of silicates⁶⁵). The parameter $B_{12} = 1479.86 \text{ eV}$ was adjusted to make the molar volume of corundum at $P = 0$ equal to the actual value. Coulomb interactions were taken into account according to the Ewald–Hansen method.³⁹ The difference between the calculated energy for the ionic model and the energy of the real crystal was only 3.1%, and therefore an interpretation of corundum as the ionic compound is quite reasonable. In a simulation of the amorphous phase at 0 K, the initial CSR step was 50 pm and then it was gradually diminished to 1–2 pm.⁸⁸ About 250 steps were necessary to complete relaxation. The model built had the following parameters:

$V / \text{cm}^3 \text{ mol}^{-1}$	31.2	r_1 / pm for pairs

P / GPa	1.65	Al–Al	312
$E / \text{kJ mol}^{-1}$	–15289	Al–O	175
		O–O	268

The difference in energies of amorphous Al_2O_3 and crystalline corundum, equal to 274 kJ mol^{-1} , is the heat of crystallisation of amorphous Al_2O_3 . The heat of crystallisation of liquid alumina at 2300 K is 109 kJ mol^{-1} (see Ref. 89). These values are in reasonable agreement taking into account the difference in temperatures. The molar volume of amorphous Al_2O_3 is closer to the molar volume of γ - Al_2O_3 crystal (spinel type, $27.83 \text{ cm}^3 \text{ mol}^{-1}$) rather than of α - Al_2O_3 ($25.57 \text{ cm}^3 \text{ mol}^{-1}$). The real density of amorphous oxide films, to our knowledge, have not been measured. The volume of γ - Al_2O_3 increases by $\sim 12\%$ upon amorphisation.

Structural characteristics of models of amorphous alumina are in good agreement with the experimental data.⁹⁵ However, $g_{ij}(r)$ functions determined in independent studies^{88, 101} differ substantially. This is mainly due to the difference in the pair potentials used. Mean CN for the models⁸⁸ are as follows: $z(\text{Al–O}) = 4.47$ and $z(\text{O–Al}) = 2.98$. These values exceed the normal atom valences by factor ~ 1.5 , and therefore an assumption of the presence of a continuous random bond network in the structure of amorphous alumina may be rejected. The value of $z(\text{Al–O})$ is slightly lower than in the γ - Al_2O_3 crystal lattice ($0.7 \times 6 + 0.3 \times 4 = 5.4$), which is typical of dense non-crystalline structures.

Distributions of CN in the amorphous oxide are rather broad. Their calculation with the radius of the closest neighbour sphere of 240 pm gave the following results:

Number of neighbours	1	2	3	4	5	6	7
Number of Al^{3+} ions	–	–	8	102	78	12	–
Number of O^{2-} ions	–	42	222	36	–	–	–

Most of Al^{3+} ions have four and five O^{2-} neighbours, and most of oxygen atoms have three Al^{3+} neighbours. These data do not confirm the suggestion of the existence of such structural elements as the AlO_3 trigonal pyramid.

A model of liquid (overcooled) Al_2O_3 was constructed⁶⁶ using the MD method with the same parameters as in Ref. 88. Coulombic interaction was taken into account according to the Ewald–Hansen method.³⁹ The model contained 500 ions. The calculated molar volume of the liquid oxide at $P = 0$ ($34.3 \text{ cm}^3 \text{ mol}^{-1}$) was very close to the actual value ($34.3 \text{ cm}^3 \text{ mol}^{-1}$ at 2300 K, see Ref. 102). The Al–Al, Al–O, and O–O distances were found to be equal to 313, 174, and 286 pm, so the heating by 2000 K affected noticeably only the O–O pairs. Mean CN of Al–O pairs was equal to 4.50 and their distribution was still very broad. Both at $T = 0 \text{ K}$ and $T = 2000 \text{ K}$, the system had a relatively small number of aluminium ions with octahedral coordination; the predominant values were $z(\text{Al–O}) = 4$ and 5.

The topological characteristics of the Al_2O_3 structure were calculated (see Refs 66 and 88).

T / K	0	2000
ρ_1	1.051	1.056
s	1.16	1.13

Consequently, the structure of non-crystalline alumina lies on the lower boundary of the area of topologically dense systems. This accounts for difficult glass formation in the ordinary cooling of a liquid; ρ_1 and s values contradict the assumption of a layered structure of the oxide.

4. Models of non-crystalline Fe_2O_3

Fe_2O_3 oxide has not been obtained in an amorphous state, and in the liquid state it is unstable and readily decomposes to FeO and oxygen. However, Fe^{3+} ions are present in complex oxides in various concentrations depending on the oxidation potential of the medium. Models of non-crystalline Fe_2O_3 oxide were constructed using MD and CSR methods at 0 K and 2000 K.^{103–106} The models contained 500 ions in the basic cube. The pair

potentials (1) with parameters $B_{11} = 0$, $B_{22} = 1500$ eV, $R_{ij} = 29$ pm were applied, the value of $B_{12} = 2114.2$ eV was calculated

Table 3. Calculated parameters of the models of non-crystalline Fe_2O_3 .¹⁰³

Parameter	0 K	2000 K
$V/\text{cm}^3 \text{ mol}^{-1}$	39.0	40.2
$E/\text{kJ mol}^{-1}$	−14418	−14168
$r_1(ij)/\text{pm}$ for pairs		
Fe–Fe	331	327
Fe–O	191	190
O–O	298	291
$z(\text{Fe–O})$	4.7	4.7
ρ_1	1.07	1.05
s	1.21	1.18

according to the actual density of the crystal with the corundum lattice. The models were constructed in a way similar to that for Al_2O_3 . Table 3 shows the parameters of the models for Fe_2O_3 at 0 K and 2000 K.

The Fe–O distance of 190 pm can be compared with the diffraction data for $\text{Fe}_2\text{O}_3 \cdot 4(\text{Na}_2\text{O} \cdot 2\text{SiO}_2)$ (see Ref. 107) and $\text{CaO} \cdot \text{Fe}_2\text{O}_3$ (see Ref. 108) glasses where it lies in the range of 196–203 pm. In order to elongate the Fe–O distance to 198 pm, the B_{12} parameter was increased to 2453.0 eV.^{104–106}

These data show that the structures of Fe_2O_3 and Al_2O_3 are close to each other. At 0 K, 64 out of 200 iron ions have four neighbours, 105 ions have five, and 31 ions have six O^{2-} neighbours.^{103–106} A relatively big Fe^{3+} ion cannot arrange a rigid group of oxygen ions around it, as takes place in B_2O_3 , and the network of bonds is not created. Slightly increased value of the s parameter is due to the presence of big pores. According to the value of ρ_1 , the structure of non-crystalline oxide is rather dense.

The hysteresis effects in Fe_2O_3 are small. Construction of a model of amorphous oxide at 0 K using the CSR method, an increase in the temperature up to 2000 K using the MD method and consequent cooling back to 0 K led to a decrease in the energy relative to the initial value by only 0.05%.

5. Models of UO_2

Models of crystalline and liquid UO_2 have been constructed (see Ref. 109). A model of rigid ions with charges +4 and −2 has been used. The parameters of the potential (1) were as follows: $B_{11} = 0$, $B_{12} = 869.98$ eV, $R_{12} = 42.7$ pm, $B_{22} = 11272.6$ eV, and $R_{22} = 13.63$ pm for $r < 120$ pm, while at longer distances the potential $u(r)$ was represented in a polynomial form. All potentials were cut off at 520 pm. In addition, the dipole-dipole interactions were included in a potential for U–O pairs.

A model of UO_2 crystal (96 ions in the basic cube) gave a good fit with the experimental data on elastic constants and the dielectric properties. It was shown that the self-diffusion coefficient of O^{2-} ions in the temperature range of 2500–3300 K, while the system is still solid, is of the order of $10^{-5} \text{ cm}^2 \text{ s}^{-1}$, which is typical of liquids, *i.e.* the oxide under these conditions is a superionic conductor. In the liquid state (at 3200–4200 K), the self-diffusion coefficient of oxygen changes from 7×10^{-5} to $1.4 \times 10^{-4} \text{ cm}^2 \text{ s}^{-1}$, which is 3–4-fold greater than that for the uranium ions. The structure of the oxide has not been described.¹⁰⁹

6. Models of non-crystalline P_2O_5

Phosphate slags are important in metallurgy. Phosphate glasses attract considerable attention due to their prospective use in optoelectronics. P_2O_5 easily forms glasses. It possesses the high viscosity, and its use as an additive allows preparation of glasses with variable composition. The properties of phosphate glasses have been reviewed.^{110–113} Hysteresis of the properties, *i.e.* their

dependence on the prehistory of a sample, is a typical feature of the phosphate glasses.

Experimental data on the structure of phosphate glasses obtained by diffraction methods are rather numerous. Crystalline P_2O_5 is built up either of isolated P_4O_{10} molecules or of infinite layers of tetrahedral PO_4 groups (see Ref. 112). One of bonds between pentavalent phosphorus and oxygen atoms is double. The distance $r_1(\text{P–O})$ determined for a NaPO_3 glass¹¹⁴ is equal to 155 pm. The structure of this oxide is represented by long chains of PO_4 tetrahedra linked with other chains through sodium ions. X-ray studies of $[\text{M}(\text{PO}_3)_2]_n$ ($\text{M} = \text{Zn, Cu, Mn, Ca, Mg}$)¹¹⁵ gave the value of $r_1(\text{P–O})$ of 155 pm, which was virtually independent of the composition. However, the magnesium derivative behaved abnormally. Its density is higher than that calculated from a general linear correlation on the number of the M element in the Periodic Table (2.45 instead of the interpolated value 2.25 g cm^{-3}), and the interionic M–O distance is reduced (190 pm for Zn, 195 for Cu, 220 for Mn, 250 for Ca, and 190 for Mg). The first SF peak for magnesium phosphate appears at $K = 15.5 \text{ nm}^{-1}$ (instead of 17.0 for the other compounds) and is also abnormally high. It was supposed¹¹⁵ that the anomalies of magnesium phosphates are due to the formation of phosphate rings in this glass.

The structure of glasses with a composition $\text{M}(\text{PO}_3)_2$ ($\text{M} = \text{Zn, Mg, Ca, Sr, Ba}$) were investigated by neutron scattering method.¹¹⁶ O–O, P–O, and M–O pairs give the principal contributions into the TPCF (with shares of ~47%, 28%, and 15%, respectively). Separation of the TPCF into partial contributions is ambiguous. Nevertheless, for all glasses it was found that $z(\text{P–O}) \simeq 4$, $z(\text{Ca–O}) \simeq 4$ as well. The most reliable results are those for the P–O and O–O pairs:

Parameter	Zn	Mg	Ca	Sr	Ba
$r_1(\text{P–O})/\text{pm}$	154	153	154	154	154
$z(\text{P–O})$	3.9	4.0	4.0	4.0	4.2
$r_1(\text{O–O})/\text{pm}$	251	250	248	252	252
$z(\text{O–O})$	4.5	4.7	4.3	3.8	4.5

PO_4 tetrahedra are linked to each other *via* two bridging oxygen atoms forming presumably non-straight chains.¹¹⁶ Cations are placed between the chains and are surrounded by different numbers of oxygen ions. One of the oxygen atoms in the tetrahedron is doubly bound to the phosphorus atom. However, the computational accuracy is not sufficient to differentiate bonds of phosphorus with bridging and terminal oxygen particles.¹¹⁶

The applicability of the ionic model to P_2O_5 is not obvious. The electronegativities of oxygen and phosphorus atoms (according to Pauling) are equal to 3.5 and 2.1, respectively. From their difference of 1.4, the degree of the P–O bond ionicity is only 39%, which is substantially lower than for silica (51%).

Computer models of non-crystalline P_2O_5 were constructed using the MD and CSR methods.¹¹⁷ The Born–Mayer pair potentials (1) with ion charges +5 and −2 were applied. The interaction parameters B_{12} and B_{22} were determined using the experimental data on $\text{Ca}(\text{PO}_3)_2$ (with $B_{11} = 0$). The $r_1(\text{P–O})$ was adjusted to 155 pm in a model of glassy oxide by varying the B_{12} parameter. The B_{22} parameter for the model of $\text{Ca}(\text{PO}_3)_2$ at 300 K was adjusted to reproduce the actual volume $8.40 \text{ cm}^3 (\text{g-ion})^{-1}$ (see Ref. 118). Models of glasses were obtained by rapid cooling from 2000 K to 0 K within the CSR method with a 2 pm step; one typical run included 500 iterations. In the simulation of cooling under isobaric conditions (P close to 0), both the $r_1(\text{P–O})$ distance and the volume of the system changed slightly (by 1–3 pm and 1%–3%, respectively). Therefore, the parameters were corrected and MD-relaxation at 2000 K followed by cooling to 0 K was performed again. This cycle was repeated until the calculated parameters conformed with the experimentally established values for $r_1(\text{Ca–O})$ and molar volume of $\text{Ca}(\text{PO}_3)_2$ glass. Finally, the values of $B_{12} = 1847.66$ eV and $B_{22} = 1009.98$ eV

were obtained. The latter is substantially less than that proposed for silicates (1500 eV).⁶⁵

The B_{ij} values found for $\text{Ca}(\text{PO}_3)_2$ oxide were used in order to construct models for P_2O_5 at 2000 K and 0 K using the MD and CSR methods. All models relaxed in 1000 steps at 6000 K (2.04 fs per step), then the system was cooled to 2000 K and annealed for two runs of 1000 steps each. A model of the glass at 0 K was obtained by switching from the MD to the CSR method (with 2 pm shifts) using models for liquid oxide after a molecular dynamic run of 1000 steps at 2000 K.

For the model of pure P_2O_5 at 2000 K and 0 K, the molar volumes were 46.2 and 45.6 $\text{cm}^3 \text{mol}^{-1}$, which is substantially less than the molar volume of the real glass (55.0 $\text{cm}^3 \text{mol}^{-1}$, see Ref. 118). In part, this discrepancy may be explained by a difference in the properties of real glasses prepared by different ways

—2 does not provide the dominant tetrahedral coordination of phosphorus particles in pure P_2O_5 . Better agreement with the experimental data may be achieved either by decreasing ion charges or taking into consideration three-particle interactions typical of covalent bonding. As it will be demonstrated below, the tetrahedral coordination of phosphorus ions in the glass may be obtained within the framework of the pair interaction by selecting lower effective ion charges.

7. Models of non-crystalline V_2O_5

The oxide V_2O_5 forms a glass upon ordinary cooling of the liquid. Glasses with the composition $\text{V}_2\text{O}_5 - (\text{Li}_2\text{O}, \text{Ag}_2\text{O}, \text{BaO}, \text{SiO}_2)$ were prepared by quenching between rotating cylinders.¹¹⁸

The structure of liquid V_2O_5 was studied by X-ray diffraction at 953 K and 1173 K.⁵¹ According to these data, the position of the first peaks in the PPCF at 1000 K for the V—V, V—O, and O—O pairs were at 345, 180, and 256 pm, respectively. The mean CN value of V—O was 5.2. The temperature practically did not affect the structure of the melt, and this is believed to be similar to the structure of a crystal built of zigzag chains of oxygen bipyramids with vanadium ion at the centre, which are linked to each other through remote oxygen ions into a continuous network.⁵¹ Addition of lithium, potassium, calcium, and lead oxides to V_2O_5 results in a decrease in the V—O distance (to 168 pm at 25 mol.% of PbO). However, the V—V, V—O, and O—O distances determined by X-ray and neutron diffraction of V_2O_5 were equal to 336, 170, and 276 pm, respectively, and CN of V—O pairs was 3.6.¹¹⁹ A model in which vanadium atoms occupy centres of VO_4 tetrahedra and every three vertices of the tetrahedron are common for neighbouring tetrahedra was suggested.¹¹⁹ In a liquid state, large clusters of tetrahedra have to decompose into constituents, and some vanadium atoms in the centres of tetrahedra may be substituted by oxygen atoms.

In a $\text{V}_2\text{O}_5 \cdot 4.4\text{TeO}_2$ glass, two V—O distances were found by neutron diffraction: 161 pm (CN 1.0) and 199 pm (CN 4.0).¹²⁰

The structure of liquid V_2O_5 was simulated.^{121–123} An MD-model of the oxide at 1050 K with the effective ion charges of +3.95 and –1.58 was described.¹²¹ The model contained 560 particles in the basic cube. The V—O distance was 178 pm, and CN for V—O was 6.1; the pressure of the system was ~30 GPa. A model of liquid oxide with the actual molar volume 78.4 $\text{cm}^3 \text{mol}^{-1}$ at 1000 K was constructed.¹²² The model contained 336 ions in the basic cube, ion charges were +5 and –2. The value of B_{12} (2970.0 eV) was determined from the lattice parameter of the crystalline oxide. For this model, the energy of the ionic V_2O_5 crystal appeared to be higher than the actual value (–38 314 kJ mol^{-1}) by ~13%. This difference is probably due to a significant contribution of covalent bonding in the real oxide. Besides, the model did not take into account van der Waals contributions to the total energy.

From the model, V—O distance was 180 pm, CN was 4.94, and the pressure was ~2 GPa. It was concluded that the structure of the V_2O_5 melts is loose and built up of oxygen bipyramids with vanadium ions in the centres and CN of V—O pairs close to 5.¹²² It was established that the CN distribution is rather narrow, and more than 92% of vanadium ions have five oxygen neighbours. The distribution of O—V—O azimuthal angles has an intense peak at 90° and a small peak at 155°. These angles are typical of a distorted trigonal bipyramid with the vanadium atom in the centre. Distribution of the Voronoi polyhedra also confirms the pyramidal structure.

A series of models for oxides with a general formula M_2O_5 was constructed using the potentials (1) at zero pressure.¹²³ The number of particles in all models was 497. For the model corresponding to V_2O_5 (with $B_{12} = 2970$ eV), the calculated energy was –33 160 kJ mol^{-1} at 2000 K and –33 390 kJ mol^{-1} at 1000 K (the difference between them is less than 0.4%).¹²² However, molar volumes for these models differed by 23% (62.3 and 78.4 $\text{cm}^3 \text{mol}^{-1}$, respectively). Checking with the use of the same programme demonstrated that each model is rather stable

Table 4. Distribution of CN for models of P_2O_5 at 2000 K.

CN	P—O (O—P)	O—O	CN	P—O (O—P)	O—O
1	(2)	—	6	18	96
2	(352)	—	7	—	165
3	(1)	1	8	—	65
4	19	—	9	—	23
5	105	3	10	—	2

(the transition from the MD to the CSR method implies an exclusively high cooling rate). Interionic distances for the P—P, P—O, and O—O pairs at 2000 K appeared to be equal to 313, 158, and 228 pm, respectively. The mean CN for P—O pairs was 4.99. Table 4 shows the distributions of CN in the model of P_2O_5 at 2000 K.

Similar results were obtained at 0 K. Distributions of CN for P—O pairs had a maximum at $z(\text{P—O}) = 5$. About 74% of phosphorus ions occupy centres of 5-vertex trigonal bipyramids, however a noticeable part of P^{5+} ions are surrounded by four or six O^{2-} ions (~13%–14% both). Virtually all O^{2-} ions in the P_2O_5 models have two P neighbours bridging PO_n groups. A bond group analysis indicate complete polymerisation of the structure.

Distribution of the O—P—O and P—O—P angles is as follows: $\theta(\text{O—P—O}) = 106.5 \pm 25.8^\circ$, $\theta(\text{P—O—P}) = 157.4 \pm 11.8^\circ$. Hence, the PO_5 bipyramids are linked through shared vertices, and the P—O—P angles are close to the Si—O—Si angles in silica.

The presence of a ring component of the structure was also analysed. A P—O pair with a distance between the ions less than 175 pm was considered as a link. In models of P_2O_5 at 2000 K and 0 K the 6- and 8-membered rings were found; and almost all particles of the model were included in the rings. The following topological parameters of P_2O_5 models at 2000 K were found: $\rho_1 = 0.931$ and $s = 1.51$. These values imply that the structure of P_2O_5 is rather loose and close in this sense to the structure of silica. According to these parameters, the tendency to glass formation also should be high, which is in agreement with the experimental data.

In the simulation of P_2O_5 at 0 K with the actual molar volume of 55.0 $\text{cm}^3 \text{mol}^{-1}$ by the CSR method, the interionic distances for the P—P, P—O, and O—O pairs were 323 pm, 161 pm, and 239 pm, respectively. The pressure was found to be about –30 GPa, CN of the P—O pairs decreased to 4.9, *i.e.* the tetrahedral configuration was still little represented (19% of the phosphorus ions). Distributions of azimuthal angles and topological parameters of the model were practically unchanged.

It is difficult to compare the real structure and the models of P_2O_5 at 2000 K due to the absence of experimental data. However, for amorphous P_2O_5 , the deviations from the real glass were significant; especially in CN of the P—O pairs. A model of ionic bonding with the use of the potential (1) with ion charges +5 and

during MD-relaxation for hundreds of steps (~ 1 ps). Thus, in this case two rather stable oxides with different prehistory and structures were found. Probably, this effect is analogous to the compacting of silica (by 10%–15% in volume), which had been reproduced earlier by MD method.⁹

Calculated^{122, 123} V–V, V–O, and O–O distances were 350, 180, and 257–259 pm, respectively. They are close to the experimental values⁵¹ but differ noticeably from the results of another study.¹¹⁹ The CN values for V–O pairs change from 4 to 6, where $\sim 70\%$ of vanadium ions have the CN = 5, and the mean CN is equal to 4.9–5.0.¹²³ For the models of liquid V_2O_5 , the values of topological parameters are as follows: $\rho_1 = 0.885$ and $s = 2.71$.¹²² Therefore, the structure of oxide is rather loose.

Taking into account the discrepancy in diffraction data, it is difficult to discuss the correctness of the models of vanadium pentoxide. A covalent component may give a substantial contribution to the interaction of particles in this oxide.

8. Models of non-crystalline WO_3

Diffraction data on the structure of non-crystalline tungsten oxides are scarce. For amorphous films of WO_3 , the electronographic study gave the values of W–W and W–O distances of 378 pm and 188 pm and the corresponding CN 5.7 ± 0.4 and 5.8 ± 0.2 .¹²⁴ A structure of bulk WO_3 glass was studied by anomalous X-ray scattering.¹²⁵ For the W–O pair two distances were found: 182 (W=O) and 220 pm (W–O); the mean distance is equal to 196 pm (CN 5.2). It was shown that for the O–O pairs the distance is 287 pm (CN 7.0) and for the W–W pairs, 372 pm (CN 4.2). Therefore, the results of the two studies^{124, 125} are in some disagreement. A study of $2Na_2O \cdot WO_3$ and $Na_2O \cdot 2WO_3$ glasses gave W–O distance close to 180 pm and CN 4.7 and 5.2, respectively.¹²⁶

The potential (1) with the parameters $B_{11} = 0$, $B_{22} = 1500$ eV, and $R_{ij} = 29$ pm was applied in models of liquid and amorphous WO_3 oxide composed of 500 ions.^{127, 128} The B_{12} parameter was determined provided the W–O distance was taken to be 180 pm, and was found to be 3400 eV. First, a CSR model at 0 K and zero pressure was constructed. Then the increases in temperature up to 2000 K were simulated by the MD method. After the relaxation, the system was cooled again to 0 K using the CSR method to check it for probable hysteresis effects. The molar volume of the amorphous oxide at 0 K was found to be equal to $28.7 \text{ cm}^3 \text{ mol}^{-1}$ and to $28.9 \text{ cm}^3 \text{ mol}^{-1}$ for the liquid one at 2000 K. The molar volume of the crystal at 300 K is $31.3\text{--}32.2 \text{ cm}^3 \text{ mol}^{-1}$ (see Ref. 129), which exceeds that of the amorphous oxide by 9%–12%. The reason for this effect is a rather loose structure of the crystal.

The adequacy of a purely ionic bonding approximation may be estimated for WO_3 . The atomisation energy of WO_3 was calculated using the Born–Haber cycle.¹³⁰ The sum of the first six ionisation potentials found in this way was 193.33 eV, and the actual sum is 193.7 eV. Therefore, the ionic bonding approximation is reasonable, and the higher ionisation energy of tungsten atoms is compensated by the Coulomb energy of ion interactions.

The mean thermal expansion coefficient for WO_3 models in the range of 0–2000 K is very small ($3.1 \times 10^{-6} \text{ K}^{-1}$). This is explained by the small ratio of the thermal energy at 2000 K to the total energy (0.0044). By the same reason, the low thermal expansion coefficient of SiO_2 (E_{kin}/E is 0.006) may be explained. Structure of WO_3 does not change substantially on heating, and the mean heat capacity is close to its classical limit $3R = 24.9 \text{ J(g-ion K)}^{-1}$.

The values of W–W, W–O, and O–O interionic distances were equal to 352, 179, and 238 pm at 2000 K and to 351, 179, and 236 pm at 0 K, respectively.¹²⁷ They very little depend on temperature. The W–O distance is in good agreement with the diffraction data. The first PPCF peak of the W–O pairs is isolated. The mean CN of the W–O pairs is 5.98; CN distributions of the W–O and O–W pairs were identical and rather narrow at 2000 K and 0 K.^{127, 128}

CN	1	2	3	4	5	6	7
Number of W ions	—	—	—	—	11	107	7
Number of O ions	4	371	—	—	—	—	—

Thus, $\sim 86\%$ of tungsten ions have 6 neighbouring oxygen atoms and are in the octahedral environment. Other tungsten atoms have 5 or 7 neighbours. Tetrahedral coordination was not observed in the models. This is at variance with the approximate structure interpretations.¹²⁶

It is noteworthy, that the content of W^{6+} ions with CN 6 in the WO_3 oxide is somewhat less than the content of Si^{4+} with CN 4 in silica (92%). Therefore, the first coordination sphere of W^{6+} ions is less rigid, due to the larger size of the tungsten ions and strong repulsion of the six surrounding O^{2-} ions.

The topological characteristics of WO_3 models are as follows:^{127, 128}

T/K	0	2000
ρ_1	0.979	0.972
s	1.55	1.42

The structure of the oxide is loose, but the values of ρ_1 are not very low. Pure WO_3 does not form glasses,¹¹⁸ but on sufficiently rapid cooling (quenching between rotating cylinders) it is possible to obtain a glassy oxide.¹³¹ Hence, the values of $\rho_1 = 0.97\text{--}0.98$ lie on the very limit of glass formation for the MO_3 oxides.

9. Models of non-crystalline Na_2O

Pure sodium oxide does not form glasses on cooling of a liquid. Diffraction data for sodium silicates have been reviewed.¹³² According to these data, the Na–O interionic distances at 300–1373 K are 233–240 pm and CN for the Na–O pairs lie in the range of 4–6. The molar volume of the liquid oxide at 1673 K is $33.0 \pm 4.6 \text{ cm}^3 \text{ mol}^{-1}$ (see Ref. 133).

Models of liquid and amorphous Na_2O were constructed with the pair potentials (1).^{103, 127, 134, 135} For the O–O pairs, the value of B_{22} was taken to be equal to 1500 eV, as for silicates. For the Na–Na pairs, the calculations gave $B_{11} = 842.2$ eV.^{10, 12} The B_{12} coefficient can be calculated from the molar volume of the crystalline oxide. Taking into account only two first terms in (1), the value of $B_{12} = 1601.9$ eV ($R_{ij} = 29$ pm) was obtained.^{103, 134} However, if the B_{11} value is chosen as 0, then $B_{12} = 1814.5$ eV. Since the interaction of the Na–Na pairs gives a small contribution to the energy, the value of $B_{11} = 0$ was chosen.¹²⁷

MD-models were constructed with account for Coulomb interactions according to Ewald–Hansen.³⁹ The molar volume of the non-crystalline oxide appeared to be equal to 27.6 to $28.6 \text{ cm}^3 \text{ mol}^{-1}$ at 0 K and $33.0\text{--}36.0 \text{ cm}^3 \text{ mol}^{-1}$ at 2000 K. Interpolation to 1673 K gives the value of $\sim 34.6 \text{ cm}^3 \text{ mol}^{-1}$, which is in good agreement with the experimental results. The Na–O distance is 222 pm at 0 K (see Ref. 134) and 228 pm at 2000 K.⁶⁴ In another study¹²⁷ the value of 222 pm was found at 2000 K. The deviations from $r_1(\text{Na–O})$ in silicates (233 to 240 pm) is reasonable, since this distance in a $Na_2O\text{--}SiO_2$ system increases with increase in the silica content.¹³⁴ The mean CN for the Na–O pairs is 2.9, which is less than the CN in the antifluorite crystal (4.0). This value is close to the lowest limit of the range of diffraction data for sodium silicates. The distribution of CN shows that only half of Na^+ ions have exactly four neighbours.

$z(\text{Na–O})$	3	4	5
Number of sodium ions	48	88	30

TPCF of the oxide contains only distinct first peaks attributed to the Na–O and Na–Na pairs, which precludes the interpretation of the structure from the diffraction data.¹³⁵

The topological characteristics of the Na_2O model at 0 K and 2000 K ($\rho_1 = 1.062$ and 1.018 , $s = 1.06$ and 1.01) show that the oxide has a rather dense structure in both amorphous and liquid states. The fact that the structure of amorphous oxide is dense explains the low tendency of Na_2O towards glass formation.

V. Simulation of homologous series of non-crystalline oxides

1. Models of non-crystalline oxides in the M_2O series

The description of oxides with a definite stoichiometry and using the potential (1) with B_{12} as the only variable parameter allows one to construct a series of models differing in the $r_1(M-O)$ interionic distances, which is equivalent to changes in the ion radius of the M ion. If real oxides are satisfactorily described by the potentials (1) with constant R_{ij} , B_{11} , and B_{22} , then the properties of the oxides can be calculated by an interpolation of data obtained for other members of the series. In that case, the efficiency of computational methods enhances substantially.

This idea was proposed in studies devoted to oxides of $2MO \cdot SiO_2$ series^{136–139} and then extended to other oxides. Two series of models for M_2O at 0 and 2000 K with the pair potentials (1) and the values of B_{12} ranging from 545.3 to 9999.0 eV, $B_{11} = 0$, $B_{22} = 1500$ eV, and $R_{ij} = 29$ pm, were considered.¹³⁵ Each model contained 249 ions. Estimates made from the molar volume of antifluorite-type crystals at $p = 0$ gave $B_{12} = 626.67$ eV for Li_2O , 3844.1 eV for K_2O , and 5320 eV for Rb_2O (the structure of Cs_2O is more complex). Coulomb interactions were taken into account by the Ewald–Hansen method.³⁹ The period of the basic cube was adjusted so that the pressure was close to zero. Due to fluctuations in the pressure, the molar volume of the models was determined with an error of 0.2%–0.3% at 0 K and 2%–4% at 2000 K.

Figure 3 shows the dependence of parameters of M_2O models on B_{12} at 2000 K. The adequacy of the potentials used can be checked by comparing the molar volumes for the models with the experimental data. An interpolation using the data from Fig. 3 for Li_2O with $B_{12} = 626.67$ eV gives the molar volume at 2000 K $7.9 \text{ cm}^3 (\text{g-ion})^{-1}$ and at 1673 K $7.75 \text{ cm}^3 (\text{g-ion})^{-1}$.¹³⁵ The actual value at 1673 K $[6.47 \pm 0.83 \text{ cm}^3 (\text{g-ion})^{-1}]$ (see Ref. 133) is less by 16%. For Na_2O at 2000 K the calculated molar volume was $12.0 \text{ cm}^3 (\text{g-ion})^{-1}$ at $B_{12} = 1601.94$ eV. The actual volume $11.0 \pm 1.5 \text{ cm}^3 (\text{g-ion})^{-1}$ at 1673 K (see Ref. 133) is close to the calculated value. For the K_2O model at 2000 K, the molar volume appeared to be equal to $15.5 \text{ cm}^3 (\text{g-ion})^{-1}$, which is also in accordance with the experimental value of $17.2 \pm 2.2 \text{ cm}^3 (\text{g-ion})^{-1}$ at 1673 K.¹³³ As it is clearly seen from Fig. 3, the $r_1(M-O)$ distance depends almost linearly on $\ln B_{12}$. The $r_1(M-M)$ and $r_1(O-O)$ distances depend monotonically on B_{12} .

Calculation of the TPCF for liquid oxides at 2000 K for X-rays showed that in the case of Li_2O , the M–M pairs do not contribute significantly due to a small scattering amplitude of Li atoms. For sodium and potassium oxides, the contribution of the M–M pairs is greater. The highest TPCF peak is due to the

M–O pairs. However, because of the mutual interference of the PPCF oscillations the corresponding TPCF are close to unity already at distances longer than 0.5 nm.

The mean CN for the M–O pairs also increase as B_{12} increases, i.e. with an increase in size of M^+ . In crystals, $z(M-O)$ is equal to 4, and melting or amorphisation is accompanied by a decrease in the CN of the M–O pairs. For the entire M_2O series, the range $2.6 < z(M-O) < 3.6$ is typical. Distributions of $z(M-O)$ become broader with the increase in B_{12} .

$z(M-O)$	2	3	4	5	6
Number of ions at					
$B_{12} = 545.3$	81	85	—	—	—
1601.9	48	88	30	—	—
3844.1	6	63	85	11	1
9999.0	8	71	76	10	1

For a broad distribution of CN, it is impossible to isolate any stable element of the structure, and the system should resemble more or less dense packing of spheres with different diameters. The broad distributions of O–M–O and M–O–M azimuthal angles also point to this fact.

Temperature only slightly affects the structure of the oxides. The $r_1(M-O)$ distances change insignificantly, but for the M–M and O–O pairs they increase noticeably with heating due to the thermal expansion. The ratio of molar volumes $V_{2000 \text{ K}}/V_{0 \text{ K}}$ for $B_{12} = 545.3$ eV is equal to 1.08 (for Li_2O), 1.16 (for Na_2O), and 1.12 (for K_2O). An important role of the temperature is due to the fact that E_{kin} at 2000 K makes a noticeable part of E (from 2.6% for Na_2O up to 4.1% for K_2O).

The topological coefficient ρ_1 increases from 0.95 to 1.06 as B_{12} increases (see Fig. 3), while the s coefficient decreases from 1.17 to 1.00. Therefore, structures of the oxides with $B_{12} > 1600$ eV (including Na_2O , K_2O , Rb_2O) are close to the dense one. That is why it is difficult to prepare these compounds in a glass state.

If M–O distance in non-crystalline M_2O oxides is suggested to be equal to the sum of ion radii and usual values are taken for M^+ ions (viz., 68 pm for Li^+ , 98 pm for Na^+ , 133 pm for K^+ , and 149 pm for Rb^+), then the radius of O^{2-} appeared to be 118 ± 7.7 pm, which is in agreement with the estimates of its crystallographic radius on the fluoride scale (121–128 pm).¹⁴⁰ Thus the approximate value of the radius is 120 pm.

Analysis of the thermodynamic properties of the oxide models was performed.¹³⁵ Comparison of experimental values for total energy of M_2O crystals with the results of simulations at $B_{11} = 0$ and $B_{22} = 1500$ eV (taking account of only Coulomb interactions and electron shell repulsion) demonstrated that the difference is 12% for Li_2O and gradually decreases to 4% for Cs_2O .

Oxide	Li_2O	Na_2O	K_2O	Rb_2O	Cs_2O
$-E(\text{calc.})/\text{kJ} (\text{g-ion})^{-1}$	1020.1	852.9	770.5	740.2	695.7
$-E(\text{exp.})/\text{kJ} (\text{g-ion})^{-1}$	910.8	788.2	738.0	692.4	667.4

The deviations are probably caused by the fact that the R_{M-O} parameter for light ions differs from the conventional value of 29 pm. In principle, the agreement between the experimental and simulated results may be improved by adjusting the R_{ij} values specifically for each oxide. A contribution of covalent interactions to the potential, which decreases for heavier Group I cations and which was not taken into account in the simulation, may be another reason for the deviations.

Amorphisation energies ΔE_{am} for the models decrease from $40 \text{ kJ} (\text{g-ion})^{-1}$ for Li_2O to $14 \text{ kJ} (\text{g-ion})^{-1}$ for Cs_2O (see Ref. 135). Heats of melting [from $19.7 \text{ kJ} (\text{g-ion})^{-1}$ to $6.4 \text{ kJ} (\text{g-ion})^{-1}$] are 1.6–3.4-fold less than ΔE_{am} and also gradually decrease as B_{12} increases. The ratio of volumes of amorphous and crystalline phases also changes analogously. Amorphisation of a model of a Li_2O crystal at 0 K is accompanied by an increase in the volume by 34%, and for model of Cs_2O by 4%. These features of amorphisation are due to structural changes. Amorphisation of Cs_2O is accompanied by a decrease

Figure 3. Properties of models of non-crystalline M_2O oxides at 2000 K.

in the mean CN for the M–O pairs from 4 to 3.6; for Li₂O, the CN for the M–O pairs decreases to 2.5.

The change in the Gibbs energy along the homologous series may be calculated using the expression¹³⁸

$$\delta G_y = \int_{y_1}^{y_2} \langle U_{12} \rangle dy, \quad (11)$$

where $y = \ln(B_{12})$, y_1 and y_2 refer to the initial and final states, $\langle U_{12} \rangle$ is the mean equilibrium value of energy of electron shell repulsion of the M–O pairs. In (11), the integration is performed at constant pressure and temperature. Using the values of $\langle U_{12} \rangle$ obtained from the molecular dynamic experiments, the value of δG_y may be calculated. Further, taking into account that $\delta G = \delta E + p\delta V - T\delta S$, the change in entropy δS for each member of the series may be determined. The change in $\delta S/Nk$ is shown in Fig. 3: as B_{12} increases, the configurational entropy of the oxide (at a constant mass of M^+ ion) increases monotonically, *i.e.* gradual disordering of the structure takes place, which is manifested particularly in the broadening of CN distributions. The maximum change in entropy for the system considered is $\sim 2Nk$.

The term δS_y represents only the configurational part of the change in entropy. If the mass of m_i ion is changed to m_j on going from one oxide to another, then the contribution

$$\delta S_m = \frac{3}{2}NkX_M \ln(m_j m_i^{-1}),$$

has to be added to the value of δS_y , where $X_M = 2/3$ is the ionic contribution of the M^+ ion.

2. Models of non-crystalline oxides in the MO series

MO series includes such important components of industrial slags and glasses as MgO, CaO, SrO, BaO, and probably BeO, FeO, MnO, PbO, *etc.* The first model of CaO composed of 216 ions was constructed using MD and CSR methods with the pair potentials (1) and the following parameters: $B_{11} = 0$, $B_{12} = 3283$, $B_{22} = 1500$ eV, and $R_{ij} = 29$ pm.⁶⁵ The value of B_{22} was adjusted so as the O–O distance in the models of calcium and iron silicates was close to the values determined by diffraction methods (~ 323 pm, see Ref. 141). For the Ca–O pairs, the parameter $B_{12} = 3283$ eV was from the density of crystalline CaO. The electrostatic energy appeared to be -4037 kJ mol⁻¹, and the energy of electron shell repulsion was 483 kJ mol⁻¹. The total energy (not accounting for zero vibrations) was equal to -3554 kJ mol⁻¹, which is in reasonable agreement with the experimental value⁶⁵ of the energy of the crystal (-3378 kJ mol⁻¹); the difference being 5.2%. The modulus of bulk compressibility was 171 GPa compared to the experimental value of 115 GPa. Therefore, the Born–Meyer potentials are not quite precise, but they can be used for construction of models.

An investigation of models of non-crystalline MO oxides (composed of 216 ions) was performed.^{103,142} The Coulomb interactions were taken into account using the Ewald–Hansen method.³⁹ The models with $B_{12} = 400$ –800 eV describe hypothetical oxides with very small M^{2+} ions. Models corresponding

to MgO, FeO, CaO, SrO, and BaO have B_{12} equal to 1441.4, 1900.0, 3283.0, 4744.1, and 8885.1 eV, respectively. The B_{12} values were determined from the experimental lattice parameters. The calculated values of energy of the crystals using the Born–Meyer potential was lower than corresponding experimental values by 2.2%–5.8%. This difference indicates a certain inaccuracy of the potentials (1).

A model of amorphous phase at 0 K was constructed using the MD method starting from a random initial state.^{103,142} Then the temperature was increased up to 2000 K by the MD method and the system was relaxed during several hundreds steps to reach the equilibrium state. Some models were constructed with the use of the previous ones with other B_{12} values. The amorphisation energies [45 – 65 kJ (g-ion)⁻¹] were calculated as differences between energies of the amorphous phase and the crystal. Their ratios to the heats of melting of the corresponding oxides increased from 1.18 to 1.84 on going from MgO to BaO. The amorphisation was accompanied by a substantial increase in a volume of crystal (by 17% for BaO and 38% for MgO).

Dependencies of V/N , $r_1(ij)$, mean CN $z(M-O)$, ρ_1 , and $\delta S/Nk$ on B_{12} are shown in Fig. 4. An increase in B_{12} results in a monotonic increase in the M–M and M–O distances, while the O–O distance changes non-monotonically. The volume of oxides passes through a minimum at $B_{12} = 800$ –1900 eV.

The reason for the appearance of the minimum can be understood when the change in the CN of M–O pairs is considered. As it is seen from Fig. 4, if $B_{12} \leq 500$ eV then CN equals 2 and the system has a chain structure. The O–M–O and M–O–M azimuthal angles at 2000 K are close to 160° and correspond to the zigzag –M–O–M–O– arrangement of the ions. Analysis of distribution of CN demonstrated that when $B_{12} \leq 500$, virtually all M^{2+} ions have two neighbours (O^{2-} ions) and vice versa. The distance $r_1(M-O)$ is 110–120 pm. In the case of M^{2+} ion with the smallest size (Be), the distance is 180 pm in the crystal and 151 pm in the amorphous oxide. Therefore, models with $B_{12} \leq 500$ eV are hypothetical.

An abrupt decrease in the molar volume when the value of B_{12} approaches 800 eV is caused by a rapid increase in the CN of the M–O pairs from 2 to 3. When CN is 3, a layered trigonal structure appears. The O–M–O and M–O–M angles are 108 – 112° , *i.e.* the closest neighbours of M(or O) ions occupy vertices of strongly flattened trigonal pyramids. The contribution of ions with $z(M-O) = 2$ or 4 is relatively small ($< 30\%$), thus oxides with $B_{12} = 800$ eV have rather ordered structures.

The transition to $B_{12} \geq 1900$ eV results in a substantial broadening of distribution of CN for the M–O pairs, and the mean CN approaches the value of 6, typical of the MO crystal lattice. In the range of $B_{12} = 1441$ –1900 eV, the CN is almost constant [$z(M-O) = 4.14$ – 4.90], and consequently the molar volume changes only slightly. This is probably due to the high stability of the structure with $z = 4$ and a tetrahedral coordination of ions. However, this coordination is observed only as a mean value since the distributions of CN $z(M-O)$ in MgO and FeO models are rather broad.

Figure 4. Properties of models of non-crystalline MO oxides at 2000 K. Numbers denote pairs of ions.

$z(\text{M}-\text{O})$	3	4	5	6	7
Number of M ions					
for a model of MgO	12	74	22	—	—
for a model of FeO	1	26	61	19	1

Temperature affects the structure of oxides relatively little, since even at 2000 K the thermal energy is only 1.0%–1.7% of the total energy. The mean heat capacity for all models [19.8–26.6 J (g-ion K)^{−1}] is close to the classical value $3R = 24.9$ J (g-ion K)^{−1}.

The value of the topological parameter ρ_1 is low for models with $B_{12} \leq 800$ eV (see Fig. 4), *i.e.*, the corresponding structures are rather loose. The s parameter is 2.68 for $B_{12} = 500$ eV and even 4.00 for $B_{12} = 400$ eV. However, the MgO model already has a quite dense structure ($\rho_1 = 1.04$ at 2000 K and 1.05 at 0 K). Other models have $\rho_1 = 1.07$ –1.08 and $s = 1.00$ –1.07. These structures are topologically dense, which accounts for the difficulty in obtaining the real MO oxides in a glassy state.

The properties of models with $B_{12} \leq 800$ eV vary with a substantial hysteresis.¹⁴² A model constructed with $B_{12} = 500$ eV from a random initial state by the CSR method gave a molar volume of only 5.85 cm³ (g-ion)^{−1} and an energy of −2394.4 kJ (g-ion)^{−1}. Its annealing (2000 K) is accompanied by an increase in the volume up to 11.2 cm³ (g-ion)^{−1}. For simulation of this process, more than 1000 steps of the MD method were required. After cooling to 0 K using the CSR method and subsequent relaxation, the volume was equal to 11.4 cm³ (g-ion)^{−1}. The energy of this state is 18.3 kJ (g-ion)^{−1} lower than that of the initial state. At higher B_{12} values, the hysteresis effects are almost unnoticeable. They are typical of loose structures and their nature is similar to the processes that occur in the compacting of silica.

Changes in the Gibbs energies and entropies on moving along the MO series were calculated as for M₂O.¹⁴² This required that the integration of repulsion energies $\langle U_{12} \rangle$ was performed according to the equation (11). It was demonstrated, that the configurational entropy of oxides at 2000 K virtually does not change in the range $500 \leq B_{12} \leq 2550$ eV and begins to increase when $B_{12} > 2550$ eV. This growth is caused by broadening of distributions of CN and azimuthal angles and by the increase in the degree of disordering on going from loose to the topologically dense systems.

3. Models of non-crystalline oxides in the M₂O₃ series

A series of models for amorphous and liquid M₂O₃ oxides was constructed with the potentials (1) and parameters $B_{12} = 580$ –5000 eV. The value of 800.0 eV corresponds to boron oxide, 1479.86 to Al₂O₃, 2114.2 and 2453 to Fe₂O₃; other models correspond to hypothetical oxides. Data for the three above-mentioned compounds have already been discussed. A collapse in this series occurs when $B_{12}^{\text{cr}} = 550$ eV; the lowest value of 580 eV only slightly exceeds the critical one.

All models contained 500 ions in the basic cube. The edge length of the basic cube was selected so as to give the pressure close to zero. Fig. 5 shows the characteristics of the models in the M₂O₃ series at 2000 K. The $r_1(\text{M}-\text{M})$ and $r_1(\text{M}-\text{O})$ distances depend

almost linearly on $\ln B_{12}$. The molar volume of the oxide has a deep minimum at $B_{12} \simeq 1480$ eV. The first members of the series have the mean values of CN equal to 3. This value increases monotonically up to ~ 5.9 when $B_{12} = 5000$ eV. As in the case of the MO series, the minimum of the molar volume is due to a rapid increase in the CN and a rearrangement of the structure in the range 1150–1480 eV.

Distributions of CN for the M–O and O–M pairs are the most narrow when $B_{12} = 590$ and 800 eV and rapidly broaden at larger B_{12} values. Boron oxide is the most ordered in the configurational sense. The value of $z(\text{M}-\text{O}) = 4$ can be obtained for an oxide with $B_{12} = 1195$ eV. In such an oxide, the values of $z(\text{O}-\text{M})$ equal to 2 and 3 have to occur in the ratio 1:2, which does not allow one to provide as good ordering of the oxygen subsystem as in boron oxide, where $z(\text{O}-\text{M}) = 2.00$.

Data on CN are confirmed by the character of the distributions of azimuthal angles. At 2000 K, these distributions are as follows:

B_{12} / eV	$\theta(\text{O}-\text{M}-\text{O})$ / deg	$\theta(\text{M}-\text{O}-\text{M})$ / deg
580	121.7 ± 14.9	160.1 ± 10.1
800	119.3 ± 10.2	153.2 ± 19.2
1480	106.9 ± 23.3	121.1 ± 18.6
2453	105.4 ± 26.9	113.1 ± 19.6
5000	98.8 ± 28.0	108.4 ± 23.5

The O–M–O angle approaches 90° at higher B_{12} values, which roughly corresponds to an octahedral packing of the closest neighbours. In this case, $z(\text{M}-\text{O}) \simeq 6$ and $z(\text{O}-\text{M}) \simeq 4$, *i.e.* the surrounding of the oxygen atom by the metal atoms is almost tetrahedral. This is in keeping with the mean M–O–M angle (109°), which is therefore close to that of the ideal tetrahedron.

Taking into account that the effective radius of the O^{2−} ion for non-crystalline oxides is ~ 120 pm (see above), the radii of the M³⁺ ions can be calculated for B_{12} from the plot of $r_1(\text{M}-\text{O})$ depicted in Fig. 5. The model with $B_{12} = 3500$ eV corresponds to the oxide with the ionic radius of 92 pm. The radii of Y³⁺ and Ti³⁺ ions (93 and 95 pm, respectively) are close to this value. A system with $B_{12} = 5000$ eV corresponds to an ion with a radius of 108 pm, which is close to the radius of La³⁺ (115 pm). Further increase in B_{12} results in a region of unreal hypothetical large cations.

The topological characteristics (ρ_1 and s) in the M₂O₃ series indicate a noticeable looseness of the models with $B_{12} = 580$ eV (0.695 and 3.50, respectively) and with 800 eV (0.787 and 2.34). Nevertheless, the model of Al₂O₃ is almost dense ($\rho_1 = 1.056$ and $s = 1.16$). On further movement along the series the structure of oxides remains topologically dense.

The changes in the configurational Gibbs energy and entropy were calculated for the M₂O₃ series according to the equation (11). Dependence of $\delta S/Nk$ on B_{12} is shown in Fig. 5. When $B_{12} > 2453$ eV, the entropy is virtually constant and $\delta S_y = 9.6 \pm 0.9$ J (g-ion K)^{−1}. A decrease in B_{12} to 800 eV and transition to a more ordered layered structure of boron oxide is accompanied by a decrease in the configurational entropy. Further decrease in B_{12} results in a slight increase in the entropy due to

Figure 5. Properties of models of non-crystalline M₂O₃ oxides at 2000 K. Numbers denote pairs of ions.

greater disorder because of the broadening of CN distributions mentioned above.

4. Models of non-crystalline oxides in the MO₂ series

Non-crystalline oxides of the MO₂ series include silica and a glass-forming GeO₂ oxide. It is also possible to obtain glassy TeO₂ by quenching it between rotating cylinders.¹³¹ Such oxides as TiO₂, SnO₂, and ZrO₂ do not form glasses on ordinary cooling of a liquid.¹⁴³

Glassy SiO₂ and GeO₂ have been intensely studied by diffraction methods. The $r_1(ij)$ distances for GeO₂ were determined using anomalous X-ray scattering: $r_1(\text{Ge}-\text{Ge}) = 310-320$ pm, $r_1(\text{Ge}-\text{O}) = 160$ pm, $r_1(\text{O}-\text{O}) = 280$ pm.¹⁴⁴ The following r_1 distances for glassy GeO₂ were reported:¹⁴³ 315–345 pm for Ge–Ge pairs, 170–174 pm for the Ge–O pairs, and 283–285 pm for the O–O pairs. The mean CN for the Ge–O pairs lies in the range of 3.9–4.0. The mean Ge–O–Ge azimuthal angle is 133° (see Ref. 145). In an Na₂O·4GeO₂ glass, the Ge–O distance is 180 pm.¹⁴⁶ For pure TeO₂, no diffraction data were found. For a glass of composition V₂O₅·9TeO₂, neutron diffraction gave the Te–O distances of 192 pm ($z = 2.71$) and 216 pm ($z = 0.85$ pm).¹²⁰ In a SiO₂–TiO₂ glass (< 10 mol.% of TiO₂), the Ti–O distance appeared to be equal to 189–191 pm.¹⁴⁶

Models for MO₂ oxides composed of 498 ions in the basic cube were constructed using the MD and CSR methods at 0 K and 2000 K.⁵³ The pair potentials (1) were applied with the following parameters: $Z_1 = +4$, $Z_2 = -2$, $B_{11} = 0$, $B_{22} = 1500$ eV, $R_{ij} = 29$ pm. Since for this series $B_{12}^{\text{tr}} = 734$ eV, the values of B_{12} were chosen in the range of 850–8000 eV; the values $B_{12} = 1729.5$ eV and 1848 eV were proposed for silica and for simulations of the Si–O pairs in silicates, respectively.⁸⁴

Figure 6 shows the characteristics of MO₂ models as the function of B_{12} . The distance of $r_1(\text{M}-\text{O})$ depends linearly on $\ln B_{12}$. The M–M and O–O distances also increase with increase in B_{12} . When $B_{12} = 850$ eV, $z(\text{M}-\text{O}) = 3.70$. Extrapolation of the curve in Fig. 6c to the stability limit gave $z(\text{M}-\text{O}) = 3.5$, i.e. CN of 3 and 4 are equiprobable.

Distributions of CN for the M–O pairs in the models have the following form:

$z(\text{M}-\text{O})$	3	4	5	6	7	8	9	Mean CN
Number of M ⁴⁺ ions								
at $B_{12} = 850.0$	50	116	—	—	—	—	—	3.70
1729.5	7	152	7	—	—	—	—	4.00
3500.0	—	12	58	80	15	1	—	5.61
8000.0	—	—	1	47	86	30	1	6.91

The increase in B_{12} (i.e. the increase in the size of an M⁺ ion) is accompanied by an increase in the mean CN for the M–O pairs and broadening of its distribution. The MO₂ structure rearranges in the range $750 < B_{12} < 1000$ eV, when the trigonal structural elements are replaced by tetrahedral ones. A small minimum of the molar volume near $B_{12} = 1250$ eV (see Fig. 6e) is due to the rearrangement. A similar process is typical of oxides of the MO series in the range $800 < B_{12} < 1440$ eV (see above).

The next rearrangement of the structure occurs in the range $2000 < B_{12} < 3000$ eV. Here, $z(\text{M}-\text{O})$ increases abruptly up to 6 (see Fig. 6c), the distribution of $z(\text{M}-\text{O})$ becomes substantially broader, and the elements of the tetrahedral networks typical of silica disappear. Further increase in B_{12} does not lead to any new structural rearrangement.

These results agree with the results of analysis of the azimuthal angle distribution. When $B_{12} \leq 1848$ eV, the mean O–M–O angle is close to the tetrahedral one, and the $\theta(\text{M}-\text{O}-\text{M})$ angle is 156–160°. Similar distributions were obtained for silica (see above). Further increase in B_{12} is accompanied by a decrease in the mean value of O–M–O and M–O–M angles, but their distributions broaden by a factor of 2–3. The values of topological parameters ρ_1 (see Fig. 6b) and s indicate that the structures of oxides in the MO₂ series are loose when $B_{12} < 3500$ eV and close to the dense one when $B_{12} \geq 5000$ eV.

Figure 6. Properties of models of non-crystalline MO₂ oxides at 2000 K.

Comparison of the models with the real oxides in respect of $r_1(\text{M}-\text{O})$ distances and M⁴⁺ ion radii was performed.⁵³ Oxides with $B_{12} < 1700$ eV are hypothetical. The value of $B_{12} = 2080$ eV corresponds to GeO₂, 2940 eV to TiO₂, and 3410 eV, to TeO₂. A model with $B_{12} \approx 3500$ eV corresponds to ZrO₂ and with, $B_{12} \approx 5000$ eV to UO₂. An intermediate value (between 5000 and 8000 but closer to 5000 eV) corresponds to CeO₂.

An increase in temperature from 0 to 2000 K affects insignificantly the structure of the models. Positions of TPCF peaks do not virtually shift and their heights decrease only slightly. Coordination numbers for the M–O pairs also insignificantly depend on temperature. This is due to the fact that even at 2000 K the thermal energy of the oxides is very small compared to their total energy (0.5%–0.7%). The thermal expansion coefficient is also very small and almost equal to zero when $B_{12} = 8000$ eV.

The changes in the Gibbs energy and entropy along the MO₂ series were calculated⁵³ using the equation (11). The magnitude of $\delta S/Nk$ increases monotonically as in the M₂O and MO series (see Fig. 6a).

The relation between the topological looseness of oxide structures and their tendency to glass formation has been discussed above. Since SiO₂ and GeO₂ readily form glasses on ordinary cooling of a liquid, and TiO₂, SnO₂, and ZrO₂ do not form glasses, the value $B_{12} \approx 2500$ eV may be selected as the limit of glass formation. The $\rho_1 = 0.92$ and $s \approx 1.25$ coefficients correspond to this point. An estimate of ρ_1 from the plot (see Fig. 6b) for TeO₂ gives $\rho_1 = 0.94$ at $B_{12} \approx 3410$ eV, which only slightly exceeds this limit (0.92). This is in accordance with the fact that pure TeO₂ does not form a glass on ordinary cooling of a liquid but does form it on quenching between rotating cylinders.

5. Models of non-crystalline oxides in the M₂O₅ series

Non-crystalline oxides of the M₂O₅ series include such compounds as P₂O₅ and V₂O₅ along with As₂O₅, Nb₂O₅, Ta₂O₅, etc. Among these oxides, only P₂O₅ and V₂O₅ form glasses on ordinary cooling of a liquid, and niobium and tantalum oxides do not form glasses even on quenching between rotating cylinders.¹³¹ The properties of P₂O₅ and V₂O₅ models were described above. There are very few diffraction data on the structures of melts and glasses containing M₂O₅ oxides. The structure of an Nb₂O₅·2B₂O₃·2K₂O glass was studied by XRD; the values of 190, 311, 317, and 385 pm were obtained for the Nb–O, Nb–B, O–O, and Nb–Nb distances, respectively.¹⁴⁷ The mean CN for the Nb–O pairs is ~ 6.0 . The structure of the oxide contains a network of cyclic elements with six- and four-membered groups, such as NbO₆, BO₃, and BO₄.¹⁴⁷

Thus, the data on the structure of non-crystalline oxides of this series are quite fragmentary. There have been only a few studies on their thermodynamic properties. The Physicochemical properties of the non-crystalline M_2O_5 oxides were studied¹²³ using MD method. The potentials (1) were used with the following parameters: $Z_1 = +5$, $Z_2 = -2$, $B_{11} = 0$, $B_{22} = 1500$ eV, and $R_{ij} = 29$ pm. The dipole-dipole and dipole-quadrupole interactions were not taken into account. The critical value $B_{12}^c = 918$ eV, so the models were constructed for the range of $B_{12} = 950$ – 8000 eV.¹²³ Spherically symmetrical potentials provide the equivalence of all M–O bonds, which is typical of non-crystalline oxides. Each model comprised 497 ions. The Coulomb interactions were taken into account using the Ewald–Hansen method.³⁹ The edge length parameter of the basic cube was adjusted to maintain the pressure close to zero.

In order to examine the presence of hysteresis phenomena in the oxides, after heating of the system up to 2000 K its cooling to 0 K was simulated. The calculated energy appeared to be somewhat lower than the corresponding value for the initial models constructed using the CSR method (by $\sim 0.5\%$). It was shown that temperature insignificantly affects the properties of the oxide models. At zero pressure, the volume of the system increases by not more than 2% when the temperature changes from 0 K to 2000 K. In this respect, M_2O_5 oxides are similar to the MO_2 oxides. Positions of the TPCF peaks do not shift when the temperature is increased but the peaks become broader and less intense. The values of CN for the M–O pairs also change only slightly, as well as the position of the centres and widths of the O–M–O and M–O–M azimuthal angle distributions. The thermal energy is only 0.4%–0.6% of the total energy.

Figure 7 shows the dependences of the simulated characteristics for M_2O_5 oxides on B_{12} . The molar volume has a deep minimum at $B_{12} = 1500$ eV. The mean CN for the M–O pairs increases from 3.6–4.0 at $B_{12} = 950$ eV to 7.4–7.9 at $B_{12} = 8000$ eV. Such changes of the characteristics indicate a substantial structural rearrangement in the range of B_{12} values from 950 eV to 2500 eV. The structure of the first oxide ($B_{12} = 950$ eV) is intermediate between continuous random network with $z(M-O) = 4$ and layered trigonal [$z(M-O) = 3$] structures. Distributions of $z(M-O)$ in the M_2O_5 oxides are as follows:

$z(M-O)$	3	4	5	6	7	8	9	10
Number of M^{4+} ions								
at $B_{12} = 950$	59	83	—	—	—	—	—	—
1500	—	76	63	3	—	—	—	—
2500	—	20	98	24	—	—	—	—
3500	—	11	93	38	—	—	—	—
5000	—	—	24	76	36	5	1	—
8000	—	—	—	17	61	49	14	1

When $1500 \leq B_{12} \leq 3500$ eV, the distributions of $z(M-O)$ are limited by 4–6, but at $B_{12} \geq 5000$ eV their distribution becomes noticeably broader and shifts towards the greater values. A trigonal bipyramid with $z(M-O) = 5$ dominates as a structural element only in the range of B_{12} values from 2500 eV to 3500 eV.

Comparison of the models constructed with the real M_2O_5 oxides can be performed by the analysis of the $r_1(M-O)$ distances. For liquid V_2O_5 , this distance is close to 180 pm. The curve on Fig 7d allows one to estimate the value of B_{12} as ~ 2980 eV. An estimate made from the density of the crystal at 0 K and $p = 0$ gives a close value (2970 eV). A radius of 120 pm may be taken for O^{2-} ion. In this case, the difference $r_+ = r_1(M-O) - 120$ pm indicates that B_{12} is ~ 1800 eV for P_2O_5 , 2400 for As_2O_5 , 3360 for Sb_2O_5 , 3940 for Nb_2O_5 , 3940 for Ta_2O_5 , and 4230 eV for Bi_2O_5 . Therefore, the range of B_{12} from 1800 to 4230 eV corresponds to the real M_2O_5 oxides. And consequently, models with $B_{12} \leq 1500$ or $B_{12} \geq 5000$ eV are hypothetical. For models of real oxides, the distributions of $z(M-O)$ are such that the ordering type can not be described by an alternation of certain elements, a like trigonal bipyramid or an octahedron as it was suggested for V_2O_5 .⁵¹ An

Figure 7. Properties of models of non-crystalline M_2O_5 oxides at 2000 K. Numbers denote pairs of ions.

oxide with $B_{12} = 2500$ eV (the closest real oxide is As_2O_5) occupies the best position: for this oxide the distribution is almost symmetrical relative to $z(M-O) = 5\%$ and 69% of M^{5+} ions have exactly five O^{2-} neighbours.

It should be kept in mind that distributions of CN of the M–O pairs in real oxides may be more narrow than in the corresponding models. In general, relatively small models of non-crystalline substances composed of several hundreds or thousands particles contain more ‘defects’ per atom than the real substances. This fact has been established for amorphous silicon and germanium but it also holds for other oxides. The reason for the higher defectiveness is boundary conditions in the basic cube. Presumably, the same reason causes very slow (compared to the real oxide) decrease in the self-diffusion coefficients in the models on cooling.

According to the values of ρ_1 , all M_2O_5 oxides have loose structures, especially in the cases when $B_{12} < 5000$ eV (see Fig. 7b). This is typical of all real M_2O_5 oxides. The reason for the looseness is presumably the unfavourable stoichiometry (seven atoms per molecule), which cannot exist in more or less regular networks.

Substantial complication of the oxide structures with an increase in B_{12} is accompanied by a small decrease in the mean value of the O–M–O azimuthal angle (from 110 to 100°). However, the width of distribution of this angle increases from 18 to 31°. The value of M–O–M angle changes along the series much more strongly (from 165 to 116°), and the distribution width is doubled. In well-ordered network structures of B_2O_3 and SiO_2 , the widths of angle distributions obtained in computer simulations were usually 8–10°. This feature also does not permit reliable conclusions on the presence of distinct structural elements in M_2O_5 oxides.

The looseness of structures is clearly seen in the visual study of spatial models constructed from balls of different diameters with the coordinates taken from the results of computer simulations of the oxides. For instance, large irregular pores situated between such groups as MO_4 , MO_5 , or MO_6 linked through shared vertices, can be seen in a spatial model built based on a calculation for $B_{12} = 2500$ eV. The surface of the pores is formed by oxygen ions and their repulsion stabilises the shape of pores. The packing of O^{2-} ions does not contain any linear or layered elements.

The maximum pore size was 163 pm, i.e. a positive ion or a neutral atom of a relatively large size may easily occupy the pore. In the model, six pores with radii > 140 pm, six pores with radii between 130 and 140 pm, etc. were found. These results, in particular, allow one to estimate the solubility of noble gases in

the oxides. An analysis of bound groups showed that all M_2O_5 oxides are completely polymerised (in terms of the polymer theory of slags).

According to Fig. 7b, for V_2O_5 with $B_{12} = 2970$ eV, $\rho_1 \approx 0.96$, and for Nb_2O_5 and Ta_2O_5 with $B_{12} = 3940$ eV, $\rho_1 \approx 1.00$. Thus, the glass formation limit for the M_2O_5 oxides lies in the range $0.96 < \rho_1 < 1.00$ ($\rho_1 \approx 0.97$) that is slightly higher than for the MO_2 oxides. This shift is due to a more complex structure of the M_2O_5 oxides. Therefore, P_2O_5 , V_2O_5 , As_2O_5 , and Sb_2O_5 should readily form glasses but liquid Bi_2O_5 should not form a glass on ordinary cooling in air, since the estimate of ρ_1 for this oxide is $\sim 1.0-1.1$.

The changes in the configurational entropy along the M_2O_5 series were calculated using the equation (11). The entropy initially decreases with the increase in B_{12} and then goes through a shallow minimum at $B_{12} \approx 2500$ eV (see Fig. 7a). This minimum is due to the fact that the distribution of CN for the M–O pairs is rather narrow and almost symmetrical with its centre close to 5.0 for $B_{12} = 2500$ eV. When $B_{12} < 2500$ eV, the structure of oxide becomes more complex, since $z(M-O) = 4$ and 5 are almost equally probable. At $B_{12} > 3500$ eV, the CN distribution width rapidly increases, resulting in the increase in entropy. When $B_{12} \geq 5000$ eV, the width of CN distribution and the configurational entropy remain almost unchanged.

6. Models of non-crystalline oxides in the MO_3 series

Oxides of the MO_3 series include such components of glasses and metallurgic slags as CrO_3 , MoO_3 , and WO_3 . Pure MoO_3 and WO_3 form glasses on ordinary cooling of melt,¹⁴³ as well as on flattening.¹³¹ There are very few diffraction data on the structure of the MO_3 oxides. Thus, the structural information on complex oxides should be used. The study on the structure of Na_2O-WO_3 glass¹²⁶ was already cited.

A series of computer models for MO_3 oxides at 0 and 2000 K was constructed using the MD and CSR methods.¹³⁰ All models contained 500 ions in the cube. The potentials (1) with the following parameters were applied: $Z_1 = +6$, $Z_2 = -2$, $B_{11} = 0$, $B_{22} = 1500$ eV, $R_{ij} = 29$ pm. The critical value of B_{12} for this series is 1101 eV. Therefore, the values of B_{12} were chosen in the range of 1150–9999 eV. The models were constructed in a way similar to other M_mO_n series. The Coulomb interactions were taken into account using the Ewald–Hansen method.³⁹ The edge length of the basic cube was adjusted to maintain the pressure close to zero.

A model with $B_{12} = 1150$ eV was in a special position. The pressure in the system remains positive at 2000 K and at any volume, which means that the system was in the state of a strongly compressed gas. In vacuum, this gas contains the MO_3 molecules with ionic bonding in the form of centred regular triangles. Visual analysis of a spatial model constructed on the base of results of computation with $B_{12} = 1150$ eV demonstrated that the oxide is composed of separate MO_3 groups, which represent almost planar triangles with the M^{6+} ions in their centres. The planes of the triangles are randomly oriented, however there is a tendency on a

rotation of one of the vertices towards the centre of the neighbouring triangle. This arrangement gives a gain in energy. Many large pores and cavities were found in the model. The MO_3 groups are aggregated into clusters of 4–5 groups, and the clusters are relatively remote from each other.

The dependencies of the characteristics for the MO_3 models on B_{12} are shown in Fig. 8. The $r_1(ij)$ values increase monotonically with increase in B_{12} , the molar volume goes through a minimum at $B_{12} \approx 3400$ eV. As in the case of other oxides, this minimum is due to a rapid increase in CN for the M–O pairs from 3.00 at $B_{12} = 1150$ eV to ~ 6 at $B_{12} = 3400$ eV and further up to ~ 8.0 .

At $B_{12} = 3400$ eV, the M–O distance is 179 pm, which almost coincides with the W–O distance in tungstenate glasses. So far, this model can be attributed to WO_3 oxide. In fact, in addition to $r_1(M-O)$, the mean CN for the M–O pairs (6.0) also coincides with the experimental data.¹²⁶ However, the distribution of $z(M-O)$ reveals that CN equal to 5 and 7 are also present in the models, though the value 6 (octahedral arrangement) dominates.

$z(M-O)$	4	5	6	7	8	9	10
Number of M^{6+} ions with $B_{12} =$							
1850	41	66	17	—	—	—	—
3000	—	27	93	5	—	—	—
4800	—	13	97	15	—	—	—
9999	—	—	5	31	59	26	4

When $3000 \leq B_{12} \leq 4800$ eV, the majority of O^{2-} ions have two neighbouring M ions and they play a role of bridging particles linking two neighbouring MO_n groups. Only at $B_{12} = 9999$ eV, do the majority of O^{2-} ions have three M neighbours. As regards the $z(ij)$ distribution, the oxide structure with $B_{12} = 4800$ eV is the most ordered.

Distributions of CN for the O–O pairs have specific features. When $B_{12} \geq 3400$, they have an usual form with a maximum near $z(M-O) = 8-9$. However, when $B_{12} \leq 1850$ eV, these distributions exhibit two maxima at $z = 3-4$ and $6-7$. The first maximum is especially high for the model with $B_{12} = 1150$; it is attributed to the above-mentioned configuration, in which a vertex of one of the MO_3 triangles is directed towards the centre of another triangle. The first maximum is assigned to O^{2-} ions that do not link the two triangles. The second maximum is assigned to the bridging O^{2-} ions. An increase in B_{12} results in a gradual smearing of the structural elements and the system turns into the dense one. This can be seen from the values of the topological parameters ρ_1 and s . At $B_{12} = 1850$ eV, $\rho_1 = 0.780$ and $s = 2.0$; increase in B_{12} is accompanied by an increase in ρ_1 to 1.05 and a decrease in s to ~ 1.0 , which indicates the appearance of a dense structure. When $B_{12} \leq 4800$ eV, all models have loose structures.

Distributions of the O–M–O azimuthal angles are very broad (the standard deviations up to $25-30^\circ$) for all models besides the model with $B_{12} = 1150$ eV. Distributions of M–O–M angles are more narrow, their standard deviations increase from 9.2 (at $B_{12} = 1850$ eV) to 24.8° (at $B_{12} = 9999$ eV).

Taking account of ionic radii, the models were identified as follows:¹³⁰

Figure 8. Properties of models of non-crystalline MO_3 oxides at 2000 K. Numbers denote pairs of ions.

MO ₃	CrO ₃	ReO ₃	TeO ₃	MoO ₃	WO ₃
B_{12} /eV	2300	2800	2930	3260	3400

Therefore, real MO₃ oxides form a rather narrow group corresponding to a small region $2300 \leq B_{12} \leq 3400$ eV in the homologous series. Other models are hypothetical.

For models of the MO₃ oxides, thermal energy at 2000 K is 0.5% of the total energy. Thus, temperature has little effect on their structure. The average heat capacity C_p is close to the classical value $3R = 24.9$ J (g-ion K)⁻¹.

Change in the configurational entropy δS along the series¹³⁰ (see Fig. 8a) has a rather deep minimum at $B_{12} \simeq 3000$ eV, and is almost constant at higher B_{12} . Again, the entropy behaviour may be explained by structural effects, although in the interval corresponding to the real oxides the entropy changes insignificantly.

VI. Simulation of binary non-crystalline oxide systems

1. Simulation of non-crystalline silicate systems

a. Models of systems of M₂O—SiO₂ type

Numerous studies are devoted to silicate systems due to their practical importance. Structural data for silicates¹⁴¹ and M₂O·2SiO₂ bisilicates¹³² were reviewed. Lithium bisilicate does not form a glass on ordinary cooling of a melt, for sodium bisilicate the glass formation is difficult, and potassium bisilicate readily forms a glass.¹⁴³ However, it was stated¹⁴⁸ that a lithium bisilicate glass was prepared by ordinary cooling of a melt. Negative deviations from the ideal thermodynamic state of M₂O were observed in M₂O—SiO₂ systems.

Experimental data on the structure of alkali metal silicates were obtained by X-ray and neutron scattering. It was established that the Si—O distance almost does not depend on the composition and temperature of oxide and is close to 161 pm, and $z(\text{Si—O}) \simeq 4.0$. For the M—O pairs (M = Li, Na, K), the M—O distance and the mean CN increases in the series Li → K. Data given by different authors disagree. For Li, the M—O distances lie in the range of 190–260 pm, for Na in the range of 222–248 pm, and for K in the range of 265–275 pm. The CN for the Li—O pairs varies from 3 to 4, for the Na—O pairs, from 4 to 6, and for K—O and Cs—O pairs, from 5 to 7.5.

It should be noted that the structural data for lithium silicates are unreliable. The contribution of the Li—O pairs to the total PCF is very small both for X-rays and neutrons, and thus this peak is almost indistinguishable in the TPCF above the background of false oscillations due to the Fourier transformation of the structural factor.

Structural studies of Na₂O—SiO₂ glasses with 19 mol.%–35 mol.% of Na₂O showed that the Na—O, Si—O, Si—Si, and O—O distances are 235, 162, 320, and 264 pm, respectively; $z(\text{Si—O}) = 4.0$ and $z(\text{Na—O}) \simeq 6$.^{149,150} For potassium silicates with 14 mol.%–20 mol.% of K₂O, the CN for the K—O pairs was $\sim 10 \pm 1$.¹⁵⁰ It was established that Na⁺ and K⁺ ions occupy pores formed by the silicon-oxygen network.

Structures of M₂O·2SiO₂ bisilicates (M = Li, Na, K), and of (Li_{0.63}Na_{0.37})₂·2SiO₂ were investigated using scattering of a pulsing neutron beam.¹⁵¹ Contributions of the Li—O pairs appeared insignificant. An approximate interpretation gave the following values of the interionic distances:

Pair	Li—O	Na—O	Si—O	O—O
$r_1(ij)$ /pm	~ 200	~ 240	161–163	263–265
$z(ij)$	—	—	3.9–4.0	4.4 (Li), 4.9 (Na)

Data on computer simulations of binary systems such as Li₂O—SiO₂,^{152–155} Na₂O—SiO₂,^{35,83,134,153,154,156–161} K₂O—SiO₂,^{153,154,161,162} as well as oxides in the M₂O·2SiO₂ series (see Ref. 132) have been published. Different potentials were applied in the simulations. In many studies,^{131,134,152,153,155,162} the potentials (1) with accurate account of the Coulomb interactions using the Ewald–Hansen method³⁹ were used. An accelerated computational scheme was developed¹⁵³ in which the Ewald sums

were calculated for the sublattice of one basic cube octant on initial steps and the interpolation was performed for all intermediate points. In¹⁵⁴ the Ewald sums were truncated. A combination of the Keating's three-particle potential for three-atom combinations of silicon and oxygen particles, with the Lennard–Jones potentials for interactions of sodium particles with the other particles was applied³⁵ for the Na₂O—SiO₂ oxides. In the majority of simulation studies, only structural aspects were carefully explored, and little attention was paid to the thermodynamic properties.

Models for M₂O—SiO₂ systems (M = Li, Na, K) comprising 800 ions in the basic cube were constructed.¹⁵⁴ Concentration of M₂O varied from 1.47 mol.% to 23 mol.%. Generally, reasonable agreement between simulation and diffraction data for melt structures was achieved.¹⁵¹ However, the Si—O distance appeared to be somewhat shorter (157 pm instead of 161–162 pm). No clustering of M⁺ ions was observed. The addition of an M₂O oxide does not affect the basic structure of silica and leads only to the appearance of non-bridging O²⁻ ions (*i.e.* particles with CN for the O—Si pairs differing from 2). The mean Si—O—Si angle was somewhat larger than the actual value ($\sim 155^\circ$ instead of $\sim 143^\circ$). This deviation can be explained by the contribution of covalent bonding to the interparticle interactions in real oxides that has not been taken into account in the model.¹⁵⁴ It was found that a change in the molar volume affects substantially the azimuthal angles and CN for the M—O pairs. Vibrational frequencies for various ions were also estimated.¹⁵⁴

Structural differences of sodium and potassium silicate glasses are due to the different degrees of nanoscale inhomogeneities in the distribution of terminal oxygen ions (which have only one silicon neighbour) and the alkali metal ions bound to them. These inhomogeneities were considered¹⁶¹ to be a specific feature of alkali-silicate glasses.

Models of a melt (1000–4000 K) and glass (300 K) of 2Li₂O·SiO₂ were constructed using the MD method and with accounting for Coulomb interactions using the Ewald method.^{152,155} The density for the model of glass was taken to be equal to the actual value. The models comprised 576 ions; the Born–Meyer potentials were used. Charges of lithium, silicon, and oxygen ions were +1, +4, and –2, respectively. Values of 160 and 186–193 pm were obtained for Si—O and Li—O distances; the mean CN for these pairs were 4.0 and 3.5, respectively. The calculated interionic distances were compared with the experimental results¹⁵¹ (see below).

Pair	Li—O	Li—Li	O—O	Li—Si	Si—Si
$r_1(ij)$ /pm					
calculation	186–193	248–260	258	306–310	320
experiment ¹⁵¹	223(?)	—	263–265	—	320

The agreement between these data is moderate, although the experimental estimates for the Li—O pairs are hardly accurate. Monomeric and dimeric structural groups SiO₄⁴⁻ (43 groups) and Si₂O₆⁶⁻ (18 groups) were found along with SiO₃²⁻ chains. The mean CN for the Li—O pairs in the models lie in the range of 3–4 (the experimental value is 3.1, see Ref. 151).

The following values of self-diffusion coefficients (D) were calculated from the slope of the regression line for ion shifts vs. time:

Ion	Li ⁺	Si ⁴⁺	O ²⁻
$10^5 D$ /cm ² s ⁻¹			
melt (3000 K)	21.5	1.88	2.23
glass (1000 K)	1.09	0.184	0.283

As could be expected, the diffusion of lithium ions is rather fast, while for silicon and oxygen the values of self-diffusion coefficients are close to the limits of the MD calculations.

Having revealed in the models the O²⁻ ions with 2 (bridging), 1 (terminal), and 0 (free) closest Si neighbours, the authors calculated the equilibrium constant for the reaction $2\text{O}^- = \text{O}^0 + \text{O}^{2-}$ in terms of the polymer theory of slags.¹⁵⁵

The constant for the $2\text{Li}_2\text{O} \cdot \text{SiO}_2$ glass at 300 K was 0.0032, which implies that almost all the oxygen atoms belong to the SiO_4^{4-} monomers.

Models of melts (2000 K) and glasses (605 K) with composition of $2\text{M}_2\text{O} \cdot \text{SiO}_2$ ($\text{M} = \text{Li}, \text{Na}, \text{K}$) were also constructed.¹⁵³ According to a more recent publication,¹⁶³ these models contained 110–120 ions in the cube. For the Li–O pairs, the distance of 260 pm was obtained. This value is definitely overestimated, since the sum of the ionic radii is $74 + 120 = 194$ pm. Self-diffusion coefficients of ions at 1010 K were also calculated in this study. The following values were obtained:

Ion	Li^+	Na^+	K^+	Si^{4+}	O^{2-}
$10^5 D / \text{cm}^2 \text{ s}^{-1}$	15	3.3	2.3	0.98	2.0

The MD method was used¹⁵⁶ to construct a model of $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$. The repulsion of ions was described by the Pauling formula (6) with the power coefficient $n = 10$. The basic cube contained 3000 ions. Interionic distances and CN were as follows:

Pair	Na–Na	Na–Si	Si–Si	Na–O	Si–O	O–O
$r_1(ij) / \text{pm}$	~310	335	312	228	162	262
$z(ij)$	–	5.1	?	5	4	–

These results are in agreement with diffraction data¹⁵¹ for the Si–O and O–O pairs.

Models of sodium silicates containing 4.846 mol.% to 30.1 mol.% of Na_2O were constructed;¹⁵⁷ the models comprised 700–900 ions. The size of the basic cube was chosen taking into account the actual density of a melt. The pair potentials (1) with parameters adjusted to the properties of α -quartz were used. The relaxation was performed in the sequence 6000–3000–1500–293 K for 10 000 steps at each temperature. The results obtained agreed well with the diffraction data. A difference in bond lengths between the silicon atom and the bridging (165 pm) and terminal (< 156 pm) oxygen atoms was observed. It was found that the portion of bridging oxygen ions with $z(\text{O}–\text{Si}) = 2$ decreases from 95% to 65% with increase in the Na_2O content, while the portion of terminal ions increases from 5% to 35%. The models were inhomogeneous on a nanometer scale, so that the sodium atoms were clustered around non-bridging oxygen atoms.

Models of amorphous (0 K) and liquid (2000 K) bisilicates $\text{M}_2\text{O} \cdot 2\text{SiO}_2$ with the Born–Meyer potentials were constructed using the CSR and MD methods.¹³² The following values of B_{ij} were selected: 0 for the M–M and M–Si pairs, 2055.4 (Si–Si), 1729.5 (Si–O), 1500 eV (O–O), and 545.3, 925.1, 1601.94, 3844.1, and 9999.0 eV for the M–O pairs in five different models. The third and the fourth models related to sodium and potassium bisilicates, respectively. The distance in the M–O pairs depends almost linearly on $\ln B_{13}$ (atom numbering is as follows: 1 for M, 2 for Si, and 3 for O). As B_{13} increases, the M–Si and M–O distances increase monotonically, the M–M distance changes non-monotonically, and the Si–Si, Si–O and O–O distances remain almost unchanged. At $B_{13} = 626.7$ eV in the model that corresponds to lithium silicate, $r_1(\text{M}–\text{O}) = 181$ pm. Diffraction data give the higher value (186–193 pm). For sodium and potassium silicates, the agreement between the corresponding values is substantially better. All model distances for sodium silicate obtained in^{132, 156} agree well with the experimental data.

The adequacy of the models constructed may be examined by comparing the calculated and actual molar volumes at 2000 K and zero pressure.

Oxide	$\text{Li}_2\text{O} \cdot 2\text{SiO}_2$	$\text{Na}_2\text{O} \cdot 2\text{SiO}_2$	$\text{K}_2\text{O} \cdot 2\text{SiO}_2$
$V/N / \text{cm}^3 (\text{g-ion})^{-1}$			
calculation	9.73	10.2	11.6
experiment ¹³³	8.1	9.5	11.6

For lithium bisilicate, the difference between the results of simulation and experimental data reaches 20%, but for sodium and potassium bisilicates it does not exceed 4%–6%. For rubidium bisilicate, the interpolation of V/N at $B_{13} = 5320$ eV

gives the value $11.9 \text{ cm}^3 (\text{g-ion})^{-1}$, while the experimental value (extrapolated to 2000 K) is 12.0 .¹³³

The reason for the deviations observed is probably the more distinct manifestation of hysteresis phenomena on going from Na to Li. At a pressure of 4 GPa and 673 K, the density of lithium silicates increases by 6%–9% in 15 min, while that of sodium trisilicate, by 3.2%, and of potassium trisilicate, by 0.2%.¹¹⁸ Overestimated molar volume for models of lithium bisilicate may be due to their metastability. Furthermore, it is also possible that the Born–Meyer potentials are poorly applicable for the description of lithium oxide.

It is noteworthy that model M–O distances^{132, 152, 155} are shorter than those obtained from diffraction studies, while the molar volume for the models is larger than that of the real oxides. This contradiction might be explained assuming that the diffraction data for the Li–O pairs are inaccurate and the PPCF peak for the Li–O pair in the total PCF is attributed incorrectly.

For MD simulation of lithium silicates, the values $B_{13} = 1443$ eV and $R_{13} = 29$ pm were selected.¹⁵⁴ The calculated M–O distance (200 pm) was close to that obtained from diffraction data. However, with this value of B_{13} the molar volume of a model Li_2O crystal was equal to the actual value [$4.974 \text{ cm}^3 (\text{g-ion})^{-1}$] only at a pressure of 98 GPa. Thus, the assumption on overestimated Li–O distances obtained from diffraction studies seems reasonable.

The CN values for the M–O pairs in the models of bisilicates¹³² were as follows:

B_{12} / eV	545.3	925.1	1601.9	3844.1	9999.0
$z(\text{M}–\text{O})$					
2000 K	2.48	3.36	4.97	5.41	6.10
0 K	2.20	2.54	3.59	5.21	7.15

In M_2O crystals, the CN for the M–O pairs is 4.0. Melting or amorphisation are accompanied by a decrease in the CN. On going from a simple oxide to bisilicate, the CN increases substantially and when $B_{13} \geq 1601$ eV it already exceeds 4. For sodium bisilicates, the agreement between $z(\text{M}–\text{O})$ obtained from the simulation (4.97 at 2000 K) and diffraction (5.8 at 1373 K, see Refs 51, 141) is quite reasonable.

An increase in CN for the M–O pairs on going from simple oxide to bisilicate at $B_{13} \geq 1601$ eV is partially due to an abrupt decrease in the molar volume, although the formation of a silicate network is another important factor. In the case of M^{n+} ions with $n \geq 2$ (for example, Ca^{2+}), the transition from MO to $\text{MO} \cdot 2\text{SiO}_2$ leads to a relatively small change in the CN for the M–O pairs (from 5.1 in CaO to 5.6 in bisilicate). This can be explained by the fact that ions with charges ≥ 2 form a coordination sphere around O^{2-} ions, and its structure is almost independent of the composition of the complex oxide.

Interparticle distances for the O–O pairs may be compared with those obtained from the diffraction analysis. In real lithium, sodium, and potassium silicates, $r_1(\text{O}–\text{O}) = 263$ –266 pm.^{141, 151} This distance in the models is 259–262 pm.^{132, 156} Small deviations are probably due to the use of different computational schemes. The experimental values for $z(\text{O}–\text{O})$ appeared equal to 5.6 for all bisilicates,¹⁴¹ while the model CN gradually decrease from 5.75 at $B_{13} = 545.3$ eV to 4.89 at $B_{13} = 9999$ eV.¹³² The agreement of these results may be regarded as good, since the PPCF peaks of the Na–O and K–O pairs overlap with the peaks of the O–O pairs, which makes accurate calculations of partial CN difficult. In this sense, the simulation gives more precise results.

Analysis of the shape of TPCF for bisilicates at 2000 K (for X-rays) obtained from simulations demonstrated that peaks assigned to the Li–Li, Li–Si, and Li–O pairs are totally absent due to the small scattering factor of lithium atom. For potassium silicate, K–O and Si–O peaks do not overlap. Comparison of these data with the diffraction data¹⁴¹ showed that the assignment of peaks¹⁴¹ is in accordance with the results of simulation only in the case of potassium bisilicate. When $r > 500$ pm, the TPCF are

virtually equal to the asymptotic value of 1.00 due to a mutual interference of oscillations of six PPCF.

Comparison of the experimental data with the results of simulations shows that in diffraction studies of multi-component systems a correct interpretation can be made, in the best case, only for one or two first TPCF peaks. Consequently, the computer simulation of these systems is of special importance.

Additional information on the structure of compounds considered may be extracted from the $z(\text{O}-\text{O})$ distributions in bisilicates. The distributions exhibit two maxima at CN equal to 3 and 6. For instance, the CN distribution for binary $\text{Na}_2\text{O} \cdot 2\text{SiO}_2$ oxide has the form:¹³²

$z(\text{O}-\text{O})$	2	3	4	5	6	7	8	9	10
Number of Na^+ ions	—	64	23	9	118	48	11	1	—

The value 3 is typical of isolated SiO_4^{4-} tetrahedra and CN 6 is typical of two linked tetrahedra with a shared vertex. In the model of SiO_2 at 2000 K, $z(\text{O}-\text{O})$ lies in the range from 5 to 12 with a strong maximum at 6–7, and the mean CN is 7.14. Therefore the presence of values $z < 5$ in bisilicates indicates partial decomposition of an oxygen-silicon network and the appearance of unshared vertices. Oxygen ions occupying these vertices, according to the polymer theory of slags, are called terminal O^- ions. If the radii of the closest spheres for the $\text{O}-\text{O}$ and $\text{O}-\text{Si}$ pairs were identical, the number of terminal O^- ions would be equal to the number of O^{2-} ions with $z(\text{O}-\text{Si}) = 1$.

For the $\text{M}-\text{O}$ pairs, the distributions of CN are very broad (for instance, in sodium bisilicate the CN values lie in the range from 2 to 8, and for potassium bisilicate, in the range from 3 to 11). Hence, ions with charge +1 cannot form a rigid coordination sphere around them. Small ions with large charge, such as Si^{4+} , can do this: 100 out of 110 Si^{4+} ions have exactly four O^{2-} neighbours. Spatial distribution of neighbours around Si^{4+} ions is approximately tetrahedral, the $\text{O}-\text{Si}-\text{O}$ azimuthal angles are $109^\circ \pm (11-13^\circ)$. The mean value of the $\text{O}-\text{Si}-\text{O}$ angle is close to the ideal tetrahedral value, but this distribution is rather broad. The values of $\text{M}-\text{O}-\text{M}$ angles vary from Li to Cs over a wide range, although their mean value is almost constant ($93-97^\circ$).

The topological characteristics of the above models are as follows:

B_{13} / eV	545.3	925.1	1601.9	3844.1	9999.0
ρ_1	0.886	0.930	0.959	0.962	0.988
s	2.05	1.77	1.42	1.60	1.42

It is seen that the structure of alkali metal bisilicates is loose, and when $B_{13} \leq 925$ eV the values of ρ_1 are even lower than for pure silica (0.93). The addition of M_2O oxide with small M^+ ions (such as Li^+) results in the increase in the looseness of the system and in the appearance of large cavities (pores) therein.

The thermodynamic properties of liquid and amorphous bisilicates were simulated.¹³² It was established that the increase in B_{13} leads to a gradual increase in the molar volume. The ratio of molar volumes $V_{2000\text{ K}}/V_{0\text{ K}}$ is close to 1.00 at $B_{13} = 545.3$ eV and increases to 1.12 for $B_{13} = 9999$ eV. The mean heat capacity C_p of the oxides is close to $3R$. Changes in volume in the formation of one mole of a complex oxide from the simple ones is positive for $B_{13} \leq 1602$ eV and negative for $B_{13} \geq 3844$ eV. The change in energy in the formation of one mole of bisilicate is negative for all values of B_{13} and lies in the range from -27 kJ mol $^{-1}$ to -118 kJ mol $^{-1}$. Therefore, negative deviations from the ideality should be observed for these oxides. The values of ΔE_{form} found are very close to the experimental heats of formation of the corresponding crystalline lithium, sodium, and potassium bisilicates. Thus, the ionic model of complex oxides works adequately in respect of their thermodynamic properties. Even selection of a very simple form of the pair potentials (1) leads to agreement with the experimental data.

Changes in the Gibbs energy and entropy along the $\text{M}_2\text{O} \cdot 2\text{SiO}_2$ series were calculated according to the equation (11).¹³² It was established that the increase in B_{13} is accompanied

by a decrease in ΔG_{form} (formation of a complex oxide from the simple ones). These results are not only in qualitative, but (for lithium and sodium bisilicates) also in quantitative agreement with the experimental data. Values of ΔG_{form} for other silicates were predicted.¹³² It was shown that the configurational entropy passes through a minimum at $B_{13} = 1602$ eV as B_{13} increases and then increases by only $\sim 0.4Nk$. Changes in entropy ΔS in a formation of one mole of a complex oxide from the simple ones depends on B_{13} in a similar way and has a minimum at $B_{13} = 3844$ eV.

Models of oxides in a binary $(\text{Na}_2\text{O})_x(\text{SiO}_2)_{1-x}$ system composed of 500 ions with various x were constructed using the CSR and MD methods with the pair potentials (1).¹³⁴ The results of the simulation are summarised in Table 5.

The values of molar volumes were obtained with an error of several percent due to slow changes in pressure in the CSR calculations. Therefore, the molar volume changes non-monotonically as a function of composition. Nevertheless, there is a distinct minimum of the molar volume at $x = 0.2-0.3$. In general, a noticeable compression of a system occurs in the formation of binary oxides from pure non-crystalline Na_2O and SiO_2 (by 8%–9% in middle range of compositions). Comparison with the experimental data for the crystalline compounds demonstrated that the calculated volume of glass exceeds the corresponding experimental value by $\sim 10\%$ in all cases. The energy of glasses per one mole of a complex oxide depends virtually linearly on x with deviations from additivity not exceeding 1.2%. Changes in the energy ΔE_{form} are positive for $x < 0.5$ and negative for $x > 0.5$. In the case of potassium silicate at 1200 K, the transition of excess enthalpy ΔH_{form} to positive values is almost unnoticeable.¹⁶² The error in the determination of ΔE_{form} is 15 to 20 kJ (g-ion) $^{-1}$. The experimental values for the partial enthalpy of SiO_2 at $x = 0.10-0.22$ and $T = 1200-1800$ K is ~ 0.9 kJ mol $^{-1}$, i.e. substantially less than the error of simulation.

Positions of PPCF peaks obtained in simulation are in good agreement with the experimental data (see above), especially for sodium bisilicate. The TPCF calculated for this model agrees well with the published data¹⁶⁵ but differs from those from another study.¹⁶⁴ Positions of the peaks found in Ref.¹³⁴ are in agreement with the results of calculation.¹⁵⁶ Longer Na–Na, Na–O and shorter Na–Si distances were obtained in a simulation with the use of three-particle potentials.³⁵

Distributions of CN for the Na–O pairs appeared rather broad; for instance, at $x = 0.666$, the values of $z(\text{Na}-\text{O})$ lie in the range from 1 to 7 and the mean CN is 3.33 ± 0.95 . Distribution of $\text{O}-\text{Si}-\text{O}$ angles lies within the range of $90-140^\circ$ ($114 \pm 8.4^\circ$). Therefore, the distribution of O^{2-} ions around Si^{4+} ions is mostly tetrahedral, though 9% of silicon ions have two, three, or five O^{2-} neighbours.

Neglecting an Ewald potential terms with a cubic symmetry (in order to save computational time) may lead to serious errors. For example, at $x = 0.5$ the Na–Na distance without taking account of the cubic contributions is 258 pm, while accounting for these terms gives 288 pm; Na–Si distances are 261 and 313 pm,

Table 5. Parameters of models of glasses in the system $(\text{Na}_2\text{O})_x(\text{SiO}_2)_{1-x}$ at 0 K.

Parameter	x	1.0	0.8	0.67	0.5	0.33	0.2	0.1	0.0
V/N / cm ^{3} mol $^{-1}$		27.6	28.4	25.3	27.3	25.8	25.4	26.5	27.2
$r_1(ij)$ / pm for pairs									
Na–O		222	229	229	228	233	226	237	—
Si–O (exp. ¹⁶⁴)		—	160	160	161	163	162	161	161
Na–O		—	—	—	235	236	—	—	—
Si–O		—	—	—	162	162	—	—	—
ρ_1		1.073	1.01	1.03	0.98	1.00	0.96	0.93	0.93

respectively. Thus, the simplification of the computational algorithm is not always justified.

When $T = 0$ K and $x \leq 0.5$, the energy of formation $\Delta E_{\text{form}} > 0$, so that a tendency for separation of components should be observed. This point was specially considered for a $\text{K}_2\text{O}-\text{SiO}_2$ system.¹⁶² It was shown that K^+ ions occupy large pores of the oxygen-silicon network. Basing on analysis of diffraction data, it was proposed¹⁶⁵ that the melt (glass) is built up of two types of microgroups, viz. with high alkali metal content ($\text{Na}_2\text{O} \cdot 2\text{SiO}_2$) and with high silicon content (with composition close to silica) in the range $0.2 \leq x \leq 0.33$. These microgroups cannot exist in models with $N \approx 500$.

The addition of Na_2O to SiO_2 leads to a rapid increase in ρ_1 and abrupt decrease in s . Therefore, the addition of Na_2O causes an effective depolymerisation of the structure, i.e. a decomposition of the tetrahedral network of bonds. The system is depolymerised to a noticeable degree already at $x = 0.5$. Models³⁵ constructed with accounting of three-particle potentials give higher values of ρ_1 . For example, a calculation³⁵ at $x = 0.333$ gave the value of $\rho_1 = 1.056$, which is typical of dense non-crystalline systems. Results of simulation^{134, 156} agree well with each other in respect of ρ_1 (for instance, at $x = 0.33$, $\rho_1 \approx 0.96$).

The applicability of the polymer theory of slags (PTS) to the $\text{Na}_2\text{O}-\text{SiO}_2$ oxides was analysed.¹³⁴ The basic parameters of this theory are the degree of polymerisation α , molar ratios of different anions, and polymerisation constant K_p . Solutions of associates are usually regarded as ideal ones. To use a polymer model, the following conditions have to be met: 1) CN for the Si-O pairs has to be equal to 4 for all Si atoms; 2) the oxygen atom with two closest silicon neighbours is considered as a 'bridging' O^0 atom; 3) the oxygen atom with one closest silicon neighbour is considered as a 'terminal' O^- atom; 4) 'free' oxygen O^{2-} ion does not have any closest Si neighbours.

Further, the n_0 , n_1 , and n_2 will be used to denote numbers of 'bridging', 'terminal' atoms, and 'free' ions, respectively. The degree of polymerisation is given by the formula:¹³⁴

$$\alpha = n_0 [2n(\text{Si})]^{-1},$$

where $n(\text{Si})$ is a number of silicon ions. For pure SiO_2 , $\alpha = 1$ if all O particles have two Si neighbours. The polymerisation constant is defined as the equilibrium constant for the reaction $2\text{O}^- = \text{O}^0 + \text{O}^{2-}$ within the ideal solution approximation.

$$K_p = X(\text{O}^0)X(\text{O}^{2-}) [X(\text{O}^-)]^{-2},$$

where $X(\text{O}_k) = n_k/n(\text{O})$ is a ratio of O_k particles to the total number of oxygen particles in the system. The α and K_p parameters can be calculated from the computer simulations. For models of $(\text{Na}_2\text{O})_x(\text{SiO}_2)_{1-x}$ glasses, the following values were found:

x	0.800	0.667	0.500	0.333	0.20
α	0.197	0.336	0.542	0.715	0.87
K_p	0.104	0.064	0.027	0.044	0.051

K_p were determined approximately due to the small value of n_2 for $x \leq 0.5$. If the condition $z(\text{Si}-\text{O}) = 4.00$ (for each silicon ion), as well as the condition on the electrical neutrality of the system are met, the following expression holds:¹³⁴

$$K_p = \frac{\alpha[x - 2(1-x)(1-\alpha)]}{8(1-x)(1-\alpha)^2}.$$

This expression holds satisfactorily for sodium silicate models.

In order to determine the polyanionic composition of a model in terms of the PTS, it is necessary to distinguish complex $\text{Si}_m\text{O}_n^{q-}$ anions as bound groups of particles in which each silicon atom is linked to at least one other silicon atom of the same group through a bridging oxygen atom. Distributions of the bound groups calculated for $(\text{Na}_2\text{O})_x(\text{SiO}_2)_{1-x}$ models are shown below:

x	0.8	0.667	0.5	0.333
Group	$1^{12}2^64^{15}1$	$1^{11}2^43^24^{17}1^{19}1$	$1^32^31^68^1$	110^1

The notation $1^{12}2^6\dots$ means that 12 SiO_4^{4-} 'monomers', 6 $\text{Si}_2\text{O}_7^{6-}$ dimers, and so on, were found in the model. When $x \leq 0.333$, all oxides are completely polymerised (in accordance with the PTS). Another PTS parameter is the equilibrium K_{11} constant for the reaction

Within the ideal solution approximation K_{11} is given by:

$$K_{11} = n_2 n(\text{Si}_2\text{O}_7^{6-}) [n(\text{SiO}_4^{4-})]^{-2}.$$

Values of K_{11} for models of sodium silicate vary in a wide range (from 1.56 at $x = 0.5$ to 3.46 at $x = 0.8$).

In agreement with the PTS, ionic ratios $Y(i)$ are defined as ratios of numbers of polyanions composed of i particles to the total number of all polyanions and free anions O^{2-} ; the ionic ratio $Y(\text{O}^{2-})$ is defined similarly. These parameters characterising the anionic composition of silicates only slightly depend on temperature.

In terms of the theory of perfect ionic solutions, the thermodynamic activity of M_2O in $\text{M}_2\text{O}-\text{SiO}_2$ oxides is equal to the ionic ratio $Y(\text{O}^{2-})$. It was found¹³⁴ that in an $(\text{Na}_2\text{O})_x(\text{SiO}_2)_{1-x}$ system $Y(\text{O}^{2-})$ is always close to x , i.e. the solutions should be ideal. In fact, however, strong negative deviations from the ideal state are observed for Na_2O ; and the activity coefficient of Na_2O at $x = 0.6$ and $T = 2000$ K is 0.092. Nevertheless, the value of $Y(\text{O}^{2-})$ under these conditions is ~ 0.60 .

Therefore, the polymer theory of slags, being self-consistent to some extent (in respect of concentrations of different types of particles and polyanions), does not predict correctly the thermodynamic activity of the components. Therefore, the PTS parameters (α , K_p) obtained from a fit to the thermodynamic properties rather than to the structural data, are only effective measures. Within this approximation, the PTS is simplified (like the model of associated solutions).

Models of $\text{Na}_2\text{Si}_2\text{O}_5$ glass were constructed using the MD method in a temperature range of 1000–2000 K (1080 ions, density of 2.5656 g cm^{-3}).¹⁵⁹ The potentials proposed earlier¹⁶⁶ included pairwise and three-particle interactions. The Coulomb terms were calculated according to Ewald. It was shown that PCF and structural factor of the model at 1000 K are in good agreement with the diffraction data and with the results of MD simulation of sodium silicate¹⁵⁷ with the Buckingham potentials.¹⁶⁷ It was found that 98% of silicon ions have CN of 4.0% and 2% have CN of 3.0. Only 5% of oxygen ions are bridging and therefore do not have neighbouring sodium ions. Sodium ions are situated in pores of the silicate network close to the terminal oxygen atoms and diffuse between site positions of the structure via a jumping mechanism. The value of activation energy of self-diffusion of sodium ions (54.3 kJ mol^{-1}) was close to the experimental value (66.6 kJ mol^{-1}).

The penetration of inert gases (Ne, Ar, N_2) into SiO_2 , Na_2SiO_3 , $\text{Na}_2\text{Si}_2\text{O}_5$, and sodium-aluminosilicate glasses was investigated using the MD method.¹⁶⁸ The results of the simulation demonstrated that none of the above glasses absorbs nitrogen and argon, while neon can penetrate into the first three of them.

b. Models of $\text{MO}-\text{SiO}_2$ systems

The structure of liquid FeO was investigated by X-ray anomalous scattering.^{141, 169} In the simulation of the oxide, B_{ij} values for Fe–O and O–O pairs were adjusted to achieve the agreement between the simulated interionic distances and the experimental results.¹⁷⁰ The following values were obtained: $B_{11} = 1300$, $B_{12} = 1900$, $B_{22} = 1500 \text{ eV}$ (alternatively, the value of $B_{22} = 905.6$ was taken⁹). The agreement between the results of simulation and the diffraction data was good (Table 6). Using the same B_{ij} values and taking $R_{ij} = 29 \text{ pm}$, reasonably good agreement with the experimental data was achieved for energy, molar volume, and compressibility of FeO crystals.

Table 6. Interionic distances and coordination numbers for liquid FeO.

Parameter	Model for FeO (see Ref. 170)	Experiment ¹⁶⁹
r_1 /pm for pairs		
Fe–Fe	313	315
Fe–O	207	205
O–O	317	320
z for pairs		
Fe–Fe	12.6	11.8
Fe–O	5.8	5.7
O–O	12.3	12.2

The structure of some non-crystalline oxide systems, *viz.*, FeO–SiO₂, MgO–SiO₂, and CaO–SiO₂ were investigated by X-ray scattering.^{51, 141, 171} Interionic distances were determined by interpretation of certain TPCF peaks. Structural analysis of MgSiO₃¹⁷² and CaSiO₃¹⁷³ glasses was performed. Structure of CaSiO₃ glass was also studied by X-ray diffraction and Raman spectroscopy. The TPCF exhibits only three peaks at 164 pm, 243 pm, and 364 pm. The Raman spectrum for this glass was similar to the corresponding spectra of pyroxenes, which contain chains of SiO₄^{4–} tetrahedra linked through vertices as the main structural elements; the chains are linked to each other *via* Ca²⁺ ions. Ring anions, such as Si₄O₁₂^{8–}, Si₅O₁₅^{10–}, were rare. The peak at 164 pm was attributed to the Si–O pairs. The maximum at 243 pm was a result of overlapping of Ca–O and O–O contributions. A structural model of CaSiO₃ glass based on the pyroxene structure was proposed,¹⁷³ in this model one half of oxygen atoms were bridging.

In the case of an MgSiO₃ glass, the X-ray TPCF contains five peaks.¹⁷² A peak at 163 pm was attributed to the Si–O pairs, and at 208 pm to the Mg–O pairs (the sum of the ionic radii of Mg and O is 207 pm). The mean CN for the Mg–O pairs was 4.1. A structural model of an MgSiO₃ glass was also constructed on the basis of the pyroxene structure. There, the main structural elements were also chains of SiO₄^{4–} tetrahedra linked through vertices. The magnesium ions are situated between the chains. Each Mg²⁺ ion has four oxygen neighbours at a distance of 208 pm and two more neighbours at a distance of 250 pm. Mg²⁺ ions occupy two types of sites: in almost ideal octahedral sites with $z = 6$ and in rather irregular sites with $z = 7$.

The Born–Meyer pair potentials were used in simulations of 2MO·SiO₂ (M = Mg, Ca, Sr, Ba, Fe),^{136–139} CaO–SiO₂ (see Ref. 65), and FeO–SiO₂ (see Ref. 170) complex oxides. The following values for parameters were taken (numbering of atoms: 1 states for M, 2 for Si, 3 for O): $B_{11} = B_{12} = 0$, $B_{22} = 2055.4$ eV,⁹ $B_{23} = 1729.5$,⁹ $B_{33} = 1500$, and $R_{ij} = 29$ pm. Models of (FeO)_{*x*}(SiO₂)_{1–*x*} for the whole range of compositions $0 \leq x \leq 1$ were constructed.¹⁷⁰ The models contained ~ 500 ions in the basic cube. Densities were taken from a reference book.¹⁷⁴ The Coulomb interactions were taken into account using the Ewald–Hansen method.³⁹ Positive deviations from the ideal state found for the energy of formation amounted to few tens kJ mol^{–1}. The experimental values of changes in energy in the formation of a complex oxide lie in the range from –6.3 kJ mol^{–1} to 2.5 kJ mol^{–1}. The heat of formation for crystalline fayalite (2FeO·SiO₂) is 33.5 kJ mol^{–1}. The Fe–O and Si–O distances depend insignificantly on the composition of the binary oxides.¹⁷⁰ For other pairs, this dependence is more pronounced though also not very strong. The results of the simulation showed that the interpretation of diffraction data is not correct for complex oxides in all cases due to a possibility of attributing false TPCF peaks to the real ones.

Distributions of CN for the Fe–O pairs in (FeO)_{*x*}(SiO₂)_{1–*x*} models are rather broad. For instance, at $x = 0.5$ and $T = 2000$ K, $2 \leq z(\text{Fe–O}) \leq 5$ (the mean value is 3.3); in the fayalite ($x = 2/3$), $2 \leq z(\text{Fe–O}) \leq 6$ and the percentage of Fe²⁺

ions in octahedral coordination is 2.1%. Measurements of the Mossbauer effect in silicate slags gave close estimates (1.1%–2.0%).¹⁷⁵ Most of Fe²⁺ ions in the models have three or four O^{2–} neighbours.

Distributions of O–Fe–O, Fe–O–Fe, O–Si–O, and Si–O–Si azimuthal angles for linked three-atom combinations were calculated.¹⁷⁰ Distributions of Fe–O–Fe and O–Fe–O angles are spread over the range of 45–180° and have a flat maximum near 90°. The diffusion corresponds to scatter of the CN values for the Fe–O and O–Fe pairs. For the O–Si–O angles, the coordination sphere radius was adjusted to obtain $z(\text{Si–O}) = 4$. In this case, the distribution of the $\theta(\text{O–Si–O})$ angles is a Gaussian with $\theta = 108 \pm 15^\circ$. The width of this distribution is equal to the corresponding width obtained for the model of SiO₂ at 2500 K.⁵⁵ Hence, on going from pure silica to fayalite the configuration of ions in SiO₄^{4–} groups changes insignificantly. However, the models considered¹⁷⁰ are closer to the tetrahedral configuration than other models.⁵⁵ The distribution of angles in fayalite generally agree with the diffraction data.¹⁷⁶

The topological parameter ρ_1 for pure FeO is 1.08, *i.e.* the structure of the oxide is dense. The addition of SiO₂ is accompanied by increase in the structural looseness. The following parameters were found for a model of FeO at 2000 K:¹⁷⁰

x	1.00	0.80	0.67	0.50	0.25	0
ρ_1	1.08	0.98	1.00	0.96	0.93	0.93
s	1.13	0.90	1.08	1.19	1.40	1.62

It is clearly seen that the addition of FeO to SiO₂ initially affects ρ_1 insignificantly, and for $x \leq 0.4$ the depolymerisation of the tetrahedral network does not take place. However, in the range $0.5 \leq x \leq 0.6$ the ρ_1 parameter increases due to the transition to a dense structure with the octahedral coordination. In fact, at $x = 0.5$ the CN $z(\text{Fe–O}) = 3.5$ and at $x = 0.667$, $z(\text{Fe–O}) = 4.0$, while for pure FeO $z(\text{Fe–O}) = 5.8$. The short-range order in FeO is analogous to that in liquid NaCl.

The adequacy of the PTS for (FeO)_{*x*}(SiO₂)_{1–*x*} was examined.¹⁷⁰ The main condition of the theory, $z(\text{Si–O}) = 4$, is not met for all silicon atoms, but the number of Si ions with three or five O^{2–} neighbours is relatively small.

$z(\text{Si–O})$	3	4	5
$x = 0.8$	5	35	5
0.667	7	58	6
0.5	5	89	6
0.25	15	105	15
0	4	75	3

The values of α and K_p were calculated from n_0 , n_1 , and n_2 (the numbers of oxygen ions), and the distributions of Si_{*m*}O_{*n*} bound groups were also found (Table 7).¹⁷⁰

The bound group distribution shows that for $x \leq 0.5$, the system is almost completely polymerised. Cyclic anions were absent in the models.

'Polymerisation constants' K_p listed in Table 7 depend on the FeO content: they increase with increase in x (as in the Na₂O–SiO₂ system). This increase does not agree with the model of ideal polymer solution. Values of K_p obtained in different studies were summarised.¹⁷⁷ The value 0.08 obtained in Ref. 178 at 1573 K is

Table 7. Characteristics of models of (FeO)_{*x*}(SiO₂)_{1–*x*} oxides.

x	α	K_p	K_{11}	Bound groups	$X(\text{O}^{2-})$
0.8	0.19	0.085	3.3	1 ¹⁶² 8 ³ 3 ⁴ 1	0.79
0.667	0.34	0.072	0.68	1 ¹⁵² 3 ³² 6 ¹⁹ 12 ¹ 17 ¹	0.68
0.5	0.56	0.039	—	1 ¹⁴ 19 ⁵ 1	(0.78)
0.25	0.82	(0.025)	—	135 ¹	(0.5)

Note. Values with low precision are indicated in parentheses.

the closest to data of Ref. 170, but the majority of K_p values calculated by fitting to the thermodynamic activities of components lies in the range of 0.7–2.0. As in the case of sodium silicates, these polymerisation constants are effective parameters and they do not describe the real structure. The K_{11} values also strongly depend on the composition.

The results of simulation of $(\text{FeO})_x(\text{SiO}_2)_{1-x}$ oxides showed that for $x \leq 0.5$ the system is almost completely polymerised to form a spatial silicon-oxygen network.¹⁷⁰ A loose structure with the low mean CN is maintained there. An assumption on predominance of linear and cyclic anions¹⁷⁹ in the range $0.2 \leq x \leq 0.5$ was not confirmed. The relatively slight dependence of K_p on concentration is in agreement with the associated ideal solution theory. In the thermodynamic respect, the $\text{FeO}-\text{SiO}_2$ system is close to the ideal one. The calculated activity of FeO for $x \geq 0.667$ is in reasonable agreement with the experimental data. Therefore, the PTS model reflects correctly some substantial features of structures of $\text{FeO}-\text{SiO}_2$ melts and glasses for $x \geq 0.5$. However, for lower x values the model is inadequate due to virtually complete polymerisation of the system.

The proportions of oxygen particles present as 'free' O^{2-} ions or included into SiO_4^{4-} groups calculated by different authors for the $\text{FeO}-\text{SiO}_2$ melts were summarised.¹⁸⁰ Results of computer simulation are in good agreement with the computation.¹⁸¹ For other systems (for example, sodium silicates), such agreement was not achieved.

It should be taken into consideration that the interpretation¹⁷⁰ of the polymerisation is purely structural, since it does not assume the formation of the valence bonds, and it is due to sum of the Coulomb forces and forces of the electron shell repulsion. Therefore, the reason for the polymerisation in ionic models is totally different from that underlying the PTS. The agreement of the results of simulation with the conclusions from PTS for $x > 0.5$ is probably due to the fact that the adequacy of the PTS is defined directly by the structure rather than by bonding type that determines the structure.

A similar study of structures and the properties of $(\text{CaO})_x(\text{SiO}_2)_{1-x}$ oxides at 2000 K was performed.⁶⁵ The metasilicate ($x = 0.5$) is formed from simple liquid oxides with a decrease in volume by $\sim 5\%$. Changes in the energy in the formation of the metasilicate is $-4.8 \pm 20 \text{ kJ mol}^{-1}$; the experimental value is -40 kJ mol^{-1} . The reasonable agreement between the simulated characteristics and the experimental results^{51,141} as regards the positions of the TPCF peaks and CN was achieved. The majority of Ca^{2+} ions have five or six oxygen neighbours, however $\text{Ca}-\text{O}$ pairs with CN ranging from 3 to 9 are also present.

The addition of CaO to SiO_2 leads to a linear increase in ρ_1 up to 1.00 at $x = 0.5$. But the addition of FeO initially almost does not change ρ_1 . The smaller Fe^{2+} ion deforms the network structure not as strongly as the Ca^{2+} ion. However, already when $x \geq 0.65$ the difference between the structures of these silicates becomes insignificant.

The PTS was also applied to analyse the structures of $\text{CaO}-\text{SiO}_2$ models.⁶⁵ The difference between $\text{FeO}-\text{SiO}_2$ and

$\text{CaO}-\text{SiO}_2$ systems in terms of degree of polymerisation α , polymerisation constant K_p , and the bound group distribution, is rather small. When $x \leq 0.5$, the polymerisation is almost complete. However, the deviations from the ideal state for the $\text{CaO}-\text{SiO}_2$ system are negative and significant. Adjustment of the activity coefficients within different version of the PTS gives the value of $K_p \approx 0.0016-0.0045$.¹⁷⁷ The difference between these (effective) K_p and the value found by the structural analysis is due to the inadequacy of the ideal PTS modification and probably due to an insufficient model size.

A series of models of $2\text{MO} \cdot \text{SiO}_2$ oxides was constructed using the Born–Meyer potentials ($B_{13} = 1441.4-8885.1 \text{ eV}$).¹³⁷⁻¹³⁹ Additionally, two hypothetical models with $B_{13} = 500 \text{ eV}$ and 800 eV were also considered.¹³⁶ Each model contained 497 ions. Figure 9 illustrates some properties of the models. The molar volume depends on non-monotonically B_{13} . It has a minimum near 800–1000 eV. The molar volume of simple MO oxides similarly depends on B_{13} . An increase in the volume at $B_{13} < 800 \text{ eV}$ indicates an abrupt increase in the structural looseness of the oxide. The interparticle $r_1(\text{M}-\text{O})$ distances for the models increases gradually with an increase in B_{13} . The transition from pure MO to the silicate affects the $r_1(\text{M}-\text{O})$ distance insignificantly. A similar effect was observed for CN of the $\text{M}-\text{O}$ pairs. At $B_{13} = 500 \text{ eV}$, the value of $z(\text{M}-\text{O})$ in the orthosilicate is 2.00, which indicates the presence of chain structural elements. At $B_{13} = 800 \text{ eV}$, $z(\text{M}-\text{O}) = 3.3$, *i.e.* the trigonal elements should dominate in the structure. For simple MO oxides, the CN for the $\text{M}-\text{O}$ pairs with the same values of B_{13} are 2.0 and 3.5, respectively (see above). Hence, the structure of first coordination spheres of M^{2+} ions are the same in both the orthosilicate and the simple oxide. The addition of SiO_2 leads to a broadening of the $\text{O}-\text{M}-\text{O}$ angle distributions, *i.e.* results in a certain disordering of the oxide structure.

It should be noted that the $\text{Mg}-\text{O}$ distance behaves abnormally for magnesium orthosilicate.¹³⁹ This distance for the model at 2000 K (196 pm) is substantially shorter than the experimental value (208–216 pm). Coordination numbers for the $\text{M}-\text{O}$ pairs are also noticeably smaller (3.7 instead of 4.7–5.0). The repulsion parameter for the $\text{Mg}-\text{O}$ pairs was determined from the compressibility data for MgO crystals. Presumably, this characteristic has to be corrected for a non-crystalline phase.

A specific arrangement of the $\text{O}-\text{O}$ pairs with maxima of distributions of their CN at $z = 3$ and 6 was found for models with $B_{13} = 3283-8885$ (from calcium to barium silicate). A reason for the appearance of these maxima becomes obvious on consideration of the spatial models.¹³⁶ Silicon ions are situated in almost planar parallel layers separated by $\sim 0.61 \text{ nm}$. A layer of SiO_4^{4-} corresponds to each Si^{4+} layer. The centre of the model is occupied by a figure composed of two SiO_4 tetrahedra linked through a shared vertex to form an almost ideal trigonal prism Si_2O_7 the centre and six vertices of which are occupied by the O^{2-} ions. The central O^{2-} ions have CN for the $\text{O}-\text{O}$ pairs equal to 6, and each O^{2-} ion in the vertices of the prism has three O neighbours. The

Figure 9. Properties of models of non-crystalline $2\text{MO} \cdot \text{SiO}_2$ oxides at 2000 K.

ratio of the ions with CN 3 and 6 is 6. In models of $\text{MO} \cdot \text{SiO}_2$ oxides, the similar type of ordering of O^{2-} ions was revealed.

Thus, for $2\text{MO} \cdot \text{SiO}_2$ oxides with large M^{2+} ions (such as Ba^{2+}) an association of silicate tetrahedra to form Si_2O_7 trigonal prisms with approximately layered arrangement of tetrahedra is typical. The space between layers is loosely filled with M ions and some of the O ions. A part of M ions is situated in the layers as well. Large pores with an average radius of ~ 0.44 nm (the size of ions was not taken into account) were also observed. A decrease in the size of M ions leads to their stronger interactions with oxygen ions. As a result, M ions begin to form bridges between the SiO_4^{4-} tetrahedra and between the tetrahedra and oxygen ions as well. This leads to a disordering of the structure and to its loosening. It is clearly seen from the plots of ρ_1 and s vs. B_{13} (see Fig. 9). An analysis of bound group distribution demonstrated that the increase in B_{13} is accompanied by the increase in the number of monomers and a decrease in the size of bound groups.

A series of MD models for an $(\text{MnO})_x(\text{SiO}_2)_{1-x}$ system was constructed¹⁶² using the potentials (1). The heat of formation for the models was negative for $x > 0.4$ and positive for the models high silica content. This corresponds to a stratification of a liquid phase in the system. The reason for the switching of the ΔH_{form} sign lies in the strong effect of small Mn^{2+} ions on the structure of the silicon-oxygen network. The smaller M^{2+} ions, the stronger the distortion of the network and the higher the energy of the system, leads to a broadening of the area of stratification of a liquid phase in the binary $\text{MO}-\text{SiO}_2$ system.¹⁶²

The applicability of the PTS to orthosilicates at various B_{13} was examined.¹³⁶ An increase in B_{13} from 500 to 8885 eV leads to a decrease in K_p by a factor of 3 (see Fig. 9). The effective values of K_p calculated according to the thermodynamic activity of MO oxide vary over a substantially wider range: from 1.0 in iron silicates to 3×10^{-4} in barium silicates.¹⁸² The difference from the structural data is due to the non-ideal nature of the solutions.

Calculation of the changes in configurational entropy along the $2\text{MO} \cdot \text{SiO}_2$ series showed that the transition to values $B_{13} < 1441.4$ eV leads to a decrease in the entropy.¹³⁶ When B_{13} grows in the range 1441–1900 eV, the entropy passes through a flat maximum and further remains almost constant. The entropy of simple MO oxides behaves similarly (see Fig. 4).

Changes in the Gibbs energy in the formation of orthosilicates starting from simple oxides are positive for $B_{13} \leq 1441$ eV. This indicates the instability of the complex oxide with respect to probable decomposition into two phases. In fact, in $\text{BeO}-\text{SiO}_2$ and $\text{MgO}-\text{SiO}_2$ systems at 2000 K the area of a monophase liquid is very narrow. However, in the $\text{FeO}-\text{SiO}_2$ system ($B_{13} = 1900$ eV) this area becomes much broader.

A model of amorphous $\text{ZnO} \cdot 3\text{SiO}_2$ using the MD method with the BMH potentials was constructed.¹⁸³ The model contained 264 ions, viz. Zn^{2+} , Si^{4+} , and O^{2-} , in the basic cube with the edge of 15.38 pm (the density is 2.87 g cm^{-3}). First, heating of the system up to 10 000 K followed by cooling to 300 K in ~ 30 ps were simulated. As a result, the first PPCF peaks appeared isolated, the Si–O, Si–Si, and Zn–O distances were 162 pm, 318 pm, and 198 pm, respectively. The mean CN for the Zn–O pairs was estimated (not very reliably) as 4.41, since coordination numbers 4 and 5 were predominant in the distribution in accordance with the diffraction data. For Zn^{2+} ions with CN of 4.0, the mean Zn–O distance was 197 pm and 204 pm for ions with CN 6. According to the shape of the PPCF for the O–O pairs, a conclusion was made on the presence in the structures of SiO_4 tetrahedra linked *via* edges. In this case, the CN of the corresponding Si ions is 5; this results in a low value of the O–Si–O angle (89°). The majority of oxygen ions adjacent to Zn ions have three neighbours. In general, the arrangement of particles in the model resembled that in ZnSiO_3 crystal of the pyroxene type. MD data demonstrated that Zn cannot completely substitute silicon atoms in the network and therefore destroys the silicon framework.

c. Models of $\text{M}_2\text{O}_3-\text{SiO}_2$ systems

$(\text{B}_2\text{O}_3)_x(\text{SiO}_2)_{1-x}$ melts readily form glasses, while the $(\text{Al}_2\text{O}_3)_x(\text{SiO}_2)_{1-x}$ oxides form glasses only for $x < 0.65$. Among the systems considered, only the structure of the $(\text{Al}_2\text{O}_3)_x(\text{SiO}_2)_{1-x}$ glasses (see Ref. 184) was studied experimentally. It was established that for $x = 0.061-0.469$ the position of the first TPCF peaks shifts monotonically from 162 to 179 pm with increase in x . Since this peak is a result of overlapping of Si–O and M–O contributions and the $r_1(\text{Si}-\text{O})$ distance is 161–162 pm, the M–O distance may be estimated as 199 pm. The O–O distance is 260 pm.

It is usually assumed that the amorphous Al_2O_3 oxide may act both as a modifier and a network-forming component, *i.e.* aluminium particles can either occupy cavities between the SiO_4^{4-} tetrahedra or substitute the silicon atoms in the silicon-oxygen network. The CN for the Al–O pairs are usually 4 or 6.

The following oxide systems were studied by the computer simulation methods: $\text{B}_2\text{O}_3-\text{SiO}_2$,⁶⁴ $\text{Al}_2\text{O}_3-\text{SiO}_2$,⁶⁶ $\text{Fe}_2\text{O}_3-\text{SiO}_2$,¹⁰⁴ and the $\text{M}_2\text{O}_3 \cdot \text{SiO}_2$ series (see Refs 185, 186). The potentials (1) were used in these studies, the potential parameters were taken from the corresponding models of pure M_2O_3 oxides. The Coulomb interactions were taken into account using the Ewald–Hansen method.³⁹ Each model contained ~ 500 ions in the basic cube.

It was demonstrated that the molar volume of $(\text{B}_2\text{O}_3)_x(\text{SiO}_2)_{1-x}$ oxides decreases substantially in the formation of a complex oxide from the simple non-crystalline ones (by 12% for $x = 0.667$). The energy of the complex oxide formation appeared very small for $x \geq 0.7$, for the lower x and $T = 0$ K it is positive and reaches the value 42 kJ mol^{-1} ; however, this energy is negative at 2000 K. Hence, cooling of the system results in destabilisation of the oxide thermodynamically.

First TPCF peaks are split into two narrow subpeaks that represent contributions of the B–O and Si–O pairs. The height of the left subpeak (at 134–139 pm) increases and the height of the right one (at 161–162 pm) decreases as x decreases. Most of B ions have three oxygen neighbours and Si ions have four oxygen neighbours. Spatial arrangement of neighbours around the boron and silicon ions are almost independent of each other. The structure of all oxides is loose, the ρ_1 parameter increases from 0.79–0.83 in B_2O_3 to 0.93 in SiO_2 (with a small minimum at $x = 0.5$). It was concluded⁶⁴ that the $\text{B}_2\text{O}_3-\text{SiO}_2$ oxide are copolymers of two B_2O_3 and SiO_2 polymers. The BO_3^{3-} and SiO_4^{4-} are linked through shared vertices as a result of random combination of the two figures.

Models of the $\text{Al}_2\text{O}_3-\text{SiO}_2$ oxides at 0 K and 2000 K were constructed using the MD and CSR methods.⁶⁶ Each model contained ~ 500 ions. The potentials (1) were used. The increase in the molar volume in the formation of a complex oxide from the simple ones at 0 K was 10% for $x = 0.5$, and ΔE_{form} was $70-100 \text{ kJ mol}^{-1}$ for $x = 0.2-0.667$. Therefore, the system exhibits positive deviations from the ideal state. The addition of small amounts of Al_2O_3 to SiO_2 results in an abrupt increase in energy, and therefore the amorphous phase appears thermodynamically unstable at 0 K. The positive ΔV_{form} remains at $T = 2000$ K, but ΔE_{form} changes the sign, which means that liquid oxides are formed from the simple oxides with the liberation of heat. The experimental values of ΔE_{form} are very small (of the order of several kJ mol^{-1}).

The Al ions with $z(\text{Al}-\text{O}) = 4$ dominate in the models. The portion of these ions increases from 51% for $x = 1.0$ to 76% for $x = 0.2$. These values are in agreement with the estimates based on viscosity of the melts. A decrease in x favours the transition of Al^{3+} ions into the coordination state with the CN 4 and their inclusion into the tetrahedral network. Therefore, for $x < 0.4$ the value of ρ_1 is almost constant. The coordination number 6 is rather rare ($< 6\%$). After 4, the most typical value of CN is 5. It was shown⁶⁶ that the PTS can be applied to the $\text{Al}_2\text{O}_3-\text{SiO}_2$ oxides if the inclusion of the ions into the tetrahedral network is

taken into consideration. The K_p constant varies from 0.21 ($x = 1$) to 0.15 ($x = 0.2$).

2. Simulation of borate systems

The results of simulation of $\text{Na}_2\text{O}-\text{B}_2\text{O}_3-\text{SiO}_2$ ionic glasses using the MD method have been published.⁸⁴ An addition of sodium oxide leads to the increase in CN for the B–O pairs from 3 to 4, and sodium atoms occupy the nearest pores of the structure. The changes in the CN of boron atoms was confirmed by the NMR data.¹⁸⁷

The structure of $\text{B}_2\text{O}_3-\text{Li}_2\text{O}$ glasses with 0%, 10%, and 20% of Li_2O were studied¹⁸⁸ using the X-ray scattering and MD-simulation. The potentials (1) were applied. The models contained from 1656 to 1728 ions in the basic cube. It appeared that the B–B and Li–O distances did not depend on the concentration, and the structure is built of the randomly linked BO_3 and BO_4 groups. The lithium ions are weakly bound with the boron ions and are located mostly in pores of the boron-oxygen network. The vibrational spectra of the glasses were also calculated. They resembled the IR-absorption spectra, but differ from the Raman spectra.

Models of B_2O_3 and $\text{Na}_2\text{O} \cdot 2\text{B}_2\text{O}_3$ were constructed using the MD method with the mixed ion-covalent potentials.¹⁸⁹ The Born–Meyer potentials (1) were applied for all pairs of atoms; additionally, the three-particle potentials were used for O–B–O and O–B–B combinations. For the $\text{Na}_2\text{O} \cdot 2\text{B}_2\text{O}_3$ oxide the value of 3.4 for $z(\text{B}-\text{O})$ was obtained, which is in agreement with the results for lithium borate.¹⁸⁸

Nanoscale structural inhomogeneities for the alkali-borate glasses both in liquid and glassy states were revealed by the small angle X-ray scattering.⁸² In order to reproduce this effect in MD-models, the size of the models has to be enlarged substantially.

Simulation of the crystallisation process of liquid $2\text{MgO} \cdot \text{B}_2\text{O}_3$ using the MC method was performed.¹⁹⁰

3. Simulation of phosphate and vanadate glasses

Structures of the metaphosphate glasses containing Zn, Mg, Ca, Sr, Ba, and Na were studied by X-ray diffraction methods.¹⁹¹ The following values of CN for the M–O pairs were found:

M	Zn	Mg	Ca	Sr	Ba	Na
$z(\text{M}-\text{O})$	4.1	4.6	6.8	7.0	7.8	5.7

For Ca, Sr, Ba, and Na the CN are close to those in crystalline compounds, but the values for Zn and Mg are abnormal.

Models of $(\text{CaO})_x(\text{P}_2\text{O}_5)_{1-x}$ oxides with $x = 0.8, 0.667, 0.5, 0.333$, and 0.2 were constructed¹¹⁷ using the Born–Meyer potentials with the charge of phosphorus atoms equal to +5. The Coulomb interactions were taken into account using the Ewald–Hansen method.³⁹ Such characteristics of the metaphosphates, as $r_1(\text{P}-\text{O}) = 155$ pm and the molar volume of $8.40 \text{ cm}^3 (\text{g-ion})^{-1}$ were reproduced with high accuracy. The values of ΔE_{form} reached -66 kJ mol^{-1} , which is extremely small compared to the total molar energies of the oxides (from -3405 for CaO to $-36\,930 \text{ kJ mol}^{-1}$ for P_2O_5 at 2000 K). However, these values are significant if compared with the $RT = 16.6 \text{ kJ mol}^{-1}$. Thus, the negative deviations from the ideal state should be expected. Changes in the volume of the system in the formation of one mole of a complex oxide are always positive and equal to $5.26 \text{ cm}^3 \text{ mol}^{-1}$ for the metaphosphate at 2000 K.

The calculated TPCF for X-rays has only three distinct maxima. The first one is attributed to the P–O pairs, the second one is a result of overlapping of Ca–O and O–O contributions. The third maximum is a result of overlapping of Ca–Ca, Ca–P, and P–O contributions. Therefore a reliable interpretation of the experimental diffraction data for these complex oxides is very difficult. The $r_1(\text{P}-\text{O})$ distance depends slightly on the CaO concentration (it changes from 150 pm for $x = 0.80$ to 159 pm for $x = 0$). For the metaphosphate, $r_1(\text{P}-\text{O}) = 153-156$ pm. For the phosphorus ions with $z(\text{P}-\text{O}) = 5$, the distance is slightly longer than for the ions with $z(\text{P}-\text{O}) = 4$.

The distributions of CN for the P–O pairs are given below:

$z(\text{P}-\text{O})$	$x = 0.8$	0.667	0.5	0.333	$x = 0.0$
4	33	40	30	18	19
5	31	46	71	94	105
6	2	4	9	12	18

The tetrahedral coordination of the phosphorus ions dominates (50%) for $x = 0.8$; with a decrease in x , the maximum of the distribution shifts to $x = 5$. In pure P_2O_5 , the CN varies in the range 4–6: ca. 13%–14% of P^{5+} ions in the oxide have $z(\text{P}-\text{O}) = 4$ or 6. The less the P_2O_5 concentration in the model, the greater the portion of the phosphorus ions having $z(\text{P}-\text{O}) = 4$. Diffraction data usually give the values of CN for the P–O pairs close to 4 and even less (to 3.8).¹⁹² Therefore, the Born–Meyer potentials with charge of the phosphorus ions equal to +5 do not allow one to obtain purely tetrahedral coordination of the phosphorus ions in the models. Presumably, this fact is indicative of the substantial contribution of the covalent bonding in phosphates.

For the Ca–O pairs, the following values of CN were found: 5.6 in pure CaO , 4.7 for the model with $x = 0.5$; for $x = 0.333$, the CN increases up to 6.5.¹¹⁷ The diffraction data¹⁹³ reveal a minimum of the CN values at $x = 0.333$; usually, the CN values given by the diffraction exceed the simulation data by ~ 1.5 . This difference is due to different schemes used for calculation of the CN.

The distributions of CN for the O–O pairs have specific features. For pure P_2O_5 , the distribution has a usual form, i.e. a curve with a broad maximum at CN $z = 7$. The same shape is maintained at $x = 0.333$, but an additional maximum appears at the CN of 4. In the range $0.500 < x < 0.800$, the distributions of $z(\text{O}-\text{O})$ exhibit two maxima: $z(\text{O}-\text{O}) = 3$ and 6–7. A similar effect was observed earlier for the computer models of complex oxides, such as $2\text{MO} \cdot \text{SiO}_2$ and $\text{M}_2\text{O} \cdot 2\text{SiO}_2$ (see above). This is due to the formation of rather rigid coordination spheres composed of O^{2-} ions surrounding the central metal ions (like SiO_4^{4-}) and fusion of these groups through a shared vertex. If $z(\text{P}-\text{O}) = 4$, then in such a distorted tetrahedron each O^{2-} ion has three O^{2-} neighbours, i.e. $z(\text{O}-\text{O}) = 3$. In the case of $z(\text{P}-\text{O}) = 5$, the coordination sphere of the P^{5+} ion is a trigonal bipyramid and two out of five O^{2-} ions have $z(\text{O}-\text{O}) = 3$ and three O^{2-} ions have $z(\text{O}-\text{O}) = 4$. In the fusion of two groups with $z(\text{P}-\text{O}) = 4$, the common O^{2-} ion has $z(\text{O}-\text{O}) = 6$. For the fusion of two groups with $z(\text{P}-\text{O}) = 4$ and 5 or 5 and 5, the common O^{2-} ion may have $z(\text{O}-\text{O})$ from 6 to 8.

At $x = 0$, the model almost does not contain O^{2-} ions with $z(\text{O}-\text{O}) = 3$. Hence, each O^{2-} ion has two P^{5+} neighbours and is shared between two PO_5 groups. It is clearly seen from the distributions of CN for the P–O pairs. For $x = 0.333$, ca. 20% of O^{2-} ions have $z(\text{O}-\text{P}) = 1$ and for these ions $z(\text{O}-\text{O}) = 3-4$. However, O^{2-} ions with $z(\text{O}-\text{P}) = 2$ should have $z(\text{O}-\text{O}) = 6-7$. Therefore, the distribution of $z(\text{O}-\text{O})$ exhibits two maxima, viz., a small peak at CN $z = 4$ and a high one at CN $z = 7$. When $x \geq 0.500$, the two maxima are maintained in the $z(\text{O}-\text{O})$ distribution but the height of the peak at $z(\text{O}-\text{O}) = 6$ decreases with growth of x due to decrease in the number of O^{2-} ions which have two P^{5+} neighbours.

The distributions of the O–P–O azimuthal angles are very broad for all compositions and do not indicate the presence of any specific configurations of ions. This is caused by the rather broad distributions of $z(\text{P}-\text{O})$. With a decrease in x , the proportion of large bound groups increases, and at $x \leq 0.500$ the complete polymerisation of the structure occurs.

A probable contribution of a ring component to the structure was also analysed. Rings with a minimum size more than eight members were totally absent. A decrease in x results in an increase in the number of rings, and the six- and eight-membered rings predominate in the structure. The four-membered rings are almost absent due to the high energy of the corresponding spatial figure.

For all values of $x < 0.8$, the structure of oxides appeared loose. According to the ρ_1 values (from 0.96 for $x = 0.8$ to 0.93 for $x = 0$), the $\text{CaO}-\text{P}_2\text{O}_5$ oxides should readily form glasses when $x < 0.8$. But in practice for the $\text{CaO}-\text{P}_2\text{O}_5$ system it is possible to obtain glass by rapid cooling only at $x < 0.57$.¹¹⁸ The difference between these limits is noticeable; it indicates that several additional effects leading to the crystallisation of real calcium phosphates with high CaO content, exist.

A model of AlPO_4 glass (192 particles in the basic cube) was built by MD method with the Born–Meyer potentials.¹⁹⁴ A total time for one run was 24 ps (2 ps at 20 000 K, 2 ps at 10 000 K, and 20 ps at 1500 K). It was established that the structure is a network of AlO_4 and PO_4 tetrahedra fused to each other through vertices like in silica. However, a proportion of oxygen ions are terminal. The calculated TPCF are in reasonable agreement with the experimental data.¹⁹⁵

Pair	P–O	Al–O	O–O	P–P	Al–P	Al–Al
$r_1(ij)$ /pm						
calculation	150	180	245	320	325	330
experiment ¹⁹⁵	160	160	260	310	310	310

The distributions of CN are as follows: $z(\text{P}-\text{O}) = 4$ (96.7%) and 5 (3.3%), $z(\text{Al}-\text{O}) = 3$ (10%) and 4 (90%). The mean $\text{P}-\text{O}-\text{P}$ angle is 164° . The network of bonds in the model is not perfect, but it is generally more ordered than in silica. It is possible that the structure of aluminium phosphate contains clusters linked by bridging oxygen ions.

Models of $2\text{ZnO} \cdot \text{P}_2\text{O}_5$ and $2\text{Na}_2\text{O} \cdot \text{P}_2\text{O}_5$ glasses containing 407 and 481 ions in the basic cube were constructed.¹⁹⁶ The Born–Meyer potentials were used. The PO_4 tetrahedra were the main structural elements of the models obtained, they can aggregate to form larger polymeric groups. The degree of polymerisation and the portion of long chains are less in sodium phosphate. Fragments with branching points are totally absent. The sodium and zinc ions occupy randomly the cavities of the tetrahedral network. The coordination numbers for the $\text{Na}-\text{O}$ pairs lie in the range from 3 to 6 and from 4 to 6 for $\text{Zn}-\text{O}$.

A model of $\text{Pb}(\text{PO}_3)_2$ was also constructed¹⁹⁷ using the MD method. The force functions (6) were applied (the functions were assumed to be zero for distances $r > 0.55$ nm). The interaction parameters were adjusted so as to achieve agreement between peak positions for the calculated and experimental TPCF.

Ion	O	P	Pb
r_i /pm	120	15	99
Z_i	−1.136	2.840	1.136

The Coulomb interactions were taken into account approximately. The model contained 630 ions in the basic cube. Cooling of the system from 15000 K to 300 K was performed at an average rate of $1.23 \times 10^{13} \text{ K s}^{-1}$. The final density of the glass was taken equal to the actual value (4.74 g cm^{-3}).

It was shown that the models of crystalline metaphosphate contain chains of the PO_4 tetrahedra linked through their vertices. The chains are linked to each other via Pb^{2+} ions, which are attracted to non-bridging oxygen ions. The following distances were found in the crystal: 156 and 146 pm ($\text{P}-\text{O}$), 235 and 261 pm ($\text{O}-\text{O}$), 289 and 301 pm ($\text{P}-\text{P}$), and 382 pm ($\text{Pb}-\text{Pb}$). For models of the glass, the first PPCF peak for the $\text{P}-\text{O}$ pairs was isolated with positions of 145 pm and CN equal to 4.0. This distance is shorter than the value found in amorphous iron-lead metaphosphate (155–158 pm, see Ref. 198) and in nickel-copper pyrophosphate (154.3–154.5 pm, see Ref. 192) using the X-ray diffraction methods, but it is close to the value (150 pm) obtained in Ref. 199. The distributions of the $\text{O}-\text{P}-\text{O}$ and $\text{P}-\text{O}-\text{P}$ azimuthal angles (from 95° to 125° and from 130° to 180° , respectively) demonstrate that the orientation of the neighbouring PO_4 tetrahedra is random. No fusion of the tetrahedra via their edges or faces was found. The following values were obtained for the interatomic distances and the coordination numbers:

Pair	O–O	O–Pb	P–Pb	O–P	P–P	Pb–Pb
$r_1(ij)$ /pm	245	243	371	151	304	390
CN	5.82	6.94	5.50	4.00	2.00	5.00

Therefore, only distances for the $\text{P}-\text{P}$ and $\text{Pb}-\text{Pb}$ pairs change noticeably upon amorphisation.

An analysis of the bound groups distribution in the model revealed linear chains comprising from one to eleven PO_4 tetrahedra, rings of 5–10 tetrahedra, and larger associates.¹⁹⁷ A secondary network, which is formed by the lead ions bound to non-bridging oxygen ions, was also found.

A structural model for a $\text{Ba}(\text{PO}_3)_2$ glass with the phosphate network composed of the PO_4 tetrahedra was constructed by the MC method based on the neutron scattering and NMR data.²⁰⁰

One of the possible reasons for the non-coincidence of the results of different simulations of non-crystalline phosphates is the use of different density values. If the density is chosen to be equal to that of the real glass, the calculated pressure may appear strongly negative or positive. Since it is for the phosphate systems that the most substantial differences were observed, this indicates again the insufficient accuracy of the Born–Meyer potentials due to the neglecting of the covalent contribution.

Models of the $(\text{CaO})_x(\text{V}_2\text{O}_5)_{1-x}$ oxides were constructed using the MD method.²⁰¹ The Born–Meyer potentials (1) were applied. The value of B_{ij} for the $\text{V}-\text{O}$ pairs was selected to be 2970 eV. The charges were +2, +5, and −2 for calcium, vanadium, and oxygen ions, respectively. Changes in the energy in the formation of a complex oxide from the simple ones was negative in all cases reaching the value -43 kJ mol^{-1} for $x = 0.5$. The $\text{V}-\text{V}$ and $\text{V}-\text{O}$ distances were virtually the same (350 and 180 pm) for all the compositions. It was demonstrated that the increase in the CaO content leads to a gradual transition from a loose network structure to a dense one. At $x = 0.333$ and 0.5, the network is built up of oxygen polyhedra arranged around the vanadium ions and linked through their vertices. The coordination numbers of the vanadium ions for such compositions are close to 5.

4. Simulation of tungstate glasses

Models of $\text{Na}_2\text{O}-\text{WO}_3$ (see Ref. 127) and $\text{CaO}-\text{WO}_3$ (see Ref. 128) systems were studied by the MD and CSR methods. The Born–Meyer potentials (1) were used; the value for the $B(\text{W}-\text{O})$ parameter was chosen to be 3400 eV. The models with 100 mol.%, 80 mol.%, 60 mol.%, 40 mol.%, 20 mol.%, and 0 mol.% of WO_3 were considered. An increase in the molar volume (by 10%) was found for the $\text{Na}_2\text{O}-\text{WO}_3$ in the formation of a complex oxide from the simple ones. The value of ΔE_{form} for 60% of Na_2O at 2000 K was -102 kJ mol^{-1} . It was shown that the distributions of $z(\text{W}-\text{O})$ are rather narrow and have the centres near 6. The mean CN values depend insignificantly on the composition (varying from 5.7 to 6). However, the distribution of the $\text{O}-\text{W}-\text{O}$ azimuthal angles is rather broad ($90 \pm 10^\circ$). Hence, for the preferred octahedral coordination of the W^{6+} ions the arrangement of oxygen ions around the W^{6+} may differ substantially for different ions. In general, W^{6+} ions form their closest coordination sphere not so rigidly as Si^{4+} ions in silicates.

In pure WO_3 and in oxides with the WO_3 content more than 50%, almost all the oxygen ions have CN equal to 2, *i.e.* they are bridging particles (in terms of the PTS). The addition of Na_2O results in a decrease in the number of such ions, *i.e.* the depolymerisation of the network of the $\text{W}-\text{O}$ bonds occurs. The distribution of the $\text{W}-\text{O}-\text{W}$ azimuthal angles is very broad, and the mean values decrease from 150° to 135° with an increase in Na_2O concentration. The distributions of CN for the $\text{Na}-\text{O}$ pairs are broad, this is due to the fact that relatively large sodium ions cannot form a stable coordination sphere. In the topological sense, all the models containing WO_3 were loose with values of ρ_1 in the range from 0.98 to 0.96; the s factor varied in the range from 1.06 to 1.55.

For the molar volume of the $(\text{CaO})_x(\text{WO}_3)_{1-x}$ system positive deviations from the additivity (up to $2.35 \text{ cm}^3 \text{ mol}^{-1}$ for $x = 0.8$) were observed; for the energy, negative deviations were observed (up to -101 kJ mol^{-1} for $x = 0.6$) similar to the $\text{Na}_2\text{O}-\text{WO}_3$ system. Presumably, this type of deviation is typical of systems including cations with strongly different charges. The negative deviations for the energy could be anticipated, since stable compounds are formed in the $\text{CaO}-\text{WO}_3$ system.

Positions of the first TPCF peaks for the $\text{Ca}-\text{W}$, $\text{W}-\text{W}$, $\text{Ca}-\text{O}$, and $\text{W}-\text{O}$ pairs depend insignificantly on the concentration. For pairs of oppositely charged ions ($\text{Ca}-\text{O}$, $\text{W}-\text{O}$) it is not surprising, but for the $\text{Ca}-\text{W}$ and $\text{W}-\text{W}$ pairs such behaviour is anomalous. This may be due to strong indirect interactions of these ions via intermediate O^{2-} ions. The value of $r_1(\text{W}-\text{O}) = 177-179 \text{ pm}$ is close to the corresponding value for real $\text{Na}_2\text{O}-\text{WO}_3$ glasses ($\sim 180 \text{ pm}$) and for models of these oxides ($172-180 \text{ pm}$). In the $\text{CaO}-\text{WO}_3$ models, the $r_1(\text{W}-\text{O})$ distances depend on the WO_3 concentration weaker than in the sodium tungstenate models.

The mean CN for the $\text{Ca}-\text{O}$ pairs decrease noticeably with a decrease in x . To the contrary, for ions with a high charge, such as W^{6+} , the mean $z(\text{W}-\text{O})$ is virtually constant over the whole range of the concentrations and very close to 6. The tungsten particles form rather stable octahedral WO_6 groups with the neighbouring oxygen atoms. For the $\text{Na}_2\text{O}-\text{WO}_3$ system at 2000 K, the mean $z(\text{W}-\text{O}) = 5.52-5.93$, *i.e.* the addition of Na_2O distorts the octahedral structure more than that of CaO . In the ideal octahedron, the $r_1(\text{O}-\text{O})$ distance should be equal to $\sqrt{2}r_1(\text{W}-\text{O})$. This expression holds with good accuracy. The distribution of the $\text{O}-\text{W}-\text{O}$ azimuthal angles for the complex oxide has two maxima with the most probable values of ~ 90 and 173° . These angles are typical of a distorted octahedron with the tungsten ion in its centre and oxygen ions in the vertices.

The distributions of CN for different pairs of ions have specific features. For the $\text{W}-\text{O}$ pairs, these distributions are very narrow, especially when $x \geq 0.4$. For $x = 0.8$, only 2.5% of the W ions have five oxygen neighbours. When $x \leq 0.2$, the distribution becomes slightly broader and the percentage of the 'oddly' coordinated tungsten ions reaches $\sim 14\%$. The distributions of $z(\text{O}-\text{O})$ for $x \leq 0.4$ have two maxima, *viz.*, at CN equal to 4 and 8. The value of 4 corresponds to the oxygen ions in one of the vertices of an isolated WO_6 octahedron. The value $z = 8$ corresponds to the oxygen ions that are common for two fused octahedra. The decrease in x from 0.8 to 0 is accompanied by a gradual decrease in the portion of oxygen ions with $z(\text{W}-\text{O}) = 4$; and these ions are totally absent in pure WO_3 oxide. This is caused by the aggregation of the WO_6 octahedra into the united polymer network.

In the case of models of the $3\text{CaO} \cdot 2\text{WO}_3$ oxide at 2000 K, the first TPCF peaks for the $\text{Ca}-\text{Ca}$, $\text{Ca}-\text{W}$, $\text{Ca}-\text{O}$, and $\text{O}-\text{O}$ pairs are relatively small, while peaks for the $\text{W}-\text{W}$ and $\text{W}-\text{O}$ pairs are much higher. For the $\text{W}-\text{O}$ pairs, this behaviour is not surprising, since it is a result of strong attraction of oppositely charged tungsten and oxygen ions. However, for the $\text{W}-\text{W}$ pairs this effect had not been observed earlier. The first PPCF peak for the $\text{W}-\text{W}$ pairs is almost completely isolated, which indicates the highly ordered mutual arrangement of the tungsten ions. Since these ions repel, the reason for the ordering should be their indirect interactions via intermediate oxygen ions. If $\text{W}-\text{O}$ distance is strictly fixed and the angle formed by vectors from an oxygen atom to two closest W neighbours is close to 180° , then the $\text{W}-\text{W}$ distance should be close to $2r_1(\text{W}-\text{O})$, *i.e.* 354 pm. The actual value of $r_1(\text{W}-\text{W})$ is 358 pm. The data show that the octahedral WO_6 groups linked via a shared vertex are ordered in such a way that their spatial diagonals passing through this vertex have a tendency to be arranged along certain direction. The $\text{W}-\text{O}-\text{W}$ azimuthal angles in the models vary from 135 to 178° , and their mean value is $151.8 \pm 15.9^\circ$.

The analysis of the Voronoi polyhedra^{43,44} constructed for the central tungsten ions demonstrates that the dominant polyhedra

(from 92.5% for $x = 0.8$ to 63% for $x = 0.2$) have the form 0-6-0-0, which corresponds to the cube, that is the Voronoi polyhedron for an ideal octahedron (the notation 0-6-0-0 means the numbers of triangular, rectangular, *etc.* faces of the polyhedron). There are 59 polyhedra of the 0-6-0-0 type and 29 polyhedra of the 1-3-3-0 type (the cube with truncated vertex) in pure WO_3 . Overall, they constitute 70% of all polyhedra for the model considered. The volume of the polyhedron with a tungsten atom increases with a decrease in x , and the distribution of the volumes broadens. For instance, at $x = 0.8$ the volumes of the polyhedra are equal to $5928 \pm 231 \text{ pm}^3$, and at $x = 0$ they are $6506 \pm 458 \text{ pm}^3$. The degree of sphericity also decreases from 0.511 to 0.488. The mean face areas depend only slightly on the concentration x but the width of their distribution increases as x decreases. Therefore, the increase in the WO_3 content results in disordering of the Voronoi polyhedra constructed around the tungsten atoms.

A study of the 'polymerisation' in the $\text{CaO}-\text{WO}_3$ oxides was performed by analysis of the W_mO_n bound groups. The tungsten atoms with a common oxygen neighbour at a distance shorter than 200 pm were considered as a group. For this distance, $z(\text{W}-\text{O}) \simeq 6.0$, and in addition no $\text{O}-\text{O}$ pairs were found, *i.e.* all the oxygen atoms have only W neighbours. The following bound groups were found in the models:

x	0.8	0.6	0.4	0.2	0.0
Group	$1^5 2^3 5^5 18^1$	$1^7 12^1 51^1$	93^1	108^1	125^1

The notation $1^5 2^3 \dots$ means that five WO_6^{6-} monomers, three $\text{W}_2\text{O}_{11}^{10-}$ dimers, and so on were found in the model. When $x \leq 0.4$, the system is completely polymerised, for $x = 0.6$ and 0.8 there exist isolated monomers surrounded only by CaO matrix. The models of $\text{Na}_2\text{O}-\text{WO}_3$ oxides behave similarly.

For $x = 0.8$, only one eight-membered ring was found in the model. The distribution of the bound groups demonstrates that this ring is a part of a bound group of 18 tungsten ions. For $x = 0.6$, 21 rings were found that included about 60 tungsten ions. Since the model contained only 70 ions altogether, the most of them were included into the ring. A comparison with the bound group distribution showed that these rings are not isolated but they are incorporated into two 12^1 and 51^1 groups. Attempts to account all these sophisticated 'polyanions' would result in a substantial complication of the polymer theory.

Finally, all rings found in the models with $x \leq 0.4$ belong to one bound group containing all tungsten ions of the models, since the oxides are completely polymerised for such concentration.

5. Simulation of other binary oxide systems

Models of binary $(\text{CaO})_x(\text{Fe}_2\text{O}_3)_{1-x}$ systems and oxides of the $\text{CaO} \cdot \text{M}_2\text{O}_3$ series were constructed^{202, 203} using the MD and CSR methods. The Born-Meyer potentials (1) were applied. The change in the molar volume in the formation of a complex oxide in the $\text{CaO}-\text{Fe}_2\text{O}_3$ system at 2000 K was small, this parameter is positive for $x = 0.5-0.7$ and negative for $x = 0.333$. The value of ΔE_{form} does not exceed 45 kJ mol^{-1} . According to the values of the heats of formation, the oxides in this system are close to the ideal ones. At 0 K, the values of ΔE_{form} are positive, so the oxides should readily decompose. It was shown that Ca^{2+} and Fe^{3+} ions form their first coordination spheres virtually independent of the value of x . The mean CN for the $\text{Ca}-\text{O}$ pairs is 5.0-5.2, and $z(\text{Fe}-\text{O})$ is 4.7-5.3. The topological characteristics point to the dense structures.

Models of oxides in the $\text{CaO} \cdot \text{M}_2\text{O}_3$ series at 2000 K were constructed using the potentials (1).²⁰³ The B_{23} parameter for the $\text{M}-\text{O}$ pairs (numbering of atoms as follows: 1 for Ca, 2 for M, and 3 for O) varied in the range of 800-5000 eV. It was demonstrated that the molar volume has a minimum at $B_{23} = 1480 \text{ eV}$, which corresponds to the $\text{CaO} \cdot \text{Al}_2\text{O}_3$ system. The coordination numbers for the $\text{Ca}-\text{O}$ pairs were close to 6 in all cases, and $z(\text{M}-\text{O})$ increases gradually from 3.3 ($B_{23} = 800 \text{ eV}$) to 5.9 ($B_{23} = 5000 \text{ eV}$). For $B_{23} = 1470 \text{ eV}$, most

M^{3+} ions have four O^{2-} neighbours; a distorted octahedral packing dominates. At higher B_{23} values, the structure is dense. When B_{23} increases from 800 to 2453 eV the configurational entropy of the oxides initially increases slightly and then again decreases slightly. A decrease in the size of M^{3+} can result in an increase in the negative deviations from the ideal state (as regards thermodynamics).

Models of oxides in the $FeO-Fe_2O_3$ system with 0 mol.%, 25 mol.%, 50 mol.%, 75 mol.%, and 100 mol.% of FeO at 0 K and 2000 K were constructed using the MD and CSR methods.¹⁰⁵ Change in the molar volume in the formation of complex oxides from the simple ones was positive (up to $4.3 \text{ cm}^3 \text{ mol}^{-1}$), the value of ΔE_{form} was also positive and did not exceed 27 kJ mol^{-1} . It was established that the structure of the coordination spheres of Fe^{2+} and Fe^{3+} in glasses and melts almost was not changed with variation of the FeO content. The topological parameter ρ_1 has a minimum (1.02) at 60% of FeO , which indicates small looseness of these oxides. The results of computer simulation¹⁰⁵ allowed one to estimate the equilibrium oxygen pressure over the $FeO-Fe_2O_3$ oxides. It was possible to predict the decomposition of magnetite Fe_3O_4 on heating, but the accuracy in determination of the decomposition temperature was not very high.

Solutions of oxygen in Fe_2O_3 at 0 K and 2000 K were studied by the MD and CSR methods.¹⁰⁶ In order to determine the preferred form of existence of the oxygen particles, the solutions of the atomic oxygen (O^0), as well as O^- and O^{2-} ions were considered. A possible reaction $2O^- = O^0 + O^{2-}$ was also taken into account, i.e. it was assumed that the dissolution of O_2 in the oxide, which dissociates according to the scheme $O_2 \rightarrow 2O^0$, should be accompanied by an increase in O^- concentration and a decrease in O^{2-} concentration. Charges of iron ions were not changed in this case. The heat of dissolution of oxygen as O^0 (ΔH) was estimated as $\sim 1000 \text{ kJ (mol } O_2)^{-1}$ at 0 K and $768 \text{ kJ (mol } O_2)^{-1}$ at 2000 K. The heat of dissolution of oxygen as O^- was $428 \text{ kJ (mol } O_2)^{-1}$. Since that the dissolution as O^- is preferable. The solubility of O_2 at 1700 K may be described by the expression $X(O^-) = 1.3 \times 10^{-10} p_{O_2}^{1/4}$, where X is the ionic portion of O^- in the oxide and p_{O_2} is the partial pressure of the oxygen expressed in atm. units. The solubility decreases rapidly as temperature decreases.

VII. Simulation of multi-component systems

It was shown by NMR,²⁰⁴ that the aluminium ions in multi-component silicate glasses have tetrahedral coordination at any Al_2O_3 content, while silicon ions have one or two terminal oxygen neighbours. The coordination number for the B–O pairs is mainly 4. In lead-fluoride-silicate glasses, the silicon ions always have two terminal O^{2-} neighbours.

Several complex oxides in $K_2O-Na_2O-SiO_2$, $CaO-Na_2O-SiO_2$, and $B_2O_3-Na_2O-SiO_2$ systems were investigated using the MD method.^{84, 205, 206} It was shown that the inclusion of Na^+ ions leads to destruction of Si–O–Si bonds; Na^+ ions occupy the cavities between 3–8 non-bridging oxygen ions. Small rings are formed and the number of silicon ions with five oxygen neighbours increases. However, when the volume or temperature are increased, the Si ions with $z(\text{Si–O}) = 5$ disappear.

A ‘poly-alkali effect’ caused by a mutual influence of different ions of alkali metals was studied for silicate glasses using the MD method.²⁰⁷ The calculated values of electrical conductivity for the glasses indicate the presence of the effect (a minimum on the plot of conductivity vs. composition). Heating of the system results in a weakening of the effect due to easier relaxation of anions. Preferable ways of diffusion of alkali metal ions in the glass were determined. The application of NMR to structural studies of the alkali- and aluminosilicates including the analysis of the poly-alkali effect were reviewed.²⁰⁸ Alkali metal ion transfer was also studied.²⁰⁹

Models of aluminosilicates, such as $7CaO \cdot Al_2O_3 \cdot 2SiO_2$, $5CaO \cdot Al_2O_3 \cdot 2SiO_2$, $3CaO \cdot Al_2O_3 \cdot 2SiO_2$, $CaO \cdot Al_2O_3 \cdot 2SiO_2$,

were constricted using the MD method at 400 K.²¹⁰ Comparison of the CN values calculated from the PPCF and the characteristics of the Voronoi polyhedra showed that for all pairs, except Ca–O, reasonably good agreement was achieved. The deviations for the Ca–O pairs were due to the formation of clusters of admixturing atoms around the oxygen anions.²¹¹ Structures of $CaO \cdot Al_2O_3 \cdot 2SiO_2$ were studied using the X-ray diffraction and the MD method. It was established that the structures include a framework of fused SiO_4 and AlO_4 tetrahedra and Ca^{2+} ions. The framework contains four- and six-membered rings. The main structural defects resulting in disordering are three- and five-membered rings.

A series of models (1300 atoms in the basic cube) for melts with 10 different compositions in the $NaAlSiO_4-SiO_2$ system at 2500–4500 K and 2–5 GPa was constructed using the MD method.²¹² The run duration was 0.1 ns. The Coulomb interactions were taken into account according to the Ewald method. It appeared that more than 90% of silicon and aluminium ions have CN = 4, and more than 90% of oxygen ions have two neighbouring cations. These results insignificantly depend on temperature. It was established that the T–T coordination (T = Al or Si) depends more on the composition than the T–O coordination. If a model contains more than 1000 ions, the self-diffusion coefficients and conductivity no longer depend on the size of a model; for $N = 400-600$, these characteristics are overestimated by 10%–100%. A cut-off of the Ewald sums additionally distorts the model. The dependence of structure on the number of particles in the model is not so pronounced. The replacement of silicon ions by Al + Na pairs leads to a decrease in the mean T–O–T angle, which is due to the increase in the number of Al–O–Al bridges and the broadening of the azimuthal angle distributions. The PCF oscillations are virtually absent at distances exceeding 500 pm.

MD-models of sodium aluminosilicates with the ratio $a = Al_2O_3/Na_2O = 0.25-2.0$ were constructed.²¹³ At $a = 1$, an extremum of the sodium ion self-diffusion coefficient and its activation energy was observed, it was analogous to that for the viscosity and conductivity. When $a < 1$, the size of rings in the structure decreases, and a minimum concentration of terminal oxygen ions was observed for $a = 1$. When $a > 1$, the groups of neighbouring oxygen particles with $z(O-O) = 3$ appear.

Models of glassy pyrope ($Mg_3Al_2Si_3O_{12}$) and grossular ($Ca_3Al_2Si_3O_{12}$) were constructed using the MD method at 300 K.²¹⁴ Good agreement with the X-ray data on their structure was achieved. The first PPCF peaks for the Si–O and Al–O pairs in pyrope appeared broader than those in grossular. It was found that Al–O–Al combinations were present in the structure, i.e. Al ions do not avoid close proximity to each other. A proportion of Al ions act to modify the network.

Two series of ionic models of MO and MO_2 solutions in non-crystalline $(CaO)_x(SiO_2)_{1-x}$ oxides with $x = 1, 2/3, 1/2, 1/4$, at 0 and 2000 K were constructed using the MD method.²¹⁵ The models corresponded to real and hypothetical oxides. The ratios of the activity coefficients γ_{MO}/γ_{CaO} and $\gamma_{MO_2}/\gamma_{SiO_2}$ were calculated for various x . It was demonstrated that for the MO series the γ_{MO}/γ_{CaO} ratio increases with the increase in the size of M ion for $x > 0.8$ and decreases for $x < 0.8$. This means that for $x > 0.8$ the $CaO-SiO_2$ oxides behave as the basic and for $x < 0.8$ as the acidic ones. However, this rule does not hold for admixtures of the MO type; and neither oxide of the $CaO-SiO_2$ system is neutral in respect of these admixtures. Therefore, the thermodynamic scale of basicity for simple oxides, and hence the meaning of the neutral oxide may be established only for admixtures of a certain type (such as MO) in the $CaO-SiO_2$ system. These scales may differ for different types of admixtures.

Models of an amorphous $(AgI)_x(AgPO_3)_{1-x}$ system for $x = 0-0.5$ were constructed using the Reverse MC method and data on neutron and X-ray diffraction together with X-ray absorption fine structure (EXAFS).^{216, 217} For the initial configuration, it was assumed that PO_4 tetrahedra are linked in a chain via two bridging oxygen ions of each tetrahedron and the chains

are linked through the silver ion and two terminal oxygen ions. The number of ions in the basic cube was 3840–5376. Reasonably good agreement between the experimental and simulated structural factors and EXAFS spectra was achieved. No AgI microcrystals were found in the models. It was established that the iodide admixtures are situated in the pores of the phosphate network. The size of pores decreases with a decrease in the AgI concentration. It was shown that the first distinct peak in the total structural factor is due to density correlations of the phosphate network, which increase with the addition of iodide, rather than due to the distribution of the AgI admixtures. The concentration of the tunnel-shaped pores passes the percolation threshold in the range $0.2 < x < 0.3$, that provides rapid diffusion of Ag^+ ions, and the structure acquires the superionic conductivity.

A model of $(\text{AgI})_x(\text{Ag}_2\text{O} \cdot 2\text{B}_2\text{O}_3)_{1-x}$ glass (960 particles in the basic cube, $x = 0.1$ and 0.6) was constructed using the BMH pair potentials.²¹⁸ It was demonstrated that the calculated structural factor of the model has a peak in the small angle region at 9 nm^{-1} (detected earlier by the neutron scattering), which is due to correlations in arrangement of AgI clusters embedded into the boron-oxygen network. Addition of AgI up to $x = 0.6$ does not affect the structure of the boron-oxygen framework.²¹⁹ In the case of $(\text{LiCl})_x(\text{Li}_2\text{O} \cdot 2\text{B}_2\text{O}_3)_{1-x}$ glass ($x = 0$ and 0.6), the addition of chloride leads to a decrease in $z(\text{B}-\text{O})$, which finally results in a more open boron-oxygen framework and lower structural ordering. The boron-oxygen network is composed mainly of statistically linked BO_3 and BO_4 groups. Glasses with overall composition $\text{Na}_2\text{O}-\text{B}_2\text{O}_3-\text{NaCl}$ were investigated by the MD method.²²⁰ The effects of separation of phases in the glass were successfully reproduced within the atomic model.

VIII. Simulation of ion transfer processes

A parameter such as electrical conductivity, which is sensitive to the bonding type, is a useful tool to examine the adequacy of the ionic model. In the case of covalent bonding, the oxide should be a dielectric. For the cases of mixed ionic/covalent bonding, it is very difficult to use the computational methods to estimate the electrical conductivity while this can be easily estimated within the ionic model. To this end, it is necessary to consider the forces of external field given by the eEz_i term, where E is the external electric field in the summation of all forces applied to an atom. In MD-simulation, it is necessary to calculate the charge flows for each type of ion in the direction of E and their sum, which is the current. Reliable averaging of the data is needed due to strong fluctuations of the flows. Another point is that the ion transfer cannot be examined in rather weak fields comparable with those normally used in practice. The electric field of the order of $10^8-10^9 \text{ V m}^{-1}$ corresponds to the electric force making a noticeable drifting flow. Substantial structural distortions of the melt occur in stronger electric fields. Nevertheless, calculations of the conductivity for models of oxide systems are a good test for the adequacy of the ionic concept.

The study of processes of the ion transfer in electric fields at 2000 K for oxides in the $\text{CaO}-\text{SiO}_2$ system showed that the mechanism of ion transfer is drifting.²²¹ The values of the calculated conductivity are in good agreement with the experimental data for melts with conductivity higher than $50 (\text{Ohm m})^{-1}$ (for CaO concentration exceeding 65 mol.%). For systems with the conductivity below $10-20 (\text{Ohm m})^{-1}$ the accuracy of the computational methods is not sufficient. The effect of 'removal' of Si^{4+} ions by surrounding O^{2-} ions was found. Therefore, the Si^{4+} ions give a negative contribution to the total conductivity. The reason for this effect is the high stability of the complex SiO_4^{4-} ions.

IX. Conclusion

All data considered above show that for many oxide systems (except for phosphate and several other) the ionic model allows

one to obtain results that are in reasonably good agreement with the experimental data on the thermodynamic, structural, diffusion, and electrochemical (mobility in the electric field) properties. Good results were obtained even using such simple interparticle potentials, as the Born–Meyer potential. Complicated modifications of the potential describe certain objects with higher precision, but make the prediction of properties of complex systems based on data for the simpler ones more difficult.

The prediction of the vibrational spectra on the basis of simple ionic model is not so confident. The agreement with the experimental IR and Raman spectra is more difficult to achieve. Therefore, these properties were not considered here. Further investigations are needed in this field. Nevertheless, the results discussed show that clear understanding of the structural features and properties of non-crystalline oxide systems may be achieved by a combination of experimental and computer simulation methods.²²²

Abstract. The data on radiolytic transformations of ions of uranium, neptunium, plutonium, americium, curium and transcurium elements in aqueous solutions are generalised. The results of studies on the kinetics of fast reactions of these ions with primary products of water radiolysis (hydrated electron e_{aq}^- , H, OH, and O^- radicals and H_2O_2), many inorganic (Cl_2^- , NO_3^- , SO_4^{2-} , CO_3^{2-} , O_3^- etc.) and organic free radicals are analysed. The mechanism of γ - and α -radiolysis of solutions of actinide ions is discussed. The bibliography includes 183 references.

I. Introduction

Aqueous solutions of actinides are widely used in nuclear power engineering and radiochemical industry. Firstly, many systems meant for processing of nuclear materials are aqueous solutions. When these solutions are highly radioactive, actinide ions can undergo various radiolytic transformations induced by the radiation from the radionuclides present. It is clear that this can markedly influence technological processes.

Secondly, actinide ions are present in radioactive wastes (including highly radioactive liquid wastes). It is obvious that the knowledge of the regularities of radiation-induced chemical processes involving these ions is needed to correctly solve the problems of prolonged storage and disposal of these wastes: to store liquid wastes in tanks or to dispose of them in deep geological formations, to develop a technology for isolation of α -nuclides from wastes and to carry out this isolation, to dissolve plutonium-containing precipitates, etc.

Thirdly, in the case of accidents at nuclear power plants, radionuclides (fission-product elements, plutonium, etc.) can get into water; in those places where these elements are concentrated, radiolytic transformations of actinide ions can occur. These transformations may have an influence on the behaviour of

actinides in the environment, and this should be taken into account in radioecological investigations.

Actinide ions can exist in aqueous solutions in a variety of oxidation states (for example, the oxidation number of americium varies from two to seven); therefore a wide range of radiation-induced redox reactions can be studied.

The radiation chemistry of aqueous solutions of actinide ions has been developed since the mid-1940s; its development started soon after the discovery of plutonium.¹ Early studies dealt with radiolysis of aqueous solutions of plutonium induced by its own α -radiation; later, radiolysis under the action of external ionising radiation (X-rays) was also investigated. Somewhat more recently, first studies dealing with the radiation chemistry of aqueous solutions of americium, uranium and neptunium ions were accomplished (see, for example Ref. 1). It should be noted that in the majority of these studies, the occurrence of a certain radiolytic transformation has been detected only qualitatively. The mechanisms of these transformations have been studied since the 1960s. Significant progress along this line has been achieved by virtue of the method of pulse radiolysis with fast recording of short-lived species (this method is described in detail in two monographs^{2,3}). The results obtained up to 1980 are summarised in Ref. 1.

The present paper surveys the current state of the radiation chemistry of aqueous solutions of actinides. It is largely based on the data published during the past 15 years. The results obtained before 1980 have been surveyed in monographs^{1,4} and in a handbook.⁵ However, in some cases, to make the presentation more complete, some earlier studies are also discussed. This is done when their results need to receive a different interpretation due to the appearance of new information. In addition, published data on the radiolysis of solutions of actinides in nitric acid are considered in detail, because these systems are important from the practical viewpoint.

II. General information about the mechanism of radiolysis of water

Studies of aqueous solutions (including solutions of actinides) in radiation chemistry are based on the following views on the mechanism of radiolysis of water.^{1,6} The primary products formed in this process are the hydrated electron e_{aq}^- , a hydrogen atom, an OH radical (its dissociated form is the O^- radical ion), molecular hydrogen H_2 , hydrogen peroxide (its dissociated forms

A K Pikaev, V P Shilov, A V Gogolev Institute of Physical Chemistry of the Russian Academy of Sciences, Leninskii prosp. 31, 117915 Moscow, Russian Federation. Fax (7-095) 335 17 78. Tel. (7-095) 330 41 70 (V P Shilov)

Received 6 September 1996

Uspekhi Khimii 66 (9) 845–873 (1997); translated by Z P Bobkova

are HO_2^- and O_2^{2-}) and H_{aq}^+ and OH^- ions. This can be written as follows

The radical species formed in the radiolysis (e_{aq}^- , H, and OH) as well as hydrogen peroxide enter into various reactions with dissolved compounds (evidently, including actinide ions) and thus cause various radiolytic transformations of the latter.[†]

In dilute aqueous solutions (in which concentrations of solutes are up to $\sim 10^{-3}$ – 10^{-2} mol litre⁻¹), the radiation yields of the above primary products of radiolysis of water hardly depend on the concentration of the solution. The respective values for γ -radiation and for high-energy electrons are listed in Table 1.

Table 1. Radiation yields of the products ^a [molecule (100 eV)⁻¹] of water radiolysis induced by γ -radiation of ⁶⁰Co and by high-speed electrons with an energy of 1 MeV or higher.^{1,6}

pH	$G_{e_{\text{aq}}^-}$	G_{H}	G_{OH}	G_{H_2}	$G_{\text{H}_2\text{O}_2}$	$G_{\text{H}_{\text{aq}}^+}$	G_{OH^-}
0–2	3.05	0.6	2.95	0.45	0.8	—	—
4–9	2.8–2.9	0.6	2.8–2.9	0.45	0.75	3.3–3.4	0.5–0.6
12–13	3.05	0.55	2.9	0.4	0.75	—	—

^a Radiolysis of water also affords oxygen atoms; however, their yield is negligibly small.

In concentrated solutions, these yields do depend on the concentration, because the solute can react with the primary products in ‘spurs’ and tracks. In addition, the ‘direct’ influence of the ionising radiation on the substance becomes apparent in these solutions. It also cannot be ruled out that excited water molecules are involved in radiolytic transformations.

Actinides emit α -particles with an energy of 5–6 MeV; having passed through a material (including water), these particles form cylindrical tracks with high concentrations of primary products of radiolysis. Consequently, the yields of the latter differ markedly from those obtained in the case of γ -irradiation or irradiation with high-energy electrons. The yields of products formed upon the action of α -particles emitted by actinides have not been determined. They were measured for the α -particles with an energy of 5.3 MeV emitted by ²¹⁰Po (Table 2). The yields of products

Table 2. The yields of primary products of water radiolysis induced by α -particles.

Energy/ MeV	Medium ^a		$G_{e_{\text{aq}}^-} + G_{\text{H}}$		G_{OH}	G_{H_2}	$G_{\text{H}_2\text{O}_2}$	G_{HO_2}	Ref.
	I	II							
5.3	H ₂ SO ₄	0.4	0.55	0.35	1.4	1.3	0.2	7	
6.4		(7)	—	0.4	—	0.95	0.085	8	

^a Here and in the other Tables, the following designations are used: I — aqueous solution; II — concentration of the solution in M; the number in parentheses — pH of the medium.

obtained upon the action of α -particles with an energy of 6.4 MeV were also included in the Table. Comparison of the data presented in Tables 1 and 2 indicates that in the case of α -particles, the yields of the radical products of water radiolysis decrease, while those of the molecular products increase. Another specific feature is that HO_2 radicals (or O_2^- as the dissociated form) are formed in a relatively high yield among the primary products.

[†] In this review, the radiation yields of the primary products of water radiolysis are denoted by the letter G , the corresponding product being shown as the subscript (for example, $G_{e_{\text{aq}}^-}$); the overall yield of a product (with allowance for secondary reactions) is symbolised by the letter G with the product given in parentheses; the yield of the consumption of a species, for example U(IV), is denoted by $G[-\text{U(IV)}]$ and the yield of its formation is written as $G[\text{U(IV)}]$.

When the concentration of actinides in a solution is relatively high, their α -radiation is fairly intense. This can lead to radiolytic transformations of the solutes (including actinides). Radiolysis of actinides induced by their own α -radiation is referred to as self-radiolysis.

III. The reactivity of actinides in aqueous solutions

The radiation-induced chemical processes involving actinide ions in solutions comprise their interaction with primary products of water radiolysis and with inorganic and organic free radicals resulting from the radiolysis as well as the reactions of actinide ions in unstable oxidation states (arising upon radiolytic reduction or oxidation) with stable compounds present in the solution. Rate constants for these processes have been measured by various methods;^{9–13} the method of pulse radiolysis with spectrophotometric recording of short-lived species has been used most often. In some cases, conductometric recording has been employed. Some rate constants have been estimated by computer modelling of radiolytic processes.

1. The reactivity of actinide ions towards the primary products of radiolysis of water

Numerous studies have dealt with the kinetics of reactions of actinide ions with the primary products of water radiolysis. The rate constants for the reactions of uranium, neptunium, plutonium, americium, berkelium and californium ions with hydrated electrons, H, OH and O^- radicals and with hydrogen peroxide have been determined.

a. Reactions with the hydrated electron

The rate constants of the reactions of actinide ions with e_{aq}^- in acidic, nearly neutral, carbonate-containing and alkaline media are listed in Table 3. The reactions of the hydrated electron with tetra-, penta-, hexa- and heptavalent actinides (An) have large rate constants (from $\sim 2 \times 10^9$ to $\sim 1 \times 10^{11}$ litre mol⁻¹ s⁻¹). The rates of the majority of these reactions are diffusion-controlled. As in the case of other diffusion-controlled reactions, there is no correlation between the rate constants and the redox potentials E° of the corresponding pairs of actinide ions, although the extreme values of E° differ by ~ 2 V, and the redox potential of the U(IV)/U(III) pair is -0.6 V.^{21,34–39} A noticeable shift of the potential to the negative region observed for Th(IV) and Am(III) ions results in a decrease in the rate constants.

The reaction rates are ‘insensitive’ to the change in the formal charge and in the number of water molecules in the equatorial plane of the actinide ion. This can be seen in the case of complex ions of hexavalent uranium: $\text{UO}_2(\text{H}_2\text{O})_n^{2+}$, $\text{UO}_2(\text{H}_2\text{O})_{n-1}\text{OH}^+$, $\text{UO}_2(\text{IMDA})$, $\text{UO}_2(\text{NTA})^-$, $\text{UO}_2(\text{C}_2\text{O}_4)_2^{2-}$, and $\text{UO}_2(\text{CO}_3)_3^{4-}$. The rate constants for all these ions are close to one another.

The decrease in the charge of tetravalent actinide ions in solutions containing sulfuric acid also has no significant influence on the rate constants. The formation of AnSO_4^{2+} ions may not be accompanied by an increase in the electron density in the orbitals of the actinide ion accepting an electron.

Schmidt *et al.*²⁸ have studied the mechanism of reduction of pentavalent neptunium ions with hydrated electrons in a weakly acidic medium using pulse radiolysis with conductometric recording of short-lived species. They obtained results indicating that at pH 3.6–5.8, the reduction of NpO_2^+ to $\text{Np}(\text{OH})^{3+}$ occurs *via* the intermediate formation of $\text{NpO}_2 \cdot 6\text{H}_2\text{O}$, $\text{Np}(\text{OH})_4 \cdot 4\text{H}_2\text{O}$, $\text{Np}(\text{OH})_3^+$ and $\text{Np}(\text{OH})_2^{2+}$. The rate constant for the transformation of $\text{NpO}_2 \cdot 6\text{H}_2\text{O}$ into $\text{Np}(\text{OH})_4 \cdot 4\text{H}_2\text{O}$ is 1.5×10^6 s⁻¹, while the rate constants for the protonation of $\text{Np}(\text{OH})_4$, $\text{Np}(\text{OH})_3^+$ and $\text{Np}(\text{OH})_2^{2+}$ are 3.75×10^{10} , 4.0×10^{10} , and 4.28×10^{10} litre mol⁻¹ s⁻¹, respectively. These researches also determined the p*K* values for the equilibria between NpO_2OH and NpO_2^+ , $\text{Np}(\text{OH})_2^{2+}$ and $\text{Np}(\text{OH})_3^+$. They were equal to 8.7 and 4.5, respectively.

Note. The following designations are used: IMDA — iminodiacetate, NTA — nitrilotriacetate.

When Np(V) is reduced to Np(IV), the structure of the neptunium ion changes (from NpO₂⁺ to Np⁴⁺), and this can significantly hamper the reaction. Nevertheless, the reaction rate in an acid medium is close to its diffusion limit. Therefore, it was suggested²⁸ that the electron transfer in this reaction is a non-adiabatic process, which yields Np(IV) in an electronically excited state as an intermediate product having an ‘inappropriate’ electronic configuration. Then this configuration rearranges into the configuration corresponding to a hydrolysed ion of tetravalent neptunium.

The rates of the reactions of e_{aq}⁻ with tetravalent uranium, neptunium and plutonium in acidic media or with heptavalent

neptunium and plutonium in alkaline solutions are most probably larger than the diffusion limit. This is due to a tunnel mechanism of these reactions (detailed information about the tunnel mechanism of reactions of e_{aq}⁻ can be found in a monograph⁴⁰).

In a carbonate-containing medium, the rate constants for the reactions of the hydrated electron with An(VI) depend only slightly on the concentration of carbonate ions. It has been concluded that the reaction rates are limited by the diffusion of the reacting species.²⁷ It was also suggested that the composition of the AnO₂(CO₃)₃⁴⁻ complex ions does not change over the studied ranges of concentrations of carbonate ions. Therefore, variation of

the carbonate concentration influences the reaction rate only to the extent to which it changes the viscosity of the medium.

The rate constant for Np(V) is approximately an order of magnitude lower than that for Np(VI). This is due to the fact that the transition of Np(V) into Np(IV) is accompanied by a structural rearrangement.²⁷ The influence of the concentration of carbonate ions on the reaction rate in the case of Np(V) is also slight. It was noted that in this case, too, ion diffusion is the crucial factor.²⁷ The reaction of e_{aq}^- with Np(IV) occurs faster than the corresponding reaction with Np(V). This is due to the fact that Np(IV) is converted into Np(III) without a change in the structure.

The rate constants for the reactions of actinides with the hydrated electron in dilute alkaline solutions differ only slightly from those in weakly acidic solutions. The reaction rates decrease markedly at $[OH^-] \geq 7.5$ M. Several possible reasons for the decrease in the reaction rates in concentrated alkaline solutions have been proposed.²⁴ They include an increase in the viscosity of these solutions, capture of electrons in deeper traps, the formation of pairs of the $M^+ \dots e_{aq}^-$ type (M^+ is an alkali metal cation) and the change in the activity coefficients of ions at high ionic strengths.

b. Reactions with a hydrogen atom

The reactions of actinide ions with hydrogen atoms are significant in acidic solutions. In these solutions, the hydrated electron reacts with H^+ being thus converted into an H atom. This reaction is fast: $k = 2.4 \times 10^{10}$ litre mol⁻¹ s⁻¹ for solutions with pH 2.1–6.⁵ The reaction of an actinide ion with e_{aq}^- in an acidic medium is possible in the case where the product of the rate constant for the reaction of the actinide ion with the hydrated electron by the actinide concentration is comparable with the product of the rate constant for the reaction of e_{aq}^- with H^+ by the concentration of the latter. In neutral media, the reactions of H atoms are less significant because the role of the interaction of e_{aq}^- with H^+ is low and the radiation yield of H amounts to ~20% of the yield of e_{aq}^- (see Table 1). In alkaline media, processes involving H barely occur, because this species reacts with OH^- to give a hydrated electron.

The rate constants for the reactions of An(VI), An(V) and An(IV) with H are markedly lower than those for the corresponding reactions with the hydrated electron. This can be seen from the comparison of the data presented in Tables 3 and 4.

This difference can be explained by the fact that the redox potential of the H atom (–2.3 V) is less negative than that of e_{aq}^- (–2.87 V).⁶ The difference between the reaction mechanisms also plays a certain role. The mechanism of the interaction of e_{aq}^- with any ion consists in electron transfer. The reactions of the H atom apparently involve the water incorporated in the hydration shell of the ion. It cannot be ruled out that this reaction starts with the

Table 4. Rate constants for the reduction of actinide ions with H atoms in aqueous solutions.

Am(V)	HClO ₄	1.0	200	43

Figure 1. Dependence of the rate constants for the reactions of H atoms with actinyl ions in a 1 M solution of HClO₄ on the redox potentials of the AnO₂²⁺/AnO₂⁺ pairs.

insertion of H into a water molecule to give H₃O, and then electron transfer from H₃O to the central ion occurs.

The dependences of the logarithms of the rate constants for the reactions of H with all the AnO₂²⁺ ions studied on the redox potentials of the AnO₂²⁺/AnO₂⁺ pairs (or on the free energy of the reaction) are nearly linear (Fig. 1). Thus, the mechanisms of these reactions are identical and their rates are not controlled by diffusion. However, since there are no data on the rate of the exchange of water molecules coordinated by actinyl ions, this mechanism cannot be interpreted in detail.

For the reactions of actinyl ions with H, no linear correlation between the logarithm of the rate constant and the E° value is observed. It should also be noted that the rate constants for the reactions of H with NpO₂⁺ and AmO₂⁺ differ by two orders of magnitude, although the difference between the E° values for the Np(V)/Np(IV) and Am(V)/Am(IV) pairs is not that large.

The reactions considered above are reduction processes. Oxidation by H atoms is also known; for example, it reacts with U(V), Np(III) and Pu(III). The rate constants for these reactions are presented in Table 5. It can be seen that on passing from a solution in perchloric acid to a solution in sulfuric acid the rate constants for Pu(III) and Np(III) increase. This is due to the fact that the redox potential of the An(IV)/An(III) pair in sulfuric acid is smaller than that in perchloric acid and the potential of the Np(IV)/Np(III) pair is also smaller. In the case of U(V), the nature of the acid has apparently no influence on the rate of the process.

Table 5. Rate constants for the oxidation of actinide ions with H atoms in aqueous solutions.^{42, 44}

Actinide	Medium		$10^{-6} k$ /litre mol ⁻¹ s ⁻¹
	I	II	
U(V)	HClO ₄	0.1	~400
	H ₂ SO ₄	0.4	10–400
Np(III)	HClO ₄	1.0	63
	H ₂ SO ₄	1.0	190
Pu(III)	HClO ₄	3.0	< 1
	HClO ₄ + H ₂ SO ₄	0.2 + 1.8	6

Evidently, oxidation with an H atom is not an elementary process. It may involve the intermediate formation of a hydride ion as has been observed for the oxidation of Fe²⁺ ions (see, for example, Ref. 6).

c. Reactions with OH and O⁻ radicals

The OH radical exists in acidic, neutral and weakly alkaline media.

In an alkaline medium, electrolytic dissociation affords the O⁻ radical ion. The pK value for the corresponding equilibrium is 11.9 (see, for example, Ref. 6). The rate constant for the OH + OH⁻ reaction is large,⁵ 1.2×10^{10} litre mol⁻¹ s⁻¹; therefore, at pH > 13, it is the O⁻ radical ion that reacts with dissolved

substances including actinides in dilute solutions (with concentrations of no more than $\sim 10^{-3}$ mol litre⁻¹).

The results of studies on the kinetics of the reactions of OH with An(III), An(IV) and An(V) and the reactions of O⁻ with An(V) and An(VI) are presented in Tables 6 and 7. The rate constants of these reactions do not depend on the redox potentials of the Anⁿ⁺¹/Anⁿ pairs; for example, the potentials of the U(IV)/U(III) and Am(IV)/Am(III) pairs are -0.52 and 2.62 V, respectively, whereas the rate constants for the reactions of U(III) and Am(III) are 4.1×10^8 and 3.4×10^8 litre mol⁻¹ s⁻¹ (Table 6). Structural rearrangements also have no influence on the reaction rate [oxidation of Np(IV) and Np(V) provide an example]. It is noteworthy that on passing from a weakly to a strongly acidic medium the rate constant of the reaction of OH with Pu(III) decreases about four-fold, whereas the rate of a similar reaction with Am(III) increases by the same factor.

Table 7. Rate constants for the reactions of penta- and hexa-valent neptunium ions with O⁻ radical ions in aqueous solutions of LiOH.^{53, 54}

Ion	[LiOH] ^a	$10^{-7} k^b$	Ion	[LiOH] ^a	$10^{-7} k^b$

	0.51	4.2		(in NaOH)	

^a Concentration is expressed in mol litre⁻¹, ^b k — in litre mol⁻¹ s⁻¹.

Two possible mechanisms for the oxidation with OH radicals have been proposed. According to one of them, the reaction rate is limited by abstraction by the OH radical of an H atom from a water molecule in the hydration shell of the ion, as has been postulated by Berdnikov⁵⁵ for transition metal ions in general. According to the other mechanism, the radical adds to an actinide ion, and after that, a rearrangement in its inner shell occurs, which is accompanied by the elimination of OH⁻. The latter mechanism was proposed by Golub *et al.*⁴⁵ and supported by Lierse *et al.*⁵¹

d. Reactions with hydrogen peroxide

Hydrogen peroxide can act, with respect to actinide ions, both as an oxidising and a reducing agent. This depends on the pH of the

^a Estimated from a figure presented in Ref. 61.

solution and on the redox potential of the actinide pair in this solution. Recall that depending on the pH, hydrogen peroxide exists as H₂O₂, HO₂⁻ (the pK value for the corresponding equilibrium is 11.9⁶) or O₂²⁻ (this ion is formed at pH > 13.5). The rate constants for the oxidation of actinide ions with hydrogen peroxide in aqueous solutions are presented in Table 8.

Comparison of the rate constants with the redox potentials of the corresponding pairs of actinide ions shows a clear-cut tendency for the constants to decrease upon an increase in the potentials. This, in principle, may attest to an outer-sphere mechanism of these processes. However, the oxidation of Np(III) results in the accumulation of Np(V), *i.e.* a two-electron process occurs, and only after some period, Np(IV) appears in the solution as a result of the reaction between Np(III) and Np(V).

Table 8 presents the rate constant for the bimolecular oxidation of Pu(III); however, in a large number of experiments,⁶² the reaction rates were described by the equation:

$$-\frac{d[\text{Pu(III)}]}{dt} = k[\text{Pu(III)}]^2[\text{H}_2\text{O}_2]. \quad (2)$$

The researchers cited⁶² believe that the mechanism of this reaction includes the formation of a peroxide complex, which slowly decomposes to give Pu(IV).

Oxidation of An(IV) is a single-electron process yielding An(V) and OH. This is confirmed by the fact that the oxidation of U(IV) by hydrogen peroxide in a solution saturated with benzene gives rise to phenol.⁵⁷ Oxidation of An(V) in acidic solutions affords only An(VI) and OH. However, it should be noted that during γ -radiolysis in an alkaline solution, Np(V) reacts with hydrogen peroxide to give a peroxo-complex.⁶³

The reduction of actinide ions with hydrogen peroxide results in the formation of HO₂ in addition to the reduced ions. Apparently, the reduction involves intermediate formation of a peroxo-complex.

The rate constants for the reduction of actinide ions with hydrogen peroxide in aqueous solutions are listed in Table 9. Their magnitudes increase with an increase in the difference between the redox potentials of the actinide pair and O₂/H₂O₂. This regularity is especially typical of Pu(IV). The difference between the formal potentials of the Pu(VI)/Pu(V) and O₂/H₂O₂ pairs in an acidic medium is 0.24 V, while that for the same reagent in a solution of NaHCO₃ is 0.15–0.20 V; the corresponding rate constants differ by 4 orders of magnitude. The formation of peroxo-complexes mentioned above also has some influence on the reaction rate.

Table 9. Rate constants for reduction of actinide ions with hydrogen peroxide in aqueous solutions.

^a Rate constant for the formation of the peroxo-complex. ^b Estimated from a figure presented in Ref. 61. ^c Rate constant in the equation $-d[\text{Pu(III)}]/dt = k[\text{Pu(IV)}]^2[\text{H}_2\text{O}_2]$. ^d Rate constant for the formation of the peroxo-complex of Pu(IV) from the equation $d[\text{complex}]/dt = k[\text{Pu(IV)}]^2[\text{H}_2\text{O}_2]$. ^e First-order rate constant, s⁻¹. ^f Peroxide complex (decomposition).

In alkaline solutions in which the peroxide exists as HO₂⁻ and actinide anions are present, not only is the difference between the redox potentials significant but is the charge of the anion also. As the pH value increases, the rate constants, for example, for Np(VII) and Np(VI), decrease; this is due to the decrease in the difference between the potentials (the redox potentials of actinide pairs change more sharply than that of the O₂/H₂O₂ pair). However, the rate constants for Np(VII) and Np(VI) at identical pH values are close, although the potentials of the Np(VII)/Np(VI) and Np(VI)/Np(V) pairs differ by ~0.4 V. This behaviour may be due to the fact that the charge of the Np(VII)-containing anion is 3–, while that of the Np(VI) anion is 2–.

2. Reactivity of actinide ions towards ‘secondary’ inorganic and organic free radicals

In aqueous solutions, the primary radical products resulting from water radiolysis (e_{aq}⁻, H, OH, O⁻) react with dissolved compounds and are thus converted into ‘secondary’ radicals. For example, the reaction of e_{aq}⁻ with NO₃⁻ affords NO₃²⁻ radical ion, while reactions of OH with HSO₄⁻ or HCOO⁻ give rise to SO₄⁻ or CO₂⁻, respectively. In relatively concentrated solutions (more than ~0.1 mol litre⁻¹), ‘secondary’ radicals can also arise *via* the direct action of the ionising radiation on the dissolved substance. The formation of the NO₃ radical upon direct ionisation of the nitrate ion can serve as an example.

The secondary radicals possess various redox properties. Data on the redox potentials of these radicals have been reported in a number of studies.^{72–74} The potentials of the secondary radicals SO₄⁻, NO₃⁻ and Cl₂⁻ are comparable with those of the OH radical (the E° values of the latter are 1.9, 2.32 and 2.73 V in a 1 M solution of OH⁻, at pH 7 and in a 1 M solution of H⁺, respectively⁶). Therefore, the transformation of the OH radical into any other radical decreases the probability of accumulation of actinide ions in higher oxidation states during radiolysis. Note also that the introduction of certain substances in the solution makes it possible to convert the OH radical into a ‘secondary’ radical acting as a reducing agent. For example, the reaction of OH with formate ion affords the CO₂⁻ radical ion, which possesses strong reducing properties. The hydrated electron can be converted into an oxidising radical; for example, by the reaction with the peroxodisulfate ion (this reaction yields SO₄⁻). A significant radiation-induced chemical process is the reaction of e_{aq}⁻ with dinitrogen oxide; in this reaction, the OH radical (or O⁻) appears in the solution instead of the hydrated electron.

The SO₄⁻, NO₃⁻, CO₃⁻, Cl₂⁻, HO₂⁻, COOH and some other radicals also belong to the group of ‘secondary’ radicals.

a. Reactions with sulfate radicals

The SO₄⁻ radical ions are formed during radiolysis of solutions of sulfuric acid or sulfates upon the oxidation of HSO₄⁻ ions with OH radicals and upon the direct action of the ionising radiation on the sulfate ions. These radical ions can also result from irradiation of solutions containing peroxodisulfate ions.

The acid form of SO₄⁻ is the HSO₄ radical. The pK value for its dissociation is unknown. One may only believe that in neutral and probably in weakly acidic solutions, the sulfate radical exists mostly as SO₄⁻.

The rate constants for the reactions of actinide ions with sulfate radicals are listed in Table 10. It can be seen that these radicals rapidly oxidise tri- and penta-valent actinide ions and are much less reactive towards tetravalent actinide ions. The rates of reactions with U(V) and Np(III) are most likely diffusion-controlled. In the sequence Np(III)–Pu(III)–Am(III), the reactivity decreases, owing to an increase in the redox potential of the An(IV)/An(III) pair.

The main difference between the reactivities of the SO₄⁻ and OH radicals is manifested in their reactions with tetravalent actinide ions. Obviously, the oxidation of non-oxygenated ions into dioxo-ions cannot be regarded as an elementary chemical reaction. It may consist of two steps, which can formally be represented as the formation of an An⁵⁺ ion and its subsequent hydrolysis. Even in the case of U(IV), which is relatively easy to oxidise, no linear correlation exists between the measured rate constant for the pseudo-first-order reaction and the concentration of the metal ions. It cannot be ruled out that the reaction with the

Table 10. Rate constants for the reactions of actinide ions with sulfate radicals.

Actinide	Medium		$10^{-6} k$ /litre mol ⁻¹ s ⁻¹	Ref.

Am(III)	H ₂ SO ₄ + Na ₂ S ₂ O ₈	1.0 + 1.0	2.5×10	See ^b

^a The k value depends on the concentration of U(IV); it decreases as this concentration increases. ^b Unpublished results of the authors of this review.

OH radical involves the intermediate formation of $\text{An}(\text{OH})^{4+}$, which apparently facilitates oxygenation. Perhaps this pathway is not characteristic of the sulfate radical.

b. Reactions with the NO_3 radicals

The NO_3 radicals arise in the radiolysis of acidic or neutral solutions containing nitrate ions due to the oxidation of nitric acid molecules and (to a markedly lesser extent) nitrate ions by OH radicals, or due to the direct action of ionising radiation on NO_3^- and HNO_3 (see, for example, Ref. 78).

The rate constants for the reactions of actinide ions with NO_3 radicals in aqueous solutions are presented in Table 11. The published data are limited to Np(V), Pu(III) and Am(V); however, some conclusions and predictions can also be made about the reactivity of the NO_3 radical with respect to other actinides.

Table 11. Rate constants for the reactions of actinide ions with NO_3 radicals.

Ion	Medium		$10^{-8} k$ /litre $\text{mol}^{-1} \text{s}^{-1}$	Ref.
	I	II		
Np(V)	HNO_3	1.0	8.8	49
	HNO_3	2.0	7.0	49
	HNO_3	5.0	8.4	49
	$\text{HNO}_3 + \text{LiNO}_3$	1.0 + 3.0	9.2	49
	$\text{HNO}_3 + \text{LiNO}_3$	1.0 + 6.0	6.4	49
Pu(III)	HNO_3	2.0	2.5	77
Am(V)	HNO_3	2.5	2.5	76

In the case of reactions of neptunoyl ions, the concentration of nitric acid or nitrate ions exerts no significant influence on the rate constant. A similar behaviour can be proposed for reactions of other actinoyl ions with this radical. The Pu(III) ions are oxidised relatively rapidly by the NO_3 radical. The Np(III) ions having a smaller redox potential should react with a larger rate constant. The potentials of the Am(IV)/Am(III) and $\text{NO}_3/\text{NO}_3^-$ pairs are commensurable; therefore, it may be expected that Am(III) would react with NO_3 at a low rate. The reactions of An(IV) with NO_3 occur apparently at lower rates than An(IV) + SO_4^- . The rate of the reaction between U(V) and NO_3 should be diffusion-controlled. This is attested by the fact that non-charged HSeO_3 radicals having a smaller redox potential react with U(V) at a diffusion-controlled rate: the rate constants for the U(V) + HSeO_3 reaction in 0.1 and 0.9 M solutions of HClO_4 are 1.4×10^{10} and 1.8×10^{10} litre $\text{mol}^{-1} \text{s}^{-1}$, respectively.⁷⁵

c. Reactions with molecular ions of halogens and with $(\text{CNS})_2^-$

The Cl_2^- , Br_2^- and I_2^- molecular ions derived from halogens and $(\text{CNS})_2^-$ derived from the pseudo-halogen arise during the radiolysis of aqueous solutions as a result of oxidation of halide and thiocyanate ions with OH radicals. These species are formed in several steps: first, OH adds to Hal^- (Hal^- is a halide or thiocyanate ion); the resulting HalOH^- radical ion decomposes to give Hal and OH^- , and then Hal reacts with Hal^- . In addition, these radical ions can result from oxidation of Hal^- with SO_4^- and NO_3 , from reduction of Hal_2 (for example, with e_{aq}^-) and from the direct action of ionising radiation on Hal^- .

The rate constants for the reactions of the radical ions Hal_2^- with actinide ions are listed in Table 12. The following general conclusions about the reactivity of these radical ions can be drawn.

As a rule, these radical ions are less reactive with respect to actinide ions than sulfate and nitrate radicals. This is due to the fact that the redox potentials of Hal_2^- are smaller.

Almost all the reactions involving Hal_2^- are characterised by rate constants smaller than those of the diffusion limit; in this case, it may be expected that the free energies of the reactions (or the difference ΔE° between the redox potentials of the reacting species) would have a substantial influence. The logarithms of

^a The constants are expressed in litre $\text{mol}^{-1} \text{s}^{-1}$.

the rate constants for similar reactions of Np(III) and Pu(III) with Cl_2^- , Br_2^- and I_2^- radical ions depend linearly on ΔE° (Fig. 2).

The rates of reactions of Hal_2^- with tri- and pentavalent actinide ions are greater than those for tetravalent actinide ions [for example, according to our data, the presence of $\sim 10^{-2}$ mol/litre⁻¹ of Np(IV) or Pu(IV) has no influence on the rate of consumption of Cl_2^-], because oxidation of the latter is hampered due to the difference between the structures of the initial and oxidised ions. The mechanisms of the reactions of Hal_2^- with actinide ions include a step of formation of short-lived non-oxygenated and monooxygenated ions; the probability of transformation of these ions into final products (actinoyl ions) depends on their stability.

Oxygenated ions are also formed upon oxidation of some other ions, for example, Ti(III) and V(III). The rate constants for the reactions of Cl_2^- with the Ti(III)-, Np(III)- and Pu(III)-contain-

Figure 2. Dependence of the rate constants for the reactions of trivalent neptunium (I) and plutonium (II) with Cl_2^- (1), Br_2^- (2) and I_2^- (3) on the difference between the redox potentials of the reacting species.

ing aqua-ions are 1.1×10^7 , 1.0×10^9 and 3.0×10^7 litre mol⁻¹ s⁻¹, respectively, although the redox potentials for the Ti(IV)/Ti(III), Np(IV)/Np(III) and Pu(IV)/Pu(III) pairs are equal to 0.1, 0.14, and 0.97 V, respectively. The redox potential of the V(IV)/V(III) pair is 0.34 V, and the reaction of Cl₂⁻ with the V(III) aqua-ion is slower ($k < 10^6$ litre mol⁻¹ s⁻¹) than the Ti(III) + Cl₂⁻ reaction. Evidently, the oxidation of Np(III) and Pu(III) ions is not accompanied by a structural rearrangement and, therefore, it is more efficient than the oxidation of the 3*d*-element ions under consideration (even though in the case of actinide ions, valence electrons are transferred from the lower *f* orbitals).

In concentrated solutions of chlorides, inner-sphere chloro-complexes are formed; they are more reactive towards Cl₂⁻ than the corresponding aqua-ions. The logarithms of the rate constants are proportional to the concentration of chloride ions. These correlations have been obtained for the reactions of Cl₂⁻ with Np(V), Pu(III), Ce(III) and with some ions of 3*d* elements.

d. Reactions with the CO₃⁻ radical ion

The CO₃⁻ radical ions are formed during radiolysis of carbonate- and hydrogencarbonate-containing solutions. They result from reactions of the OH or O⁻ radicals with carbonate or hydrogencarbonate ions or from the direct action of ionising radiation on these ions. If the solution contains peroxodisulfate ions, CO₃⁻ can also arise *via* the reaction of SO₄⁻ with the carbonate ion. Recall that carbonates are always present as an impurity in solutions of alkali; radiolysis of these solutions can also afford CO₃⁻. The rate constants for the reactions of actinide ions with the CO₃⁻ radical ion in aqueous solutions are presented in Table 13. It should be emphasised that, depending on the concentrations of the solutes, CO₃⁻ reacts in carbonate, hydrogencarbonate and alkaline carbonate solutions with carbonate, hydroxocarbonate and hydroxo-complexes of actinides and with their oxo-anions. In these reactions, the radical ion under consideration acts as an oxidising agent.

The similarity of the electrostatic properties and structures of ions of 5*f* elements (including these ions in carbonate complexes) accounts for the linear correlations between the logarithms of rate constants and the ΔE° values of the reacting species. These correlations hold for the reactions of CO₃⁻ with the carbonate complexes of Am(III), Ce(III), Pu(III)²⁹ and U(V), Np(V), Pu(V).²¹

Table 13. Rate constants for the reactions of actinide ions with CO₃⁻ radical ions.

Actinide	Medium		10 ⁻⁵ <i>k</i> /litre mol ⁻¹ s ⁻¹	Ref.
	I	II		
U(V)	K ₂ CO ₃	0.05	4.9 × 10 ⁴	21

	Na ₂ CO ₃ + NaOH	0.5 + 0.6	2.4 × 10 ²	53
	Na ₂ CO ₃ + NaOH	0.5 + 1.0	4.4 × 10 ²	53
	Na ₂ CO ₃	0.05	1.5 × 10 ²	21
Np(IV)	Carbonate solution	—	< 5 × 10	10
Np(III)	K ₂ CO ₃	1.0	3.3 × 10 ⁴	29
	K ₂ CO ₃	3.0	1.4 × 10 ⁴	29
Pu(VI)	Na ₂ CO ₃	0.01	1.5 × 10 ²	83
Pu(V)	Na ₂ CO ₃	5 × 10 ⁻³	5.0 × 10	83
	Na ₂ CO ₃	0.05	2.7 × 10 ²	21
Pu(IV)	Carbonate solution	—	< 5 × 10	10
Pu(III)	K ₂ CO ₃	1.0	7.0 × 10 ³	29
	K ₂ CO ₃	1.1	5.6 × 10 ³	29
	K ₂ CO ₃	4.3	6.7 × 10 ³	29
	K ₂ CO ₃	3.0	2.5 × 10 ²	29
Am(III)	K ₂ CO ₃	4.6	2.7 × 10 ²	29
	K ₂ CO ₃	6.0	1.5 × 10 ²	29

The influence of the concentrations of the carbonate ions and of alkali on the reaction rate is associated with changes in the compositions of the coordination spheres of the ions and, as a consequence, in their electrostatic charges and redox potentials.

e. Reactions with the HO₂, O₂⁻ and O₃⁻ radicals

The HO₂ and O₂⁻ radicals can arise in aqueous solutions containing oxygen (mostly in reactions of oxygen with H and e_{aq}⁻). The yields of the HO₂ radicals as a primary product of radiolysis induced by heavy charged particles (including the α-particles emitted by actinides) are relatively high (see Table 2). The HO₂ and O₂⁻ radicals are in equilibrium with each other (*pK* is 4.7⁶). The O₃⁻ ion radicals are formed in an alkaline medium upon the reaction of O⁻ with oxygen. Besides, HO₂ and O₂⁻ are intermediate species formed in the reduction reactions involving hydrogen peroxide, and O₃⁻ or its acid form HO₃ [the *pK* value for the corresponding equilibrium is 6.15 (see Ref. 6)] also arise when ozone reacts with e_{aq}⁻ and H.

The rate constants for the reactions of actinide ions with HO₂, O₂⁻ and O₃⁻ radicals are listed in Table 14. Two types of reactions with actinide ions are known for HO₂ and O₂⁻, namely, electron transfer and formation of a complex. It is also noteworthy that the lifetime of O₂⁻ increases with increase in the pH, and for concentrations of alkali of more than 1 M, it reaches tens of seconds and

longer. Therefore, even relatively slow reactions of O_2^- with actinide ions can occur in alkaline solutions.

Attention is drawn to the fact that the reduction of Np(VI) with O_2^- radical ions occurs faster than reduction of Np(VII) under comparable conditions, although the redox potentials of the Np(VII)/Np(VI) and Np(VI)/Np(V) pairs are 0.6 and 0.15 V, respectively. In all probability, this is due to the different charges of the Np(VII)- and Np(VI)-containing ions (3- and 2-, respectively) and different structures of these ions in solution.

Reduction reactions of actinide ions with O_3^- radicals are unknown. However, decomposition of these radicals in aqueous solutions may yield hydrogen peroxide, which possesses reducing properties.

f. Reactions with organic free radicals

Organic free radicals are generated during radiolysis of aqueous solutions containing organic compounds. In concentrated solutions, they can arise from the direct action of ionising radiation on a dissolved compound.

Information on the reactivity of organic free radicals towards actinide ions is especially important for predicting the behaviour of extraction systems used in the radiochemical industry. All the organic free radicals studied exhibit reducing properties in reactions with actinide ions. The rate constants for these reactions are listed in Table 15.

It can be seen that the rates of reactions of COOH, $(CH_3)_2COH$ and electron adducts of *o*-phenanthroline, 2,2'-bipyridinium and 4,4'-dipropyl-2,2'-bipyridinium with actinide ions are high. It has been assumed that these reaction rates are limited by diffusion. Calculation of the diffusion limit rate constant for the Np(VI) + $(CH_3)_2COH$ reaction based on the Smolukhovskii equation has shown⁹¹ that the calculated and experimental values are close to each other. In addition, it was found that the activation energies for the reactions of U(VI) with the electron adducts of *o*-phenanthroline and 2,2'-bipyridinium are 10 and 16.7 kJ mol⁻¹, respectively. These magnitudes are typical of reactions the rates of which are diffusion-controlled or are close to the diffusion limit.

Uranium, neptunium, plutonium and americium ions react with the H adducts of *o*-phenanthroline and 2,2'-bipyridinium much more slowly than with the corresponding electron adducts. This is due most likely to the difference between the structures of the electron and H adducts. Thus it has been suggested⁹² that the electron adduct of *o*-phenanthroline is protonated at the second nitrogen atom in the molecule, whereas in the case of the H adduct, the additional hydrogen atom adds to one of the ring carbon atoms. Therefore, the excess electron in the electron adducts is delocalised over the aromatic π -system, whereas in H adducts, this system is broken to give a cyclodienyl type radical. In the former case, the transfer of an electron occurs readily, while in the latter case it is hampered.

It should be emphasised that the reactivity of actinide ions towards organic free radicals has been markedly less studied than their reactivity with respect to inorganic radicals. This is especially true for the organic radicals that are formed upon radiolysis of extraction systems used for practical purposes. Certainly, more extensive studies in this field would be expedient.

Thus, the following general conclusions can be drawn about the reactivity of actinide ions towards inorganic and organic free radicals in aqueous solutions (see also Refs 1, 11–13).

(1) If the ΔE° value of the species involved in reactions occurring by the mechanism of outer-sphere electron transfer is relatively large (~ 2.3 V and larger), the rates of these reactions are diffusion-controlled or are close to the diffusion limit. However, if the reaction occurs by a complicated mechanism including, for example, complex formation or a structural rearrangement of the actinide ion, this conclusion may be false.

(2) When the reaction rate is not diffusion-controlled, it often depends on the redox potentials of the actinide ions and the radicals participating in the reaction. For example, the reactivity

Table 15. Rate constants for the reactions of actinides with organic free radicals.

of radicals in oxidation processes changes in the following sequence: $SO_4^- > NO_3^- > OH^- > Cl_2^- > Br_2^- > I_2^- > O_3^-$.

(3) If the structures of actinide ions and free radicals reacting with them are similar, for analogous reactions the rates of which are not diffusion-controlled, the logarithms of rate constants obey a linear correlation with the ΔE° values of the reacting species (see Figs 1 and 2).

(4) The reactivity of actinide ions is markedly influenced by the formation of complexes. It was noted above that the rate constants for reactions of Np(III) and Pu(III) with the Cl_2^- radical ion increase following an increase in the concentration of chloride ions in the solution. This is due to the formation of inner-sphere chloride complexes possessing a higher reactivity towards Cl_2^- (it has been found that an increase in the concentrations of HClO_4 , LiClO_4 or H_2SO_4 barely influences the rates of the corresponding reactions).

(5) A structural change in the coordination sphere of an actinide ion upon reaction is among the factors having an influence on the reaction rate. For example, this is true for oxidation of An(IV) or reduction of An(V). In these processes, non-oxygenated multi-charged cations are converted into oxygenated cations and *vice versa*. The reactivity can depend on the stability of intermediate ions.

(6) If the rate of the reaction of an actinide ion with a radical ion is not diffusion-controlled, the rate constant depends on the charge of the actinide-containing ion. Among other factors, this may be due to hydrolysis of actinide ions. In some cases, the magnitude of this effect surpasses the influence of the redox potential. This is observed in the reactions of O_2^- with Np(VI) and Np(VII) ions in alkaline media.

IV. Uranium

Radiolytic transformations of uranium ions in aqueous solutions induced by γ - and α -radiation have been studied fairly comprehensively. The main results obtained in these studies are outlined below and are interpreted resorting to the published data on the kinetics of reactions of uranium ions with the products of radiolysis of water and with 'secondary' free radicals.

1. γ -Radiolysis of acidic aqueous solutions of uranium ions

The behaviour of uranium ions in aqueous solutions under the action of X-rays and γ -radiation has been studied; this includes reduction of U(VI) in the presence of acceptors of OH radicals and in the absence of oxygen as well as oxidation of U(III) and U(IV) in deaerated solutions and oxidation of U(IV) in solutions saturated with air.

It is known¹ that when aerated solutions of U(VI) (> 0.2 mol litre⁻¹) in 0.05 M H_2SO_4 are exposed to γ -radiation, the concentration of U(VI) ions does not change and no hydrogen peroxide is detected. This can be explained in the following way: U(VI) is reduced in reactions with e_{aq}^- and H (H is formed not only as a product of water radiolysis but also in the reaction of e_{aq}^- with H^+) to U(V); however, the latter is again oxidised to U(VI) in reactions with OH and H radicals and also with hydrogen peroxide. In neutral and weakly acidic solutions, peroxide complexes of U(VI) are formed; after relatively prolonged irradiation, they precipitate. In sufficiently acidic media, these complexes are soluble, and no precipitate is formed. In solutions saturated with air, U(VI) ions form a complex with the HO_2 radical; disproportionation of this complex yields U(VI) and hydrogen peroxide.

Reduction of U(VI) occurs in solutions containing organic compounds (Table 16).^{93, 94} In these systems, reactions of H and OH with organic compounds (we denote them by RH_2) are significant. These reactions afford 'RH' radicals able to reduce U(VI). The U(V) ions resulting from reduction of U(VI) disproportionate to give U(IV) and U(VI). Note that the intermediate formation of U(V) in the radiolytic reduction of U(VI) and oxidation of U(IV) has been confirmed electrochemically.¹

The formation of one U(IV) ion requires two reducing radicals or two OH radicals. Hydrogen peroxide oxidises U(IV) to U(V) or oxidises U(V) to U(VI), and the OH radical thus formed reacts with RH_2 . Therefore, the theoretical reduction yield of U(VI) attained in the case where all the OH radicals are trapped by an organic compound should be $(G_{e_{\text{aq}}^-} + G_{\text{H}} + G_{\text{OH}})/2 = 3.3$ ion (100 eV)⁻¹. [This is valid, provided that 'RH reduces U(VI)']. In the presence of *tert*-butyl alcohol, no reduction by an organic radical occurs, because the free radical resulting from the reaction of *tert*-butyl alcohol with OH and H radicals is not a reducing agent (see

Table 16. Reduction yields of U(VI) in γ -radiolysis of deaerated solutions of U(VI) containing organic compounds RH_2 .^{93, 94}

RH_2	$[\text{RH}_2]$ /M	$G[-(\text{U(VI)})]$ (see ^a)	RH_2	$[\text{RH}_2]$ /M	$G[-(\text{U(VI)})]$ (see ^a)

$(\text{CH}_3)_3\text{COH}$	0.05	0.8	$\text{H}_2\text{C}_2\text{O}_4$ (see ^b)	0.01	0.3
$(\text{CH}_3)_3\text{COH}$	0.1	0.9	$\text{H}_2\text{C}_2\text{O}_4$ (see ^b)	0.1	2.3
			$\text{H}_2\text{C}_2\text{O}_4$ (see ^b)	0.3	2.7

^a Expressed in ion (100 eV)⁻¹. ^b Estimated from a figure presented in Ref. 93.

Table 16). Since in this system hydrated electrons not only reduce U(VI) but also react with H^+ to give H atoms and the latter can partly react with *tert*-butyl alcohol, the reduction yield attained can be found from the following expression:

$$G[-\text{U(VI)}] = G[\text{U(IV)}] < \frac{1}{2}(G_{e_{\text{aq}}^-} + G_{\text{H}} - G_{\text{H}_2\text{O}_2}), \quad (3)$$

i.e. $G[-\text{U(VI)}]$ should be smaller than 1.4 ion (100 eV)⁻¹.

It has been shown⁹³ that the reduction yield of U(VI) in solutions containing $\text{H}_2\text{C}_2\text{O}_4$ decreases when sulfuric acid is added. This can be explained by the fact that HC_2O_4^- , $\text{H}_2\text{C}_2\text{O}_4$ and HSO_4^- compete for OH radicals (the rate constants for the corresponding reactions are commensurable⁹⁵). The two species mentioned first react to give reducing radicals, whereas the reaction with HSO_4^- affords an oxidising radical, which, like the OH radical, is able to oxidise U(IV) and U(V).

When the concentration of organic substances is high, recombination of OH radicals in spurs is partially suppressed, and the reduction yield of U(VI) thus increases.⁹⁴

Reduction of U(VI) also occurs⁹⁶ in solutions of nitric acid containing sulfanilamide. The latter reacts with nitrous acid and with NO_3 radicals formed in this system, and this precludes the reverse oxidation of U(V) and U(IV). The reduction yield of U(VI) amounts to 1.3 ion (100 eV)⁻¹.

Radiolytic processes in aqueous solutions of U(IV) have also been the objects of several experimental and computer studies.⁹⁷ In deaerated solutions of U(IV) in perchloric acid, U(IV) is oxidised to U(VI).¹ The oxidation yield increases as the concentration of U(IV) increases; for $[\text{U(IV)}] = 0.05$ mol litre⁻¹ in 0.1 M HClO_4 , it is 2.45 ion (100 eV)⁻¹. At higher concentrations of U(IV), the yield is somewhat lower. In some cases, both $G[-\text{U(IV)}]$ and $G(\text{H}_2)$ have been measured. It was found that $G(\text{H}_2)$ is much larger than G_{H_2} . The most significant processes in this system are oxidation of U(IV) with OH radicals and with hydrogen peroxide, oxidation of U(V) with H atoms, disproportionation of U(V), reduction of U(IV), U(V) and U(VI) with hydrated electrons and the interaction of U(III) with U(V) and U(VI). With allowance for all these reactions and for the data of Table 1, the $G[-\text{U(IV)}]$ value, which is equal to $G[\text{U(VI)}]$, is 2.3 ion (100 eV)⁻¹.

It has been noted⁴⁴ that oxidation of U(III) [resulting from the reduction of U(IV) with H atoms] may be ignored in the mechanism of the oxidation of U(IV), because U(III) reacts rapidly with U(V) and U(VI), the concentrations of which are much higher than the steady-state concentration of H atoms. The U(V) ions are long-lived species; therefore their concentration during γ -radiolysis is relatively high.

Vladimirova⁹⁷ carried out computer modelling of the radiolysis of deaerated solutions of U(IV) in perchloric acid. Unfortunately, the researcher assumed without proof that the reaction of U(VI) with HO_2 yields U(IV) rather than a complex of U(VI) with HO_2 .

When deaerated solutions of U(IV) in aqueous sulfuric acid are exposed to γ -radiation, as in the case of solutions in perchloric acid, U(IV) is oxidised.¹ In a 0.4 M solution of sulfuric acid, the $G[-\text{U(IV)}]$ value increases following an increase in the concen-

tration of U(IV) and is $2.0\text{--}2.4\text{ ion (100 eV)}^{-1}$ in the range of its concentrations of $0.02\text{--}0.05\text{ mol litre}^{-1}$. Upon further increase in the concentration of U(IV), the yield decreases; in a $0.5\text{ mol litre}^{-1}$ solution, $G[-\text{U(IV)}]$ is $\sim 0.8\text{ ion (100 eV)}^{-1}$. Evidently, the mechanisms of the radiolysis of solutions containing sulfuric and perchloric acids are similar. In all probability, the decrease in $G[-\text{U(IV)}]$ at high concentrations of U(IV) is due to the fact that some of the uranium ions trap the reducing radicals from spurs. Study of radiolytic oxidation of U(IV) has shown that at elevated temperatures, H atoms are also involved in the oxidation, in addition to OH and H_2O_2 ; therefore, in this case, the oxidation yield is higher than that at room temperature.

γ -Radiolysis of deaerated aqueous solutions of U(IV) in hydrochloric acid has been studied in a number of publications.^{1, 57} It was found that the oxidation yield decreases upon an increase in the concentration of HCl and increases following an increase in the concentration of U(IV); however, $G[-\text{U(IV)}]$ is much lower than that in solutions containing sulfuric acid.

Oxidation of U(IV) induced by γ -radiation or X-rays in air-saturated solutions in sulfuric acid has been the object of several studies.¹ It was noted that the radiolytic oxidation of U(IV) ions in this system is complicated by their spontaneous oxidation with the atmospheric oxygen. The initial oxidation yields slowly increase when the concentration of U(IV) increases and decrease as the dose rate increases.

Radiolytic oxidation of U(IV) in $0.5\text{--}3\text{ M HNO}_3$ saturated with air has been studied.⁹⁸ To bind nitrous acid which is able to oxidise U(IV), hydrazine (up to $0.1\text{ mol litre}^{-1}$) was added to the solutions. The oxidation yields were found to decrease with an increase in the concentration of nitric acid. In the presence of U(VI), the yields decrease somewhat. In this system, U(IV) is oxidised by the NO_3 radical (arising in the reaction of OH radicals with nitric acid and NO_3^-), by molecular oxygen and by hydrogen peroxide. The U(VI) introduced into the solution is reduced by intermediate compounds formed in the oxidation of hydrazine; therefore, the oxidation yield of U(IV) diminishes.

A scheme consisting of twenty reactions has been proposed for the mathematical description of radiolytic oxidation of U(IV) in solutions containing nitric acid.⁹⁹ The results obtained in terms of this scheme, after selection of unknown rate constants, were apparently in satisfactory agreement with the experimental data.

The oxidation yields of U(IV) during radiolysis of hydrochloric-acid solutions (with a dose rate of 0.39 Gy s^{-1}) saturated with air are lower than those in aerated solutions of sulfuric acid.¹ For example, the maximum yield in air-saturated 0.8 M HCl amounts to $7.8\text{ ion (100 eV)}^{-1}$.⁵⁷

Trivalent uranium is oxidised during radiolysis in aqueous solutions to give U(IV).¹ Thus its oxidation yield in hydrochloric acid reaches $\sim 12\text{ ion (100 eV)}^{-1}$. If we assume that U(III) is oxidised *via* interaction with H, OH, Cl_2^- and H_2O_2 , the calculated oxidation yield is $8.2\text{ ion (100 eV)}^{-1}$. The experimental value is markedly higher. Perhaps, the solutions were not completely free from oxygen during irradiation.

2. α -Radiolysis of acidic aqueous solutions of uranium ions

Most of the studies dealt with the oxidation of U(IV) in deaerated and aerated aqueous solutions of various acids during α -radiolysis. It has been noted¹ that when solutions of U(VI) in sulfuric acid are exposed to α -particles emitted by radon, uranium is not reduced. When a solution containing both U(IV) and U(VI) has been irradiated by α -particles from radon, U(IV) has been oxidised. In a study of α -radiolysis of deaerated solutions of U(IV) in sulfuric acid, it has been found that the oxidation yield of U(IV) and the yield of formation of molecular hydrogen diminish following an increase in the concentration of U(IV). Uranium(IV) is oxidised by hydrogen peroxide, OH and HO_2 radicals, whereas H atoms (in this medium, they appear instead of hydrated electrons) reduce the resulting U(VI). Thus

$$G[-\text{U(IV)}] = \frac{1}{2}G_{\text{OH}} + G_{\text{H}_2\text{O}_2} + \frac{3}{2} - G_{\text{HO}_2} - [G_{\text{H}_2} - G(\text{H}_2)] - \frac{1}{2}(G_{e_{\text{aq}}^-} + G_{\text{H}}). \quad (4)$$

For example, the $G[-\text{U(IV)}]$ value calculated for a $2 \times 10^{-3}\text{ mol litre}^{-1}$ solution of U(IV) in $1.5\text{ M H}_2\text{SO}_4$ using the primary yields of the products of α -radiolysis of water given in Table 2 is $1.19\text{ ion (100 eV)}^{-1}$. This value differs somewhat from that found experimentally [$1.08\text{ ion (100 eV)}^{-1}$]. This difference can be due to the fact that the primary yields refer to a 0.4 M solution of sulfuric acid, while the experimental value was measured for $1.5\text{ M H}_2\text{SO}_4$.

The oxidation yield of U(IV) in aerated acidic solutions is markedly higher; it increases with an increase in the concentration of U(IV) and with a decrease in the dose rate.¹ The reactions occurring during α -radiolysis of solutions saturated with air are the same as those occurring during γ -radiolysis. The facts that the oxidation yields induced by α - and γ -radiolyses are high and that they depend on the radiation dose rate indicate that the oxidation of U(IV) follows a chain mechanism.

Study of the influence of the energy of helions (*i.e.* linear transfer of energy) on the $G[\text{U(VI)}]$ values for the oxidation of U(IV) in 0.4 M solutions of H_2SO_4 saturated with oxygen or nitrogen has shown that the oxidation yields in oxygen-saturated solutions increase with an increase in the energy of helions, whereas for solutions saturated with nitrogen, the opposite dependence is observed.¹⁰⁰

Oxidation of U(IV) in $0.2\text{--}11.5\text{ M}$ solutions of HClO_4 exposed to intense α -radiation from ^{244}Cm has been studied.¹⁰¹ Curium was added to the solution as a solid salt or as its solution. In the former case, the oxidation yield was equal to $1.6\text{ ion (100 eV)}^{-1}$ in $0.2\text{--}1\text{ M}$ solutions of HClO_4 and increased gradually following an increase in the concentration of the acid; in $10\text{--}11\text{ M HClO}_4$ the oxidation yield was equal to $\sim 6\text{ ion (100 eV)}^{-1}$ $\{[\text{U(IV)}] = 6.6 \times 10^{-3}\text{ mol litre}^{-1}\}$. It was shown that the yield is almost independent of the dose rate but increases with an increase in the concentration of U(IV). When curium was introduced as a solution, the oxidation yields were $2.7, 7.5$ and $50\text{ ion (100 eV)}^{-1}$ for concentrations of HClO_4 of $0.2, 4$ and 7 M , respectively. Evidently, the latter value was markedly overestimated. Oxidation of U(IV) occurs *via* the same reactions as it does in solutions containing sulfuric acid. The higher yields attained in this case can be due to the influence of the products of decomposition of HClO_4 ($\text{ClO}_2, \text{Cl}_2, \text{ClO}_2^-$) formed during radiolysis.

It was found¹⁰¹ that the oxidation yield of U(IV) in nitric-acid solutions during radiolysis induced by α -particles from ^{244}Cm decreases as the content of HNO_3 increases. For concentrations of the acid of $0.5\text{--}1$ and $2\text{--}8\text{ M}$, the yields are ~ 2 and $\sim 1\text{ ion (100 eV)}^{-1}$, respectively. When the concentration of HNO_3 is further increased, the yield drops almost to zero. The yields in solutions containing nitric acid are lower than those in solutions of sulfuric and perchloric acids. This is due to the formation of HNO_2 , which reacts with H_2O_2 and, possibly, with HO_2 .

V. Neptunium

Vast information dealing with radiolytic transformations of neptunium ions in acidic, carbonate-containing and alkaline solutions exposed to γ - and α -radiation can be found in the literature.

1. γ -Radiolysis of acidic aqueous solutions of neptunium ions

γ -Radiolysis of aerated solutions of Np(VI) containing perchloric acid results in accumulation of Np(V); $G[-\text{Np(VI)}] = G[\text{Np(V)}] = 2.4\text{ ion (100 eV)}^{-1}$.¹⁰² The mechanism of this process in a weakly acidic solution includes reactions of Np(VI) with e_{aq}^- , H, HO_2 and H_2O_2 as well as reverse oxidation of Np(V) with OH radicals; the calculated value of $G[-\text{Np(VI)}]$ {or $G[\text{Np(V)}]$ } is $2.3\text{ ion (100 eV)}^{-1}$. The yield measured in another study¹⁰² coincides with this value. However, earlier publications (they have been considered in a previous monograph¹) report values

of 4.0 to 6.7 ion (100 eV)⁻¹, depending on the concentrations of Np(VI) and HClO₄. Among other reasons, such high yields may be due to the presence of organic impurities in the solutions used. In a 3.4 M solution of HClO₄, $G[-\text{Np(VI)}]$ was found to be 1.9 ion (100 eV)⁻¹. This low yield can be due to the fact that the reduction of Np(VI) with hydrogen peroxide and HO₂ radicals is retarded and also due to the fact that HO₂ participates to some extent in the oxidation of the resulting Np(V).

The radiolytic behaviour of Np(V) in aerated solutions in perchloric acid has been studied in detail.¹⁰² It was found that Np(V) is fairly stable in these solutions. In particular, in 1 M HClO₄, the formation of Np(VI) has been observed only at relatively high radiation doses. In the presence of acceptors that transform hydrated electrons and H atoms into OH radicals, Np(V) is oxidised irreversibly into Np(VI) under the action of γ -irradiation.¹⁰² In solutions with pH $\geq$ 4, dinitrogen oxide was used as the acceptor. The initial oxidation yield $G[-\text{Np(V)}]$, which is equal to $G[\text{Np(VI)}]$, was 2.1 ion (100 eV)⁻¹. At pH $\leq$ 1, xenon trioxide served as the acceptor; it reacted with H to give XeO₂ and OH. It should be noted that in this system, HO₂ radicals and, finally, hydrogen peroxide are also converted into OH radicals. The oxidation yield depends on the concentration of XeO₃; it increases from 6 for 1×10^{-3} mol litre⁻¹ of XeO₃ to 13.5 ion (100 eV)⁻¹ for 2×10^{-2} mol litre⁻¹ of XeO₃. The mechanism of the radiolytic oxidation of Np(V) in the presence of the acceptors mentioned above has been discussed in Ref. 1.

Radiolytic reduction of Np(VI) and oxidation of Np(IV) in solutions containing sulfuric acid have been studied. Reduction of Np(VI) in these solutions has been described in a number of publications (they are discussed in Ref. 1). The reduction yields range from 4.5–5.0 ion (100 eV)⁻¹ in $\sim 10^{-3}$ – 10^{-2} M solutions of H₂SO₄ to 2.5–3.0 ion (100 eV)⁻¹ in ~ 0.4 – 0.5 M solutions of this acid.

The mechanisms of reduction of Np(VI) in solutions of sulfuric and perchloric acids are similar. The calculated reduction yield in these solutions is 2.3 ion (100 eV)⁻¹. The experimental $G[-\text{Np(VI)}]$ values for solutions in sulfuric acid are higher, which is apparently due to the presence of organic impurities.¹

Reduction of Np(VI) with the heteropoly-blue PW₁₂O₄₀⁴⁻ in a 0.1 M solution of H₂SO₄ has been studied by pulse radiolysis.¹⁰³ The rate constant of the corresponding reaction was measured to be 3.2×10^8 litre mol⁻¹ s⁻¹. This is smaller than the diffusion limit rate constants for reactions of oppositely charged ions. The kinetic restrictions during electron transfer are apparently due to the fact that the excess electron is delocalised over the tungsten atoms shielded by the negatively charged oxygen atoms.¹⁰⁴

Radiolytic oxidation of Np(IV) to Np(V) in aqueous solutions of sulfuric acid has been studied by several researchers (these studies have been surveyed in Ref. 1). In particular, it was found that in aerated solutions the yield increases from ~ 13 to 15 ion (100 eV)⁻¹ on passing from 1×10^{-2} M to 0.4 M H₂SO₄. Oxidation of Np(IV) in aerated solutions is accomplished *via* reactions with HO₂ (this radical results from interaction of H with O₂), OH and H₂O₂. Therefore, the theoretical value of $G[-\text{Np(IV)}]$ is 15.5 ion (100 eV)⁻¹ for 0.4–0.5 M H₂SO₄. This value differs only slightly from the experimental result.

Data on radiolytic processes including reduction of Np(VI) and oxidation of Np(IV) in nitric acid solutions have been reported.

When solutions of Np(VI) in 1×10^{-3} – 2 M HNO₃ are exposed to high-energy electrons or to γ -radiation, Np(V) ions are formed.^{1,4} The reduction yields decrease with an increase in the concentration of nitric acid or in the dose rate. A peculiar feature of the radiolysis of these solutions is the existence of an induction period at high concentrations of HNO₃.

During γ -radiolysis of aerated solutions of Np(VI) in nitric acid, the following intermediate species are formed: NO₃²⁻ (resulting from the reaction of e_{aq}⁻ with NO₃⁻), HNO₃⁻ (the reaction of H with NO₃⁻) and NO₃ (the reactions of OH with HNO₃ and NO₃⁻ and direct action of ionising radiation on the nitrate ion). When the concentration of NO₃⁻ is low, the reaction between H and O₂ is also possible. The OH radical can participate in the oxidation of

the Np(V) formed, but at low radiation doses, this process can be neglected. In an acidic medium, the NO₃²⁻ and HNO₃⁻ radical ions are converted into NO₂; the latter reacts with water to give HNO₂ and NO₃⁻. In concentrated solutions of nitric acid, NO₂ and NO₃ radicals can also arise from the direct action of the ionising radiation on HNO₃ and NO₃⁻.⁶

The NO₃ radicals oxidise Np(V) and undergo dimerisation or hydrolysis. Hydrolysis yields NO₂ and hydrogen peroxide. The dimer N₂O₆ can reduce Np(VI).¹ The dimerisation of NO₃ radicals is fairly significant in concentrated solutions of HNO₃ in which these radicals are formed in a high yield upon interaction of NO₃⁻ and HNO₃ with OH and also upon direct action of the ionising radiation on the solute. In addition, trapping of reducing radicals by nitrate ions in spurs should also be taken into account. Nitrous acid reduces Np(VI) and destroys hydrogen peroxide. As the concentration of H⁺ increases, the rate of the reaction of this acid with Np(VI) decreases, while the rate of the reaction with hydrogen peroxide increases.

Reduction of Np(VI) in aerated 1×10^{-3} – 5×10^{-2} M solutions of HNO₃ occurs *via* its reactions with the HO₂ radical, hydrogen peroxide and nitrous acid. The reaction between HNO₂ and H₂O₂ in these solutions can be ignored. The resulting Np(V) is oxidised by the NO₃ and OH radicals. When the concentration of HNO₃ is 1 M or higher, the mechanism of radiolytic transformations becomes somewhat different. Firstly, hydrogen atoms are consumed in the reactions with NO₃⁻, whereas the reaction between H and O₂ plays only a minor role; secondly, the rates of reactions of Np(VI) with HO₂ and HNO₂ decrease; thirdly, the reaction between HNO₂ and H₂O₂ accelerates; fourthly, Np(V) is reduced by nitrous acid. A decrease in the dose rate results in a decrease in the concentrations of H₂O₂ and HNO₂; hence, the rate of the reaction between these species decreases, and the proportions of H₂O₂ and HNO₂ that react with Np(VI) increase.

The existence of an 'induction period' in concentrated solutions of HNO₃ can be explained by the fact that the reaction between Np(VI) and hydrogen peroxide in these systems occurs slowly, and Np(V) appears only after accumulation of a fairly large amount of HNO₂ in the solution.

The influence of U(VI) on the radiolytic reduction of Np(VI) in solutions of nitric acid has been studied.¹ An increase in the concentration of U(VI) leads to an increase in the yield of Np(V). It was postulated that a cation–cation complex formed by U(VI) and Np(V) plays an important role in this process. However, later it has been shown¹⁰⁵ that the radiolytic transformations in this system can be interpreted without invoking the idea of cation–cation interactions. It was noted¹ that the introduction of Ce(IV) (up to $\sim 2 \times 10^{-2}$ mol litre⁻¹) exerts no influence on the yield of Np(V).

On exposure to γ -radiation, Np(IV) ions in aerated and deaerated solutions of nitric acid are oxidised to Np(V) (for concentrations of HNO₃ ranging from 1×10^{-3} to 0.5 M) and to Np(VI).^{1,106} The oxidation yield of Np(IV) in aerated solutions depends on the concentration of nitric acid: initially, it increases from 7 to 9 ion (100 eV)⁻¹ following an increase in the [HNO₃] value from 5×10^{-3} to 0.1 M, and then it decreases to 1.5 to 2.6 ion (100 eV)⁻¹ for [HNO₃] = 1–6 M. In the case of deaerated solutions, this yield is almost constant, 4.0 to 4.6 ion (100 eV)⁻¹ ([HNO₃] = 5×10^{-3} – 0.4 M).^{1,106}

During γ -radiolysis of deaerated solutions, NO₂, NO₃ and HNO₂ are formed; Np(IV) reacts with OH, HO₂, H₂O₂ and e_{aq}⁻, and Np(III) reacts with Np(V). The role of the reaction between HNO₂ and H₂O₂ is relatively small. The formation of NO₃ under the action of ionising radiation can be neglected at [HNO₃] $\leq$ 0.4 M. It is assumed that HNO₂ does not react with Np(IV). For concentrations of HNO₃ equal to 0.1 and 0.4 M, the reaction of Np(IV) with e_{aq}⁻ and, hence, the reaction between Np(III) and Np(V) can be ignored. For these solutions

$$G[-\text{Np(IV)}] = G_{\text{OH}} + 2G_{\text{H}_2\text{O}_2} = 4.55 \text{ ion (100 eV)}^{-1}.$$

The experimental $G[-\text{Np(IV)}]$ values found for the above concentrations of HNO₃ are close to this value. The fact that at

low concentrations of HNO_3 , the $G[-\text{Np(IV)}]$ values are smaller is due to the occurrence of the reactions between Np(IV) and e_{aq}^- and between Np(III) and Np(V) .

In 5×10^{-3} – 0.5 M solutions of HNO_3 saturated with air, the oxidation yield of Np(IV) should be higher than that in deaerated solutions, since the former contain HO_2 radicals (resulting from the reaction of H with O_2) able to oxidise Np(IV) . In aerated 1 to 6 M solutions of HNO_3 , the reaction with HO_2 is insignificant, H_2O_2 reacts completely with HNO_2 , and the OH radicals are consumed to give NO_3 . The yield of NO_3 is larger than G_{OH} owing to the direct action of the ionising radiation on NO_3^- and HNO_3 . However, $G[-\text{Np(IV)}] < G_{\text{OH}}$. This is apparently due to the fact that not all the NO_3 radicals are consumed in the reaction with Np(IV) ; some of these radicals can be hydrolysed and involved in the oxidation of nitrous acid. A decrease in the concentration of Np(IV) is favourable for the side reactions of NO_3 .

According to Rotmanov *et al.*,¹⁰⁷ prolonged irradiation of solutions of tetravalent neptunium in aqueous nitric acid results in the establishment of steady-state (equilibrium, as the researchers state) concentrations of HNO_2 , Np(IV) , Np(V) and Np(VI) . For example, when the initial concentrations of Np(IV) and HNO_3 are 3×10^{-3} and 1 mol litre^{-1} , the steady-state concentrations are the following: $7.5 \times 10^{-5} \text{ mol litre}^{-1}$ (HNO_2) and 3%, 92% and 5% [Np(IV) , Np(V) and Np(VI) , respectively]. In the case where the concentrations of Np(IV) and HNO_3 are 3×10^{-3} and 6 mol litre^{-1} , the steady-state concentrations are equal to $1.6 \times 10^{-4} \text{ mol litre}^{-1}$ and 36%, 40% and 24%, respectively. It can be seen that as the concentration of nitric acid increases, the steady-state concentrations of Np(IV) and Np(VI) increase. This is due to the reaction between Np(VI) and HNO_2 and to disproportionation of Np(V) .

2. α -Radiolysis of acidic aqueous solutions of neptunium ions

α -Radiolysis of tetravalent and hexavalent neptunium has been studied in solutions containing perchloric and nitric acids. Under the action of its own α -radiation, Np(VI) ions in 0.48 – 1.7 M solutions of HClO_4 are converted into Np(V) .¹ The rate constant for the reduction in 0.044 – 0.3 M solutions of Np(VI) is $3.1 \times 10^{-9} \text{ s}^{-1}$. Using this value, the half-life period of ^{237}Np (2.2×10^6 years) and the energy of α -particles (4.8 MeV), $G[\text{Np(V)}]$ was found to be $6.4 \text{ ion (100 eV)}^{-1}$.

The processes occurring during α -radiolysis are the same as those occurring during γ -radiolysis. The theoretical reduction yield [achieved when the reducing radicals, precursors of H_2 , are completely trapped from spurs by Np(VI)] is 5.8 or $6.5 \text{ ion (100 eV)}^{-1}$, depending on which $G_{\text{H}_2\text{O}_2}$ value (from Table 2 or from Ref. 108) has been used for calculations.

Reduction of Np(VI) (present in a concentration of 1.5×10^{-3} to $1 \times 10^{-2} \text{ mol litre}^{-1}$) in solutions of perchloric acid induced by the α -radiation from ^{244}Cm has been studied.¹⁰⁸ It was shown that owing to the low content of Np(VI) and to the high acidity, the reaction of Np(VI) with H_2O_2 occurs slowly; therefore, it does not come to an end at the instant when the concentrations of Np(VI) and Np(V) are measured. For example, for a solution containing $1.5 \times 10^{-3} \text{ mol litre}^{-1}$ of Np(VI) and $1.0 \text{ mol litre}^{-1}$ of HClO_4 (and for a dose rate of 2.25 Gy s^{-1}), the reduction yields found at the moment of measurement and after the completion of the reaction are 1.6 and $3.5 \text{ ion (100 eV)}^{-1}$, respectively.

Under the action of α -particles, Np(IV) in aerated solutions of perchloric acid is oxidised to Np(V) {at $[\text{HClO}_4] < 1 \text{ M}$] or to Np(VI) {at $[\text{HClO}_4] > 1 \text{ M}$ }.¹⁰⁷ The oxidation yields are 0.8 to $1.8 \text{ ion (100 eV)}^{-1}$ depending on the concentrations of the acid and Np(IV) .

During α -radiolysis of aerated solutions of Np(IV) in which $[\text{HClO}_4] < 1 \text{ M}$, H reacts with O_2 , Np(IV) reacts with OH , HO_2 , H_2O_2 and e_{aq}^- and Np(III) reacts with Np(V) . The partial trapping of reducing radicals in the spurs by Np(IV) ions (their concentration is fairly high) should also be taken into account. Therefore, the yield of Np(IV) can be found from the equation:

$G[-\text{Np(IV)}] = 3(G_{\text{H}} + G_{\text{HO}_2}) + G_{\text{OH}} + 2G_{\text{H}_2\text{O}_2} - G_{e_{\text{aq}}^-} - 2QG_{\text{H}_2}$, (5) where Q is a coefficient characterising the proportion of reducing radicals trapped by Np(IV) ions in the spurs.

The minimum oxidation yield should be obtained when the reducing radicals in the spurs are completely trapped by Np(IV) ions. This is equal to ~ 0.9 – $1.2 \text{ ion (100 eV)}^{-1}$.

When solutions of Np(V) in 4 – 6 M HClO_4 are exposed to α -radiation, an 'induction period' is observed;¹⁰⁷ during this period, Np(VI) ions do not appear but small amounts of Np(IV) are formed.

The transformations of Np(IV) and Np(VI) ions induced by α -radiation in solutions of nitric acid have been studied repeatedly.^{1,4} Both Np(IV) and Np(VI) are converted into Np(V) under the action of α -particles. The yields attained in these processes are listed in Table 17.

The reduction yield of Np(VI) during α -radiolysis of its solutions containing nitric acid is basically determined by the same reactions as in the case of γ -radiolysis. The calculated yield

Table 17. The reduction yields of Np(VI) and oxidation of Np(IV) in α -radiolysis of aerated nitric-acid solutions of neptunium (concentration of neptunium $\sim 10^{-3} \text{ mol litre}^{-1}$).^{1,4}

$[\text{HNO}_3]$ /M	G /ion (100 eV) ⁻¹	$[\text{HNO}_3]$ /M	G /ion (100 eV) ⁻¹
Reduction, dose rate 2.7×10^{-3}		Oxidation, dose rate 2.7×10^{-2}	
1.0×10^{-3}	3.0–3.2	5.0×10^{-3}	2.3
1.0×10^{-2}	5.0	1.0×10^{-2}	2.6
0.1	6.0	5.0×10^{-2}	3.0
0.5	6.6 ^a	0.1	3.4
1.0	5.7 ^a	0.3	3.8
2.0–2.1	4.2	0.5	4.2
		1.0	4.0

^a For these data no dose rate is given in Ref. 4.

for a $1 \times 10^{-3} \text{ M}$ solution of HNO_3 amounts to $3.4 \text{ ion (100 eV)}^{-1}$, which is close to the experimental value.¹ When the concentration of HNO_3 is increased to $\sim 0.5 \text{ M}$, the $G[-\text{Np(VI)}]$ value increases to $6.6 \text{ ion (100 eV)}^{-1}$. This is due to the fact that the nitrate ions suppress the formation of H_2 in the spurs. When this process is suppressed completely, $G[-\text{Np(VI)}]$ should be equal to $6.2 \text{ ion (100 eV)}^{-1}$. The reasons for the decrease in the yield at $[\text{HNO}_3] \geq 1 \text{ M}$ are the same as in the case of γ -radiolysis.

Oxidation of Np(IV) in a $1 \times 10^{-3} \text{ M}$ solution of HNO_3 should proceed *via* its reactions with OH , HO_2 and H_2O_2 . Besides, Np(IV) ions can be reduced by the radicals (precursors of H_2) that they trap in the spurs. As the concentration of HNO_3 increases, nitrate ions trap more and more reducing radicals in the spurs; therefore, the yield should decrease. However, owing to the low dose rate, the reaction between HNO_2 and hydrogen peroxide occurs slowly; H_2O_2 is mostly consumed for oxidation of Np(IV) , and thus the yield of the process increases.

Study of the behaviour of neptunium ions in solutions of nitric acid exposed to larger dose rates of α -radiation created by ^{244}Cm has shown^{109,110} that in 0.11 M HNO_3 , Np(VI) is totally reduced to Np(V) ; however at higher concentrations of the acid (0.33 and 0.62 M), steady states are established, both Np(VI) and Np(V) being present in the solution. In a 1.1 M solution of HNO_3 and at a radiation dose of 30 – 40 kGy , Np(IV) appears. When the dose rate or the concentration of the acid increases, the content of Np(IV) also increases. An increase in the dose rate results in a decrease in the reduction yield. For example, in a solution containing $0.62 \text{ mol litre}^{-1}$ of HNO_3 and $2.3 \times 10^{-3} \text{ mol litre}^{-1}$ of Np(VI) , $G[-\text{Np(VI)}]$ diminishes from 3.5 to $2.2 \text{ ion (100 eV)}^{-1}$ as the dose rate increases from 1.65 to 4.56 Gy s^{-1} ; evidently, this is due to the reaction between HNO_2 and H_2O_2 .¹⁰⁹

On exposure to the same type of radiation, Np(IV) is oxidised to give Np(V) and Np(VI) . When the radiation dose is sufficiently large, Np(IV) in solutions with $[\text{HNO}_3] < 1 \text{ M}$ is totally oxidised

yielding Np(V) (80%–95%) and Np(VI).¹⁰⁹ The oxidation yield diminishes following an increase in the dose rate. Thus in a solution containing $0.75 \text{ mol litre}^{-1}$ of HNO_3 and $\sim 2 \times 10^{-3} \text{ mol litre}^{-1}$ of Np(IV), the $G[-\text{Np(IV)}]$ value diminishes from 1.4 to 0.4 ion $(100 \text{ eV})^{-1}$ as the dose rate increases from 0.65 to 4.9 Gy s^{-1} . This is caused by acceleration of the reaction between HNO_2 and H_2O_2 . In solutions with $[\text{HNO}_3] > 1 \text{ M}$, steady states for Np(IV), Np(V) and Np(VI) are established. As the concentration of the acid increases, the proportions of Np(IV) and Np(VI) increase, while that of Np(V) decreases.¹¹²

The possibility of computer modelling of the changes in the oxidation states of neptunium ions during α - and γ -radiolysis in solutions in nitric acid has been shown.^{111–116} A scheme consisting of 26 reactions was composed; with the use of experimental radiation-chemical yields and the known rate constants for some reactions, this scheme made it possible to describe adequately the radiolytic oxidation of Np(IV) and Np(V) and also the reduction of Np(VI) and Np(V) in 1–6 M solutions of HNO_3 .

Measurement of the solubility of Np(IV) and Np(V) hydroxides in a 5.3 M solution of NaCl has shown that upon prolonged storage of this system, the solubility of Np(IV) hydroxide increases with time, owing to α -radiolysis.¹¹⁷ The solubility of the samples of Np(IV) and Np(V) hydroxides was found to be 10^{-5} – 10^{-6} M at pH 8–13.

3. γ -Radiolysis of alkaline aqueous solutions of neptunium ions

The development of a radiolytic method for the preparation of heptavalent neptunium, plutonium and americium is an important achievement in the radiation chemistry of aqueous solutions. Heptavalent actinides are formed upon irradiation of alkaline solutions of hexavalent actinide ions in the presence of acceptors of hydrated electrons.

The radiolytic method for the preparation of Np(VII) was developed by Pikaev *et al.*^{118,119} It consists in the γ -irradiation of an alkaline (in 1 M NaOH) solution of Np(VI) ($2 \times 10^{-4} \text{ mol litre}^{-1}$) saturated with N_2O . Dinitrogen oxide reacts with e_{aq}^- to give O^- radical ions. In the absence of N_2O , the hydrated electron reduces the Np(VII) formed and reacts with Np(VI). Apart from N_2O , $\text{S}_2\text{O}_8^{2-}$, $\text{H}_3\text{IO}_6^{2-}$, BrO^- and BrO_4^- ions have also been used as scavengers for hydrated electrons. The characteristic features of the method, the yields of Np(VII) under various experimental conditions and the mechanism of oxidation have been considered in detail previously.¹

The rate constant for the reaction of Np(VII) with Np(V) has been estimated by pulse radiolysis.⁵⁴ It is equal to $\sim 2 \times 10^7 \text{ litre mol}^{-1} \text{ s}^{-1}$ in 0.033–2.0 M solutions of LiOH. In solutions of NaOH, this reaction occurs more slowly.

When hydrogencarbonate or carbonate solutions of Np(VI) ($2 \times 10^{-4} \text{ mol litre}^{-1}$) saturated with N_2O or solutions containing $0.1 \text{ mol litre}^{-1}$ of $\text{K}_2\text{S}_2\text{O}_8$ are subjected to γ -radiolysis, no Np(VII) is formed.⁵³ A slight quantity of Np(VII) arises in a 0.5 M solution of Na_2CO_3 containing $0.01 \text{ mol litre}^{-1}$ of NaOH. An increase in the concentration of NaOH to $0.02 \text{ mol litre}^{-1}$ results in the accumulation of $3 \times 10^{-5} \text{ mol litre}^{-1}$ of Np(VII); in a 0.03 M solution of NaOH, almost all the Np(VI) is converted into Np(VII). In this case, the formation of Np(VII) in the presence of N_2O occurs without any 'induction period', Np(VI) being completely converted into Np(VII) at a radiation dose of $\sim 600 \text{ Gy}$. The yield of Np(VII) increases from 0.7 to 4.8 ion $(100 \text{ eV})^{-1}$ following an increase in the concentration of NaOH from 0.02 to 0.1 M, and then somewhat decreases {to 4.1 ion $(100 \text{ eV})^{-1}$ at $[\text{NaOH}] = 1 \text{ M}$ }. Obviously, the reaction of Np(VI) with CO_3^- plays an important role in these systems.

Neptunium(VI) is not oxidised in carbonate-containing solutions. This can be explained by the high redox potential of the Np(VII)/Np(VI) pair and also by the fact that Np(VI) exists as $\text{NpO}_2(\text{CO}_3)_3^{4-}$ under these conditions.⁵³ When the solution is alkalinised, $(\text{NpO}_4 \cdot n\text{H}_2\text{O})^{2-}$ ions appear in it, and they react with

CO_3^- radical ions. Apparently, the oxidation process consists in the transfer of an electron from Np(VI) to CO_3^- .

Irradiation of aerated alkaline solutions of Np(VII) gives rise to Np(VI) ions.¹ If the radiation rate is larger than 300 Gy and $[\text{NaOH}] = 0.5$ – 1 M , the reduction yield is 2.2 to 2.4 ion $(100 \text{ eV})^{-1}$. This is in agreement with the calculated value, which is equal to 2.2 ion $(100 \text{ eV})^{-1}$.

Reduction of Np(VI) and Np(V) in aerated alkaline solutions under the action of γ -radiation of ^{60}Co has been studied.^{120,121} It was found that Np(VI) is reduced to Np(V) and then to Np(IV). The reduction yield hardly depends on the concentration of alkali over the range of concentrations studied (0.9 to $8.5 \text{ mol litre}^{-1}$) and amounts to 1.4–1.6 ion $(100 \text{ eV})^{-1}$ (for radiation doses smaller than 650 Gy). However, the yield diminishes upon an increase in the dose.

The yield markedly increases in the presence of organic substances acting as acceptors of O^- radical ions. In a 2 M solution of NaOH containing $0.013 \text{ mol litre}^{-1}$ of ethylenediaminetetraacetate ions, the yield is 8.5 ion $(100 \text{ eV})^{-1}$ (for a dose of 109 Gy). If the solution contains $1.5 \text{ mol litre}^{-1}$ of NaOH and $0.26 \text{ mol litre}^{-1}$ of formate ions, $G[-\text{Np(VI)}] = 5.8 \text{ ion (100 eV)}^{-1}$ (for doses of $\leq 250 \text{ Gy}$). When carbonate ions are introduced in the solution, the yield barely changes. No reduction of Np(VI) is observed in the presence of nitrite or nitrate ions under low radiation doses (up to 2–3 kGy). However, when the doses are relatively high (more than 10 kGy), a peroxo-complex of Np(V) is formed in solutions containing NO_3^- .^{63,120,121}

Irradiation of aerated alkaline solutions of Np(V) results in the formation of Np(IV) as the corresponding hydroxide, which precipitates from the solution.

It should be noted that γ -radiolysis of alkaline aqueous solutions of Np(V), Np(VI) or their mixtures is accompanied by specific oscillations.^{120–122} They are manifested as a periodical variation of the optical density of the solution. Initially (at low doses), the optical density decreases owing to radiolytic reduction, and then increases due to the light scattering caused by the formation of a finely dispersed suspension. When the irradiated solution is allowed to stand for several hours, the suspension coagulates to give a precipitate, and the optical density decreases. Repeated irradiation results again in the formation of a finely dispersed suspension, and the optical density thus increases. These oscillations of the optical density can be observed until neptunium is entirely reduced to Np(IV).

The mechanism of reduction includes reactions of neptunium ions with e_{aq}^- , O_2^- , and HO_2^- and partial reverse oxidation of the reduced ions with O^- and O_3^- radicals. Based on this mechanism, the following equations were obtained:^{120,121}

$$G[-\text{Np(VI)}] = G[\text{Np(V)}] = G_{e_{\text{aq}}} + G_{\text{H}} + 2G_{\text{H}_2\text{O}_2} - G_{\text{OH}}, \quad (6)$$

$$G[-\text{Np(VI)}] = G[\text{Np(IV)}] = \frac{1}{2}(G_{e_{\text{aq}}} + G_{\text{H}} + 2G_{\text{H}_2\text{O}_2} - G_{\text{OH}}). \quad (7)$$

In all probability, Eqn. (6) is valid for the reduction of Np(VI) to Np(V), while Eqn. (7) holds for the reduction of Np(VI) to Np(IV).

For solutions containing 1 mol litre^{-1} of an alkali, the yields of the products of water radiolysis at pH 12–13 (see Table 1) can be used to calculate the reduction yields from Eqns (6) and (7). In this case, these yields amount to 2.2 ion $(100 \text{ eV})^{-1}$ [for the reduction to Np(V)] and 1.1 ion $(100 \text{ eV})^{-1}$ [for the reduction to Np(IV)]. The value of 1.4–1.6 ion $(100 \text{ eV})^{-1}$ given above for doses below 650 Gy indicates that at these doses, both Np(V) and Np(IV) are produced.

The increase in the reduction yields for solutions containing ethylenediaminetetraacetate or formate ions is due to the interaction of these substances with the O^- radical ions to give organic radicals that act as reducing agents and reduce an additional amount of Np(VI). For these systems, Eqns. (6) and (7) are transformed into the following expressions:

$$G[-\text{Np(VI)}] = G[\text{Np(V)}] = G_{e_{\text{aq}}} + G_{\text{H}} + G_{\text{OH}} + 2G_{\text{H}_2\text{O}_2}, \quad (8)$$

$$G[-\text{Np(VI)}] = G[\text{Np(IV)}] = \frac{1}{2}(G_{e_{\text{aq}}} + G_{\text{H}} + G_{\text{OH}} + 2G_{\text{H}_2\text{O}_2}). \quad (9)$$

The substitution of the numerical values should give the yields equal to 8.0 [for the reduction to Np(V)] and 4.0 ion (100 eV)⁻¹ [for the reduction to Np(IV)]. The value found experimentally for a solution containing ethylenediaminetetraacetate is close to that calculated from Eqn. (8); thus, at low radiation doses, Np(VI) in this system is reduced only to Np(V). The yield found for a solution containing formate ions [5.8 ion (100 eV)⁻¹ for doses below 250 Gy] implies that in this case, Np(VI) is reduced to give both Np(V) and Np(IV).^{120, 121}

The formation of a peroxo-complex of Np(V) in solutions containing nitrate ions is due to the fact that the products of radiolytic transformations of NO₃⁻ protect the arising Np(V) from reverse oxidation (with O⁻ and O₃⁻ radical ions) to Np(VI) and from its subsequent reduction to Np(IV) [apparently, the product of reaction between NO₃⁻ and e_{aq}⁻ is not able to reduce Np(VI)].⁶³ Thus, after a sufficient quantity of Np(V) has been accumulated and the greater part of Np(VI) has been consumed, the possibility for the interaction of Np(V) with H₂O₂ appears.

The reduction of Np(V) in aerated alkaline solutions occurs *via* its reaction with hydrated electrons. Since Np(IV) is poorly soluble in alkali and precipitates from alkaline solutions, its reverse oxidation with O⁻ and O₃⁻ radical ions proceeds at a slow rate, if at all. Hydrated electrons also react with oxygen in this system; however, O₂⁻ (and obviously HO₂⁻) are unable to reduce Np(V). The O⁻ and O₃⁻ radical ions partially oxidise Np(V) to Np(VI) and also react with hydrogen peroxide and with O₂⁻.

VI. Plutonium

Transformations of plutonium ions in solutions of mineral acids induced by X-ray-, γ - and α -radiations have been studied by many researchers. The interest in these processes is caused by the fact that, after dissolution, plutonium reacts with the products of radiolysis of the solvent (water and acids) resulting from the action of the radiation of fission-product elements and actinides. The fact that the redox potentials for pairs of plutonium ions in various oxidation states are close to one another accounts for their simultaneous existence in solutions. This fact should be taken into account during isolation, purification and preparation of plutonium compounds.

1. γ -Radiolysis of acidic aqueous solutions of plutonium ions
Radiolytic transformations of plutonium ions induced by X-ray or γ -radiation and high-energy electrons have been studied in solutions of various acids. Radiolysis has been investigated for solutions of Pu(VI), Pu(IV) and Pu(III), solutions containing plutonium in several oxidation states and solutions containing plutonium together with uranium.

In a study¹²³ (see also Ref. 1) of the behaviour of Pu(VI) ions in 0.2–0.5 M solutions of HClO₄ under the action of γ -radiation from ⁶⁰Co, it has been found that for solutions containing 4.3 × 10⁻³ mol litre⁻¹ of Pu(IV) and 0.2 mol litre⁻¹ of HClO₄, the reduction yield immediately after irradiation (with a dose of ~7.5 kGy) amounted to 0.8 ion (100 eV)⁻¹; this corresponds to the following equation:

$$G[-\text{Pu(VI)}] = G_{e_{aq}^-} + G_H - G_{OH}.$$

Twenty four hours later the reduction yield in the same solutions was 2.3 ion (100 eV)⁻¹. The theoretical yield is equal to:

$$G[-\text{Pu(VI)}] = G_{e_{aq}^-} + G_H + 2G_{H_2O_2} - G_{OH}.$$

Ten days after irradiation the yield was 1.2 ion (100 eV)⁻¹. The equation for the theoretical yield is the following:

$$G[-\text{Pu(VI)}] = \frac{1}{2}(G_{e_{aq}^-} + G_H + 2G_{H_2O_2} - G_{OH}).$$

The dissimilar reduction yields measured within various periods after irradiation are due to the occurrence or absence of the reaction of Pu(VI) with H₂O₂ and to disproportionation of the Pu(V) formed. It should be noted that when the radiation dose is high and the solution is kept after irradiation for a long period,

Pu(III) appears. This is due to the reaction between Pu(IV) and Pu(V) and also, possibly, to the reduction of Pu(IV) with hydrogen peroxide (*via* the formation of a peroxide complex). The results of the γ -radiolysis of deaerated solutions of Pu(VI) are similar to those obtained for aerated solutions.

During the γ -radiolysis of solutions of Pu(III) in 0.2 and 0.5 M HClO₄, no plutonium ions in other oxidation states are accumulated.^{1, 123} In these solutions, oxidation of Pu(III) and reduction of Pu(IV) completely counterbalance each other.

When aerated solutions of 4 × 10⁻³ mol litre⁻¹ of Pu(IV) and 1 × 10⁻³ mol litre⁻¹ of Pu(III) in 0.2 and 0.5 M HClO₄ are exposed to γ -radiation, Pu(III) is accumulated.^{1, 123} The Pu(IV) ions are reduced by H atoms, e_{aq}⁻, HO₂ and H₂O₂ (*via* the intermediate formation of a peroxide complex). The OH radicals participate in the oxidation of Pu(IV).

When a solution containing 3.6 × 10⁻⁴ mol litre⁻¹ of plutonium in 0.3 M HClO₄ (and apparently saturated with nitrogen) has been exposed to X-ray radiation, only oxidised [Pu(V) and Pu(VI)] and reduced [Pu(III) and Pu(IV)] forms of plutonium ions have been distinguished.¹ Under the action of this kind of radiation, plutonium can be reduced or oxidised depending on the ratio of the oxidised and reduced forms in the initial solution. In solutions containing plutonium and uranium, both reduction and oxidation of plutonium ions occur. The yield and the degree of reduction increase with an increase in the concentration of U(VI), the process occurring at the expense of U(V).

The behaviour of plutonium ions in solutions containing sulfuric acid is markedly influenced by the formation of complexes with sulfate ions. This process results in a decrease of the formal redox potentials of the Pu(VI)/Pu(V) and Pu(IV)/Pu(III) pairs; therefore, hydrogen peroxide no longer reduces Pu(IV) but, instead, it mostly oxidises Pu(III). In this case, disproportionation of Pu(V) occurs more rapidly.

The results concerning the radiolytic reduction of Pu(VI) in solutions of sulfuric acid and obtained in a number of studies have been discussed in the previous monograph.¹ The reduction yields vary from 1.2 to 2.5 ion (100 eV)⁻¹ depending on the concentrations of Pu(VI) and sulfuric acid and also on the dose rate. The yields decrease with an increase in the concentration of sulfuric acid or sulfate ions and with a decrease in the concentration of Pu(VI). The mechanism of radiolytic transformations is identical to that for solutions in perchloric acid.

During γ -radiolysis of both aerated and deaerated 1 × 10⁻³ mol litre⁻¹ solutions of Pu(III) in 0.4 M H₂SO₄, Pu(III) is oxidised to Pu(IV).¹ In the case of aerated solutions, post-radiation slow oxidation of Pu(III) with the hydrogen peroxide resulting from radiolysis is observed. The initial yields of Pu(IV) and H₂O₂ are 6.6 ion (100 eV)⁻¹ and 4.0 molecule (100 eV)⁻¹, respectively; this is in agreement with the calculated values. In deaerated solutions containing 10⁻⁴–10⁻³ mol litre⁻¹ of Pu(III), the yields of Pu(IV) and H₂ are 5.5 and 3.6 molecule (100 eV)⁻¹.

In 0.2 M HCl, hexavalent plutonium is reduced to pentavalent plutonium.¹²³ When the radiation dose is ~29 kGy, the reduction yield amounts to 0.56 equivalents (100 eV)⁻¹. The resulting Pu(V) disproportionates to give Pu(IV) and Pu(VI). The yield attained in a 0.5 M solution of HCl is somewhat lower. In hydrochloric acid, OH radicals are consumed, and Cl₂⁻ radical ions arise instead. The latter participate in the oxidation of Pu(V). Trapping of OH radicals or their precursors from the spurs by chloride ions decreases G_{H₂O₂}, increases G_{OH} and decreases G[-Pu(VI)]. Irradiation of a 4 × 10⁻³ mol litre⁻¹ solution of Pu(III) in 0.5 M HCl gives rise to Pu(IV), which is formed as a peroxide complex or as a polymer. Radiolytic oxidation of Pu(III) to Pu(IV) in a deaerated 0.8 M solution of HCl during γ -radiolysis occurs with a yield of 4–5 ion (100 eV)⁻¹ at a radiation dose of ~1 kGy or 0.7 ion (100 eV)⁻¹ when the radiation dose is above 3.8 kGy.¹ The oxidation yield of Pu(III) in aerated solutions of hydrochloric acid also decreases following an increase in the dose, which is due to consumption of oxygen and also to reverse reduction of Pu(IV).

Radiolysis of solutions of Pu(III) in hydrochloric acid has been studied under various conditions.¹²⁴ It was found that in a deaerated solution containing $0.8 \text{ mol litre}^{-1}$ of HCl and $1 \times 10^{-3} \text{ mol litre}^{-1}$ of Pu(III), the initial values of $G[\text{Pu(IV)}]$ and $G(\text{H}_2\text{O}_2)$ are $5.0 \text{ ion (100 eV)}^{-1}$ and $0.6 \text{ molecule (100 eV)}^{-1}$, respectively. The yield increases somewhat when $[\text{Pu(III)}] = 10^{-2} \text{ mol litre}^{-1}$. When the radiation doses are 3–5 kGy, a steady state is established, *i.e.* the ratio of the concentrations of Pu(III) and Pu(IV) remains constant. Irradiation of a $1 \times 10^{-3} \text{ mol litre}^{-1}$ solution of Pu(IV) results in the appearance of Pu(III), the initial yields of Pu(III) and H_2O_2 being equal to $0.36 \text{ ion (100 eV)}^{-1}$ and $0.18 \text{ molecules (100 eV)}^{-1}$, respectively. When a solution containing $4.9 \times 10^{-4} \text{ mol litre}^{-1}$ of Pu(III) and $5.2 \times 10^{-4} \text{ mol litre}^{-1}$ of Pu(IV) is exposed to γ -radiation, Pu(III) is oxidised to only a small extent, whereas $G(\text{H}_2\text{O}_2)$ is equal to 0.46 to $0.83 \text{ molecule (100 eV)}^{-1}$.

In a solution of Pu(III) in 0.8 M HCl saturated with oxygen, the yields of Pu(IV) and H_2O_2 are $6.5 \text{ ion (100 eV)}^{-1}$ and $4.0 \text{ molecule (100 eV)}^{-1}$, respectively (they do not depend on the radiation dose up to $\sim 1 \text{ kGy}$).¹²⁴ When the dose is $\sim 2 \text{ kGy}$, the system remains unchanged, while at 4.5 kGy, a peroxide complex of Pu(IV) is formed.¹²⁴ In 9 M HCl saturated with oxygen, Pu(III) is oxidised with an initial yield of $8.2 \text{ ion (100 eV)}^{-1}$.

The majority of studies dealing with the radiation chemistry of aqueous solutions of plutonium are devoted to the radiolysis of its solutions in nitric acid. This is due to the fact that systems containing nitric acid are often used in the processing of irradiated nuclear fuel.

Study of the γ -radiolysis of solutions of Pu(VI) and mixtures of Pu(IV) and Pu(VI) in 0.5 and 1.5 M solutions of HNO_3 has shown that in solutions containing 3×10^{-3} , 5×10^{-3} and $1 \times 10^{-2} \text{ mol litre}^{-1}$ of plutonium, Pu(VI) is not reduced (for radiation doses of up to $\sim 29 \text{ kGy}$). The results obtained by other researchers are somewhat different (see Ref. 1). It was found that when 2×10^{-4} – $2 \times 10^{-3} \text{ mol litre}^{-1}$ solutions of Pu(VI) in 0.001–0.5 M HNO_3 are exposed to γ -radiation, Pu(VI) is consumed. The reduction yields were found to decrease with an increase in the dose rate and in the concentration of HNO_3 . An important role in the systems under consideration belongs to the formation of nitrous acid (upon the reduction of HNO_3 and NO_3^- with H atoms and e_{aq}^-) and its subsequent reactions with Pu(VI) and H_2O_2 as well as to the reverse oxidation of the resulting Pu(V) with NO_3 radicals. The mechanism of radiolysis of nitric acid solutions of Pu(VI) under these conditions has been discussed in detail previously.¹ The influence of the reaction conditions on the reduction yield of Pu(VI) was also considered in the monograph cited. The authors obtained equations describing the dependence of $G[\text{Pu(VI)}]$ on the dose rate and on the concentration of Pu(VI).

The character of the reduction of Pu(VI) in 0.3–8 M (at a dose rate of 2.67 Gy s^{-1}) depends on its concentration.^{125, 126} When $[\text{Pu(VI)}]_0 = 5 \times 10^{-3} \text{ mol litre}^{-1}$, no reduction occurs in the above range of concentrations of HNO_3 up to a dose of 2.4 MGy. When $[\text{Pu(VI)}]_0 = 0.1 \text{ mol litre}^{-1}$, Pu(VI) is reduced to Pu(IV) in 0.3–4 M HNO_3 and is not reduced in 8 M HNO_3 (at a dose of 2.4 MGy). In 0.3–1.0 M solutions of HNO_3 , reduction starts immediately after the beginning of irradiation, whereas in the case of 3–4 M solutions, the process starts after an induction period. The presence of an induction period is also observed in the reduction of a $\sim 5 \times 10^{-2} \text{ mol litre}^{-1}$ solution of Pu(VI) in 1 M HNO_3 and of a $1 \times 10^{-2} \text{ mol litre}^{-1}$ solution of Pu(VI) in 0.3 M HNO_3 .

An induction period is a typical feature of autocatalytic processes. Autocatalytic reduction of Pu(VI) was observed for the first time about 40 years ago during α -radiolysis of nitric acid solutions of Pu(VI). It was suggested that slow accumulation of Pu(V) and its disproportionation give rise to Pu(IV). The latter reacts with HNO_2 and H_2O_2 thus yielding Pu(III), which reduces Pu(VI) and Pu(V).

It has been shown¹²⁵ that when Pu(IV) is added to the starting solution of Pu(VI), the initial rate of reduction of the latter increases and the induction period is shortened. This is true for solutions in which $[\text{Pu(VI)}] > 5 \times 10^{-3} \text{ mol litre}^{-1}$. The addition

of Pu(IV) to a solution in which $[\text{Pu(VI)}] \leq 5 \times 10^{-3} \text{ mol litre}^{-1}$ does not result in acceleration of the reduction; on the contrary, Pu(IV) is oxidised. During γ -radiolysis in HNO_3 solutions, HNO_2 is accumulated.¹²⁵

When Pu(VI) is reduced by nitrous acid, an equilibrium is established. Pu(VI) is consumed in three processes. Firstly, the Pu(V) formed disproportionates. Secondly, Pu(IV) reacts with Pu(V), and the resulting Pu(III), in its turn, reacts with Pu(VI), *i.e.* the corresponding equilibrium is established. Thirdly, Pu(IV) is reduced with nitrous acid, and Pu(III) reacts with Pu(VI) and Pu(V).

The overall rate of reduction of Pu(VI) and the rate of its reduction by nitrous acid were calculated.¹²⁵ The latter was found to be 2–3 times lower than the observed rate. Therefore, it was suggested that Pu(VI) and Pu(IV) are reduced by the precursors of nitrous acid, namely, e_{aq}^- and H. It was also found that the degree of reduction of Pu(VI) depends on its concentration and on the concentration of HNO_3 .

The kinetics of reduction of Pu(VI) for various conditions of γ -irradiation have been calculated.¹²⁷ The results of calculations were in satisfactory agreement with experimental data. However, it has been noted¹²⁸ that for 1 M HNO_3 with $[\text{Pu(VI)}] = 1 \times 10^{-2} \text{ mol litre}^{-1}$ and for 3 M HNO_3 with $[\text{Pu(VI)}] = 0.1 \text{ mol litre}^{-1}$, the reaction of Pu(VI) with hydrogen peroxide should also be taken into account. When deaerated nitric acid solutions of mixtures of Pu(III) and Pu(IV) are exposed to X-rays, Pu(V) and, possibly, Pu(VI) are accumulated. The initial oxidation yield decreases from 0.052 to $\sim 0.004 \text{ ion (100 eV)}^{-1}$ as the concentration of HNO_3 increases from 0.3 to 2 M. The introduction of nitrate ions leads to a decrease in the yield of oxidation.

The behaviour of Pu(IV) ions during γ -radiolysis in nitric acid has been studied in detail.¹²⁹ In a 0.3 M solution of HNO_3 at $[\text{Pu(IV)}]_0 = 1 \times 10^{-3} \text{ mol litre}^{-1}$ [owing to disproportionation of Pu(IV), the solution contained some quantities of Pu(III) and Pu(VI)] and at a dose rate of 2.17 Gy s^{-1} , oxidation of Pu(IV) is observed. When the $[\text{Pu(IV)}]_0$ value is increased to $8 \times 10^{-3} \text{ mol litre}^{-1}$, the oxidation occurs only at the beginning of irradiation, and then reduction of Pu(VI) occurs instead. When the dose rate (I) is equal to 1.33 Gy s^{-1} , reduction of Pu(VI) is also observed. In a 1 M solution of HNO_3 containing $1 \times 10^{-2} \text{ mol litre}^{-1}$ of Pu(IV) at $I = 1.33 \text{ Gy s}^{-1}$, a steady state is established after accumulation of $\sim 1 \times 10^{-3} \text{ mol litre}^{-1}$ of Pu(VI). The process of oxidation in 6 M HNO_3 at $[\text{Pu(IV)}]_0 = 1 \times 10^{-2} \text{ mol litre}^{-1}$ and $I = 2.17 \text{ Gy s}^{-1}$ occurs at a constant rate up to a dose of $\sim 1 \text{ MGy}$. The initial oxidation yields depend on the concentrations of Pu(IV) and HNO_3 and on the dose rate. The concentration of the nitrous acid formed was also measured in the study cited. To estimate the yields of oxidation of Pu(IV), equations were proposed that permit prediction of its behaviour under various conditions.

In a study of γ -radiolysis of solutions of Pu(III) in nitric acid, it has been found that in the case of deaerated solutions, the initial yields of Pu(IV) and HNO_2 are identical and amount to $7.8 \text{ ion (100 eV)}^{-1}$.¹²⁸ In solutions saturated with oxygen, $G[\text{Pu(IV)}] = 8.4 \text{ ion (100 eV)}^{-1}$, whereas $G[\text{HNO}_2]$ is close to zero.

The initial yields of Pu(IV) both in deaerated solutions and in solutions saturated with oxygen are close to the following value:

$$G_{e_{\text{aq}}} + G_{\text{H}} + G_{\text{OH}} + 2G_{\text{H}_2\text{O}_2} = 8.2 \text{ molecule (100 eV)}^{-1}.$$

Evidently, hydrated electrons and H atoms react in this system with nitrate ions and with non-dissociated nitric acid to give NO_3^{2-} and HNO_3^- , respectively; these species are finally converted into NO_2 and N_2O_4 . Nitrogen dioxide and its dimer are able to oxidise Pu(III).¹²⁸ The OH radicals participate in the oxidation of Pu(III) and in the reactions with NO_3^- and HNO_3 to give NO_3 radicals. The latter oxidises Pu(III). Hydrogen peroxide, apparently, reacts slowly with Pu(III), each molecule of the peroxide oxidising two Pu(III) ions (*via* the intermediate formation of OH radicals). In solutions saturated with oxygen, H atoms partly react with oxygen thus yielding HO_2 radicals; each of these radicals is able to oxidise

three Pu(III) ions. Therefore, the initial yield of Pu(IV) in these solutions is somewhat higher than that in deaerated solutions.

In conformity with the proposed mechanism, the initial yield of HNO₂ should be equal to $G_{\text{eq}} + G_{\text{H}} = 3.65$ ion (100 eV)⁻¹. The value found experimentally¹²⁸ for deaerated solutions is markedly higher. However, in solutions saturated with oxygen, the yield of HNO₂ is close to zero.¹²⁸ This casts doubt on its high yield in deaerated solutions.

When the radiation doses are high, the quantity of Pu(IV) formed is sufficient for its reaction with nitrous acid. This should result in a decrease in the yield of Pu(IV), and this is actually observed in the experiment.¹²⁸

The influence of U(VI) ions on the radiolytic transformations induced by X-rays of plutonium ions in deaerated 0.3 M solutions of HNO₃ has been studied.¹ The initial oxidation yield of plutonium was found to decrease from 0.05 ion (100 eV)⁻¹ observed in the absence of U(VI) to zero for solutions containing 0.3 mol litre⁻¹ of U(VI). At higher concentrations of U(VI), plutonium is reduced. The introduction of dichromate ions in U(VI)-containing solutions of plutonium in nitric acid results in oxidation of plutonium accompanied by reduction of Cr₂O₇²⁻. The dependences of the behaviour of plutonium on the ratio of concentrations of hexavalent chromium and uranium, on the concentration of HNO₃ and on the radiation dose were investigated.

Study of radiolytic transformations of Pu(VI) in 3 M HNO₃ in the presence of U(VI) has demonstrated that the introduction of U(VI) shortens the induction period observed for the reduction of plutonium in the absence of uranium ions.¹²⁶ A similar phenomenon was observed in solutions containing Pu(IV) and Pu(VI). It was shown that U(V) resulting from radiolysis reduces Pu(VI) and Pu(IV).

The behaviour of Pu(IV) and Pu(VI) ions in 4 M solutions of HNO₃ exposed to high-energy electron pulses generated by a U-12 linear electron accelerator has been studied.¹³⁰ It was found that, irrespective of the ratio of the concentrations of Pu(IV) and Pu(VI), the dose rate (for medium dose rates of 35–200 Gy s⁻¹) and the temperature (in the range 10–90 °C), the irradiation results in the reduction of Pu(VI) to Pu(IV). In some cases, $G[-\text{Pu(VI)}]$ is proportional to $I^{-1/2}$; the rate of reduction was found to depend on the temperature. The mechanism of radiolysis of this system has been discussed comprehensively by Tkhorzhnitskii and Egorov,¹³¹ who proposed an equation for the reduction yield of Pu(VI) [or the yield of formation of Pu(IV)]. This equation relates $G[\text{Pu(IV)}]$ to I , $[\text{Pu(V)}]$ and $[\text{Pu(III)}]$. However, the dependence of the yield of Pu(IV) on I found by these researchers differs from that described in a previous study.¹³⁰

To elucidate the role of polyvalent ions in the reduction of plutonium induced by pulse electron radiation, 4 M solutions of HNO₃ containing Pu(VI), Pu(IV), U(VI), Ru, Rh, Pd, Mo, Ce and other elements have been studied.¹³⁰ It was found that Pu(VI) is reduced only when uranium and palladium are present simultaneously. Uranium(VI) increases the 'reducing capacity' over the whole process, whereas Pd(II) is active only at the beginning of the process.¹³¹ On exposure to radiation, U(VI) is converted into U(V), while Pd(II) transforms into Pd(I), Pd(III) and Pd(IV); the latter results from disproportionation of Pd(III). Palladium(IV) is reduced by nitrous acid, U(V), Pd(I), Pu(III), Pu(IV) and Pu(V) to give Pd(II). This accounts for the fact that Pu(IV) is partly oxidised during the radiolysis of its solutions in the presence of Pd(II) but in the absence of U(VI). Note that the reduction yield of Pu(VI) in the presence of U(VI) and Pd(II) decreases with an increase in the radiation dose.

Radiolytic transformations of Pu(VI) in 0.01–0.1 M solution of HNO₃ containing Np(VI) have been studied.¹³² It was found that at a $[\text{Pu(VI)}]/[\text{Np(VI)}]$ ratio of 12.5, both Pu(VI) and Np(VI) are reduced. Plutonium remains in the solution in the hexavalent state at radiation doses below 320 Gy.

The same researchers¹³² studied the reduction of Pu(VI) and oxidation of Pu(IV) in 0.5–4 M solutions of HNO₃ at $[\text{Pu}]/[\text{Np}]$ ratios of 0.005–0.125. When $[\text{HNO}_3] = 0.5$ M, neptunium exists as Np(V), whereas in 2–4 M solutions of HNO₃, some Np(VI) can

also be found in the system. It was found that in 0.5 M HNO₃, the reduction of Pu(VI) in the presence of neptunium occurs when $[\text{Pu}] \geq 5 \times 10^{-4}$ mol litre⁻¹, the rate of the reduction being higher than that in the absence of neptunium. At the same time, in 2–4 M solutions of HNO₃, reduction of Pu(VI) mixed with neptunium is observed at $[\text{Pu}] \geq 10^{-2}$ mol litre⁻¹. The reduction of Pu(VI) starts after an induction period corresponding to a 75%–80% reduction of Np(VI). The reduction yield depends on the concentration of plutonium and does not depend on the concentration of HNO₃. In the absence of neptunium, the rate of reduction decreases with an increase in the concentration of the acid.

Radiolytic oxidation of Pu(IV) in the presence of neptunium in 0.5 M HNO₃ has been studied.¹³³ It was found that the smaller the concentration of plutonium, the larger its proportion being oxidised. In the presence of Pu(VI), the rate of oxidation decreases. After prolonged irradiation, steady-state concentrations of Pu(VI) and Pu(IV) are established. The mechanism for the γ -radiolysis of this system was proposed, equations were derived and the concentrations of Pu(VI) at various doses were calculated.¹³³

2. α -Radiolysis of acidic aqueous solutions of plutonium ions

In the majority of cases, α -radiolysis of plutonium induced by its own radiation has been studied. Sometimes α -radiolysis results in the oxidation of plutonium; however, most often it leads to a decrease in its average oxidation number.

As early as the 1940–1950s it was found¹ that the rate of reduction of Pu(VI) induced by α -radiation in 0.48–1.9 M solutions of HClO₄ containing either only Pu(VI), or Pu(VI) + Pu(IV), or Pu(VI) + Pu(IV) + Pu(V) obeys zero-order kinetics, the rate constant k being equal to 1.18×10^{-2} days⁻¹. The reduction yield is expressed by the following equation

$$G[-\text{Pu(VI)}] = k(100T_{1/2}/0.693E), \quad (10)$$

where $T_{1/2}$ is the half-life of the corresponding plutonium isotope (days) and E is the average energy of α -particles (eV).

The half-life of ²³⁹Pu is 2.411×10^4 years, $E = 5.106$ MeV (11.8%), 5.144 MeV (15%) and 5.157 MeV (73%).¹³⁴ It follows from Eqn. (10) that $G[-\text{Pu(VI)}] = 2.92$ ion (100 eV)⁻¹.

Under the action of its own α -radiation, Pu(VI) is reduced to Pu(V); the latter disproportionates. The Pu(IV) thus formed reacts with Pu(V) to give Pu(III) and Pu(VI).¹ Reduction of Pu(VI) in 0.2 M HClO₄ under the action of α -particles emitted by ²¹⁰Po has been studied.¹²³ When the radiation dose is lower than 3 kGy, Pu(V) forms in the solution, and $G[-\text{Pu(VI)}] = 3.2$ ion (100 eV)⁻¹. When the dose is higher than 3 kGy, Pu(IV) is formed, and $G[-\text{Pu(VI)}] = 1.6$ ion (100 eV)⁻¹. Finally, when the dose exceeds 11 kGy, Pu(III) is accumulated, and $G[-\text{Pu(VI)}] = 1.1$ ion (100 eV)⁻¹. These results do not depend on whether or not air is present in the solution. The theoretical yield for the reduction of Pu(VI) to Pu(V) is 3.0 ion (100 eV)⁻¹, which is in agreement with the experimental result.

In a 1 M solution of HClO₄ containing ~ 0.01 mol litre⁻¹ of ²³⁹Pu(IV) (at 25 °C), the average oxidation number of plutonium changes by 0.014 every day until it becomes 3.02–3.05.¹ The gas evolved from the solution consists of oxygen (60%) and hydrogen (40%). The solution was found to contain a substantial amount of chloride ions, which obviously had been formed by the action of ionising radiation on the perchlorate ions. The theoretical reduction yield of Pu(IV), like that for the reduction of Pu(VI), is 3.0 ion (100 eV)⁻¹. The $G[-\text{Pu(IV)}]$ value calculated from an equation similar to Eqn. (10) is 3.5 equivalent (100 eV)⁻¹. The slight difference between these values can be due to the fact that Pu(IV) accepts some of the reducing radicals from the spurs.

The radiolytic transformations of ²³⁸Pu(IV) and ²³⁸Pu(VI) in 1 M HClO₄ have been described.¹³⁵ The radiation dose rate was ~ 0.15 Gy s⁻¹. The concentration of Pu(IV) remained constant, whereas Pu(VI) was reduced to give Pu(IV) and Pu(III). Using the data presented in this study, we calculated that $G[-\text{Pu(VI)}] = \sim 0.16$ ion (100 eV)⁻¹. The reduction yield is so low, because in the 1 M solution of HClO₄, the reaction between Pu(VI) and H₂O₂

occurs slowly; therefore, hydrogen peroxide is accumulated and can react with OH, H and e_{aq}^- in the bulk of the solution and in the spurs.

An increase in the dose rate of α -radiation by 3–4 orders of magnitude somewhat changes the course of radiolysis. Study of the reduction of Pu(VI) in 2 M HClO₄ under the action of the α -particles emitted by ²⁴⁴Cm (at a dose rate of 3.95 Gy s⁻¹) has led to the following results.¹⁰⁸ Initially, the concentration of reduction slowly decreases [we calculated the reduction yield to be 0.01 ion (100 eV)⁻¹], and then, after ~82%–83% of Pu(VI) has been consumed (this takes ~100 h), its concentration starts to increase { $G[\text{Pu(VI)}] = 0.003$ ion (100 eV)⁻¹}.

When a solution of Pu(VI) in a 0.11 M solution of H₂SO₄ is exposed to α -particles, Pu(IV) is formed;¹²³ $G[-\text{Pu(VI)}] = G[\text{Pu(IV)}] = 3$ equivalent (100 eV)⁻¹. The mechanism of reduction is identical to that observed in the case of solutions in perchloric acid. The reduction yield of Pu(VI) barely depends on the concentration of H₂SO₄ as it varies from 0.001 M to 0.3 M and is close to 3 equivalent (100 eV)⁻¹ (see Ref. 1).

It was found¹ that on exposure to α -radiation, Pu(VI) and Pu(IV) ions in 0.06–1.5 M solutions of HCl are reduced at a rate of 1%–0.3% of the average oxidation number per 24 h. Study of the radiolytic reduction of Pu(IV) in a solution of a mixture of HClO₄ and HCl has demonstrated that $G[-\text{Pu(IV)}]$ diminishes as [HClO₄] decreases and as [HCl] increases. For example, in 1 M HClO₄, the yield is 3.5 equivalent (100 eV)⁻¹ whereas in 1 M HCl, it is equal to zero. Plutonium ions in low oxidation states are oxidised in HClO₄ solutions containing 0.1 mol litre⁻¹ of Br⁻. Evidently, this is accomplished *via* the same reactions as the oxidation during α -radiolysis in hydrochloric acid.

Study of the behaviour of ²³⁸Pu(OH)₄ in solutions of NaCl has shown^{135–137} that when [NaCl] is less than 3 M, Pu(IV) is oxidised to Pu(V), while at [NaCl] > 3 M, Pu(IV) is converted into Pu(VI). The mechanism of radiolysis includes trapping of OH radicals from the spurs and the formation of oxidising agents (Cl, Cl₂⁻, HClO, ClO⁻). The yield of H₂O₂ should diminish with an increase in the concentration of NaCl. In solutions containing less than 3 mol litre⁻¹ of NaCl, the yield of H₂O₂ [expressed in equivalent (100 eV)⁻¹] is apparently half that of the oxidising agents. The latter convert Pu(IV) into Pu(V) and Pu(VI); the hexavalent plutonium is reduced by hydrogen peroxide to Pu(V), which is stable in the presence of H₂O₂. In solutions containing more than 3 mol litre⁻¹ of NaCl, the yield of H₂O₂ is low, and thus Pu(VI) is not reduced and is accumulated or is reduced to a small extent.

Radiolytic transformations of plutonium ions in concentrated solutions of NaCl have been studied.¹³⁸ This study was undertaken in view of the intended burial of solid radioactive wastes in depleted salt pits. It was noted that the reaction of PuO₂²⁺ with hypochlorite ions resulting from α -radiolysis of these solutions plays an important role in the process.

In a study of the reduction of Pu(VI) (~7 × 10⁻³ mol litre⁻¹) in solutions of NaNO₃ (the initial pH value was 3), it has been shown that Pu(V) is accumulated initially, and then the process gradually decelerates. At this time, formation of Pu(IV) as a colloid begins. It was found¹ that the $G[-\text{Pu(VI)}]$ value changes from 4.4 to 7.2 ion (100 eV)⁻¹ as the concentration of NO₃⁻ ions increases from 0.1 to 5 mol litre⁻¹. An equation for calculating the theoretical $G[-\text{Pu(VI)}]$ values in these systems was derived, and the calculated values were compared with experimental results.¹

The data on the α -radiolysis of solutions of HNO₃ with concentrations of less than 0.5 mol litre⁻¹ have been discussed in the monograph cited.¹ It was noted that under these conditions, only H₂O₂ is accumulated. It has been calculated¹³⁹ that in a 0.4 mol litre⁻¹ solution of ²³⁹Pu (at a dose rate of 2.7 × 10⁻³ Gy s⁻¹), the rate of formation of H₂O₂ is equal to 2 × 10⁻⁶ mol (litre h)⁻¹, and over a period of 30 days the concentration of Pu(VI) should decrease by ~25%. However, this does not occur in reality, because after 30 days, the induction period is completed. The low initial rate of reduction of Pu(VI), present in a concentration of less than 0.01 mol litre⁻¹ in HNO₃ solutions, is presumably due to its reverse oxidation by nitrous acid.¹³⁹

The reduction of Pu(VI) in solutions of nitric acid induced by its own α -radiation has been studied by many investigators.^{1, 139–143} The following characteristic features of this process are noteworthy.

Reduction in solutions with pH 3.8 at [Pu(VI)] = 8 × 10⁻³ mol litre⁻¹ is characterised by an induction period. In more dilute solutions, Pu(VI) is reduced without an induction period. The initial reduction yields vary from 4 to 6 equivalent-s (100 eV)⁻¹.¹ In 1–4 M solutions of HNO₃, Pu(VI) is reduced to Pu(IV);¹⁴¹ in more dilute solutions of nitric acid, Pu(III) is also formed.^{1, 139} When [HNO₃] is more than 0.5 M, α -radiolysis of solutions of Pu(VI) is accompanied by accumulation of HNO₂. The introduction of Pu(IV) shortens the induction period but has only a slight influence on the maximum rate of reduction of Pu(VI).^{1, 139}

It has been found¹⁴¹ that in 4–6 M solutions of HNO₃, plutonium remains in the tetravalent state for several years if the dose rate of α -radiation does not exceed 0.3 Gy s⁻¹. At higher dose rates, Pu(VI) is accumulated. The yield of Pu(VI) depends on the concentration of HNO₃; as it increases from 0.9 to 9 M, the yield decreases from 0.0013 to 0.0008 ion (100 eV)⁻¹. An increase in the dose rate also decreases the yield of Pu(VI). In the opinion of the researchers cited,¹⁴¹ Pu(IV) is oxidised *via* the reactions with OH radicals and nitrogen oxides; hydrogen peroxide acts as a reducing agent. The decrease in the rate of reduction upon an increase in the concentration of HNO₃ was explained by the formation of a complex of Pu⁴⁺ with nitrate ions.

The behaviour of Pu(VI) and Pu(IV) in nitric acid solutions exposed to intense α -radiation has been investigated in greater detail in other studies.^{1, 142, 143} In 6 M solutions of HNO₃ containing up to 0.1 mol litre⁻¹ of Pu(IV) under a dose rate of 4.6 Gy s⁻¹, Pu(VI) is accumulated; the rate of its formation gradually decreases, and finally a steady state is established. The initial rate of oxidation depends linearly on the concentration of Pu(IV). In solutions containing less than 1.8 × 10⁻² mol litre⁻¹ of Pu(VI), no reduction occurs over a period of 40 days; at [Pu(VI)] = 1.8 × 10⁻² mol litre⁻¹, reduction occurs to only a slight extent.¹⁴² When some Pu(IV) is introduced into solutions of Pu(VI), Pu(VI) is reduced to a noticeable extent but not entirely: steady-state concentrations of Pu(IV) and Pu(VI) are established.¹⁴⁰ According to our estimate, the yields of oxidation of Pu(IV) at [Pu(IV)]₀ ≈ 2 × 10⁻³ mol litre⁻¹ are 0.019 and 0.022 equivalent (100 eV)⁻¹ for 1 and 6 M HNO₃, respectively.

In a study of the reduction of Pu(VI) in 0.3–6 M HNO₃ exposed to the α -radiation from ²⁴⁴Cm, it has been found that at [HNO₃] > 1 M, Pu(VI) is reduced to Pu(IV); this process starts after an induction period.¹⁴⁰ This period becomes shorter following an increase in the dose rate and in the concentration of Pu(VI) and becomes longer upon an increase in the concentration of HNO₃. According to our estimate, the reduction yield of Pu(VI) is 0.08 equivalent (100 eV)⁻¹ and it does not depend on the dose rate in the range of 0.95–9.2 Gy s⁻¹. In a 0.3 M solution of HNO₃, hexavalent plutonium is reduced to Pu(V), steady-state concentrations of Pu(V) and Pu(VI) being established.

It was found^{142, 143} that, Pu(III) in solutions of nitric acid is oxidised on exposure to α -radiation. Under the action of α -particles emitted by curium ($I = 4.2$ Gy s⁻¹), Pu(III) in 0.12 M HNO₃ is partly oxidised to Pu(IV), which forms a peroxide complex. In addition, small amounts of Pu(VI) are accumulated. The degree of conversion of Pu(III) is 20%, and the initial oxidation yield is 3.8 ion (100 eV)⁻¹. When the concentration of HNO₃ increases, the rate and the degree of conversion of Pu(III) increases, and at [HNO₃] > 1 M, trivalent plutonium is completely transformed into the tetravalent state. No peroxide complex is formed in solutions containing more than 0.5 mol litre⁻¹ of HNO₃. When [HNO₃] = 2.9 M, the oxidation yield reaches 74 ion (100 eV)⁻¹, which indicates that a chain process occurs. The introduction of nitrite ions causes a slight increase in the rate of oxidation. The addition of sulfamic acid, which binds HNO₂, decelerates the oxidation or even completely terminates it.

In our opinion, in a 0.12 M solution of HNO_3 , nitrate ions trap almost all the reducing radicals from the spurs. Therefore, OH and HO_2 radicals and nitrous acid act as the main oxidants for plutonium(III), *i.e.*:

If we substitute the yields of the products of water radiolysis (see Table 2) in Eqn. (11), we obtain an oxidation yield equal to 3.9 ion $(100 \text{ eV})^{-1}$, which coincides with the experimental result.^{142, 143}

When the concentration of HNO_3 increases, the yield of oxidants decreases owing to the reaction between HNO_2 and H_2O_2 ; however, HNO_2 (or NO, according to another reaction scheme) reduces nitric acid and thus a chain process develops leading to high oxidation yields. Sulfamic acid binds not only HNO_2 but, apparently, also the oxidising radicals, namely, OH and NO_3 . Therefore, oxidation slows down or even stops.

A series of studies^{144–151} have been devoted to the mathematical modelling of processes that occur in solutions of nitric acid containing plutonium ions and exposed to γ - or α -radiation. The influence of various factors on these processes, for example, the concentration of HNO_3 , oxidation states of plutonium and radiation dose rate, was considered. The calculations were based on experimental results obtained for about 30 reactions. The modelling made it possible to interpret the course of the process and the contributions of individual stages. In some cases, the rate constants for the reactions were estimated; however, they did not always coincide with the values measured experimentally.

Study of the α -radiolysis of solutions of Pu(VI) and Np(VI) in nitric acid has shown that Pu(VI) is not reduced until all the Np(VI) present has been reduced.¹³¹ To elucidate the mechanism of the process, a set of differential equations based on kinetic regularities were composed and numerical integration with known initial conditions was carried out. Comparison of experimental results demonstrated that the period of 'retention' of Pu(VI) depends on the $[\text{Pu(VI)}]_0/[\text{Np(VI)}]_0$ ratio. The main feature characterising the radiolysis in the system under consideration is that Np(VI) is reduced more rapidly. The decrease in the rate of reduction of Pu(VI) in the presence of Np(VI) was explained not only by the fact that the latter reacts faster with hydrogen peroxide and with nitrous acid but also by the fact that Np(VI) reacts with Pu(V).

Study of the radiolysis of solutions of nitric acid containing Np(IV) and Pu(IV) induced by the α -radiation of ^{244}Cm has shown that the initial rates of accumulation of Np(V) and consumption of Pu(IV) differ from those for systems containing only Np(IV) or Pu(IV).¹⁵² In particular, it was noted that the rate of oxidation of Np(IV) increases, (among other reasons) due to oxidation of Np(IV) by Pu(IV) ions. A model for the radiolysis in this system was proposed and the redox processes occurring in the system were described using 42 reactions.

3. Gas evolution in the radiolysis of acidic solutions of plutonium ions

During some technological operations involving aqueous solutions of plutonium in nitric acid, the formation of explosive gas mixtures is possible. Primary attention in the study of gas evolution during radiolysis is paid to prevention of the formation of these mixtures. Before 1980, gas evolution during radiolysis had been measured many times. In the case of α -radiolysis, gases are formed in markedly higher yields than upon γ -radiolysis.¹

α -Radiolysis of solutions of plutonium ($0.188–0.42 \text{ mol litre}^{-1}$) in 1–9.9 M HNO_3 has been found to be accompanied by the formation of hydrogen, oxygen, nitrogen, dinitrogen oxide and nitrogen monoxide (hydrogen is the component formed in the highest yield). The yields decrease from 0.2 to 0.018 molecule $(100 \text{ eV})^{-1}$ as the concentration of HNO_3 increases from 1 to 9.9 M. The yields of oxygen for these concentrations are 0.082 and ~ 0 molecule $(100 \text{ eV})^{-1}$. The yields of nitrogen, dinitrogen oxide and nitrogen monoxide in a 9.7 M solution of HNO_3 are equal to 0.043, 0.0031 and 6×10^{-4} molecule $(100 \text{ eV})^{-1}$, respectively.

Several samples of a 8.5 M solution of HNO_3 containing $\sim 1 \text{ mol litre}^{-1}$ of Pu(IV) have been stored for 52 months. Gases were formed in the following average yields, molecule $(100 \text{ eV})^{-1}$: $G(\text{the sum of gases}) = 0.060$, $G(\text{H}_2) = 0.033$, $G(\text{O}_2) = 0.021$, $G(\text{N}_2) = 0.005$; traces of nitrogen oxides were also detected.

The decrease in the concentration of hydrogen upon an increase in the concentration of HNO_3 (and, obviously, plutonium ions) is due to trapping of reducing radicals from the spurs, which suppresses the formation of hydrogen. Molecular oxygen arises upon the direct action of the radiation on NO_3^- and HNO_3 and also upon the reactions of H_2O_2 and HO_2 with plutonium ions [mostly with Pu(IV)]. In 1 M HNO_3 , the yield of O_2 resulting from the direct action can be neglected. The $G(\text{O}_2)$ value is much smaller than $G_{\text{H}_2\text{O}_2}$; this is due to the reaction between HNO_2 and H_2O_2 . As the concentration of HNO_3 increases, the rate of this reaction increases; therefore, $G(\text{O}_2)$ decreases. Nitrogen and its oxides appear upon direct action of the radiation on NO_3^- and HNO_3 .

We calculated $G(\text{H}_2)$ values for the α -radiolysis of solutions of Pu(IV) (50 g litre^{-1}). For solutions in 1 M HNO_3 , 1 M HClO_4 and 0.1 M H_2SO_4 , the following values were found, molecule $(100 \text{ eV})^{-1}$: 0.21, 0.38 and 1.6, respectively. In our opinion, the fact that the yields attained in HNO_3 and HClO_4 are smaller than that in H_2SO_4 can be explained in the following way. In a dilute solution of H_2SO_4 , Pu(IV) ions form sulfato-complexes, which react with e_{aq}^- and H more slowly than the aqua-complex. In addition, in solutions of sulfuric acid, Pu(III) is oxidised by the H atoms, and this process affords H_2 . In HNO_3 and HClO_4 solutions, plutonium ions accept more precursors of H_2 from the spurs than in H_2SO_4 .

An equation has been reported,¹⁵³ which permits the calculation of the amount of hydrogen evolved from highly radioactive wastes containing, among other components, nitrates and plutonium. The yields of hydrogen evolved by plutonium-containing brines under the action of α -particles emitted by ^{239}Pu vary from 0.6 to 1.5 molecule $(100 \text{ eV})^{-1}$ depending on the composition of the brine.¹⁵⁴ It has been noted¹⁵⁵ that the yield of hydrogen in the α -radiolysis of nitrate-containing solutions of plutonium almost does not depend on the form [Pu(IV) or Pu(VI)] in which plutonium occurs in the system.

4. Radiolysis of alkaline aqueous solutions of plutonium

During γ -radiolysis of aerated alkaline solutions of Pu(VI), plutonium is first reduced to Pu(V) and then to Pu(IV).^{63, 156} The reduction yield is 1.5–1.6 ion $(100 \text{ eV})^{-1}$, irrespective of the concentration of alkali, over the concentration range studied (1 to 6 M). As in the case of γ -radiolysis of alkaline aqueous solutions of Np(VI), specific 'oscillations' in the variation of the optical density of the solution exposed to radiation are observed. The oscillations include an initial decrease in the intensity of absorption of Pu(VI) caused by its reduction to Pu(V), its subsequent increase caused by the formation of a fine suspension and light scattering from its particles, a further decrease in the absorption intensity caused by precipitation, *etc.* However, as distinguished from γ -radiolysis of alkaline solutions of Np(VI), in this case, no peroxide complex of Pu(V) was detected in nitrate-containing solutions; this is due to the low stability of this complex.

The mechanism of radiolytic transformations of Pu(VI) in aerated alkaline solutions is similar to that for Np(VI). The main distinction is that the Pu(V) resulting from reduction disproportionates to give Pu(IV) and Pu(VI).^{63, 156}

Radiolysis of alkaline aqueous solutions of Pu(VI) in the presence of acceptors of radical reducing agents transforming them into radicals acting as oxidants affords Pu(VII) ions. This was observed for the first time by Pikaev *et al.*¹¹⁸ In this study, alkaline solutions of Pu(VI) saturated with dinitrogen oxide were exposed to radiation. As noted above, dinitrogen oxide reacts with e_{aq}^- yielding the O^- radical anion. More recently, oxidation of Pu(VI) has been studied more comprehensively.¹⁵⁷ With allowance for the induction effect, the initial yield of Pu(VII) in a 1 M solution of NaOH was equal to 5.4 ion $(100 \text{ eV})^{-1}$. The mechanism of radio-

lytic oxidation of Pu(VI) in alkaline solutions is similar to that for Np(VI).

The formation of Pu(VII) has also been observed^{158, 159} in the γ -radiolysis of aerated solutions of Pu(VI) in 1 M NaOH in the presence of $\text{S}_2\text{O}_8^{2-}$. It was found that $G[\text{Pu(VII)}] = 4.0 \text{ ion (100 eV)}^{-1}$ at $[\text{Pu(VI)}] = 5.1 \times 10^{-4}$ and $[\text{S}_2\text{O}_8^{2-}] = 0.07 \text{ mol litre}^{-1}$. This value is close to the yield of Np(VII) obtained in a 1 M solution of NaOH containing $\text{S}_2\text{O}_8^{2-}$ ions. These ions react with e_{aq}^- , and the $\text{S}_2\text{O}_8^{3-}$ ion radicals thus formed react with OH^- and are finally converted into O^- . The experimental $G[\text{Pu(VII)}]$ value is lower than the calculated value [$\sim 4.7 \text{ ion (100 eV)}^{-1}$]; this is apparently due to the occurrence of side reactions of O_3^- ion radicals (resulting from the reaction of O^- with O_2) and/or $\text{S}_2\text{O}_8^{3-}$ ion radicals. When $[\text{Pu(VI)}] = 5 \times 10^{-3} \text{ mol litre}^{-1}$, the yield of Pu(VII) amounts to $\sim 2 \text{ ion (100 eV)}^{-1}$. The decrease in the yield compared to that attained in more dilute solutions of Pu(VI) is due to the fact that in an alkaline medium the stability of the $\text{S}_2\text{O}_8^{3-}$ ion radicals can be relatively high and sufficient for them to react partly with Pu(VI).

The irradiation of aerated alkaline solutions of Pu(VII) results in its reduction.¹⁵⁷ The reduction yield does not depend on the concentrations of Pu(VII) (the concentration range used was $2.4 \times 10^{-4} - 1 \times 10^{-3} \text{ mol litre}^{-1}$) or the alkali (in the range 0.87–3.5 M); it is $2.35 \text{ ion (100 eV)}^{-1}$. The mechanism of the process has been discussed previously.¹

The behaviour of Pu(IV) and Pu(VI) in 1–15 M solutions of NaOH containing nitrate ions has been studied.¹⁶⁰ The solutions were irradiated for 2 years by α -particles emitted by plutonium. Initially, Pu(V) was accumulated in the solution over the precipitate of Pu(IV) hydroxide and then its amount decreased. The decrease in the concentration of Pu(V) began after 1–2, 7, 20 and 56 days in 1, 2–9, 10 and 15 M solutions of NaOH, respectively.

The researcher cited¹⁶⁰ did not discuss what oxidising and reducing agents could have been involved in the reactions in this system. He attributed the decrease in the concentration of Pu(V) to a change in the degree of crystallinity of Pu(IV) hydroxide. In our opinion, two processes occur in this system, namely, oxidation of Pu(IV) in the precipitate and reduction of Pu(V) in the bulk of the solution. The oxidation is accomplished by O^- radical ions and hydroperoxide HO_2^- . Note that HO_2^- is able to oxidise freshly precipitated Pu(IV) hydroxide.¹⁶¹ The reduction of Pu(V) might be accomplished by e_{aq}^- , H and NO_3^{2-} ion radicals (resulting from reactions of e_{aq}^- and H with nitrate ions). According to our estimates, $G[-\text{Pu(V)}]$ decreases from 15.5 to $2.6 \text{ ion (100 eV)}^{-1}$ as the concentration of NaOH increases from 1 to 15 M. These high yields may be associated not only with Pu(V) ions but also with plutonium in a colloidal form.

Hexavalent plutonium introduced in alkaline solutions is gradually reduced.¹⁶¹ The initial reduction yields, which we have determined using the data about the variation of the concentration of Pu(VI) reported by Delegard,¹⁶⁰ decrease from 25.2 to $2.6 \text{ ion (100 eV)}^{-1}$ as the activity of NaOH increased from 0.6 to 3.4 M. If we assume that the yields of the products of the α -radiolysis of water in alkaline solutions are equal to those in sulfuric or perchloric acid, the theoretical reduction yield of Pu(VI) to Pu(V) should be $\sim 3 \text{ ion (100 eV)}^{-1}$. The higher values could be due to the presence of organic impurities and/or co-precipitation of Pu(VI) with Pu(V). As time goes on, some Pu(V) in the precipitate is converted into Pu(IV); therefore, the colour of the precipitate changes.¹⁶⁰

VII. Americium

1. γ -Radiolysis of aqueous solutions of americium ions

The studies performed before 1980 dealt with γ -radiolysis of weakly acidic solutions of Am(III) saturated with dinitrogen oxide and solutions of Am(VI) in nitric or in phosphoric acid and alkaline solutions of Am(VI). The most significant results are presented in Table 18.

The method of pulse radiolysis with fast recording of short-lived species has been used to elucidate the mechanism of radiolytic oxidation of Am(III).^{52, 165} It was found that short-lived Am(IV) ions are formed intermediately in this process; these ions were identified based on the broad optical absorption band with a maximum at 340 nm, which appears under the action of an electron pulse. Based on the accumulation of Am(IV), the rate constants for the reaction of Am(III) with OH under various conditions were measured (see Table 6). This reaction has also been studied by pulse radiolysis (see, for example, Refs 30 and 166).

In solutions of Am(III) saturated with N_2O , Am(IV) ions are consumed in a second-order reaction. For $[\text{Am(III)}]_0 > 2 \times 10^{-3} \text{ mol litre}^{-1}$, this reaction was found to be disproportionation of Am(IV). The rate constants for this process ($2k$ values) at pH 2.0 and pH 2.6–3.2 are 4.5×10^6 and $6 \times 10^6 \text{ litre mol}^{-1} \text{ s}^{-1}$, respectively.⁵² According to another study,³⁰ at pH 5.2, the $2k$ value is $1.0 \times 10^7 \text{ litre mol}^{-1} \text{ s}^{-1}$. When the concentration of

Am(III) is lower, in addition to the disproportionation of Am(IV), its reactions with HO_2 and H_2O_2 occur in the system.

In aerated solutions, Am(IV) also disappears through a second-order reaction. This is the interaction of Am(III) with HO_2 . The rate constants measured for this process are listed in Table 14. It can be seen that the rate constant depends on the pH of the solution. This was explained by the fact that Am(IV) ions are hydrolysed to different extents at different pH values.

The rate constant for the reaction of Am(IV) with hydrogen peroxide was measured (see Table 9). An attempt has been made⁵² to determine the rate constant for the reaction between Am(IV) and Am(V). According to an approximate estimate, the upper limit for this rate constant is $3 \times 10^4 \text{ litre mol}^{-1} \text{ s}^{-1}$.

Pulse radiolysis experiments^{30, 31, 166} indicate that the reaction of e_{aq}^- with Am(III) affords Am(II). It is responsible for an absorption band with a maximum at 310 nm³¹ or 312 nm.³⁰ The rate constants found for this reaction are listed in Table 3. The intensity of the optical absorption of this ion decreases with a decrease in the pH of the solution. The Am(II) ion is unstable. At pH 4.7, it disappears with a half-life of 70 μs .³¹ When the concentration of Am(III) is large and the dose per pulse is low, Am(II) reacts with water.³⁰ The rate constant for this reaction is $9.7 \times 10^4 \text{ s}^{-1}$.

The results obtained using pulse radiolysis made it possible to propose a mechanism for the oxidation of Am(III) in the γ -radiolysis of its weakly acidic solutions saturated with N_2O . This mechanism has been discussed in detail previously.¹

The transformations of Am(VI) ions during the γ -radiolysis have been studied in aqueous solutions containing nitric or phosphoric acid and also in alkaline solutions. In the latter case, irradiation was used to obtain Am(VII).

Based on the possible mechanism of the radiolytic transformations of Am(VI) in nitric acid solutions exposed to γ -radiation, an equation for $G[-\text{Am(VI)}]$ has been derived.¹ Calculations in terms of this equation led to yields of 5.0 and 5.3 ion (100 eV)⁻¹ for 0.1 and 1 M solutions of HNO_3 , respectively. This is close to experimental results. For a 4.7 M solution of HNO_3 , this equation cannot be used, because in this case, the direct action of the ionising radiation on HNO_3 and NO_3^- should be taken into account.

In the radiolysis of solutions of Am(VI) in phosphoric acid, the H_2PO_4 radical, which is an oxidant, plays an important role.¹⁶⁷ Therefore, it cannot be ruled out that this radical, like OH radical, can oxidise the Am(V), Am(IV) and Am(III) ions formed. However, these oxidation reactions might be slow, and recombination of $\text{H}_2\text{PO}_4^\cdot$ to give $\text{H}_4\text{P}_2\text{O}_8$ can compete with them. This provided grounds for the conclusion that the theoretical yield should lie in the range $0.77 \leq G[-\text{Am(VI)}] \leq 1.4 \text{ ion (100 eV)}^{-1}$. The experimental value is much higher. The possible reasons for this discrepancy have been discussed in the previous monograph.¹

Under certain conditions, γ -radiolysis of alkaline solutions of Am(VI), like that for neptunium and plutonium, yields Am(VII). Dinitrogen oxide and $\text{S}_2\text{O}_8^{2-}$ have been used as scavengers for hydrated electrons (see Table 18).¹⁶⁸ The details of the procedure for preparing Am(VII) as well as the mechanism of the oxidation have been considered in the monograph.¹

2. α -Radiolysis of aqueous solutions of americium ions

Radiolysis of aqueous solutions of americium induced by its own α -radiation has been studied in various media: in nitric, sulfuric, hydrochloric and phosphoric acids, in carbonate-containing solutions, in the presence of sodium bromate, in 'unsaturated' phosphotungstic acids, etc. Radiolytic transformations of Am(VI), Am(V) and Am(III) ions in solutions of perchloric acid have also been studied. With allowance for the possible mechanism of the reduction of Am(VI) in perchloric acid, one can calculate its theoretical yield; it is equal to 3.0 ion (100 eV)⁻¹. This result is in agreement only with some of the values found experimentally (see Table 18). The scatter of experimental values for the yields is caused by the use of solutions of different degrees

of purity. The reduction of Am(VI) with water contributes somewhat to the process.¹⁶⁹ The decrease in $G[-\text{Am(VI)}]$ to 0 in 12 M HClO_4 can be explained by the change in the yields of the products of water radiolysis and by the sharp retardation of the reaction between Am(VI) and H_2O_2 .

As Am(V) accumulates in the solution, its reduction by the HO_2 radical or e_{aq}^- becomes possible. Hydrogen peroxide does not react with Am(V) until Am(VI) is fully consumed.

The data on the radiolytic behaviour of Am(VI) presented in Table 18 have been obtained at a dose rate of α -radiation lower than 0.2 Gy s^{-1} . α -Radiolysis of solutions of Am(VI) in 0.1–11 M HClO_4 at a dose rate of 0.01 – 4.6 Gy s^{-1} has been studied.¹⁷⁰ In this study, ^{244}Cm was used as the source of α -radiation. The initial reduction yield in a 0.13 M solution of HClO_4 ($I = 2.9 \text{ Gy s}^{-1}$) is $3.1 \text{ ion (100 eV)}^{-1}$. When the concentration of the acid is increased to 0.5–1 M, the yield decreases somewhat, but when the concentration becomes larger than 2 M, the yield of reduction increases: in a 7 M solution of HClO_4 , it is $\sim 48 \text{ ion (100 eV)}^{-1}$. Obviously, such a high yield is due to the presence of organic impurities.

In the case of 0.2 M solutions of HClO_4 containing variable amounts of NaClO_4 , the yield increases monotonically with an increase in the concentration of NaClO_4 and reaches $5.5 \text{ ion (100 eV)}^{-1}$ at $[\text{NaClO}_4] = 7 \text{ mol litre}^{-1}$.¹⁷⁰ The reduction yield was found to depend somewhat on the concentration of Am(VI). When the concentration of HClO_4 is 1 M, the yield does not depend on the dose rate; however, in a 5.5 M solution of HClO_4 , it is proportional to I^2 .

It is noteworthy that the increase in the reduction yield at high concentrations of HClO_4 or NaClO_4 , among other reasons, is due to the fact that Am(VI) reacts with the products of radiolytic decomposition of the perchlorate ion. In particular, it has been found¹⁷¹ that Am(VI) ions are reduced at a relatively high rate when ClO_2 is passed through a solution of Am(VI) in perchloric acid.

In a study of Kornilov *et al.*,¹⁷¹ $G[-\text{Am(VI)}]$ was shown to be independent of the concentration of Am(VI), which is at variance with an earlier study.¹⁷⁰ In fact, in 0.5 M HClO_4 , the yield is equal to 2.3 – $2.5 \text{ ion (100 eV)}^{-1}$ in the range of Am(VI) concentrations of $(1.5$ – $6) \times 10^{-3} \text{ mol litre}^{-1}$.

During the α -radiolysis in perchloric acid solutions, Am(V) is reduced to Am(III) (see Table 18). An equation for $G[-\text{Am(V)}]$, which is equal to $G[\text{Am(III)}]$, has been obtained¹ with allowance for the mechanism of radiolysis of Am(V) in perchloric acid. Using this equation, it was found that the theoretical yield amounts to $1.5 \text{ ion (100 eV)}^{-1}$. Experimental values are close to this result. The fact that the yield increases somewhat at high concentrations of Am(V) ions is due to the fact that these ions trap the reducing radicals from the spurs.

It has been found¹⁷² that prolonged storage of weakly acidic saturated solutions of NaClO_4 containing Am(III) and Cm(III) results in the formation of precipitates. The quantity of the precipitate increases with time, and the colour changes from light brown to black. The time required for the formation of the precipitates decreases with an increase in the dose rate. The optical absorption spectrum of the solution above the precipitate exhibits bands typical of Am(V) (4%) and of the products of radiolytic decomposition of ClO_4^- ions. The solution changes from weakly acidic to neutral. X-ray diffraction analysis has shown that the precipitates contain NaCl (80%), NaClO_3 (20%) and americium and curium hydroxides. The precipitates were dissolved, and it was found that $\sim 30\%$ of americium in them occurred in the pentavalent state.

Several researchers have studied α -radiolysis of solutions of Am(VI) in sulfuric acid. The values found for the reduction yields of $^{241}\text{Am(VI)}$ vary from 1.2 to $4.0 \text{ ion (100 eV)}^{-1}$ (see Table 18). Probably, the processes occurring in the α -radiolysis of solutions of Am(VI) in sulfuric acid and in perchloric acid are the same. In this case, the theoretical $G[-\text{Am(VI)}]$ value should be $3.0 \text{ ion (100 eV)}^{-1}$. The differences between the experimental

and calculated values are apparently caused by the same reasons as in the case of solutions in perchloric acid.

It should be noted that the $G[-\text{Am(VI)}]$ values obtained for concentrated solutions of sulfuric acid are smaller than those for dilute solutions. This can be explained by the fact that HSO_4^- ions and sulfuric acid partially trap the OH radicals from the spurs and, hence, the $G_{\text{H}_2\text{O}_2}$ value decreases. The HSO_4^- (or SO_4^-) radicals are oxidants and they, like OH radicals, can oxidise the Am(V) formed.

Pentavalent americium is reduced in solutions of sulfuric acid under the influence of α -radiation (see Table 18). In a solution containing 1 mol litre $^{-1}$ of H_2SO_4 , Am(V) is first consumed at a constant rate, and then the rate decreases.

In the case of solutions in nitric acid, the reduction of Am(VI) and Am(V) as well as the influence of $\text{S}_2\text{O}_8^{2-}$ and BrO_3^- ions on the stability of Am(VI) towards α -radiolysis have been studied. The reduction of Am(VI) during the α -radiolysis in nitric acid includes the same reactions as that during γ -radiolysis. With allowance for this fact, an equation for $G[-\text{Am(VI)}]$ has been derived.¹ Application of this equation to a 0.5 M solution of HNO_3 leads to a theoretical yield of 4.74 ion (100 eV) $^{-1}$. The experimental $G[-\text{Am(VI)}]$ values found by various researchers differ fairly markedly from one another (see Table 18). Apparently, this is due to insufficient purity of the solutions used in some of the studies.

Study of the behaviour of Am(VI) in solutions of HNO_3 and LiNO_3 under the action of the α -radiation of ^{244}Cm has shown¹⁷³ that at $[\text{HNO}_3] \leq 6$ M, Am(VI) is reduced to Am(V) [up to the instant when Am(VI) disappears, not more than 4% of Am(III) is accumulated]. At $[\text{HNO}_3] > 6$ M, the amount of the Am(III) formed increases. This is due to disproportionation of Am(V). The reduction yields of Am(VI) markedly increase in the presence of LiNO_3 . According to our estimates, in a 2.9×10^{-3} M solution of Am(VI) containing 0.01 mol litre $^{-1}$ of HNO_3 and 1 mol litre $^{-1}$ of LiNO_3 , the yield is equal to 48 ion (100 eV) $^{-1}$. If $[\text{LiNO}_3] = 9.1$ M, $G[-\text{Am(VI)}] = 75.5$ ion (100 eV) $^{-1}$. In all probability, the so high yields are due to the presence of nonidentified impurities in the solution.

In solutions containing nitric acid, Am(V) is reduced under the influence of α -particles to Am(III) (see Table 18). The reduction yield of Am in 0.01 M HNO_3 almost does not differ from those obtained in dilute HClO_4 or H_2SO_4 . When $[\text{HNO}_3]$ is increased to 4.5 M or $[\text{LiNO}_3]$ is increased to 1 M, the interaction of nitrate ions with reducing radicals starts to contribute to the process; therefore, the reduction yield of Am(V) decreases. In 6–9 M HNO_3 , disproportionation of Am(V) becomes significant; hence, the observed reduction yield increases.

Study of α -radiolysis of solutions of Am(VI) in nitric acid containing $\text{S}_2\text{O}_8^{2-}$ ions has shown that at a constant concentration of HNO_3 , the reduction yield of Am(VI) decreases upon an increase in the concentration of $\text{S}_2\text{O}_8^{2-}$. Conversely, when the concentration of $\text{S}_2\text{O}_8^{2-}$ is constant, $G[-\text{Am(VI)}]$ increases with an increase in the concentration of HNO_3 . A detailed interpretation of these findings has been reported previously.¹

As in the case of Am(VI), $\text{S}_2\text{O}_8^{2-}$ ions have an influence on the stability of Am(V) ions during the α -radiolysis in solutions of nitric acid. The reduction yields of Am(V) obey complex dependences on the concentrations of Am(V), HNO_3 and $\text{S}_2\text{O}_8^{2-}$ and on the dose rate. The introduction of bromate ions into a nitric acid solution of Am(V) decreases the rate of its reduction during α -radiolysis.

Pentavalent americium is reduced during the α -radiolysis in hydrochloric acid (see Table 18). The reduction occurs *via* reactions with HO_2 , H_2O_2 and with hydrogen atoms resulting from the radiolysis of water and interaction with e_{aq}^- . Chloride ions react with OH radicals in the bulk of the solution and partly in the spurs (in the latter case, this reaction decreases $G_{\text{H}_2\text{O}_2}$). The Cl_2^- radical ions arising from the interaction of OH with Cl^- can both oxidise Am(V) and react with H_2O_2 (in the latter case, OH is formed). The resulting Am(VI) is reduced by hydrogen peroxide and by chloride ions.

The behaviour of Am(III) in concentrated solutions of NaCl under the action of α -radiation has been studied.^{136, 162} Radiolytic

transformations of Am(III) in a 5 M solution of NaCl at pH 8.3 was investigated.¹⁶² Americium(V) is formed as the final product of α -radiolysis. The mechanism of radiolysis includes the interaction of OH with Cl^- (formation of Cl_2^-) and, in the opinion of the researcher,¹⁶² the formation of HClO . The ion ClO^- and, perhaps, Cl_2^- act as oxidising agents. The reactions of Cl_2^- with Am(V) and H_2O_2 as well as reactions of Am(VI) with H_2O_2 and Cl^- can occur in this system.

In phosphoric acid, reduction of Am(VI), Am(V) and Am(IV) has been studied (see Table 18). We shall consider the most significant results of these studies. As in the case of γ -radiolysis, Am(VI) is reduced to Am(III); $G[-\text{Am(VI)}]$ is almost independent of the concentration of H_3PO_4 but decreases following an increase in the dose rate. The mechanism of reduction of Am(VI) during the α -radiolysis includes the same reactions as that during γ -radiolysis. As in the case of γ -radiolysis, the yields found experimentally are markedly higher than the calculated values; the possible reasons for this are also the same.

Some studies have dealt with the stability of the complex of Am(IV) with phosphotungstate (see Table 18). The stability of the complex of Am(IV) with $\text{P}_2\text{W}_{17}\text{O}_{61}^{10-}$ depends on the pH and on the concentration of the phosphotungstate ion. Erin *et al.*¹⁶⁴ believe that Am(IV) is reduced both radiolytically and by water. Study of the stability of Am(VI) in solutions of $\text{P}_2\text{W}_{17}\text{O}_{61}^{10-}$ has shown¹⁷⁴ that Am(VI) is converted into Am(IV). According to our estimates, the $G[-\text{Am(VI)}]$ values vary from 3.3 to 0.35 ion (100 eV) $^{-1}$ as the pH changes from 0 to 6.

VIII. Other actinides

Data on the radiolysis of aqueous solutions of transamericium elements are scarce. This is due to the fact that these elements are relatively unavailable and are characterised by short half-lives. Some information about the radiolysis of solutions containing curium, berkelium and californium ions have been reported.

1. Solutions of curium ions

Several studies have been devoted to α -radiolysis of aqueous solutions of Cm(IV) in the presence of complex-forming agents. It has been found¹ that in a 15 M solution of CsF at 10.5°C, $^{244}\text{Cm(IV)}$ is reduced under the action of its own α -radiation to Cm(III), the rate constant for reduction and the $G[-\text{Cm(IV)}]$ value being equal to 2.17×10^{-4} s $^{-1}$ and 3.08 ion (100 eV) $^{-1}$, respectively. The reduction yield of Cm(IV) should be determined by its reactions with H , e_{aq}^- , HO_2 and H_2O_2 and by the reverse oxidation of the resulting Cm(III) by the OH radical. Unfortunately, since there are no data on the yields of the primary products of α -radiolysis of concentrated aqueous solutions of fluoride ions, it is impossible to calculate the theoretical reduction yield of Cm(IV) and to compare it with the experimental value.

The stability of Cm(IV) prepared by oxidation of Cm(III) on heating with peroxodisulfate in the presence of $\text{K}_{10}\text{P}_2\text{W}_{17}\text{O}_{61}$ has been studied.^{1, 175} At room temperature (without removal of the oxidant), Cm(IV) is reduced to Cm(III); the yield is 2.63 ion (100 eV) $^{-1}$.

In the presence of the oxidant, the rate of the process in the initial period [before the Cm(IV) is reduced by $\sim 50\%$] is constant; then a deviation from the linear dependence is observed. For the initial period, $G[-\text{Cm(IV)}]$ is 4.74 ion (100 eV) $^{-1}$. In another study, a complex of Cm(IV) with phosphotungstate has been used.¹⁷⁵ It was found that the consumption of Cm(IV) as well as that of Am(IV) or Cf(IV) obeys the equation

$$-\frac{d[\text{An(IV)}]}{dt} = k_0 + k_1[\text{An(IV)}], \quad (12)$$

where k_0 is the rate of the radiation-chemical process.

The reduction yield estimated from the k_0 value is more than 20 ion (100 eV) $^{-1}$ (in the pH range of 1.5–6.1 and at a concentration of the heteropolyanion of 0–0.012 mol litre $^{-1}$). In the studies under consideration, the concentration of phosphotung-

state exceeded the concentration of curium; therefore, e_{aq}^- and H should react mostly with the heteropolyanion to give 'heteropoly-blue'. The rate constant for the corresponding reaction of e_{aq}^- is $\sim 1.2 \times 10^{11}$ litre mol $^{-1}$ s $^{-1}$.⁵ Therefore, it cannot be ruled out that heteropolyanions accept the precursors of H₂ from the spurs. Evidently, the heteropoly-blue reacts with Cm(IV). The reduction yield can be found from the equation

$$G[-\text{Cm(IV)}] = G_{e_{aq}^-} + G_H + G_{\text{HO}_2} + 2G_{\text{H}_2\text{O}_2} + 2AG_{\text{H}_2} - G_{\text{OH}}, \quad (13)$$

where A is the factor characterising the decrease in the yield of hydrogen caused by trapping of its precursors by heteropolyanions in the spurs.

In the limiting case, the reduction yield of Cm(IV) in α -radiolysis can reach 5.8 ion (100 eV) $^{-1}$. The high yields reported by Kuno *et al.*¹⁵⁵ are most likely caused by the presence of organic impurities.

Deaerated solutions of Cm(III) containing perchlorate ions and *tert*-butyl alcohol (added as an acceptor of the OH radicals) have been studied by pulse radiolysis.¹⁶⁶ It was found that upon the passage of an electron pulse, an optical absorption with a maximum at 240 nm appears. This absorption was attributed to Cm(III) arising in the reaction with e_{aq}^- . However, the large negative redox potential of the Cm(III)/Cm(II) pair casts doubt upon this interpretation. In a solution saturated with N₂O, the action of an electron pulse gives rise to optical absorption with a maximum at 260 nm. This was assigned to Cm(IV) resulting from the reaction of Cm(III) with OH radicals.

2. Solutions of berkelium ions

Oxidation of Bk(III) induced by γ -radiolysis has been studied in a biphasic system consisting of a 6 M aqueous solution of HNO₃ and a 0.2 mol litre $^{-1}$ solution of di(2-ethylhexyl) phosphate (DEHP) in decane.¹⁷⁶ It was found that upon irradiation, berkelium is converted almost entirely into the tetravalent state and is extracted into the organic phase. In this system, Bk(III) is oxidised by NO₃ radicals. The resulting Bk(IV) is partially reduced by nitrous acid and is partially extracted into the organic phase.

In a solution containing 2 mol litre $^{-1}$ of K₂CO₃, trivalent berkelium is oxidised to Bk(IV) under the influence of its own β -radiation. The half-transformation period is 2.5 h, which corresponds to $G[-\text{Bk(III)}] = 5.45$ ion (100 eV) $^{-1}$. The mechanism of the process has been considered in the monograph.¹ Based on this mechanism, an equation for $G[\text{Bk(IV)}]$ was obtained; the theoretical yield found from this equation is 8.2 ion (100 eV) $^{-1}$. The experimental result is markedly smaller. It is most likely that, owing to the low concentration of Bk(III), the radicals acting as oxidants are not completely consumed in the reactions with Bk(III) and participate in side processes (for example, they react with H₂O₂ and/or O₂ $^-$).

By virtue of pulse radiolysis, the formation of Bk(II) has been observed upon exposure of a deaerated 2.5×10^{-3} mol litre $^{-1}$ solution of Bk(III) containing *tert*-butyl alcohol (pH 5) to an electron pulse.³² The appearance of Bk(II) is due to the reaction of Bk(III) with e_{aq}^- (the rate constant for this reaction is presented in Table 3). The absorption spectrum of Bk(II) has a maximum at 310 nm (the molar extinction coefficient at this wavelength is 230 m² mol $^{-1}$). This ion is short-lived; the rate constant for its disappearance is 1.53×10^5 s $^{-1}$.

The resistance of ²⁴⁹Bk(IV) to its own β -radiation in acidic solutions has been considered in a number of studies (see, for example, Refs 1 and 177–179). In solutions of sulfuric acid, Bk(IV) has been found to be reduced under the influence of its own β -radiation and by water; the $G[-\text{Bk(IV)}]$ values range from 0.83 to 6.5 ion (100 eV) $^{-1}$ and decrease with an increase in the concentration of the acid. In perchloric acid solutions, the reduction yields measured by various researchers vary from 2.4 to 10.2 ion (100 eV) $^{-1}$. The yields of Bk(IV) for several types of solution are listed in Table 19.

The theoretical $G[-\text{Bk(IV)}]$ value can be found based on the mechanism including the reactions of Bk(IV) with H, e_{aq}^- , HO₂ and

Table 19. The yields of reduction of Bk(IV) in β -radiolysis in various media.

H₂O₂ and the reaction of the resulting Bk(III) with OH. The presence of air in the solution exerts no influence on $G[-\text{Bk(IV)}]$, because the HO₂ radical resulting from the reaction of H with O₂, like the H atom itself, reduces one Bk(IV) ion. Taking into account the whole set of reactions, we obtain a $G[-\text{Bk(IV)}]$ value of 2.3 ion (100 eV) $^{-1}$. Experimental values are markedly higher in most cases. Evidently, this is due to the presence of organic impurities in the solutions used. The OH radical reacts with RH₂ present as an impurity. The 'RH' radical thus formed is capable of reducing Bk(IV).

Apparently, the most reliable data have been obtained by Erin *et al.*¹⁷⁷ The authors took into account the experience of the earlier researchers and paid primary attention to the purification of the initial sample of ²⁴⁹Bk. It was shown that consumption of Bk(IV) in solutions containing perchloric or nitric acid obeys zero-order kinetics, *i.e.* Bk(IV) is reduced only *via* reactions with the products of water radiolysis. In 2–5 M HClO₄, reduction is accomplished by e_{aq}^- , H, H₂O₂, HO₂ and by the products of decomposition of ClO₄ $^-$ induced by the direct action of ionising radiation. As a result, the reduction yield is somewhat higher than that in 1 M HClO₄. In nitric acid [as in solutions of Am(VI) with similar compositions], H₂O₂ and HNO₂ act as the reducing agents; some of the Bk(III) thus formed is oxidised again by NO₃ radicals.

The relatively high reduction yields of Bk(IV) in sulfuric acid are obviously caused by the presence of organic impurities. The decrease in $G[-\text{Bk(IV)}]$ following an increase in the concentration can be due to the interaction of HSO₄ $^-$ with OH radicals, which suppresses the reactions of these radicals with RH₂. The HSO₄ (SO₄ $^-$) radicals are able to oxidise Bk(III); however, they react with organic compounds much more slowly than OH radicals. In addition, in concentrated solutions of H₂SO₄, the HSO₄ $^-$ ions partly accept the OH radicals from the spurs, which results in an increase in G_{OH} and a decrease in $G_{\text{H}_2\text{O}_2}$.

β -Radiolysis of solutions of Bk(IV) in mixtures of perchloric and nitric acids and of perchloric acid with lithium nitrate has been studied.¹⁸⁰ As the content of nitrate ions in the solutions increases, $G[-\text{Bk(IV)}]$ increases as has also been observed for solutions in nitric acid containing no HClO₄.

It has been reported¹ that when the biphasic system consisting of a 0.05 mol litre $^{-1}$ solution of DEHP in decane and a 6 M aqueous solution of HNO₃ and containing 1.04×10^{-6} mol litre $^{-1}$ of Bk(IV) and 3.6×10^{-3} mol litre $^{-1}$ of Ce(III) is exposed to α -radiation from ²⁴⁴Cm, Bk(IV) is formed and passes to the organic phase. The maximum degree of oxidation, equal to $\sim 30\%$, is achieved when the radiation dose is ~ 360 kGy (the dose rate is ~ 1.6 Gy s $^{-1}$). The average $G[\text{Bk(IV)}]$ value is ~ 0.01 ion (100 eV) $^{-1}$.

In 6 M HNO₃, e_{aq}^- and H are converted into NO₂ and then into HNO₂, and the latter reacts with hydrogen peroxide. The OH

radicals react with NO_3^- and HNO_3 to give NO_3 radicals. The latter oxidise Ce(III). The resulting Ce(IV) enters into the reactions with HNO_2 and Bk(III). After that, the reduction of Bk(IV) and its transfer into the organic phase compete with each other. Since the potential of the Bk(IV)/Bk(III) pair decreases, Bk(IV) does not react with HNO_2 in the organic phase.

The stability of Bk(IV) in a solution of perchloric acid exposed to α -particles emitted by ^{244}Cm has been studied.¹⁸¹ According to our calculations, at $[\text{HClO}_4] = 1-5 \text{ M}$, the $G[-\text{Bk(IV)}]$ values vary from 4.2 to 5.1 ion $(100 \text{ eV})^{-1}$. At higher concentrations of the acid, the yields increase. As noted above, the theoretical yield for α -radiolysis in a 1–5 M solution of HClO_4 is 3.0 ion $(100 \text{ eV})^{-1}$. The higher values obtained experimentally are caused most probably by the presence of impurities introduced into the solution together with curium.

A study¹⁸² has been devoted to the behaviour of Bk(IV) in solutions of nitric acid under the action of β - and α -radiation (^{244}Cm was used as the source of α -radiation). The reduction of Bk(IV) was found to obey zero-order kinetics. Depending on the concentrations of HNO_3 and Bk(IV) and also on the dose rate, the $G[-\text{Bk(IV)}]$ values vary from 8.5 to 13.5 ion $(100 \text{ eV})^{-1}$. The theoretical value should be 4.5–5.5 ion $(100 \text{ eV})^{-1}$. Higher values are achieved due to the presence of impurities.

3. Solutions of californium ions

The formation of Cf(II) upon interaction of e_{aq}^- with Cf(III) in a deaerated solution of californium(III) containing *tert*-butyl alcohol (pH 5.1–5.3) has been detected by pulse radiolysis.³³ The rate constant measured in this study is presented in Table 3. It was found that Cf(II) is responsible for an absorption band with a maximum at 270 nm (the molar extinction coefficient at this wavelength is equal to $50 \text{ m}^2 \text{ mol}^{-1}$). The consumption of Cf(II) occurs according to first-order kinetics with a rate constant of $7 \times 10^4 \text{ s}^{-1}$. In solutions saturated with N_2O , the formation of Cf(IV) was not detected.

Two studies have been devoted to the reduction of $^{249}\text{Cf(IV)}$, bound into a complex with $\text{P}_2\text{W}_{17}\text{O}_{61}^{10-}$ induced by its own α -radiation in the presence of $\text{S}_2\text{O}_8^{2-}$ (see Ref. 1). At the beginning of the process [before ~50% of Cf(IV) is reduced], its rate does not depend on the concentration of Cf(IV), *i.e.* the reaction has the zero order; then the rate decreases and starts to depend on [Cf(IV)]. Calculation of $G[-\text{Cf(IV)}]$ based on the results of these studies leads to a value of 32.8 ion $(100 \text{ eV})^{-1}$. Evidently, this high yield is due to impurities.

It has been found¹⁷⁵ that Cf(IV) bound into a complex with $\text{P}_2\text{W}_{17}\text{O}_{61}^{10-}$ is reduced in α -radiolysis, the reduction yield being 7.5–31 ion $(100 \text{ eV})^{-1}$ in the pH range of 2.5–6.1 and at a concentration of the phosphotungstate of 0 to $6.1 \times 10^{-3} \text{ mol litre}^{-1}$. The high yields are apparently due to the presence of impurities.

IX. Conclusion

The above consideration indicates that substantial progress has been achieved in the chemistry of aqueous solutions of actinides. Radiolytic transformations of uranium, neptunium, plutonium and americium ions induced by γ - or α -radiation in aqueous solutions under various conditions have been studied in detail; in many cases, the mechanisms of these transformations have been identified. Interesting data about the influence of ionising radiation on aqueous solutions of berkelium ions have been obtained. The first results on the radiolysis of solutions of californium are available. The rate constants for many reactions between actinide ions and the primary products of radiation-induced decomposition of water and with inorganic free radicals (SO_4^- , NO_3 , CO_3^- , *etc.*) have been measured using the method of pulse radiolysis. Short-lived intermediates of a number of redox reactions of actinide ions in irradiated aqueous solutions have been identified and studied. A procedure for radiation-induced synthesis of heptavalent neptunium, plutonium and americium has been developed.

However, there are problems to be solved in this field of radiation chemistry. Some of them are formulated below. Note that this list is incomplete, but it points to possible lines of subsequent research in this practically important field of science.

Firstly, radiolysis of aqueous solutions of actinides in nitric acid still remains little investigated. This is mainly due to the fact that radiolytic transformations of nitric acid itself are not completely clear. The foregoing can be illustrated, for example, by the fact that the published values for the molar extinction coefficient of the NO_3 radical, which is among the major intermediate species in the radiolysis of this acid, differ by factors of 4–5 (see, for example, Refs 78 and 183).

Secondly, actinide ions undergo radiolytic transformations induced by their own α -radiation. However, no data about the yields of hydrated electrons in α -radiolysis can be found in the literature, which hampers in some cases interpretation of the results obtained.

Thirdly, the reactivity of actinide ions towards organic free radicals has not been adequately studied. This information would be especially important for describing and predicting the radiolytic behaviour of these ions, for example, in extraction systems used to process irradiated nuclear fuel.

Fourthly, additional investigations of the radiolytic transformations of actinide ions in biphasic systems are needed. This would be of interest for the technologies of separation and isolation of radionuclides from industrial solutions.

Fifthly, radiolysis of alkaline aqueous solutions of actinides has been studied only recently. The corresponding studies are of interest in view of the target-directed disposal of highly radioactive alkaline wastes stored in some nuclear centres. In this connection, it should be specially emphasised that it would be expedient to study the influence of ionising radiation on the solubility of plutonium hydroxides in alkaline solutions.

Finally, the problem of the influence of organic impurities on the radiolysis of aqueous solutions of actinides still remains acute. This refers, first of all, to the use of curium as an internal source of radiation. We repeatedly mentioned in the review that the presence of such impurities leads to increased radiation yields. Therefore, development of special methods for the purification of the samples of α -emitters prior to their introduction into solutions and employment of the external irradiation technique (for example, as was done in the 50–60s for the radiolysis of aqueous solutions under the action of α -particles emitted by ^{210}Po) are urgent tasks.

VIII. Mercuration by organomercury salts and hydroxides	807
IX. Other methods of synthesis of organomercury compounds	809
X. Conclusion	810

Abstract. New data on the methods of synthesis and practical applications of organic compounds of mercury are surveyed and treated systematically. The bibliography includes 180 references.

I. Introduction

The chemistry of organic compounds of mercury is one of the most extensive and thoroughly investigated fields of organometallic chemistry.^{1–7} Organomercury compounds (OMC) proved to be convenient objects for the solution of a series of fundamental problems of theoretical organic chemistry.^{8,9} They are also of practical importance, particularly in organic synthesis.^{3,7,10–12}

The original studies, published up to 1980, have been dealt with systematically in reviews^{4,5,9} and monographs,^{1–3,6–8} but during the last 15 years many new studies on the synthesis of OMC have been published. Certain data on particular aspects of the chemistry of OMC during the period indicated have been surveyed in reviews^{10–12} and dissertations.^{13–17} In the present review, a systematic and critical account is given of new and most significant, from our point of view, literature data on the methods of synthesis and applications of OMC.

II. Insertion of a mercury atom in a C–Hal bond

The method of synthesis of OMC by the insertion of a Hg atom in a C–Hal bond was historically the first employed,¹ but it has still not lost its importance because of the availability of the initial reactants and the relative simplicity of the preparative use of the reaction. Thus the interaction of 8-(1-bromoalkyl)quinolines **1** with metallic mercury afforded¹⁸ the corresponding bromomercurioquinoline derivatives **2**, which are convenient models for the study of mechanisms of the S_E1-N type.^{8,18}

R = H, Me.

The reactions of hexahalotoluenes with metallic mercury have been investigated.^{19,20} Thus the interaction of pentabromobenzyl bromide (**3**) with mercury in benzene results in the formation of pentabromobenzylmercury bromide (**4**).

On the other hand, pentachlorobenzyl chloride **5** does not react with mercury under these conditions [when the reaction mixture is irradiated with UV light, 1,2-bis(pentachlorophenyl)ethane is formed].

In the presence of a catalyst ($\text{Et}_4\text{N}^+\text{Br}^-$, $\text{Et}_4\text{N}^+\text{I}^-$, or NaBr), the bromide **3** and the chloride **5** react with mercury to form symmetrical OMC — bis(pentabromobenzyl)- and bis(pentachlorobenzyl)mercury. On UV irradiation, the latter decompose with liberation of mercury and the formation of 1,2-bis(pentachlorophenyl)ethanes (on irradiation with UV light for 2 h, compound **4** does not change). The influence of reaction conditions (solubility, the presence of a catalyst and atmospheric oxygen, illumination) on the composition and yield of the products of the interaction of the halogenated benzyl halides **3** and **5** with metallic mercury has been studied.²⁰ The optimum method of synthesis of type **4** benzylmercury derivatives has been proposed (DMF, Br^- , darkness, absence of atmospheric oxygen, 20 °C).

The interaction of metallic mercury with propargyl halides **6** has been investigated.²¹ On ethyne–allene rearrangement in a sealed tube under a nitrogen atmosphere and in sunlight in the course of 2 h,⁸ the allenyl derivatives of mercury **7** are formed. Their structure has been confirmed by IR and NMR spectroscopic data.

The synthesis of allyl ketones, which proceeds *via* the formation of allylic OMC, has been described.^{22, 23}

$\text{R} = \text{Me}, \text{Ph}, 4\text{-ClC}_6\text{H}_4, 2\text{-FC}_6\text{H}_4.$

The substitution of a halogen by mercury is known³ to occur only on interaction of aryl halides with an alkali metal amalgam; the reaction with metallic mercury does not take place. The reactions of sodium amalgam with a series of aryl halides have been studied.²⁴ Thus the reaction of *o*-dibromobenzenes **9** with Hg/Na in THF for 2 h at 80 °C leads to *o*-arylenemercury trimers **10**, which are of preparative interest as crown-compounds for the interphase transfer of anions.²⁵

$\text{R}^1 = \text{R}^2 = \text{H}, \text{R}^3 = \text{R}^4 = \text{OMe}; \text{R}^1 = \text{R}^2 = \text{R}^3 = \text{R}^4 = \text{Me}.$

Compound **11** is formed as a result of the reaction of tetrachloro-1,2-diiodobenzene with mercury on heating (100 °C) in a sealed tube for four days.²⁴ When the reaction time is reduced to 24 h, only bis(3,4,5,6-tetrachloro-2-iodophenyl)mercury is formed.

In conclusion of this section, one should note that, despite the long history of the use of reactions of the above types in syntheses of OMC, the mechanisms of these reactions have been scarcely studied.^{3–8} However, on the basis of the conditions (temperature, irradiation) under which mercury interacts with halogen-contain-

ing compounds, it is possible to make a choice in favour of a radical mechanism of the above reactions. Here the greatest activity is shown by iodides, while the bromo-derivatives react only when the carbon–bromine bond has been activated, for example by conjugation with a multiple bond,^{18–21} and chlorides are altogether inactive. Apparently, the limits of the applicability of the method of synthesis of OMC under consideration are determined primarily by the availability of the corresponding halo-derivatives and are not restricted by the choice of reaction conditions, which are standard in most cases.³

III. Substitution by mercury of other metal atoms and functional groups

This approach to the synthesis of OMC is universal because it makes it possible, by varying the structures of the initial reactants, to synthesise in one stage a wide variety of mercury-containing substances with the required combinations of substituents at the mercury atom.

Thus bis(1-bicyclo[1.1.0]butyl)mercury has been obtained²⁶ in 75% yield by the reaction of the 1-lithiobicyclo-[1.1.0]butane–tetramethylethylenediamine (TMEDA) complex with mercury(II) chloride in THF. The reaction of substituted 2,2'-dihalobiphenyls **12** with lithium or butyllithium²⁴ and also of biphenylene with the Buli–TMEDA complex led to the synthesis²⁷ of the corresponding organolithium compounds, which on subsequent treatment with HgCl_2 in ether give rise to cyclic biphenylenemercury trimers **13** in low (2%–3%) yields.

$\text{R} = \text{H}, \text{Me}, \text{Et}; \text{X} = \text{Cl}, \text{Br}.$

1-Naphthylmercury chloride and 1,8-di(chloromercurio)-naphthalene (depending on the molar reactant ratio) have been synthesised similarly by the reaction of 1-bromonaphthalene with butyllithium in a hexane–ether mixture with subsequent addition of HgCl_2 in THF.²⁸

The optimum conditions have been found²⁹ for the reactions of lithium derivatives of (dimethylaminomethylcycloheptadienyl)tricarbonyl-manganese and -rhenium **14** with organic and metal carbonyl mercury salts, leading to the formation of symmetrical [$\text{R} = (\text{CO})_3\text{MC}_5\text{H}_3(\text{CH}_2\text{NMe}_2)$] and asymmetric ($\text{R} = \text{Cl}, \text{Br}$) OMC **15**.

M = Mn, Re; R = Cl, Br, (CO)₃MC₅H₃(CH₂NMe₂); X = Cl, Br.

The lithium salts **14** have been synthesised *in situ* by the reaction of BuLi with the corresponding (dimethylaminomethyl)cyclopentadienyl)tricarboxymetal derivatives in THF at -70°C . Compounds **15** were characterised by ¹H and ¹³C NMR as well as IR spectroscopic data. Under these conditions, a downfield shift of the signals due to the CH₂ and Me groups in the ¹H NMR spectra relative to the signals of these groups in the initial complexes was observed. According to Suleimanov *et al.*,²⁹ the reason for this is the coordination of the nitrogen atom to the mercury atom, which has been confirmed by X-ray diffraction (XRD) study of the symmetrical OMC **15**. It was established that the length of the Hg–C bond (2.042 Å) is reduced compared with the statistical mean value 2.07 Å. The dimethylaminomethyl fragment has the conformation in which the lone pairs of the nitrogen atoms in the molecules of compound **15** are directed towards the mercury atom, but the Hg–N distance (2.933 Å) corresponds to only a weak secondary bond.

[2-(Bromomercurio)-1,3-xylylene]-18-crown-5 has been synthesised by the reaction of (2-lithio-1,3-xylylene)-18-crown-5 with HgBr₂ in THF and its reactions on treatment with magnesium and methylmagnesium iodide have been studied.³⁰

The existence of an intramolecular coordinate bond Hg···O with two out of the five oxygen atoms has been established by X-ray diffraction for all the OMC presented.³⁰ Similar reactions have been achieved with (2-lithio-1,3-xylylene)-15-crown-4.³⁰

The organosilicon compounds **16** have been obtained by the reaction of tris(dimethylphenylsilyl)methyl lithium with the chloride of the corresponding metal in an ether–THF mixture.³¹

M = Zn, Cd, Hg.

The structures of the organometallic compounds obtained have been established by X-ray diffraction. They proved to be dimeric³¹ as a result of the formation of chloride bridges.

The phosphoalkenylmercurated compounds **17** in the form of the *E*- and *Z*-isomers have been synthesised in 30%–63% yields from the corresponding lithium salts **18** and mercury chloride in a hexane–THF mixture (Scheme 1).³²

Scheme 1

It was established that the *Z*-isomers are thermodynamically more stable than the *E*-isomers, which are converted into the *Z*-isomers after a time.

A laboratory method has been developed recently³³ for the synthesis of Bu₂Hg by the reaction of Bu^tMgCl with HgCl₂ in THF. The yield of bis(*tert*-butyl)mercury was then 73%.

A method has been proposed for the synthesis³⁴ of functionally substituted OMC involving the use of organozinc compounds¹⁸ *via* the intermediate formation of bis(iodo-methylene)mercury.

R = Buⁿ, cyclo-C₅H₁₁, PhCH₂, AcO(CH₂)₃, EtOCO(CH₂)₃, NC(CH₂)₃, Cl(CH₂)₄, Br(CH₂)₃P(O)(EtO)₂CH₂CH₂.

1-Chloromercurio-2-(dimethylaminomethyl)cymantrene has been obtained in 73% yield the reaction of [2-(dimethylaminomethyl)cymantrenyl]ytterbium iodide (**19**) or bis[2-(dimethylaminomethyl)cymantrenyl]ytterbium with HgCl₂ in THE.³⁵

When mercury acetate is refluxed with tricarbonylcyclopentadienylmanganese in alcohol (molar reactant ratio 5:1), tricarbonyl[η⁵-pentakis(acetoxymercuro)cyclopentadienyl]manganese is formed.³⁶ It was subsequently used in the syntheses of a series of pentasubstituted derivatives of cymantrene.³⁶

Organylmercury acetates **20** are formed readily as a result of the transmetallation of organoboron compounds with mercury acetate.³⁷

R = Alk, Ar.

The interaction of the *E*-isomer **21** with mercury acetate in THF at room temperature and subsequent treatment with sodium chloride lead to the organomercurioalkenes **22** with retention of the configuration.³⁸ On treatment with an alkaline solution of Na₂SnO₂ in a THF–water mixture, the latter are readily symmetrised with formation of fully substituted mercurioalkenes having the *E*-configuration.³⁸

R = C₈H₁₇, Cl(CH₂)₃, I(CH₂)₃, AcO(CH₂)₈, PhO(CH₂)₃.

The reaction of compound **22** with CO and MeOH in the presence of a catalyst (Li_2PdCl_4 and MgO or Pr_2NEt) afforded a mixture of the *cis*- and *trans*-isomers of the corresponding unsaturated acid esters in 70%–80% yields.³⁹

Treatment of tris(dimethoxyboryl)methane with mercury salts in THF results in the substitution of the dimethoxyboryl groups by HgX with formation of trimercured methane.⁴⁰

X = F, Cl, Br, OAc.

The interaction⁴¹ of terminal alkynes with organoaluminium hydrides in the presence of Cp_2ZrCl_2 proceeds regio- and stereo-selectively with formation of (*E*)-alkenylalanes, which react with HgCl_2 in THF to form the corresponding (*E*)-alkenylmercury chlorides.

R = C_8H_{17} , Ph, $\text{CH}_2=\text{CMe}$, C_6H_{13} .

The exchange of tin for mercury as a result of the reaction

R = Me, Ph

has been achieved.⁴² The yield of the reaction products is 90%.

It has been shown that⁴³ the demetallation reactions of the tributylstannyl derivatives of α,β -unsaturated carboxylic acids **23** on treatment with mercury salts proceed selectively with formation (after treatment of the reaction mixture with potassium chloride) of butylmercury chloride and the corresponding acids **24**. The mercuration of the double bonds was not observed in a single instance.

R = H, Me, Ph; X = Cl, OAc.

The interaction⁴⁴ of organophosphorus compounds with mercury acetate has been studied. The structure of the products formed depends on the reactant ratio and the reaction conditions. Thus the reaction of equimolar amounts of diethyl *p*-nitrophenyl phosphate and $\text{Hg}(\text{OAc})_2$ in hexane or toluene leads to *p*-nitrophenyl acetate and the mercury salt of the phosphate **25**.

When the reaction is carried out in the presence of an excess of mercury acetate in acetic acid and on heating, compounds **26** and **27** are formed. The interaction of equimolar amounts of diethyl *p*-tolyl phosphate and mercury acetate leads to the salt **28**.⁴⁴

However, when an excess of the mercury salt is employed and the reaction is carried out in acetic acid, the product is compound **29**. The reaction of mercury acetate proceeds similarly also with other phosphates.⁴⁴

The interaction of equimolar amounts of compound **30** and mercury acetate at 20 °C affords a mixture of the products **31** and **32**.

In the presence of an excess of mercury acetate, the product of mercuration in the aromatic ring, namely compound **33**, is formed together with compounds **31** and **32**.

In the reaction of the phosphate **34** with mercury acetate, the only product is compound **35** regardless of the molar reactant ratio.

The interaction of α -naphthyl phosphate with mercury acetate leads to the mercuration of the aromatic ring and simultaneously to the substitution of the ethyl group by the mercurioacetate group.

The synthesis of alkyl- and aryl-mercury chlorides by treating diethoxyphosphinylmercury chloride with acyl peroxides has been described.⁴⁵ The reaction is carried out in benzene with heating.

R = $\text{C}_{11}\text{H}_{23}$, $\text{C}_{15}\text{H}_{31}$, $\text{C}_{17}\text{H}_{35}$, Ph, 4- $\text{CH}_3\text{C}_6\text{H}_4$, 4- FC_6H_4 , 4- ClC_6H_4 .

According to the authors,⁴⁵ the reaction proceeds *via* a radical mechanism.

The mechanism is confirmed by the fact that, in the reaction of *p*-toluyl peroxide with diethoxyphosphinylmercury chloride, a small amount of the mixed anhydride of *p*-toluic acid and diethyl phosphate, *p*- $\text{MeC}_6\text{H}_4\text{COOP}(\text{O})(\text{OEt})_2$ is formed.⁴⁵ The anhydride readily polymerises on distillation.

A convenient method has been developed⁴⁶ for the synthesis of bis(2,2,6,6-tetramethylpiperidin-4-yl)mercury (**36**) by the electrochemical reduction of 2,2,6,6-tetramethyl-4-oxopiperidine at a mercury cathode in a highly acid medium. Compound **36** is the starting reactant in the synthesis of the stable nitroxyl radical and bis(2,2,6,6-tetramethylpiperidin-4-yl-1-oxyl)mercury,⁴⁶ which is used as the mercury label in biochemical research involving the establishment of the structure of proteins.

Mercuration of the anhydrides of naphthalene-1,8- and naphthalene-2,3-dicarboxylic acids with HgO afforded respectively naphtho[1,8-*d,e*]-2,1-oxamercuracyclohexan-3-one (**37**) and naphtho[2,3-*d*]-2,1-oxamercuracyclopentan-3-one (**38**) respectively.⁴⁷ On interaction with nucleophiles (Nu), they give rise to the corresponding naphthalenecarboxylic acids — convenient synthons for the synthesis of various heterocyclic compounds.

Nu = KI, H₂S, HCN; R = I, SH, CHO.

However, a reinvestigation⁴⁸ of the nucleophilic demercuration of compound **37** in aqueous acetic acid established that its interaction with potassium iodide or bromide leads to 8-iodo(-bromo)mercurionaphthoic acids **39** and **40** in 30% and 19% yields respectively) and to only traces of demercuration products — 8-iodo- and 8-bromo-naphthoic acids **41** and **42**.

The mercuration product **44** is formed in the reaction of the anhydride of biphenyl-2,2'-dicarboxylic acid (**43**) with mercury acetate in the presence of NaOH. Its treatment with hydrogen chloride affords 2'-chloromercuriobiphenyl-2-carboxylic acid (**45**).⁴⁹

When compound **44** is treated with nucleophiles (KI, H₂S, HCN) in acetic acid, 2'-iodomercurio-, 2'-mercapto-, and 2'-formyl-biphenyl-2-carboxylic acids are formed.⁴⁹ The reaction

of the anhydride **43** with HgO in an aqueous solution of acetic acid is also described in the same communication. It is shown that the reaction product is the mercury salt of biphenyl-2,2'-dicarboxylic acid **46** (65% yield). This salt has also been obtained by the reaction of the dicarboxylic acid **47** with mercury oxide.⁴⁸

Interesting results have been obtained⁵⁰ on refluxing mercury salts HgX₂ with acetic anhydride in acetonitrile. The mercury derivatives of ketene **48** were then synthesised in 60%–80% yields.

X = AcO, NO₃, ClO₄.

The reaction is accelerated in the presence of traces of sulfuric or perchloric acid. Compounds **48** are also formed when mercury salts HgX₂ are treated with ketene in acetonitrile at 20 °C.

Stable organic derivatives of monovalent mercury **49** have been synthesised in 60%–80% yields by the reaction of monovalent mercury salts Hg₂X₂ with acetic anhydride under the same conditions.⁵⁰

On treatment with a dilute HCl solution, compounds **49** liberate Hg₂Cl₂ quantitatively, while the ketene derivative **48** dissolves in hydrochloric acid with formation of Hg²⁺ salts. When the mercurated ketenes **48** and **49** are treated with gaseous HCl in the absence of moisture, ketene and acetyl chloride are obtained.⁵⁰ The extensive synthetic possibilities of compounds **48** and **49** are demonstrated by the following reactions:⁵⁰

The reactions of various cyclopropane derivatives with mercury salts continue to attract the attention of investigators.^{51–57} Thus it has been shown that the interaction of phenylcyclopropane with a mixture of Bu^tOOH and mercury trifluoroacetate in methylene chloride at 20 °C leads to a mixture of the products **50** and **51** in an overall yield of 83%.⁵¹

When mercury acetate is used, the reaction does not occur.

The interaction of cyclopropane with a mixture of mercury acetate and Bu^tOOH in the presence of HClO₄ (CH₂Cl₂, –40 °C, followed by 2 h at 20 °C) and subsequent treatment with KBr lead to a mixture of Bu^tOO(CH₂)₃HgBr, [BrHg(CH₂)₃]₂O, and AcO.(CH₂)₃HgBr, the structures of which have been established on the basis of ¹H, ¹³C, and ¹⁹⁹Hg NMR and IR spectroscopic data.⁵²

Successive interactions of *o*-nitrocyclopropylbenzene with mercury salts HgX₂ and further with saturated aqueous solutions of NaX led to the synthesis^{53,54} of the corresponding compounds **52**, which are of preparative interest^{54,55} for the synthesis of mercury-containing heterocyclic compounds.

The mode of the conjugate mercuration of substituted *o*-nitrocyclopropylbenzenes by mercury acetate in formic acid depends on the nature of the substituents in the aromatic ring.⁵⁶ Under all the conditions investigated, the conjugate mercuration process is accompanied by the conversion of *o*-nitrocyclopropylbenzenes into mercurated *o*-nitrosopropiophenones **53** (Scheme 2).

Scheme 2

The behaviour of 1,1-dichloro- and 1,1-dibromo-2-phenylcyclopropanes in conjugate mercuration reactions has also been investigated.⁵⁷ It was established that, on treatment of 1,1-dichloro-2-phenyl- and 1,1-dichloro-2-methyl-2-phenylcyclopropanes with mercury acetate in hydroxylated solvents, the aromatic ring is mercurated in the *ortho*- and *para*-positions, while the three-membered ring is not involved.

R = H, Me; R' = Me, AcO, CHO.

1,1-Dibromo-2-phenylcyclopropane gives rise to an aromatic mercurio-derivative only in methanol.⁵⁷ In formic and acetic acids, the reactions of mercury acetate with 1,1-dibromo-2-phenyl- and 1,1-dibromo-2-methyl-2-phenylcyclopropanes proceed with the opening of the small ring. This process takes place stereo- and regio-specifically and leads to the alkenes **54** with the *Z*-configuration.

R = H, Me; R' = H, Me.

IV. Addition of mercury salts to a C = C bond

One of the most important and general methods for the formation of a carbon–mercury bond is mercuration,^{1–7} which can be regarded as electrophilic interaction of mercury-containing cations with electron-excess systems.

Among the methods for the synthesis of OMC, the reactions involving the addition of mercury salts to the multiple bonds in alkenes and ethynes in the presence of various nucleophiles are of special importance. An enormous number of mercury compounds, which possess a series of unique properties, have been synthesised by this method.^{3,6} These substances are remarkable because they exhibit strikingly a dual reactivity, like tautomeric compounds. In some cases, they react as true organometallic substances, whilst in others they behave like π -complex adducts of the mercury salt with an unsaturated compound as an addend, which can be substituted as a whole.³ Apparently, the vigorous development of methods of synthesis of OMC has continued because of these extremely interesting properties.⁷ During the last decade, attention has been concentrated on various aspects of the conjugate mercuration of unsaturated compounds.

Thus the hydroxymercuration of silicon-containing alkenes — trimethyl-vinylsilane **55** and allyltrimethylsilane **56** — with mercury acetate in the 1:1 water–THF mixture has been studied.⁵⁸ The demercuration of the resulting hydroxymercuroacetate by the initial treatment with an alkaline solution of NaBH₄ and then with HCl leads to a complex mixture of reaction products.

The hydroxymercuration of the alkene **55** with mercury acetate in a D₂O-THF-*d*₈ mixture affords only 2-acetoxymercurio-1-deuterioxy-2-trimethylsilylthane (**57**) and, when CD₃COOD is used as the solvent, 2-acetoxymercurio-1-deuterio-2-acetoxy-2-trimethylsilylthane (**58**) is formed.⁵⁸

The hydroxymercuration of the allyl derivative **56** under the same conditions with subsequent demercuration of the resulting intermediate mercury-containing derivative also affords a mixture of products.⁵⁸

The interaction of the alkene **56** with mercury acetate in glacial acetic acid at room temperature leads to allyl mercurioacetate **59**, the reaction of which with Hg(OAc)₂ in CD₃COOD affords the demercurated compound **60**. The hydroxymercuration of compound **59** in a D₂O-THF-*d*₈ mixture leads only to the product **61**, which is converted into isopropyl alcohol on demercuration.⁵⁸

A method for the selective hydroxymercuration of alkenes by mercury salts, formed *in situ* from HgO and carboxylic acids under the influence of ultrasound, has been described.⁵⁹ Thus the interaction of oct-1-ene with HgO and RCOOH in proportions of 1 : 1 : 2 in aqueous THF leads to compound **62**, which affords a 85% yield of 2-octanol on reduction with NaBH₄.

R = Me, Bu^t, C₉H₁₉, CBr₃, Pr, Ph.

The hydroxymercuration of limonene leads, after reduction, to a mixture of the alcohols **63** and **64**, the ratio of which depends on the reaction conditions.⁵⁹

The highest yield (80%) of α-terpineol **63** is observed in Bu^tOH as the solvent, using C₁₇F₁₅COOH, and an exposure to ultrasound for 7 min. When the analogous reaction with 4-vinylcyclohexene was carried out in the presence of Hg(OAc)₂, the yield of 1-(cyclohex-3-enyl)ethanol (**65**) did not exceed 20%, while in the presence of PrCOOH and HgO with exposure to ultrasound for 2 h the yield of the alcohol **65** was 67% with 100% selectivity.⁵⁹

The biomimetic asymmetric hydroxymercuration of alkenes, catalysed by β-cyclodextrin, has been achieved.⁶⁰

Ar = Ph, 4-MeC₆H₄, 4-ClC₆H₄;

R = H, CH₂OH, COOH, COOMe, COOEt, COOPrⁱ.

The asymmetric solvomercuration of alkenes has been carried out⁶¹ in chiral micellar systems with addition to the reaction mixture of the optically active salts PhCH(OH)·CHMeN⁺Me₂·C₁₂H₂₅Br⁻ or PhCH(OH)CHMeN⁺Me₂·C₁₆H₃₃Br⁻.

Compounds **66** were obtained as a result.

R = Ph, Buⁿ, Me(CH₂)₄CH(OH).

The interaction of styrene derivatives **67** with mercury acetate in methanol at 25 °C leads to the methoxymercuration products **68**, the reduction of which with NaBH₄ in MeOH gives rise to the corresponding methyl ethers.⁶²

R¹, R², R³ = H, Me.

Allylbenzene reacts with mercury acetate under analogous conditions. subsequent demercuration of compound **69** leads to 2-methoxy-1-phenylpropane.⁶²

The presence of the allyl group in the molecule of the quinone **70** made it possible to carry out the conjugate mercuration reaction with mercury acetate in methanol,⁶³ which led to the formation of the organomercury compound **71**.

The mechanism of the mercuration of the C=C bond has been investigated⁶⁴ in relation to the methoxymercuration of ethene by mercury acetate in MeOH and the hydroxymercuration of 2-methylpropene by mercury perchlorate in water.

It was established that both reactions take place stereoselectively and that the addition of mercury to the C=C bonds proceeds *via* the formation of the intermediate **A** and its elimination proceeds *via* the intermediate **B**.

The protolysis of compound **72** is accompanied by the formation of the initial ethene, whilst the protolysis of

$\text{HOCH}_2\text{CH}_2\text{HgClO}_4$ is accompanied by hydride transfer with formation of acetaldehyde.⁶⁴

The protolysis of compound **73** in the presence of carboxylic acid salts leads to Bu^tOH .⁶⁴

The nitratomercuration of a series of alkenes *via* the addition of mercury nitrate to the latter in methylene chloride at 0 °C has been achieved.⁶⁵ The reactions take place stereospecifically and, depending on the structures of the groups R and R', the *trans*- or *cis*-adducts **74a–c** are formed in ~100% yield. On treatment of the freshly prepared adducts **74** with bromine at 0 °C, HgNO_3 is substituted by the halogen.⁶⁵

R = Bu, R' = H (**a**); R = C_6H_{11} , R' = H (**b**); R = R' = Et (**c**);

R, R' = ,  (**d**).

The interaction of nonconjugated dienes **75** with mercury nitrate and 80% hydrogen peroxide in CH_2Cl_2 at 20 °C followed by treatment with KCl or KBr leads to unstable mercurated hydroperoxides **76**, which are readily reduced by NaBH_4 to the cyclic peroxides **77a–c** in 64%–77% yields.⁶⁶

R = R' = H (**a**); R = R' = Me (**b**); R = H, R' = Me (**c**).

The monoalkenes **78a–j** interact with an equimolar amount of mercury acetate in 30% aqueous H_2O_2 and are converted on subsequent treatment with KBr into the mercurated hydroperoxides **79a–j** and the alcohols **80a–j**.^{67, 68}

$\text{R}^2 = \text{R}^3 = \text{H}$: R¹ = Ph (**a**), 2-MeC₆H₄, (**b**), 4-MeC₆H₄, (**c**),

4-MeOC₆H₄, (**d**), Bu, (**e**);

R¹ = Ph, R² = Me, R³ = H (**f**); R¹ = H, R² + R³ = (CH₂)₄ (**j**).

The yields of compounds **79** and **80** and their ratio depend on the nature of the alkene **78**. Thus the arylalkenes **78a–d** or the geminally substituted alkenes **78f** form only the corresponding hydroperoxides **79** in ~90% yield. Monoalkyl- or 1,2-dialkylalkenes afford mixtures of compounds **79** and **80** in low yields.⁶⁷ The reductive demercuration of compound **79** with sodium tetrahydroborate results in the formation of the alkylhydroperoxides **81a–j**⁶⁸ and not cyclic peroxides as in the case of compounds **77**. In contrast to the alkenes **78**, the interaction of

(*Z*)- or (*E*)-but-2-ene with $\text{Hg}(\text{OAc})_2$ in 30% H_2O_2 leads to the more complex mixture of reaction products **82–84**.⁶⁷

The reaction involving the acetoxymercuration of isomeric methylenecyclopropanes (methylenespiropentane **85** and bicyclopropylidene **86**) has been investigated.⁶⁹ The main reaction path is the formation of the adducts **87** and **88** respectively at the double bonds with retention of the three-membered ring. However, this is accompanied, albeit to only a slight extent, by the competitive addition to the C–C bond of cyclopropane with formation of compounds **89** and **90**.

The stereoselectivity of the reaction of mercury acetate with dimethylbicyclo[2.2.2]oct-5-ene-2,3-*cis*-endo-dicarboxylate in acetic acid has been studied.⁷⁰ Several reaction products (compounds **91**, **92**, and **93**) were isolated in proportions of 11:4:5 respectively.

The formation of the unsaturated organomercury compound **93** in this reaction is due to the characteristic features of the structure of the intermediate, which in reactions of this type has the structure of a β -mercury-substituted carbonium ion.⁷⁰ The results obtained indicate severe steric requirements for the approach of the mercurating agent to the double bond of the initial compound while the coordination interaction of the carboxylate groups and the mercury atom plays a less significant role in this instance.⁷⁰

It has been established by ¹H, ¹³C, and ¹⁹⁹Hg NMR method⁷¹ that, in the interaction of mercury salts with bicyclo[2.2.2]octa-2,5-diene **94** in methanol, the main reaction path involves the formation of products with the *endo*-disposition of the mercury atom (the ratio of the adducts is 34:58:8).

X = Cl, OAc.

The regioselectivity and stereospecificity of the reactions of mercury salts with dimethylbicyclo[2.2.2]octa-2,5-diene-2,3-dicarboxylate (**95**) in various solvents have also been investigated.⁷² The reagents employed were mercury acetate in MeOH or AcOH, mercury nitrate, and the $\text{Hg}(\text{OAc})_2\text{--NaN}_3$ (1:3) system in methanol. The products were isolated after treating the reaction mixture with an aqueous solution of NaCl.

In contrast to the mercuration of the diene **94**,⁷¹ in the mercuration of the diene **95** with mercury acetate and nitrate in methanol the dominant path becomes the formation of the *trans*-solvatoadduct **96** with the *exo*-disposition of the Hg atom.⁷²

Compounds **96**, **97**, and **98** in proportions of 66:21:13 are formed in the reaction with mercury acetate.⁷²

The use of mercury nitrate as the reactant leads to the solvatoadducts **96** and **97**, the content of compound **96** in the reaction mixture increasing to 77%.⁷² When the reaction with mercury acetate is carried out in AcOH or with the Hg(OAc)₂–NaN₃ system in methanol, the *endo*-products **98** and **99** are mainly formed in ~70% yield.

The regioselectivity and stereochemistry of the mercuration of the tricyclic diene **100** and triene **101** by a mixture of Hg(OAc)₂ and NaN₃ followed by the addition of NaCl to the reaction mixture have been investigated in a series of studies.^{73–81}

It was established that⁷³ the interaction of the diene **100** with mercury acetate in acetic acid results in the formation of the *trans*-solvatoadduct **102** with the *endo*-disposition of the mercury atom.

Different stereochemistry and regiochemistry were observed in the reaction of the diene **100** with the Hg(OAc)₂–NaN₃ mixture. Depending on the reactant ratio, only the *exo*-(*cis*-adduct) **103** (for the ratios 1:1:3) or a mixture of the *exo*-(*cis*-adduct) **103** and the *endo*-(*cis*-adduct) **104** (for the ratios 1:1:1) is formed,^{74–76} with the isomer **103** predominating.

When the reaction of the triene **101** is carried out in acetic acid, the mercury salt adds preferentially to the double bond of the cyclohexadiene fragment with formation of the *endo*-(*cis*-adduct) **105**. However, in methanol the double bond of the four-membered ring is involved in the reaction with mercury nitrate and *endo*-(*trans*-isomer) **106** is formed as the main product.^{77,78}

The study of the regiochemistry and stereochemistry of the azidomercuration of the triene **101** showed that the double bond of the cyclohexadiene fragment is involved preferentially in the reaction with formation of the *endo*-(*cis*-adduct) **107**; the attack on the four-membered ring proceeds from the sterically less accessible side and also involves the formation of the *endo*-(*cis*-isomer) **108**.⁷⁹

Such unusual regiochemistry in the conjugate mercuration of the diene **100** and the triene **101** may be due to the coordination interaction between the mercury salt and the sterically close double bonds⁸⁰ or, in more general terms, between the mercury salt and suitable functional groups of the substrate.⁸¹

This has been recently confirmed by a study⁸² in which the possibility of the formation of a complex in the HgCl₂–bicyclo[2.2.2]octa-2,5-diene **94** system in acetonitrile was investigated by ¹⁹⁹Hg NMR. It was established that, for a series of solutions with a constant concentration of the mercury salt and a variable concentration of the diene, a pronounced downfield shift of the ¹⁹⁹Hg resonance signal is observed, which indicates the formation of a complex, probably having the structure **109**.

[94]/[HgCl ₂]	1.25	1.5	2.0	2.5	3.0	5.0
Δδ(¹⁹⁹ Hg) /ppm	11.88	14.85	18.20	21.80	25.61	43.56

On the basis of the data obtained and using the conditions for the validity of the δ(¹⁹⁹Hg)^{–1}–[**94**] linear equation,^{83,84} the complex formation constant *K_f* and the relative chemical shift in the ¹⁹⁹Hg NMR spectrum for complex **109** were found by the method of least squares.⁸² These quantities proved to be 0.55–0.08 and 186±26 ppm respectively.

Apart from the azidomercuration reactions leading to the simultaneous formation of C–Hg and C–N bonds, aminomercuration, reactions, which result in the formation of bonds of the same type, have been described.^{85,86} The conditions for the direct amination of the alkenes **110a–d** by treatment with aniline and mercury acetate in an aqueous medium with the intermediate formation of the aminomercuration products **111a–d** have been elucidated.⁸⁵ Subsequent reduction of compounds **111** with NaBH₄ in an alkaline medium leads to the amines **112a–d**.

R¹ = R² = R³ = H (**a**); R¹ = Me, R² = R³ = H (**b**);
R¹ = R² = Me, R³ = H (**c**); R¹ = R² = R³ = Me (**d**).

The reactions of the methyl esters of unsaturated acids with Hg(OAc)₂ and ArNHR led to the synthesis of the corresponding α-mercured esters, which were then reduced with NaBH₄ in an alkaline medium to the methyl esters of the corresponding β-aminoacids.⁸⁶

R¹ = R² = H; R¹ = R² = Me; Ar = Ph, 4-MeC₆H₄, 4-ClC₆H₄; R³ = H, Me.

Organomercury reagents, which had been rarely used previously^{3,6,7} for the conjugate mercuration of alkenes, have been employed for this purpose in recent years.^{87,88} Nevertheless, these reactions should be regarded as a convenient method of synthesis of asymmetric OMC.

The mercuration of styrene and cyclohexene by polyfluoroalkylmercury salts with participation of MeOH and HNMe₂ as nucleophiles has been investigated.⁸⁷ It was established that conjugate addition takes place in accordance with the Markovnikov rule with formation of the asymmetric OMC **113** in 24%–65% yields.

$R^1 = H$, $R^2 = Ph$; $R^1 + R^2 = (CH_2)_4$; $R^3 = CF_3$, C_3F_7 ; $B = OMe$, NMe_2 .

In the case of perfluoropropene in the presence of caesium fluoride in DMF, asymmetric fully substituted OMC with a perfluorinated substituent were obtained.⁸⁸

$R = Ph$, C_6Me_5 , $Ph_2C=CH$, 1,2,4,5-Me₄C₆HgOCOCF₃.

New aspects of the addition of mercury salts to a C=C double bond in various substrates have been investigated in a recently published series of studies.^{43,89–93} In particular, the regiochemistry and stereochemistry of the reaction involving the addition of mercury salts to benzobarrelene and tetrafluorobenzobarrelene in acetic acid and methanol have been investigated⁴³ and the influence of the structure of the substrate on the regiochemistry of the reaction has been examined. It follows from the data obtained⁴³ that the reaction products are formed as a result of the attack by the mercury salt on the double bond of the cyclohexadiene fragment both from the side of the arene ring and from the side of the bridging ethylene group. It is postulated here that the regiochemistry of the mercuration reaction is determined by the 'reagent–substrate' interaction and, in relation to the dienes indicated above, it may occur in two ways: the reagent–two double bonds of the cyclohexadiene fragments (**A**) and the reagent–double bond of the cyclohexadiene fragment–benzene ring (**B**).

$R = H$, F ; $X = OAc$, N_3 .

According to the authors,⁴³ the preferential formation of the transition state **A** is characteristic of the reactions investigated. This suggests that the system of two skeletal double bonds exhibits more marked chelating properties relative to the mercury atom than the double bond–arene fragment system.

It has been established⁸⁹ that the regiochemistry of the mercuration reaction of bornylene **114** depends on the nature of the mercuring agent and the solvent.

It is important to note that the ratio of the regioisomeric adducts in the reaction of bornylene **114** with mercury azide is reversed when bornylene interacts with mercury acetate. According to Sokolova *et al.*,⁸⁹ this is due to the occurrence of the reactions *via* different mechanisms. The regiochemical data provide grounds for the hypothesis that mercury azide adds to bornylene **114** in accordance with a concerted mechanism *via* the transition states **C** and **D**. The transition state **C** is preferred in view of the smaller steric hindrance.

$X = OAc$, $OCOEt$, N_3 ; $R = Me$, Et .

On the basis of the ratio of the regioisomers in the reaction of bornylene **114** with mercury acetate in alcohols and acetic acid, Sokolova *et al.*⁸⁹ suggested that the mercurenum intermediate **E** is formed in the reactions with mercury acetate and propionate and is then converted into the above reaction products.

$X = OAc$, $OCOEt$.

The preferential formation of the reaction products as a result of attack by the nucleophile on the 3-position, for which the steric factor is less important, is possible precisely for this mechanism.

The kinetics of the mercuration of bornylene⁹⁰ and cyclohexene⁹¹ have been investigated in various solvents (H_2O – $MeCN$, $MeOH$, $EtOH$, $PrOH$, $AcOH$) in the presence of sodium acetate and lithium perchlorate. The introduction of NaOAc into the mixture reduces sharply the rate of addition of mercury acetate to compound **114** and cyclohexene in alcohols. The formation of acetoxy-adducts then becomes the main path in the mercuration of compound **114** while the content of solvato-adducts falls from 76% (in the absence of NaOAc) to 19% (in 4×10^{-4} M NaOAc).⁹¹ A reaction mechanism with participation of ion pairs and a solvated mercurenum ion as intermediates has been proposed^{90,91} and confirmed by the method of stationary concentrations.

According to Kartashov *et al.*,⁹¹ the influence of NaOAc on the rate of formation of the reaction products is manifested *via* the common ion effect ($X = OAc$).

The reaction of mercury acetate with bornylene **114** has been investigated⁹² in the THF– H_2O and $MeCN$ – H_2O mixed solvents (75:25 by volume) and the influence of the addition of NaOAc on the rate of reaction and the composition of the products was studied. It was established that the addition of NaOAc to the $MeCN$ – H_2O mixture diminishes the amount of the rearranged product **115** and alters radically the ratio of the regioisomeric solvato-adducts **116a,b** and **117a,b**, stimulating the formation of the products of the addition of $Hg(OAc)_2$ to the bornylene double bond.

R = H (a), Ac (b).

It is believed⁹² that the reaction of mercury acetate with bornylene **114** proceeds with participation of the ion pair **F** and the free mercuronium ion **G**, but these intermediates have different structures.

The considerable amount of the rearranged product **115** and the preferential formation of the solvato-adduct **116a** (in the absence of added NaOAc) give grounds for the assumption that the mercuronium ion **G** has the asymmetric structure **H**.⁹² When NaOAc is added, whereupon the reaction proceeds *via* the ion pair **F**, the preferential formation of the solvato-adduct **117a** and the appreciable inhibition of the Wagner–Meerwein rearrangement, leading to the product **115**, can apparently be explained by the more symmetrical structure of the cationic fragment **I** in the ion pair **F**.

The steric hindrance generated by the methyl group in the 1-position of the intermediate **I** to the approach of the nucleophile (OR) promotes the addition of the nucleophile ($-\text{OR}$) to the more accessible C(3) atom with the preferential formation of the product **117a**.⁹²

The kinetics of the addition of Hg(OAc)_2 to strained and unstrained alkenes have been investigated in MeOH in the presence of NaOAc.⁹³ The phenomenon of the salt effect led to the conclusion that, in the reactions with unstrained alkenes derived from allyl, cyclopentene, and cyclohexene, the reactant is the $^+\text{HgOAc}$ ion. In the case of strained alkenes such as compounds **118**–**120**, the reactant is Hg(OAc)_2 .

On the basis of these investigations, the mechanisms of the reaction involving the solvatomercuration of alkenes having different structures have been proposed.⁹³

The reactions involving the addition of a new mercury salt — mercury dinitroamidate (MDNA) **121** — to alkenes such as ethene, propene, *cis*- and *trans*-but-2-enes, and norbornene have been studied recently.⁹⁴ In most cases, water, methanol, and diethyl ether were used as the solvent.

When ethene is passed into an aqueous MDNA solution for 5 h, the mercury-containing derivative of diethyl ether is precipitated in 51% yield.

When an aqueous solution of MDNA is acted upon by propene, a product with an unknown structure, soluble in water and the usual organic solvents, is precipitated.

The addition of MDNA to *cis*- and *trans*-butenes in water leads, as in the case of ethene, to the corresponding dimercurated ethers **122** and, depending on the structure of the alkenes, different adducts are formed, which the authors⁹⁴ believe to be the *threo*- and *erythro*-isomers.

The product of the addition of MDNA to cyclohexene in water is also, according to IR spectroscopic data, a mercurio-derivative of the corresponding ether **123**.⁹⁴

It was found that, when MeOH is used in the above reactions, the competition for the intermediate mercuronium cation is won not by $-\text{OMe}$ but by $-\text{N}(\text{NO}_2)_2$.⁹⁴ As a result, *N,N*-dinitro- β -dinitramidemercurioethylamine is formed in 95% yield and the product of the conjugate methoxymercuration — 1-methoxy-2-dinitramidemercurioethane is formed in only 5% yield as a result of the interaction of ethene with MDNA in methanol.

The conjugate mercuration involving the use of MDNA is extremely sensitive not only to the nature of the solvent but also to the structure of the alkene.⁹⁴ Thus the ratio of the products of the addition of MDNA to alkenes in methanol changes significantly on passing from ethene to its alkyl derivatives. According to ^1H NMR spectroscopic data, in the case of propenes the methoxymercuration products predominate over the corresponding *N,N*-dinitramidemercuration products, while in the case of but-2-enes only the methoxymercuration products are formed.

The addition of MDNA to norbornene in MeOH takes place with formation of only the methoxymercuration product having the *exo*-(*cis*-structure).⁹⁴

As a result of the addition of Hg(OAc)_2 to the double bond in the oximes **124** containing γ - or δ -alkenyl substituents, the intermediate compounds cyclize to the corresponding cyclic nitrones **125**. The latter react *in situ* with *N*-methylmaleimide (THF, 60 °C), forming the mercurated cyclic adducts **126** as a mixture of the *endo*- and *exo*-isomers.⁹⁵

$n = 1, 2$.

The addition of mercury salts HgX_2 to the $\text{C}=\text{P}$ double bond present in stable triphenylphosphonium ylides led to the formation of the corresponding salt-like adducts **127**, which are dimeric according to X-ray diffraction data.⁹⁶

$\text{X} = \text{Cl}, \text{I}$.

V. Addition of mercury salts to a $\text{C}\equiv\text{C}$ bond

This is one of the most general and universal methods of synthesis of unsaturated organomercury substances, which are of considerable scientific interest, for example for the study of stereochemical problems in organometallic chemistry.^{3,6} During the last 10–15 years, the studies on these lines have continued. Thus, the reaction of methylethyne **128** with the complex $\text{HgCl}_2 \cdot \text{HCl}$ has been investigated.⁹⁷ It was shown that the absorption of compound **128** at the freezing point of the $\text{H}_2\text{O}-\text{HCl}-\text{HgCl}_2$ system leads to (*E*)-1-chloromercurio-2-chloropropene **129**, which proved to be relatively unstable in air.

The reaction of compound **129** with a dilute hydrochloric acid solution leads to 2-chloropropene, the initial $\text{MeC}\equiv\text{CH}$, and acetic acid. The last compound is formed on hydration of $\text{MeC}\equiv\text{CH}$ formed from compound **129** as a result of β -elimination.

The interaction of mercury(II) chloride with vinylacetyne affords the *E*-1,2-adduct **130**.⁹⁷

Compound **130** proved to be more stable than compound **129** during storage. However, on treatment with KI it decomposes with formation of the initial vinylacetyne while treatment with HCl converts it into 2-chlorobuta-1,3-diene.⁹⁷

The conjugate alkoxymercuration of 2-methylbut-1-en-3-yne **131** by mercury acetate in various media has been studied.⁹⁸ A mixture of the products **132–134** is formed in alcohols, whilst in acid the sole product is compound **135** (Scheme 3).

The adducts **132–135** are readily reduced by NaBH_4 with formation of the corresponding unsaturated compounds.⁹⁸

The *E,Z*-stereochemistry of the addition of mercury salts to acetylenic hydrocarbons has been studied in a series of investigations.^{99–101} The reaction of methylphenylethyne with mercury acetate in acetic acid gives rise to a mixture of the isomers **136** and **137**, the reaction with mercury trifluoroacetate affords the three isomers **136–138** whilst that with $\text{Hg}(\text{OAc})_2$ in methanol results in the formation of only one product — (*Z*)-2-chloromercurio-1-methoxy-1-phenylprop-1-ene (**139**).⁹⁹

The protodemercuration of the alkene **136** in aqueous HCl solution yields the ketone **140**, whilst that of the alkenes **137–139** leads to the ketone **141**. The ketones were identified by gas–liquid chromatography.⁹⁹

The study of the stereochemistry of the reaction of methylphenylethyne with $\text{Hg}(\text{OCOR})_2$ in acetic and propionic acids showed¹⁰⁰ that the composition of the reaction product is

Scheme 3

$\text{R} = \text{Me}, \text{Et}$.

determined by the reactant ratio. When the reactant ratio is 2 : 1 (with R = Me), only the *E*-isomers **142** and **143** are formed in proportions of 3 : 2. For a reactant ratio of 1 : 1, the *Z*-isomer **144** is formed in addition to the reaction products **142** and **143** (in proportions of 86 : 8 : 6). When the ratio of the initial reactants is 1 : 2, the yield of the *Z*-isomer **144** increases and reaches 15%.

R = Me, Et.

The reaction of diphenylethyne with mercury acetate in acetic acid leads only to the *E*-adduct $\text{ClHg}-\text{C}(\text{Ph})=\text{C}(\text{Ph})-\text{OAc}$.¹⁰¹

A study of the reactions of diphenylethyne with mercury salts in alcohols (R = Me, Et, Prⁱ) established^{102, 103} that mercury acetate reacts with diphenylethyne in methanol and ethanol to form the corresponding (β-alkoxyvinyl)mercurio-adducts as a mixture of the *Z*- and *E*-isomers. Mercury trifluoroacetate reacts with diphenylethyne in ethanol and propan-2-ol with a high degree of stereoselectivity, forming the *Z*-isomers, the structure of which has been established by X-ray diffraction.

Contrary to the data of Bassetti *et al.*,¹⁰³ Kartashov *et al.*¹⁰⁴ established that the main product of the reaction of mercury acetate with diphenylethyne in methanol is a compound which contains no double bond, namely 1,1-di(chloromercurio)-2,2-dimethoxy-1,2-diphenylethane (**145**), which can be partly converted into (*Z*)-1-chloromercurio-2-methoxy-1,2-diphenylethane (**146**) under the reaction conditions (20 °C, 24 h).

The reactions of arylphenylethyne **147** with mercury acetate in methanol and acetic acid have been studied.¹⁰⁵ The reaction in methanol has an unusual regiochemistry as a result of the addition of the electrophilic fragment $^+\text{HgOAc}$ to the carbon atom to which the substituted phenyl group is attached. The reaction product is the saturated compound **148**.

R = 4-Me, 4-OMe.

In acetic acid, the reaction proceeds with formation of the *E*-adducts **149**.¹⁰⁵

The kinetics of the reactions have also been investigated and the kinetic data have been analysed.¹⁰⁵ The influence of the addition of sodium acetate on the rate of formation and structure of the products **148** and **149** has been determined for the reaction in methanol. It was shown that the addition of NaOAc diminishes the rate of reaction, which becomes a minimum at a salt concentration of 3.0×10^{-3} M. For the reaction in acetic acid at the same

NaOAc concentration, no decrease in rate was observed.¹⁰⁵ This can probably be accounted for by the characteristic features of the methoxymercuration of acetylenic compounds for which we believe that the same general mechanism of conjugate mercuration is valid as for alkenes,^{91–93} examined in detail in the previous section.

In acetic acid, the only intermediate is apparently the ion pair **J**, which dissociates in methanol to the anion ^-OAc and the cation **K**. In the case of the ion pair **J**, the triple bond is only slightly loosened and the positive charge is mainly concentrated on the mercury atom. In methanol, the ion pair **J** is converted into the cation **K** more rapidly than into the corresponding reaction products, but at the limiting sodium acetate concentrations the reaction probably proceeds preferentially *via* the ion pair **J** (as in acetic acid), which, being less reactive than the cation **K**, is converted more slowly into adducts and solvato-adducts.

The unusual regiochemistry of compounds **148** can be explained by assuming that the free mercuronium ion **K** has an asymmetric structure, as in reactions with alkenes.⁹² In this case, a complex may be formed between the electrophilic fragment of the intermediate **L** and the benzene ring with its higher electron density, the π-complex being subsequently converted into the products **148**.¹⁰⁵

The interaction of equimolar amounts of 1,2-dialkylbut-3-yne-1,2-diols with mercury(II) chloride in alcohol leads to the corresponding derivatives of the mercurated furan **150** in high yields.¹⁰⁶

Other reactions of functionally substituted ethynes with mercury salts are also of interest. Thus the interaction of the ketones **151** or alcohols **152** containing a triple bond, with mercury acetate in acetic acid leads¹⁰⁷ only to the *E*-adducts **153** and **154**, which afford the corresponding 5-(4-R-phenyl)-3-phenylpyrazoles on interaction with hydrazine hydrate.

The addition of amines to compound **131** in the presence of mercury acetate has been investigated.¹⁰⁸ It has been suggested that the reaction results in conjugate aminomercuration of the enyne **131** with formation of conjugate organomercuriodienes **155**.

$\text{R} = \text{R}' = \text{Me}, \text{Et}; \text{R} + \text{R}' = (\text{CH}_2)_5, (\text{CH}_2)_2\text{O}(\text{CH}_2)_2.$

The demercuration of the adducts **155** with NaBH_4 in an alkaline medium leads to alkenylamines and aminoalcohols¹⁰⁸ which are difficult to obtain by other methods.

The thiocyanatomercuration products **157** have been obtained by the interaction of ethyne and its derivatives **156** with mercury salts HgX_2 in the presence of the thiocyanate anion.^{109,110} These compounds are formed regioselectively (in accordance with the Markovnikov rule) and stereospecifically (*E*-isomer).

$\text{R} = \text{R}' = \text{H}; \text{R} = \text{Bu}, \text{R}' = \text{H}; \text{R} = \text{OAc}, \text{R}' = \text{H}; \text{R} = \text{R}' = \text{Et};$

$\text{X} = \text{Cl}, \text{SCN}.$

The HgX group is readily substituted by hydrogen with retention of configuration on treatment of compound **157** with strong acids (H_2SO_4 , HBF_4) and NaBH_4 . It is also readily substituted by the halogens on treatment with iodine and bromine in pyridine or with CuCl_2 in acetonitrile.¹⁰⁹

VI. Mercuration of aromatic compounds

Many aromatic compounds (benzenoid and nonbenzenoid) are capable of entering into the mercuration reaction with divalent mercury salts, which leads to aryl-substituted OMC. The applicability of this reaction is very wide.

Many new examples of the mercuration reactions of aromatic compounds have been described during the last 15 years, which indicates that the studies on these lines are of current interest. Thus the mercuration of polyfluorobenzene derivatives with a mixture of mercury trifluoroacetate and fluorosulfonic acid in proportions of 1 : 2 has been achieved.¹¹¹

$\text{Ar} = \text{C}_6\text{F}_5, 4\text{-MeC}_6\text{F}_4, \text{C}_6\text{F}_4\text{H}, 3\text{-NO}_2\text{C}_6\text{F}_4, 3\text{-BrC}_6\text{F}_4, 4\text{-HOC}_6\text{F}_4, 4\text{-NH}_2\text{C}_6\text{F}_4, 3\text{-HOCC}_6\text{F}_4, 4\text{-MeOC}_6\text{F}_4.$

A mixture of organomercury polymers has been obtained by the mercuration of 1,2,4-trichlorobenzene (**158**) on heating with an excess of mercury trifluoroacetate. The individual OMC **159–162** were isolated from this mixture by extraction with benzene or xylene.¹¹²

The position of the mercuritrifluoroacetate group in compounds **159–162** was determined by their reaction with iodine. Treatment of compound **158** with mercury trifluoroacetate while refluxing in CF_3COOH leads to a regiospecific reaction, which results in the formation of compound **163**. On refluxing in an excess of the chloride **158**, compound **163** isomerises to compound **160** with its subsequent symmetrisation to compound **162**.¹¹² The structures of the above OMC were demonstrated by their independent synthesis *via* organolithium compounds or by the Nesmeyanov reaction.¹¹²

Other benzene derivatives (with both electron-donating and electron-accepting substituents) are readily mercured on heating with a mixture of HgO and CF_3COOH forming the OMC **164** and **165**.¹¹³ The mercuration reaction then obeys the usual rules^{3,7} governing the direction of electrophilic substitution.

$\text{R} = \text{H}, \text{R}' = \text{COOH}; \text{R} = \text{Me}, \text{R}' = \text{COOH}; \text{R} = \text{Me}, \text{R}' = \text{Cl}.$

3,4,5-Trimethoxybenzoic acid is also comparatively readily mercured by mercury acetate with formation of 2-chloromercurio-3,4,5-trimethoxybenzoic acid, which is converted into the polymeric OMC **166** on treatment with sodium carbonate in acetone.¹¹⁴

The interaction of benzene and its derivatives^{115,116} with a mixture of mercury oxide and trichloroacetic acid on heating (60–70 °C) leads to 90%–100% yields of the corresponding mercuration products:

$\text{Ar} = \text{Ph}, 4\text{-MeC}_6\text{H}_4.$

The mercuring capacity of mercury dinitroamidate **121** in relation to a series of aromatic compounds has been investigated.⁹⁴ It was established that benzene is not mercured by an ethereal solution of MDNA, since on prolonged refluxing of MDNA with benzene the decomposition of the mercury salt is faster than the mercuration reaction. However, refluxing of an aqueous solution of MDNA with benzene for 2 h leads to the product of monomercuration in the benzene ring (in 55% yield).⁹⁴ The more nucleophilic 1,2,4,5-tetramethylbenzene is readily mercured on refluxing in a methanol solution of MDNA. This reaction proceeds even in ether at room temperature.⁹⁴

R = H, Me.

The mercuration of aniline in the *para*-position and of *N,N*-dimethylaniline with the aid of MDNA in alcoholic solution takes place very readily (in several minutes⁹⁴).

R = H, Me.

The mercuration of a large series of sulfanilamide preparations by heating them with HgO in acetic acid has been achieved.¹¹⁷ Dimercurated compounds were then obtained.

R = H, C(=NH)NH₂, , , .

3-Acetoxymercurio- and 3-chloromercurio-5-nitrosalicylaldehydes have been synthesised by mercurating 5-nitrosalicylaldehyde with mercury acetate.¹¹⁸ It has been suggested that these OMC be used for the simultaneous introduction of mercury and pH-sensitive functional groups into proteins which do not contain thiol groups in order to investigate their structure.¹¹⁸

With the aim of synthesising mercury-containing reagents for the determination of carbonyl groups in biochemical research, *O*-substituted hydroxylamine, which makes it possible to introduce aminoxy-groups into proteins under mild conditions, was mercurated.¹¹⁹

In order to obtain radiopharmaceutical preparations labelled with radioactive iodine (¹²³I), 15-(4-iodophenyl)pentadecanoic acid was synthesised by mercurating 15-phenylpentadecanoic acid with mercury trifluoroacetate and subsequent treatment with radioactive iodine.¹²⁰

The mercuration of benzylideneazine with HgO in glacial acetic acid at 37–39 °C for 3 h leads to polymercured compounds which are insoluble in many solvents and decompose at 200 °C without melting.¹²¹

n = 2–5.

In contrast to this, arene azomethines interact with mercury acetate in alcohols (MeOH, EtOH) to form the corresponding products of *ortho*-mercuration in the *N*-substituted benzene ring in 80%–92% yields.¹²²

R = H, Me, OMe, Cl, Br, I; R' = OMe, NO₂.

It follows from MINDO calculations of the regioselectivity of the mercuration of *N*-benzylideneaniline, *N*-benzylidene-2-toluidine, and 2-methoxy-*N*-(4-nitrobenzylidene)aniline that the electron density in the *N*-substituted benzene ring in the stable conformation is higher¹²³ and mercuration in this fragment takes place preferentially.¹²²

The mercuration of aromatic azo-compounds by mercury acetate or trifluoroacetate on refluxing in methanol leads only to monomercured compounds.^{124, 125}

R = Me, NO₂, COOH;

Ar = 2,4-(HO)₂C₆H₃, 3,4,5-(HO)₃C₆H₂, α-C₁₀H₇, β-C₁₀H₇;

R = Bu, C₁₀H₂₁, OBu, OC₈H₁₇; X = OAc, OCOCF₃.

In order to enhance the fungicidal and bactericidal activities of potential pesticides, a series of heterocyclic compounds have been mercurated by mercury acetate in acetic acid.^{126–130} Mercury then substitutes a hydrogen atom in the benzene ring linked to the nitrogen atom of the heterocycle or to the nitrogen atom of the amino-group in the *para*- (if it is free) or *ortho*-position. Depending on the reactant ratio, mono- and di-mercurated derivatives are formed.

R = H, Br; n = 1, 2.¹²⁶

R¹ = Me, R² = Et; R¹ = R² = Me;

R³ = H, Hal, Me, OMe, NO₂, COOH.¹²⁷

R, R' = H, Alk, Hal, NO₂, COOH, OH, C₁₀H₇.^{128–130}

The mercuration of 2-phenylpyridine, benzo[*h*]quinoline, 1-phenylpyrazole, 3,4,5-trimethyl-1-phenylpyrazole, bis(pyrazol-1-yl)methane, and 1,2-[bis(pyrazol-1-yl)]ethane by mercury acetate in alcohol afforded the corresponding OMC **167**–**171a,b** in 50%–90% yield.^{131, 132}

X = OAc, Cl.

It is difficult to deduce any kind of rules from the above data.^{131, 132} However, we may note that, as in previous studies,^{126–130} in the presence of aryl and heteroaryl fragments in the molecule, mercuration takes place in the benzene ring (regardless of the nature of the substituent in the latter) and does not involve the heterocyclic ring. Only in the absence of an activated benzene ring in the structure of the mercured compound does mercuration take place in the heterocycle (with formation of compounds **169** and **171a,b**). We may note that, as for the majority of pyrazoles entering into S_E reactions, the mode of substitution is determined predominantly by the pyridine nitrogen atom (this can be seen from the study of the mercuration products).

Comparison of the data in Refs 126–130 and in Refs 131 and 132 shows that in the case of compounds **167**, **168**, and **170** the formation of *para*-isomers is not observed at all, whereas Mahapatra and coworkers^{126–130} noted their predominant formation.

A special study by the EPR method demonstrated that, in the interaction of mercury trifluoroacetate with certain arenes (acenaphthene, anthracene, biphenyl, *p*-terphenyl, pyracene, hexahydopyracene, and triptycene) in trifluoroacetic acid, type **M** radical-ions are formed initially, which is followed by the effective mercuration of the arenes listed above. The following mechanism of the mercuration of benzenoid aromatic systems with the aid of mercury trifluoroacetate, which includes the generally known^{3, 7} stages involving the formation of π - and σ -complexes in the corresponding S_E reactions, has been proposed¹³³ on this basis.

Thus the data presented above have shown that aromatic electrophilic mercuration reactions can have, in principle, an oxidation-reduction stage. However, this conclusion is apparently valid only for the most reactive aromatic hydrocarbons¹³³ and electrophiles with sufficiently marked oxidising properties.

Heterocyclic compounds containing π -electron-excess systems are also readily mercured by mercury salts.³ In particular, 3-phenylsydnone is mercured by mercury(II) chloride or acetate in methanol.¹³⁴ Depending on the reaction conditions and the

reactant ratio, the fully substituted OMC **172** or 4-acetoxymercuro-3-phenylsydnone **173** are formed.

The sydnone **173** exhibits a high antibacterial activity against *Staphylococcus aureus* and *Escherichia coli*.¹³⁴

Under analogous conditions, the *N*-substituted pyrroles **174** are mercured in the 2-position.¹³⁵ The OMC **175** obtained are readily symmetrised on treatment with NaI in acetone with formation of the OMC **176**, which afford bis(pyrrol-2-yl)-mercury on interaction with alkali.

R = Ac, O₂SPh.

The 1-substituted tetrazoles **177** are smoothly mercured at room temperature by mercury salts in an alkaline medium at a ring carbon atom with formation of the symmetric C-mercuriotetrazoles **178** regardless of the reactant ratio.¹³⁶

R = Me, Ph; X = Br, I, AcO.

In neutral and acid media, the mercuration of the tetrazoles **177** takes place under more severe conditions with formation of either compounds **178** or the 5-acetoxymercuro-derivatives **179** depending on the reactant ratio.¹³⁶

It is of interest that 2-substituted tetrazoles do not enter into similar reactions under the conditions described.¹³⁶

Being largely electron-deficient, six-membered π -electron heterocyclic compounds are mercured with difficulty under severe conditions. Thus the C-mercuration of 2,4-dimethoxypyrimidine by mercury acetate on refluxing in acetic acid with formation of 5-acetoxymercuro-2,4-dimethoxypyrimidine has been described.¹³⁷ Various methods for the direct C-mercuration of pyrimidine derivatives (uracil, 2-thiouracil, *S*-ethyl-2-thiouracil) as well as purine derivative (theobromine) have been investigated.¹³⁸ The following reagents were employed: HgSO₄ + H₂SO₄, Hg(OAc)₂, MgO + CF₃COOH, Hg(OAc)₂ + HClO₄, and Hg(OCOCF₃)₂. It was found that only uracil is effectively mercured, affording 5-chloromercuiouracil in 85% yield after the treatment of the reaction mixture with KCl. In other cases, the mercuration of pyrimidine derivatives results in the formation of a mixture of the C(5)- and N-mercured compounds in low yields.¹³⁸ The mercury-containing heterocycles have been used¹³⁸ for the synthesis of the corresponding iodo-derivative by their treatment with a boiling aqueous KI₃ solution.

The effect of the mercurating system — a 1:1 mixture of mercury acetate with CF_3COOH — on ferrocene has been investigated.¹³⁹ It was established that, for the 1:1:1 ratios of the above reactants in an ether–alcohol mixture at room temperature, ferrocene is smoothly mercurated, giving rise to only the monomercurated product — ferrocenylmercury acetate (yield 86%). Under analogous conditions¹³⁹ but with the 2:2:1 reactant ratios, only the dimercurated product — 1,1'-diacetoxymercurioferrocene — is formed in 67% yield. These compounds are of considerable preparative interest for the synthesis of ferrocene derivatives.

The mercuration of arylferrocenes by treatment with $\text{Hg}(\text{OAc})_2$ in a CH_2Cl_2 – MeOH mixture and subsequent treatment of the reaction mixture with an aqueous solution of LiCl led to a mixture of three isomeric OMC, which were separated chromatographically.¹⁴⁰

$\text{R} = \text{Ph}, 4\text{-MeOC}_6\text{H}_4, 4\text{-ClC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4.$

The mercuration of azomethines of the ferrocene series by mercury acetate has been described.^{141–146} After the addition of LiCl to the reaction mixture, the corresponding 2-chloromercurio-derivatives were isolated in 60%–85% yields in all cases.

$\text{R} = \text{H}, \text{Me}, \text{Ph}; \text{Ar} = 4\text{-MeOC}_6\text{H}_4, 4\text{-MeC}_6\text{H}_4, \text{Ph}, 4\text{-ClC}_6\text{H}_4, 4\text{-BrC}_6\text{H}_4, 4\text{-IC}_6\text{H}_4, 4\text{-NO}_2\text{C}_6\text{H}_4, 3\text{-ClC}_6\text{H}_4, 3\text{-BrC}_6\text{H}_4, 3\text{-NO}_2\text{C}_6\text{H}_4, \alpha\text{-C}_{10}\text{H}_7, \beta\text{-C}_{10}\text{H}_7, 2\text{-ClC}_6\text{H}_4.$

The structures of the substances synthesised were investigated by ^1H and ^{13}C NMR and X-ray diffraction methods.^{141, 144–146} In particular, the study of the ^{13}C NMR spectra for three series of 2-chloromercurioferrocenylimines ($\text{R} = \text{H}, \text{Me}, \text{Ph}$) led to the discovery of a satisfactory linear correlation between the chemical shifts of the carbon atoms in the ferrocenyl fragment and the Hammett constants σ_m and σ_p of the substituents in the arene ring.¹⁴⁵

An intramolecular coordinate bond between the Hg and N atoms (2.087 Å) has been discovered in a series of 2-chloromercurioferrocenylimines on the basis of X-ray diffraction data for the latter. It proved to be shorter by 0.35–0.45 Å than the sum of the van der Waals radii of the nitrogen and mercury atoms.^{141, 144, 146}

$\text{R} = \text{H}, \text{Me}, \text{Ph}; \text{Ar} = \text{Ph}, 4\text{-ClC}_6\text{H}_4.$

Pentakis(acetoxymercurio)pentamethylruthenocene has been obtained in 88% yield by the reaction of pentamethylruthenocene with mercury acetate (molar ratio 1:5) in the 1:1 ethanol–ether mixture.¹⁴⁷ It is halogenated on treatment with KI_3 or KBr_3 with formation of the corresponding pentahalopentamethylruthenocenes. The structures of the compounds have been established by X-ray diffraction.

The direct mercuration of *o*- and *m*-carbaboranes by treatment with HgO in CF_3COOH has been achieved.¹⁴⁸ It leads to the substitution of the hydrogen atom at the boron atom in the 9-position in the carbaborane ring by mercury. The mercuration of the dicarbaboranyl $\text{Fe}(\text{III})$,¹⁴⁹ $\text{Ni}(\text{IV})$, and $\text{Co}(\text{III})$ ¹⁵⁰ complexes takes place in the same position and under the same conditions.

$\text{M} = \text{Fe}, \text{Ni}, \text{Co}.$

1,1-Diarylethenes have an excess π -electron density, as a result of which it is possible to achieve their electrophilic vinylmercuriation on treatment with an equimolar amount of HgX_2 in acetonitrile or an ether–THF mixture with formation of compounds **180**.¹⁵¹

$\text{R} = \text{R}' = \text{H}, \text{Me}, \text{Cl}, \text{MeO}; \text{R} = \text{F}, \text{R}' = \text{MeO};$

$\text{R} = \text{Cl}, \text{R}' = \text{Me}; \text{X} = \text{BF}_4, \text{CF}_3\text{COO}.$

If the reaction is carried out in methanol, then electrophilic substitution and conjugate addition of the mercury salt to the double bond result in the formation of a mixture of the products **180** and **181**, the ratio of which depends on the initial reactant ratio.¹⁵¹

VII. Mercuration of CH acids

Apart from aromatic compounds, compounds with mobile hydrogen atoms, capable of giving rise to a stable carbanion, may be mercurated.¹⁵² The range of such compounds proved to be fairly wide.^{4–7} and it has been increasing continuously in connection with the synthesis of new substances and with the search for new mercurating agents. In particular, the reactions involving the α -mercuration of a large series of CH acids having $\text{pK}_a < 29$ with the aid of $\text{Hg}[\text{N}(\text{SiMe}_3)_2]_2$, have been investigated^{153, 154} which led to the synthesis of the symmetrical fully substituted OMC **182** in 50%–85% yield.³ Heating of compounds **182** with HgCl_2 in water or ethanol affords the corresponding chloromercurio-derivatives **183**.¹⁵³

Weaker CH acids — acetonitrile and pinacoln ($\text{pK}_a > 31$) — could not be made to undergo this reaction.¹⁵³

It has been observed recently⁹⁴ that MDNA readily mercurates compounds with mobile hydrogen atoms such as acetone, acetylacetone, and malonic, nitroacetic, and nitromalonic esters in nonpolar and polar organic solvents, as well as water. The mercuration of acetone and acetylacetone by MDNA at room temperature in ether leads to the substitution of only one hydrogen atom, whilst the mercuration of the nitroacetic and malonic esters under the same conditions affords dimercurated products.⁹⁴

R = Et, Ph; X = OAc, OCOCF₃; n = 1–3.

Y = O, S, NMe; X = OAc, OCOCF₃; n = 1–3.

n = 1–3.

However, the mercuration of 1,2- and 1,4-dimethylpyridinium salts under the same conditions yielded¹⁶⁴ the salts **201** with a Hg–Hg bond, which are stable at room temperature.

X = I, ClO₄, OAc.

We may note that in all the heterocyclic systems enumerated, only the methyl group in the α- or γ-position relative to the heteroatom is mercurated. The mercuration of the alkyl group (Me, Et) linked directly to the ring nitrogen atom has never been observed.

The structures of the salts **195**–**201** have been established^{160–164} by studying their chemical properties and on the basis of the results of elemental analysis, as well as ¹H NMR and IR spectroscopic data. The salts are of preparative interest for the synthesis of functionally substituted salts of heterocyclic cations, because the mercury-containing groups may be comparatively readily substituted by other groups.³

Furthermore, studies on the antimicrobial activities of the α-alkylmercurated pyrylium salts **195** and **196**, the pyridinium salts **200** and **201**, the quinolinium salts **198**, and the benzazolum salts **199** have shown¹⁶⁵ that this group of mercury-containing heterocyclic compounds possesses a striking antimicrobial activity with a wider activity spectrum than the familiar preparations.

Somewhat unusual results have been obtained¹⁶⁶ on mercuration of 2-alkyl-substituted 4,4,5,5-tetramethyl-1,3-dioxolanium salts **202** with mercury acetate or trifluoroacetate. In this case, the 1,3-dioxolane ring is opened in the course of mercuration on refluxing the reactants, which results in a high yield of α-mercurio-substituted carboxylic acids **203**–**205**, the ethyl esters of acetic or trifluoroacetic acid, and pinacol **206**. Depending on the molar reactant ratio, monomercurated (compound **203**), dimercurated (compound **204**), and trimercurated (compound **205**) carboxylic acids are obtained. According to elemental analysis and IR spectra,¹⁶⁶ the YHg group always enters into their compositions regardless of the nature of the mercurating agent (Scheme 4).

Thus the reactions constitute a convenient method of synthesis of α-mercurated carboxylic acids.

Successive treatment of the η⁶-fluorene-η⁵-cyclopentadienyl-iron cation with Bu⁺OK and HgX₂ mercury salts in a 1:1

R = H, Me; Y = ClO₄, BF₄; X = OAc, OCOCF₃.

MeCN–dimethylcellosolve mixture led to the synthesis¹⁶⁷ of the corresponding mercury-containing complexes **207** for the first time. Mono- and di-mercurated compounds **207** are formed in 75%–82% yield depending on the molar reactant ratio.¹⁶⁷

X = OAc, OCOCF₃, Cl; Y = BF₄, PF₆; n = 1, 2; Cp = C₅H₅.

An interesting method for the mercuration of cubanes has been described for 4-cyano-1,1-diisopropylcarbamoylecubane as an example.¹⁶⁸ Successive treatment of the cubane with the lithium–tetramethylpiperidine–MgBr₂ system and then with HgCl₂ leads to the dimercurated cubane **208**.

VIII. Mercuration by organomercury salts and hydroxides

The reactions presented in this section can be regarded as a direct method for the synthesis of asymmetric fully substituted OMC containing different types of Hg–element bonds.

The interaction of the organomercury hydroxides RgOH **209** (R = Ph, CH₂Ph, cyclo-C₆XH₁₁) with the nitriles PhCH(R')CN (R' = H, Et, Ph) has been investigated.¹⁶⁹

Depending on the nature of the group R in the molecule of the hydroxide **209** and the reaction conditions, mixtures of mono-mercurated (compound **210**) and dimercurated (compound **211**)

derivatives or only the dimercurated compounds are formed from phenylacetonitrile.¹⁶⁹ In the presence of small amounts (5%–10%) of KOH, only the dimercurated compounds **211** are obtained.

R = Ph, CH₂Ph.

Cyclohexylmercury hydroxide does not react with PhCH₂CN even in the presence of KOH. When Ph₂CHCN interacts with compound **209**, metallic mercury is liberated and the dimer **212** is formed, while PhCH(Et)CN does not react with compound **209** at all.¹⁶⁹

According to ¹⁹⁹Hg NMR data, compound **210** (R = Ph) is partly symmetrised in solutions in chloroform and pyridine.¹⁶⁹

However, in the solid state it is an individual compound. This is indicated indirectly by the depression of the melting point (by 20–25 °C) of the prepared mixture of compound **210** and HgPh₂. IR and NMR spectroscopic data have shown that compounds **210** and **211** exist mainly as the C-form.¹⁶⁹

Treatment of malonodinitrile with RHgX leads to the formation of only the dimercurated product.¹⁷⁰

R = Ph, CH₂Ph; X = OH, OAc.

The organomercury derivatives **213**, which exists mainly in the C-form, have been obtained by treating the substituted dinitriles RCH(CN)₂ with organomercury hydroxides R'HgOH or acetates R'HgOAc.¹⁷¹

R = Me, Ph; R' = Ph, CH₂Ph.

It is of interest to note that a degenerate exchange reaction, occurring with dissociation of the C–Hg bond, has been observed¹⁷¹ for the phenylmercury derivative of methylmalonodinitrile.¹⁷¹ Nevertheless, the organomercury dinitriles **213** are not symmetrised in solution,¹⁷¹ in contrast to the organomercury derivative of phenylacetonitrile **210** investigated earlier.¹⁶⁹

The organomercury salt CF₃HgOCOCF₃ interacts readily⁸⁸ with unsaturated compounds capable of being deprotonated in an alkaline medium.

R = PhC≡C, Cl₂C=CCl.

The reaction of RHgOMe with hydrogen peroxide in methanol afforded the OMC **214**.¹⁷²

In benzene, diethyl ether, and methylene chloride, compounds **214** interact with an excess of H₂O₂ and are converted into the

hydroperoxides RHgOOH. However, according to IR spectroscopic data,¹⁷² the latter are complexes of the type (RHgO)₂·H₂O₂

A new method of synthesis of fully substituted mercury-containing salts of heterocyclic cations has been described.¹⁷³ Successive treatment of 2- and 4-methylquinolinium (compounds **215** and **216**), 4-methyl-2,6-diphenylpyrylium (compound **217**), and 1,2-dimethylbenzothiazolium (compound **218**) perchlorates with an equimolar amount of a base (EtONa, Bu^tOK, NEt₃) and then with an equimolar amount of organomercury salts RHgX led to the synthesis¹⁷³ of the fully substituted 4-methylenemercury-containing salts of the corresponding heterocyclic cations **219–224** in 61%–83% yield.

Thus the reactions involving the mercuriation of the methylene derivatives of the heterocyclic bases **215a**–**218a** by mercury salts or organomercury reagents presented above make it possible to obtain diverse symmetrical (compounds **221**–**223**) and asymmetric (compounds **219**, **220**, and **224**) fully substituted 2- and 4-methylenemercuro salts of heterocyclic cations. The method is simple to use and is extremely general, and is therefore promising for the synthesis of new OMC.

IX. Other methods of synthesis of organomercury compounds

The interaction of polymethoxybenzoic acids **225** with mercury acetate in proportions of 2:1 proceeds in an unusual manner, leading even under mild conditions (aqueous methanol, 20 °C, 15–90 min) to different decarboxylation products **226**–**228** depending on the molar reactant ratio and the reaction time.¹⁷⁴

$\text{R} = 2,6\text{-(MeO)}_2\text{C}_6\text{H}_3$ (**a**); $2,3,4\text{-(MeO)}_3\text{C}_6\text{H}_2$ (**b**); $2,4,6\text{-(MeO)}_3\text{C}_6\text{H}_3$ (**c**).

The reaction of $\text{Hg}(\text{OAc})_2$ with 2,3-dimethoxybenzoic acid leads to the mercury salt **229**, while in the case of 3,4,5-trimethoxybenzoic acid the reaction does not proceed at all.¹⁷⁴

The azo-coupling reaction of compound **230** with $\text{Hg}(\text{OAc})_2$ proceeds with formation of the products of dimercuriation at the carbon and oxygen atoms (compound **231**).¹⁷⁵

$\text{R} = \text{H}, \text{Me}, \text{NO}_2$.

On the other hand, treatment of compound **230** with HgCl_2 results in the formation of only a 1:1 complex, the structure of which has not been established.¹⁷⁵

The interaction of quinolinic acid with mercury acetate in aqueous acetic acid leads to the formation of mercury pyridine-2,3-dicarboxylate **232**.¹⁷⁶

A 9:1 mixture of 2-carboxylatopyridin-3-ylmercury and 3-carboxylatopyridin-2-ylmercury, which according to the authors have a polymeric structure of type **233** with a C–Hg–O linkage, has been obtained by the decarboxylation of the **232** in DMSO at 190 °C for 1 h.

$n = 2-3$.

The structures of compounds **232** and **233** have been confirmed by IR and ^1H , ^{13}C , and ^{199}Hg NMR spectroscopic data as well as mass-spectrometric data.¹⁷⁶

A method has been developed¹⁷⁷ for the synthesis of bis(acetoxysilylmethyl)mercury compounds **234** in 80%–90% yields. It is based on the photoinitiation reaction of bis(triethylgermyl)mercury with acetoxychloromethylsilanes.

The structure of the mercury compounds **234** has been confirmed by NMR spectroscopic data. It has been noted that $^2J(\text{Hg}-\text{Si})$, $^2J(\text{Hg}-\text{H})$, and $^2J(\text{Hg}-\text{C})$ increase with increase in the number of acetoxyl-groups bound to the silicon atom.¹⁷⁷

When the Si–C bond in aryltrifluorosilanes **235** dissociated on treatment with mercury salts HgX_2 or HgO , asymmetric (compound **236**) and symmetrical (compound **237**) OMC are formed in high yields.¹⁷⁸

$\text{R} = \text{H}, \text{Me}, \text{Cl}, \text{Br}, \text{NO}_2$; $\text{X} = \text{Cl}, \text{Br}, \text{I}, \text{CN}, \text{OAc}$.

It has been noted that electron-donating substituents facilitate the above reactions, whilst electron-accepting ones hinder them. This permits certain conclusions about the reaction mechanism, which can be represented by the following scheme in a general form:⁸

There is no doubt that the more effective stabilisation of the cyclic transition state N as a result of the delocalisation of the positive charge is attained in the case of electron-donating substituents R, which thus promote the formation of the corresponding reaction products **236** and **237**.

Mercury salts HgX and HgO also cleave the Si–C bond in chloromethyltrifluorosilanes F₃SiCH_{3–n}Cl_n (*n* = 1–3) with formation of the corresponding derivatives XHgCH_{3–n}Cl_n or Hg(CH_{3–n}Cl_n)₂ in 18%–30% yields.¹⁷⁸ The replacement of a fluorine atom in organyltrifluorosilanes by an alkyl group hinders the cleavage of the Si–C bond.

A method of synthesis of dimethylmercury by the interaction of methylhydrazine with mercury oxide in diethylether has been described.¹⁷⁹

The interaction of mercury salts with derivatives of thieno[2,3-*d*]pyrimidines **238** has been achieved.¹⁸⁰ It was shown that the solvatomercuration of compound **238** in ethanol or methanol is accompanied by their intramolecular cyclisation with participation of the sulfur atom of the thioureide group, which leads to the formation of the tricyclic system **239** with a mercury-containing substituent.

R¹ = R² = Me; R¹ + R² = (CH₂)₃, (CH₂)₄; R³ = H, COPh; X = Cl, Br.

The structure of the tricyclic system **239** has been confirmed by ¹H NMR and IR spectroscopic data and also by the reaction with bromine, which leads to the bromo-derivatives **240** already known.¹⁸⁰

X. Conclusion

The data examined in the present review show that studies designed to expand the applications of already known methods and to develop new methods of synthesis of organomercury compounds have been prosecuted vigorously in recent years.

This has led to the availability of a wide range of organomercury compounds in which mercury is bound to fragments of diverse organic molecules — aliphatic, carbocyclic, aromatic, heterocyclic, organometallic, *etc.* The range of the possible practical ways of using the mercury-containing compounds obtained is extremely wide.^{2,7} Thus many of the newly synthesised compounds can be regarded as potential medicinal preparations with antibacterial^{113,115} and antimicrobial^{126,134,165} properties and also as chemical agents for the protection of plants, acting as nematocides,^{128,129,137} fungicides,^{128,129} and insectoacaricides.¹²¹

Thus the search for and development of new methods of synthesis of organomercury compounds have not lost current interest because these compounds have found applications in various branches of science, industry, medicine, and agriculture.

III. Synthesis of natural di- and poly-sulfides and their analogues	820
IV. Conclusion	824

Abstract. The structures of natural polysulfides of animal and plant origin are considered. Data are presented on the biological activity of compounds containing di-, tri-, tetra-, and pentasulfide groups. Schemes of total synthesis of the above-mentioned compounds and their structural analogues are discussed. The bibliography includes 156 references.

I. Introduction

Natural organosulfur compounds are abundant and structurally very diverse. The present review is dedicated to a group of natural organosulfur compounds that is scantily reviewed, viz., to di-, tri-, and polysulfides of plant, animal, and microbial origin. The questions pertinent to the chemistry of peptides containing a disulfide fragment are omitted from the discussion, since they have been adequately addressed in the literature (see, for example, Ref. 1).

The chemistry of simple dialkyl polysulfides of plant origin has been discussed in a number of reviews;^{2–4} therefore we shall restrict our consideration to a mere mention of the discovery of a particular substance in natural objects and discuss only those questions that are related to their biological activity.

The main subjects to be considered in the review are structurally more complex low- molecular-weight di-, tri-, tetra-, and pentasulfides. They constitute a not very abundant group of natural compounds; however, in our opinion, their structures and properties are so remarkable that they deserve special discussion.

One of the major goals of this review is to attract the attention of investigators working in the field of biologically active compounds to problems of modelling of natural sulfur-containing structures and elaboration of schemes of total synthesis of the most promising representatives of this class.

II. Natural di- and poly-sulfides, their conversions, and biological activity

1. Aliphatic di- and poly-sulfides

Aliphatic disulfides with a simple structure are the constituents of essential oils of certain plants responsible for their unpleasant odour.^{5,6} For example, the essential oil obtained by steam distillation of *Ferula illiensis* Krash. roots contains 62% of *E*- and *Z*-isomeric *sec*-butyl propenyl disulfides and a small amount of *sec*-butyl methyl- and di-*sec*-butyl disulfides.^{7,8} The *sec*-butyl propenyl disulfide has been also isolated from the essential oil of *Ferula asa foetida*.⁶ The gum of this umbellate plant contains also methylthio derivatives of allyl sulfides: Bu^sSSCH=CHCH₂SMe and PrⁿSCH₂CH=CHSSMe.

The Indian tree *Azadirachta indica* known for its potent insecticidal action produces, along with unique antifeedants of the terpenoid series (azadirachtins), also volatile polysulfides. Thus the isolation of diisopropyl di-, tri-, and tetra-sulfides as well as allylpropyl di-, tri-, and tetra-sulfides has been described.⁹ It is reported that dipropyl disulfide possesses a strong larvicidal action and suppresses the reproduction of the tiger mosquito *Aedes aegypti* and the tobacco worm *Heliothis virescens*.

The curative properties of garlic and onion have been known from time immemorial. Contemporary medicine considers the therapy with preparations of garlic or onion as a prospective trend in the treatment of atherosclerosis, coronary thrombosis, asthma, and microbial infections.^{10–12} Studies into the structure of the active principles of garlic and onion were undertaken in the last century. Thus steam distillation of garlic gives diallyl di-, tri-, and tetra-sulfides.¹³ These compounds are formed in the course of thermal or hydrolytic treatment of native substances. The latter include alliin, [(+)-*S*-allyl-L-cysteine *S*-oxide] (**1**) first isolated from the alcoholic extract of the garlic *Allium sativum* and possessing a strong bactericidal action.¹⁴ Intact garlic cloves contain up to 0.24% of alliin **1**, which is converted into *S*-allyl prop-2-ene thiosulfinate (allicin, **2**) by allinase.¹⁵ This conversion passes through the stage of formation of prop-2-ene sulfenic acid, which is further self-condensed into alliin. Allicin **2** is the main component responsible for the specific odour of garlic.

Alliin **1** constitutes 83% of the total amino acid content of garlic, 13% goes to *S*-methylcysteine *S*-oxide (**3**), and 2% to the amino acid (**4**).¹⁶ Enzymic cleavage of the amino acid **3** with allinase results in *S*-methyl methanethiosulfinate (**5**). *S*-Allyl-cysteine *S*-oxide **1** undergoes similar cleavage to give *S*-allyl methanethiosulfinate (**6**).¹⁷

The high reactivity of allicin **2** and the occurrence of other types of biochemical cleavage of alliin result in the formation of a large number of di- and tri-sulfides and their monosulfoxides

carrying different substituents. Thus a rather complex mixture of disulfides and thiosulfonates has been obtained by allinase treatment of a mixture of amino acids **1**, **3**, and **4**.

R = CH₂CH=CH₂ (**1**, **2**, **6**); Me (**3**, **5**); Prⁿ (**4**).

Many products of steam distillation of various garlic species are identical. Thus, it has been reported that the essential oil of the South American garlic *Adenocalumma alliaceum* contains 62% of diallyl di- and diallyl tri-sulfides.¹⁸

It has been established that the antithrombotic activity of garlic extracts increases upon their heating and concentration (IC₅₀ = 0.3–50 μg ml⁻¹). Their ability to prevent coronary thrombosis and atherosclerosis and increase blood coagulation time is currently ascribed to the presence of *E*- (**7**) and *Z*-achoenes (**8**), 4,5,9-trithiadodeca-1,6,11-triene-9-oxides.¹⁹ It is assumed that achoenes are formed from alliin according to Scheme 1.

β-Elimination in alliin gives thioacrolein (**9**) and prop-2-enesulfenic acid. *S*-Allylthiolation of alliin results in the sulfonium ion **10**, which undergoes β-elimination to the sulfonium ion **A**. Subsequent γ-addition of prop-2-enesulfenic acid to the cation **A** gives achoenes **7** and **8**. Boiling of alliin in aqueous methanol gives 17% of a 4:1 mixture of achoenes **7** and **8**. One of the products of alliin conversion is dihydroachoenes (**11**).²⁰

Another pathway of intermediate **10** conversion consists in the addition of a water molecule at the allylic double bond eventually resulting in 4,5,6-trithianona-1,8-diene-4-oxide (**12**) and allyl alcohol.

The involvement of intermediate thioacrolein **9** in the [4+2]-cyclic addition accounts for the formation of minor components of the extracts: 2-vinyl-4*H*-1,3-dithiine (**13**), 3-vinyl-3,4-dihydro-1,2-dithiine (**14**), and 2-(2,3-dithia-hex-5-enyl)-4*H*-1,3-dithiine

(**15**). It is noteworthy that these dithiacyclanes have been identified among other compounds isolated from extracts and distillates of garlic.²¹

The results of studies concerned with chemical conversions of garlic components have been discussed.^{22,23} Vacuum pyrolysis of diallyl disulfide (**16**) formed from alliin **2** upon the interaction of the intermediate **10** with water gives dithiines **13** and **14** in a 4.4:1 ratio. Dimerisation of thioacrolein **9** in the presence of disulfide **16** results in a tetrasulfide **15**.

The thermal reaction between alliin **2** and disulfide **16** is accompanied by the formation of thio analogues of dihydropyranyl derivatives of disulfides, compounds **17** and **18**. The mechanism of this reaction is still unclear.²⁴

Of special interest are thioacrolein reactions. In addition to the aforementioned cyclodimerisation resulting in disulfides **13** and **14** (the dimerisation at 170 K gives a mixture of these dithiines in a 9:1 ratio in a 25% yield), the formation of the thioacrolein trimer, [2-(3,4-dihydrothiopyran-2-yl)-4*H*-1,3-dithiine (**19**)] takes place.²⁵

The high antithrombotic activity of achoenes **7** and **8** and dithiines **13** and **14** has stimulated the studies aimed at the synthesis of their analogues. It has been shown, in particular, that disulfides **20** and **21** possess twice as large an antithrombotic activity as *Z*-achoenes (**8**).²⁰ This finding opens up interesting perspectives in the elaboration of valuable therapeutic drugs.

Organosulfur compounds of onion of the *Allium* genus are no less interesting. Early studies report the identification of ethyl propyl and ethyl isopropyl disulfides, butyl propyl and butyl isopropyl disulfides, diallyl disulfide, diallyl trisulfide, methyl propyl and allyl methyl tetrasulfides, allyl propyl tetrasulfide, dimethyl pentasulfide, and methyl propyl pentasulfide as the components of the onion *Allium cepa*.^{26,27} Wild varieties of onions of the *Allium* genus contain dipropyl disulfide and allyl methyl trisulfide.^{28,29} The essential oil of the onion *Allium cepa* contains no less than 100 compounds of which 39 organosulfur compounds have been reliably identified.³⁰ Methyl propyl disulfide, dipropyl disulfide, (*Z*)- and (*E*)-allyl propyl disulfide, dipropyl trisulfide, (*Z*)- and (*E*)-allyl methyl trisulfides, (*Z*)- and (*E*)-allyl propyl trisulfides, methyl propyl tetrasulfide, dipropyl tetrasulfide, (*Z*)-

and (*E*)-allyl propyl tetrasulfides, dimethyl pentasulfide, and methyl propyl pentasulfide are the major components. The ratio of allyl, methyl, and *n*-propyl residues is 85 : 13 : 2; diallyl disulfide makes up 30%–50% of the total mixture.²⁹ In addition to the polysulfides mentioned above, steam-distillation products have been found to contain cyclic and acyclic vinyl thiosulfonates. [(+)-*S*-(*E*-Propenyl)-L-cysteine *S*-oxide] (**22**), the amino acid isomeric to alliin, is the precursor of organosulfur components. Its enzymic cleavage gives stereoisomeric propanethioaldehyde *S*-oxides (**23a,b**), of which the former predominates.

Both compounds are responsible for lacrymatory properties of the onion. Their self-condensation results in the formation of *S*-*E*-propenyl *E*-prop-1-enethiosulfonates (**24a,b**). The condensation involves the intermediate prop-1-enesulfenic acid and methane- and propanesulfenic acids formed upon enzymic cleavage. Compounds **23a,b** and **24a,b** are the main carriers of the onion odour.³⁰

Zwiebelans — 1 α ,2 α ,3 α ,4 α ,5 β - and 1 α ,2 α ,3 β ,4 α ,5 β -2,3-dimethyl-5,6-dithiabicyclo[2.1.1]hexane-5-oxides (**25**, **26**) — are also the onion flavourants. Their formation is accounted for by a transformation of dipropenyl disulfide monosulfoxide, which involves the Cope rearrangement as the first step followed by [2 + 2]-cycloaddition. When a mixture of stereoisomeric dipropenyl disulfides had been used, the reaction gave six dithiabicyclanes (**25**–**30**).³¹ The synthesis of dithiabicyclanes in plants is stereospecific: *S*-(*E*)-prop-1-enyl (*E*)-prop-1-enylthiosulfonate (**24a**) gives zweibelan **25**, whereas the *Z*-isomer **24b** gives zweibelan **26**.³²

The high biological activity of dithiabicyclo[2.1.1]hexane derivatives can be inferred from the fact that a mixture of zweibelans **25** and **26** isolated from *Allium cepa* extracts inhibits by 65%–90% the biosynthesis of leukotriene TXB₂ in human cells when used in concentrations of 0.1–1.0 mg ml^{−1} (see Ref. 31). The identification of thiosulfonates **31** and Bunte salts **32** in onion extracts has been reported.³¹

The medicinal plant *Dysoxylum richii* growing in the Fiji Islands is used by the local population as a tea additive and a means of prophylaxis against diseases caused by pathogenic microorganisms. The active principle of this plant is dysoxysulfone, 2,4,5,7,9-pentathiadecane-2,2,9,9-tetraoxide **33**, which is a potent inhibitor of the proliferation of *Staphylococcus aureus*, *Bacillus subtilis*, and *Candida albicans*. The minimum inhibiting concentrations (MIC) of **33** for these microorganisms are 100, 20 and 10 μ g plate^{−1}, respectively.³³ In addition, this compound manifests high antitumour activity against human ovarian carcinoma cells (IC₅₀ = 5 μ g ml^{−1}; the corresponding value for large intestinal adenocarcinoma is 7.4 μ g ml^{−1}).³² This plant is the second representative of the *Meliaceae* family after *Azadirachta indica* that produces sulfur-containing metabolites.

High antitumour activity has also been observed for 2,3,5,7,9-pentathiadecane-9,9-dioxide **34** isolated from the 'Shitake' fungus *Lentinus edodes* (IC₅₀ for murine leukemia cells is 0.62 μ g ml^{−1}).³⁴

The Hawaiian sea algae *Dictyopteris plagiogramma* are rich in saturated and unsaturated linear C₁₁ hydrocarbons. The isolation of oxo-oligosulfides **35** and diacetoxysulfide **36**, which can be considered as precursors of undeca-1,3,5-trienes, has been described.^{35–37}

2. Saturated cyclic di- and poly-sulfides

Cyclic oligo- and poly-sulfides **37**–**43** have been isolated and identified as carriers of antibacterial activity in extracts of the red algae *Chondria californica*.³⁸ These thiacyclanes can be regarded as the products of condensation of formaldehyde with hydrogen sulfide. The highest antibiotic activity in this series of compounds is manifested by 1,2,3,5-tetrathiane-5,5-dioxide (**43**), which inhibits the growth of *Vibrio anguillarum*, *Proteus mirabilis*, *Salmonella typhimurium*, and *E.coli* in a concentration of 10 μ g ml^{−1}. Sulf-oxides **40** and **41**, which can be obtained from 1,2,4-trithiolane **37**, also possess antibiotic activity. 1,2,3,5,6-Pentathiepane (**39**) is identical to the so-called lenthionine produced by the fungus *Lentinus edodes*. Lenthionine is biogenetically related to lenthinic acid (**44**).³⁹ Extracts of other *Chondria* species are devoid of antimicrobial activity and do not contain cyclic polysulfides.

Cyclic polysulfides of the type 1,2,4-trithiolane (**37**), 1,2,3,5,6-pentathiepane (**39**), 1,2,4,5-tetrathiane (**45**), and 1,2,3,4,5,6,7-heptathiocane (**46**) have been isolated from the cultural fluid produced by *Thermococcus* cells.⁴⁰ Studies of biological activity of these compounds have revealed that the highest fungicidal activity is exerted by pentathiepane **39** ($7.8 \mu\text{g ml}^{-1}$ with respect to *Microsporum canis*). The *in vitro* antihelminthic activity against *Caenorhabditis elegans* has been established for thiolane **37**. It has been found that alkyl-substituted polysulfides **46** are unstable and decompose to yield sulfur and disubstituted cyclic polysulfides.

Saturated six- and seven-membered di- and tri-sulfides are rather rare. So far only one seven-membered cyclic disulfide **47** isolated from the alga *Dictyopteris plagiogramma* is known.³⁵ 5-Methylthio-1,2,3-trithiane (**48**) has been isolated from the green algae *Chara globularis*.⁴¹

3. 1,2-Dithiolanes and their derivatives

Of great biological importance are functionally substituted derivatives of 1,2-dithiolane isolated from animal and plant objects.

Thus the diastereoisomeric 1,2-dithiolane-1-oxides brugierol (**49a**) and isobrugierol (**49b**), which control plant growth have been isolated from the methanolic extract of the bark of *Brugiera conjugata*.^{42, 43}

A potent plant growth inhibitor, whose action is similar to that of abscisic acid, is asparagusic (1,2-dithiolane-4-carboxylic) acid (**50**) isolated from young sprouts of asparagus (*Asparagus officinalis* L.).⁴⁴

Asparagusic acid sulfoxides (**51a,b**) obtained by extraction of asparagus sprouts with methanol manifest high growth-regulating activity.⁴⁵ It is noteworthy that dihydroasparagusic acid (**52a**) and its diacetate (**52b**) have also been isolated from the asparagus plant. This suggests that asparagusic acid plays the key role in the biochemically important process of acetyl group transport mediated by acetyl-CoA.

This group of disulfides includes lipoic acid (**53**) and its sulfoxide, β -lipoic acid (**54**), present in both animal and plant organisms. Lipoic acid plays the role of an acetyl group transfer factor and a factor promoting the growth of bacteria and *Protozoa*. In the form of protein-bound ϵ -lipoyllysine (**55**), lipoic acid and its reduced form, dihydrolipoic acid, are the coenzymes for pyruvate dehydrogenase and α -ketoglutarate dehydrogenase responsible for oxidative decarboxylation of α -keto acids with the transfer of the acetyl group to coenzyme A. The participation of lipoic acid in thiol-disulfide conversions of proteins, oxidative phosphorylation, and arachidonic acid conversion into prostaglandin H has also been established.^{1, 46} Lipoic acid participates in the primary step of the quantum of light conversion in photosynthesis.⁴⁷ In the form of vitamin N, lipoic acid is used in the treatment of liver disorders, diabetes, atherosclerosis and other diseases resulting from disturbances in lipid metabolism.

X = S (**53**), SO (**54**).

4-Dimethylamino-1,2-dithiolane — nereistoxin (**56**) — isolated from the sea worm *Lumbriconereis heteropoda* possesses unique insecticidal activity.^{48, 49} This simple molecule has served as a model in the synthesis of highly effective insecticides.⁵⁰ For example, the compound bensultap (**57**), which exhibits high selectivity against Coleoptera,⁵¹ has been recommended for suppressing the reproduction of the Colorado potato beetle without any detriment to beneficial insects, bees, and fish. The practical application of 5-dimethylamino-1,2,3-trithiane (**58**) as insecticide has been reported.^{49, 52}

The bark of the Brazilian tree *Cassipourea guianensis* contains a group of alkaloids of the 1,2-dithiole type. The main component of the extract, gerardin (**59**), is a potent fungistatic agent. Quinesins A, B, C, and G (compounds **60–63**, respectively) possess high insecticidal activity.^{53–55} The antibiotic leunamycin (**64**) produced by *Streptomyces* sp. and possessing strong anti-tumor activity^{56, 57} is also a 1,2-dithiole derivative.

4. 1,2-Dithiins

Increasing attention is presently focussed on a novel class of sulfur-containing heterocyclic compounds, 1,2-dithia-cyclohexa-3,5-dienes, in connection with their unusual structure and a broad spectrum of biological activity. Thus very promising candidates for antiviral and antibacterial agents are acetylenic derivatives of this heterocycle. Red coloured thiarubins A (**65**) and B (**66**) are produced by many plants used as curative agents in the folk medicine of some African countries. For example, leaves of the African plant *Aspilia africana*, which contain thiarubins A and B, are used for the treatment of abdominal infections. It has been noted also that these leaves are chewed by chimpanzees.⁵⁸ 3-(Hex-5-en-1,3-diynyl)-6-(1-propynyl)-1,2-dithiin **65** possesses antiviral, fungicidal, and antibacterial activities (when used at a concentration of $10^{-7} \text{ mg ml}^{-1}$) and inhibits the growth of *Candida albicans* at the level of the drug funizone.⁵⁹

Other sources of thiarubins are: *Aspilia mossambicensis*, *A. plurisetta*,⁶⁰ *Ambrosia artemisiifolia*,⁶¹ *Pegolettia senegalensis*,⁶² *Wedelia hookeriana*,⁶³ *Schkhuria multiflora*,⁶⁴ *S. senecioides*,⁶⁵ *Chaenactis douglasii*, *Eriophyllum lanatum*⁶⁶ and *Eriophyllum caespitosum*.^{65, 67}

It is noteworthy that thiarrubins are present in the plants together with the corresponding thiophenes (**67**, **68**).⁶⁸

Some plants of the *Compositae* family produce dihydrothiarrubins (**69**, **70**) and thiophenes genetically linked to them (**71**, **72**). For instance, dithiin **69** has been isolated from *Picradeniopsis woodhousei*,⁶⁹ *Lasthenia*,⁷⁰ and *Ogedaea boliviana*,⁷¹ whereas 2,5-disubstituted thiophene **72** is present in the plant *Melampodium divaricatum*.⁷²

3-Vinyl-3,4-dihydro-1,2-dithiin (**14**) isolated from garlic has been also identified among compounds that determine the odour of cooked asparagus.⁷³

The chemistry of 1,2-dithiin derivatives has been reviewed.⁷⁴

5. Di- and poly-sulfides carrying aromatic or heteroaromatic substituents

Di- and poly-sulfides having in their structure a functionalised aromatic or heterocyclic (imidazoline, thiazole) fragment possess valuable biological activity. Compounds, in which these fragments are either linked together with S–S bonds, or contain a cyclic polysulfide fragment or a terminal methylthio substituent, have been isolated.

Thus polycarpamines A–D (compounds **73**–**76**) isolated from the ascidia *Polycarpa aurata* manifest high *in vitro* inhibitory activity against *Candida albicans* and *Saccharomyces cerevisiae*.⁷⁵ The sponges *Psammoplysilla purpurea* contain psammoplysins A (**77**) and D (**78**) suppressing the growth of the gram-positive bacteria *Staphylococcus aureus* and *Trychophyton mentagrophytes*.⁷⁶

Amino acids of unusual structure **79** have been isolated from the starfish *Astropecten latespinatus*. They exhibit cytotoxic activity against KB-cells ($IC_{50} = 3 \times 10^{-6}$ mg ml⁻¹).⁷⁷

The disulfide polycarpine (**80**) has been recently isolated from a methanolic extract of the ascidian *Polycarpa aurata*. At a concentration of 0.19 μmol litre⁻¹ it inhibits inosine monophosphate dehydrogenase. The fact that the inhibition can be eliminated by excess of dithiothreitol suggests that alkaloid **80** reacts with sulfhydryl groups of the enzyme.⁷⁸

73: R' = H, R'' = OMe;
74: R', R'' = O;
75: R', R'' = S;
76: R' = OMe, R'' = COOMe.

79: R = H, Me.

The tunicate *Lissoclinum perforatum* residing in North England contains 6,7-benzo-1,2,3,4,5-pentathiepanes with an annulated aromatic fragment: lissoclinotoxins A (**81**) and B (**82**) and isolissoclinotoxin A (**83**).^{79, 80} Lissoclinotoxin A **81** is a potent antimicrobial agent. Its activity against *Staphylococcus aureus*, *Streptococcus faecalis*, and *Citrobacter* sp. (MIC = 0.08–0.6 μg kg⁻¹) markedly exceeds that of the cephalosporine antibiotic cephotaxim. It also manifests sufficiently high activity against *E. coli*, *Salmonella* sp., *Proteus* sp., and *Pseudomonas aeruginosa*. Lissoclinotoxins A and B, especially compound **82** suppress ichthyopathogenic strains of *Aeromonas salmonicida* 643 and *Vibrio anguillarum* 5536.

Lissoclinotoxin A demonstrates a rather high activity against the malaria pathogen *Plasmodium falciparum*, which is resistant to antimalarial drugs, such as mefloquine, galofantrine, and chloroquine. It exhibits the remarkable capacity to inhibit the growth of leukemia L 1210 cells when used at a concentration of 1 μg ml⁻¹. Lissoclinotoxin A manifests cytotoxic properties suppressing cell division in the sea urchin test.⁸⁰

The antitumor activity of varacin exceeds 100-fold that of 5-fluorouracil. Lissoclinotoxins C (**87**) and D (**88**), genetically related to lissoclinotoxin A, have been isolated from the tropical ascidia *Lissoclinum vareau*.⁸¹ These molecules are not diastereotopic. Lissoclinotoxin D, a dimeric derivative of lissoclinotoxin C, exerts fungicidal activity against *Candida albicans* at the same level as lissoclinotoxin A, whereas compound **88** is inactive.

The tropical ascidia *Lissoclinum vareau* contains varacin (**84**) possessing the fungicidal activity against *Candida albicans* and inhibiting the growth of human carcinoma HCT-116 cells ($IC_{90} = 0.05$ μg ml⁻¹).⁸¹

81: R¹ = Me, R² = R³ = H;
83: R¹ = R³ = H, R² = Me;
84: R¹ = R² = Me, R³ = H;
85: R¹ = R² = Me,
 R³ = COO(CH₂)₂SiMe₃ (TEOC).

Lissoclinotoxins **81–83** and varacin **84** are the first presently known natural benzopentathiepine derivatives. Analysis of ^1H NMR spectra of compounds **81**, **84**, and their derivatives allowed one to conclude about the chirality of these molecules. Thus diastereotopicity of C(7)-methylene group protons has been observed in the spectrum of *N*-trimethylsilylethoxycarbonyl-varacin (*N*-TEOC-varacin) (**85**)⁸² and lissoclinotoxin A (**81**).⁸³ In compound **86**, the protons of the trimethylsilylethoxymethyl group are diastereotopic.

Thus, the interconversion of the benzopentathiepine system does not take place at room temperature. The inversion barrier in the lissoclinotoxin A molecule is 29 kcal mol⁻¹.⁸³ Calculations performed by the molecular mechanics method suggest that the chair (**A**) conformation for compound **84** is preferential as being energetically the most favourable. The second stable conformation, the energy of which is 8.7 kcal mol⁻¹ higher, is the 'twist' conformation **C**. The transition from the conformation **A** to the conformation **C** proceeds *via* the conformation **B**, the energy of which is higher than that of the conformation **A** by 34 kcal mol⁻¹.

The ^1H NMR spectrum of a varacin derivative **89** contains double signals of the proton of the benzene ring and of both methoxy groups. This suggests the presence of two stereoisomers. A sample enriched with one isomer by 75% could be obtained by crystallisation.

A benzotrithiane derivative **90** with fungicidal and antimicrobial activities against gram-positive and gram-negative bacteria (MIC = 0.1–0.6 $\mu\text{g ml}^{-1}$) and the fungi *Candida albicans* (40 $\mu\text{g ml}^{-1}$) and *Trichophyton mentagrophytes* (20 $\mu\text{g ml}^{-1}$) has been isolated from the tropical ascidian *Lissoclinum perforatum*.⁷⁹

The ascidia *Aplidium pliciferum* contains a trisulfide **91a** possessing antimicrobial, antitumour, and cytotoxic activities.⁸⁴ In alkaline media, the sulfur-containing ring is inverted to give a more stable diastereoisomer **91b** with an opposite configuration of the chiral carbon atom. Using NMR and molecular mechanics methods, it has been established that the trithiane ring in the epimer **91b** has a chair conformation in which the hydroxyl group occupies the equatorial position, whereas the imidazole ring is in the axial position. Based on the analysis of the NMR spectrum of the natural isomer **91a**, the chair conformation with the axial position of the hydroxyl group has been ascribed to the trithiane ring. Molecular modelling offers an alternative interpretation which entails rapid interconversion of two possible chair configurations. Both stereoisomers possess high biological activity: IC₅₀ values for their cytotoxic action against leukemia P 388 cells are 13 and 12 $\mu\text{g ml}^{-1}$, respectively.⁸⁴

An unusual cyclopeptide ulthiacyclamide (**92**) the molecule of which is built of two unusual amino acids is produced by the ascidian *Lissoclinum patella*. It is reported that compound **92** possesses strong cytotoxic activity and inhibits the growth of leukemia L1210 (at a concentration of 0.35 $\mu\text{g ml}^{-1}$) and human carcinoma CEM cells (at a concentration of 0.012 $\mu\text{g ml}^{-1}$).^{85–87}

The terpenoid disulfide menispermamide (**93**) has been isolated from the plant *Tinospora malabarica* of the *Menispermaceae* family.⁸⁸ This compound is the first representative of sulfur-containing terpenoids of the clerodane series.

6. Antibiotics containing an enediyne fragment

Considerable interest in the past decade has been addressed to novel antibiotics, the aglycone fragment in which is an oxotrisulfide having the skeleton of a bicyclo[7.3.1]trideca-5-ene-3,7-diyne.

Thus calichemycin γ_1 (**94**) produced by the culture of *Microspora echinospora* possesses extraordinary antitumour activity, which exceeds 4000-fold that of adriamycin, one of the best modern cancerostatic agents.^{89–95}

The antitumour and cytotoxic activities of calichemycin γ_1 and its synthetic analogue, calichemycin θ_1 (**95**)⁹⁵ in which the trisulfide fragment had been replaced by the etylthio group, have been studied with respect to a vast variety of cells beginning with the relatively stable melanoma SK MEL 28 cells (IC₅₀ = 1.6 $\times 10^{-9}$ M) and ending up with highly sensitive leukemia MOLT-4 cells (IC₅₀ = 10⁻¹² M).

Esperamycins A₁, A₂ and A_{1b} (compounds **96–98**, respectively) also appear to be potent cancerostatic agents.^{96–98} These strikingly remarkable molecules are unique in all the elements of

R = SSMe (**94**), Ac (**95**).

their structure. Thus the structure of the carbohydrate skeleton and of the aglycone of the antibiotics has no precedents in the chemistry of natural compounds. Carbohydrate fragments involve rare thio- and amino sugars linked through a unique, hydroxylamine bond. The structures of the polysubstituted benzoic acids deserve individual mention.

96-98

96: R' = H, R'' = Pr^t; **97**: R' = Ac, R'' = Bu^t; **98**: R' = H, R'' = Et.

The mechanism of the anticarcinogenic effect of enediyne antibiotics entails active involvement of the trisulfide fragment. At the first stage, the enediyne system forms associates with double-stranded DNA; the complex formation affects predominantly the DNA region enriched with pyrimidine bases. Using ¹H NMR technique, the formation of a 1 : 1 complex with a duplex containing the A-C-C-T fragment, and of a 1 : 1 complex with the T-T-T-T fragment has been established. It is reasoned that the coordination with the pyrimidine-containing fragments is conformationally more favourable than that with the purine fragments.⁹⁹

An important role in the binding to DNA is ascribed to the side chain of enediyne antibiotics **94-98**. The analysis of six models of calicheamicin complex formation has led to a conclusion that the model that involves the binding of rhamnose, thiobenzoic acid, and the thio sugar to the DNA region 5'-T-C-C-T/3'-A-G-G-A is more preferable.^{100, 101} Cleavage of the trisulfide fragment is crucial for the stage of conjugated addition of the thiol residue according to the anti-Bredt rule. Bioreduction to the dihydrothiophene intermediate **A** initiates the key Bergman cyclisation, eventually resulting in the conversion of enediyne into diyl (**A** → **B**). Diyl **B** is responsible for DNA cleavage that begins with hydrogen detachment from the 2-deoxyribose residue.^{102, 103} The mechanism of activation of calicheamicin θ₁ (**95**) is different in that an oxygen-, sulfur-, or nitrogen-containing nucleophile is used as an activator, whereas enediynes **94** and **96-98** are activated by thiols.⁹⁵ The problem of complex formation of calicheamicin γ₁ is also discussed in a paper by Mah *et al.*,¹⁰⁴ which also gives a detailed list of references.

R = NHCOOMe.

7. Sulfur-containing piperazinediones

Let us now dwell on the characteristics of fungal metabolites that have a polythiapiperazinedione fragment in their structure. The chemistry and toxicology of these compounds and the literature coverage of up to 1980 have been reviewed.^{105, 106}

Glyotoxin (**99**) produced by *Aspergillus fumigatus*, *Gliocladium fimbriatum*, and *Penicillium terlikowski* is highly toxic against homoiothermal organisms.¹⁰⁷⁻¹⁰⁹ Dehydroglyotoxin (**100**) and the corresponding trisulfide (**101**) have been isolated from the metabolites of the fungus *Pithomyces chartarum*.^{110, 111} The tetrasulfide (**102**) termed glyotoxin G has been identified as a minor metabolite of *Aspergillus fumigatus*.^{109, 112}

99, 102

100, 101

n = 2 (**99**, **100**), 3 (**101**), 4 (**102**).

The fungus *Aspergillus tamari* produces a chlorophenolic metabolite aspirochlorine (**103**).^{113, 114} Aspirochlorine (**103**) is highly active *in vitro* against gram-positive bacteria and fungi (IC₅₀ = 0.1–50 mg kg⁻¹); however, in contrast with the epidi-thiapiperazine-2,5-diones (**99-102**) described above, it exhibits only slight fungicidal and antiviral activities.¹¹⁵ The above-mentioned differences in biological activity can be due to differences in the strain of bicyclo[2.2.2] systems in **99** and **100** and bicyclo[3.2.2] systems in **103**. Like glyotoxins **99-102**, aspirochlorine is a strong immunosuppressor and inhibits phagocytosis.¹¹⁶

103

A phytopathogen *Phoma lingam* affecting rape and cabbage produces several toxins. One of them, phomalirazine (**104**), is produced exclusively by this fungus. The other two compounds, sirodesmins PL (**105**) and H (**106**), are also metabolites of the fungus *Sirodesmium diversum*.^{117, 118} The latter also produces sirodesmins B (**107**) and C (**108**).

105-108

105: n = 2, R = Ac;

106: n = 2, R = H;

107: n = 4, R = Ac;

108: n = 3, R = Ac.

Sirodesmins possess antiviral activity against *Vaccinia*, *Herpes*, and Newcastle disease viruses.¹¹⁹ Phomalirazine is the precursor of sirodesmins. Its biosynthesis begins with tyrosine and serine and involves isoprene (Scheme 2).¹¹⁸

Sporidesmins A, E, and G (**109–111**) isolated from the culture of the fungus *Phthomyces chartarum* possess marked antibiotic activity.^{108, 111, 120}

Metabolites of the fungus *Arachniotus aureus* have been found to contain dithiapiperazinedione aranotine (**112**) and its diacetate **113**, which exhibit *in vitro* and *in vivo* antiviral effects.^{121, 122} The latter is also produced by *Aspergillus*.¹²³

Chetocine (**114**)¹⁰⁸ and chetomine (**115**) are metabolites of the fungi *Chaetomium minutum* and *Ch. cochliodes*.¹²⁴ The latter compound is highly toxic against homoiothermal organisms. High antibacterial activity has been established for chetocine **114** (MIC for *Staphylococcus aureus* is $0.01–0.001$ mg ml⁻¹), and its cytotoxicity index (IC₅₀) with respect to P-815 tumour cells is 0.038 mg litre⁻¹.

Fungi *Verticillium* produce the antibiotics verticillins A–C (**116–118**), which suppress gram-positive and gram-negative bacteria and inhibit the growth of some other fungi and cancer cells^{125, 126} (the cytotoxic effect, ED₅₀, of compounds **116** and **117** with respect to HeLa cells is 0.2 µg ml⁻¹). It is interesting to note that polythiapiperazinediones **114–118** are devoid of antiviral activity.¹²⁷

The structure of leptosines A–C (**119–121**), the secondary metabolites of the fungi *Leptosphaeria* sp. isolated from the sea alga *Sargassum forfile* has been recently established. Their high antitumour activity has been reported.^{128, 129}

III. Synthesis of natural di- and poly-sulfides and their analogues

As can be seen from the presented data, naturally occurring polysulfides present special interest by virtue of their unusual structures and remarkable physiological activity. The latter fact has stimulated studies aimed at total synthesis of these compounds and their structural analogues.

Syntheses of the biologically active linear polysulfides, viz., 2,4,5,7,9-pentathiadecane-2,2,9,9-tetraoxide (**33**), 2,3,5,7,9-pentathiadecane-9,9-dioxide (**34**), and 2,4,5,7-tetrathiaoctane-2,2-dioxide isolated from the plant *Tulbaghia violacea*¹³⁰ have been carried out starting from the corresponding polythiacyclanes. The key stage in these syntheses is the nucleophilic ring-opening of 1,2,4-trithiolane (**37**), 1,2,4,6-tetrathiepane (**38**), and 2,4,5,7-tetrathiaoctane with MeLi, trapping of thiolate ions formed by electrophiles, and subsequent regio-specific oxidation of intermediate penta- or tetra-sulfides with KMnO₄ in a mixture with Zn(OAc)₂ or FeCl₃ in order to prevent the cleavage of the final product with a base formed in the oxidation.¹³¹ The synthesis of polysulfides **33** and **34** is shown in Scheme 3.

Scheme 3

(a) MeLi; (b) MeSCH₂SSO₂Me; (c) KMnO₄, Zn(OAc)₂, MgSO₄, Me₂CO; (d) MeSSO₂Me; (e) H₂O₂, AcOH; (f) KMnO₄, MgSO₄, Me₂CO.

Much attention has been given to the synthesis of natural 1,2-dithiolane derivatives. The key problem in this synthesis is the formation of the dithiolane ring. To this end, reactions of 1,3-diol, ditosylate, dithiol, and dihalide derivatives with sodium disulfide, thiourea, thioacetic acid, or α -toluenethiol were employed. The use of (*N*-methoxycarbonyl-sulfamoyl)triethylammonium hydroxide for the formation of the disulfide bond has been described.⁴³ The interaction of the latter with 1,3-dimercaptopropan-2-ol gives 4-hydroxy-1,2-dithiolane (**122**) the oxidation of which with hydrogen peroxide results in a mixture of diastereoisomeric sulfoxides **49a,b** in a 4 : 1 ratio.

(a) $\text{Et}_3\text{N}^+\text{SO}_2\text{N}^-\text{COOMe}$, CHCl_3 , 20 °C; (b) 0.5 N NaOH;
(c) H_2O_2 , CHCl_3 , MeCN, 20 °C, 48 h.

The direct oxidation of 2-methylthiopropene-1,3-dithiol (**123**) with iodine has been used in the synthesis of 4-methylthio-1,2-dithiolane (**124**) in 78% yield. The latter was isolated together with trithiane **48** from the green alga *Chara globularis*.⁴¹

It is interesting to note that the reaction of dithiol **123** with SCl_2 gives a mixture of cyclic sulfides **124** and **48** in a 1 : 1 ratio.¹³²

The main problem in the synthesis of lipoic acid (**53**) and its derivatives is the introduction of the side chain. A simple synthesis employing octa-1,7-dien-3-ol (**125**), which is the product of butadiene telomerisation with water¹³³ in the presence of palladium complexes, has been described.¹³⁴ The hydroboration of octadienol **125** with borane results in the triol (**126**); isopropylidenation of the 1,3-diol, oxidation of the free terminal hydroxy group at C(8) with the Jones reagent, methylation, deprotection, and the reaction with thiourea give the dithiol (**127**). Its oxidation with iodine results in racemic *dl*- α -lipoic acid.

(a) $\text{PdCl}_2(\text{PPh}_3)_2$, H_2O , KOH; (b) B_2H_6 , THF, H_2O_2 –NaOH; (c) CrO_3 – H_2SO_4 , CH_2N_2 ; (d) H_2SO_4 –MeOH; (e) $(\text{NH}_4)_2\text{CS}$ –57% HI–NaOH.

More often, nucleophilic substitution in the corresponding 1,3-dihalides or 1,3-disulfonates is used in the synthesis of 1,2-dithiolanes. For example, methyl esters of (+)-(*R*)- and (–)-(*S*)-lipoic acids **129a,b** have been synthesised by the reaction of dimesylates (**128a**) or (**128b**) with sodium disulfide.¹³⁵

Good results in the synthesis of cyclic disulfides have been obtained with piperidinium tetrathiatungstate.¹³⁶ The latter reacts with dihalides to give the corresponding disulfides in a good yield and under mild conditions (25–40 °C, 4–5 h, DMF). This method has been used in the synthesis of (+)-lipoic acid **53** and asparagusic acid **50**.

The synthesis of nereistoxin (**56**) and its analogues that are used as insecticides has a number of specific features. The dihalogenamine **130**, obtained by chlorination of allyldimethylamine is the starting compound. Under the action of sulfur nucleophiles, the amine **130** is rearranged *via* an intermediate sulfonium ion into derivatives of 1,3-dithio-substituted 2-dimethylaminopropanes. The reaction of dihalogenamine **130** with Na_2S_2 directly results in nereistoxin **56**,¹³⁷ whereas its interaction with Na_2S and then with benzenesulfonylchloride gives bensultap (**57**).¹³⁸ The treatment of 1-dimethylamino-2,3-dichloropropane (**130**) with sodium thiosulfate gives the compound **131**, which gives the trisulfide **58** upon treatment with Na_2S .⁴⁹

Nucleophilic substitution underlies the synthesis of the pentasulfide lenthionine (**39**), trisulfide **37**, and the tetrasulfide **38** from the readily available CH_2Cl_2 and $\text{Na}_2\text{S}_{2.5}$.¹³⁹

The synthesis of thiarubrin A (**65**) from hexa-2,4-diyne-1,6-diol (**133**) involves 12 steps. The use of 2-(trimethylsilyl)ethanethiol as a protecting group in the formation of the 1,2-dithiylne is noteworthy.⁵⁸

R = $\text{Me}_3\text{SiCH}_2\text{CH}_2$.

(a) $\text{Me}_3\text{Si}(\text{CH}_2)_2\text{SH}$, KOH – DMF, 20 °C; (b) Bu_4NF , molecular sieves 3 Å; (c) I_2 , 20 °C, 30 min.

The formation of the disulfide bond upon oxidation of dithiols or their derivatives with iodine has been used in syntheses of structurally complex metabolites. Thus in the synthesis of ultracyclamide (**92**) it is the *S*-acetamidomethyl derivative **134** formed upon cyclodimerisation of the corresponding *S*-acetamidomethyl tripeptide (**135**) effected by diphenylphosphorazidate (DPPA) and triethylamine that undergoes oxidation with iodine.¹⁴⁰ The oxazole ring in the molecule **92** is formed by treatment of the intermediate disulfide **136** with an excess of thionyl chloride. This synthesis of a cytotoxin **92** competes favourably (as regards the overall yield and the number of stages) with the synthesis involving bis-cyclisation of cystine with the 2,2,2-trifluoroethyl ester **137**.¹⁴¹

R = CH_2NHCOMe .

(a) DPPA – Et_3N , DMF; (b) I_2 , MeOH; (c) SOCl_2 , 0 °C, 17 h.

An original method for the introduction of a 1,2-dithiolan-3-one fragment as a spirofusion with an 18-membered lactam containing a thiazole ring has been offered in Ref.¹⁴². The nitrosylation of thiolanone **138** gives the oxime **139**. Subsequent protection of the keto group of the dienone fragment as the *O*-methyloxime followed by Beckmann rearrangement under the action of 2,6-dimethylbenzoyl chloride results in a mercapto acid **140**, which was further converted into the thioester **141**. Treatment of the latter with sodium hydrogen sulfide and iodine with subsequent deprotection are followed by cyclisation leading to (*S*)-deoxyunamycin (**142**), which is stereoselectively oxidised into (+)-leinamycin (**64**).

R = OCH_2OMe .

(a) Am^iONO , NaOMe , 23 °C, 1.5 h; (b) $\text{MeONH}_2 \cdot \text{HCl}$, Py; (c) 2,6- $\text{Me}_2\text{C}_6\text{H}_3\text{COCl}$, Py; (d) EtSH , THF, 20 °C, 20 min; (e) NaSH , THF, I_2 , 10 min; (f) 33% HCHO , 3 N HCl , Me_2CO ; (g) 3- $\text{ClC}_6\text{H}_4\text{CO}_3\text{H}$, THF, 0 °C, 45 min.

The total synthesis of the disulfide antibiotic aspirochlorine (**103**) from 4-chlororesorcinol includes 14 stages. The most notable are the final steps shown in Scheme 4. The methoxy group is introduced into the piperazinedione ring by treatment with *tert*-butyl hypochlorite in methanol in the presence of sodium methoxide. This is followed by substitution of two methoxy groups for the acetylthio groups under the action of thioacetic acid in the presence of boron trifluoride etherate. And, finally, the closure of the disulfide bridge is performed by treatment of bithioacetate **143** with *O*-methylhydroxylamine and camphorsulphonic acid.¹¹⁴

Scheme 4

(a) Bu^tOCl , NaOMe ; (b) NaOEt – EtOH ; (c) AcSH , $\text{BF}_3 \cdot \text{Et}_2\text{O}$; (d) MeONH_2 , *d*-camphorsulphonic acid, THF, 23 °C.

Considerable attention has been paid to the synthesis of benzopentathiepine **144** and its analogue **145**. Benzopentathiepine is formed by treatment of benzene-1,2-dithiol with S_3Cl_2 in ether, the yield being up to 80%.^{143, 144} An analogous scheme is used to obtain pentathiepine **145**.

An interesting method for the introduction of a pentathiepine fragment¹⁴⁵ is based on the reaction of aromatic *o*-dibromides with sulfur in liquid ammonia. In this case, trisulfide derivatives **147** are formed along with the main reaction product **146**.

The interest in the synthesis of varacin (**84**) and lissoclinotoxins (**81**–**83**) is explained primarily by their valuable biological activity. Schemes of total synthesis of varacin (**84**) and isolissoclinotoxin (**83**) from vanillin in which the pentasulfide fragment was prepared from *o*-dimercaptobenzenes are described. Thus the treatment of 2,3-dibromoveratric aldehyde **148**, which was obtained from vanillin, with copper propanethiolate and remethylation of hydroxy groups resulting from partial demethylation of methoxy groups gave the dipropylthio derivative **149**.¹⁴⁶ This was followed by the reaction of **149** with nitromethane, reduction of the nitro group with lithium aluminium hydride, and protection of the resulting amino group. Splitting of the thioester groups with sodium in ammonia and the reaction of disodium dithiolate **150** with S_2Cl_2 gives a mixture of benzotriothiole and benzopentathiepine **84** in a total yield of 86%. The final stage is non-selective, because trisulfide **88** is formed along with varacin **84** in a 1 : 1 ratio.

R = TEOC.

(a) PrSCu , quinoline–Py, 160 °C; (b) $(\text{MeO})_2\text{SO}_2$ – K_2CO_3 , Bu_4NI , CH_2Cl_2 – H_2O ; (c) MeNO_2 , $\text{NH}_4\text{OAc}/\text{AcOH}$, 23 °C; (d) LiAlH_4 , THF, 65 °C, 25 min; (e) 4- $\text{NO}_2\text{C}_6\text{H}_4\text{OR}$, Et_3N – CH_2Cl_2 ; (f) Na/NH_3 ; (g) S_2Cl_2 –THF, 25 °C, 45 min; (h) CF_3COOH , CHCl_3 , 20 °C, 50 min.

The key step in the synthesis of isolissoclinotoxin A (**83**) is the reaction of 5,6-dibromovanillin with copper butanethiolate resulting in the dithioether **151**.¹⁴⁷ The protection of the phenolic hydroxyl at position 4 with methoxymethyl chloride and subsequent introduction of the nitrogen-containing substituent according to the aforementioned reaction sequence give compound **152**. Reduction of the *o*-butylthio groups with sodium in ammonia and subsequent treatment of the dithiolate anion with S_2Cl_2 give a mixture of penta- and tri-sulfides in a 2.4 : 1 ratio.

$R = \text{CO}(\text{CH}_2)_2\text{SiMe}_3$; $R' = \text{CH}_2\text{OMe}$; $n = 1, 3$.

(a) Bu^nSCu , quinoline–Py, 160 °C; (b) $(\text{MeO})_2\text{SO}_2 - \text{K}_2\text{CO}_3$, Bu_4^nNI , $\text{CH}_2\text{Cl}_2 - \text{H}_2\text{O}$; (c) CH_2ClOMe , Pr_2NEt , CH_2Cl_2 , 23 °C; (d) MeNO_2 , $\text{NH}_4\text{OAc}/\text{AcOH}$; (e) LiAlH_4 , THF, 65 °C, 25 min; (f) $4\text{-NO}_2\text{C}_6\text{H}_4\text{OR}$, $\text{Et}_3\text{N} - \text{CH}_2\text{Cl}_2$; (g) Na/NH_3 (yield 50%); (h) $\text{S}_2\text{Cl}_2 - \text{THF}$, 25 °C, 45 min (yield 67%); (i) CF_3COOH , CHCl_3 , 20 °C, 50 min (yield 86%);

In the scheme of the synthesis of varacin (**84**),¹⁴⁸ of special note is the approach allowing selective introduction of a pentasulfide fragment. The initial product is the substituted anthranilic acid **153** which is readily formed from diester **154**. Treatment of the acid **153** with isopentyl nitrite in the presence of carbonic sulfide and isopentyl alcohol gave cyclic dithioether **155** formed *via* intermediates **A** and **B**. In order to introduce the nitrogen-containing substituent, silyl protection was removed and the alcohol formed **156** was introduced into the reaction with phthalimide. Splitting of the phthaloyl protection by hydrazinolysis resulted in a free amino group further protected as a BOC derivative to give the compound **157**. Treatment of the latter with S_2Cl_2 cleaves the orthoester and yields the pentathiepine ring. It is of note that the transfer of the formyl residue from the sulfur-containing to the nitrogen-containing substituent occurs in the course of pentathiepine **158** formation.

$R = \text{Bu}^t\text{Ph}_2\text{Si}$; $R' = \text{Penti}$.

(a) Pent^tONO , PentOH , CS_2 , CH_2Cl_2 , 75 °C, 30 min; (b) Bu_4NF , THF, 23 °C, 30 min; (c) phthalimide, $\text{EtOOCN} = \text{NCOOEt}$, PPh_3 , THF, 25 °C, 27 h; (d) N_2H_4 , EtOH , $(\text{Boc})_2\text{O}$, $4\text{-Me}_2\text{NC}_5\text{H}_4\text{N}$, CH_2Cl_2 ; (e) S_2Cl_2 , THF, 20 °C, 25 min; (f) $\text{HCl} - \text{MeOH}$.

The conversion of the easily accessible disulfide glyotoxin **99** into the tetrasulfide glyotoxin **G 102** was effected by treatment with sulfur and lithium α -toluenethiolate (0.1 equivalent) in CS_2 .¹¹²

An increasing number of papers have been dedicated to the synthesis of calicheamicin (**94**) and esperamycins (**96–98**). The introduction of the trisulfide fragment is not a challenging task. For example, the synthesis of a model compound **160** from the corresponding thiol was carried out by a standard procedure.¹⁴⁹

$R = \text{NHCOOMe}$.

The references^{150–156} are related to the total synthesis of sulfur-containing enediyne antibiotics and their fragments.

IV. Conclusion

As can be seen from the data presented, the natural polysulfides constitute a promising group of low-molecular-weight bioregulators. The chemistry of many of them is of substantial interest.

Thus the long-standing controversies about the nature of the biologically active substances of onion and garlic have been

resolved only very recently and required the use of sophisticated analytical procedures. One cannot but mention in this connection the promising studies dedicated to the modelling of structures of biologically active components of garlic.

There is no doubt that the knowledge of the mechanisms of action of unique trisulfide enediyne antibiotics will open up new routes in the search for inhibitors of growth of malignant tumours.

Some polysulfides of marine organisms draw attention with a combination of high biological activity and relatively simple structures. Taking into account the present-day level of organic synthesis, it may be thought that further development of technological methods for the synthesis of the most promising natural compounds and their active analogues is quite a realistic task. In this respect an appropriate example is the organisation of the large-scale manufacture of a selective insecticide bensultap, an analogue of the natural insecticide nereistoxin.

It is thought that keen attention of synthetic chemists will be drawn to natural aromatic polysulfides and dithiin derivatives possessing high antitumour activity.

Thus the chemistry of natural polysulfides offers a vast field for specialists in organic synthesis, who are interested in the synthesis of complex structures, as well as for all those who are engaged in the design of biologically active compounds.

The material presented herein prompts a conclusion that further developments in the field of chemistry and biochemistry of natural polysulfides and their analogues will have consequences which are valuable from the practical point of view for medicine and agriculture. Also of significance is the acquisition of fundamental knowledge of the reactivity and stereochemistry of sulfur-containing cyclic systems.

Nitrobutadienes and their halogen derivatives: synthesis and reactions

R V Kaberdin, V I Potkin, V A Zapol'skii

Contents

I. Introduction	827
II. Synthesis of nitrobutadienes and their halogen derivatives	827
III. Addition reactions	832
IV. Substitution reactions	834
V. Other reactions	839

Abstract. The main methods of the synthesis of nitrobutadienes and their halogen derivatives, which are multipurpose electrophiles, are surveyed. The literature data on their chemical transformations are generalised, the possibilities for the preparation of new polyfunctional derivatives of different classes on the basis of nitro- and halo-nitrobutadienes that have been inaccessible earlier are demonstrated. The bibliography includes 112 references.

I. Introduction

The chemistry of nitro compounds has been intensively studied during the last 20–25 years. Since 1970, many scientific papers, monographs,^{1–3} and reviews^{4–18} on the synthesis and the properties of these compounds have been published.

The interest in nitro compounds is primarily due to the possibilities of their application as unique intermediate products for the synthesis of various organic compounds. It should be noted that at present most attention is attracted to aliphatic nitro compounds. Thus, a review⁴ that first suggested the versatility and importance of aliphatic nitro compounds in organic synthesis appeared back in 1979. The results of subsequent studies in this direction (see for instance^{5,6}) have confirmed the importance of new investigations in the chemistry of nitro compounds of the aliphatic series.

At present, much attention is paid to the synthesis and the properties of nitro-alkenes and -alkadienes. Studies along the first direction are rather diverse and mostly concern such specific questions as the synthesis of nitrogen-containing heterocycles involving O and N atoms of the alkene nitro group,⁹ methods of synthesis and reactions of allylic nitro compounds and their derivatives,¹⁵ and others.^{12,16}

Recently interest increased in nitrobutadienes, and especially their halogen derivatives. These highly reactive substances were used to develop preparative methods for the synthesis of complex polyfunctional derivatives of different classes, that have been virtually inaccessible before. Thus an original method for the

synthesis of a valuable amino acid, lysine, from 1-nitrobuta-1,3-diene has been proposed. A convenient route for building of isothiazole cycle from 2-nitropentachlorobuta-1,3-diene and sulfur has been developed. Halogen derivatives of nitrobutadienes are suitable model objects for elucidation of the features of nucleophilic vinylic substitution ($S_N\text{Vin}$).

The publications that cover this subject, published before 1985, have been only partially discussed in monographs^{1–3} and a review.⁸ We have surveyed and systematised the results of investigations performed during the last two decades in the chemistry of nitrobutadienes and their halogen derivatives.

II. Synthesis of nitrobutadienes and their halogen derivatives

Basically, two main methods for the synthesis of nitrobutadienes including their halogen derivatives are used: (1) the direct nitration of butadiene and its derivatives by different nitrating agents; (2) the synthesis from more complex aliphatic nitrocompounds by elimination of different molecules (hydrogen halides, acetic acid, *etc.*). In some cases the formation of different geometric isomers of the nitro-substituted butadienes is possible. However, the configuration and the ratio between *E*- and *Z*-isomers have not been determined for all the halogenonitrobutadienes synthesised, therefore, we specify the isomeric form only if it is given in the literature, cited.

1. Preparation of nitrobutadienes and their halogen derivatives by nitration of dienes

a. Synthesis of mononitrobutadienes

The direct nitration of butadiene (**1**) by nitric acid results in 1-nitrobutadiene (**2**).^{19,20}

The conditions of this and other nitration reactions are summarised in Table 1. Dinitrogen tetroxide, dinitrogen pentoxide, and N_2O_4 in an oxygen flow can be used as the nitration agents in reaction with butadiene.^{8,21,22} However, the formation of nitrobutadienes was not observed in these cases, the reactions lead to the products of addition of NO_2 and ONO_2 to the diene **1**: 1,4-dinitrobut-2-ene (**3**), 4-nitrobut-2-enylnitrate (**4**) or 1-nitrobut-3-enyl-2-nitrate (**5**). The latter were used for the synthesis of nitrobutadiene **2** (see Section II.2).

Recently, the nitration of butadiene by trifluoroacetyl nitrate has been proposed, the reagent being generated *in situ* from ammonium nitrate and trifluoroacetic anhydride. A mixture of 1,2- and 1,4-nitro-trifluoroacetates thus formed (**6** and **7**, respectively) was treated with potassium acetate in ether or by sodium hydride in THF to give one isomer of the nitrodiene **2** in 89% yield.^{23,24} On the basis of IR-spectrum, *E*-configuration was assigned to the diene **2**. The nitrotrifluoroacetoxylation of butadiene may be represented by the following scheme:

b. Synthesis of halogenonitrobutadienes

The direct nitration of the corresponding dienes is mostly used for the preparation of polyhalogenonitrobutadienes and products of their oxidative destruction.

The nitration of 1,1,2,4,4-pentachlorobutadiene (**8**) with concentrated HNO_3 occurs at the dichlorovinyl group by electrophilic substitution of the H atom by the nitro group with the formation of 2-nitropentachlorobuta-1,3-diene (**9**) in ~40% yield.²⁵

The same authors studied the interaction of the diene **8** with other nitration reagents.²⁶ It has been shown that the nitration of the diene **8** by a mixture of HNO_3 and H_3PO_4 (10:1) allowed one to increase the yield of the target product **9** up to 58%–60%, the duration of nitration was thus shortened three- to four-fold. Increase or decrease in the content of phosphoric acid in the reaction mixture increases the reaction time and decreases the yield of the nitrodiene.

The nitration of the diene **8** by nitric acid and the 10:1 HNO_3 – H_3PO_4 mixture is accompanied by oxidative destruction, which leads to trichloroacrolein **10** (in ~12% yield) and trichloroacrylic acid **11** (in ~5%–7% yield).

The nitrodiene **9** was synthesised in 54%–55% yield by nitration of the diene **8** by a mixture of HNO_3 and H_2SO_4 (10:1). The higher content of H_2SO_4 in the mixture results in the activation of side reactions of chlorination and nitrochlorination of the starting diene **8**, which lead to 1,1,2,3,4,4,4-heptachlorobut-1-ene (**12**) and 3-nitro-1,1,2,4,4,4-hexachlorobut-1-ene (**13**).

The nitration of mixed bromochlorobutadienes has been studied in detail using 1-bromo-1,2,4,4-tetrachlorobuta-1,3-diene (**14**) which contains a β,β -dichlorovinyl group, as an example. Its

interaction with concentrated HNO_3 leads to 4-bromo-1,1,3,4-tetrachloro-2-nitrobuta-1,3-diene (**15**) (in 40% yield); bromodichloroacrylic acid (**16**) was found as a by-product.²⁷

If an $\text{HNO}_3(\text{conc.})$ – $\text{H}_3\text{PO}_4(\text{conc.})$ nitration mixture is used, the yield of the target product **15** is considerably increased, and under the optimum conditions amounts to 52%–53%.²⁸

The nitration of a mixture of two geometric isomers of bromochlorobutadiene **14** (*Z/E* = 25:75) resulted in the nitrodiene **15** in the form of two isomers in practically the same ratio. The individual isomers were isolated by column chromatography on silica gel.

The nitration of mixed pentahalogenobutadienes containing two Br atoms in the molecule have been studied using 1,2-dibromo-1,4,4-trichlorobuta-1,3-diene (**17**) and 1,3-dibromo-1,4,4-trichlorobuta-1,3-diene (**18**) as examples. Reaction of the *E*-isomer of the diene **17** with concentrated HNO_3 gave (*E*)-3,4-dibromo-2-nitro-1,1,4-trichlorobuta-1,3-diene (**19**) in 40% yield. If the mixture of concentrated HNO_3 and H_3PO_4 (10:1) was used for the nitration of the diene **17**, the yield of the nitrodiene **19** increased by 8%–10%.²⁹

The dibromotrichlorodiene **18** behaves in nitration similarly to the diene **17**.²⁹ 1,3-Dibromo-2-nitro-1,4,4-trichlorobuta-1,3-diene (**20**) was obtained as one isomer (in 35% yield) by reaction of *E*-isomer of diene **18** with HNO_3 . The nitration of the diene **18** by the mixture of HNO_3 – H_3PO_4 (10:1) allowed one to increase the yield of the target product **20** to 48%–50%.

Thus, the nitration of all the above-discussed polyhalogenobutadienes containing the β,β -dichlorovinyl group† proceeds in the usual way with the substitution of the H atom by the nitro group.

The behaviour of halogenobutadienes containing α,β -dihalo-vinyl groups, in reaction with nitric acid has been studied only with the example of (*Z*)-1,1,2,3,4-pentachlorobuta-1,3-diene (**21**). The action of concentrated HNO_3 on the diene **21** results in the substitution of the only H atom by nitro group with the formation of 1,2,3,4,4-pentachloro-1-nitrobuta-1,3-diene (**22**) (in ~49% yield).³¹ The use of a nitration mixture consisting of concentrated HNO_3 and H_3PO_4 allows one to obtain the target nitrodiene **22** in 55%–56% yield.

Hexachlorobutadiene (**23**) (~6%), trichloroacrylic acid (**11**) (~8%), and dichloromaleic acid (**24**) (in ~4% yield) are the by-products of the reaction. The use of fuming HNO_3 directs the reaction towards the preponderant formation of the valuable acid **24** (60%).³²

† It is interesting to note that 1,1,4,4-tetrachlorobuta-1,3-diene with two β,β -dichlorovinyl groups under the action of 58%–60% HNO_3 gives the addition product — 1,1,4,4-tetrachloro-1,4-dinitrobut-2-ene. No products of the substitution of H atoms by the nitro group were registered.³⁰

3. Other methods for the synthesis of nitrobutadienes

Among other methods for the synthesis of the nitro derivatives of butadiene, one should mention first of all the oxidation of the salts of 1,4-dinitrobut-2-ene into 1,4-dinitrobuta-1,3-diene **36**.^{52–54} The addition of 1 mol of an oxidising agent (Br_2 , I_2 , $\text{K}_3\text{Fe}(\text{CN})_6$, AgNO_3) to the suspension of **3** in ether gives dinitrobutadiene **36** in 50%–55% yield. Bromine, which has high oxidising potential, is the most universal oxidising agent.⁵³

The treatment of the butene **3** with methanolic KOH and bromine in methanol at -10°C gives diene **36** in 79% yield.⁴⁵

The redox titration has demonstrated that the transformations of the conjugated dianions proceeded as two-electron redox processes.⁵⁵

It has been found⁵⁵ that the nitrodiene **36** can be prepared in 50% yield by reaction of butene **3** with butyllithium in a mixture of THF and hexametaphol at -70 to -50°C and subsequent bromination at this temperature. The nitrodiene **2** was also found in the reaction products in 5% yield. The compound **36** presumably resulted from the two-electron oxidation process.

On the basis of a combination of several spectral data^{46, 54, 57} the *E,E*-structure was ascribed to the diene **36**.

A series of mixed nitroperhalogenobutadienes was obtained by exchange of the halogen atoms. Thus in the reaction of the nitrodiene **9** with AlBr_3 substitution of one or two Cl atoms by Br in the nitrodichlorovinyl fragment occurs depending on the ratio of the reagents.⁵⁸ At the ratio of **9**: AlBr_3 = 1:1 in refluxing bromoethane, a mixture of mono- and di-substituted products, 1-bromo-1,3,4,4-tetrachloro-2-nitrobuta-1,3-diene (**45**) and 1,1-dibromo-3,4,4-trichloro-2-nitrobuta-1,3-diene (**46**) in the molar ratio of 1.0:5.3 (GLC) is formed in 71% total yield.

The use of an excess of AlBr_3 (**9**: AlBr_3 = 1.0:1.5) gives the diene **46** in 55% yield. The nitrobutadiene **46** was also prepared in 71% yield by the action of AlBr_3 on the diene **45**.

The reaction of the nitrodiene **9** with sodium iodide in acetone (the Finkelstein reaction) results in 1,3,4,4-tetrachloro-1-iodo-2-nitrobuta-1,3-diene (**47**) in 59% yield.⁵⁸

The butadiene **46** also exchanges only one Br atom for I in the nitrodibromovinyl fragment under analogous conditions, giving 1-bromo-3,4,4-trichloro-1-iodo-2-nitrobuta-1,3-diene (**48**) in 54% yield.⁵⁸

The substitution of halogen atoms by nitrite ion, which has been well studied in the alkyl halide series, is represented by only two examples in the synthesis of nitrobutadienes.

1,3,4,4-Tetrachloro-1,2-dinitrobutadiene (**49**) was synthesised by the reaction of 2-nitrodiene **9** with potassium nitrite in aqueous medium with triethylbenzyl ammonium chloride (TEBA) as a phase-transfer catalyst.⁵⁹

The study of the effect of temperature, the duration of reaction, the reagent ratio, and the KNO_2 concentration on the course of the reaction has shown that the optimum conditions are as follows: 5% TEBA and a twofold molar excess of the 30% KNO_2 solution. In all cases, the conversion of the nitrodiene **9** was not complete, the yield of **49** did not exceed 29% with respect to the diene **9** consumed. The use of other phase-transfer catalysts, *e.g.*, tetraethylammonium chloride, dibenzo-18-crown-6, and 18-crown-6 gave no advantages in comparison with TEBA.

The nitrobutadiene **49** was obtained as a 3:1 mixture of two isomers, which were separated by column chromatography on silica gel and characterised by spectroscopy. It was estimated that the main product was the *Z*-isomer **49a**, the other compound the *E*-isomer **49b**:

1,2,3,4-Tetranitrobuta-1,3-diene (**51**) was obtained by the reaction of 1,2,2,3,3,4-hexachlorobutane (**50**) with KNO_2 in methoxyethanol at 120°C and isolated as salt in 91% yield.⁶⁰

III. Addition reactions

The development of methods for the synthesis of nitro- and nitrohalogen derivatives of butadiene paralleled their examination as the starting compounds for numerous chemical reactions.

1. Nucleophilic reactions

As a result of the electron-accepting effect of the nitro group, nitrobutadienes are able to participate in nucleophilic addition reactions. It has been shown, for example, that the simplest nitroalkadiene, 1-nitrobutadiene **2**, readily reacts with various nucleophilic reagents. The direction of these reactions depends on the nature of the nucleophile. They may occur both at the 1,2- and 1,4-positions of the diene system. Thus, the reaction of the nitrodiene **2** with aniline gives mostly 1-anilino-4-nitrobut-2-ene **52** (57%) characterised as the *N*-acetate.²⁴

The reaction of the nitrodiene **2** with ethanethiol preferentially occurs at the nitrovinyl group.⁶¹ The diene **2** reacts analogously with thiophenol to give the 1,2-adduct **53** in 54% and the 1,4-adduct in 13% yield:²⁴

The addition of C-nucleophiles to nitrodienes has been studied using the reaction of the compound **2** with ethyl nitroacetate **55**

Scheme 2

and nitromalonate **56** in the presence of triethylamine as examples.^{22, 62, 63} This reaction occurs at the 1,4-position and results in ethyl 2,6-dinitrohex-4-enoate (**57**) and diethyl 1,5-dinitropent-3-ene-1,1-dicarboxylate (**58**) in 32% and 35% yields respectively. The ester **57** was obtained in the form of two isomers, (*E*)-**57a** and (*Z*)-**57b**; also in the second case the product of bis-addition, ethyl 1,5,9-trinitronona-2,7-diene-5-carboxylate (**59**) was isolated (Scheme 2). Hydrogenation of the adducts **57** and **58** on a palladium catalyst in acidic ethanol resulted in the formation of ethyl 2,6-diaminohexanoate, its hydrolysis gave D,L-lysine hydrochloride **60** in 70% yield. This reaction is an original route for the preparation of a valuable amino acid, lysine.

In reactions with nucleophiles, dinitrobutadienes may give addition products of one or two molecules of the reagent as well as substitution products. The addition product of two molecules of ethanol, 2,3-diethoxy-1,4-dinitrobutane (**61**), has been isolated in 52% yield in the treatment of the nitrodiene **36** with ethanol at 25 °C.⁶⁴ The product of bis-addition **62** is also formed in the reaction of the diene **36** with ethanethiol.

X = O (**61**), S (**62**).

With more reactive arenethiols, the nitrodiene **36** gives the product of substitution of a nitro group, *e.g.* its reaction with thiophenol results in 4-nitro-1-phenylthiobuta-1,3-diene (**63**) in 42% yield.⁶⁵ The reaction of the nitrodiene **36** with *p*-toluenethiol in methanol proceeds analogously and gives 4-nitro-1-*p*-tolylthiobuta-1,3-diene (**64**) (28%).⁶⁶ In this case, presumably, the nucleophilic addition-elimination is realised. The direction of nucleophilic attack at the terminal C atom, which has never been observed earlier in reactions of aliphatic dinitrodiene with other nucleophiles, has been rationalised⁶⁶ as being due to the steric factors: the bulky reagent molecule and the stability of the conjugated system formed. On the basis of ^1H NMR spectra, an *E,E*-configuration was ascribed to compounds **63** and **64**.

Ar = Ph (**63**); *p*-MeC₆H₄ (**64**).

The oxidation of the 1-arylthio-4-nitrobutadienes **63**, **64** was used for the preparation of hitherto unknown and inaccessible 4-nitro-1-sulfonylbutadienes.⁶⁷

In the reaction of the dinitrodiene **36** with aniline, the C(2) and C(3) atoms are subjected to nucleophilic attack to give the product of bis-addition, 2,3-dianilino-1,4-dinitrobutane (**65**) isolated as a mixture of D,L- and *meso*-isomers in 65% overall yield.⁶⁸

The nitrodiene **36** reacts with CH-acids to give the addition product at one of the nitrovinyl fragments; the other nitrovinyl fragment isomerises in the presence of a base into the nitroallyl system, which does not enter into addition reactions.^{47, 51}

X = $-\text{CH}(\text{COOH})_2$ (**66**), $-\text{CH}(\text{COOPh})_2$ (**67**), $-\text{CH}(\text{COOMe})_2$ (**68**);
B = base.

It has already been mentioned that tetranitrobutadiene **43** is unstable. However it was possible to accomplish some chemical transformations of this compound *in situ* without its isolation from the reaction mixture. Thus the reaction of 1,1,4,4-tetranitrobutane-2,3-diol diacetate (**44**) with an equivalent quantity of alkali in ether and subsequent chlorination of the formed tetranitrobutandiol salt **44a** results in 1,4-dichloro-1,1,4,4-tetranitrobutane-2,3-diol (**69**) (Scheme 3). The diacetate **44** is readily deacetoxyated even under the action of weak bases. Its treatment with aniline resulted in a quantitative yield of 2,3-dianilino-1,1,4,4-tetranitrobutane (**70**).⁵¹

Scheme 3

2. Electrophilic reactions

Nitrobutadienes are far less reactive in electrophilic substitution reactions in comparison with butadiene, as the nitro group imparts a pronounced electrophilic character to the diene system. Only the reactions of electrophilic halogenation of nitrobutadienes are known. It has been found²⁰ that the nitrobutadiene **2**

adds bromine at the vinyl group with the formation of the dibromide **71** (no yield is reported).

The bromination of the nitrobutadiene **32** in chloroform proceeds slowly, however in a more polar solvent, such as acetic acid, it quickly adds two Br₂ molecules to form the tetrabromide **72**.⁶⁹

The bromination of the dinitrodiene **36** proceeds analogously, its product, tetrabromodinitrobutane **42**, is used in the synthesis of dibromodinitrodiene **41**.^{44–50}

The chlorination of the nitrodiene **36**, which results in the formation of the tetrachlorodinitrobutane **40** has been discussed earlier⁴⁴ (see Section II.2).

3. Cycloaddition reactions

The Diels–Alder reaction involving nitrobutadienes has not been adequately explored. It is known²⁰ that the 1-nitrodiene **2** reacts with maleic anhydride **73**, however the yield of the adduct **74** is only 4%.

The nitrodiene **2** does not react with benzoquinone, α -naphthoquinone, acrylonitrile, acrolein, and dimethyl acetylenedicarboxylate even at 90–100 °C, at > 100 °C the reaction mixture resinifies.²⁰

The 2-nitrodiene **32** has been shown to dimerise spontaneously in the process of its synthesis.⁷⁰ Dimerisation occurs as a [4 + 2]-cycloaddition reaction in which one nitrodiene molecule acts as a diene and the second one is a dienophile.

The nitrodiene **32** acts as a diene component in reactions with the maleic anhydride **73**, nitroethylene **75**, acrolein **76**, and acrylonitrile **77** and forms the corresponding adducts **78–81**.⁶⁹

X = NO₂ (**75**, **79**), CHO (**76**, **80**), CN (**77**, **81**).

The nitrovinyl fragment in the molecules of 2-nitrodienes manifests dienophile properties. Thus the reaction of the nitrodiene **32** with cyclopentadiene **82** gives the adduct **83**.⁶⁹

The behaviour of the diene **36** with pronounced electrophilic properties in the Diels–Alder reaction has been studied most extensively. Compound **36** has been shown to participate in reactions both as a diene and as a dienophile.^{47, 70–72} It acts as a

dienophile in the reaction with cyclopentadiene **82**. Thus at room temperature (48 h) 1 mol of diene **82** is added to the 1,2 position of the nitrodiene **36** to give 2-nitro-3-(2-nitroethenyl)bicyclo[2.2.1]hept-5-ene (**84**) in a 57% yield. If compound **84** is refluxed with the diene **82** in benzene for 8 h, the addition of the second mole of diene at the exocyclic double bond occurs with the formation of 3,3'-dinitro-2,2'-bis(bicyclo[2.2.1]hept-5-enyl) (**85**) (in 60% yield).

The nitrodiene **36** does not react with the anhydride **73**, which is a typical dienophile, *i.e.* it is inactive in the classical Diels–Alder synthesis. It turned out, however, that **36** undergoes the reverse Diels–Alder synthesis with nucleophilic dienophiles. It acts as a diene-acceptor in reactions with styrene and its derivatives, and the second components act as dienophiles-donors. The reaction of nitrodiene **36** with equimolar quantities of styrene and its *p*-substituted derivatives results in 1,4-adducts (Scheme 4), which spontaneously eliminate HNO₂ and are converted, depending on the reaction conditions, into either the corresponding 3-nitrobiphenyls **86–89** (on refluxing in toluene), or the bicyclic nitrocompounds **90–93** (on heating with the excess of styrene), or dimers (on heating with acetic acid).^{70–72}

Scheme 4

R = H (**86**, **90**), *p*-Cl (**87**, **91**), *p*-Br (**88**, **92**), *p*-Me (**89**, **93**).

IV. Substitution reactions

It is known that the occurrence of nucleophilic substitution reactions in the series of chlorine derivatives of butadiene depends to a considerable extent on the number of Cl atoms in the molecule and the nature of the terminal group and sometimes requires drastic conditions.⁷³

The development of convenient methods for the synthesis of highly electrophilic halogenonitrobutadienes allowed one to study in detail their behaviour in nucleophilic vinyl substitution reactions. The necessity of the studies of these reactions has been proved by quantum-chemical calculations that have been performed for a few halogen-substituted nitrobutadienes.

1. Quantum-chemical calculations

The quantum-chemical calculations of spatial and electronic structures were performed by semi-empirical methods CNDO/2,

Table 3. Effective charges (q) on atoms in halogenonitrobutadiene molecules (quantum-chemical calculation).

Compound	Method of calculation	q						
		C(1)	C(2)	C(3)	C(4)	N _i	N _t	O
9	CNDO/2	+0.118	+0.066	+0.112	+0.085	+0.453	—	−0.293
9	MINDO/3	+0.471	−0.272	+0.111	+0.343	+1.120	—	−0.550
9	MNDO	+0.127	−0.029	−0.008	+0.104	+0.188	—	−0.070
<i>E</i> - 15	MNDO	+0.134	−0.031	+0.005	+0.021	+0.362	—	−0.297
<i>Z</i> - 15	MNDO	+0.134	−0.028	+0.005	+0.022	+0.361	—	−0.298
<i>E</i> - 22	MNDO	+0.018	+0.083	−0.012	+0.078	—	+0.480	−0.290
<i>Z</i> - 22	MNDO	+0.019	+0.085	−0.030	+0.079	—	+0.472	−0.293
<i>E</i> - 28	MNDO	+0.026	+0.025	−0.070	+0.138	+0.475	+0.469	−0.293
<i>Z</i> - 28	MNDO	+0.028	+0.017	−0.052	+0.119	+0.477	+0.468	−0.297

Note. N_i and N_t are internal and terminal N atoms respectively. The averaged charge values are given for O atoms.

MINDO/3, and MNDO^{74–76} for the nitrobutadienes **9**, **15**, **22**, and **28**. It has been shown using diene **9** as an example that the results obtained by these methods are in satisfactory agreement with each other.⁷⁵

The molecules of mononitrodienes **9**, **15**, and **22** were found to be nonplanar with vinyl groups located in the planes that are virtually mutually perpendicular and with a violated conjugation in the diene chain. The molecule of dinitrodiene **28** exists in a nonplanar *s-trans*-conformation with the torsion angle C=C–C=C of 142.8°. The main geometric parameters of the molecules, such as bond lengths and angles, are in agreement with the analogous values for related compounds.^{2,77}

The lowest unoccupied molecular orbital (LUMO) is mostly (67%–85%) localised at the dihalogenonitrovinyl fragment of the molecule, mostly at the C atom adjacent to the =C(NO₂)– group and with the maximum positive charge. Consequently, the position adjacent to =C(NO₂)– is the most favourable for nucleophilic attack in the dihalogenonitrovinyl group. However, the exceptionally high positive charge at the N atom of the nitro group makes possible also the attack of hard nucleophiles at the =C–NO₂ fragment (Table 3).

The highest occupied molecular orbital (HOMO) is mostly (~70%) localised at the trihalogenovinyl group. In comparison with highly electrophilic dihalogenonitrovinyl groups, which represent hard electrophilic centres, the trihalogenovinyl fragments are soft electrophilic centres. The monochloronitrovinyl group in the nitrodiene **28** is less electrophilic than the dichloronitrovinyl group.

Thus, the quantum-chemical analysis shows that halogenonitrodienes must be active in processes of nucleophilic vinylic substitution ($S_N\text{Vin}$).

2. Interaction with C-nucleophiles

Reactions of halogenonitrobutadienes with organolithium compounds, which should be described as soft nucleophiles, according to the hard and soft acid-base principle have been studied only for mononitrodienes **9** and **22**.

The reaction of the nitrodiene **9** with methyl lithium (**9**: MeLi = 1:2, −75 to −70 °C) gives 1,1,2-trichloro-4-methyl-3-nitropenta-1,3-diene (**94**) (in 63% yield).^{78,79}

The reaction of the nitrodiene **9** with *n*-butyllithium under the same conditions results in a mixture of products of di- and monosubstitution, viz., 4-butyl-1,1,2-trichloro-3-nitroocta-1,3-diene (**95**) and 1,1,2,4-tetrachloro-3-nitroocta-1,3-diene (**96**), in the molar ratio of 1.5:1 in 58% overall yield. Increase in the amount of butyllithium practically does not change the ratio of the products formed, but decreases their overall yield. At the equimolar reagents ratio, the monosubstituted product **96** was isolated in 30% yield. It should be noted that the substitution is accompanied by considerable resinification.

The residual Cl atom of the nitrovinyl group of the monobutyl derivative **96** is readily substituted under the action of aniline, which results in the formation of 4-anilino-1,1,2-trichloro-3-nitroocta-1,3-diene (**97**).

In contrast to the 2-nitrodiene **9**, the 1-nitrodiene **22** reacts with both methyl- and butyllithium with the substitution of only the Cl atom (at position 2) and the formation of the corresponding 2-alkyl-1,3,4,4-tetrachloro-1-nitrobuta-1,3-dienes (**98** and **99**).⁸⁰

R = Me (**98**), Bu (**99**).

Under the optimum conditions (**22**: RLi = 1.0:1.2, −75 °C) the yield of the products is 36%–38%. The structure of the alkadienes **98** and **99** has been confirmed by spectral data and by a reaction of the butadiene **98** with fuming nitric acid leading to the formation of chlorocitraconic anhydride (**100**) and some other carbonyl compounds.

3. Interaction with thiols

The reactions of halogenonitrobutadienes with thiols, which, according to the Pearson's scale, are soft nucleophiles, have mostly been studied using pentahalogenodienes with terminal and inter-

The interaction of 1-nitrodiene **22** with amines occurs with substitution of only the α -Cl atom in α,β -dichloro- β -nitrovinyl group to give 2-amino-1,3,4,4-tetrachloro-1-nitrobuta-1,3-dienes (**168**–**173**) in 57%–89% yields.^{31,93} X-Ray structural analysis has shown that **168**–**173** have *E*-configurations.⁹⁴

R = H; R' = Ph (**168**), *m*-MeC₆H₄ (**169**), CH₂Ph (**170**), Bu^t (**171**);
RR' = CH₂(CH₂)₃CH₂ (**172**), (CH₂)₂O(CH₂)₂ (**173**).

The reaction of the dinitrodiene **28**, the molecule of which has two types of chloronitrovinyl fragments, with primary and secondary amines leads to the substitution of two geminal Cl atoms in the β,β-dichloro-α-nitrovinyl group with the formation of the corresponding 4,4-diamino-1-chloro-1,3-dinitrobuta-1,3-dienes (**174–181**) in 55%–75% yields.⁹⁵

R = H; R' = Ph (**174**), CH₂Ph (**175**), *m*-MeC₆H₄ (**176**),
2,4-Me₂C₆H₃ (**177**), Bu^t (**179**);
R = R' = CH₂Ph (**178**);
R – R' = CH₂(CH₂)₃CH₂ (**180**), (CH₂)₂O(CH₂)₂ (**181**).

The reaction of the dinitrobutadiene **28** with benzotriazole occurs with participation of both nitrovinyl groups.^{36,91} When a 1 : 4 mixture of diene **28** and benzotriazole was refluxed in ether, the substitution of the NO₂ group in the chloronitrovinyl fragment and one of the geminal Cl atoms in dichloronitrovinyl group by the azole residues occur to form 1,4-di(1-benzotriazolyl)-1,4-dichloro-2-nitrobuta-1,3-diene (**182**) in 55% yield. With a larger excess of benzotriazole (eightfold), the substitution of all the remaining Cl atoms occurs to give 1,1,4,4-tetra(1-benzotriazolyl)-2-nitrobuta-1,3-diene (**183**) in 45% yield (Scheme 7).

6. Reactions with bifunctional nucleophilic reagents

Polyhalogenonitrobutadienes react readily with various bifunctional nucleophiles, which allows one to synthesise a series of heterocyclic systems. On the basis of nitrodiene **9**, **15**, and **46**, preparative methods for the synthesis of earlier inaccessible heterocyclic compounds, containing the trihalogeno-1-nitropropenylidene radical in the side chain have been developed.^{85,96–99} In particular, the imidazolidine derivatives **184**, **185** were prepared by reaction of nitrodiene **9**, **15**, and **46** with ethylenediamine (Scheme 8), and reactions of the nitrodiene with monoethanolamine lead to the oxazolidine derivatives **186**, **187**. The nature of the solvent is very important for the reaction of the nitrodiene **15** with monoethanolamine. It turned out that the main reaction product in aqueous ethanol (5% H₂O) is the linear product **188**, i.e. monoethanolamine behaves as an N-nucleophile, which may

Scheme 8

9, **184**, **186**, **189**, **191**, **193–198**, **202**: X = Y = Cl;
15, **185**, **187**, **188**, **190**, **192**, **199–201**, **203**: X = Br, Y = Cl;
46, **184**, **186**, **189**, **191**, **193–198**, **202**: X = Cl, Y = Br.

Z = (CH₂)₂, (CH₂)₃, (CH₂)₆

The reaction of 1-nitrodiene **22** with bifunctional reagents occurs with the substitution of only one Cl atom in the α -position of the α,β -dichlorovinyl group to give the corresponding 2-mono-substituted products in preparative yields.³¹ The diene **22** reacts with monoethanolamine and cysteamine at the N-nucleophilic centre only in the presence of sodium ethoxide to form 1,3,4,4-tetrachloro-2-(2-hydroxyethylamino)-1-nitrobuta-1,3-diene (**204**) and 1,3,4,4-tetrachloro-2-(2-mercaptopethylamino)-1-nitrobuta-1,3-diene (**205**), respectively (Scheme 9).

1-Ethoxypentachlorobutadiene **218** is known¹⁰⁴ to be useful in the synthesis of a valuable squaric acid.

V. Other reactions

1. Synthesis of isothiazole derivatives

It is known that pentachlorobuta-1,3-dienes react with sulfur to form tetrachlorothiophenes.¹⁰⁵ Introduction of the nitro group into the polychlorodiene system considerably changes its reactivity. It has been recently shown^{106–108} that the reaction of the 2-nitrodiene **9** with sulfur occurs in a different direction with the participation of the nitro group and results in the formation of 4,5-dichloro-3-trichloromethylisothiazole (**220**) in 52% yield. This new, previously unknown reaction opens a convenient way to the construction of the isothiazole ring.

The unusual course of this reaction can be explained by the peculiarities of the electronic and molecular structure of the nitrodiene **9**. As has been shown by the quantum-chemical calculations,⁷⁵ C(4) and N atoms are closer to each other than C(4) and C(1) atoms, and the HOMO is mostly (about 70%) localised at the trichlorovinyl group, dominantly at the C(4) atom. Under the reaction conditions (180–200 °C), the sulfur molecules exist in the form of biradicals 'S_n·', the direction of their attack is determined by the HOMO structure. Thus a possible scheme for the process may be presented as the attack of a sulfur atom at C(4), subsequent elimination of SO₂ and cyclisation accompanied by migration of Cl atom.

New methods for the preparation of previously inaccessible, valuable products, such as isothiazole derivatives have been developed. Thus starting from compound **220** a biologically important 4,5-dichlorothiazole-3-carboxylic acid (**221**) was obtained in 92% yield.^{107, 109}

2. Reduction of nitro-substituted pentachlorobuta-1,3-dienes

The reduction of 2-nitro- (**9**) and 1-nitropentachlorodienes (**22**) by tin dichloride in acidic medium proceeds in an unusual way and results in the formation of oximes of 1,1,3,4,4-pentachlorobut-3-en-2-one (**222**) (75%) and of 1,2,3,4,4-pentachlorobut-3-en-1-ol (**223**) (59%), respectively.¹¹⁰

9: X = NO₂, Y = Cl;
22: X = Cl, Y = NO₂.

It has been found by spectral methods that oximes **222** and **223** are formed in one isomeric form: their configuration has been

determined by measuring the Nuclear Overhauser Effect (NOE) according to the NOEDIFF technique. The OH and CHCl₂ groups in the molecule of the oxime **222** are in the *syn*-position relative to the C=N bond, while in the oxime **223** the groups OH and CHClCCl=CCl₂ are in *anti*-position. It is interesting to note that the compound **222** hydrolyses on prolonged refluxing with concentrated HCl to form 1,1,3,4,4-pentachlorobut-3-en-2-one (**224**), which is used in the synthesis of medicinals.¹¹¹

Partial reduction of the nitrodiene **9** has been observed on its interaction with acyclic phosphites, 2-nitrosopentachlorobutadiene **225** (~ 10%) being one of the products.¹¹²

R = Me, CH₂CF₂CHF₂, CH(CF₃)₂; R' = NCO, RO.

* * *

Thus, nitrobutadienes and their halogen derivatives are valuable intermediates that may be used for the synthesis of compounds of different classes; original synthetic procedures were developed on their basis.

Of numerous methods of preparation of nitrobutadienes, the most convenient are the reactions of nitration of the corresponding dienes; they are especially promising in the synthesis of chlorosubstituted nitrobutadienes and their mixed bromochloro-containing analogues. The main types of chemical transformations of nitrobutadienes are addition and substitution reactions. The former are characteristic of the unsubstituted nitrodiene, while the latter are typical of their halogen derivatives.

Using halogenonitrobutadienes as examples, the formerly unknown peculiarities of the chemical behaviour of the nitro group in a polychlorodiene system have been elucidated. The possibility for the adequate interpretation of the regioselectivity of the nucleophilic vinylic substitution of the halogen atom and nitro group has been discussed in terms of the hard and soft acid-base principles.

It should, however, be noted that there are no data on fluorosubstituted nitrobutadienes. The development of the methods of their preparation and participation in chemical transformations is, to our mind, very interesting in both theoretical and practical aspects.

V. Conclusion	855

Abstract. Published data on the structure, properties and methods for the synthesis of inorganic sulfonates of polyvalent iodine are surveyed. Primary attention is devoted to the reactions of these compounds with organic substrates. The bibliography includes 129 references.

I. Introduction

Derivatives of hypervalent iodine were described for the first time back in the late XIX century.¹ The unusual ability of iodine to exhibit valences of III and V in organic compounds immediately attracted the attention of chemists. The first monograph on the chemistry of polyvalent iodine containing a systematic account of the data on the synthesis of organic derivatives of iodine(III) and iodine(V) was published as early as 1914.² However, by the late 70s, the interest in compounds containing polyvalent iodine had markedly decreased. The data accumulated by that time have been surveyed fairly completely in two reviews.^{3,4}

In the early 80s, derivatives of polyvalent iodine again attracted the attention of researchers; this was due to the wide use of these compounds in various fields of organic synthesis.^{5–15}

The progress in the chemistry of polyvalent iodine derivatives is largely determined by the stability of these compounds. In particular, it is known that the high instability of aliphatic iodoso-derivatives is due to the extremely high nucleofugal properties of the iodoso-fragment, which is among the best known leaving groups.¹⁶ The main factor influencing the stability of both organic and inorganic derivatives of polyvalent iodine is the presence of highly nucleofugal ligands or counter-ions in their molecules. The stabilising influence of nucleofugal counter-ions or ligands on compounds of polyvalent iodine is clearly illustrated by the fact that these compounds normally contain anions of strong acids, such as tetrafluoroborate (BF_4^-),^{17,18} perchlorate (ClO_4^-),¹⁷ nitrate (NO_3^-),¹⁹ tosylate (TsO^-),^{20,21} etc, as ligands. Compounds containing anions of sulfonic acids [tosylate, trifluoromethanesulfonate (triflate, TfO^-), or methanesulfonate (mesylate, MsO^-)] as well as sulfate or hydrogensulfate are readily available and most

convenient to work with. It is the sulfonate derivatives of polyvalent iodine that are used most often in synthetic organic chemistry.²² One of the most important applications of polyvalent iodine sulfonates is the synthesis of covalent tosylates, triflates, fluorosulfates and other compounds,^{23–26} which are difficult to obtain by other methods.

Organic sulfonate derivatives of trivalent iodine, like the other representatives of this class of compound, have been referred to collectively as 'iodoso-salts',⁴ which reflects the fact that these compounds have been derived from iodoso-compounds and from the corresponding acids (similarly to the interaction between acids and bases to give salts).

This analogy is made even closer by the fact that treatment of any arylidososulfonate with an alkali affords the initial iodoso-derivative.⁴

'Iodoso-salts' are usually stable and can be easily prepared; therefore, they have found wide application in organic synthesis.

In recent years, a wide range of organic derivatives of polyvalent iodine with various sulfonate ligands at the iodine atom have been obtained, for example, phenyliodonium sulfates,²⁷ hydroxy(mesyloxy)iodoarenes,²⁸ perfluoroalkyliodoso(hydroxy)-tosylates^{29–31} and μ -oxodiphenylbis(trifluoro-methanesulfonate-*O*)diiodine.^{23,32} Study of the reactivities of these compounds has shown that derivatives of iodosylperfluoroalkanes and -arenes containing nucleofugal sulfonate and sulfate groups as substituents at the iodine atoms are convenient reagents for the transformation of alkenes into vicinal disulfonates and cyclic sulfates.^{27,28} At the same time, iodonium sulfates react with alkyl iodides as oxidative deiodinating agents. These reactions afford covalent monosulfates.³³

The properties of other organic sulfonate derivatives have been studied in detail by American^{21,34–38} and Japanese^{39–41} researchers. The chemical properties of these compounds have been surveyed in several reviews (see, for example, Refs 7, 42, and 43). However, inorganic sulfates and sulfonates of hypervalent iodine have not been even mentioned in these reviews. This stimulated us to consider systematically studies devoted to the structure, methods for the synthesis and the chemical properties of inorganic sulfonates and sulfates of polyvalent iodine. For convenience, in the subsequent discussion, the word 'inorganic' is omitted from the expression 'inorganic sulfonates and sulfates of polyvalent iodine'.

II. The structure of sulfonates and sulfates of polyvalent iodine

Although the chemistry of organic derivatives of polyvalent iodine has been thoroughly studied and their nomenclature has been developed, there is still no exhaustive classification for the numerous sulfonates and sulfates of iodine (both organic and inorganic). One of the most widely used classifications of organic (including sulfonate and sulfate) derivatives of trivalent iodine is based on the formal account of the number of carbon and heteroatomic ligands at the iodine atom.^{4,7} According to this approach, related organic sulfonates are often considered as different structural classes. At the same time, the fact that all organic sulfonates and sulfates of polyvalent iodine [for example, $\text{RI}(\text{HSO}_4)_2$, $\text{R}_\text{F}\text{I}(\text{OSO}_2\text{F})_2$, $\text{PhI}^+\text{OSO}_3^-$, $\text{PhI}(\text{OH})\text{OTs}$, $\text{PhI}(\text{O}-\text{H})\text{OMs}$, $\text{Ar}_2\text{I}^+\text{OSO}_2\text{X}^-$ ($\text{X} = \text{OH}$, F , CF_3) and $\text{RPhI}^+\text{TfO}^-$] contain trivalent iodine is an argument for using a classification based on the valence state of iodine.

Classification of inorganic sulfonates and sulfates of polyvalent iodine takes into account the valence of the iodine atom and the types of sulfonate and sulfate ligands. The main types of known sulfonates and sulfates of polyvalent iodine are presented in Table 1. Inorganic derivatives are divided into two subgroups corresponding to I(III) and I(V).

Until the structure of iodine fluorosulfate as a derivative of I(III), $\text{I}(\text{OSO}_2\text{F})\text{I}$ (**1**), had been established unambiguously by X-ray diffraction analysis,⁴⁴ the majority of researchers^{45–49} had regarded this compound as a derivative of monovalent iodine. Despite the fact that no structural data have been obtained for iodine triflate, it would be legitimate to suggest (by analogy with the compound **1**) that this derivative, which is usually described by the formula $\text{I}(\text{SO}_2\text{CF}_3)_2$, also has a 'dimeric' structure, $\text{I}(\text{SO}_2\text{CF}_3)_2\text{I}$ (**2**). A convincing argument supporting this hypothesis is that these two reagents behave similarly in reactions with halogens.⁵⁰ Therefore, in the subsequent discussion, we use the formulae **1** and **2** rather than $\text{I}(\text{OSO}_2\text{F})$ and $\text{I}(\text{SO}_2\text{CF}_3)$ for iodine fluorosulfate and triflate, respectively.

Analysis of the published data indicates that the nomenclature of iodine sulfonates and sulfates is also ambiguous, since for these

compounds, various names are used. Table 1 presents the names that are used most frequently.

The structure of sulfonates and sulfates of polyvalent iodine has been studied using some representatives of this class as examples. In most cases, these compounds have been characterised by spectroscopic methods (^{19}F NMR, Raman, UV and IR spectroscopy), and the structure of iodine fluorosulfate **1** has been studied by X-ray diffraction analysis.⁴⁴ The most important feature of this structure is that both fluorosulfate groups are bound to one iodine atom (*i.e.* the formal oxidation state of one of the iodine atoms is +3, while that of the other atom is –1). With allowance for the two lone electron pairs present at the I(+3) atom, the geometry of its environment is a distorted trigonal bipyramid (a T-shaped structure), which is in line with the hypervalent nature of this compound. The lengths of the I–O bonds (2.26 Å) are greater than the sum of the covalent radii of I and O atoms indicating that these bonds are ionic to a certain extent. A significant feature of the geometry of the fluorosulfate **1** is the existence of an intermolecular O...I bond with a length of 3.05 Å. This bond is arranged almost across the I–I bond; this results in a distortion of the plane in which other bonds between the ligands and the 'central' iodine atom lie. The main structural parameters of the molecule **1** are shown in Fig. 1.

According to the Martin's classification of polycordinated derivatives of Group A elements,⁵¹ the compounds under consideration belong to the 10-I-3 type of structures. This means that the central iodine atom is surrounded by three ligands, and its valence shell contains ten electrons (including two lone pairs). The equatorial positions are occupied by the second iodine atom and by the two lone electron pairs. Fluorosulfate groups are in the axial positions. From numerous X-ray diffraction studies,^{52–56} it is known that organic derivatives of trivalent iodine are built similarly. The structure of $\text{I}(\text{SO}_2\text{F})_2\text{I}$ also resembles those of transition metal complexes.

The structures of iodine tris(fluorosulfates) and triflates have been studied by conductometry, calorimetry and spectroscopy. It was found that they behave as electrolytes in solutions of the corresponding acids. The high specific electrical conductivities of

Table 1. Types of inorganic sulfonates and sulfates of polyvalent iodine.

iodine tris(sulfonates) have been explained by their self-ionisation:^{57, 58}

Iodine tris(sulfonates) have also been studied by nuclear quadrupole resonance (NQR) spectroscopy and Mössbauer spectroscopy.⁵⁹ The results of these studies together with X-ray diffraction data for a related structure, tris(acetato)iodine(III) $\text{I}(\text{OCOCH}_3)_3$, imply that these compounds, like other derivatives of trivalent iodine, have T-shaped configurations.⁵⁹

The spectral characteristics of interhalogen fluorosulfates and interhalogen triflates, which are derivatives of trivalent iodine, make it possible to conclude that the geometries of their molecules are identical to those of other compounds of this class.^{49, 60}

The tentative inferences about the structures of iodosyl and iodyl sulfonates are based on some of their physicochemical properties. The fact that iodosyl and iodyl derivatives are insoluble in the corresponding acids is strong evidence for their polymeric structures.^{61, 62} The associated structure of iodosyl and iodyl sulfonates, postulated by Dasent and Wadington,⁶³ may be due to bridge binding of sulfonate groups or to the formation of chains consisting of $-\text{I}-\text{O}-\text{I}-$ fragments. This type of association is also supported by the Raman spectrum⁶³ of the iodyl fluorosulfate $(\text{O}_2\text{I})\text{SO}_3\text{F}$ (**3**), which does not dissociate to give O_2I^+ and SO_3F^- ions. The fact that the absorption band of the O_2I group is shifted by 50 cm^{-1} to shorter wavelengths points to a polymeric structure of this compound. The vibrational spectra of iodyl and iodosyl sulfonates also point to a polymeric structure of these compounds. In particular, the presence of a vibration band at 650 cm^{-1} in the spectrum of iodosyl fluorosulfate $(\text{OI})\text{SO}_3\text{F}$ (**4**) indicates that the OI groups are strongly associated and that $-\text{I}-\text{O}-\text{I}-$ chains are formed. In addition, the spectrum of this compound contains bands at 1350 , 1150 and 1000 cm^{-1} corresponding to vibrations of the SO_3 fragment. The two former frequencies are typical of bidentate bridging SO_3 groups, while the latter frequency, which is the lowest, is characteristic of monodentate SO_3 groups.⁶² Based on the spectral parameters of iodosyl trifluorosulfate and on the known structural features of other derivatives of polyvalent iodine, it can be assumed that the molecule of the compound **4** is a trigonal bipyramid, in which the base is formed by one oxygen atom and two lone electron pairs and the axial positions are occupied by the oxygen atoms of the fluorosulfate group.

Among polymeric iodine sulfates and sulfonates, only iodosyl sulfate $(\text{OI})_2\text{SO}_4$ (**5**) has been studied by X-ray diffraction analysis.⁶⁴ The results of this study indicate that this compound has a layered structure (sandwich-like layers parallel to the 001 plane). Each layer, in turn, consists of infinite helical chains (OI) linked to one another through SO_4 tetrahedra (Fig. 2). It should be noted

Figure 2. Projection of the polymeric chain in $(\text{OI})_2\text{SO}_4$ along the 010 plane.

that the same structure for the compound **5** has been proposed⁶³ based on its vibrational spectra.

If the two lone electron pairs are taken into account, the overall geometry of bonds surrounding the iodine atom is a distorted trigonal bipyramid, the iodine atom being located at its centre. The four oxygen atoms lie in the equatorial plane, while the two lone pairs occupy the axial positions. The $\text{I}-\text{O}$ bond lengths are dissimilar, namely: $\text{I}-\text{O}(1)$ 1.97 , $\text{I}-\text{O}(2)$ 2.53 and $\text{I}-\text{O}(3)$ 2.42 Å .

The molecular structure of the iodosyl sulfate **5** accounts for its instability with respect to water. Water molecules easily attack the SO_4 groups to give H_2SO_4 , the IO group being converted into I_2O_3 .⁶⁴

Valuable information about the reactivity of inorganic sulfonates can be obtained by studying their electrolytic dissociation. Study of the electrical conductivities of solutions of fluorosulfates, triflates and sulfates in concentrated sulfuric acid has shown that the majority of sulfonate derivatives dissociate in solution.^{65–67} It has also been found that in solution in trifluoromethanesulfonic acid, the fluorosulfate ligand in iodine tris(fluorosulfate) $\text{I}(\text{OSO}_2\text{F})_3$ **6** is readily replaced by a triflate ligand.⁶⁷ Fluorosulfonic (HSO_3F) and pyrosulfuric ($\text{H}_2\text{S}_2\text{O}_7$) acids have been found to be suitable solvents for iodine(III) interhalogen fluorosulfates.^{50, 60} Conductometric and spectroscopic studies of solutions of these compounds in the above acids indicate that iodine sulfates completely dissociate into ions and that dissociation is accompanied by quantitative formation of solvated cations $\text{IX}_2^+(\text{Solv})$ and $\text{I}_2\text{X}^+(\text{Solv})$. Study of the behaviour of solutions and melts of an equimolar mixture of $\text{I}_3\text{OSO}_2\text{F}$ (**7**) and $\text{IX}_2\text{OSO}_2\text{F}$ shows that exchange between the halide ligands occurs in these systems.

$\text{X} = \text{Cl}, \text{Br}$.

The ionic nature of the iodine–ligand bonds has also been confirmed by X-ray diffraction data,^{45, 64} which indicate that, whereas in organic sulfonates of trivalent iodine an increase in the nucleofugal capacity of the ligand results in an increase in the degree of ionicity of the bond (*i.e.* in an elongation of the $\text{I}-\text{O}$ bond), the $\text{I}-\text{O}$ bond (2.47 and 2.53 Å ⁶⁴) in iodosyl sulfate **5** is longer than the $\text{I}-\text{O}$ bond in iodine fluorosulfate **1** by approximately 0.2 Å , although the fluorosulfate group exhibits super-nucleofugal capacity. This seeming anomaly may be due to the fact that the iodine atom in the fluorosulfate **1** is bound to two oxygen atoms, whereas the iodine atom in the compound **5** (owing to the polymeric structure of iodosyl sulfate) is linked to four

oxygen atoms. Therefore, it may be expected that iodosyl sulfate would be a stronger electrophile than iodine fluorosulfate.

Thus, the data on the structures of inorganic sulfate and sulfonate derivatives of polyvalent iodine indicate that there is a clear-cut relationship between the nature of the ligands at the iodine atom and the structure of a particular derivative. It can be expected that the reactivity and physicochemical properties of these compounds would depend on the nature and the number of ligands and, in particular, that their electrophilicity would increase with an increase in the number and nucleofugal properties of sulfonate and sulfate residues.

III. Methods for the synthesis of sulfonates and sulfates of polyvalent iodine

The fairly intense development of the chemistry of this class of compound has resulted in the appearance of diverse methods for their synthesis most of which have been surveyed in reviews^{68–70} published in 1970 and 1974. However, the progress achieved in recent years has scarcely been surveyed, and in the recent review,⁷¹ methods for the synthesis of iodine sulfonates received little attention. We have attempted to fill this gap.

1. Iodine fluorosulfates

In most cases, various iodine sulfonates are synthesised by specific methods. Peroxydisulfuryl difluoride **8** proved to be the most convenient starting compound for the synthesis of iodine, chlorine and bromine fluorosulfates.⁷² Although **8** belongs to the class of peroxides, it differs from most of the known peroxides in that it is completely non-explosive and quite stable in the isolated state.²⁵

Since peroxydisulfuryl difluoride easily dissociates into relatively stable free radicals, the majority of reactions of this compound (including interaction with halogens) apparently involve fluorosulfate radicals.^{73,74} The reaction of the peroxide **8** with a halogen affords various fluorosulfates of this halogen. In 1959, the first halogen fluorosulfate — fluorine fluorosulfate — was prepared in this way.⁷⁵ The first iodine fluorosulfate was obtained from another compound, namely, silver fluorosulfate.⁷⁶ However, since this starting compound is too expensive, this method has not found practical application, and later, iodine fluorosulfate has been mostly obtained using peroxydisulfuryl difluoride.⁷⁷

The reaction of iodine with excess peroxydisulfuryl difluoride gives iodine tris(fluorosulfate) **6** in a good yield.⁵⁸

The main advantage of this method is that the resulting product requires no purification; only excess peroxide should be removed *in vacuo*. Iodine tris(fluorosulfate) is a non-volatile solid (m.p. 32 °C), which is hydrolysed fairly readily with water.⁷⁸ It can also be obtained by the reaction of the peroxide **8** with iodine chloride.⁷²

Another widely used fluorosulfate, the compound **1**, was prepared for the first time in 1965 by thermal decomposition of iodine tris(fluorosulfate).⁴⁹

The compound **1** is a non-volatile diamagnetic solid.⁴⁹ An alternative and a more convenient method for the synthesis of iodine fluorosulfate **1** consists in the oxidation of iodine with an equimolar amount of peroxydisulfuryl difluoride with heating.⁴⁹

When the reactants are taken in equimolar amounts, iodine fluorosulfate **1** is formed as the major reaction product. However, in addition to the compounds **1** and **6**, other iodine fluorosulfates of the composition $\text{I}_n\text{OSO}_2\text{F}$ are also formed in the $\text{I}_2\text{--S}_2\text{O}_6\text{F}_2$ system; this will be discussed below.

Not long ago, yet another method for the synthesis of the compound **1** has been proposed.⁷⁹ It involves oxidation of elemental iodine or perfluoroalkyl iodides with a milder oxidising agent, chlorine fluorosulfate ClOSO_2F (**9**).

The reaction of peroxydisulfuryl difluoride **8** with excess iodine gives rise to triiodine monofluorosulfate **7**.⁴⁹

A high yield of the product is achieved when iodine is taken in a slight excess with respect to its stoichiometric amount and the reaction mixture is slowly heated to 85 °C. Triiodine monofluorosulfate **7** is a hygroscopic solid; it melts at 92 °C with evolution of iodine.

Study of the magnetic, cryoscopic and spectral properties of the $\text{I}_2\text{--S}_2\text{O}_6\text{F}_2$ system has shown that, depending on the mole fraction of the peroxydisulfuryl difluoride present, several iodine fluorosulfates can be formed in the system.⁸⁰ The results of this study are presented as the dependence of the melting point of the system on the mole fraction of the compound **8** (Fig. 3). The maxima in this plot correspond to various iodine fluorosulfates. In particular, the researchers identified $\text{I}_7\text{OSO}_2\text{F}$, $\text{I}_3\text{OSO}_2\text{F}$ (**7**), $\text{I}(\text{OSO}_2\text{F})_2\text{I}$ (**1**), and $\text{I}(\text{OSO}_2\text{F})_3$ (**6**). Molecular weights of the components were determined by cryoscopy.

Figure 3. The $\text{I}_2\text{--S}_2\text{O}_6\text{F}_2$ system.

Another frequently encountered class of fluorosulfates of trivalent iodine comprises interhalogen fluorosulfates. These compounds can be synthesised using two approaches: direct introduction of a halogen or an interhalogen into the molecule of iodine trifluorosulfate⁵⁰ and the replacement of halide ligands at the iodine atom in a iodine interhalogen fluorosulfate or of two iodine atoms in triiodine monofluorosulfate by other halogens.^{50,81}

The former method has synthetic limitations. The reaction with chlorine occurs spontaneously at room temperature, whereas the reactions with bromine and iodine are initiated by heating the mixture to 85 °C.

Hal = Br, I.

Solid reaction products slowly crystallise out of the melt, and excess halogen is easily distilled off upon evacuation of the mixture cooled below room temperature. However, in the case of interhalogen derivatives ICl and IBr, which act as ionising solvents, it is very difficult to isolate solid crystalline products from a viscous solution containing an excess of an interhalogen compound.

An attempt to prepare diiodobromine fluorosulfate $\text{I}_2\text{BrO-SO}_2\text{F}$ (**10**) by the addition of elementary iodine to bromine fluorosulfate failed. The reaction yielded the compounds **1** and **7**.⁶⁰ In those cases where the reaction mixture was kept at room temperature, bromine volatilised, and the excess of the reagent formed a complex with the iodine fluorosulfate **1**.

Thus, if the halogen in the Hal_2 molecule is more electron-withdrawing than the halide ligands at the iodine atom in the interhalogen compound, the reaction yields new interhalogen fluorosulfates. Otherwise, substitution of the halogen in $\text{Hal}(\text{O-SO}_2\text{F})_2\text{Hal}$ occurs.

The second approach to the synthesis of iodine(III) interhalogen fluorosulfates by the replacement of halide ligands at the iodine atom is used more frequently.⁶⁰ The compounds **7** and **10** have been used as the initial compounds for the synthesis of various interhalogen derivatives. Some examples of these reactions are given below.

As in the case of addition, in this case, too, the higher electronegativity of the halogen atom entering the molecule compared to that of the halogen atom being displaced is the main driving force of the process. These reactions might occur *via* intermediates such as $\text{IX}_2\text{X}'_2\text{SO}_3\text{F}$, where $\text{X} = \text{I}$ or Br and $\text{X}' = \text{Cl}$ or Br . However, no experimental data supporting the existence of these intermediates have been obtained. In our opinion, this is due to their low stability.

The results of a study of the UV spectra and electrical conductivities of molten mixtures of symmetrical poly- and interhalogen fluorosulfates or their solutions in strong acids indicate the formation of non-symmetrical interhalogen cations. The similarity of the halogen exchange reactions in solutions and melts is due to the fact that in both cases, ionic dissociation of substrates occurs. The outcome of the exchange reactions is determined by the entropy and enthalpy factors, and they are favourable for the formation of a thermodynamically more stable non-symmetrical cation rather than of a symmetrical cation.

Oxidation of iodine with peroxydisulfuryl difluoride **8** results most typically in trivalent iodine. However, heating of the reaction mixture to 90–130 °C and the use of an excess of the peroxide **8** (the molar ratio of the reactants was 1 : 7) made it possible⁴⁹ to isolate iodine pentafluorosulfate **11**.

The same compound is formed in the pyrolysis of iodine tris(trifluorosulfate) **6**.⁴⁹

Iodine pentafluorosulfate was obtained by treatment of another fluorosulfate derivative of pentavalent iodine, namely, iodine trifluorobis(fluorosulfate) **12**, with sulfur trioxide.⁴⁹

Iodine trifluorobis(fluorosulfate) needed for this synthesis can be prepared by the reaction of iodine with an excess of fluorine fluorosulfate at room temperature.⁸²

After removal of the peroxide and excess hypofluorite, the product **12** is obtained in a quantitative yield. As should be expected, the ¹⁹F NMR spectrum of the iodine trifluorobis(fluorosulfate) **12** points to two types of the environment of the fluorine atom. At 25 °C, the fluorine atoms bound to iodine are responsible for a broad band, which splits below –10 °C into two peaks in a ratio of 2 : 1.⁸² The non-equivalence of the fluorine atoms is not manifested for the *cis*- and *trans*-isomers of iodine trifluorobis(fluorosulfate), which is in agreement with the tetragonal bipyramidal structure proposed for **12**.

Recently, it has been found that compound **12** and its analogues of the general formula $\text{IF}_n(\text{OSO}_2\text{F})_{5-n}$ can be obtained by insertion of sulfur trioxide into the I–F bond in iodine pentafluoride.⁸³ Moreover, by varying the molar ratio of the starting compounds, the reaction can be directed at the preparation of a particular compound of this group.

$n = 0 - 5$.

Thermolysis of one of these compounds, namely, iodine difluorotris(fluorosulfate) $\text{IF}_2(\text{OSO}_2\text{F})_3$ **13**, was found to yield the compound described by the formula $\text{OIF}_2\text{OSO}_2\text{F}$ **14**.

2. Iodine triflates

There are no direct methods for the synthesis of iodine triflates except for the synthesis of iodosyl and iodyl triflates, which is considered below in the section devoted to iodosyl and iodyl sulfonates. Therefore, iodine triflates are prepared by exchange reactions between derivatives of trivalent iodine, incorporating residues of oxygen-containing acids, with trifluoromethanesulfonic acid, which displaces anions of weaker acids from these iodine derivatives. For example, the synthesis of iodine tris(triflate) **15** from the tris(fluorosulfate) **6** and iodine tris(trifluoroacetate) is based on the fact that trifluoromethanesulfonic acid **16** is stronger than fluorosulfonic and trifluoroacetic acids.^{59, 67}

Iodine tris(triflate) **15** can also be obtained *in situ* by the reaction of iodine with peroxydisulfuryl difluoride without isolation of the intermediate iodine tris(trifluorosulfate).⁶⁷

These reactions do not give mixed compounds of the $\text{I}(\text{OSO}_2\text{F})_x(\text{OTf})_{3-x}$ type, because iodine tris(triflate) **15** is soluble only in trifluoromethanesulfonic acid, and the corresponding fluorosulfate is soluble in HOSO_2F and HOTf .

Iodine tris(triflate) **15** is a white hygroscopic solid melting at 119 °C; it is stable during heating to 170 °C *in vacuo*.

At present, the reaction of iodine tris(triflate) with an equimolar amount of iodine still remains the only plausible method for the preparation of iodine monotriflate **2**.⁶⁷

Iodine triflate **2** is a brown hygroscopic solid, m.p. 122 °C. On heating above 170 °C, it decomposes.

Interhalogen triflates, like interhalogen fluorosulfates, are formed in the oxidative addition of halogens to the iodine triflate **2**.⁵⁰

X = Cl, Br, I.

Despite the fact that various halogens can enter into this reaction, only the product of addition of bromine has been isolated in a pure state so far.⁵⁰ Spectroscopic studies have shown that dichloroiodine(III) triflate **17** is very unstable and readily decomposes.

Iodine adds to molten iodine triflate **2**; however, the reaction product has not been isolated;⁶⁷ apparently, this is due to the fact that triiodine triflate $\mathbf{I}_3\mathbf{OTf}$ decomposes at this temperature.

3. Complex salts of iodine tris(sulfonates)

As noted above, iodine sulfonates are self-ionised in solutions of the corresponding acids. This is a rationale of the amphoteric properties of iodine sulfonates.

The basic properties of iodine tris(fluorosulfate) **6** are manifested in its reaction with tin tetrafluorosulfonate **18** in peroxydisulfuryl difluoride.⁶⁵ This reaction results in the formation of a bright yellow complex salt **19**.

At the same time, in the reactions with alkali metal sulfonates, iodine tris(sulfonates) behave as acids.^{65, 67}

M = K, Rb, Cs.

These reactions are fairly convenient for the synthesis of iodine tetrakis(sulfonate) derivatives.

An alternative method for the preparation of the complex salt **20** and its sodium analogue **21** is the reaction of sodium (or potassium) iodide with excess peroxydisulfuryl difluoride **8** at room temperature.^{84, 85} In these reactions, iodine is oxidised to the trivalent state instead of being displaced from the molecule. The researchers believe that the corresponding metal fluorosulfonates $\mathbf{MSO}_3\mathbf{F}$ (M = Na, K) are formed initially, and then they are converted into the complex salts $\mathbf{M}[\mathbf{I}(\mathbf{SO}_3\mathbf{F})_4]$ **20** and **21**.

M = K (**20**), Na (**21**).

Tetracoordinated triflate iodates **22** are formed upon oxidation of alkali metal iodides with peroxydisulfuryl difluoride in trifluoromethanesulfonic acid.⁶⁷

Yet another method for the synthesis of complex sulfonates is ligand exchange at a tetracoordinated iodine atom. In this case, potassium tetrachloroiodate **23** serves as the initial compound for the preparation of the salt **20**.⁸⁵

A similar triflate salt **22** can be obtained by the replacement of the fluorosulfate group by a triflate group in the reaction of the salt **20** with an excess of trifluoromethanesulfonic acid **16**.⁶⁷

4. Iodosyl and iodyl sulfonates and sulfates

Analysis of various types of iodine sulfonates presented in Table 1 makes it possible to conclude that iodosyl and iodyl sulfonates are the most abundant type of compound among the derivatives in question. Therefore, it is expedient to consider in a separate Section the methods for synthesis of iodosyl sulfonates, which are I(III) derivatives containing an OI group, and iodyl sulfonates, which are I(V) derivatives containing an O₂I group.

The first attempts to synthesise iodosyl sulfonates date back to the late XIX century. As has already been noted, the first representative of this class, iodosyl sulfate (**5**, the Chrétien reagent), was obtained as early as 1898 by thermal decomposition of iodic acid in concentrated sulfuric acid.⁸⁶

Later, iodosyl sulfate **5** was prepared[†] by heating iodine pentoxide in concentrated sulfuric acid.⁸⁷ The researchers believe that in the first stage, the oxide $\mathbf{I}_2\mathbf{O}_5$ decomposes to $\mathbf{I}_2\mathbf{O}_3$. Iodine trioxide, which possesses basic properties, reacts, in its turn, with sulfuric acid to give iodosyl sulfate **5**.

More recently, iodosyl sulfate has been prepared using a redox reaction between elementary iodine and sodium (or potassium) iodate in concentrated sulfuric acid.⁸⁸

M = Na, K.

Concentrated nitric acid was also used as the oxidising agent for the synthesis of iodosyl sulfate **5**.⁸⁸

Iodosyl sulfate **5** reacts with sulfuric acid to give iodosyl hydrogensulfate **24**.⁷⁰

The compound **24** is unstable; in the opinion of the researchers cited,⁷⁰ it polymerises. It can serve as the initial compound in the synthesis of one more derivative of trivalent iodine, namely, iodosyl hydrogenpyrosulfate **25**.

Based on conductometric and spectroscopic studies, it was proposed that, unlike the initial iodosyl hydrogensulfate **24**, the compound **25** is ionic.⁷⁰

Iodosyl fluorosulfate **4** was synthesised for the first time in 1960 by the hydrolysis of iodine tris(fluorosulfate).⁵⁸

Later, its structure and properties were studied.⁶² This compound and related iodosyl triflate **26** were prepared by the reaction of iodine with iodine pentoxide and the corresponding acid.⁶²

[†] In the same study,⁸⁷ the structure of iodosyl sulfate was determined for the first time.

X = F (**4**), CF₃ (**26**).

In 1980, a new method for the preparation of iodosyl fluorosulfate **4** was proposed. The method consists in the oxidation of iodine with ozone in the corresponding acid under mild conditions.⁸⁹

Iodosyl sulfate **5** was also synthesised in this way.

However, the heavy drawbacks of this method associated with the use of gaseous ozone preclude its adaptation as a preparative procedure.

Sulfonate iodosyl derivatives are also formed when HIO₃ or HI₃O₈ is used instead of iodine pentoxide.^{62, 87}

X = F, CF₃.

When the two latter reactions are carried out in trifluoromethanesulfonic acid and without iodine, they afford iodyl triflate **27** rather than iodosyl triflate **26**.⁶²

The corresponding iodyl fluorosulfate **3** can formally be regarded as the product of insertion of sulfur trioxide into the I–F bond of iodyl fluoride O₂IF. Unfortunately, the attempt to synthesise iodyl fluorosulfate in this way was unsuccessful;⁹⁰ however, this derivative can be obtained relatively easily by the reaction of peroxydisulfuryl difluoride **8** with iodine penta- and tetraoxides.⁹⁰

At the same time, the reaction of the peroxide **8** with potassium iodate gives rise to compound **29**.⁶¹

The Raman spectra of **29** indicate that this compound is a stoichiometric mixture of potassium fluorosulfate and iodyl fluorosulfate. This implies that, unlike iodine tris(fluorosulfate) which forms complex salts, iodyl fluorosulfonate does not accept the fluorosulfate group.⁶¹

Oxidation of iodosyl fluorosulfate **4** with the peroxide **8** affords iodyl fluorosulfate **3**.⁶²

An alternative method for the preparation of iodyl fluorosulfate is based on the interaction of potassium metaperiodate with fluorosulfonic acid.⁹¹

To the best of our knowledge, no data on the synthesis of iodyl sulfates have been reported, whereas iodyl hydrogensulfate **30** has

been thoroughly studied. The latter compound has been synthesised by heating iodic acid in concentrated sulfuric acid.⁹²

Like iodyl and iodosyl sulfonates, iodyl hydrogensulfate **30** is polymeric. However in a highly dilute solution in sulfuric acid, this compound exists as the solvated monomer (O₂I)HSO₄·H₂SO₄.⁹³ When the concentration of the solution increases, the solvent molecule is eliminated from the solvate, and the iodyl fragments are joined together yielding polymeric chains.⁹³

Apart from iodyl hydrogensulfates, iodyl pyrosulfate **31** is also known. This derivative is readily formed upon heating of iodine pentoxide with liquid sulfur trioxide.⁹⁴

Iodyl pyrosulfate **31** can also be obtained by the reaction of liquid sulfur trioxide with potassium or tin iodate. However, when I₂O₄ was introduced into this reaction, it resulted in the formation of a mixed salt — iodosyl iodyl pyrosulfate **32**.⁹⁴

IV. Reactions of sulfonates and sulfates of polyvalent iodine

Sulfonates and sulfates of polyvalent iodine, synthesised about a century ago, have only recently attracted the attention of organic chemists as extremely reactive compounds; in some cases, the use of these reagents makes it possible to accomplish some transformations that have previously been impossible. These compounds are especially useful owing to two characteristic features of their chemical behaviour. Firstly, they are efficient oxidants and, secondly, the iodine atom in them exhibits clear-cut electrophilic properties in reactions with various organic substrates. By varying the oxidation state of the iodine atom and the nature of heteroatomic ligands, one can change substantially the particular manifestation of these properties and thus control the reactivity of sulfonates and sulfates.

Valuable information about the reactivity of iodine sulfonates could be obtained from a systematic consideration of the published data on the reactions of these compounds with alkyl halides, alkenes and aromatic compounds. Unfortunately, no systematic studies on the reactions of sulfonates with these substrates have been carried out. The available data are fairly scattered and mostly refer to the reactions of iodosyl sulfonates, iodine fluorosulfate and iodine tris(fluorosulfate). In fact, in the detailed reviews by Fokin *et al.*^{25, 71} devoted to synthetic applications of halogen fluorosulfates, reactions of iodine fluorosulfates are considered only cursorily.

Therefore, we attempted to classify the published data on this topic according to the type of reactions of iodine sulfonates and sulfates with unsaturated and aromatic compounds and with alkyl halides, in order to identify the common features of these reactions as functions of the nature of heteroatomic ligands at the iodine atom and its oxidation state.

1. Oxidative dehalogenation

Before we discuss the reactions of oxidative dehalogenation, we would like to emphasise that no data on this type of reaction have been reported for iodine triflates and sulfates, whereas oxidative dehalogenation of alkyl halides with iodine fluorosulfates has been studied fairly comprehensively.

In 1965, it was found that iodine fluorosulfate **1** and iodine tris(fluorosulfate) **6** vigorously react with carbon tetrachloride at room temperature.⁴⁹ Depending on the molar ratio of the sub-

strates, CCl_4 can be oxidised stepwise to give phosgene or carbon dioxide.

Iodine fluorosulfate equally readily oxidises chloroform and trichlorofluoromethane.⁴⁹ In addition to phosgene, carbon dioxide and fluorosulfonic anhydride, these reactions yield molecular chlorine. Iodine fluorosulfate **1** was found to react efficiently with pyridine to give a yellow hygroscopic solid.⁴⁹ However, the researchers were not able to identify the unstable products of the reaction. Iodine monofluorosulfate and tris(fluorosulfate) are less reactive towards fluorinated haloalkanes than fluorosulfates of other halogens. They do not react with dichlorodifluoromethane, trichlorotrifluoroethane or with primary perfluoroalkyl bromides.^{95, 96}

However, iodine monofluorosulfate and iodine tris(fluorosulfate) react relatively readily with non-fluorinated alkyl halides.⁹⁶

R = Me, Et; Hal = Cl, I.

(Triiodine monofluorosulfate has been found to be inert in all these reactions.⁷¹)

Iodine tris(fluorosulfate) **6**, as expected, is more reactive towards alkyl halides than iodine monofluorosulfate **1**, owing to the presence of three fluorosulfate ligands at the iodine atom. Thus the reaction of iodine tris(fluorosulfate) **6** with perfluoropropyl iodide **33** resulting in the replacement of the iodine atom by a fluorosulfate group occurs at 20–45 °C, whereas the same reaction involving iodine fluorosulfate **1** can be accomplished only under conditions of superacid catalysis in fluorosulfonic acid containing 15 mol.% of SbF_5 .

This process is accompanied by a slight exothermal effect.⁷¹

Based on experimental data, the researchers cited⁷¹ concluded that, in terms of their reactivity towards alkyl halides, iodine fluorosulfates can be arranged in the following series: $\text{I}(\text{SO}_3\text{F})_3 > \text{I}(\text{SO}_3\text{F})_2\text{I} > \text{I}_3\text{SO}_3\text{F}$. In other words, the activity of fluorosulfates decreases with a decrease in the number of fluorosulfate ligands.

A quantitative estimate of the oxidising ability of iodine fluorosulfates (based on the standard potentials established on platinum after it has been immersed into the compound under study) has shown that these reagents are among the strongest oxidants.⁹⁷ The results obtained in this study indicate that the above series for the reactivity of fluorosulfates in the oxidative dehalogenation coincides with the order of variation of their oxidising properties. Thus, it can be assumed that it is the oxidising capacity that determines the reactivity of fluorosulfates. This hypothesis is supported by the fact that the oxidising capacity

and the reactivity of iodine fluorosulfates in strongly acidic media (HSO_3F , $\text{HSO}_3\text{F}/\text{SbF}_5$) increase in parallel.

In the oxidative dehalogenation of RHal (Hal = Cl, I), iodine is more easily substituted by a fluorosulfate group than chlorine. An increase in the electron-withdrawing properties of groups attached to the same carbon atom as the leaving halogen atom retards the substitution of this atom by a fluorosulfate group.⁷¹ This provided grounds for assuming that during the replacement of halogen atoms in RHal , these atoms are oxidised with fluorosulfates to the trivalent state. The intermediate **A** thus formed decomposes to give the corresponding alkyl fluorosulfate and intermediate **B**.

R = Me, Et; Hal = Cl, I.

Based on the wrong idea that iodine fluorosulfate is a hypoiodite derivative, Fokin *et al.*⁹⁷ proposed the following scheme for oxidative dehalogenation:

R = Me, Et; Hal = Cl, I.

However, in view of the actual structure of the iodine fluorosulfate, which is constituted as $\text{I}(\text{SO}_3\text{F})_2\text{I}$,⁴⁴ and by analogy with iodine tris(fluorosulfate) **6**, the following reaction mechanism can be proposed:

R = Me, Et; Hal = Cl, I.

This mechanism for the substitution of a fluorosulfate group for the halogen atom in alkyl halides is supported by the data obtained by the same researchers on the interaction of iodine tris(fluorosulfate) **6** with fluoroalkenes⁹⁸ and bis(trifluoromethyl) ketene⁹⁹ (see Section IV.2) as well as by the synthesis of stable organic iodosyl fluorosulfates by oxidation of perfluoroalkyl iodides, in particular, of compound **35**.¹⁰⁰

The adducts of type **36** formed in this reaction are syrupy yellow liquids, which are stable during storage (20 °C) and decompose on heating.¹⁰⁰

Thus, analysis of the published data demonstrates that iodine fluorosulfates are convenient reagents for the preparation of esters of fluorosulfonic acid. It is noteworthy that the behaviour of other iodine sulfonates in these reactions has scarcely been studied; however, their high reactivity suggests that the use of these reagents in the processes considered above would substantially extend the potentialities of oxidative dehalogenation of alkyl halides.

2. Addition to alkenes

Electrophilic addition of iodine sulfonates has been little investigated. However, the reactions of iodine fluorosulfate **1** and iodine tris(fluorosulfate) **6** with deactivated alkenes have been studied in considerable detail.^{45, 79, 101} For example, it has been shown¹⁰¹ that iodine fluorosulfate **1** reacts in Freon 113 with fluoropropenes **37** and **38** and with tetrafluoroethylene **39** to give β -iodoalkyl fluorosulfates **40–42**.

In these reactions, the addition products are formed regiospecifically, whereas in the reactions with chlorotrifluoroethylene **43** and trifluoroethylene **44**, mixtures of regioisomers have been obtained.⁴⁵

The reaction with trifluoroethylene **44** gives compound **47** as the major product (85%), which has been isolated in a pure state.⁴⁶ Unfortunately, the products of addition of iodine fluorosulfate **1** to chlorotrifluoroethylene **43** have identical boiling points, which precluded separation of regioisomers **45** and **46**.⁴⁵

In the opinion of the researchers cited,⁴⁵ the course of the above reactions is markedly influenced by the fact that iodine fluorosulfate **1** is insoluble in Freon 113. This accounts for the relatively low reactivity of the compound **1** with respect to fluoroalkenes having less pronounced electrophilic properties. Thus the product of addition of iodine fluorosulfate **1** to octafluoroisobutene **49**, viz., compound **50**, was obtained only when the reaction mixture was kept for 3 weeks at 20–25 °C.⁴⁵

Iodine fluorosulfate **1** adds to perfluorinated cyclobutene⁴⁶ and cyclopentene⁴⁶ and readily reacts with highly electrophilic substrates such as bis(trifluoromethyl) ketene **51**.⁴⁵

The ease of the reaction with the ketene **51** was attributed⁴⁵ to the tendency of iodine fluorosulfate **1** to form intermediate complexes of type **B**; this assumption implied an electrophilic mechanism of this reaction.

When iodine fluorosulfate **1** reacts with perfluorinated methyl vinyl ether **52**, compound **53** resulting from the atypical addition of the fluorosulfate at the multiple bond is formed as the major product, whereas only traces of the normal addition product **54** have been isolated.¹⁰²

Adducts of iodine fluorosulfate with perfluoroalkenes are readily converted into acid fluorides.¹⁰² Recently, β -iodoperfluoropropyl fluorosulfate **55** has been converted into α -iodoperfluoropropionyl chloride **56**, which is a convenient intermediate for the manufacture of ion-exchange membranes.⁴⁷

Although the electrophilic properties of iodine tris(fluorosulfate) have been little studied, the available data indicate that it is more reactive than iodine fluorosulfate.⁹⁵ Iodine tris(fluorosulfate) **6** reacts with fluorinated derivatives of ethylene and propylene with heat evolution.⁹⁸ Its reactions with tetrafluoroethylene, 1,2-dichlorodifluoroethylene, chlorotrifluoroethylene and perfluoropropylene give rise to β -iodoalkyl fluorosulfates and perfluoroalkane-1,2-diyl bis(fluorosulfates), i.e. the products of formal addition of iodine fluorosulfate and peroxydisulfuryl difluoride at the double bond.^{98, 100}

In order to elucidate the nature of the multiple bond in fluorine-containing bicycloheptenes, the reaction of iodine tris(fluorosulfate) **6** with the adduct formed by hexafluoropropene and cyclopentadiene **57** has been studied.¹⁰³ Despite the fact that the compound **6** is highly electrophilic, it adds at the double bond in bicycloheptene **57** without rearrangement to give 1,2-addition products. As in the case of acyclic perfluoroalkenes, the reaction affords iodo fluorosulfate **58** and bis(fluorosulfate) **59**.

Important conclusions concerning the mechanism of this reaction could be drawn from the configurations of substituents in the reaction products. Unfortunately, the stereochemistry of the reaction was not studied.

The reaction of iodine tris(fluorosulfate) **6** with bis(trifluoromethyl)ketene **51** is of considerable interest. This reaction has permitted the synthesis of a stable organic iodosyl fluorosulfate **36**.⁹⁹

The stability of the compound **36** is due to the strong electron-withdrawing influence of the perfluoroalkyl and ester groups, which markedly hamper processes of nucleophilic substitution in this molecule.

The latter reaction also seems to be of prime importance from the theoretical viewpoint. The fact that a stable product of 1,2-addition is formed in this reaction makes it possible to rationalise the formation of bis(fluorosulfates) and β -iodofluorosulfates in the reactions of iodine tris(fluorosulfate) **6** with alkenes.^{99, 100} It was assumed that these reactions involve type **C** intermediates, which are unstable and decompose to give a bis(fluorosulfonyloxy)alkane and iodine fluorosulfate. The latter adds to the excess of the alkene giving rise to β -iodo-fluorosulfate.⁹⁹

The authors of the present review have studied electrophilic addition of iodosyl fluorosulfate **4** to various alkenes.^{104–106} In the case of simple alkenes, these reactions occur vigorously and are accompanied by strong resinification. Normal addition products were obtained only for deactivated alkenes. For example, tetrachloroethylene reacts with iodosyl fluorosulfate **4** to give β -iodofluorosulfate **60**.¹⁰⁴

One of the possible ways of controlling the reactivity of iodosyl fluorosulfate **4** is to conduct the reactions with activated acyclic and cyclic alkenes in the presence of external nucleophiles. Thus the reaction of **4** with hex-1-ene **61** in the presence of lithium perchlorate results in the formation of bis(perchlorate) **62**.¹⁰⁴

Stereochemical features of the addition of the reagent **4** to double bonds with the participation of external nucleophiles have been studied for the reactions with cyclohexene. If perchlorate anion is added as the nucleophile, the reaction affords 1,2-*cis*-diperchloroxy cyclohexane **63** in 61% yield;¹⁰⁴ if sodium azide is used instead of the perchlorate, 2-iodocyclohexyl azide **64** having the *trans*-configuration is formed.¹⁰⁴ When this reaction was carried out in acetonitrile, the product of conjugate addition, *trans*-iodoacetamide **65**, was obtained in a yield of 46%. In the presence of lithium perchlorate, in addition to the substituted acetamide **65** the yield of which increased under these conditions to 61%, diperchlorate **63** (15%) resulting from the competing addition of the nucleofugal perchlorate anion was isolated in a relatively low yield (15%).

The addition of the reagent **4** to α -pinene **66** in acetonitrile occurs regioselectively and gives the rearranged acetamide **67**.¹⁰⁷

Other rearranged products, namely, compounds **68–71**, have been obtained by the reactions of iodosyl fluorosulfate **4** with alkenes of the norbornane series.^{104, 105, 108–110}

However, the reactions with the most deactivated fluoro-containing bicyclo[2.2.1]heptenes **57** and **72** afford 1,2-adducts **73–75** as the only products.^{105, 109, 110}

The reactions in which the addition of iodosyl fluorosulfate **4** to an unsaturated molecule is accompanied by ring closure are of particular interest.^{104, 111, 112} For example, norbornenedicarboxylic acid **76** and its anhydride **77** react with **4** to give bis- γ -lactone **78**. When the reaction with the acid **76** is carried out in acetonitrile, the yield of the lactone **78** is nearly quantitative.¹⁰⁴

The reaction of the compound **4** with the cage diene **79** containing *cis*-arranged methoxycarbonyl groups in dichloromethane affords a mixture of two products, δ -lactone **80** and γ -lactone **81**.¹¹¹ When more polar acetonitrile is used as the solvent, δ -lactone **80** becomes the only reaction product.¹⁰⁴

The reaction of iodosyl fluorosulfate with diene **82** containing *trans*-methoxycarbonyl groups in acetonitrile gives rise to δ -lactone **83** and amide **84**.¹⁰⁴

A similar reaction involving triene **85** the geometry of which precludes its lactonisation yields products of addition formed with the participation of external nucleophiles.

It is of interest that in the case of unsaturated cage ester **86** containing a cyclopropyl fragment, the attack is directed at the double bond, the three-membered ring being retained in the final product **87**.¹¹²

An alternative route for the transformations of iodosyl fluorosulfate, in particular, the transfer of its SO₃ fragment onto a double bond, was discovered when this reagent was made to react with α -pinene **66** and 5-*endo*-trifluoromethylnorbornene in ether without any additional nucleophiles. These reactions, which are accompanied by skeletal rearrangements and are highly stereo- and regio-selective, result in the formation of γ -sulfones **88** and **89**.¹⁰⁶

Based on these results, all the characteristic features of the reactions of iodosyl fluorosulfate **4** with alkenes can be interpreted in terms of a single mechanism. According to this mechanism, in the first step the double bond in the substrate is attacked by the iodosyl cation (the reagent **4**).¹⁰⁴ The subsequent opening of intermediate **D** can occur under the action of either the anion of **4** or an external nucleophile.

The formation of products of skeletal rearrangements in the case of bi- and polycyclic alkenes indicates that intermediate **D** is highly ionic and, hence, that iodosyl fluorosulfate is a strong electrophile. A distinctive feature of these processes is that most of the products contain an iodine atom rather than an iodosyl group. The elimination of oxygen from the intermediate iodosyl compounds of type **E** and **F** is due to the influence of excess alkene. This type of behaviour of iodosyl compounds has been established reliably for aromatic iodosyl derivatives.^{113–115} It can be assumed that aliphatic iodosyl compounds would behave similarly. The regioselectivity of reactions in the series of fluorine-containing norbornenes and α -pinene is controlled by electronic effects of the substituents.

In the case where sultones are formed, the reaction occurs *via* compound **G**, which eliminates iodosyl fluoride. The formation of the OI–F bond is the driving force of this process.

Thus, the reactions of iodosyl fluorosulfate with alkenes considered above indicate that this reagent, like iodine mono- and tris(fluorosulfates), is highly electrophilic. By varying the conditions of the reactions involving iodosyl fluorosulfate, one can control its reactivity, which makes it possible to transform alkenes into diverse derivatives.

3. Aromatic electrophilic substitution

The ionic nature of the majority of sulfonate derivatives of polyvalent iodine accounts for their possible participation in aromatic nucleophilic substitution reactions. These reactions yield iodosylarenes, which are traditionally used in the synthesis of diaryliodonium salts.^{116–119} Therefore, the high reactivity of iodine sulfonates permits them to be used as convenient initial compounds for the preparation of diaryliodonium salts, which are efficient arylating reagents.^{120–122} In particular, treatment of chlorobenzene with iodosyl sulfate gives rise to diaryliodonium salt **90**.⁸⁸

At the same time, when di(4-nitrophenyl) ether is introduced in this reaction, cyclic product **91** is formed.¹²¹

The formation of diaryliodonium hydrogensulfates has been explained⁸³ in the following way. Electrophilic attack by the iodosyl cation $^+\text{I}=\text{O}$ on the aromatic ring yields an intermediate iodosylarene derivative the condensation of which with a second molecule of the aromatic compound gives rise to the diaryliodonium salt.

Diaryliodonium hydrogensulfates can also be obtained by using iodosyl hydrogensulfate **24**.⁹²

X = Alk, Hal.

Diaryliodonium salts also arise in the reaction of potassium iodate **28** with aromatic substrates in the $\text{H}_2\text{SO}_4\text{--AcOH--Ac}_2\text{O}$ system.⁸⁸ This method is especially significant for the synthesis of salts containing electron-withdrawing substituents.

Although potassium iodate acts as an initial compound in this reaction, it was assumed⁸⁸ that diaryliodonium salts are formed by a mechanism that includes the *in situ* generation of iodyl hydrogensulfate **30**.

The participation of iodine fluorosulfates in aromatic electrophilic substitution has been studied only for iodosyl fluorosulfate **4**. Recently, it has been found that this compound reacts efficiently under mild conditions with benzene and its derivatives containing *ortho*- and *para*-orienting substituents to give diaryliodonium hydrogensulfates **92** with a *para*-substituted aromatic ring.¹²³

R = H: X = H (**a**), Me (**b**), Bu^t (**c**), F (**d**), Cl (**e**), Br (**f**);

R = X = Me (**g**).

The fact that this reaction is regioselective confirms the ionic structure and, hence, the high electrophilicity of iodosyl fluorosulfate. Moreover, this compound is highly reactive towards deactivated substrates such as halobenzenes and nitrobenzene. The latter reaction occurs at room temperature and yields 3,3'-bis(nitrophenyl)iodonium salt **92h** as the only product.

In all cases, iodonium hydrogensulfates were isolated instead of the expected fluorosulfates. This can be due to the intermediate formation of arylidonium sulfates.

The formation of iodonium hydrogensulfates **93** in the reaction of phenyliodonium sulfate **94**, generated from iodosyl benzene and sulfur trioxide,¹²⁴ with aromatic compounds¹²⁰ can serve as experimental evidence supporting this mechanism.

Ar = Ph, 4-MeC₆H₄, 4-FC₆H₄, 4-IC₆H₄, 4-Bu^tC₆H₄,
2,4-Me₂C₆H₃, 2,4,6-Me₃C₆H₂, 3-NO₂C₆H₄.

Unlike the above reactions involving sulfates and hydrogensulfates, which occur in sulfuric acid as a solvent and give products in low yields, the reactions with iodosyl fluorosulfate proceed under mild conditions even with aromatic compounds deactivated with respect to electrophilic attack, for example, with fluorobenzene and nitrobenzene. Since this procedure readily gives diaryliodonium salts in high yields directly from aromatic compounds, and the target products can be easily isolated, this method can find wide use in organic synthesis.

An important feature of the reactions of iodosyl fluorosulfate **4** is that they enable the preparation of diaryliodonium hydrogensulfates, which are convenient synthons that can be further converted into other iodonium salts with non-nucleophilic anions (BF₄⁻, SbF₆⁻ or PF₆⁻). In recent years, these salts have been finding increasing application as catalysts of radiation-induced cationic polymerisation.¹²⁵ In order to prepare these salts, the diaryliodonium hydrogensulfates were treated, without isolation, with aqueous solutions of inorganic salts containing the anions listed above. Thus, diaryliodonium salts with the desired non-nucleophilic anions can be obtained in one stage.^{88, 120}

It may be expected that not only iodosyl sulfates, hydrogensulfates and fluorosulfates, but also other sulfonates of polyvalent iodine would be highly reactive towards aromatic compounds. In fact, recently it has been found that iodosyl triflate **26** is a convenient reagent for the synthesis of diaryliodonium triflate **95** from trimethylsilylarenes.¹²⁶

The versatility of this method was demonstrated for a wide range of alkyl- and halogen-substituted benzene derivatives. The yields of products reached 57%–93%.

It should be noted that no information about the reactions of other iodine sulfonates with aromatic compounds can be found in the literature.

4. The reactions of iodosyl triflate with trimethylsilyl cyanide and trimethylsilylacetylenes

Apart from aromatic electrophilic substitution typical of all iodosyl sulfonates, the interaction of iodosyl triflate **26** with trimethylsilyl cyanide is also of particular interest.¹²⁷ This reaction gives rise to bis(cyano)iodonium triflate **96**.¹²⁷

Crystalline bis-cyanide **96** is unstable. At room temperature, it entirely decomposes over a period of 3–5 min. Nevertheless, despite its instability, the bis-cyanide **96** obtained *in situ* is efficiently used in the synthesis of diaryl- and bis(hetaryl)-iodonium salts.¹²⁸ Bis(hetaryl)iodonium triflates **97** were prepared for

the first time in this way, the reaction being carried out under mild conditions (in dichloromethane, at a low temperature).¹²⁸

X = O, S; R = H, Br.

A similar reaction of iodosyl triflate **26** with trimethylsilylacetylenes results in the formation of bis(alkynyl)iodonium salts **98**.¹²⁹

R = Bu^t, Me₃Si, PrⁱSi.

The stability of the iodonium salts **98** was found to decrease in the following series of substituents: PrⁱSi > Me₃Si > Bu^t.

It can be seen from the presented examples that the synthetic strategy based on the use of iodosyl triflate is determined by its ability to react under extremely mild conditions with organic substrates containing readily leaving trimethylsilyl groups to give a highly reactive iodonium intermediate (for example, salt **100**), which subsequently decomposes with evolution of (Me₃Si)₂O.

This mechanism is supported by the fact that the vinyl cations **99** are stabilised by bulky substituents with positive inductive effects.¹²⁹

In conclusion, it should be noted that iodosyl triflate still remains the only reagent used for the synthesis of bis(cyano)- and bis(alkynyl)-iodonium salts.

V. Conclusion

The published data indicate that methods for the synthesis, the physical properties and mutual transformations of inorganic sulfonates of polyvalent iodine have been studied much more thoroughly than their reactions with organic substrates; this is confirmed by the number of relevant publications. There are only few studies devoted to electrophilic addition reactions involving certain iodine fluorosulfates and to electrophilic substitution for iodosyl sulfonates. Publications dealing with the electrophilic addition of sulfates and triflates of polyvalent iodine to alkenes are totally missing.

Nevertheless, the existing material indicates that these compounds possess unique reactivity, which permits them to be regarded as promising reagents in organic synthesis.

Abstract. Two physical models of radical abstraction reactions are described: the model of intersecting parabolas and the model of intersecting Morse curves. A systematic account is given of the results of the analysis of a large set of experimental data (rate constants and activation energies) for a wide variety of radical reactions. It is shown that the activation energies for such reactions depend on their enthalpies, on the force constants of the reacting bonds, the strength, length, and polarity of the X–Y bond in the $X^\bullet + HY$ reaction, and also the presence in the reactants of one or several polar groups, π -bonds, and bulky groups adjoining the reaction centre. Solvation plays an important role in processes involving polar reactants. Both methods are compared as instruments for the calculation of the activation energy and bond strengths. The limits of applicability of the methods are examined. The bibliography includes 93 references.

I. Introduction

Bimolecular radical abstraction reactions are a component of the most varied chemical processes such as combustion, halogenation, the cracking and oxidation of hydrocarbons, polymerisation and degradation of polymers, photolysis and radiolysis of organic compounds, etc. They began to be investigated vigorously as early as the 1920s.

The comparison, analysis, and generalisation of data on the reactivities of molecules and radicals in various radical reactions occupy an important place in studies on bimolecular radical abstraction reactions. The first important step in this direction

was taken almost 60 years ago when Evans and Polanyi¹ established empirically the linear relation between the changes in the activation energy ΔE and the heat of reaction Δq in a series of reactions of atomic sodium with alkyl halides. Later Semenov² demonstrated in relation to extensive experimental data that the linear relation

$$E = A' + \alpha' q \quad (1)$$

holds also in other radical abstraction reactions. The Hammett³ and Taft⁴ linear correlation equations came to be widely employed in physical organic chemistry in the 1960–1970s and are also applicable to the kinetics of radical reactions.^{5,6} It has been noted in Semenov's monograph² that these correlations may be reduced to the linear equation (1). Linear correlations of this kind assist to some extent in a systematic treatment of experimental data on activation energies and rate constants, but the possibility of using them for a deep analysis of the problem of reactivity is restricted to the range of isotypical reactions. Furthermore, the treatment of the physical sense of correlation coefficients is sometimes fairly arbitrary. Quantum-chemical methods, which constitute a theoretical alternative to experimental kinetic methods, also make it possible to calculate the rate constant for a particular individual reaction.^{7–10} However, the problem of comparison and generalisation of kinetic data referring to different classes of chemical reactions as well as the problem of correlation between the reactivities of reactants and their structures and physical characteristics remain unsolved in this case too.

Several years ago, the author of the present review used a simplified model of an elementary bimolecular reaction — the intersecting parabolas model (the IP model) — in the analysis of the activation energies for a wide variety of radical abstraction reactions.^{11–13} This model can be regarded as a further development of the empirical approach initiated in the studies of Polanyi¹ and Semenov.² As a result, it became possible to separate diverse radical abstraction reactions into classes and to differentiate in each class groups of isotypical reactions. Each reaction is

E T Denisov Institute of Chemical Physics in Chernogolovka, Russian Academy of Sciences, 142432 Chernogolovka, Moscow Region, Russian Federation. Fax (7-096) 515 35 88. E-mail denisov@icp.ac.ru

Received 12 March 1997

described by two parameters referring to the entire given class of reactions: one parameter, characteristic of the group of reactions, and one individual parameter, namely the enthalpy of reaction, characteristic of the given reaction. The creation of a hierarchical system of reactions made it possible to identify at an empirical level the physical characteristics of the reactants determining the height of the activation barrier. Another model of such reactions, namely the model of two intersecting Morse potential curves (the MPC model) has been devised recently.¹⁴ The present review is devoted to the description and comparison of the results obtained by these two methods in the analysis of a large set of experimental data referring to radical abstraction reactions in the gas^{15–19} and liquid^{5,20–26} phases.

II. The intersecting parabolas model

In the IP model,^{11–13} the radical abstraction reaction

in which a hydrogen atom is transferred from the initial (RH) to the final (XH) molecule, is regarded as the result of the intersection of two potential curves, one of which describes the potential energy $U_i(r)$ of the vibration of the H atom along the bond being dissociated in the initial molecule and the other describes the potential energy $U_f(r)$ of the vibration of the same atom along the bond being formed in the reaction product (U is the potential energy and r the amplitude of the atomic vibrations along the valence bond). The stretching vibrations of the H atom in RH and XH are regarded as harmonic and are described by the parabolic law

$$U(r)^{1/2} = br.$$

The following parameters are used to characterise the elementary step in the IP model (Fig. 1).

1. The enthalpy of reaction ΔH_e which includes the difference between the zero-point energies of the broken and generated bonds:

$$\Delta H_e = D_i - D_f + 0.5hL(v_i - v_f), \quad (2)$$

where D_i and D_f are the dissociation energies of the broken (i) and generated (f) bonds, v_i and v_f are the stretching vibration frequencies of these bonds, h is the Planck constant, and L is the Avogadro number.

2. The activation energy E_e , which is linked to the experimentally determined Arrhenius energy E by the relation

Figure 1. The energy profile of the $\text{H}^{\bullet} + \text{C}_2\text{H}_6$ reaction in the IP model.¹²

$$E_e = E + 0.5(hLv_i - RT). \quad (3)$$

3. The coefficients b_i and b_f , which describe the dependence of the potential energy on the atomic vibration amplitude along the initial (i) and final (f) valence bonds. There is a parabolic relation between the potential energy and the vibration amplitude:

$$U_i = b_i^2 r^2 \quad \text{and} \quad U_f = b_f^2 (r_e - r)^2$$

(Fig. 1). The quantity $2b^2$ is the force constant of the corresponding bond with $b = \pi v(2\mu)^{1/2}$, where μ is the reduced mass of the atoms forming the bond.

4. The distance r_e , which characterises the displacement of the abstracted atom in the elementary step.

In the IP model, these parameters are linked by the relation

$$br_e = \alpha(E_e - \Delta H_e)^{1/2} + E_e^{1/2}, \quad (4)$$

where $b = b_i$, *i.e.* refers to the attacked bonds in the molecule, while the coefficient $\alpha = b_i/b_f$ represents the ratio of the force constants of the ruptured and generated bonds raised to the power 1/2.

In the case of structurally isotypical reactions ($br_e = \text{const}$), a thermally neutral reaction ($\Delta H_e = 0$) proceeds with an activation energy E_{e0} , which is determined by two parameters, namely α and br_e (or r_e , b_i , and b_f):

$$E_{e0} = \left(\frac{br_e}{1 + \alpha} \right)^2 = \left(\frac{b_i b_f r_e}{b_i + b_f} \right)^2. \quad (5)$$

On substituting the parameter br_e in Eqn (4) by its value from Eqn (5), we obtain

$$(1 + \alpha)E_e^{1/2} = \alpha(E_e - \Delta H_e)^{1/2} + E_e^{1/2}. \quad (6)$$

Comparison of Eqns (5) and (6) makes it possible to understand the kinetic significance of the parameter br_e : it is directly proportional to the activation energy for a thermally neutral reaction raised to the power 1/2. The transition state in the IP model is characterised by the distance $r^{\ddagger}$, which is linked to the other parameters by the relation

$$\frac{r^{\ddagger}}{r_e} = \frac{E_e^{1/2}}{br_e} = \left[1 + \alpha \left(1 - \frac{\Delta H_e}{E_e} \right)^{1/2} \right]^{-1}. \quad (7)$$

In the case of a thermally neutral reaction with $\alpha = 1$, *i.e.* when the force constants of the attacked and generated bonds are equal, $r^{\ddagger}$ is equal to half the segment r_e . In the general case,

$$\left(\frac{r^{\ddagger}}{r_e} \right)_0 = \frac{1}{1 + \alpha}.$$

The parabolic model is in essence empirical, since the parameter α is calculated from spectroscopic (v_i and v_f) and atomic (μ_i and μ_f) data, while the parameter br_e (or E_{e0}) is found from the experimental activation energies E [Eqns (3) and (4)] or *via* the rate constant k by means of the Arrhenius equation

$$E = RT \ln \frac{A}{k},$$

where A is the pre-exponential factor typical for such reactions. The enthalpy of such reaction is calculated by Eqn (2) from the experimental bond dissociation energies. The calculations²⁷ showed that $br_e = \text{const}$ for structurally similar reactions. Thus $br_e = 14.74 \pm 0.21 \text{ kJ}^{0.5} \text{ mol}^{-0.5}$ for 27 reactions of peroxy radicals with the C–H bonds of aromatic alkyl-substituted hydrocarbons, which corresponds to $E_{e0} = 66.32 \pm 0.94 \text{ kJ mol}^{-1}$.²⁸

III. The intersecting Morse curves model

The model of the radical abstraction reaction based on the intersection of two Morse curves has been proposed¹⁴ to test the reliability of the results obtained with the aid of the IP model. As

Figure 2. The energy profile of the $\text{CH}_3^\bullet + (\text{CH}_3)_3\text{CH}$ reaction in the MPC model.¹⁴

in the intersecting parabolas model, the abstraction reaction reduces in this instance to the transition of a H atom from the initial to the final state (from RH to XH), the point of intersection of two unperturbed potential curves for R–H and X–H bonds corresponding to this process (Fig. 2). However, in contrast to the IP model, in this model the atomic vibrations along valence bonds are regarded as anharmonic and are described by the corresponding Morse formula²⁹

$$U(r) = D_e [1 - \exp(-ar)]^2, \quad (8)$$

where $U(r)$ is the potential energy of the reacting bond as a function of the amplitude r of the atomic stretching vibrations along this bond, D_e is the bond dissociation energy including its zero-point vibration energy $0.5hLv$, and a is a coefficient calculated by the formula $a = bD_e^{1/2}$, in which $b = \pi v(2\mu)^{1/2}$. The elementary step in the abstraction of an atom is described by the parameters D_{ei} and D_{ef} as well as the quantities E_e , b_i , b_f ($\alpha = b_i/b_f$), and r_e , as in the parabolic model [see Eqns (2) and (3)]. The parameter br_e ($b = b_i$) is linked to the other parameters by the relation

$$br_e = -D_{ei}^{1/2} \ln \left[1 - \left(\frac{E_e}{D_{ei}} \right)^{1/2} \right] - \alpha D_{ef}^{1/2} \ln \left[1 - \left(\frac{E_e}{D_{ef}} - \frac{\Delta H_e}{D_{ef}} \right)^{1/2} \right]. \quad (9)$$

The activation energy for a thermally neutral reaction is described by the equation

$$E_{e0} = D_{ei} \left\{ 1 - \exp \left[- \frac{br_e}{D_{ei}^{1/2} (1 + \alpha)} \right] \right\}^2. \quad (10)$$

Hence it is easy to obtain an expression which elucidates the physical significance of the parameter br_e :

$$br_e = -(1 + \alpha) D_{ei}^{1/2} \ln \left[1 - \left(\frac{E_{e0}}{D_{ei}} \right)^{1/2} \right].$$

The position of the transition state, corresponding to the point of intersection of two curves (Fig. 2), is characterised by the relation

$$\frac{r_e}{r^\ddagger} = 1 + \alpha \left(\frac{D_{ei}}{D_{ef}} \right)^{1/2} \frac{\ln(1 - \Delta H_e/D_{ef})}{\ln(1 - E_e/D_{ei})}. \quad (11)$$

As in the parabolic model, the parameter br_e is calculated by Eqn (9) from experimental data (α , D_{ei} , D_{ef} , E). In the case of structurally isotypical reactions, $br_e = \text{const}$. Thus $br_e = 19.35 \pm 0.48 \text{ kJ}^{0.5} \text{ mol}^{-0.5}$ for 10 RH + H[•] reactions investigated in the gas phase.¹⁴

IV. Comparison of empirical and correlation equations

The IP model can be regarded as a special case of the MPC model if one is dealing with reactions having low activation energies whereupon $E_e/D_{ei} \ll 1$ and $E_e/D_{ef} \ll 1$. On expanding the logarithmic function in Eqn (9) in Maclaurin's series [$\ln(1-x) \approx x - 0.5x^2 + \dots$] and retaining only one term, we pass in this case from Eqn (9) to Eqn (4).

In order to compare Eqn (4) for the parabolic model with the Polanyi–Semenov equation [Eqn (1)],^{1,2} it is useful to transform Eqn (4) by expressing E_e explicitly as a function of ΔH_e , α , and br_e . For not unduly high values of ΔH_e , whereupon

$$\Delta H_e \ll \frac{(br_e)^2}{1 - \alpha^2}, \quad (12)$$

we obtain the expression

$$E_e = \left(\frac{br_e}{1 + \alpha} + \frac{\alpha \Delta H_e}{2br_e} \right)^2. \quad (13)$$

Since α' in the Polanyi–Semenov equation represents the ratio $\Delta E/\Delta \Delta H$, it follows that, after substituting Eqn (13) in Eqn (1), we obtain

$$\alpha' = \frac{\Delta E_e}{\Delta H_{e2} - \Delta H_{e1}} = \frac{\alpha}{(1 + \alpha)} + \frac{0.25\alpha^2}{(br_e)^2} (\Delta H_{e2} + \Delta H_{e1}), \quad (14)$$

where H_{e2} and H_{e1} are respectively the maximum and minimum enthalpies in the series of reactions considered. Analysis of the second term shows that the empirical coefficient α' depends not only on the force constants of the reacting bonds ($\alpha = b_i/b_f$) but also on the range of variation of the enthalpies in the given series of reactions. This is natural, since the dependence of E on ΔH is nonlinear. For a sufficiently wide range of variation of ΔH , whereupon condition (12) does not hold, the dependence of α' on the parameters α , br_e , and ΔH_e becomes more complex and is expressed by the following formula obtained from Eqn (4):

$$\alpha' = \frac{\alpha^2}{1 - \alpha^2} + \frac{2\alpha}{(1 - \alpha^2)^2} f(br_e, \Delta H_e), \quad (15)$$

where

$$f(br_e, \Delta H_e) = \frac{(br_e)^2}{\Delta H_{e2} - \Delta H_{e1}} \left\{ \left[1 - \frac{\Delta H_{e1}(1 - \alpha^2)}{(br_e)^2} \right]^{1/2} - \left[1 - \frac{\Delta H_{e2}(1 - \alpha^2)}{(br_e)^2} \right]^{1/2} \right\}.$$

It is seen from Eqns (14) and (15) that the coefficient α' in Eqn (1) depends not only on the physical parameters (b_i , b_f , and r_e) but also on an incidental factor such as the range of variation of the enthalpies in the selected series of reactions. By virtue of this factor, the parameter α' in Eqn (1) can characterise only approximately the physical factors influencing the activation energy and this characterisation is less accurate the wider the range of variation of the enthalpies. This in fact explains, in particular, the experimentally observed parallel variation of α' and A' in the $\text{X}^\bullet + \text{RH}$ reactions³⁰ [see Eqns (14) and (15)]:

$\text{X}^\bullet$	$\text{HO}^\bullet$	$\text{H}^\bullet$	$\text{O}^\bullet$	$\text{CH}_3^\bullet$	$\text{CCl}_3^\bullet$
α'	0.25	0.38	0.52	0.52	0.94
$A' / \text{kJ mol}^{-1}$	31	46	64	62	67

The above considerations, concerning the Polanyi–Semenov method, refer also to the empirical procedure for the estimation of

activation energy proposed by Szabo.³¹ According to the latter, the activation energy for a radical reaction can be determined from the following simple formula:

$$E = D_i - \alpha' D_f.$$

Since $\Delta H = D_i - D_f$ and the activation energy $E = E_0 = D_i(1 - \alpha')$ when $\Delta H = 0$, it follows that $E = E_0 + \alpha' \Delta H$ and the coefficient α' is expressed by Eqn (14) within the framework of the parabolic model.

The correlations between the rate constants for a wide variety of reactions are widely used in the scientific literature:

$$\lg \frac{k}{k_1} = \rho \sigma, \quad (16)$$

where σ is the Hammett,³ Taft,⁴ *etc.* function and ρ is an empirical coefficient. Together with Eqn (1), this equation is frequently applied to radical abstraction reactions.⁶ Since the pre-exponential factor calculated per one reacting bond is constant for each series of radical reactions²⁸ and

$$\Delta E = -2.3RT \lg \frac{k}{k_1},$$

the following expression arises from Eqn (13):

$$\rho = \frac{\alpha T_0}{(1 + \alpha)T} \frac{\Delta \Delta H_e}{\Delta \Delta G_0} + \frac{\alpha^2 T_0}{4(br_e)^2 T} \frac{\Delta \Delta H_e^2}{\Delta \Delta G_0}. \quad (17)$$

Here the difference between the free energies $\Delta \Delta G_0$ concerns the reference reactions on which the comparison is based. It is linked to σ by the simple relation $\Delta \Delta G_0 = -2.3RT_0 \sigma$. As can be seen from Eqn (17), the coefficient ρ depends not only on the parameters of the reactants (α , br_e) and temperature (T_0/T), but also on the range of variation of ΔG_0 and ΔH_e . This naturally hinders its use for the identification of the physical factors determining the reactivity of the reactants. The expression for ρ becomes still more cumbersome if the series includes reactions characterised by different coefficients br_e . However, despite this, a relation of type (17) frequently reduces to an equation of type (1) in the kinetics of radical reactions, which has been noted in Semenov's monograph.²

A fairly simple empirical equation, relating the activation energies for the forward (E) and reverse ($E + \Delta H$) bimolecular reactions, has been proposed:³²

$$E(E + \Delta H) = \varepsilon^2. \quad (18)$$

By transforming Eqn (13), we obtain the following expression, within the framework of the parabolic model, for the activation energies for the forward (E_e) and reverse (E'_e) reactions (for the reverse reaction, $b' = b/\alpha$, $\alpha' = \alpha^{-1}$, and $\Delta H'_e = -\Delta H_e$):

$$(E_e E'_e)^{1/2} = \left(\frac{br_e}{1 + \alpha} \right)^2 + \frac{\Delta H_e(\alpha - 1)}{2(\alpha + 1)} - \frac{\alpha \Delta H_e^2}{4(br_e)^2}. \quad (19)$$

It is seen from the comparison of Eqns (18) and (19) that the product $E_e E'_e$ does indeed tend to a constant value with decrease in ΔH_e and $\varepsilon^{1/2} = br_e/(1 + \alpha)$.

The parabolic model of radical reactions¹² is close to the Marcus model for the transfer of an electron and a proton,³³ but differs from it by two significant features. In the IP model, one considers the involvement in the elementary step of the individual R–H and X–H bonds, each of which is characterised by an intrinsic force constant (the coefficients b_i and b_f). Furthermore, account is taken of the zero-point vibration of the bond as its inherent characteristic.

The reduction of the reaction in the IP and MPC models to the migration of the attacked atom determined by the intersection of unperturbed potential curves is an evident simplification. In fact the orbitals are perturbed in the RH + H[•] reactions and the electron densities of the orbitals of the R–H and X–H bonds overlap, which is a topic considered in quantum chemistry.^{7–10}

The question arises how the results of quantum-chemical calculations and the empirical parameter r_e , calculated with the aid of the IP and MPC models, are related. The most accurate quantum-chemical calculation of the energy profile of the abstraction reaction has been carried out for the H[•] + H₂ reaction.⁹ According to this calculation, the height of the potential barrier is 41 kJ mol^{−1}.³⁴ The following values of E_e and r_e correspond to this value of E in the IP and MPC models: $E_e = 66.1$ kJ mol^{−1} at $T = 300$ K [see Eqn (3)], $r_e = 3.67 \times 10^{-11}$ m (MPC model), and $r_e = 3.10 \times 10^{-11}$ m (IP model). The width of the potential barrier at the level of half its height is 9.6×10^{-11} m according to the quantum-chemical calculation.³⁴ Thus the distance r_e amounts to 32% of half the width of the potential barrier in the IP model and to 38% in the MPC model.

V. Classification of radical abstraction reactions

The two models of the radical abstraction reactions (IP and MPC) have an evident similarity: they take into account the relation between the activation energy and physical characteristics of the reacting bonds such as the dissociation energy and the force constant. The bond dissociation energy is an individual characteristic of the molecule entering into the reaction or formed. The force constants for the stretching vibration of bonds ($2\pi^2\nu^2\mu$) of each type (C–H, O–H, *etc.*) are virtually identical for the entire class of isotypical compounds. This important factor makes it possible to classify radical abstraction reactions in terms of the type of reacting bonds and the coefficients b characterising them. A pair of coefficients — b_i and b_f or $b = b_i$ and $\alpha = b_i/b_f$ — corresponds to each class of such reactions. In the calculation of the activation energy E_e from E and conversely, the zero-point vibration energy of the ruptured bond also becomes important [see Eqn (3)]. The quantities α , b , and $0.5hLv_i$ for the radical abstraction reactions of compounds in different classes are listed in Table 1.

Knowing these parameters, it is easy to find the analogous characteristics of the reverse reactions. For a reverse reaction, to which the index f corresponds, we have $\alpha_f = \alpha^{-1}$, $b_f = b/\alpha$, and $0.5hLv_f = 0.5hLv_i/\alpha$. For example, $\alpha_f = 0.796^{-1} = 1.256$, $b_f = (3.743 \times 10^{11})/\alpha = 4.702 \times 10^{11}$ kJ^{0.5} mol^{0.5} m^{−1}, and $0.5hLv_f = 17.4/0.796 = 21.8$ kJ mol^{−1} for the R[•] + HOR reaction.

The class of radical abstraction reactions may include a single reaction (for example, H[•] + HCl), one group of reactions (for example, R[•] + NH₃, where R[•] is any alkyl radical), or several such groups (for example, the class of reactions RO₂[•] + R'H, where R'H is a hydrocarbon, consists of three groups of reactions: RO₂[•] + R¹H, RO₂[•] + R²H, and RO₂[•] + R³H, where R¹H, R²H, and R³H are any aliphatic, unsaturated, and aromatic alkyl-substituted hydrocarbons respectively). All the reactions belonging to one group are characterised by a single parameter r_e or br_e . Table 2 presents the results of the calculation of the parameters br_e by Eqns (4) (the IP model)³⁵ and (9) (the MPC model)¹⁴ for reactions of the class H[•] + RH. The quantities br_e calculated on the basis of one model for reactions involving hydrocarbons having different structures are very close; the average values of br_e are 15.30 ± 0.59 kJ^{0.5} mol^{−0.5} in the IP model and $19.42 + 0.98$ kJ^{0.5} mol^{−0.5} in the MPC model. The activation energies were calculated by the Arrhenius equation; the quantity A calculated per reacting C–H bond is 10^9 litre mol^{−1} s^{−1} for the liquid phase and 2×10^8 litre mol^{−1} s^{−1} for the gas phase. Knowing the parameter br_e , it is possible to calculate an important characteristic of the reactivity of each group of reactions such as the activation energy for a thermally neutral reaction E_{e0} [Eqns (5) and (10)]. The energies E_{e0} may differ significantly for reactions of different classes. Thus the following values have been obtained (kJ mol^{−1}) for reactions involving aliphatic hydrocarbons R¹H:

Reaction	H [•] + R ¹ H	R [•] + R ¹ H	RO ₂ [•] + R ¹ H
E_{e0} (IP) ^{27,36}	64.8	68.2	58.1
E_{e0} (MPC) ¹⁴	66.1	71.3	61.8

^a Here and henceforth AmH = amine, AmOH = hydroxylamine, Am[•] = aminyl radical, and AmO[•] = nitroxyl radical.

For reactions of one class, the values of E_{e0} found on the basis of both models are very close, the discrepancy not exceeding 3 kJ mol⁻¹.

The classification of radical reactions carried out in this way makes it possible to observe empirically (on the basis of the parameter br_e) structural differences between reactants within one class, to compare the classes and groups of reactions in terms of reactivity (in terms of the parameter br_e or E_{e0}), and to identify the physical factors determining the reactivities of groups of reactants. The parameters br_e for different groups of reactions are presented in Table 3.

The reactions of nitrogen- and oxygen-centred radicals with O–H and N–H bonds take place in solution in two stages *via* the preliminary formation of a hydrogen-bonded complex, for example:

The observed rate constant is the product of the equilibrium constant for the first stage and the rate constant for the second stage. However, in the gas phase such reactions apparently proceed as bimolecular processes. Therefore, in order to compare

the parameters of these reactions in the gas and liquid phases and for their correct comparison with other bimolecular reactions, they were all regarded as bimolecular and the experimental pre-exponential factors were used in the calculations.

The activation energy for any individual reaction within the limits of the given group of reactions may be calculated correctly from the parameter br_e . Within the framework of the IP model, the quantity E_e was calculated by means of the following formulae:²⁷

(1) for $\alpha = 1$,

$$E_e^{1/2} = 0.5br_e + \frac{\Delta H_e}{2br_e}; \quad (20)$$

(2) for $\alpha \neq 1$

$$E_e^{1/2} = \frac{br_e}{1 - \alpha^2} \left\{ 1 - \alpha \left[1 - \frac{1 - \alpha^2}{(br_e)^2} \Delta H_e \right]^{1/2} \right\}; \quad (21)$$

(3) for $\Delta H_e(1 - \alpha^2) \ll (br_e)^2$

$$E_e^{1/2} = \frac{br_e}{1 + \alpha} + \frac{\alpha \Delta H_e}{2br_e}. \quad (22)$$

In the MPC model, the activation energy E_e was found by the numerical solution of the equation¹⁴

$$F(E_e) = D_{ei}^{1/2} \ln \left[1 - \left(\frac{E_e}{D_{ei}} \right)^{1/2} \right] + \alpha D_{ef}^{1/2} \ln \left[1 - \left(\frac{E_e - \Delta H_e}{D_{ef}} \right)^{1/2} \right] + br_e = 0. \quad (23)$$

The Newton–Raphson method combined with a special computer program was used to solve Eqn (23) for fixed values of D_{ei} , D_{ef} , and α . Table 4 presents the results of the calculation of the activation energies for the $H^+ + RH$ reactions based on the IP and MPC models as well as experimental values of $E_{e, \exp}$. The discrepancy between the calculated and experimental data for the IP and MPC models is 1.2 ± 0.8 and 1.0 ± 0.7 kJ mol⁻¹ respectively, *i.e.* it does not exceed the scatter of experimental activation energies (± 3 kJ mol⁻¹).

Table 4. Comparison of the experimental activation energies ($E_{\text{c,exp}}$)^{18,21} and the activation energies calculated on the basis of the IP³⁵ and MPC¹⁴ models for the $\text{H}^\bullet + \text{RH}$ reactions.

VI. Dissociation energies and force constants of the attacked and generated bonds

A clear-cut dependence of the activation energy on the heat (enthalpy) of reaction, which is equal in its turn to the difference between the dissociation energies of the ruptured (D_{r}) and generated (D_{g}) bonds, has been established for radical abstraction reactions.^{2,30} In both models considered in the present review, the values of D_{ei} and D_{ef} , incorporating the zero-point energy of the bond vibrations, are examined. The enthalpy of reaction ΔH_{e} therefore also includes the difference between these energies [see Eqn (2)].

As noted above, all radical abstraction reactions can be divided into groups and the activation energy E_{e0} for a thermally neutral reaction can be calculated in each group. The possibility of calculating the activation energy for any reaction of the given series (group) from the value of E_{e0} (or br_{e}) and of estimating the contribution of the enthalpy to the activation energy follows from this important factor. The contribution of ΔE_{H} represents the difference between the activation energies for the given (i th) reaction and a thermally neutral reaction characterised by the quantity E_{e0} :²⁷

$$\Delta E_{\text{H}} = E_{\text{ei}} - E_{\text{e0}}. \quad (24)$$

As an example, Table 5 presents the values of ΔE_{H} for the reactions of peroxy radicals with antioxidants of different classes.⁴⁴ It follows from the table that the ratio $\Delta E_{\text{H}}/\Delta H$ for these groups of reactions is close to 1/2.

In terms of the parabolic model, it is possible to obtain simple and physically clear equations for the estimation of ΔE_{H} as a function of α , br_{e} , and ΔH_{e} . The following simple expressions follow from the combination of Eqns (5) and (2)–(22):²⁷

(1) for $\alpha = 1$

$$\Delta E_{\text{H}} = 0.5\Delta H_{\text{e}} + \frac{0.25}{(br_{\text{e}})^2} \Delta H_{\text{e}}^2; \quad (25)$$

Table 5. The contributions of the enthalpy ΔE_{H} to the activation energy E for the reactions of a secondary peroxy radical with various inhibitors (ΔH , E , and ΔE_{H} in kJ mol^{-1}).⁴⁴

4-MeC ₆ H ₄ SH	−30.7	13.7	−13.2

(2) for $\alpha \neq 1$,

$$(1 - \alpha^2)\Delta E_H = 2\alpha(br_e)^2 - \alpha^2\Delta H_e - 2\alpha(br_e)^2 \left[1 - \frac{(1 - \alpha^2)}{(br_e)^2} \Delta H_e \right]^{1/2}; \quad (26)$$

(3) for $\Delta H_e(1 - \alpha^2) \ll (br_e)^2$,

$$\Delta E_H = \frac{\alpha}{1 + \alpha} \Delta H_e + \frac{0.25\alpha}{(br_e)^2} \Delta H_e^2. \quad (27)$$

It is seen from Eqns (25) and (27) that, for low values of the enthalpy of reaction, ΔE_H is directly proportional to ΔH_e which agrees with the Polanyi–Semenov equation.² The slope of the linear plot of ΔE_H as a function of ΔH_e depends on α , *i.e.* on the force constants of the bonds. The ratio $\Delta E_H/E_{e0} = \alpha(1 + \alpha)^{-1}$, which includes the force constants of the reacting bonds, may serve as a parameter of the sensitivity of E_e to ΔH_e for low values of the latter. For reactions of different classes, the coefficient α varies in the range from 0.6 to 1.7 and the coefficient $\alpha(1 + \alpha)^{-1}$ therefore varies from 0.38 to 0.63.

The activation energy increases with increase in ΔH_e and diminishes with increase in $|\Delta H_e|$ for $\Delta H_e < 0$. On the other hand, according to the law of conservation of energy, $E > 0$ for exothermic reactions and $E \geq \Delta H_e$ for endothermic reactions. It follows from the law of conservation of energy and Eqns (2)–(4) that the parameter br_e for one group of reactions is constant, while ΔH_e varies in the range $\Delta H_{e,\min} \leq \Delta H_e \leq \Delta H_{e,\max}$.⁴⁵ For highly endothermic reactions with $\Delta H_e > \Delta H_{e,\max}$, the activation energy is $E = \Delta H + 0.5RT$, whilst for exothermic reactions with $\Delta H_e < \Delta H_{e,\min}$ it is $0.5RT$. The limiting enthalpies of reaction $\Delta H_{e,\max}$ and $\Delta H_{e,\min}$ are related to the parameters br_e and α in the following way:⁴⁵

$$\Delta H_{e,\max} = (br_e)^2 + 2\alpha br_e(0.5hLv_f)^{1/2} + 0.5(\alpha^2 - 1)hLv_f, \quad (28)$$

$$\Delta H_{e,\min} = -\left(\frac{br_e}{\alpha}\right)^2 + 2\alpha br_e(0.5hLv_i)^{1/2} + 0.5(1 - \alpha^2)hLv_i. \quad (29)$$

As can be seen from Eqns (28) and (29), the range of variation of ΔH_e in which $br_e = \text{const}$ is wider the greater the parameter br_e . For the reactions of alkyl radicals with aliphatic hydrocarbons ($\alpha = 1$, $br_e = 17.23 \text{ kJ}^{0.5} \text{ mol}^{-0.5}$), we have $\Delta H_{e,\max} = |\Delta H_{e,\min}| = 153.1 \text{ kJ mol}^{-1}$, *i.e.* the range of enthalpies ΔH_e where $br_e = \text{const}$ is 306 kJ mol^{-1} . The enthalpies $\Delta H_{e,\max}$ and $\Delta H_{e,\min}$ for different groups of reactions are listed in Table 3.

Yet another important characteristic of radical abstraction reactions is the force constants of the ruptured and generated bonds. The dependence of the activation energy for reactions of the type $R^\cdot + RX \rightarrow RX + R^\cdot$, where $X = \text{H, Cl, Br, or I}$, on the coefficients b_i and b_f has been demonstrated experimentally.⁴⁶ It was found that $r_e = \text{const}$ in these reactions, whilst the activation energy for a thermally neutral reaction is directly proportional to the force constant of the ruptured bond. It is seen from Fig. 3 that the smaller the force constant of the C–H bond, the lower E_{e0} and that this relation is linear. The same result has been obtained⁴⁶ also for reactions of the $H^\cdot + RCl$, $H^\cdot + RBr$, and $H^\cdot + RI$ classes. Analysis of the seven classes of reactions listed above within the framework of the MPC model⁴⁷ yielded a similar result (Fig. 3). The relation

$$E_{e0}^{1/2} = \gamma \frac{b}{1 + \alpha}, \quad (30)$$

holds in this case and the proportionality coefficient γ for reactions of the $R^\cdot + RX$ and $H^\cdot + RX$ types is very close in both models: $\gamma = (4.80 \pm 0.15) \times 10^{-11} \text{ m}$. This confirms the important role of the force constant of the reacting bonds in the formation of the activation barrier. The activation energies for the $R^\cdot + RX$ reactions can be easily estimated from the empirical formula

Figure 3. Dependence of E_{e0} on the coefficient $b(1 + \alpha)^{-1}$ for the $R^\cdot + RX$ ($X = \text{H, Cl, Br, I}$) reactions on the basis of the IP (1)⁴⁶ and MPC (2)⁴⁷ models and the $H^\cdot + RX$ ($X = \text{Cl, Br, I}$) reactions on the basis of the IP (3)⁴⁶ and MPC (4)⁴⁷ models.

$$E_{e0}^{1/2} = 2.31 \times 10^{-11}b + 1.08 \times 10^{10} \frac{\Delta H_e}{b}, \quad (31)$$

while those for the $H^\cdot + RX$ ($X = \text{Cl, Br, I}$) reactions can be found from the formula

$$E_e^{1/2} = 4.81 \times 10^{-11} \frac{b}{1 + \alpha} + 1.04 \times 10^{10} \alpha \frac{\Delta H_e}{b}. \quad (32)$$

VII. The role of the X–Y bond in the $X^\cdot + HY$ reaction

The hydrogen atom migrates from Y to X in the $X^\cdot + HY$ reaction. The transition state of this reaction can be regarded conventionally as a labile formation containing the $X...H...Y$ pseudobond. The characteristics of this bond may influence the activation energy. This influence can be observed with the aid of the IP and MPC models, since each of them makes it possible to convert the activation energy for an individual reaction into the activation energy for a thermally neutral reaction [see Eqns (5) and (10)] and also to take into account the influence of the force constants of the X–H and Y–H bonds on E_{e0} [Eqn (5)]. When the hydrogen abstraction reactions are compared in relation to different classes of compounds, it is useful to employ the parameter r_e , in which the influence of ΔH_e , b_i , and b_f on the activation energy for the reaction has already been taken into account.

In the $X...H...Y$ transition state, the X–Y pseudobond is formed by three electrons. According to the Pauli principle, one molecular orbital may be occupied by only two electrons with opposite spins.²⁹ Two molecular orbitals therefore participate in the transition state: the bonding orbital of the X–Y bond, in which two electrons are accommodated, and its nonbonding orbital containing the third electron. The energy of the nonbonding orbital D_T is higher the stronger the X–Y bond; it is described by the Sato formula⁴⁸

$$D_T = D_e \{ \exp(-bD_e^{-1/2}r) + 0.5 \exp(-2bD_e^{-1/2}r) \}, \quad (33)$$

where D_e and D_T are the energies of the bonding and nonbonding X–Y orbitals respectively, $2b^2$ is the force constant, and r is the amplitude of the vibration of this bond. In the given instance, $r = r_{XH} + r_{YH} + r_e - r_{XY}$. The involvement of the nonbonding orbital of the X–Y bond in the formation of the activation barrier has come to be referred to as triplet repulsion.⁴⁹ This effect constitutes the basis of three semiempirical methods for the

calculation of the activation energies for radical substitution reactions: the ‘bond energy–bond order’ (BEBO) method,^{49, 50} the ‘bond energy–bond length’ (BEBL) method,⁵¹ and the Zavitsas method.^{52–54} In all these methods, the activation energy corresponds to the maxima on the ‘potential energy–bond order’ (BEBO) curves or the ‘potential energy–bond length’ (BEBL, Zavitsas method) curves while the potential energy curve represents a superposition of two Morse curves corresponding to the Y–H and X–H reacting bonds and the curve for the non bonding orbital of the X–Y bond [Eqn (33)].

The role of triplet repulsion in radical abstraction can be clearly traced on comparing reactions in which the energies of the X–Y bonds differ significantly.^{55, 56} The values of E_{e0} and r_e for a series of radical abstraction reactions found by the IP method^{41, 42} as well as the energies D_e of the X–Y bond are presented below.

X...H...Y	E_{e0} /kJ mol ⁻¹	$10^{11} r_e$ /m	D_e /kJ mol ⁻¹
R...H...R	68.2	4.414	382
R...H...N	60.2	3.862	361
PhO...H...OAm	41.8	2.772	~ 0
RO ₂ ...H...O ₂ R	43.1	2.854	88
RO ₂ ...H...OAr	45.3	2.885	~ 0
RO ₂ ...H...OAm	45.6	2.895	~ 0

The difference between the reactions with a high energy of the X–Y (C–C and C–N) bond, for which $E_{e0} \sim 60$ –70 kJ mol⁻¹, and the reactions with a very low energy of this bond (O–O), for which $E_{e0} \sim 40$ –45 kJ mol⁻¹ can be clearly traced. Within the limits of the error of the measurement, the parameter r_e for the last four reactions is constant: $r_e = (2.85 \pm 0.05) \times 10^{-11}$ m. This value is characteristic of reactions with zero triplet repulsion in the transition state. On substituting this quantity in Eqn (5), we obtain the following equation for the estimation of the contribution of triplet repulsion ΔE_T to the activation energy E_{e0} :

$$\Delta E_T = \frac{(b_i b_f)^2}{(b_i + b_f)^2} (r_e^2 - 2.85^2 \times 10^{-22}). \quad (34)$$

For reactions of the $R' + RH$ class, this contribution is 40.0 kJ mol⁻¹, i.e. a considerable proportion of the activation energy $E_{e0} = 68$ kJ mol⁻¹ is due precisely to the triplet repulsion in the transition state.

Another important characteristic of the X–Y bond is its polarity induced by the different electron affinities of the atoms or radicals X and Y.^{27, 55, 56} The greater the difference, the greater the polarity of the bond, its strength and its dipole moment. According to Pauling, the polarity of the X–Y bond may be characterised by the extent to which its strength differs from half the sum of the bond dissociation energies of the XX and YY molecules by virtue of the different electronegativities of the atoms X and Y:

$$\Delta EA(XY) = D_{XY} - 0.5(D_{XX} + D_{YY}). \quad (35)$$

The question arises whether the polarity of the X–Y bond affects the $X' + YH$ radical abstraction reactions. We shall compare two reactions:³⁵ $H' + H_2$ and $Cl' + H_2$.

Reaction	E_{e0} /kJ mol ⁻¹	$10^{11} r_e$ /m	D_{XY} /kJ mol ⁻¹
$H' + H_2$	58.2	3.69	436.0
$Cl' + H_2$	36.7	3.04	431.6

Evidently the dissociation energies of the H–H and Cl–H bonds are very close and the triplet repulsion in the transition states of these reactions is therefore almost identical. Nevertheless the quantities E_{e0} and r_e in these two reactions differ very considerably. The reason for this is that the H–H bond is nonpolar, while the Cl–H bond is polarised and $\Delta EA = 92.3$ kJ mol⁻¹ [Eqn (35)] for the latter. As in the HCl molecule, in the transition state there is evidently a strong attraction between Cl and H, which in fact induces a decrease in r_e and E_{e0} . If the

$H' + HCl$ reactions were characterised by the same parameter $r_e = 3.69 \times 10^{-11}$ m as the $H' + H_2$ reaction, the energy $E_{e0} = 56.5$ kJ mol⁻¹ [Eqn (5)] would have been obtained for it. The difference between the expected and observed activation energies ($\Delta E_{EA} = 36.7 - 56.5 = -19.8$ kJ mol⁻¹) must be attributed to the influence of the unequal electronegativities of the hydrogen and chlorine atoms on E_{e0} in the $H' + HCl$ reaction.

The $R' + RH$ and $RO' + RH$ reactions may serve as another example.^{55, 56}

Reaction	E_{e0} /kJ mol ⁻¹	$10^{11} r_e$ /m	D_{XY} /kJ mol ⁻¹
$R' + RH$	68.2	4.414	376
$RO' + RH$	54.8	3.553	361

In this case, the similarity of the R–R and RO–R bond dissociation energies also leads to the similarity of the triplet repulsion energies in the R...H...R and RO...H...R transition states. However, in these reactions too the quantities E_{e0} and r_e differ appreciably. The polarity of the O–C bond in the $RO' + RH$ reaction is manifested here. On substituting the dissociation energies $D(CH_3-CH_3)$, $D(CH_3O-OCH_3)$, and $D(CH_3-OCH_3)$ in Eqn (35), we obtain $\Delta EA = 80$ kJ mol⁻¹. Calculation of the contribution of the electronegativities of the O and C atoms to the activation energy for the $RO' + RH$ reaction yields $\Delta E_{EA} = -26.1$ kJ mol⁻¹, which should be regarded as very considerable bearing in mind that $E_{e0} = 54.8$ kJ mol⁻¹.

When the fragments X and Y approach one another in the X...H...Y transition state, their outer electron shells begin to repel one another. It is to be expected that the repulsion will be stronger, the larger the radii of the atoms X and Y. The examples presented below confirm this conclusion. We shall compare the $R' + RH$, $R' + HSiR'_3$, and $R_3Si' + HSiR'_3$ reactions.³⁷

Reaction	$10^{11} r_e$ /m	$10^{11} r_{XY}$ /m	D_{XY} /kJ mol ⁻¹	ΔEA /kJ mol ⁻¹
$R' + RH$	4.414	15.13	376	0.0
$R' + HSiR'_3$	4.782	18.70	376	11.0
$R_3Si' + HSiR'_3$	4.967	23.59	354	0.0

An evident parallel variation of the increment in r_e and in the bond length r_{XY} is observed. On the other hand, the strengths of the X–Y bonds in this series are similar, so that the increase in r_e is not caused by a change in the triplet repulsion. The electronegativities of the C and Si atoms are also similar and in the first and third reactions $\Delta EA = 0$.

The empirical dependence of the parameter r_e (in m) on D_{XY} , ΔEA , and r_{XY} in the interaction of radicals carrying a free valence on the C and O atoms with the C–H, O–H, Si–H, and S–H bonds has the following form:³⁷

$$10^{22} r_e^2 = 18 \left[\left(\frac{r_{XY}}{r_{HH}} \right)^{1/2} - 1 \right] + 13.7 \left(\frac{D_{XY}}{D_{HH}} \right) - 22.4 \left(\frac{\Delta EA}{D_{HH}} \right). \quad (36)$$

A similar formula has been proposed³⁷ for reactions with participation of H' :

$$10^{22} r_e^2 = 12.8 \left[\left(\frac{r_{XY}}{r_{HH}} \right)^{1/2} - 1 \right] + 13.7 \left(\frac{D_{XY}}{D_{HH}} \right) - 22.4 \left(\frac{\Delta EA}{D_{HH}} \right). \quad (37)$$

These formulae make it possible to estimate the contribution of each factor — triplet repulsion ΔE_T , electronegativity, ΔE_{EA} , and repulsion ΔE_R of the electron shells of the X and Y atoms in the transition state — to the activation barrier E_{e0} for each class of radical abstraction reactions. Since $E_{e0} = br_e(1 + \alpha)^{-1}$, it follows that, by employing the corresponding increment from Eqns (36) and (37), it is possible to calculate the contribution of a particular factor. Table 6 presents the results of such calculation for 21 classes of radical abstraction reactions.

The influence of the radius of the atom Y on the $X' + HY$ reactions is indicated by the data obtained by the present author.⁴⁶

Table 6. The contributions of triplet repulsion (ΔE_T), the electron affinity of the fragments X and Y (ΔE_{EA}), and the repulsion of the atoms forming the X–Y bond (ΔE_R) to the activation energy E_{e0} for the $X^\bullet + HY$ reaction.

Reaction	$10^{-11} b(1 + \alpha)^{-1}$ /kJ ^{0.5} mol ^{-0.5} m ⁻¹	$10^{11} r_e$ /m	ΔE_T /kJ mol ⁻¹	ΔE_{EA} /kJ mol ⁻¹	ΔE_R /kJ mol ⁻¹

H [•] + H ₂ O	2.20	3.91	76	−43	8
H [•] + SiH ₄	1.69	4.09	34	−2	15
H [•] + H ₂ S	1.88	3.60	42	−5	16

Thus linear dependences of the distance r_e on the radius of the halogen atom (Y) have been observed in the $O^\bullet + HY$ and $HO^\bullet + HY$ (Y = Cl, Br, I) reactions: $r_e = 0.29 r_Y$ and $r_e = 0.32 r_Y$ (IP model). These relations reflect the real contribution of the repulsion of the molecular orbitals of the atoms approaching one another to the formation of the activation barrier.

It is seen from the data presented in Table 6 that the triplet repulsion ΔE_T makes an additional contribution to the activation energy E_{e0} . The reactions in which the X–Y bond is not formed (for example in the $RO_2^\bullet + HOAr$ reaction) are an exception.

The difference between the electronegativities of the fragments X and Y lowers the activation energy. When the discrepancy between the electron affinities is large, this decrease may be very considerable. For example, $\Delta E_{EA} = -45$ kJ mol⁻¹ for the $HO^\bullet + SiH_4$ reaction and $\Delta E_{EA} = -43$ kJ mol⁻¹ in the reaction of H[•] with water.

The repulsion of the electron orbitals of the atoms forming the reaction centre ΔE_R plays an important role in all the radical abstraction reactions. In the interaction of radicals with molecules, the contribution of this repulsion ranges from 25 to 46 kJ mol⁻¹. In reactions of molecules with hydrogen atoms, the contribution is naturally smaller, varying from 8 to 16 kJ mol⁻¹.

Thus Eqns (36) and (37) make it possible to estimate the quantities r_e and E_{e0} for classes of reactions which have not been investigated.

VIII. The causes of the high reactivity of antioxidants

The considerations concerning the influence of physical factors on the heights of activation barriers in radical reactions of compounds in different classes, described above, may be used also to account for the kinetics of specific processes. Two such processes will be examined below: oxidation processes occurring in the presence of phenols and aromatic amines. Phenols and aromatic amines (antioxidants) react very rapidly with peroxy radicals, whereas $RO_2^\bullet$ interaction with hydrocarbons is comparatively slow.⁵⁷ We shall compare three reactions: (a) $RO_2^\bullet + C_6H_5CH_2CH_3$, (b) $RO_2^\bullet + 4-CH_3C_6H_4OH$, and (c) $RO_2^\bullet +$

$(4-CH_3C_6H_4)_2NH$, where $RO_2^\bullet$ is a secondary peroxy radical.^{28, 38, 39}

Reaction	$k(333\text{ K})$ /litre mol ⁻¹ s ⁻¹	ΔH /kJ mol ⁻¹	$10^{-7} A$ /litre mol ⁻¹ s ⁻¹	E /kJ mol ⁻¹
(a)	2.0	−8.5	2.0	44.6
(b)	1.4×10^4	−7.7	3.0	21.4
(c)	3.0×10^5	−8.0	3.0	16.1

Evidently the peroxy radical reacts with the O–H bond of *p*-cresol faster by four orders of magnitude and with the N–H bond of bis(*p*-tolyl)amine faster by five orders of magnitude than with the C–H bond of ethylbenzene. Furthermore the enthalpies ΔH of these reactions are very similar and so are the pre-exponential factors. The large difference between the rate constants is determined exclusively by the inequality of the activation energies E , which indicates in its turn that the quantities E_{e0} are different. This question has been analysed using the IP⁵⁸ and MPC⁵⁹ models. The correlation equation (36) makes it possible to establish the causes of this difference. The values of E_{e0} (kJ mol⁻¹), $10^{-11} b(1 + \alpha)^{-1}$ (kJ^{0.5} mol^{-0.5} m⁻¹), $10^{11} r_e$ (m), and the increments ΔE_R , ΔE_T , and ΔE_{EA} (kJ mol⁻¹) calculated by Eqn (36) are presented below.

HY	E_{e0}	$10^{-11} b(1 + \alpha)^{-1}$	r_e	ΔE_R	ΔE_T	ΔE_{EA}
RH	61.5	1.87	3.80	32	37	−7
ArOH	45.3	2.33	2.88	45	~ 0	0
AmH	39.0	2.16	2.80	44	15	−20

The activation energy for the thermally neutral reaction of $RO_2^\bullet$ with the C–H bond is indeed greater than in the interaction of the same radical with the O–H bond of the phenol and the N–H bond of the amine. In the case of the phenol, the comparatively low value of E_{e0} is caused by the absence of triplet repulsion (the ArO–OAr bond is very weak), while in the case of the amine the large difference between the electronegativities of the N and O atoms, which leads to the polarisation of the N...H...O reaction centre and a decrease in the activation energy for low triplet repulsion, may be regarded as such a cause. On the other hand, the high value of E_{e0} in the reactions of $RO_2^\bullet$ with the C–H bond of the hydrocarbon is caused primarily by the strong triplet repulsion

($\Delta E_T = 37 \text{ kJ mol}^{-1}$) and also by the comparatively slight polarisation of the C–O bond ($\Delta E_{EA} = -7 \text{ kJ mol}^{-1}$).

Aminyl radicals interact extremely rapidly with the O–H bond.^{60,61} For example, the rate constants for the abstraction of the H atom from phenol at 294 K is $1 \times 10^6 \text{ litre mol}^{-1} \text{ s}^{-1}$, whereas the enthalpy of this reactions is only 2 kJ mol^{-1} . The high selective reactivity of aminyl radicals in the abstraction of H atoms from the O–H bond is indicated by the comparison of the values of E_{e0} for the $\text{Am}^\bullet + \text{HY}$ reactions:⁴³

HY	RH	ArOH	AmOH	ROOH
$E_{e0} / \text{kJ mol}^{-1}$	81.7	27.6	33.2	41.1

It is seen from the data presented that the activation energy for the thermally neutral reaction involving the abstraction of H from the O–H bond is smaller by $40\text{--}54 \text{ kJ mol}^{-1}$ than for the abstraction of H from a C–H bond of the hydrocarbon. The reason for this difference is the high polarity of the O–N bond in the transition state for weak triplet repulsion. By virtue of this precise factor, aromatic amines are effective catalysts of the reaction of the phenoxyl radical with a hydroperoxide.⁶²

This process is faster than the forward reaction

For the same reason (the polarity of the N–O bond), aromatic amines can ensure multiple chain termination in the oxidation of alcohols, alkenes, and polymers, where the $\text{>C(OH)O}_2^\bullet$ and $\text{HO}_2^\bullet$ radicals participate in chain propagation. This is not observed in the oxidation of hydrocarbons. This question has been discussed in detail in another review by the present author.⁶³

IX. The influence of the π -bond and the steric effect

An aromatic ring and a double or triple bond in the α -position relative to a C–H bond weaken the latter by virtue of the delocalisation of the unpaired electron in its interaction with the π -bond. The weakening of the C–H bond is very considerable: for example, $D(\text{C–H})$ is 418 kJ mol^{-1} in ethane, 363 kJ mol^{-1} in the methyl group of propene, and 368 kJ mol^{-1} in the methyl group of toluene. Such decrease in the strength of the C–H bond diminishes the enthalpy of the radical abstraction reaction and hence its activation energy. This effect is illustrated below in relation to the reactions of the methyl radical with hydrocarbons.²⁷

Hydrocarbon	C_2H_6	$\text{CH}_3\text{CH}=\text{CH}_2$	$\text{C}_6\text{H}_5\text{CH}_3$
$\Delta H / \text{kJ mol}^{-1}$	–20.0	–75.2	–70.2
$E / \text{kJ mol}^{-1}$	52.4	37.4	39.3

Comparative analysis of the kinetics of the reactions of atoms and radicals with paraffinic (R^1H), olefinic (R^2H), and aromatic alkyl-substituted (R^3H) hydrocarbons within the framework of the IP and MPC models permitted a new important conclusion. It was found that the π -C–C bond occupying the α -position relative to the attacked C–H bond increases the activation energy for thermally neutral reaction.²⁷ The corresponding results are presented in Table 7. Evidently the activation energy for a thermally neutral reaction with participation of a hydrogen atom or a radical (alkyl, alkoxyl, *etc.*) is higher in those cases where there is a π -bond or an aromatic ring next to the attacked C–H bond. This result is independent of the method used to calculate (IP or MPC) the parameters br_e and E_{e0} . Evidently this effect is a property of the structures themselves and the π -bond exerts a dual effect on the reaction centre. On the one hand, by weakening the C–H bond the π -bond in the α -position lowers the enthalpy and hence the activation energy for the reaction. On the other hand, by interacting with the electrons of the reacting bonds, the π -orbital increases the strength of the C–Y bond in the $\text{Y}^\bullet + \text{HR}$ reaction, which increases the energy of the non bonding C–Y orbital and intensifies triplet repulsion.

The influence of bulky substituents, for example tertiary alkyl groups, on the kinetics of diverse chemical reactions is well known. A steric effect occurs also in radical reactions. Such substituents usually influence both the enthalpy of the reaction and its activation energy. The IP and MPC models examined in the present review make it possible to separate these effects and to estimate separately the contribution of steric hindrance to the activation energy.²⁷ We shall examine the thoroughly investigated radical reactions in which a radical attacks the O–H group of a sterically hindered phenol (Ar^2OH) containing two *tert*-alkyl (as a rule *tert*-butyl) groups in the *ortho*-position relative to the phenolic group. Comparison of the energies E_{e0} for isotypical reactions involving both sterically unhindered (Ar^1OH) and sterically hindered (Ar^2OH) phenols makes it possible to estimate the contribution of steric hindrance ΔE_s to the activation energy:

$$\Delta E_s = E_{e0}(\text{Ar}^2\text{OH}) - E_{e0}(\text{Ar}^1\text{OH}). \quad (38)$$

The results of the comparison are presented in Table 8. The steric hindrance increases the activation energy for a thermally neutral reaction by 8.2 ± 2.0 , 8.2 ± 1.5 , and 24 kJ mol^{-1} when oxygen-centred, nitrogen-centred, and alkyl radicals are involved respectively. The data obtained with the aid of the IP and MPC

models in most cases agree. The steric effect is manifested similarly also in the reactions of sterically hindered (Ar²O[•]) phenoxy radicals with various substrates (Table 8). The reactions of the sterically hindered diphenylpicryl radical (DPPH[•]) and the unhindered diphenylaminyl radical may serve as another example (Table 8). In the reactions of DPPH[•] with phenols, the contribution of the steric effect to E_{e0} ranges from 23 to 30 kJ mol⁻¹, *i.e.* is very considerable.

X. The polar effect in radical reactions

An extensive literature has been devoted to polar effects in chemical reactions.^{69–72} The IP and MPC models permit a fresh approach to this important problem. The introduction of a functional group into a hydrocarbon molecule alters the dissociation energy of the neighbouring C–H bonds, which is indicated by the examples presented below (the bond strengths taken from the review of McMillen and Golden⁷³).

Compound	C ₂ H ₆	C ₂ H ₅ OH	CH ₃ CHO	C ₂ H ₅ OC ₂ H ₅
D /kJ mol ⁻¹	418.4	392.5	365.3	383.7

The change in the C–H bond strength affects the enthalpies and through them the activation energies for radical abstraction reactions. If a molecule is attacked by a nonpolar group (hydrogen atom, alkyl radical), then the influence of the polar group on the activation energy is confined to a change in ΔH . This has been confirmed by data on the reactions of the methyl radical with the C–H bonds of hydrocarbons and their derivatives (alcohols, ethers, *etc.*),¹² which are characterised by a virtually identical parameter $br_e = 17.23$ kJ mol⁻¹. A similar result has been obtained when the MPC model was used.⁴⁷ Thus a polar group (OH, OR, *etc.*) influences only the enthalpy of reaction and not the energy of the reaction centre of a transition state of the type C...H...C and H...H...C.

A different picture is observed when a polar radical reacts with a C–H bond of a polar molecule. For example, the reaction of an oxygen atom with a methane C–H bond is characterised by the parameter $br_e = 13.11$ kJ^{0.5} mol^{-0.5} while the reaction with a methanol C–H bond is characterised by the corresponding parameter of 12.55 kJ^{0.5} mol^{-0.5}. For these values of br_e , the difference between the activation energies is 4.6 kJ mol⁻¹. The decrease in activation energy can be explained by the fact that the

polar OH group in the O...H...C–OH transition state interacts with the O...H...C polar reaction centre.

The IP and MPC models make it possible to isolate from the overall effect of the substituent its contribution to E . In the calculation, use is made of the values of ΔH and the activation energy for a thermally neutral reaction of the given group (reaction series), because the activation energy can be represented by the sum $E_e = E_{e0} + \Delta E_H$ (see above), where the second term takes into account only the influence of enthalpy. The polar interaction in the transition state may be inferred by comparing the values of E_{e0} in various reactions involving a hydrocarbon and the corresponding polar molecule. The contribution of the polar interaction to the activation energy (ΔE_μ) can be estimated²⁷ from the formula

$$\Delta E_\mu = \frac{(br_e)_\mu^2 - (br_e)_{RH}^2}{(1 + \alpha)^2}, \quad (39)$$

where the parameters $(br_e)_\mu$ and $(br_e)_{RH}$ refer to reactions involving a polar compound YH and a reference hydrocarbon RH respectively. The results of the calculation of the energy ΔE_μ (in kJ mol⁻¹) for the X[•] + HY gas-phase reactions are presented below:⁷⁴

X [•]	HY				
	CH ₃ OH	CH ₂ O	RCHO	CH ₃ COCH ₃	(CH ₃) ₂ O
O [•]	4.6	−4.6	−7.9	−9.4	−5.1
HO [•]	2.4	1.8	1.5	−11.4	2.8
CH ₃ O [•]	−6.0	0	−12.2	−	−
(CH ₃) ₃ CO [•]	−	−4.2	−3.1	−17.8	−

Extensive data concerning the influence of polar groups on the activation energies for abstraction reactions have been obtained by analysing experimental data on reactions with participation of alkoxy and peroxy radicals in the liquid phase.^{75–77} These data are presented in Table 9. As can be seen from the table, the interaction of a polar group with a O...H...C or O–O...H...C polar reaction centre can both diminish and increase the activation energy. A very marked decrease in activation energy (from −11 to −19 kJ mol⁻¹) has been observed in the reactions of RO[•] and RO₂[•] with aldehydes and ketones. The alcoholic group diminishes slightly the height of the activation barrier (by 1–3 kJ mol⁻¹), the reaction of RO[•] with benzyl alcohol being

an exception. In the reactions with ethers, an increase in activation energy is observed.

XI. The effect of multipole interaction

Yet another effect, namely multipole interaction, is manifested in the reactions of polar radicals with polyfunctional compounds.⁷⁸ This effect consists in the unequal reactivities of the same group, for example >CH(OH), in compounds with one and several functional groups. Factual data concerning multipole interactions have been examined in a review.⁷⁹ The corresponding kinetic data have been analysed within the framework of the IP model.⁷⁷ The multipole interaction is manifested, in particular, in the reactions of peroxy radicals RO₂[•] containing functional groups, with oxygen-containing compounds YH (Table 9). The magnitude of this effect in the transition state may be inferred from the change in the activation energy for a thermally neutral reaction on passing from a monofunctional compound YH to a polyfunctional compound ZH:

$$\Delta\Delta E_\mu = \frac{(br_e)_{ZH}^2 - (br_e)_{YH}^2}{(1 + \alpha)^2}.$$

As can be seen from Table 9, the highest values of $\Delta\Delta E_\mu$ correspond to the transition from RO₂[•] to YO₂[•] containing a carbonyl or ester group. Apparently this effect is induced by the dipole–dipole interaction in the transition state. Table 10 presents data concerning the influence of ester groups on the reactivity of CH₂ groups in reactions with peroxy radicals. The

multipole effect always reduces the activation energy for reactions of this group and in certain cases the decrease is extremely significant (down to −10 kJ mol^{−1} and even further).

XII. Solvation of the reactants in radical abstraction reactions

Yet another important effect, observed when reactions take place in the liquid phase, is associated with the solvation of the reactants. Theoretical comparison has shown that the collision frequencies of the species in a gas and in a liquid are different, the difference being due to the difference between the free volumes.⁸⁰ In a gas, the free volume is virtually equal to the volume occupied by the gas species ($V_f \approx V$), while in a liquid it is much smaller than the volume of the liquid species ($V_f \ll V$). Since the motion and collision of the species occur in the free volume, the collision frequency in a liquid is higher than in a gas by an amount $(V/V_f)^{1/3} \approx 4–2$. The activation energies for the reactions of radicals and atoms with hydrocarbon C–H bonds in a gas and in a liquid are virtually identical, that in a liquid being independent of the solvent polarity. This also applies to the parameter br_e (the IP model), which can be seen from the following examples referring to the interaction of the hydroxyl radical with hydrocarbons:⁷⁴

RH	C ₂ H ₆	C ₃ H ₈
br_e (gas) /kJ ^{0.5} mol ^{−0.5}	13.74	13.52
br_e (H ₂ O) /kJ ^{0.5} mol ^{−0.5}	13.48	13.40

Table 10. Kinetic parameters of the reactions of cumenylperoxyl radicals with compounds containing ester groups.⁷⁷

[CH ₃ CH ₂ C(O)OCH ₂] ₃ CCH ₂ CH ₃	23.7	77.4	14.76	6.8	-2.1

A different picture is observed when a polar molecule is attacked by a polar radical (HO•, RO•, RO₂•). The reaction in a polar solvent is slower than in a nonpolar hydrocarbon solution or in the gas phase. From the change in the parameter br_e , it is possible to estimate the extent to which the activation energy increases as a result of the solvation of the polar reactants:⁷⁴

$$\Delta E_{\text{sol}} = \frac{(br_e)_l^2 - (br_e)_g^2}{(1 + \alpha)^2}. \quad (40)$$

The subscripts l and g in Eqn (40) refer to the liquid and gas phases respectively. The results of the comparison are presented in Table 11. If the HO• + YH reaction takes place in aqueous solution and not in the gas phase, the parameter br_e and hence the activation energy increase. This is associated with the solvation of the reactants and the need to overcome the solvation shell by the reacting component in order to effect the elementary step. The contribution of ΔE_{sol} is particularly large in the reaction of the hydroxyl radical with aldehydes.

When a radical or atom attacks a polar O–H or N–H bond, the reactant Y forms a hydrogen bond of the type O–H...Y or N–H...Y in polar solvents.^{81, 82}

The hydrogen bond shields the reactant and slows down the reaction regardless of what kind of radical — polar or nonpolar — attacks it. A universal kinetic scale has been proposed⁸³ for the estimation of the effectiveness of such shielding. This problem has been examined in detail in a monograph.⁸⁴

Table 11. The contributions of the solvation effect to the activation energies for radical reactions.⁷⁴

XIII. Estimation of bond strength from kinetic data

The IP and MPC methods make it possible to calculate correctly the dissociation energies of bonds subjected to radical attack.^{85, 86} The parameter br_e and the enthalpy of reaction $\Delta H_{e,\text{min}} < \Delta H_e < \Delta H_{e,\text{max}}$ (see above) are used in such calculations. In order to increase the accuracy of the calculation, the rate constants for two different reactions (l and i) are measured by one method. Within the limits of the same reaction series, the pre-exponential factor calculated per reacting bond remains constant, so that the difference between the activation energies for reactions with participation of the reactants R^lH and RⁱH is

$$\Delta E_{e,i} = E_{e,i} - E_{e,l} = RT \ln \frac{n_i k_l}{n_l k_i}. \quad (41)$$

In the IP model, the relation between E and ΔH is described by Eqns (2)–(4). The following relation between the bond strength difference $\Delta D_i = D_i - D_l$ and $\Delta E_{e,i}$ follows from them:

$$\Delta D_i = \frac{2br_e}{\alpha^2} (E_{e,i}^{1/2} - E_{e,l}^{1/2}) - \left(\frac{1}{\alpha^2} - 1 \right) \Delta E_{e,i}. \quad (42)$$

For $\alpha = 1$, where the force constants of the reacting bonds are identical and $\Delta E_{e,i} \ll E_{e,l}$, we obtain

$$E_{e,i}^{1/2} = \frac{1}{2} br_e + \frac{\Delta H_e}{2br_e} \quad \text{and} \quad E_{e0}^{1/2} = \frac{1}{2} br_e.$$

For a single reaction series, $\Delta D_i = \Delta H = \Delta H_e$, whereupon

$$E_{e,i}^{1/2} - E_{e,l}^{1/2} = \frac{\Delta D_i}{2br_e} = \frac{\Delta D_i}{4E_{e0}^{1/2}}.$$

Since

$$E_{e,i}^{1/2} = (E_{e,l} + \Delta E_i)^{1/2} = \left[E_{e,l} \left(1 + \frac{\Delta E_i}{E_{e,l}} \right) \right]^{1/2} \approx E_{e,l}^{1/2} \left(1 + \frac{\Delta E_i}{2E_{e,l}} \right),$$

it follows that

$$E_{e,i}^{1/2} - E_{e,l}^{1/2} = \frac{\Delta E_i}{2E_{e,l}^{1/2}}.$$

Hence

$$\frac{\Delta E_i}{2E_{e,l}^{1/2}} = \frac{\Delta D_i}{4E_{e0}^{1/2}},$$

and the following simple formula is obtained:

$$\Delta D_i = 2 \left(\frac{E_{e0}}{E_{e,1}} \right)^{1/2} \Delta E_{ei} . \quad (43)$$

Eqns (42) and (43) are applicable to reactions in the same reaction series for which $\Delta H_{e,\min} < \Delta H_e < \Delta H_{e,\max}$ [Eqns (28) and (29) and Table 3]. In the case of very exothermic reactions ($\Delta H_e < \Delta H_{e,\min}$), the activation energy is independent of the enthalpy, while for endothermic reactions ($\Delta H_e > \Delta H_{e,\max}$) we have $\Delta E = \Delta D_i$. This method has been used to estimate the strength of the C–H bonds in hydrocarbons⁸⁵ and oxygen-containing compounds,⁸⁶ the O–H bonds in phenols⁸⁷ and hydroxylamines,⁴⁵ the N–H bonds in amines,⁴⁶ and the C–Cl, C–Br, and C–I bonds in halogen-containing compounds.⁸⁸

ROCOCHR ₂	384.1	381.1±0.6	

A similar method has been developed on the basis of the MPC model.⁸⁶ In order to calculate the dissociation energy of the attacked bond, a system of two equations, one of which refers to the *i*th reaction and the other to the reference reaction 1, is solved numerically (for *D_{e,i}*):

$$br_e + D_{e,1}^{1/2} \ln \left[1 - \left(\frac{E_{e,1}}{D_{e,1}} \right)^{1/2} \right] + \alpha D_{e,1}^{1/2} \ln \left[1 - (E_{e,1} - \Delta H_{e,1})^{1/2} \right] = 0 , \quad (44)$$

$$br_e + D_{e,i}^{1/2} \ln \left[1 - \left(\frac{E_{e,i}}{D_{e,i}} \right)^{1/2} \right] + \alpha D_{e,i}^{1/2} \ln \left[1 - (E_{e,i} - \Delta H_{e,i})^{1/2} \right] = 0 . \quad (45)$$

By solving Eqn (45), the value of *E_{e,i}* is found and then *D_{e,i}* is obtained taking into account the equality *E_{e,i}* = *E_{e,1}* + Δ*E_{e,i}*. The method has been used to calculate the dissociation energies of the C–H bonds in hydrocarbons⁸⁹ and oxygen-containing compounds.⁹⁰ Table 12 presents the values of *D*(C–H) calculated by the two methods from experimental data. These results agree well with one another. The average error in the estimation of Δ*D_i* by the IP and MPC methods is 2 and 1.6 kJ mol^{−1} respectively. The estimate by the MPC method is more accurate, but it is applicable to a narrower range of variation of Δ*E_i* (from −20 to +25 kJ mol^{−1}) than in the IP method (from −30 to +50 kJ mol^{−1}). Both methods make it possible to estimate Δ*D_i* more accurately than by the Polanyi–Semenov method.

XIV. Characteristic features of bimolecular reactions with high absolute enthalpies

The activation energies for highly exothermic radical reactions are known to be virtually zero. The disproportionation of alkyl radicals belongs to such reactions. The rate constants for reactions of this kind and the temperature ranges in which *k* = const are presented below.

Reaction	10 ^{−9} <i>k</i> /litre mol ^{−1}	<i>T</i> /K	Ref.
Me• + Et•	1.15	300–800	91
Me• + Me ₂ CH•	4.53	300–2500	92
Et• + Et•	1.40	300–1200	93
Et• + Me ₂ CH•	2.51	300–2500	92

In a liquid, such fast reactions are limited by the frequency of the diffusional encounters and their activation energies are characteristic of the diffusion of species in a liquid. The IP and MPC models agree with this observation. According to the IP model, each group of reactions is characterised by the parameter *br_e* = const. The lower the value of Δ*H_e*, the lower the position of the point of intersection of the parabolic potential curves on the potential energy axis (Fig. 4). For Δ*H_{e,min}* = Δ*H_e* the curves intersect at the point corresponding to the zero-point vibration energy of the ruptured *i*th bond. At this point, *E_{e0}* + 0.5*hL_{v,i}* and *E* = 0.5*RT*. Such activation energy is retained for all reactions with Δ*H_e* < Δ*H_{e,min}*. Analysis within the framework of the MPC model also leads to a similar result.

The question of the pre-exponential factors for such reactions has been recently examined.⁴⁵ For a separate group of reactions, the quantity *A* calculated for a single attacked bond is virtually constant. For example, for all reactions of the type RO₂• + R¹H, occurring in a hydrocarbon solution (R¹H is an aliphatic hydrocarbon), we have *A* = 10⁸ *n* litre mol^{−1} s^{−1}, where *n* is the number of C–H bonds with equivalent reactivities. This is valid for reactions with Δ*H_{e,min}* < Δ*H_e* < Δ*H_{e,max}*. For Δ*H_e* < Δ*H_{e,min}*, the parameter *r_e* increases with increase in Δ*H_e*, since the potential curves cannot intersect below point *C* (Fig. 4). With increase in *r_e*, the cross-section for the collision of a radical and a molecule and hence also the pre-exponential factor *A* increase. The dependence of *A* on Δ*H* is described by the formula⁴⁵

$$\left(\frac{A}{A_0} \right)^{1/2} = 1 + \beta (|\Delta H_e|^{1/2} - |\Delta H_{e,\min}|^{1/2}) , \quad (46)$$

where *A₀* is a pre-exponential factor typical for the given group of reactions.

The same happens with increase in Δ*H_e*. When the curves intersect at point *L* (Fig. 4), there comes a time when the Δ*H_e* > Δ*H_{e,max}* curves intersect at a distance exceeding the con-

Figure 4. The energy profile for radical abstraction reactions over a wide range of variations of ΔH_c (IP model).⁴⁵ For $\Delta H_{c, \min} < \Delta H_c < \Delta H_{c, \max}$, the parameter $r_e = \text{const}$. Beyond these limits, r_e increases by Δr_e (parabolas with vertices at points K and F).

stant value of r_e for the given group of reactions. For such reactions, $E = \Delta H_c + 0.5RT$, while the pre-exponential factor depends on ΔH_c (Fig. 5).⁴⁵

$$\left(\frac{A}{A_0}\right)^{1/2} = 1 + \beta(|\Delta H_c|^{1/2} - |\Delta H_{c, \max}|^{1/2}). \quad (47)$$

The coefficient $\beta = 1.0$ and 1.6 for reactions with C...H...C and O...H...O reaction centres respectively. Table 3 presents the values of $\Delta H_{c, \min}$ and $\Delta H_{c, \max}$ calculated by Eqns (28) and (29).

Figure 5. Dependence of E_c (1) and A (2) on ΔH_c according to the IP model.⁴⁵

Evidently the range of H_c in which $A = A_0 = \text{const}$ depends on the parameter br_e and varies within wide limits. Eqns (46) and (47) make it possible to calculate the rate constants for highly exothermic and highly endothermic reactions. As an example, Table 13 presents the results of the calculation of the quantities ΔH , A , and k (at 400 K) for the reactions of a stable nitroxyl radical — 2,2,6,6-tetramethylpiperidinyloxy — with a series of phenols.

Table 13. Dissociation energies of the O–H bonds of phenols and the kinetic parameters of the reactions of 2,2,6,6-tetramethylpiperidinyloxy with various phenols calculated by the Arrhenius equation taking into account Eqn (47).

XV. Conclusion

Thus the successive employment of the IP and MPC models for the analysis of the reactivities of the reactants in radical abstraction reactions yield very similar results. These models make it possible to divide all radical abstraction reactions into classes and to characterise quantitatively each class by a pair of force constants for the ruptured and generated bonds (b_i and b_f). In both models, these parameters are naturally identical. Each class of reactions may consist of one or several groups of reactions. All the reactions of a given group are characterised by a single parameter r_e and the energy of a thermally neutral reaction E_{c0} . The parameters r_e in the IP and MPC models differ but the values of E_{c0} are very similar. Each individual reaction is additionally characterised by the enthalpy. Thus an individual radical reaction is characterised in both models by four parameters: b_i , b_f , E_{c0} , and ΔH_c . Their number can be reduced to three: $\alpha = b_i/b_f$, $b_i r_e$, and ΔH_c .

Analysis with the aid of the IP and MPC models of extensive experimental data on the kinetics of radical reactions has shown that the reactivities of the interacting molecules and radicals are determined by diverse physical factors. The following 10 factors which determine the height of the potential barrier in radical abstraction reactions have been revealed.

1. The enthalpy of reaction ΔH_c . For low values of this enthalpy, the dependence of the activation energy E_c on ΔH_c assumes the form $E_c^{1/2} = E_{c0}^{1/2} + \alpha \Delta H_c$.

2. The force constants of the ruptured and generated bonds. A correlation between E_{c0} and the force constant of the C–X bond

has been established for the first time in relation to the reactions of a hydrogen atom and alkyl radicals with alkyl halides.

3. The strength of the X–Y bond in the $X^{\bullet} + HY$ reactions. The stronger this bond, the higher the activation energy. This relation is due to triplet repulsion in the transition state when one of three electrons occupies the nonbonding X–Y orbital.

4. The electronegativities of the fragments (radicals) X and Y. The difference between the electronegativities of these fragments (ΔEA) induces their attraction in the transition state, which lowers the activation energy. The quantity ΔE_{e0} is proportional to $-\Delta EA$.

5. The radii of the atoms X and Y, between which a hydrogen atom or some other atom is transferred. The greater the radii, i.e. the longer the X–Y bond, the stronger the repulsion in the transition state, and the greater the activation energy. It has been established empirically that the quantity ΔE_{e0} is proportional to $r_{X-Y}^{1/2}$.

6. The presence of a polar group in the molecule or radical. It influences the activation energy if the reaction centre is also polar ($\Delta EA \neq 0$). Both models make it possible to separate the influence of the polarity of the X–Y bond on the enthalpy of reaction (the polar factor) and the influence of the polar group on the activation energy for a thermally neutral reaction and also to estimate the contribution of each factor to the activation energy.

7. The presence of several polar groups in the molecule. In this case, the multidipole interaction effect, influencing the activation energy, arises. This effect differs significantly from the influence of a single polar group on the activation energy.

8. The presence of a π -bond or an aromatic ring in the α -position relative to the attacked C–H bond. The activation energy E_{e0} increases in their presence apparently as a result of the increase in the triplet repulsion between X and Y.

9. The presence of bulky groups next to the reaction centre. These groups exert a steric effect, increasing E_{e0} .

10. The solvent polarity. The solvation effect is manifested in a polar solvent if both reactants incorporate polar groups.

Some of the factors enumerated, which influence the activation energy, were not examined previously. They include the force constants of the reacting bonds, the electronegativities of the fragments X and Y, the radii of the atoms X and Y, and the presence of a π -bond next to the reaction centre. The parameters found from experimental data may be used to estimate the activation energy and the rate constants of radical abstraction reactions. The existence of correlation equations for E_{e0} or r_e makes it possible to estimate these parameters for new classes of reactions which have not yet been investigated. The bond dissociation energies can also be calculated from kinetic data with the aid of the IP and MPC methods. Overall, the models described above constitute an effective instrument for the analysis of kinetic parameters of radical reactions.

V. Conclusion	885

Abstract. Polymer blends, the preparation of which is accompanied by various chemical reactions and the formation of specific intermolecular bonds between the components, are analysed. The factors influencing the phase structure of the materials obtained are identified and their relative contributions to its formation are estimated. The influence of the blend composition, nature, and concentration of the functional groups and of the temperature regimes in the blending process is examined. A systematic treatment of the results of experimental and theoretical studies of the method of utilisation of functional groups — direct interaction of the reaction groups in the blended polymers or the introduction of low- and high-molecular reagents capable of interacting with the macromolecules of the blend components — is proposed. It is noted that quantitative data on the variation of the thermodynamic affinity of the blend components and on the rates of mass transfer controlling the formation of the phase structure are limited. Certain theoretical models of the structure of reactive polymer blends, which explain their mechanical properties, are discussed. The priority aspects of studies on the processes involved in the reactive blending of polymers are noted. The bibliography includes 212 references.

I. Introduction

The use of polymeric materials in industry has been expanding and the requirements which they must meet have become more stringent. Special interest has been shown in multicomponent blends and alloys. The creation of such polymer systems entails the potential possibility of combining the attractive qualities of each component of the polymer blend in a single material.^{1–5} Much attention has been devoted in recent years to the processes involved in the preparation of polymeric materials by blending components in which chemical reactions take place. Such blending is called reactive.³

The increased attention to reactive blending processes has been induced by the fact that only a few polymers are fully thermodynamically compatible and produce blends which are homogeneous at the molecular level.⁶ The majority of polymers

exhibit limited compatibility and their blends possess a heterogeneous morphology. Practice has shown that, precisely as a consequence of the multiphase nature of multicomponent polymer systems, the materials based on them frequently possess unique performance characteristics, for example an increased resistance to impact loads and optimum stress-strain properties. The chemical nature of the disperse phase and of the dispersion medium as well as the parameters of the phase structure, namely the volume phase ratio, the size and size distribution of the particles of the disperse phase, the degree of dispersion and the coherence of the disperse phase, and interfacial adhesion, are of primary importance in the generation of useful properties.^{7–9} The blend composition and viscoelastic properties of individual components and the conditions in the blending process determine the parameters of the phase structure and the resistance of the blends to coalescence.^{10, 11}

It follows from the fundamental relations describing the thermodynamic equilibrium in disperse systems¹² that the most effective factor which makes it possible to regulate the parameters of the phase structure is the thermodynamic affinity of the components. A low thermodynamic affinity leads to a high interfacial tension and hinders the dispersion of the components on mixing in the melt. In its turn, this leads to a low interfacial adhesion in the solid state and is responsible for the premature mechanical fracture of the material.^{8, 9} Within the framework of traditional approaches (specific selection of the chemical nature of the components, the composition of the blends, and the processing temperature, as well as the introduction of low-molecular or polymeric additives), the compatibilisation problems — the improvement of thermodynamic compatibility and the regulation of the parameters of the phase structure and of its influence on the physicomaterial characteristics of polymer blend — have been investigated fairly completely.^{13–27}

Since the end of the 1980s, reactive blending, in which physical and/or chemical interactions between the molecules of unlike blend components may occur together with blending processes (in the melt or in solution), has attracted increasing attention. The occurrence of exothermic (as a rule) processes, specific intermolecular or chemical interactions — is accompanied by a decrease in the entropy component and an appreciable decrease in the enthalpy component of the free energy. As a result of the decrease in the free energy of mixing (dispersion), the possibilities for the regulation of the phase structure parameters of multicomponent polymeric materials are expanded.

An increase in the thermodynamic affinity of two polymers may be achieved if interchain exchange reactions (mainly transesterification) take place during the blending process or certain

Received 29 January 1997

Uspekhi Khimii 66 (10) 972–984 (1997); translated by A K Grzybowski

specific intermolecular interactions occur,^{28,29} such as connecting as a result of the formation of hydrogen bonds,³⁰ ion–dipole and dipole–dipole interactions,³¹ acid–base and ion–ion interactions,³² the formation of π – π complexes,³³ and the formation of molecular charge-transfer complexes.^{34,35} In a number of instances, the decrease in the free energy of mixing (dispersion) is achieved as a result of the increase in its entropy component due to intramolecular repulsion effects.^{36,37}

The reviews of theoretical and experimental studies on compatibilisation,^{38–40} reactive extrusion,⁴¹ and reactive blending of polymers,^{6,42,43} attempts were made to interpret and classify the processes involved in the reactive blending of polymers. The number of experimental studies in the field of the reactive blending of polymers has been increasing, which necessitates a further systematic treatment and classification of the studies in this field.

A classification of multiphase reactive polymer blends with allowance for the differences in the way that reactive blending is carried out is proposed in the present review.

Group A. Reactive polymer blends capable of forming strong physical or chemical bonds between macromolecules under the conditions of thermal and mechanical influences and on specific catalysis. Polymer blends, one of which has been subjected to a preliminary chemical modification in order to introduce functional groups capable of reacting with the macromolecules of the other polymer under the blending conditions, may be assigned to the same group.

Group B. Reactive blends obtained as a result of the introduction of a third high-molecular component capable of reacting with at least one of the main components of the polymer blend to form compatibilising copolymers.

Group C. Reactive blends formed following the introduction of low-molecular components promoting intermolecular and/or intramolecular cross-linking (dynamic vulcanisation) of the phases.

A wide class of blends, formed on blending a linear or network polymer with a monomer or oligomer and subsequent chemical solidification (polymerisation, polycondensation), can also be assigned to reactive polymer systems. These are the so called partial (or complete) interpenetrating polymer networks in which the stages involving the blending of the components and their chemical reaction are as a rule separated. Such attention has been devoted in the literature^{44–47} to the study of the structures and properties of various types of interpenetrating polymer networks and we shall therefore not consider them here.

II. The influence of interchain exchange and of specific interactions in binary polymer blends (group A)

Reactive blending processes may be carried out in solution, in the melt, and in the solid phase. In the solid phase, such processes occur as a result of an external mechanical action, leading to nonelastic deformations and plastic flow. The results of studies on the mechanisms and rates of solid-phase chemical reactions at a high pressure in combination with shear deformation have been examined in detail in a number of communications^{48–51} and are outside the scope of the present review.

Examples of the preparation of group A reactive polymer blends in solution are presented in Table 1. The initial polymers are usually blended in a common solvent and the blends are then precipitated and treated in a specific temperature–time regime. Under such conditions, the most typical interchain exchange reaction for polyesters is transesterification, *i.e.* transesterification of high-molecular polyesters, leading to the formation of the corresponding block copolymers. Hydrolytic chain degradation and chain polycondensation processes occur under these conditions.⁵⁶ According to Fourier-transform infrared spectroscopic (FTIR) data, the transesterification in certain polymer blends at high temperatures may be accompanied also by thermal degrada-

Table 1. Reactive blending of polymers in solution (group A blends).

Polymer 1	Polymer 2	Brief process characteristics	Ref.

	Various polyesters	Ditto	64
PC	PPMA	"	66
PVME	SBS	"	67
PA6	PPO	"	68

Note. The following designations have been adopted for the polymers; PBT = poly(butylene terephthalate); POR = phenoxy-resin (bisphenol A polyhydroxyether); PAr = polyarylate (copolyester of bisphenol A and terephthalic and isophthalic acids in proportions of 2:1:1); PC = polycarbonate; PET = poly(ethylene terephthalate); PETG = copolyester of cyclohexane-1,4-dimethanol, ethylene glycol, and terephthalic acid (1:2:3); s-PMMA = syndiotactic poly(methyl methacrylate); PS = polystyrene; PTCB = poly-1,1,2-trichlorobuta-1,3-diene; PVC = poly(vinyl chloride); PU = polyurethane; PVP = poly-4-vinylphenol; E–VA = ethylene–vinyl acetate copolymer; PAMA = poly(alkyl methacrylates); ENR = epoxidised natural rubber; PCL = poly- ϵ -caprolactone; PPMA = poly(phenyl methacrylate); PVME = poly(vinyl methyl ether); SBS = styrene–butadiene–styrene copolymer; PA6 = polyamide 6; PPO = poly(propylene oxide).

^a According to Chong and Goh,⁶⁵ the nature of the intermolecular interaction has not been established in this case.

tion with recombination of macromolecular free radicals, which leads to the formation of graft copolymers.⁵⁷ The formation of an interpolymer microgel in a study of the Friedel–Crafts reaction occurring under mild conditions in a blend of two virtually incompatible polymers has been established.⁵⁸ According to a number of investigators,^{52–58} the compatibilisation of polymer blends is due to the formation of copolymers or interpolymers.

The compatibilisation of polymer blends is also promoted by the formation of hydrogen bonds between the blend components^{59–62} (Table 1). Signs of intermolecular association and of the formation of molecular complexes as a result of strong hydrogen bonding have been observed by high-resolution ¹³C NMR and differential scanning calorimetry in model blends of low-molecular poly(ethylene oxide) and resorcinol, which have two eutectic points on the phase diagram.⁶⁹ The compatibilisation of blends of diethyl maleate-modified ethylene–propylene rubber with polystyrene and with poly(vinyl chloride),⁷⁰ of polyamide 6 with the Mn salt of sulfonated polystyrene⁷¹ and alkaline (Li and Na) ionomers of sulfonated polystyrene,⁷² and also of the styrene–4-vinylpyridine block copolymer with the Zn salt of a carboxylated ethylene–methacrylate copolymer⁷³ is due to the formation of polymeric complexes. Examples of the compatibilisation of polymer blends as a result of specific interactions^{63–68} can also be found in Table 1. The dependence of the intensity of

the intermolecular interactions on the blend composition has been demonstrated.⁷⁴

For ecological reasons, reactive blending has been carried out recently with increasing frequency in polymer melts (in the absence of a solvent). Batch mixers and continuous screw extruders are used as the reactors. Studies on a series of model reactions in solution and in homogeneous melts have shown⁷⁵ that the mechanisms and kinetics of the reactions are virtually analogous in both homogeneous media, provided that diffusion is not the limiting factor. However, as a rule, reactive blending processes are carried out in heterogeneous melts. Interchain block or graft copolymers may then be formed in different proportions (*via* new covalent or ionic bonds). Such *in situ* compatibilisers have molecular segments chemically identical with the segments in the corresponding unreacted homopolymers. The compatibiliser segments are distributed predominantly at the interface, which entails a decrease in interfacial tension and adhesion is strengthened.⁶

The heterogeneous nature of the reactive polymer system predetermines the characteristic features of the kinetics of the chemical reaction. It has been shown in relation to the transesterification reaction in the ethylene–methyl acrylate copolymer/monohydroxylated polystyrene system^{75, 76} that the degree of conversion decreases appreciably with increase in the molecular mass of the monohydroxylated polystyrene. The graft copolymer formed at the interfaces promotes an increase in interfacial adhesion and the stabilisation of the morphology. However, its accumulation at the interface greatly reduces the overall reactivity of the system. The intensity of mechanical mixing becomes a very important factor for the given reaction, since it influences the depth of diffusion and the formation of new interfaces. A marked effect due to the introduction of small amounts of the solvent is also observed: the addition of 1 mass %–2 mass % of 1,2,4-trichlorobenzene or *n*-hexane to the melt of the ethylene–methyl acrylate copolymer/monohydroxylated polystyrene blend greatly increases the overall degree of conversion. According to the authors,^{75, 76} this effect can be accounted for by the increase in compatibility, the improvement in interfacial mixing, and the mutual diffusion in the presence of a solvent. Unfortunately, the relationship between the reaction kinetics and the phase structure of the blend as well as the operating characteristics of the material obtained had not been established in the above investigations. On the whole, information about the diffusional mobility, mutual solubility of the components, the area of interfacial contact, the concentration profiles of the reactants in the interfacial region, as well as the nature of their time variation is needed for the interpretation of kinetic data in heterogeneous reactive polymer systems.^{75, 76}

The conclusions reached in the above studies^{75, 76} agree well with the results of the investigation of transesterification in polyester blends,⁷⁷ for which the influence of the compatibility of the initial components, blending conditions (temperature, duration, and intensity of blending), the ratio of the viscosities of the components, and the presence of catalysts^{78, 79} or inhibitors⁸⁰ in the system on the rate of transesterification has been established. It has also been shown⁸¹ that, in the course of the transreaction, the viscosity of the melt changes; the viscosity increases until both components of the reactive blend have fully reacted.

Transesterification is most often employed in the preparation of group A reactive blends in the melt. An improvement of the compatibility of the components in the melt has been achieved in blends of polycarbonate with poly(butylene terephthalate),^{82–85} poly(ethylene terephthalate),^{78, 79, 86} polyarylate (the copolyester of bisphenol A and terephthalic and isophthalic acids in proportions of 2:1:1),^{87, 88} the copolyester based on cyclohexane-1,4-dimethanol and terephthalic and isophthalic acids (Kodar A150),⁸⁹ a thermotropic polyester consisting of the copolymer of 4,4'-dihydroxybiphenyl and terephthalic and isophthalic acids (Ultrax KB4002),⁹⁰ and polyamide 6.^{91, 92} The transesterification reaction is known to proceed at an appreciable rate at temperatures above 200 °C.⁷⁷ Below this temperature, the rate of

reaction falls and at higher temperatures the Kolbe rearrangement involving the carbonate groups and the pyrolysis of the ester groups makes a significant contribution.⁹³ In a number of instances, the cross-linking and degradation reactions have also been observed, for example in polyacrylamide–chloroprene rubber⁹⁴ and polyacrylic acid–epoxidised natural rubber⁹⁵ blends.

Under the conditions of intense shear blending of incompatible polymers, interchain reactions were noted, as a result of which various copolymers compatibilising the system appeared. Maxwell and Jasso⁹⁶ observed the formation of a three-dimensional network of 'intertwined' homopolymeric stands on blending poly(methyl methacrylate) with polyethylene in an elastic-melt extruder. Under analogous conditions in the blending of polypropylene with high-density polyethylene in the melt, a block copolymer (formed as a result of the cross reactions of the macroradicals), responsible for the improvement of the compatibility of the system components, appears in the blend melt together with the homopolymers.⁹⁷

The series of studies by Santra and coworkers,^{98–101} indicating unlimited mutual solubility in the melt comprising polydimethylsiloxane rubber modified by the inclusion of vinyl groups and the ethylene–methyl acrylate copolymer, is by no means unique. The unlimited mutual solubility is due to the chemical reaction between the vinyl groups at the silicon atoms in the polydimethylsiloxane chains of the rubber with the α -methine groups of the methyl acrylate fragment of the copolymer.^{98, 99} According to the results of dynamic mechanical analysis, for all blend compositions there is a positive deviation of the single glass-transition temperature from the values calculated by Fox's equation.⁹⁸ Synergistic effects have also been observed for the given system in the study of mechanical characteristics,⁹⁹ thermal stability,¹⁰⁰ and rheological properties.¹⁰¹

The improvement of compatibility in reactive blending in the melt may be achieved also as a result of specific interactions, for example the formation of hydrogen bonds between the functional groups of the blend components, as in the poly(ethylene terephthalate)/poly(ether imide) (Ultem 1000),^{102, 103} poly(ethylene terephthalate)/polyurethane, and poly(butylene terephthalate)/polyurethane¹⁰⁴ systems.

The possibilities for compatibilisation and the range of polymeric objects used in reactive blending processes are greatly expanded if one or both components are subjected to a preliminary chemical modification. The aim of the chemical modification in this instance is the introduction into the macromolecules of functional groups capable of reacting under the blending conditions with formation of graft copolymers compatibilising the system. Table 2 presents the blending processes in which one of the components is subjected to preliminary chemical modification. An example of blends with preliminary chemical modification of both components is that of blends comprising 3-mercaptopropyltrimethylsilano-grafted poly(vinyl chlorides) and chlorinated polyethylene in which compatibilisation as a result of the mutual cross-linking of the components was observed.¹³¹ The results of rheological studies, FTIR, and dynamic mechanical analysis of a blend of polypropylene modified by maleic anhydride with the Zn salt of the sulfonated ethylene–propylene–diene monomer have also demonstrated an improved mutual solubility compared with the unmodified polypropylene/ethylene–propylene–diene monomer blends as a consequence of the compatibilisation of the system *in situ*.¹³²

In order to create nucleophilic or base-functionalised polymers for reactive blending with various electrophilic polymers, graft copolymers of olefins, in particular linear low-density polyethylene, with a tertiary amine—2-methylaminoethyl methacrylate (DMAEMA)¹³³—or a secondary amine—*tert*-butylaminoethyl methacrylate (TBAEMA)¹³⁴—have been successfully synthesised. Model studies have demonstrated¹³⁵ that secondary amino-groups can form both ionic and covalent bonds, whereas only ionic bonds or polar interactions with polymers

Table 2. Reactive blending processes in the melt with participation of chemically modified polymers (group A blends).

Note. The following designations have been for the polymers: PP-g-MAn = polypropylene modified by maleic anhydride; PP-g-AA = polypropylene modified by acrylic acid; EPR-g-MAn = ethylene-propylene rubber modified by maleic anhydride; EPR-g-AnSA = ethylene-propylene rubber modified by the anhydride of succinic acid; EPDM-g-MAn = ethylene-propylene-diene monomer modified by maleic anhydride; E-MAA = ethylene-methacrylic acid copolymer; E-AEs-MAn = ethylene-acrylic ester-maleic anhydride terpolymer; S-EP-S-g-MAn = styrene-(ethylene-propylene)-styrene triblock copolymer modified by maleic anhydride; PS-g-MAn = polystyrene modified by maleic anhydride; PE-g-MAn = polyethylene modified by maleic anhydride; POLDPE = photooxidised low-density polyethylene; PA66 = polyamide 66; PP-g-GMA = polypropylene modified by glycidyl methacrylate; E-AA = ethylene-acrylic acid copolymer; OPS = oxazoline-modified polystyrene; LLDPE-g-MAn = linear low-density polyethylene modified by maleic anhydride; S-MAn = styrene-maleic anhydride copolymer; LLDPE-g-DMAEMA = linear low-density polyethylene modified by dimethylaminoethyl methacrylate; LLDPE-g-TBAEMA = linear low-density polyethylene modified by *tert*-butylaminoethyl methacrylate; EPR-g-pA = ethylene-propylene rubber modified by a primary amine; MMA-MAA = methyl methacrylate-methacrylic acid copolymer; E-AEs-GMA = ethylene-acrylic ester-glycidyl methacrylate terpolymer; EPDM = ethylene-propylene-diene monomer; PAr-g-BCB = polyarylate based on bisphenol A and terephthalic and isophthalic acids (2 : 1 : 1) modified by 1,2-dihydro-4-chloroformylbenzocyclobutene; E-MA = ethylene-methyl acrylate copolymer; HPS = monohydroxylated polystyrene; HDPE = high-density polyethylene; ZSEPDM = Zn salt of sulfonated ethylene-propylene-diene monomer.

^a Thermally reversible cyclisation reaction between the unsaturated side bonds of EPDM and the *o*-quinondimethane end groups of PAr-g-BCB.

containing carboxy- or maleic anhydride groups are characteristic of tertiary amino-groups. The reactive blending of linear low-density polyethylene, chemically modified by DMAEMA, with the styrene-maleic anhydride copolymer in the melt ensures an improved compatibility of the components. This conclusion was reached on the basis of electron microscope data and was accounted for by the strong specific polar interactions between the acid anhydride and the basic amino-groups. However, the improvement of the mechanical properties of these reactive blends proved to be slight.^{124, 125} It was also established that the secondary amino-group in TBAEMA is more reactive in relation to the carboxy- or anhydride groups than the primary or tertiary amino-groups. A decrease in the size of the particles of the disperse phase, accompanied by an increase in the tensile strength σ_b , the relative tensile elongation at break ϵ_b , and the breaking energy on impact

by 20%–50% compared with the nonreactive linear low-density polyethylene/styrene-maleic anhydride blends was observed under these conditions in systems comprising linear low-density polyethylene modified chemically by TBAEMA and the styrene-maleic anhydride copolymer.¹²⁵

A more significant increase in the stress-strain characteristics has been observed in the reactive blends of linear low-density polyethylene modified chemically by TBAEMA with the methyl methacrylate-methacrylic acid copolymer (by 500%–800%) compared with the nonreactive linear low-density polyethylene chemically modified by TBAEMA/poly(methyl methacrylate) blends.¹²⁷ Three macromolecular reactions take place in blends of linear low-density polyethylene modified chemically by TBAEMA and the methyl methacrylate-methacrylic acid copolymer: the formation of the amide, the formation of the

carboxylate anion, and the formation of the imide ring as a result of the interactions of two neighbouring carboxy- and carboxylate groups of the copolymer with the amino-group of the linear low-density polyethylene modified chemically by TBAEMA with elimination of isobutene and an alcohol.^{127, 135, 136} The last reaction leads to the formation of a graft copolymer, which increases interfacial adhesion and hence greatly improves the stress-strain characteristics of the reactive blends.

As can be seen from the relation presented in Fig. 1, the values of U_t for the reactive blends containing more than 50 mass % of the linear low-density polyethylene modified chemically by TBAEMA exceeded the additive values ('positive' effect¹³⁷). For plastics with improved (as a result of the inclusion of rubber particles in the brittle polymer matrix) impact strength, such effects have been frequently observed.^{1, 7, 10} Among the polymer blends consisting of a ductile (plastic) matrix and a brittle disperse phase, only very few exhibit 'positive' effects [for example, the polycarbonate/poly(methyl methacrylate) and polycarbonate/styrene-acrylonitrile copolymer systems].¹³⁷ Within the framework of the 'cold drawing' concept,¹³⁸ the absorption of impact energy in these systems can be explained by the plastic deformation of the brittle disperse phase. The reason for such deformation is the high compressive stress arising on bulk-phase deformation of a two-phase system by the tensile stress in the equatorial planes of spheres dispersed in a matrix and caused by the difference between the Young's moduli and the Poisson coefficients of the disperse spherical phase and the matrix. According to Liu *et al.*,¹²⁷ the 'positive' effect in the compatibilised linear low-density polyethylene chemically modified by the TBAEMA/methyl methacrylate-methacrylic acid copolymer blend can be explained by a brittle-to-ductile transition in the disperse phase. According to electron microscope data, such blends are characterised by a more finely disperse and inhomogeneous morphology than nonreactive linear low-density polyethylene chemically modified by TBAEMA/poly(methyl methacrylate)-methacrylic acid copolymer blends. The particles of the methyl methacrylate-methacrylic acid copolymer are anchored to a matrix comprising the linear low-density polyethylene modified chemically by TBAEMA with the aid of fibril-like elements, which appear as a result of the drawing of such polyethylene during impact fracture and indicate very strong adhesion between the phases.

The strong interfacial adhesion in the systems obtained by reactive blending has been confirmed by the results of the analysis of the concentration dependence of the elastic modulus E within

Figure 1. The influence of blend composition on the total absorbed impact energy U_t for nonreactive linear low-density polyethylene chemically modified by TBAEMA/poly(methyl methacrylate) blends (1) and reactive linear low-density polyethylene chemically modified by TBAEMA/methyl methacrylate-methacrylic acid copolymer blends (2);¹²⁷ [c] — content of the linear polyethylene modified chemically by TBAEMA.

Figure 2. Experimental (1, 2) and theoretical (3, 4) dependences of Young's modulus on the volume fraction of the poly(methyl methacrylate) disperse phase for nonreactive linear low-density polyethylene chemically modified by TBAEMA/poly(methyl methacrylate) blends (2, 4) and reactive linear low-density polyethylene chemically modified by TBAEMA/methyl methacrylate-methacrylic acid copolymer blends (1, 3);¹²⁷ [c] — content of the methyl methacrylate-methacrylic acid copolymer [or poly(methyl methacrylate)].

the framework of Takayanagi's adhesion theory.¹³⁹ As can be seen from Fig. 2, the experimental data for the linear low-density polyethylene modified chemically by TBAEMA/methyl methacrylate-methacrylic acid copolymer reactive blends (curve 1) virtually coincide with data calculated in accordance with the 'perfect adhesion' model (curve 3). For the nonreactive linear low-density polyethylene modified chemically by TBAEMA/poly(methyl methacrylate) blends, the experimental Young's moduli (curve 2) lie appreciably below the 'ideal adhesion' line but appreciably above the 'loose inclusions' line (curve 4). According to Liu *et al.*,¹²⁷ the transfer of stress between the phases in the given nonreactive system takes place by virtue of a mechanical interfacial contact arising on cooling the mixture, because the matrix comprising linear low-density polyethylene modified chemically by TBAEMA crystallises after the solidification of the poly(methyl methacrylate) phase inclusions and may compress them.

Cross reactions of various types always occur in the blending of polymers in melts: chain transfer by the radical degradation products and subsequent recombination of the macroradicals, chain transfer with rupture as a result of molecular and ionic reactions, and cohydrolysis and transesterification reactions. Deliberate employment of these reactions may exert a favourable influence on the morphology and properties of polymer systems.

III. Reactive blending in multicomponent polymer systems with participation of high-molecular compatibilisers (group B)

The introduction of a third high-molecular component may serve as one of the methods for the compatibilisation of blends of two incompatible polymers. Polymeric compatibilisers, consisting of reactive copolymers or chemically modified polymers of type X-Z (where Z is a long-chain reactive segment or functional group attached to the main chain), may compatibilise the polymer pair X and Y subject to the condition that Z is capable of reacting chemically with the polymer Y. Table 3 presents certain examples of systems of this kind investigated in recent years (the studies published up to 1990 have been examined in another review⁶). The chemical nature and structure of the component X and of the unreactive segment of the polymeric compatibiliser frequently differ, but the latter is nevertheless capable of specific interactions

Table 3. Processes involving compatibilisation by means of reactive copolymers or chemically modified polymers introduced separately (group B blends).

Note. The following designations have been adopted for the polymers: ABS = ternary acrylonitrile–butadiene–styrene copolymer; S-AN = styrene–acrylonitrile copolymer; PS-g-TAN = polystyrene modified by trimellitic anhydride; S-MAA = styrene–methacrylic acid copolymer; HNBR = hydrogenated nitrile rubber; PP = polypropylene; E-MAA-ICA = ethylene (80 mol. %)–methacrylic acid–isobutyl acrylate terpolymer (Surlyn 9020); E = reactive ethylene-based terpolymer (Lotader AX-8660); LCP = liquid-crystal polymer based on 6-hydroxy-2-naphthoic acid (70 mol. %) and *p*-hydroxybenzoic acid (30 mol. %) (Vectra A950); PDMPO = poly(2,6-dimethyl-1,4-phenylene) oxide; S-GMA = styrene–glycidyl methacrylate copolymer; NR = natural rubber; IPE = ionomeric polyethylene [Zn-neutralised ethylene–methacrylic acid copolymer (Surlyn 9730)]; S-VP = styrene-4-vinylpyridine block copolymer; LDPE = low-density polyethylene; PS-g-O-CPE = polystyrene (modified by oxazoline)-carboxylated polyethylene graft copolymer; PMMA = poly(methyl methacrylate); S-ECA = styrene–ethyl 2-cyanoacrylate copolymer.

^a In this cases cross-linking reactions take place together with the interfacial reactions during the blending process.

leading to an increase in the thermodynamic affinity of the components. It is noteworthy that a considerable proportion of ternary polymer systems (Table 3) may be obtained from binary blends (Table 2) by ‘dilution’ with an unmodified basic polymer (for example, polyamide/polyolefin modified by maleic anhydride/polyolefin).

In the majority of reactive blends of this category, a polyamide (polyamide 6 or polyamide 66) is used as a component which may react with compatibilisers containing the anhydride or carboxy-functional groups^{105, 140–153} with formation of amide or imide bonds. Other examples of this kind are the inclusion of either the reactive oxazoline group^{159, 161} or the epoxide group. The latter may be present in epoxidised rubber¹⁶² or in the terpolymer based on poly-ε-caprolactone. A different approach to the improvement of compatibility has been described^{156, 158, 163} — as a result of ionic interactions of interchain Na or Zn salts. This method affords rubber-modified blends with an improved impact strength.¹⁶³

The principle of the interaction of reactive groups of diverse polymers capable of forming statistical or block copolymers, acting as compatibilisers in blends, has been used in the blending in a melt of polyamide 6 with various styrene and acrylonitrile copolymers. The compatibilising effect is manifested by styrene–acrylonitrile copolymers containing functional groups of the type of maleic anhydride or oxazoline. In order to regulate the dimensions of the disperse phase of the styrene–acrylonitrile copolymer, an attempt has been made to optimise the composition of the reactive system as regards the type and concentration of the functional groups, the content of the reactive compatibiliser, and its compatibility with the styrene–acrylonitrile copolymer.^{140, 144}

The same principle has been used to improve the compatibility of blends of polyamide 6 and polypropylene by the introduction of acrylic acid-modified polypropylene as the reactive compatibiliser.¹⁴⁸ Together with the strong hydrogen-bonding interactions in such ternary blends, the terminal amino-groups of the polyamide are capable of reacting with the acid groups of the modifier. The influence of the blending conditions in the extruder (temperature, rate, the moment of rotation during blending, the presence of a vacuum, *etc.*) on the strength properties and morphology of the blends has been described. The formation of a graft copolymer on introduction of a polymeric compatibiliser has been demonstrated by IR spectroscopy.

Even a small amount of the compatibiliser may alter significantly the structure of the polymer blend. It has been shown¹⁴⁷ that maleic anhydride-modified polypropylene, introduced at a concentration up to 1.5 mass %, can fully alter the kinetics of the crystallisation and the crystalline structure of the polypropylene/polyamide 6 blend. The crystallisation of polyamide 6 is almost fully suppressed at its usual crystallisation temperature and virtually complete so called retarded (or concerted) crystallisation of polyamide 6 and polypropylene takes place. This effect had been observed earlier in noncompatibilised blend systems such as polyamide 6/poly(vinylidene fluoride), poly(butylene terephthalate)/poly(vinylidene fluoride), and polyethylene/polyoxymethylene¹⁶⁴ and also in compatibilised blends.¹⁵⁰ It has been suggested that this effect is a consequence of the dilution of the polyamide phase by the polypropylene–polyamide 6 graft copolymer.¹⁴⁷

Blends of poly(2,6-dimethyl-1,4-phenylene) oxide with Surlyn 9730 ionomeric polyethylene, which is a Zn-neutralised statistical ethylene–methacrylic acid copolymer, constitute an example of compatibilisation as a result of specific interaction in ternary polymer/polymer/polymeric compatibiliser systems.¹⁵⁸ The styrene–4-vinylpyridine block copolymer with a ratio of the styrene and vinylpyridine blocks of 59/41 was used as the compatibiliser. According to differential scanning calorimetric data, the styrene and vinylpyridine blocks of this copolymer interact with the poly(2,6-dimethyl-1,4-phenylene) oxide and ionomeric polyethylene phases respectively. According to the results of FTIR studies, the specific interaction between the vinylpyridine blocks of the compatibiliser and the ionic groups of the ionomeric polyethylene is of the ion–dipole type. The results of mechanical tests (Fig. 3) have shown that the introduction of the styrene–4-vinylpyridine block copolymer increases the values of *E* and σ_b over the entire range of compositions. The values of ϵ_b vary in parallel with increase in the content of the compatibiliser in blends enriched in poly(2,6-dimethyl-1,4-phenylene) oxide and the variation is anti-parallel in blends enriched in the ionomeric polyethylene. According to Jo *et al.*,¹⁵⁸ these results are a consequence of the increase in the degree of dispersion of the polymeric filler and the adhesion between the poly(2,6-dimethyl-1,4-phenylene) oxide and ionomeric polyethylene phases. The fractograms, obtained by scanning electron microscopy, of the blend specimens after tensile tests confirm the improvement of the interfacial adhesion in the presence of the block copolymer: in the absence of the styrene–4-vinylpyridine block copolymer, the spherical particles of the disperse phase [poly(2,6-dimethyl-1,4-phenylene) oxide] separate from the matrix owing to the weak transfer of stresses and deformations, while in the presence of the styrene–4-vinylpyr-

Figure 3. The influence of the introduction of the styrene-4-vinylpyridine block copolymer on the elastic modulus E (a), the tensile strength σ_b (b), and the relative elongation at break ε_b (c) for poly(2,6-dimethyl-1,4-phenylene) oxide/ionomeric polyethylenes of different composition blends.¹⁵⁸ Content of the styrene-4-vinylpyridine block copolymer (mass %): (1) 0; (2) 5; (3) 10.

idine block copolymer the disperse phase is deformed and elongated, as a result of which it is anchored more strongly to the matrix. The specific interaction between 4-vinylpyridine and the transition metal cation has been used also for the compatibilisation of blends comprising rubbers and amorphous polymers, for example the sulfonated polystyrene/ethyl acrylate-4-vinylpyridine copolymer,¹⁶⁵ the sulfonated ethylene-propylene-diene monomer/styrene-4-vinylpyridine block copolymer,¹⁶⁶ and the Cu-neutralised carboxylated polybutadiene/styrene-4-vinylpyridine block copolymer¹⁶⁷ blends.

IV. Reactive blending with participation of low-molecular compounds. Dynamic vulcanisation (group C)

A promising approach to the compatibilisation of polymer blends is the introduction of reactive low-molecular compounds which tend to form covalent bonds with one or both blend components and promote the formation reactions of statistical, block, or graft copolymers, linear or branched (compatibilisation mechanism I), cross-linked in one of the coexisting phases (compatibilisation mechanism II), or cross-linked in both polymer phases (compatibilisation mechanism III). Small amounts (0.1 mass %–3.0 mass %) of added low-molecular compounds are usually employed. This constitutes their main economic advantage over polymeric compatibilisers, which, apart from the expense and complexity of their synthesis, are as a rule effective at higher concentrations.

Examples of the formation of group C reactive blends are presented in Table 4. The compatibilisation mechanism I involves the formation of compatibilising copolymers under the influence of catalytic and noncatalytic interchain reactions. Toluene-*p*-sulfonic acid or phosphites catalyse transamidation reactions in

Table 4. Compatibilisation of polymer blends with participation of reactive low-molecular compounds (group C blends).

CM ^a	Compatibilised blend	Low-molecular compound	Ref.

	NR/LDPE	Peroxide and coreagents	201
	PP (or PP-g-AA)/PBD (or BNR, SEPR, NR, SBR)	Ditto	202

Note. The following designations have been adopted for the polymers: LLDPE = linear low-density polyethylene; S-VBA = styrene-vinylbenzaldehyde copolymer; EPDM-g-FA = ethylene-propylene-diene monomer modified by fumaric acid; BBR = brominated butyl rubber; TAIC = triallyl isocyanurate; ER = epoxide resin; PEI = poly(ether imide) (Ultem 1000); PI = polyimide; PAmA = poly(amic acid); SBR = styrene-butadiene rubber; EPR = ethylene-propylene rubber; BANR = butadiene-acrylonitrile rubber; VDF-HFP = vinylidene fluoride-hexafluoropropylene copolymer; ECHR = epichlorohydrin rubber; PBD = *cis*-polybuta-1,4-diene; BNR = butadiene-nitrile rubber.

^a Compatibilisation mechanisms (CM): I — formation of copolymers; II — formation of copolymers and cross-linking of one phase; III — formation of copolymers and cross-linking of both phases of the blend.

^b Blending of polymers in solution.

a melt comprising blends containing various polyamides and polyesters.^{168, 169} Free-radical reactions, initiated by peroxides and/or shear, also lead to the formation of compatibilising copolymers as a result of the recombination of the macroradicals formed, in the presence of an additional reagent — the interchain connecting agent (ICA), for example reagents such as bismaleimide.^{170, 171} In blends comprising poly(butylene terephthalate) and a fumaric acid-modified ethylene-propylene-diene copolymer, polyamide oligomers can act as ICA as a consequence of reactions with carboxy-groups.¹⁷² It is noteworthy that Table 4 does not include examples of compatibilising systems containing fillers and reinforcing agents (mica, graphite, talc, calcium carbo-

nate, cellulose, glass fibre, *etc.*). Such systems have been examined in Xanthos' review.²⁰³ Standard organofunctional silanes or titanate and zirconate compounds developed later are widely used as ICA in these systems. In the polypropylene/CaCO₃ systems, sulfonyl azides, having the general formula N₃SO₂-R'-COOH and containing the azide and carboxy-groups, are reactive in relation to both polypropylene and CaCO₃.²⁰⁴

It has been shown¹⁷³ that dimethylaminoethanol forms bonds between brominated butyl rubber and the styrene-maleic anhydride copolymer. Reactive organofunctional titanates compatibilise various polymer systems (for example, polyoxymethylene/polyacrylate²⁰⁵) via catalytic exchange reactions and also via their involvement in other reactions, depending on the type of polymer and the structure of the titanate.

The compatibilisation mechanism II (Table 4) operates in the presence in the blend of a component capable of being cross-linked on treatment with various reagents. It is usually believed^{6,203} that compatibilising copolymers are then formed simultaneously *in situ*. With the exception of plastic/plastic blends, such as polypropylene/polyethylene,¹⁷⁴⁻¹⁷⁷ poly(vinyl chloride)/polyethylene,¹⁷⁸ epoxide resin/polycarbonate,^{182,183} epoxide resin/poly(ether imide) (Ultem 1000),¹⁸⁴ and polyimide/poly(amic acid),¹⁸⁵ all the examples of the compatibilisation mechanism II refer to blends of the plastic/rubber type. These blends are obtained with the aid of the so called 'dynamic vulcanisation', *i.e.* the process involving the cross-linking of only the rubber component on blending in the melt.^{179-181,186-199}

The intercrossed (intercross-linked) rubber/rubber²⁰⁰ and rubber/plastic^{201,202} blends (Table 4) can serve as examples of the compatibilisation mechanism III. It is believed that the phase segregation in these systems is suppressed by the formation of chemical bonds in the interfacial layer. It has been postulated that such morphology occurs in various blends compatibilised by cross-linking, such as styrene-butadiene rubber/butyl rubber, natural rubber/butyl rubber, *etc.*^{1,206} which include components undergoing cross-linking at approximately the same rate. The required properties may be obtained also by reducing the overall rate of cross-linking, which favours interdiffusion and mutual overlapping of the phases.²⁰¹ In the field of study of rubber blends, efforts have been mainly concentrated on the development of common cross-linking agents (such as the triazinedithiol complex²⁰⁰) with comparable rates of vulcanisation and similar solubilities in the blend components.

Among all the variants of the reactive blending of polymers examined, dynamic vulcanisation (DV) has been most fully investigated. The thermoplastic elastomers (TPE) formed on dynamic vulcanisation are rubber materials, which can be processed in the melt like the usual thermoplastic materials but at the operating temperature possess properties analogous to those of a vulcanised elastomer.²⁰⁷ In recent years, there has been a steady growth of interest in these materials, which compete successfully with traditional thermocured rubbers in the market for industrial cured rubber products.^{11,181} The main task is to use of the DV method to create a multicomponent system with particles of the vulcanised elastomer included in a plastic matrix which can be processed in the melt. The rubber components should be vulcanised during its blending with the thermoplastic polymer.

The first compositions of this kind were obtained in the 1960s-1970s.^{208,209} A series of rules governing the appearance of the set of useful properties of materials of the TPE type have now been discovered. The study of dynamically cross-linked compositions based on a large series of rubbers and thermoplastics^{180,196,210} has demonstrated that thermoplastic vulcanisates, in which the surface energies (critical wetting surface tensions) of the plastic and elastomer are similar, the molecular length between the entanglements in the initial elastomer is small, and the plastic has a degree of crystallinity of the order of 15%-30%, possess the most effective stress-strain properties. In relation to the polypropylene/ethylene-propylene-diene mono-

mer system, obtained by the DV method in the presence of a sulfur-containing cross-linking system, it has been shown that the stress-strain behaviour of TPE depends on the particle size of the dispersed rubber, the composition of the blend (Fig. 4), and the density of the cross-links in the elastomer phase (Fig. 5).²¹⁰ It was found that a small number of cross-links [5×10^{-5} mol (ml of elastomer)⁻¹] is needed for a significant improvement of the elastic recovery after drawing. The tensile strength σ_b of the given TPE increases monotonically with increase in the number of cross-links of the elastomer phase, but the compositions remain processable as thermoplastics even for high cross-linking densities, only small changes in the hardness of the compositions being observed following a significant alteration of the degree of vulcanisation.²¹⁰ For the TPE based on polypropylene and the ethylene-propylene-diene monomer (Santoprene 201-73), it has been shown¹⁹⁰ that the elastic recovery is greater, the lower the value of Young's modulus and the higher the yield stress of the matrix polymer (polypropylene).

The dynamic vulcanisation of a component of ethylene-propylene rubber alters radically the structure and properties of the

Figure 4. Dependence of the hardness (a), tensile strength (b), and residual deformation (c) on blend composition for dynamically vulcanised TPE based on polypropylene and the ethylene-propylene-diene monomer.²¹⁰

TPE based on polypropylene and ethylene-propylene rubber.^{194,211} The blend containing noncross-linked ethylene-propylene rubber is characterised by the presence of polypropylene domains randomly distributed in the rubber matrix. Dynamic vulcanisation leads to phase inversion, as a result of which the plastic phase (polypropylene) becomes continuous. After crystallisation, its structure resembles a cobweb surrounding the particles of the cross-linked ethylene-propylene rubber. The melting behaviour of the polypropylene phase in nonvulcanised polypropylene/ethylene-propylene rubber blends is independent of the overall blend composition and the molecular mass of the ethylene-propylene rubber. In the presence of the cross-linked rubber component, an appreciable decrease in the effective (observed) melting point of the polypropylene in the blend is observed. The supermolecular structure of the polypropylene phase has been described within the framework of the 'leaf-spring' model, according to which the individual lamellae in the stacks (piles) are linked

Figure 5. The influence of the density of the cross-linking of the elastomer phase on the tensile strength σ_b (1) and the residual elongation on extension ϵ_{res} (2) for dynamically vulcanised TPE based on the polypropylene/ethylene-propylene-diene monomer blend (40/60).²¹⁰

solely to their upper and lower neighbours in the network of nodes, whilst the regions between lamellae remain unconnected. By virtue of this unusual geometry, this polypropylene with stacked lamellae can undergo almost complete elastic recovery even after appreciable deformation.¹⁹⁴

The formation of covalent bonds between the thermoplastic and rubber phases in the course of the DV process is a decisive factor in the establishment of the stress-strain properties of the TPE. It is seen from the drawing diagram for blends of different polypropylenes and rubbers (Fig. 6) that the values of σ_b for the vulcanised materials are significantly higher than for the non-cross-linked systems (curves 1). Cross-linking systems ensuring the covulcanisation of the polymeric components are preferable for the improvement of the stress-strain characteristics (curves 3). The effectiveness of covulcanisation increases if polypropylene

Figure 6. The drawing diagrams for TPE based on polypropylene/brominated butyl rubber (40/60) (a) and polypropylene modified by acrylic acid/butadiene-nitrile rubber containing terminal amino-groups (40/60) (b) blends. TPE: nonvulcanised (1) and vulcanised in the presence of tetramethylthiuram disulfide/sulfur (2), bismaleimide/dicumenyl peroxide (3), and phenolic resin (4) systems.²⁰²

has been subjected to a preliminary chemical modification, for example with acrylic acid (curves 3 and 4 in Fig. 6b). The improving of adhesion between the phases as a result of the formation of covalent bonds reduces the glass transition temperature of the amorphous regions of the polypropylene.²⁰²

Thus, by regulating the nature of the polymer chain of the compatibiliser and the reactivity of the functional groups, it is possible to alter specifically the structure and interaction energy in the interfacial layer. The increase in the cohesion energy in one of the phases as a result of specific cross-linking makes it possible to regulate effectively the degree of dispersion and the physico-mechanical properties of the filler polymer.

V. Conclusion

The development of polymer blends and alloys based on reactive or compatibilised *in situ* polymeric components is one of the fields of study of high-molecular compounds undergoing the most vigorous dynamic development. According to data from various sources, in 1993 the market in compatibilisers and ICA (without modifying agents) was estimated as 10 000–20 000 tonnes annually. It is expected⁴⁰ that by the year 2000 this amount will have increased to 80 000 annually.

The technology for the reactive blending of polymers not only opens the way to new possibilities for the employment of polymeric products already available but also permits the creation of blends the preparation of which has been economically unfavourable. The extensive possibilities of synthetic organic chemistry can be used, in principle, for the preparation by the reactive blending method of diverse high-molecular substances and polymer blends based on a relatively small number of available polymers.^{38, 39, 212}

The store of experimental data accumulated hitherto makes it possible to characterise the past stage in the study of reactive blending processes as empirical. A multiplicity of types of chemical reactions and specific interactions in polymer solutions and melts, acting on the thermodynamic compatibility of components of reactive systems and on the parameters of their phase structure, have been tested and the influence of the blend composition, concentration of functional groups, and the temperature-time blending regimes has been discovered. At the same time, in the vast majority of cases, the relations obtained must be assessed as qualitative. The fundamental conclusion that the thermodynamic affinity of the components improves on reactive blending is usually based on indirect data, such as the decrease in the particle size of the disperse phase and, more rarely, the mutual approach of the glass-transition temperatures of the coexisting polymeric phases. There has been virtually no monitoring of the degree of conversion of the reactive groups, which is of fundamental importance for the establishment of correlations between the component ratio, the concentration and nature of the reactive groups in the initial blends, and the blending regime (temperature, duration, rate, and intensity of mixing), on the one hand, and the parameters of the morphology and phase structure and the physico-mechanical characteristics of the material after the completion of the reactive blending process, on the other.

The construction of a theoretical model which would permit a quantitative prediction of a property of polymeric materials of this kind appears extremely problematical at the present time owing to the deficiency of systematic studies embracing simultaneously the chemical (the nature and kinetics of the reactions) and physico-chemical (diffusion, crystallisation, and phase segregation) aspects of the formation of the structure and the establishment of properties. The kinetic theory of macromolecular reactions in multicomponent heterogeneous solutions and melts of polymer blends in a flow (for example in the extruder or continuous operation mixer), taking into account three-dimensional diffusion and the variation of the phase state of the system during the reaction, is of particular interest. Variation of the ratio of the rates of the chemical reaction, responsible for the variation of the

composition of the reaction system, and of mutual diffusion, which controls the redistribution of the components in the bulk of the coexisting phases and in the interfacial region, opens a path to the regulation of the parameters of the phase structure (including interfacial adhesion) and ultimately of the set of technological and performance characteristics of the polymeric materials obtained by reactive blending.

Abstract. The current state and prospects for the use of natural lipopeptides and their synthetic analogues in the study of fine mechanisms of functioning of complex biological systems and in the solution of various problems of biochemistry and medicine are considered. The results of investigations related to the synthesis and biological activity of lipopeptides are summarised. The data on the application of lipopeptides as components of synthetic vaccines and antitumour drugs are discussed. The bibliography includes 71 references.

I. Introduction

Lipopeptides are compounds that contain a peptide chain to which one or several fatty acid residues are covalently linked. The molecules of the known lipopeptides comprise from four to sixteen amino acid residues.¹ Natural lipopeptides have been mostly detected in Gram-negative bacteria and Actinomycetes, though they are present also in some species of lower fungi. The majority of lipopeptides are characterised by strict structural specificity as regards the producing organism.

The search for the means directed against bacterial infections has stimulated studies on the structure of various bacteria. Thus, the first systematic studies on the cell wall of mycobacteria were begun in the 1970's.^{2–4} It was established^{4,5} that the fraction exhibiting the highest biological activity contains fragments of peptidoglycans, the minimum structural unit of which is *N*-acetylmuramyl-L-alanyl-D-isoglutamine (muramyl dipeptide, MDP). Later, the attention of numerous research groups was focussed on the study of fragments of natural peptidoglycans and their synthetic derivatives.^{6–9}

These studies have shown that bacterial lipoproteins and their fragments, lipopeptides, possess biological activity. The establishment of immunostimulating and antitumour activities of bacterial lipopeptides was followed by numerous attempts directed at the

synthesis of their analogues. However, the preparation of synthetic lipopeptides involved certain difficulties due to the presence in their structure of aliphatic and peptide fragments as well as the necessity to obtain optically pure compounds.

The biological activity of bacterial lipopeptides was studied in parallel with the analysis of approaches to the synthesis of their analogues. It was established that the synthetic analogues also possess immunostimulating properties and can exhibit pronounced antitumour activity. Owing to these properties, lipopeptides have received particular attention of investigators as potential components of synthetic vaccines and antitumour drugs.

II. The structure of a bacterial cell wall

The backbone of a bacterial wall is built predominantly of a homogeneous polymer, the peptidoglycan (murein). The peptidoglycan is a heteropolymer that consists of chains with alternating residues of *N*-acetylglucosamine and *N*-acetylmuramic acid [3-*O*-(1-carboxyethyl)-*N*-acetyl-D-glucosamine] linked together with β -1,4-glycosidic bonds.¹⁰

These unbranched chains of a heteropolysaccharide muramine form the murein skeleton. The residues of muramic acid are linked to amino acids *via* the carboxy groups of lactic acid with peptide bonds. The typical amino acids of murein are L-alanine, D-glutamic acid, *meso*-diaminopimelic acid (for Gram-negative bacteria) or L-lysine (for Gram-positive bacteria), and D-alanine. The heteropolysaccharide chains are cross-linked by peptide bridges to form a bag-shaped giant molecule, the murein bag, which functions as a backbone of the cell wall.¹⁰

In Gram-negative bacteria, the murein network has only one layer and constitutes less than 10% of the dry mass of the cell wall (in *E. coli*). Murein contains only *meso*-diaminopimelic acid but not lysine; interpeptide bridges are absent. In all Gram-negative bacteria, the structure of the murein bag is identical (Fig. 1).

Above the single-layer murein bag lies the outer layer of the cell wall, the outer membrane. In ultrathin bacterial slices, it resembles the plasmatic membrane. The outer membrane is built of proteins, phospholipids, and lipopolysaccharides (Fig. 1), and is tight against the murein layer and bonded to it by lipoproteins. Lipoproteins are covalently bound to murein layers, apparently through diaminopimelic acid; they have an outside orientation of their lipophilic termini and are thus fixed in the lipophilic bilayer

by hydrophobic interactions. This bilayer contains phospholipids and hydrophobic termini of lipopolysaccharides (lipid A); the hydrophilic termini of the latter (O-specific heteropolysaccharide side chains) are directed outside.¹⁰

By virtue of their capacity to stimulate the immune response, the components of bacterial membranes, such as murein, lipopolysaccharides, and lipopeptides have received particular attention of investigators.

III. The lipopeptide composition of the bacterial cell wall

In contrast to peptidoglycans the main structural element of which is muramyl dipeptide responsible for the biological activity, lipopeptides are heterogenous as regards their composition and biological functions. Three groups of lipopeptides can be specified.

The first group includes lipopeptides the peptide component of which contains murein-specific amino acids, first of all, D-glutamic acid, as the main structural unit. It is this amino acid composition and sequence that determine largely the immunomodulating activity of lipopeptides-1 (LP-1). As a rule, the lipid component of LP-1 includes fatty acids that increase the 'lifetime' of the compound in the organism and favour its penetration into lipophilic compartments.¹¹ A typical representative of this group is lauroyl-L-alanyl-γ-D-glutamyl-N(6)-glycyl-lantionin (1):

Lipopeptides of the second group include fragments of a lipoprotein isolated from *E. coli*. This lipoprotein is a component of the outer membrane of Gram-negative bacteria. It contains 58 amino acid residues and is produced as a secretory precursor with a signal peptide at the N-terminus. A detailed description of this lipoprotein has been given by Braun.¹² The *E. coli* lipoprotein exhibits the mitogenic activity in higher organisms and stimulates the production of B-lymphocyte clones in murine cultures. The amino acid composition of the lipoprotein 2 has been established.¹²

R¹, R² — saturated and unsaturated alkyl.

The main structural element of the second group lipopeptides is that derived from L-cysteine and three fatty acid residues (the A-fragment of compound 2). Owing to the presence of this structural unit, the lipopeptides belonging to the second group (LP-2) can be easily incorporated into biological membranes. The amino acid composition of LP-2, in contrast to that of LP-1, can vary widely. Lipopeptides of this group are characterised by a broader spectrum of biological activity.¹¹

Group 3 includes lipopeptides possessing antibiotic activity. Many representatives of this group have a cyclic or mixed (cyclic-linear) structure of their peptide chains; the lipid component is a higher fatty acid. Many compounds of this group are produced by bacteria; the functions of the majority of lipopeptides-3 (LP-3) are associated with ion transport across membranes. LP-3 are characterised by strict specificity with respect to the producing organism, which makes them different from, e.g., the lipophilic portion of the *E. coli* lipoprotein, which may be common for most bacteria.¹¹ LP-3 do not exhibit immunomodulating properties and are not considered in more detail in this article. The information about their properties can be found in a number of reviews.^{13–15}

IV. Effects of lipopeptides on the development of early stages of the immune response

The penetration of a foreign infection into the organism causes a rapid increase in the blood level of coloni-stimulating factors (CSF). These factors are synthesised by various kinds of cells, including endothelial cells, fibroblasts, macrophages, and lymphocytes.¹⁶ Their effects on pluripotent stem cells induce, after a series of differentiation stages, the formation of large amounts of various leucocytes. They include B-lymphocytes responsible for antibody synthesis and T-lymphocytes: T-helpers (T_H) manifesting helper activity, T-suppressors (T_S) manifesting suppressor activity, and cytotoxic T-lymphocytes manifesting cytotoxic activity (T_C).¹⁶ The population of killer cells includes also natural killer cells (NK) and large granular lymphocytes (LGL).¹¹

Among granulocytes, a leading role in inducing a rapid response of the organism to a foreign infection is played by neutrophils. The eosinophils (Eos) and basophils fulfil specific functions aimed at protection from parasitic organisms. Protection from bacterial and viral infections or tumour metastases is provided by monocytes (Mo) circulating in the blood and by macrophages (Mp) in tissues. The functions of these cells can be assessed using various test systems *in vivo*.

The interactions of different cells and cell systems are mediated by various factors and receptors. A prominent role in cell interactions is played by well-known factors, such as interleukins (IL-1, IL-2, IL-3, IL-4, and IL-5), colony-stimulating factors,

Immunostimulating effects produced by lipopeptides depend on the subsequent stages of the immune response. Lipopeptides stimulate phagocytic macrophages and monocytes in such a way that these cells begin to secrete factors stimulating the formation of colonies of differentiated blood cells as well as interleukin-1. The secretion of IL-1 is a signal for T-helper cells to begin proliferation. In turn, T-helper cells secrete IL-2, which stimulates the proliferation of all types of T-lymphocytes,¹⁷ as well as of IL-4 and IL-5, which in turn stimulate the proliferation and maturation of B-cells.¹¹ Interleukin-3 secreted by certain populations of T-helper cells produces a stimulating effect on the proliferation of various types of haemopoietic cells. In addition, endothelial cells (End) and fibroblasts (Fibr) begin to synthesise colony-stimulating factors. Thus the factors secreted by all these cells result in the activation of bone marrow cells that are leucocyte progenitors (Leuc. prog).¹¹ As a result, different populations of leucocytes become replenished with new cells. The increase in the number of eosinophils, cytotoxic T-lymphocytes, killer cells, and polymorphonuclear leucocytes or neutrophils (PMN) provides effective stimulation of the immune response,¹¹ since most leucocytes are destroyed while fulfilling their protective functions. Thus, the interaction of lipopeptides with monocytes and macrophages induces an immune response, which results in effective destruction

Moreover, the lauroyltripeptide **3c** was found to be as active as compound **3a**. Both compounds stimulate the production of interleukin-1 by macrophages and induce the release of CSF in the blood of mice when used in doses sufficient to protect experimental animals from bacterial infections.²³

a: *R*-isomer; b: *S*-isomer.

reaction of a glyoxylic acid ester with *N*-protected 2-aminopent-4-enoic acid; this reaction is catalysed by strong Lewis acids. The 2,2,2-trichloroethoxycarbonyl group, which is stable in the presence of strong Lewis acids, was used for *N*-protection. Of the synthetic schemes proposed, that presented here (Scheme 2) was the most effective one, since it permitted the suppression of undesirable side reactions and gave the highest yields of the final products.

The protected diethyl aminomalonate **22** was treated with allyl bromide in EtOH/EtONa to give compound **23**, which was further converted into the racemic derivative **24**. The reaction of compound **24** with butyl glyoxylate gave a mixture of diastereomers **25**. Compound **25** was then hydrolysed with α -chymotrypsin to give stereospecifically the (*S*)-acid **26**, which, in turn, was coupled with the methyl ester of D-alanine to give a mixture of diastereomers **27**. The esterification of the secondary hydroxyl of compound **27** with Boc-L-alanine in the presence of dicyclohexylcarbodiimide (DCC) and dimethylaminopyridine (DMAP) gave a mixture of diastereomers **28a,b**, which could be easily separated by crystallisation or chromatography. After removal of the *N*-trichloroethoxy-carbonyl protective group at pH 4.0 and 25 °C, the corresponding amines **29a,b** were coupled with γ -carboxy group of α -benzyl *N*-heptanoyl-D-glutamate following its activation with isobutyl chloroformate. After removal of Boc-protection with trifluoroacetic acid and treatment with hydrochloric acid in ether, the lipopeptides **30a,b** were converted into the hydrochlorides of the target products **21a,b**.

Compound **21a** induced high titers of colony-stimulating factors without exhibiting toxic effects.³⁰ Unfortunately, its activity strongly declined with time, since it was rapidly metabolised after oral administration.

The hydrochloride **21c** decomposed to give mainly the inactive ester **32** (Scheme 3) and a small amount of the hydroxy compound **31**, which still exhibited immunostimulating activity.

In order to prevent the rapid metabolic process inherent in compound **21**, its analogue with an additional methyl group in the α -position of the pimelic acid residue has been synthesised.³⁰

All the lipopeptides mentioned above (**3a**, **4**, **14**–**20**) are highly potent immunostimulators. The former representative of lipopeptides that contains the murein-specific amino acids, the lauroyltetrapeptide **3a**, stimulates *in vivo* the phagocytic activity of macrophages in mice and of human blood monocytes and enhances the activity of the reticulo-endothelial system in mice.^{20, 21} In mice, this compound induces cytotoxic lymphocytes against allogenic tumour cells and stimulates the activity of NK-cells in spleen and peripheral blood.

These activities indicate that the lauroyltetrapeptide can interact (directly or indirectly) with phagocytic cells, T-lymphocytes, and NK-cells. It was shown also that the lauroyl tetrapeptide stimulates *in vitro* the helper activity of human blood lymphocytes in the course of B-lymphocyte differentiation into plasmacytes.

In mice, the lauroyltetrapeptide manifests the adjuvant effect on DTH reactions and on the production of antibodies against

Scheme 3

various antigens, being more active than MDP in the former case and less active in the latter case.

The lauroyltetrapeptide **3a** induces the resistance of mice to various microbial infections (*Klebsiella pneumoniae*, *Listeria monocytogenes*) and inhibits the production of pulmonary metastases in mice inoculated intravenously with B16 melanoma cells or intradermally with Lewis lung carcinoma cells. It allows one to reduce the optimum dose of compounds exhibiting anticancer activity, e.g., cyclophosphamide. In all *in vivo* systems, the lauroyltetrapeptide **3a** exhibited activity at concentrations ranging from 0.1 to 3 mg kg⁻¹, whereas in mice intravenously immunised with this agent its LD₅₀ was 410 mg kg⁻¹.

The lipopeptide **20** and some other compounds increase the resistance of mice with normal and weakened immune systems against bacterial and fungal infections and enhance the immunotherapeutic activity in mice grafted with syngenic tumour cells.^{31,32} At present, these compounds are subject to clinical trials aimed at testing of their therapeutic utility, especially in those cases where the patient's immune system needs to be reinforced.

Owing to their immune activity, the lipopeptides can not only protect against bacterial infections but also interfere with other processes (e.g., metabolism of xenobiotics in liver) and thus prevent toxic effects of certain compounds on the organism.

The immunomodulating lauroylpeptides can protect mice against the toxic effects of paracetamol.³³ Equal doses of compounds **3a,c** manifest the immune activity, prevent the toxic effects of paracetamol (80% survival in mice), and cause a decrease in ethane exhalation, which is an index of lipid oxidation *in vivo*. Also, these lipopeptides reduced the microsomal cytochrome P-450 content in liver and suppressed CCl₄-induced lipid oxidation. The mechanism of their protective effects can be explained by the presence of factors secreted under the action of lipopeptides **3a,c**, such as interleukin-1 inhibiting the effect of cytochrome P-450³⁴ or other factors secreted by macrophages³⁵ or Kupffer cells.³⁶

VI. Lipopeptides-2

Studies on the biological activity of bacterial membrane components revealed that natural lipoproteins, particularly the *E. coli* lipoprotein and its fragments (natural lipopeptides), like the bacterial polysaccharide and muramyl dipeptide, exhibit the mitogenic activity and stimulate cells provoking the augmented release of interleukin-1, the production of prostaglandins E₂, F_{2α}, and interferon.^{37–39} In addition, the membrane lipoproteins are potent activators of polyclonal B-lymphocytes.

Synthetic lipopeptides, the analogues of natural lipopeptides, also exhibit immunostimulating activity. N-Terminal lipopeptides of the *E. coli* outer membrane lipoprotein, such as tripalmitoyl-S-glyceryl-L-Cys-Ser (Pam₃Cys-Ser) and its analogues with longer amino acid sequences⁴⁰ that stimulate the production of B-lymphocyte clones,⁴¹ were synthesised (Schemes 4 and 5).

The first step in the synthesis of *E. coli* lipoprotein analogues according to Scheme 4 was the preparation of a series of *N*-acylcysteines (**34**) from the original L-cysteine (**33**). Thus it was converted into *N*-behenoyl-L-cysteine (**34**) with 1,2-*O*-isopropylidene-3-*O*-tosyl-*sn*-glycerol and acid hydrolysis yielded *N*-behenoyl-S-[(2*R*)-2,3-dihydroxypropyl]-L-cysteine (**35**). If (*R,S*)-glycidol was used instead, a mixture of *N*-behenoyl-S-[(2*R,S*)-2,3-dihydroxypropyl]-L-cysteines was obtained. The esterification of the carboxyl group of cysteine into the benzhydryl ester and acylation of hydroxy groups were followed by deprotection using acidic hydrolysis (pH 5) yielding compound **36**.

The stage (e) requires special comment. The conventional peptide synthesis with dicyclohexylcarbodiimide and *N*-hydroxybenzotriazole resulted in a practically complete racemisation. The use of *N*-hydroxynorbornanedicarboximide instead of *N*-hydroxybenzotriazole gave compound **37**, which contained less than 3% of the (*S,R*)-diastereoisomer.¹¹

Scheme 4

34–37: R¹ = CH₃(CH₂)₂₀;

36, 37: R² = CH₃(CH₂)₂₃.

(a) 1,2-*O*-isopropylidene-3-*O*-tosyl-*sn*-glycerol, K₂CO₃, EtOH;

(b) H₃O⁺; (c) Ph₂CN₂; (d) R²COCl, Py; (e) DCC, *N*-hydroxynorbornanedicarboximide, C-protected peptide.

Scheme 5

(a) MeCOOBu^t, HClO₄; (b) RCOCl, *N*-ethylmorpholine; (c) Zn, citric acid; (d) 1-*O*-tosylglycerol, DBU, DMF; (e) RCOCl, Py, 4-dimethylaminopyridine; (f) CF₃COOH; (g) DCC, *N*-hydroxynorbornanedicarboximide, peptide.

At the first step of the synthesis depicted in Scheme 5, the ester **39** was obtained from the original compound, L-cysteine (**38**). Acylation of the amino group in **39** with palmitoyl chloride and subsequent reduction of the disulfide bond with zinc in acidic medium led to the *tert*-butyl ester of *N*-palmitoylcysteine (**40**). This compound was alkylated at the thiol group with 1-*O*-tosyl-

sn-glycerol, which reacted faster than 1,2-*O*-isopropylidene-3-*O*-tosyl-*sn*-glycerol, to give compound **41**, which was acylated with palmitoyl chloride to give compound **42**. Removal of the *tert*-butyl group with trifluoroacetic acid and attachment of the peptide fragment yielded the final product **43**.

In studies^{40, 42–46} on lipopeptides with various lengths of peptide chains, number of fatty acid residues and protective groups, the objects of investigation were lipopeptide monolayers. In an effort to gain information about the interaction of these compounds with a typical lipid membrane, the monolayers of lipopeptides with three fatty acid residues were mixed with those of dipalmitoylphosphatidylcholine and cholesterol. (These studies used synthetic lipopeptides that contained only the palmitic acid residues, whereas their natural counterparts contained a mixture of higher fatty acids.⁴⁷)

It was shown that the synthetic lipopentapeptide, *N*-palmitoyl-*S*-[(2*R,S*)-2,3-dipalmitoyloxypropyl]-*L*-cysteinyl-*D*-seryl-*D*-seryl-*D*-asparaginyl-*D*-alanine (**44**) exhibited the same mitogenic properties as did the natural lipoprotein.^{45, 46, 48–50}

Even after the shortening of the peptide chain from the lipopentapeptide Pam₃Cys-Ser-Ser-Asn-Ala to the lipodipeptide Pam₃Cys-Ser, the immunostimulating properties were still retained. However, tripalmitoyl-*S*-glyceryl-*L*-cysteine as such exhibited only a weak stimulating activity.⁴¹ The lipophilic, fully protected lipopeptide Pam₃Cys-Ser(Bu^t)OBu^t manifested a weak mitogenic activity. It was therefore concluded that the crucial role in the specificity of activation is played by polar head groups, in particular by hydroxy and carboxy groups of serine. Owing to these features, the synthetic mitogens described above are highly suitable objects for the study of early events of the immune response, for the isolation of specific binding proteins, and for the analysis of structure-activity relationships.⁵¹

However, these synthetic analogues of the *E. coli* N-terminal lipopeptide have one serious disadvantage, namely, they are poorly soluble in water, which prevents their application as adjuvants. To overcome this problem, the lipopeptide tripalmitoyl-*S*-glyceryl-cysteinyl-seryl-(lysyl)₃-lysine (Pam₃Cys-Ser-Lys₄), was synthesised,⁵² which is both water-soluble and, as has been demonstrated in different tests, biologically active. Compounds **45a–d**, the derivatives of 3-*O*-stearylcorinomycinolic acid, were also synthesised.⁵³

45a: (2*S*,3*R*)-isomer; **45b:** (2*S*,3*S*)-isomer;

45c: (2*R*,3*S*)-isomer; **45d:** (2*R*,3*R*)-isomer.

The main problem in the synthesis of these compounds was the elaboration of a scheme that would give all the four stereoisomers. Jacques and Grob⁵³ proposed the following paths for their synthesis (Scheme 6).

S-N-Stearyl-2-oxazolidone (**46**) was obtained by sequential treatment of *S*-4-benzyl-2-oxazolidone with butyllithium and

Scheme 6

R' = CH₃(CH₂)₁₅;

stearyl chloride. Treatment of compound **46** with 9-borabicyclo[3.3.1]nonyl trifluoromethanesulfonate (9-BBN-OTf) and condensation of the reaction product with octadecanal gave compound **47**. It was further converted into the diol **48** by

treatment with LiBH_4 in moist ether. The introduction of a trityl protection at the primary hydroxy group and acylation of the secondary hydroxy group in the diol **48** with stearoyl chloride gave compound **50a**. Removal of trityl protection to give the ester **51a** was complicated by intramolecular acyl migration. However, subsequent oxidation of the isomer mixture gave the acid **52a**.

The acid **52b** was obtained by inversion of the stereochemistry in compound **49a** at C(3). This compound was converted into the ester **53** by interaction with *p*-nitro-(or *o*-nitro-)benzoic acid in the presence of PPh_3 and diethyl azodicarboxylate (DEAD). Its de-esterification required drastic conditions [stage (I) in Scheme 6] and resulted in compound **49b**, which was then converted into the acid **52b** by analogy with compound **49a** $\rightarrow$ **52a**. The same reaction sequence, which began with (*R*)-4-benzyl-2-oxazolidone, gave the enantiomers of compounds **46**, **47**, **48**, and **53**, respectively, and the final products **52c** (2*R*,3*S*) and **52d** (2*R*,3*R*). Further, the peptide fragment was attached to acids **52a–d** with the use of the active esters method to give the lipopeptides **45a–d** [stages (*m–r*) in the Scheme 6].

However, these lipopeptides have four lysine residues, which cause certain difficulties due to the formation of high positive charges.

In the study by Kleine *et al.*,⁵⁴ two lipopeptide analogues of the *E. coli* lipoprotein, Pam_3CysOH and $\text{Pam}_3\text{Cys-SerOH}$, were conjugated with polyoxyethylene 3000 (POE) to increase the solubility of lipoproteins. The conjugates obtained possessed high solubility in water and were devoid of the formation of high positive charges. The increase in the solubility did not bring about any significant changes in the biological properties of the lipopeptide fragment. It was concluded that the polyoxyethylene component, which is inactive itself, enhances the activity of lipopeptides by increasing the percentage of lipopeptide molecules accessible to the cells.⁵⁴

VII. Possible applications of lipopeptides-2

The lipopeptide fragments of the *E. coli* membrane lipoprotein are highly effective stimulators of antibody production and activators of B-cells. Synthetic lipopeptides enhance primary and secondary immune responses to corpuscular antigens *in vitro* and *in vivo*.⁵⁵ The addition of synthetic lipopeptide fragments to acetone-killed cells of *Salmonella typhimurium* makes it possible to significantly reduce the vaccine dose. It is believed that the first step in the mechanism of action of lipopeptides is their interaction with the cell plasma membrane through incorporation of lipophilic groups into the lipid bilayer and their binding to membrane proteins. Hence, the mitogenic activation of cells can be achieved through the use of conditions of a serumless culture and the use of a mitogen that is optimally dissolved in detergent-containing solutions. Under these conditions, the mitogenic activity of compound **44** *in vitro* can be observed at as low concentrations as *e.g.* 10 ng ml^{-1} . The optimum stimulating activity was observed at concentrations around 30 mg ml^{-1} .

The adjuvant properties of the tripalmitoylpentapeptide with respect to the immune response was studied *in vitro*.⁵⁶ The immune response to sheep erythrocytes (both native and nitrophenol-treated) was strongly enhanced after the addition of various amounts of the tripalmitoylpentapeptide **44** to cell cultures. This effect was dose-dependent, the optimum adjuvant effect being manifested at the concentration range of $10–30 \text{ mg ml}^{-1}$.

A sharply pronounced adjuvant effect was observed in only those cases when the tripalmitoylpentapeptide and the antigen acted simultaneously; the addition of the lipopeptide either 24 h prior to, or 24 h after, the addition of the antigen had no effect. Hence, the adjuvant effect of the tripalmitoylpentapeptide can be associated with the formation of an adjuvant-antigen complex.

The use of lipopeptides as adjuvants is not confined to cell antigens *in vitro*. It was shown that the *in vivo* immune response to native and nitrophenol-treated sheep erythrocytes was also enhanced significantly in the presence of the lipopeptide; the *in*

vivo immune response to proteins, like ovalbumin, can also be increased after the addition of the lipopeptide.

Of special interest were the studies on the mitogenic and adjuvant activities of water-soluble lipopeptides, since in the case of high immunostimulating activity these compounds might be used commercially. $\text{Pam}_3\text{Cys-Ser-POE}$ and $\text{Pam}_3\text{Cys-POE}$ were assayed for mitogenic activity towards human B-lymphocytes *in vitro* and for adjuvant activity in mice *in vivo*. It was established that polyoxyethylene-lipopeptide conjugates exhibit the same mitogenic activity as does the water-soluble cationic lipopeptide $\text{Pam}_3\text{Cys-Ser-Lys}_4$. They exhibited biological activity even at concentrations around 30 mg ml^{-1} .

In order to investigate possible areas of the application of lipopeptide-polyoxyethylene conjugates as adjuvants for the construction of vaccines, the adjuvant activities of these compounds were compared to those of three commercially available adjuvants: Freund's adjuvant, Hunter's Titermax, a nonionic block copolymer,⁵⁷ and vegetan extracted from potatoes. Ovalbumin and synthetic melittin (a 26-membered bee venom polypeptide) were used as the antigens. The polyoxyethylene-lipopeptide conjugates were less active than $\text{Pam}_3\text{Cys-Ser-Lys}_4$ or Freund's adjuvant, while their activities were comparable with that of the Hunter's block copolymer or vegetan. In mice immunised with the antigen (ovalbumin or melittin) and $\text{Pam}_3\text{Cys-Ser-POE}$ or $\text{Pam}_3\text{Cys-POE}$, the antibody titers against both melittin and ovalbumin were similar. However, the maximum immune response (compared to that raised with the Freund's adjuvant) required repeated immunisations. In most cases, three injections were sufficient for this purpose.

The design of synthetic vaccines requires that the demand of safety of polyclonal activators used as adjuvants for routine immunisations be met. The lipopeptides tested did not exhibit any toxic or other undesirable effects in animal studies, they evoked only a 7-days-lasting inflammation at injection sites with a complete recovery of the injured area after several weeks. By contrast, animals immunised with the Freund's adjuvant developed long-lasting granulomas at injection sites.

It was thus concluded⁵⁴ that the new polyoxyethylene compounds are capable of polyclonal activation of human B-lymphocytes in culture systems and exhibit a sufficiently high adjuvant activity. They can be easily synthesised and yield stable solutions. In addition, they are non-toxic. It was therefore decided to continue the use of $\text{Pam}_3\text{Cys-Ser-POE}$ and $\text{Pam}_3\text{Cys-POE}$ as adjuvants for immunisation of animals and, after conducting appropriate tests, of human beings as well.

The synthetic mitogen tripalmitoylpentapeptide **44** and some of its analogues can non-specifically enhance the resistance of a host organism to bacterial infections. This property is particularly often exploited in studies aimed at a search for new effective antigens in the design of synthetic vaccines when a low-immunogenic peptide or a fragment of a natural protein are to be used as antigens. Since the procedure of covalent binding of a peptide and the lipopeptide adjuvant increases immunogenicity and can be easily performed, it can be used in studies of epitope specificity of various natural proteins. An example is the study by Beck-Sickinger *et al.*,⁵⁸ which is dedicated to the discovery of effective antigens against *Haemophilus influenzae* (Hi).

The *Haemophilus influenzae* type b (Hib) is the main causative of endemic bacterial meningitis in newborns and children; the non-typeable Hi is also a potent pathogen. The most severe bacterial infections in humans (meningites, arthrites, *etc.*) are caused by Hib. The antibodies against the Hib capsular polysaccharide protect humans from diseases caused by Hi. However, this way of protection is ineffective in children under one year of age who are at the highest risk of being infected with these diseases. These facts have stimulated interest in the search for other antigens.

The P6 protein (16 600 Da), which is present in the outer membrane of two typeable and one non-typeable Hi strains, is the most important antigen in raising the immunity against Hi.

Antibodies against P6 possess protective and bactericidal activities. The progenitor of P6 is a bacterial lipoprotein containing 134 amino acid residues and having at its N-terminus fatty acids linked by an amide and ester bonds to *S*-glycerylcysteine. Since this structure resembles the *E. coli* lipoprotein, lipopeptides were synthesised⁵⁸ in which different fragments of the amino acid sequence of P6 were covalently linked to *N*-palmitoyl-*S*-[(2*R,S*)-2,3-dipalmitoyloxypropyl]-L-cysteinyl-D-serine. This study has made it possible to establish the epitope specificity of antibodies. Lipopeptides containing the sequence Gln-Ile-Leu-Asp-Ala-His-Ala-Ala (P6 47-54) and the murine B-cell epitopes Gly-Glu-Tyr-Val (P6 43-46) were able to induce T-helper activity in BALB/c mice. The antibodies raised in the immunisation could adequately neutralise the Hi bacteria. Thus the use of a mixture of lipopeptides containing the above segments of the P6 protein as synthetic vaccines holds much promise for *in vivo* studies of model infection systems.

Another example of the use of adjuvants covalently bound to antigens can be found in the study carried out by Deres *et al.*⁵⁹ The covalent binding of lipopeptide adjuvants to antigens is especially advantageous for compounds that exhibit low immunogenic activity by themselves. Lipopeptides used as adjuvants enhance the immunogenic activity of antigens in synthetic vaccines.

Cytotoxic T-lymphocytes make an appreciable contribution to immunity against intracellular pathogens. This refers also to viral infections, where cytotoxic T-lymphocytes recognise viral peptides presented by molecules of the major histocompatibility complex (MHC) class I on the surface of infected cells.⁶⁰ The induction of virus-specific cytotoxic T-lymphocytes usually requires *in vivo* priming with infectious viruses. Inactivated viruses, like viral proteins or peptides, are mostly ineffective as inducers of the cell-type immune response *in vivo*, although these antigens can initiate antibody production against viral antigens.

The absence of the anticipated effect following the use of peptides as antigens can be assigned to the 'non-physiological' type of the antigen presentation (the lack of conjugation with MHC glycoproteins), since T_C can usually recognise the fragments that are derived from proteins endogenously produced by target cells but are incapable of recognising the free peptides that are not bound to the glycoproteins of the major histocompatibility complex.⁶¹ The second reason is the lack of secondary signals, such as cytokins, released by antigen-presenting cells.

Unlike native peptides, synthetic compounds attached to a lipophilic anchor (lipopeptides) can activate virus-specific cytotoxic T-lymphocytes *in vivo*.⁵⁹ The structure of one such lipopeptide, the epitope of the influenza virus nucleoprotein, which is the most adequately recognised by H-2d-restrictase [peptide NP 147-158(*R*-)], conjugated with Pam₃Cys-Ser-Ser, is given below (see formula 56).

The precise mechanism of the *in vivo* activation of cytotoxic T-lymphocytes by lipopeptides is still unknown. A possible reason for this effect is that the anchor molecule of Pam₃Cys possesses the ability to activate accessory cells that secrete factors needed for the differentiation of cytotoxic T-lymphocytes.⁵⁹ If this is true, a mixture of Pam₃Cys and a native peptide can also be used for the activation of cytotoxic T-lymphocytes.

If the effect of lipopeptides is not determined by the non-specific action of accessory cells and/or T-helper cells, other possibilities may be offered. Probably, the lipid anchor prolongs the lifetime of the antigen molecule *in vivo* relative to native peptide molecules. At the same time, it is not excluded that the lipid anchor attaches to the cell membrane and thus favours the binding of the antigen with glycoproteins of the major histocom-

patibility complex class I, thus offering a more 'physiological' path of antigen presentation.

The major problem, which restricts the use of peptide vaccines in natural populations, is that T-cells in individuals with different MHC always recognise different peptides from viral proteins together with their own corresponding MHC. Thus, universal synthetic vaccines stimulating the growth of populations providing the cell-type immune response to a certain viral antigen should contain all of the relevant epitopes recognised by T-cells. The fulfilment of this condition is not a very difficult task because of the relatively good availability of synthetic Pam₃Cys-Ser-Ser-peptide conjugates. Pam₃Cys-Ser-Ser covalently linked to peptides is particularly suitable for the design of vaccines, since the production of neutralising antibodies, another important element of the antiviral immunity, can also be achieved through the conjugation of Pam₃Cys-Ser-Ser to the corresponding epitopes.

VIII. The use of lipopeptides-2 in the fight against the human immunodeficiency virus

The problem of infection of humans with the immunodeficiency virus presently becomes a formidable challenge; therefore, many recent studies deal with the development of vaccines against the immunodeficiency virus, which can induce antibody synthesis and simultaneously elicit associated cytotoxic responses.

Vaccinations against the human immunodeficiency virus (HIV) with the use of inactivated viruses raises the problem of their therapeutic safety for human beings. The use of viral genes in the composition of recombinant vectors also requires further investigation. Peptide vaccination is a very promising approach; however, free peptides are often little immunogenic. The interest in lipopeptide vaccines is not incidental for these reasons. Their use is devoid of side effects, and this vaccination can be applied to humans. Moreover, the immune response induced will be free from that against the vector molecule, as is the case with recombinant vaccines. Therefore, the combination of lipopeptides inducing the cell-type response with lipopeptides stimulating antibody production will provide effective protection against the immunodeficiency virus.

The study carried out by Loleit *et al.*⁶² is an example of the use of lipopeptides for immunisation against HIV. These authors found that the C-terminal segment of the reverse transcriptase (RT) of HIV 1 contains a highly immunogenic determinant that causes the proliferation of T-cells in different mouse strains and partly overlaps with the B-cell epitope. The lipopeptide *N*-palmitoyl-*S*-[(2*R,S*)-2,3-dipalmitoyloxypropyl]-L-cysteinyl-D-seryl-D-serine was used as the adjuvant, for it does not exhibit toxic effects characteristic of Freund's adjuvant and increases the immunogenicity of free peptides.⁵²

In order to assess the ability of the lipotripeptide Pam₃Cys-Ser-Ser to enhance peptide-specific immune responses *in vivo*, Loleit *et al.*⁶² have immunised mice of different strains (BALB/c, C3H/HeJ, C57BL/6) with the 22-meric conjugates Pam₃Cys-Ser-Ser-[RT-(522-543)] and Pam₃Cys-Ser-Ser-[RT-(528-549)] of the reverse transcriptase of HIV-1, which contain the T-helper epitope [RT-(528-543)] of the reverse transcriptase. The results of this study⁶² indicate that Pam₃Cys-Ser-Ser is an effective adjuvant capable of inducing T-helper and B-cellular responses to peptide sequences that represent the fragments of the C-terminal region of the reverse transcriptase of HIV-1.

The procedures used for the attachment of lipids or lipopeptides to HIV-derived peptides were also described by other groups of investigators.^{63,64} Thus, Martinon *et al.*⁶³ used the C₁₄-fatty acid peptide (HDA) as well as C-terminal fragments of peptides from the V3 region of a nucleoprotein epitope corresponding to the outer envelope proteins of HIV-1 (Env). Defoort *et al.*⁶⁴ synthesised the lipopeptide Pam₃Cys and modified it through a lysine spacer with four molecules of the HIV-1 Env-peptide to obtain the so-called multiplet antigenic system (MAPS). Both

products could induce antibody production and a cytotoxic response to HIV.

According to the most recent data, some peptides can be recognised in both mice and humans.⁶⁵ In order to assay the epitope of the reverse transcriptase RT-(528-549) for immunogenicity towards human T-lymphocytes, Loleit *et al.*⁶² have studied T-cell responses in HIV-infected individuals. The first analyses of cytotoxic responses to the C-terminal region of reverse transcriptase of HIV-1 revealed that the lipopeptide Pam₃Cys-Ser-Ser-[RT-(528-549)] could be recognised by cytotoxic T-lymphocytes of patients at different stages of the disease.

Thus, the ability of lipopeptide conjugates to induce efficient humoral and T-cell responses and the lack of toxic effects makes them probable candidates for the components of synthetic vaccines designed for use in humans.

IX. The antitumour activity of lipopeptides-2

Another important aspect of the biological action of *E. coli* cell wall lipopeptides is their antitumour activity.^{66, 67}

The modification of their peptide residues with taurine yielded compounds that were highly active *in vivo* and could destroy pulmonary metastases. One of these compounds is the sodium salt of *N*-hexadecanoyl-*S*-[(2*R*)-2,3-didodecanoyloxypropyl]-*L*-cysteiny-*L*-alanyl-*D*-isoglutamyl-glycyl-*L*-taurine **57** (CGP 31362).

Its synthesis is similar to that of compound **44** and its analogues (Schemes 4 and 5). The peptide fragment of compound **57** was modified with taurine, which imparted to it a greater polarity.^{68, 69}

Compound **57** can be incorporated into membranes of phospholipid liposomes.⁶⁹ Liposomes are unique carriers for targeted delivery of biologically active substances to phagocytosis-active cells *in vivo*. This delivery results in the activation of phagocytes and, correspondingly, in the destruction of established lung, lymphoid, and liver metastases. Like other circulating particles, liposomes are rapidly ingested by free and fixed phagocytic cells. The advantage of such physiological 'death' of liposomes is that they deliver immunomodulators to cells of the reticulo-endothelial system.

Compound **57** incorporated into liposomes can activate human blood monocytes as well as mouse peritoneal and bone marrow macrophages.⁷⁰ Periodical injections of this compound caused *in situ* activation of macrophages.⁷¹ Noteworthy, macrophages that phagocytised liposomes with incorporated compound **57**, retained their antitumour activity over a period of several days, thus favouring the destruction of established cancer metastases.

Compound **57** is a more potent anticancer agent in comparison with muramyl-peptide derivatives, since it stimulates the antitumour activity at lower doses and activates monocytes in the absence of γ -interferon. Monocytes stimulated by compound **57** exhibit both the activity related to tumour necrosis and interleukin-1 activity, whereas monocytes stimulated by muramyl-peptides manifest only tumour necrosis activity.

On the basis of numerous experiments, Utsugi *et al.*⁷¹ concluded that compound **57** can efficiently stimulate macrophages responsible for the lysis of tumour cells; this compound is a better activator of monocytes and macrophages than muramyl-peptides.

X. Conclusion

The data considered in this review show the increasing interest in the components of bacterial membranes, specifically, in lipopeptides.

The synthesis of analogues of bacterial lipopeptides is related to the fine organic synthesis of complex conjugates. This can be exemplified by the above-described methods of synthesis of compound **44** and its analogues containing a peptide fragment and three fatty acid residues. The synthesis of compounds of a mixed composition makes a contribution to the development of organic synthetic chemistry.

Since lipopeptides are optically active compounds, their synthesis brings about a number of specific problems associated with their preparation. So far the synthesis of the majority of lipopeptides is marked by complexity and multiphasity. Unfortunately, these difficulties are an obstacle on the way to the elaboration of a large set of modified analogues of natural compounds for research purposes.

A study of the biological activity of lipopeptides that are the components of bacterial membranes permits to expand the view of both the structural organisation of membranes and the activity of compounds of a mixed composition in the fight against various infections.

The pharmacological effects of natural lipopeptides and their synthetic analogues have been demonstrated in animal models *in vivo*. In addition to immunomodulating properties, lipopeptides exhibit antitumour activity and have been extensively used in recent years in the fight against the human immunodeficiency virus.

As lipopeptides do not possess toxic properties, it may be assumed that compounds of this class will find wide use in the design of contemporary synthetic vaccines as well as in the treatment of malignant tumours and autoimmune diseases.

Abstract. The available data on the problem of hypothetical crystalline carbon nitride are considered. These involve the crystal structure, the nature of chemical bonding, and physical properties of carbon nitride of which the most interesting is its predicted high hardness comparable with that of diamond. The experiments aimed at synthesising carbon nitride are described, and properties of the materials obtained are characterised. The results of thermodynamic calculations pertinent to carbon nitride and processes of its synthesis are discussed. The bibliography includes 144 references.

I. Introduction

An extensive class of materials have been synthesised on the basis of metal and non-metal nitrides, and these materials have wide application in various areas of science and technology.^{1,2} The existence of carbon nitride is highly probable, since carbon and nitrogen can form strong chemical bonds with each other, in particular, single bonds. Various chemical compounds (including polymers) composed solely of carbon and nitrogen are known.^{3,4} Elements, such as boron, aluminium, silicon, and phosphorus readily form nitrides, which are used to produce valuable ceramics. However, for carbon surrounded by the above-mentioned elements in the Periodic Table no corresponding nitride has been obtained so far. It is surprising that until very recently the problem of carbon nitride synthesis had not even been raised. An exception is the work of Franklin⁵ who heated mercury thiocyanate to obtain a voluminous solid residue close in composition to C₃N₄, though containing from 0.6% to 2.4% hydrogen. The author called this product carbon nitride but did not study its structure and properties.

II. Theoretical analysis. Chemical bonding, crystal structure, and predicted properties

The fundamental studies of Cohen and Liu^{6–8} were initially aimed at the development of methods allowing prediction of some properties of solids on the basis of readily accessible data. One of such important properties is the bulk modulus (B) determined by the relation

$$B = -V \frac{dp}{dV} = V \frac{d^2u}{dV^2}, \quad (1)$$

where V , p , and u are volume, pressure, and energy, respectively. Theoretical analysis of the effect of covalence on the bulk modulus of semiconductors and insulators of the type of diamond and zinc blende with the tetrahedral structure showed that for the compounds composed of elements situated in the middle of the Periodic Table the magnitude of B depends only on the distance d between the nearest-neighbour atoms and is determined by a very simple relation⁶

$$B = 1761d^{-3.5}, \quad (2)$$

where B is expressed in GPa and d , in Å. For compounds composed of Group III and IV elements, this formula provides fairly acceptable values: as a rule, deviations from the experimental data are close to 2% (*e.g.*, 2.6% for gallium arsenide). At the same time, for materials including Group II and VI elements the deviation is markedly larger: for example, it reaches 14.4% for zinc sulfide. The deviations are due to the fact that formula (2) has been proposed⁶ only for compounds with non-polar bonds. If the chemical bonds in a crystal are polar, the bulk modulus is determined not only by the distance between the nearest neighbours but also by the above-mentioned polarity, which is taken into account by introducing an empirical term into the formula (2)

$$B = (1971 - 220\lambda)d^{-3.5}. \quad (3)$$

Here, B is expressed in Mbar, and the parameter λ accounts solely the extent of bond ionicity: $\lambda = 0$ for the elements of Group IV (*e.g.*, for carbon in the diamond form); $\lambda = 1$ for materials composed of Group III and V elements (boron nitride, gallium arsenide, indium phosphide, *etc.*); finally, $\lambda = 2$ for compounds

including Group II and VI elements (cadmium and zinc sulfides, selenides, tellurides). Comparison of experimental data for 25 materials (chemical elements and binary compounds of the AB type) has shown⁷ that formula (3) allows the prediction of the magnitude of bulk moduli with a fairly acceptable accuracy.

The importance of the formula (3) is determined not only in that it allows the calculation of bulk moduli, but also in that it indicates the direction of search for new superhard materials: obviously, one should seek for minimum interatomic distances and nonpolar chemical bonds. Already in 1985 it was mentioned that the above requirements may be met by a hypothetical carbon–nitrogen compound with the tetrahedral structure;⁶ however, only in reports,^{8,9} which stimulated all subsequent studies, the problem of crystalline carbon nitride synthesis was clearly formulated with the prediction of its unusual chemical properties.

The crystal of β -silicon nitride has served as the prototype. In this compound, formal substitution of carbon atoms for silicon leads to a hypothetical structure called by analogy β -carbon nitride. In this crystal, the unit cell is hexagonal and contains 14 atoms (*i.e.*, it is a dimer of carbon nitride C_3N_4 with the stoichiometric formula C_6N_8). The carbon atoms are in the centres of slightly distorted tetrahedra, whereas the nitrogen atoms have a nearly planar-trigonal configuration. This results in a complex array of CN_4 tetrahedra linked through their apexes. In this lattice, the carbon and nitrogen atoms are in sp^3 - and sp^2 -hybridisation, respectively. Alternatively, this structure, belonging to the hexagonal space group C_{6h}^2 may be regarded as a combination of distorted layers. It may also be considered as a network of 6-, 8-, and 12-membered rings of alternating carbon and nitrogen atoms¹⁰ and as the structure of the phenacite (Be_2SiO_4) type of 3-, 4-, and 6-membered rings formed by the CN_4 tetrahedra.¹¹

Non-empirical quantum-mechanical calculations of β - C_3N_4 carried out by the pseudopotential method within the framework of localised orbitals formalism^{8,9} have shown that the length of the C–N bond is 1.47 Å. This magnitude correlates well with the sum of the tetrahedral covalent radii of carbon and nitrogen. The energy of cohesion was found to be 81 eV per unit cell or 5.8 eV per atom (see Ref. 8) (the value of 81.5 eV for the energy of cohesion per unit cell was given in Ref. 9). Representation of the total energy as a function of volume in the Murnaghan and Birch equation of state has permitted computation of the bulk modulus, which proved to be 4.27 ± 0.15 Mbar. The determination of the bulk modulus requires that formula (3) be refined taking into account that the carbon and nitrogen have different coordination numbers equal to 4 and 3, respectively. The resulting formula¹² is

$$B = \frac{N_c}{4} \frac{1972 - 220\lambda}{d^{3.5}}, \quad (4)$$

where, in contrast to the formula (3), B is expressed in GPa rather than in Mbar and N_c is the mean coordination number. In the case of C_3N_4 , $N_c = 3.43$, $d = 1.47$, $\lambda < 1$ and, depending on the λ value and according to work,¹² $B = 410$ – 440 GPa, which correlates well with the above value.

Thus, the predicted bulk modulus of β -carbon nitride is comparable with that of diamond (443 GPa). It will be shown below that somewhat different calculations give different values of the bulk modulus, and in some cases it proves to be higher than that of diamond. However, even if it is not so, most of the calculations indicate that β - C_3N_4 shifts boron nitride, the second hardest compound after diamond ($B = 369$ GPa⁷), to the third position. To get a more complete picture, note that for solidified noble gases $B = 1$ – 2 GPa, for ionic solids $B = 10$ – 60 GPa, for non-transition metals $B = 2$ – 100 GPa, for transition metals $B = 100$ – 300 GPa, and finally for covalent solids $B = 100$ – 443 GPa.¹² It is the high predicted hardness of carbon nitride (close to a record value) that stimulated further studies. According to the formulas (3) and (4), such a high hardness is due to small interatomic distances and low polarity of the C–N bond.¹³ The predicted very high energy of cohesion of β -carbon

nitride gives hope that its existence may well be realised, at least as a metastable phase.

The above-mentioned quantum mechanics calculations of the β - C_3N_4 crystal (see Refs 8 and 9) yielded maps of the electron density distribution. In particular, it turned out that the valence electrons are localised between the carbon and nitrogen atoms in such a way as to form two electron density maxima: the larger maximum near the nitrogen atom and the smaller one near the carbon atom. The values of electron density normalised to the number of valence electrons in a unit cell are 4.6 and 2.7, respectively. It also followed from the calculations that, as regards its polarity, the C–N bond in β - C_3N_4 is intermediate between the bond in the purely covalent diamond and that in the partially ionic boron nitride. It is of note, that the local electron density maximum near the carbon atom is nearly the same as in diamond. Consequently, no substantial charge transfer along the C–N bond takes place in carbon nitride, and this in turn means that the charge density asymmetry along the C–N bond is due to the non-bonding electrons of nitrogen.

Yet another interesting property is the high mean volumetric sound velocity in β - C_3N_4 making up 1.1×10^6 cm s^{−1}.⁹ This is 20% higher than in β - Si_3N_4 and is also indicative of high thermal conductivity of β - C_3N_4 determined by its high Debye temperature.¹²

It has been noted (see, *e.g.* Ref. 14) that the nitrogen atoms in β - C_3N_4 are not equivalent. There are two sorts of these atoms — N_1 and N_2 . Atoms N_1 (they account for a quarter of all nitrogen atoms) are in the centres of equilateral triangles with their apexes occupied by the carbon atoms. The nitrogen atoms are surrounded by three carbon atoms whose location is little different from the planar one. The distances between N_1 – N_1 and N_2 – N_2 are 2.46 and 2.69 Å, respectively. These distances are not large; therefore, repulsive interactions are possible for the pairs of unshared electrons of the nearest nitrogen atoms. The above interactions were determined by non-empirical quantum-mechanical calculation and found to be 1.13 and 0.67 eV for N_1 – N_1 and N_2 – N_2 , respectively.¹⁴ As a result, the crystal is destabilised by 2.14 eV per monomer chain of C_3N_4 . The above statement does not rule out the possibility of β - C_3N_4 existence as a metastable phase, though it is indicative of its definite energy loading.

The structure of β - C_3N_4 was the first that has been proposed for the crystalline carbon nitride. It is not, however, the only possible one. Although it has been noted⁸ that a simple structure of the zinc blende type is energetically unfavourable, because the first antibonding zone is occupied, subsequent quantum-mechanical and molecular-dynamic calculations pointed to the possible existence of rather diverse crystalline modifications of carbon nitride.

α -Carbon nitride, which is topologically equivalent to α -silicon nitride, was studied by the method of density functional in the approximation of the local density for the exchange and correlation of electrons.¹¹ Its structure may be described as an ABAB... sequence of packed layers of β - C_3N_4 (A) and their mirror reflections (B). The unit cell contains 28 atoms, *i.e.* it corresponds to the formula $C_{12}N_{16}$ (tetramer of C_3N_4). The dependences of total energy on volume for α - and β - C_3N_4 are very similar. Nonetheless, the α -form was found to be somewhat more favourable energetically, by 0.266 eV per monomer unit.

Analysis of α - and β - C_3N_4 has been carried out¹⁵ by the non-empirical Hartree–Fock method in the 6-31G** basis set. In this case, special attention was given to the optimisation of geometry of the molecule and to the realisation of a pyramidal configuration of the nitrogen atom as, for example, in trimethylamine rather than of a planar one as has been assumed.^{8,9} On the one hand, optimisation of the β - C_3N_4 geometry did not lead to substantial changes in its configuration: it still remained close to the planar one. Accordingly, the crystal energy was not strongly changed: it decreased in the optimisation by 4.4 kcal per monomer unit. On the other hand, considering the possibility of pyramidal configuration of the nitrogen atom in α - C_3N_4 , the optimisation was

found to result in the lowering of the crystal energy by 54.0 kcal per monomer unit. It was inferred from the calculations that α -C₃N₄ is more stable than β -C₃N₄.^{11, 15} However, the difference of energies reported in Ref. 15 proved to be larger than that in Ref. 11: it was 25.1 kcal per monomer unit for the optimised structures. The values of bulk moduli calculated recently¹⁵ are noticeably lower than those found in the previous studies. For example, for the optimised and non-optimised structures of β -C₃N₄ they were 250 and 357 GPa, respectively. Certainly, these values are also rather high but still they are much smaller than for diamond. Yet another important result of the studies cited¹⁵ is that the bulk modulus proved to be very sensitive to the geometric configuration of the nitrogen atom.

Optimisation of the geometry of α -C₃N₄ yielded yet another interesting result. The calculations have shown that the tetrahedral lattice of α -C₃N₄ contains spheroid cavities 4.1–5.2 Å in diameter with pyramidal nitrogen atoms inside. This crystal should be characterised by a negative Poisson ratio: stretching of crystal in any direction should lead to its expansion in the perpendicular direction. The phenomenon of the negative Poisson ratio is known. It was observed, for example, for α -cristobalite, when it was stretched in definite directions.^{16, 17}

The conclusions made in the work cited¹⁵ are interesting but not indisputable because of insufficient accuracy of the current computational techniques. The results of molecular-dynamic simulation¹⁸ (in accordance with the data of Refs 8 and 9) confirmed the planar configuration of the nitrogen atom in β -C₃N₄. In the case of α -C₃N₄, one half of nitrogen atoms proved to be in the planar configuration, whereas the second half was found to be in the pyramidal configuration with a bond angle C–N–C of 115°, high values of the bulk moduli being obtained for both α - and β -C₃N₄. Thus, the problem of the structure of α -C₃N₄ remains to a considerable extent open.

Cubic carbon nitride¹¹ is similar to willemite-II (high-pressure phase of Zn₂SiO₄). It can be obtained when zinc and silicon in willemite-II are replaced by carbon, and oxygen is replaced by nitrogen. Relevant calculations show that the pressure of the α -C₃N₄ transition to the cubic form is 68 GPa. Of all C₃N₄ modifications, cubic carbon nitride should possess the highest density (0.2957 atom-mol cm⁻³). Such a high density and the topology of bonds in cubic carbon nitride suggest its high heat conductivity. The mechanical stability of cubic carbon nitride under normal and high pressures also follows from the calculations.¹¹

Pseudocubic carbon nitride (in a number of publications, it is this modification that is called cubic) has a structure of the α -CdIn₂Se₄ type.¹¹ It may be classified as a structure resembling zinc blende with one carbon vacancy per cubic cell.¹⁰ The pseudocubic carbon nitride is similar to β -C₃N₄ in that each

Figure 1. Structure of graphite-like carbon nitride.

carbon atom has four neighbouring nitrogen atoms and each nitrogen atom has three neighbouring carbon atoms. However, the CNC angle in the pseudocubic carbon nitride is close to 109.47°, which is characteristic of *sp*³-hybridisation, and not to 120° characteristic of *sp*²-hybridisation as in β -C₃N₄. β -C₃N₄ was reported^{10, 11} to be somewhat more stable than the pseudocubic form, whereas the opposite result was obtained in another study.¹⁸ This is due to the insufficient accuracy of calculation techniques.

Graphite-like carbon nitride has a layered structure and relates to β -C₃N₄, like graphite relates to diamond. The layer structure is shown in Fig. 1. This ‘perforated’ layer is seen to consist of a series of triazine rings linked through nitrogen bridges. The layers are stacked as ABCABC...,¹⁰ though the ABAB... type is also possible.¹¹ Non-empirical molecular-dynamic calculations have shown that the interlayer distance is 3.07 Å, which is 8% smaller than in graphite and graphite-like boron nitride.¹⁰ For the two-coordinate nitrogen atom (nitrogen in the triazine ring) the bond angle is 116°, and the mean C–N bond length is 1.36 Å, *i.e.* it is close to the sum of Slater radii of carbon and nitrogen.

Similar results were obtained¹⁸ by the method of density functional in the local density approximation for the exchange and correlation functionals. To simplify calculations, it was assumed that all the nitrogen atoms in the system are equivalent, and the corresponding atoms in the neighbouring layers are strictly one under another. The length of the C–N bond was found to be 1.38 Å and the interplanar distance, 3.2 Å. Both values are in good agreement with the above-cited results.¹⁰ The phase transition pressure of graphite-like carbon nitride in the cubic modification is 12 GPa.¹¹ Essentially, the graphite-like carbon nitride is the most stable of all modifications analysed so far. The calculated properties of different phases of carbon nitride are presented in Table 1.

Table 1. Characterisation of different phases of carbon nitride.

Note. The following designations were used: Z is the number of monomers per unit cell; a and c are unit cell parameters; B' is the pressure derivative of the bulk modulus; E_c is the energy of cohesion; E_0 is the total energy; ρ is density; ε is dielectric constant. To unify the data from different publications, the values of bulk modulus are all expressed in GPa, the energy of cohesion, in eV per monomer unit, and density, in g cm^{–3}.

^a Calculations included geometry optimisation. ^b Two-coordinate nitrogen. ^c Pyramidal nitrogen.

In conclusion, let us note briefly some other results of theoretical calculations. The geometric coordinates of atoms in the crystal lattices of carbon nitride were determined.^{10, 11} Electronic and optical properties of β -C₃N₄ and the dependence of optical properties on pressure were estimated in the local

density approximation.²¹ The normalised density functions of β -, pseudocubic, and graphite-like C₃N₄ were calculated.²⁴ Electronic and optical properties of β -C₃N₄ were discussed and an idea of the possible existence of carbon nitride in the form of nanotubes, was suggested.²⁵

III. Carbon–nitrogen films: preparation, properties, formation mechanism

After the pioneering studies of Cohen and Liu,^{6,8} many attempts have been made to materialise their ideas. Most of the studies concerned with the synthesis of crystalline carbon nitride aimed at preparing carbon–nitrogen films. This was by no means the easiest way to obtain carbon nitride (in our view, it is just the opposite), but rather the direction in which, by the beginning of this series of studies, advanced techniques had been developed and rich experience gained in the synthesis of carbon films, including the diamond-like ones.[†]

One of the most common ways for preparing thin films is chemical vapour-phase deposition. In its application to carbon–nitrogen materials, it consists essentially in having the initial substances in their specific forms (atomic, molecular, cluster, or ionised) either existing in, or brought into, the gas phase (by vaporisation, or spray) and forming the target films by interaction on the surface of a specially selected substrate.

As regards the initial substances to be used for the synthesis of carbon nitride, it is natural to rely on its constituent elements, *viz.*, nitrogen and carbon. Nitrogen is used either in pure state or in its mixture with argon. Of the carbon allotrops, graphite is most often used, while diamond and glassy carbon are employed on rarer occasions. The latter is a low-density ($\sim 1.5 \text{ g cm}^{-3}$) non-ordered graphite-like material with a microscopically turbostratic structure consisting of an ordered (local order) network of sp^2 -hybridised carbon atoms.³⁷

As the carbon source for preparing carbon–nitrogen films, various hydrocarbons can be used that, in contrast to graphite, do not require special vaporisation: methane,^{38–44} ethylene,^{45,46} acetylene,^{47,48} cyclohexane,⁴⁷ cyclopentane,⁴⁹ and benzene.^{50,51} Ammonia may well be used as the nitrogen source.^{43,44} However, in all of the above-mentioned cases the resulting films contained considerable amounts of hydrogen, which naturally hampered the identification of carbon nitride in them. It is also noteworthy that even when the initial substances were hydrogen-free, it might be present in films as an admixture.⁵²

In a number of studies specially devoted to the search for carbon nitride, the sources of carbon were hydrogen-containing compounds, such as the already mentioned methane,^{53,54} low-molecular-weight polyethylene,^{55,56} and wax.⁵⁵ Ammonia was used as the nitrogen source;^{54,56–58} incidentally, it was noted⁵⁷ that ammonia was to some extent even more convenient than molecular nitrogen because its chemical bonds are markedly weaker than those in N_2 .

The transfer of carbon to the gas phase and the preparation of chemically active particles necessary for vapour-phase deposition are energy-consuming processes. In the preparation of carbon–nitrogen films, this is achieved in a few ways. Of these, the most popular seems to be magnetron discharge.^{58–76} In yet another method the graphite to be volatilised is used as an electrode to which voltage is applied^{24,58,70,77–84} so that the process is as a rule realised in an electric arc mode. Also rather widespread are the methods of laser ablation of graphite^{85–96} and glassy carbon,⁷¹ graphite vaporisation under the action of an electron beam^{97–100} or a beam of argon ions,^{57,101–103} and radiofrequency diode spraying.^{104–113} A beam of carbon ions was also used to prepare carbon–nitrogen films.^{114,115} The films can also be obtained by pyrolysis (see below).

[†] Furthermore, irrespective of the carbon nitride problem, investigations have continued on the synthesis of carbon films doped with nitrogen to enhance their performance. In this connection no effort was made to introduce the maximum amount of nitrogen in films (it amounted, as a rule, to a few atomic percent and sometimes to percent fractions), and no measurements intended to detect carbon nitride were carried out. Therefore, when citing some recent publications on this topic,^{27–36} we do not discuss them in detail.

In most cases, silicon is used as a substrate on which the process of film formation takes place, see, for example, Refs 53–58, 60–71, 75–78, 80, 83, 85, 87–90, 92, 94–103, 106–108, 111, 113–115. The role of the substrate is also played by sodium chloride,^{56–59,62,72,101} potassium chloride,^{58,70} glass,^{24,59,91,94,104,106,107,109,110,113} quartz,^{98,113} potassium bromide,^{106,110,112} glassy carbon,^{62,107,110} sapphire,^{72,74,100} mica,^{58,83} copper,^{102,115} gold,¹¹⁵ beryllium,¹⁰² magnesium,¹¹⁵ zirconium,^{59,60,75} germanium,¹⁰⁸ tantalum,^{114,115} molybdenum,^{114,115} tungsten,¹¹⁵ nickel,^{79,85} steel,^{66,67,73,81} tungsten carbide,^{97,98} cemented carbides,⁶⁷ and a NiP/AlMg system.¹⁰⁵ Alkali metal halides are convenient as substrates because they are readily soluble in water, which facilitates the isolation of films in a pure state. As regards mica, it was noted⁵⁸ that some of its lattice parameters are close to those of $\beta\text{-C}_3\text{N}_4$.

Yet another method for the preparation of carbon–nitrogen films is based on ionic implantation. It differs from the methods listed above in that the carbon itself is bombarded with an ionic nitrogen beam and is the substrate on which a film is formed. The corresponding beam is usually generated by an ion gun. Various carbon modifications may be used as substrates: graphite,^{115–121} diamond,^{121,122} glassy carbon.^{24,37,123}

The properties of carbon–nitrogen films were studied in detail. We shall give special attention to the properties that are directly related to the problem of carbon nitride preparation. In this context, two questions seem to be of prime importance: how much nitrogen is incorporated into films and whether these films have a crystalline phase.

Before proceeding to the consideration of the respective data, note that the properties of carbon–nitrogen films depend substantially on both the method of synthesis and the parameters of the process. Therefore, the results reported by different authors differ noticeably.

The concentration of nitrogen in films was determined by the electron energy loss spectroscopy, Rutherford backscattering, Auger electron spectroscopy, *etc.* The content of nitrogen in films varied over a wide range.

Nitrogen content (at. %)	Ref.
20	37, 55, 75, 83, 95, 117, 118, 121
20–30	24, 64, 69, 76, 78, 82, 87, 94, 104, 106, 123
30–40	56, 57, 61, 62, 65, 70, 71, 73, 74, 80, 81, 88, 90, 91
40–50	54, 58–60, 85, 86, 92, 96, 99–101, 103, 105, 107–110, 114, 115, 124

There are only a few papers reporting the contents of nitrogen in films approaching the value of 57.1 at.% corresponding to C_3N_4 : 58,⁵³ 54.6,⁶⁸ 57,^{72,102,111} 83 at.%.⁹⁷ Note that the nitrogen level of 58% was determined disregarding the hydrogen content in the film; furthermore, the accuracy of measurement was 20%. The reason for an anomalously high value of 83 at.% is unclear. The only thing to be mentioned in this connection is that the distribution of nitrogen in the films is far from being always regular: its concentration on the film surface was repeatedly noticed to be higher than inside the film.⁸³ In particular, this may be due to the fact that not all the nitrogen contained in the film is chemically bound. Thus, in a study¹²² unrelated to the problem of carbon nitride synthesis, it was noted that the surface concentration of nitrogen in the film prepared by the bombardment of diamond with nitrogen ions may be as high as 81 at.%, while at a depth of 20 Å it is twice as low. One should bear in mind that all of the above-cited nitrogen concentrations represent the mean values. Therefore, one should not rule out the possibility that even in films with low nitrogen levels its local concentrations may exceed considerably the mean value. Thus it was found¹⁰¹ that at the mean nitrogen concentration of 45 at.% its local level may achieve 59 at.%.

X-Ray and electron diffraction studies were undertaken to detect crystalline phases in carbon–nitrogen films. Some films proved to be totally amorphous,^{24, 62, 71, 72, 74, 77, 80, 83, 91, 98, 113} whereas crystallites were also detected in a background of predominantly amorphous phase, see *e.g.* Refs 54–61, 64, 71, 78, 85–90, 99, 102, 104, 107–109, 112, 114, which were attributed directly to β -C₃N₄ on the basis of diffraction measurement results.^{56, 75, 78, 85, 86, 88–90, 99, 102, 108, 109, 112, 114, 119} The formation of β -C₃N₄ was also confirmed by the results of X-ray photoelectron,⁷⁵ Raman,⁷⁸ and IR spectroscopy.⁵⁵ Crystallites proved to vary in size: from very small, not exceeding 10 nm,^{58, 60, 61, 64, 85, 86} to markedly larger with a size of 100 nm,^{59, 102} and even up to 0.4 μ m (see Ref. 99) and 0.5 μ m.¹⁰⁸ Needle-shaped crystallites 300 nm in size were obtained.⁵⁴ Their diffraction pattern was found to be similar to that of α -C₃N₄, while β -C₃N₄ was not detected. As a result of laser-induced microbursts at the interface of frozen ethanol and liquid nitrogen layers, microcrystals up to 100 μ m in size were obtained;⁷¹ however, their composition was not established.

Despite the fact that in some of the above-cited studies fairly definite conclusions on the existence of C₃N₄ crystallites in carbon–nitrogen films have been made, they nonetheless should be considered with caution. These films have complex structures, they may include different phases, and finally, they often contain admixtures of other elements (hydrogen, oxygen, *etc.*) affecting the results of measurements. For example, it was noted¹²⁵ that some data on electron diffraction in such films are closer to the analogous data for the carbon phase of lonsdelite than to C₃N₄. In this context, one should agree with the arguments of Fang¹²⁶ that the available evidence of the formation of crystalline carbon nitride is rather ambiguous.

Let us analyse other properties of carbon–nitrogen films. Numerous measurements of the thickness of such films^{53, 55–58, 61, 63, 66, 69, 72, 74, 75, 81, 83, 84, 92, 94, 96–100, 105–107, 110, 115} show that it varies within wide limits ranging from tens of angstroms⁵³ to micrometers. The thickest films were 2 μ m (Ref. 66) and 3.9 μ m (Ref. 74). A film separated from the substrate (by dissolving NaCl) was found to be 50 nm thick.⁷²

Undoubtedly, the formation of films involves chemical bond formation between carbon and nitrogen. This was confirmed by X-ray photoelectron spectroscopy;^{53–57, 71, 76, 84, 85, 88–90, 97–99, 101, 103, 105, 106, 114, 116–119, 122} in some cases, certain information was obtained on the character of the bonds formed. Thus the formation of weakly polarised carbon–nitrogen bonds characteristic of C₃N₄ was established.^{55–57, 90} It was also shown that the hybridisation of carbon may be sp^2 and sp^3 .^{57, 75, 99, 101, 105} In general, judging from the X-ray photoelectron spectra, the composition of carbon–nitrogen films is rather complex and may include various functional groups.^{37, 77, 117, 121}

Carbon–nitrogen films were analysed in detail by vibrational spectroscopy. One of the most characteristic features of the IR spectra of these films is the presence of a band at 2200 cm^{-1} attributed to the nitrile group ($\text{C}\equiv\text{N}$).^{24, 55, 59, 62, 63, 68, 70, 77, 87, 91, 92, 94–96, 98, 106, 109, 111–113} Analogous results were obtained by employing Raman spectroscopy.^{60, 73, 81, 82, 84, 89, 90, 95, 109} The formation of nitrile groups was also confirmed by X-ray photoelectron spectroscopy.^{37, 55, 65, 90, 98, 121, 122}

The fact that the nitrile groups are present in films obtained by different methods and under different conditions (in particular, the $\text{C}\equiv\text{N}$ group is virtually always observed in the IR spectra) makes it possible to conclude that the formation of nitrile groups is a common phenomenon in the preparation of carbon–nitrogen films. However the nitrile group was considered as an admixture,^{92, 96, 127} though it appears to be an admixture in relation to a hypothetical carbon nitride.

The formation of nitriles in the interaction of carbon with nitrogen is not surprising because of the strength and energetic

advantage of the triple carbon–nitrogen bonds. The high strength of this bond ensures its stability under drastic conditions of film formation (high temperatures, large energies of nitrogen and carbon ions).

It is difficult to characterise nitriles in the carbon–nitrogen films. It is possible that these compounds are of the paracyanogen type, which is a polymer with a complex branched structure.¹²⁸ It contains $\text{C}\equiv\text{N}$ and $\text{C}=\text{N}$ bonds. It is noteworthy that, according to the spectral data, the formation of $\text{C}=\text{N}$ bonds in the carbon–nitrogen films is quite possible.^{53, 65, 68} It is also noteworthy that in 1979, when the problem of carbon nitride synthesis was not yet adequately formulated, paracyanogen was prepared by the method of reactive radiofrequency sputtering,¹²⁹ which was subsequently often used for the synthesis of carbon nitride. It was also pointed out^{72, 90, 130} that paracyanogen structures can be formed in the carbon–nitrogen films. It was found⁹⁶ that nitriles can be removed from the film by annealing. After annealing, a material corresponding in its composition to C₂N was obtained. This does not contradict the above-mentioned high strength of the $\text{C}\equiv\text{N}$ bond and can be explained by the destruction of nitrile-containing compounds (including paracyanogen) upon prolonged heating without cleavage of the triple bonds.

To conclude the review of nitriles in carbon–nitrogen films, we can mention a study,⁸⁰ which suggested the formation in carbon–nitrogen films of a nitrile compound called polycyanimine, which was found to be rather similar to paracyanogen in structure.

The application of vibrational spectroscopy has revealed yet another phase often occurring in the carbon–nitrogen films. In the IR spectra of films obtained by different methods, three commonly occurring peaks were repeatedly found at 1500, 1300, and 700 cm^{-1} .^{62, 87, 94, 109, 112} Analogous bands were observed at 1500 and 1300 cm^{-1} in the Raman spectra.^{37, 60, 71, 81, 86, 90, 95, 109, 120, 131} The first of them (*G*-branch) is ascribed to graphite-like carbon, the second band (*D*-branch) was attributed to non-ordered carbon, whereas the band at 700 cm^{-1} was ascribed to the extraplanar deformational vibrations of graphite-like regions (in all cases, the carbon atoms are in sp^2 -hybridisation). It is important that for symmetry reasons all of these vibrations must be active in the Raman spectra and inactive in the IR spectra. However, the substitution of a few carbon atoms by nitrogen atoms in the graphite rings results in symmetry perturbation and the corresponding vibrations become IR-active. Thus, the carbon–nitrogen films are believed to include graphite-like structures in which some carbon atoms are replaced by nitrogen atoms. This is supported by NMR data.⁶³ It was suggested that compounds of the composition C₂N and C₅N⁶³ can be formed, as well as compounds in which one nitrogen atom is linked with three carbon atoms.²⁴ The possibility of the existence of the above-mentioned graphite-like nitrogen-containing compounds has been long known. For example, they can be prepared by pyrolysis of polyacrylonitrile incorporated into urea.¹³²

Interesting ideas were expressed by Sjöström *et al.*^{69, 76} on the basis of data from quantum mechanics calculations, X-ray photoelectron spectroscopy, and electron microscopy: it was concluded that the sp^2 -hybridised graphite-like carbon–nitrogen planes are bent and cross-linked by sp^3 -hybridised bonds. It is important that the bend of the plane is due to the incorporation of five-membered rings, *i.e.* a fullerene-like carbon–nitrogen structure appears.

Crystalline carbon nitride has been supposed to have high hardness since the very first studies; therefore, it was natural to check this with the carbon–nitrogen films. One could not expect a record hardness because of complex film composition, though the possibility of preparing films with good performance was not ruled out. In practice, it proved to be the case. Mechanical characteristics of films (hardness, elasticity modulus, elastic recovery, friction coefficient, adhesion) were studied in numerous studies.^{55, 57, 59, 60, 64, 66, 69–71, 73, 74, 76, 81–87, 89, 90, 97, 98, 103, 113} As a result, it was found that carbon–nitrogen films possess high hardness, large elastic recovery, good adhesion to different

materials (primarily, to silicon), and some other valuable properties. For instance, on the surface of titanium nitride the hardness of a carbon–nitrogen film corresponds to that of diamond and is higher than that of cubic boron nitride.⁶⁶ The elastic recovery of films amounts to 84%–85%.^{64,76} In the indentation of films, microcracks (as in titanium nitride) are not formed, and plastic deformation occurs instead. On the surface of titanium carbide the film hardness reaches 6500 kg mm⁻² on Knoop's scale (see Ref. 97). As noted by the authors, no films of such hardness with a thickness of 1 mm have been obtained previously.

The density of films was measured in a number of studies, it was found to be 2.2 and 2.30 g cm⁻³ (see Refs. 59, 65, respectively). A film with a density of 3.4 g cm⁻³ was prepared¹⁰² which is close to the theoretical value of 3.47 g cm⁻³ for β -C₃N₄.

Some other properties of carbon–nitrogen films were also studied. Since they are not of direct relevance to the problem of carbon nitride synthesis, we shall make only a brief mention of them. In a study,¹¹³ the EPR method was employed to study paramagnetic properties of films. The spin density was found to vary from 1.1×10^{18} to 1.1×10^{19} cm⁻³. It was concluded that the EPR-active centres are localised on carbon atoms. They were attributed to the unordered phase with *sp*²-hybridised carbon. The nitrogen contained in the film decreases the concentration of this phase and possibly increases the concentration of the phase with *sp*²-hybridised carbon.

Studies^{58–60, 80, 87, 91, 94, 96, 106, 113} were concerned with the determination and analysis of the electrical conductivity of C–N films, and their optical properties (refractive index, reflection factor, extinction coefficient, width of optical band gap) were also studied.^{70, 73, 80, 87, 91, 94, 98, 104, 113} These films were characterised by high heat conductivity⁹⁶ (note that this property had been predicted theoretically). In some cases, the thermal stability was assessed. The films remain stable for 30 min at 350 °C,⁶³ they can withstand heating up to 800 °C.⁸⁵

Detailed studies of the properties of carbon–nitrogen films have predetermined discussion, in a number of reports, of their performance and prospects of practical uses. There are indications of the possibility of their application as semiconductors with a variable band gap⁶¹ and wear-resistant coatings.^{61, 87} Such films were reported¹⁰⁵ to be suitable as protective coatings in systems of magnetic registration. In this respect, they are superior to the purely carbon films.

Information about processes occurring during the film formation is very scarce. As a matter of fact, one can speak only about the type of particles involved in these processes.

As the nitrogen interacting with carbon has been subjected previously to energy impact (radiofrequency discharge, electric arc, electron cyclotron resonance, laser radiation, *etc.*), it was always in the ionised or atomic state, the proportion of different active particles being dependent on experimental conditions. Thus, in experiments on ionic implantation, the nitrogen ions had an energy of 160 keV;¹²³ in analogous experiments^{37, 118, 121} an ion gun produced N₂⁺ ions with an energy of 500 eV, whereas the plasma of electron cyclotron resonance yielded low-energy nitrogen ions with an energy of 20–30 eV.¹⁰⁰ In another study⁶⁵ ion beams comprised atomic nitrogen and N⁺ ions, the latter present in amounts from 2.5% to 25%;⁶⁵ or 80% of N₂⁺,¹⁰² or 96% of N₂⁺ and 4% of N⁺.¹¹⁶

Carbon also exists in the ionised or atomised state in the process of film formation. The use of beams of C⁺ was reported.^{114, 115} Evaporation in an electric arc leads to the formation of carbon atoms and clusters, as well as C⁺, C₂⁺, and electrons.^{58, 82} In experiments on laser ablation of graphite, atomic carbon, C₂, and other carbon clusters were formed.⁸⁹ Irrespective of the problem of carbon nitride synthesis, laser vaporisation of graphite was studied;¹³³ it was shown that atomic carbon, as well as C₂, C₃, and C₄ clusters were formed.

The plasma over substrate contained not only carbon and nitrogen. The formation of CN radicals is also possible.⁷⁷ The

presence of these particles in the reaction system is important for the understanding of the formation of the above-mentioned nitriles.

Numerous studies were concerned with the measurement of the rates of the film growth.^{53, 55–60, 62, 64–66, 68, 70, 71, 74, 75, 81, 84, 88, 92, 96, 99, 100, 105, 107, 113} It was found to vary from 1 Å min⁻¹ (see Ref. 53) to 5 nm s⁻¹ (see Ref. 64). The growth rate is an important characteristic of both the yield and the mechanism of the process. It was shown^{93, 96} that the film growth rate determines the nitrogen content in it. It follows that the key stage of the film growth is not the process in the gas phase, but rather the reaction between carbon and nitrogen on the growing surface. This reaction may be preceded by the dissociation of N₂⁺ upon its collision with the surface.^{102, 118}

Summarising the above considerations, it may be stated that the carbon–nitrogen films possess a number of valuable characteristics and are of obvious practical interest. As regards the possibility of preparation of crystalline carbon nitride by non-pyrolytic film formation (in particular, in the form of an individual substance and not as a microphase), we are rather pessimistic despite some progress in this direction. In our view, the major difficulty lies in that the energy of the particles used in the process of film preparation exceeds considerably that of the chemical bonds in the hypothetical carbon nitride. Even when low-energy nitrogen atoms are used, their energy is 20–30 eV, while the strongest chemical bonds have a dissociation energy of 10 eV, and in the case carbon nitride it does not exceed 4 eV (judging from the cohesion energy level, see Table 1). If one uses higher-energy particles, the corresponding energies differ by orders of magnitude. The high energy of the particles involved in the reaction to promote a high rate of the process means that the time for the energy to dissipate is then too short, and the energy is spent in the cleavage of the newly formed C–N bonds. Nonetheless, some bonds have enough time to form, though in the light of what has been said above, the conditions are more favourable for the formation of stronger double and triple bonds, rather than of single C–N bonds, as in carbon nitride, and this was indeed observed experimentally. Apparently, for the same reason even when carbon nitride crystallites are formed, they are very small.

IV. Pyrolysis

Pyrolytic processes underlie the synthesis of numerous materials; therefore, their use for the preparation of carbon nitride appears quite natural. Clearly, it is preferable to use high-nitrogen substances as precursors of carbon nitride. Depending on the conditions of the process, the final product may be obtained in the form of a voluminous mass (*e.g.*, a powder) or as a thin film. The latter case was realised¹³⁴ in the pyrolysis of 3,3'-diaminobenzidine and melamine. The corresponding reactions lasted for 1 h at 800 °C (heating to 800 °C was accomplished at a rate of 10 °C min⁻¹). The decomposition products of the above-mentioned substances contained 11.7 mass% and 39 mass% of nitrogen, respectively, and small quantities of hydrogen (0.8 mass% and 2 mass%). The volatile products of the reaction were nitrogen, ammonia, and hydrogen cyanide. This study¹³⁴ was not concerned with carbon nitride synthesis, therefore it is not discussed at all. However, this task was already in view in the next study by the same authors.¹³⁵ In this case, melamine, 1,2,4-triazole, diaminomaleonitrile, polymerised hydrogen cyanide, dicyanoimidazole, tetracyanoethylene, its mixture with ammonia, and hexaazatriphenylenehexacarbonitrile were subjected to pyrolysis. The reactions were also conducted at 800 °C and yielded a solid residue containing from 25 mass% to 45 mass% of nitrogen.

However, this attempt to prepare carbon nitride failed: the results of X-ray analysis indicated that the product was amorphous, while its pycnometric density was 1.71 g cm³, which is considerably less than the theoretical value for β -C₃N₄. Judging

by the results of Raman spectroscopy and ^{13}C NMR, the carbon in the synthetic product is in the sp^2 - and not in sp^3 - hybridisation, while the product itself seems to have a characteristic graphite-like structure in which certain carbon atoms are replaced by nitrogen.

Pyrolysis of triazine derivatives gave interesting results.^{136, 137} The reactions proceeded according to the scheme:

where X is chlorine or fluorine and M is silicon¹³⁶ or tin.¹³⁷

The process may be regarded as a condensation in which the group Me_3M of one molecule of the substrate interacts with X of another molecule. This results in the elimination of the corresponding silane or stannane, while two triazine rings are linked by a nitrogen bridge. This linkage should lead to the appearance of the structure shown in Fig. 1 and theoretically predicted for the graphite-like carbon nitride (see above). The presence of such structure was confirmed by spectral measurements.^{136, 137} Unfortunately, the product obtained in these studies proved to be amorphous. Thermolysis was conducted at 400–500 °C, the tin derivative being thermally less stable than that of silicon. The products were obtained as films up to 0.5 μm thick. The deposition rate achieved was 300 $\text{\AA min}^{-1}$. The tin derivative (but not that of silicon) could also be obtained as a powder when the reaction was carried out at 200 °C. Depending on the experimental conditions, the product included small quantities of admixtures. Thus, the pyrolysis of the silicon derivative yielded a film of the composition $\text{C}_3\text{N}_4\text{O}_{0.3}\text{Si}_{0.02}\text{F}_{0.05}$. The authors^{136, 137} were correct in pointing out that the material they had prepared might prove to be a convenient precursor for the synthesis of crystalline carbon nitride (at least, graphite-like). The reason for the optimism is not only the stoichiometric composition of the product, but also that, in contrast to other carbon nitride precursors, it contains only C–N bonds (with no account of admixtures).

Combined pyrolysis of pyridine and chlorine at 800 °C yielded a product of approximate stoichiometry of C_5N .¹³⁸ Judging by the results of electron diffraction, it has a layered structure, and it is not ruled out that, as in a number of cases considered above, this is a graphite-like product in which some (one out of six) carbon atoms are replaced by nitrogen.

In conclusion, a study can be mentioned¹³⁹ in which the process was not thermal in character and the product was not a film. Etching of diamond or graphite with a microwave nitrogen plasma produced a soft porous low-density carbon–nitrogen material of a structure similar to the turbostratic structure of graphite or the hexagonal structure of boron nitride. This material decomposes at 900 °C or even at lower temperatures.

V. High pressure

The synthesis of numerous carbon materials (including that of diamond) is carried out under high pressure, and it seems natural that higher pressures would favour the preparation of carbon nitride. The expedience of high pressures for the synthesis of carbon nitride was pointed out in a number of papers (see, e.g., Refs 9, 11, 135).

Pyrolysis of 1,3,5-triazine and tetracyanoethylene was carried out at a temperature of 1400 °C and a pressure of 5 GPa, and reaction lasted for 30 min.¹⁴⁰ The product of triazine pyrolysis was found to contain no nitrogen whatsoever, while pyrolysis of tetracyanoethylene yielded a graphite-like material of composition $\text{C}_{4.66}\text{N}$. Judging from electron energy loss spectroscopy, the carbon contained in this product was exclusively in sp^2 -hybridisation. Apparently, as in a number of cases considered above, pyrolysis of tetracyanoethylene yielded a graphite-like product in which some of the carbon atoms were replaced by nitrogen.

Other authors¹³⁵ described low- and high-pressure pyrolysis (225 MPa) of hexaazatriphenylhexacarbonitrile and tetracyanoethylene for 70 h at 700 °C. However, in this case, too, amorphous products were obtained with nitrogen contents of 36.1 mass % and 39.3 mass %, respectively. Incidentally, it was noted that these products (having the same structure as the low-pressure pyrolysis products) may be convenient precursors for the synthesis of carbon nitride.

Pyrolysis of paracyanogen for 75 h at 725 °C and 0.3 GPa yielded graphite-like carbon as the sole product.¹²⁸ The authors noted that paracyanogen is inconvenient for the carbon nitride synthesis because it can undergo decomposition at relatively low temperatures.

As far as we know, there is only one instance of the use of the method of shock-wave compression for carbon nitride synthesis.²⁶ The product of pyrolysis of melaminoformaldehyde resin and the products of low-temperature combustion of tetrazole and its sodium salt were the objects for the shock impact. These materials were compressed by shock under the conditions typical of the synthesis of diamond and wurtzite-like boron nitride, where the pressure seemed to reach 60–250 GPa. However, no carbon nitride was obtained; instead diamond was detected the structure of which proved to be much more ordered than that of diamond prepared from carbonaceous precursors. It is believed¹³⁹ that the reason for unsuccessful attempts²⁶ to obtain carbon nitride was the presence of hydrogen in the original reagents. The expedience of the use of hydrogen-free compounds was also pointed out in Ref. 135. In our opinion, this is not the only reason. Other reasons will be considered below.

We have already demonstrated that in various attempts to synthesise carbon nitride the final product contained, as a rule, nitrogen at levels below the required 57.1 at.%. In order to overcome this deficit, it was recommended¹⁴¹ to use lithium azide (or other metal azide) as the nitrogen source and to subject its mixture with a non-diamond form of carbon to shock-wave compression under a pressure of about 100 kbar. As a control, it was proposed to conduct the experiment so as to provide for the synthesis of carbon nitride in one part of the reactor and, in another part separated from the first one, for the analogous synthesis of silicon nitride (the synthesis may also be carried out in a single mixture). This may permit obtaining additionally a new phase of silicon nitride (boron may also be added to the system to obtain the 'elusive' BCN phase). The proposed approach is substantiated by the fact that the shock-wave compression of a mixture of boron with lithium azide allows the synthesis of cubic boron nitride.

Interesting results were reported¹⁴² on a reaction of carbon with nitrogen. It was carried out at 2000–2500 K and a pressure of 30 ± 5 GPa. The carbon sources were graphite, amorphous carbon, and fullerene C_{60} . This resulted in the formation of a crystalline phase with cubic symmetry. The X-ray diffraction pattern of this phase does not correspond to that for $\beta\text{-C}_3\text{N}_4$, though the very fact of preparation of a crystalline carbon–nitrogen phase is remarkable.

VI. Thermodynamics

The scarcity of our knowledge about the range of thermodynamic stability of carbon nitride determines largely the fact that until now attempts to synthesise crystalline carbon nitride, in particular in the pyrolytic mode, have been unsuccessful. Hence, it is still unclear what process parameters (temperature, pressure) should be 'aimed at' to ensure successful synthesis. Despite the evident topicality of the thermodynamic analysis of conditions of the carbon nitride synthesis, only few studies were concerned with this problem.

Having analysed the available data on the dissociation energies of single C–N bonds ($286\text{--}305 \text{ kJ mol}^{-1}$), the authors²³ assumed that the cohesion energy of carbon nitride should be $E_c = 858\text{--}915 \text{ kJ (mol C}_3\text{N}_4)^{-1}$. As noted above, the repulsion

of unshared electron pairs of nitrogen should make a noticeable contribution to the energy of a carbon nitride crystal.¹⁴ Taking into account this repulsion, one obtains a more accurate range of cohesion energy values, $E_c = 806\text{--}863 \text{ kJ (mol C}_3\text{N}_4)^{-1}$. The cohesion energy is directly related to the thermal effect of the reaction.

Thermodynamic analysis of this reaction allows calculation of the standard enthalpy of carbon nitride formation. It was found²³ that $\Delta H_f^\circ = 147\text{--}204 \text{ kJ (monomer unit C}_3\text{N}_4)^{-1}$. The entropy of C_3N_4 was calculated using the Latimer rule and amounted to $19 \text{ J (K mol C}_3\text{N}_4)^{-1}$, i.e. $77 \text{ J (K monomer unit C}_3\text{N}_4)^{-1}$. Thus, $\Delta S_f^\circ = -78 \text{ J (K mol C}_3\text{N}_4)^{-1}$; $T\Delta S^\circ = -23 \text{ kJ (mol C}_3\text{N}_4)^{-1}$ at 298 K ; and $\Delta G_f^\circ = 171\text{--}227 \text{ kJ (mol C}_3\text{N}_4)^{-1}$.

Knowledge of the thermodynamic properties of carbon nitride made it possible to follow the dependence of the thermodynamic potential of its formation on pressure.²³ This was done with the aid of the Gibbs–Duhem equation using the Birch–Murnaghan equation of state. As a result, the dependences of the specific volume of carbon nitride on pressure were determined for isothermal conditions (298 K).²³ In a thermodynamically unfavourable case [$\Delta G_f^\circ = 227 \text{ kJ (mol C}_3\text{N}_4)^{-1}$ under normal pressure], $\Delta G_f^\circ = 0$ (i.e. the reaction becomes possible) under a pressure of 150 GPa , and at 75 GPa in the optimal case [$\Delta G_f^\circ = 171 \text{ kJ (mol C}_3\text{N}_4)^{-1}$]. One should also bear in mind that to permit the reaction at a sufficient rate (it is short conversion times in the shock-wave compression that could be the reason for failure to synthesise carbon nitride²⁶) rather high temperatures are required and this necessitates increased pressure. Thus in synthesis at 1300 K (this temperature is characteristic of the high-pressure synthesis of diamond) it is necessary to increase pressure by another 30 GPa to make the reaction possible. Such pressures are considerably higher than those realised in the attempts to synthesise carbon nitride (except for the shock-wave compression). Nonetheless, it was noted²³ that since nowadays static pressures up to 200 GPa are achievable, the potential possibility of carbon nitride synthesis is preserved. Thermodynamic analysis of carbon nitride with stoichiometry C_4N_3 which contains some C–C bonds besides the C–N bonds, has been carried out.²³

Thermodynamic analysis of the temperature dependence of the pressure of $\beta\text{-C}_3\text{N}_4$ formation in a system containing solely carbon and nitrogen was carried out.²² In the estimation of the standard enthalpy of carbon nitride formation, it was assumed (based on the equality of bond lengths) that the dissociation energy of its C–N bonds is the same as in methylamine, viz., 80 kcal mol^{-1} . As a result, the enthalpy of $\beta\text{-C}_3\text{N}_4$ formation was found to be $18.6 \text{ kJ (monomer unit C}_3\text{N}_4)^{-1}$ which is much less than the values used in Ref. 23. The results of calculation are shown in Fig. 2. These were used for elucidating the possibility of carbon nitride synthesis through detonation of explosives. It is known that the detonation may lead to the formation of diamond but not carbon nitride because the pressure of detonation products is considerably lower than the pressure of carbon nitride condensation. Possibly, it is this that was the reason that diamond rather than carbon nitride was formed under the shock-wave compression of a number of substrates.²⁶

Yet another approach to the synthesis of carbon nitride has been analysed.²² It is based on adiabatic explosion with subsequent isochoric cooling of the products formed. It was found that with isochoric cooling the system shifted first to the area of thermodynamic stability of diamond and then to that of carbon nitride. Thus, under the conditions considered carbon nitride should be formed through vaporisation of carbon from diamond and condensation of the vapour formed with nitrogen.

Figure 2. The line of $\beta\text{-C}_3\text{N}_4$ condensation in the carbon phase diagram according to Bundy.¹⁴³

The dashed line shows the calculated graphite–diamond equilibrium.¹⁴⁴

VII. Conclusion

The properties predicted theoretically for crystalline carbon nitride make this product highly attractive. In our view, the actual situation with carbon nitride is similar to that in which the phenomenon of high-temperature superconductivity was a few years ago and the problem of synthetic diamond several decades ago: there are no theoretical restrictions, but experimental efforts fail until a certain stage is reached. The major difficulties seem to be associated with insufficient knowledge of the optimum conditions of carbon nitride synthesis and with the possibility of occurrence of numerous competitive processes leading to the formation of various carbon phases and C–N compounds that are more stable thermodynamically than carbon nitride under given conditions. Nonetheless, the material discussed above enables one to feel optimistic about the synthesis of crystalline carbon nitride. In this review, we touched only briefly upon the possibility of synthesis of a carbon nitride with stoichiometry different from C_3N_4 . However, such a possibility does exist and should be taken into account in relevant studies.

V. Syntheses based on boraadamantanes accompanied by rearrangements involving the boron atom	919
VI. Conclusion	921

Abstract. Published data on the skeletal transformations of oxa-, aza-, bora- and polythia-cage compounds accompanied by replacement of one heteroatom by another, of a heteroatom by a carbon atom or of a carbon atom by a heteroatom are surveyed. Skeletal transformations of compounds with oxacage structures leading to compounds with carbocage structures are considered. The bibliography includes 65 references.

I. Introduction

Synthetic methods based on skeletal rearrangements occupy a prominent place in the chemistry of cage and heterocage compounds. The types of these rearrangements are quite diverse; rearrangements typical of cage compounds do not necessarily occur in their hetero-analogues. The most famous skeletal rearrangement of carbopolycyclanes, namely, the thermodynamically controlled isomerisation induced by strong Lewis acids, the discovery of which has opened up the way to adamantane, its homologues, polymantanes and many other cage compounds, provides an example of 'non-universal' processes. This rearrangement has found no use in the synthesis of heteroorganic derivatives, because their skeletons are unstable in strongly acidic media. However, a large number of rearrangements occur successfully in reactions of both cage and heterocage compounds. This group includes the rearrangement of (hetero)cubanes into (hetero)snowtanes, photoisomerisation of (hetero)polycyclodienes, skeletal interconversions of functionally substituted (2,4,6,8-tetrathia)adamantanes and (2,4,6,8-tetrathia)protoadamantanes, *etc.* These rearrangements have been considered in the monographs by Fort¹ and Bagrii,² in the well known reviews dealing with the chemistry of cage and heterocage compounds^{3–5} and in a number of reviews specially devoted to skeletal rearrangements of this type of compound.^{6–9}

In addition to rearrangements that are common to cage compounds and their hetero-analogues and to those peculiar only to cage compounds, there exist skeletal rearrangements, which are typical only of heterocage derivatives, because they

involve the hetero-function. The picture of skeletal rearrangements of (hetero)cage compounds is not complete without this type of rearrangements. However, they have not been considered in the monographs and reviews mentioned above. The purpose of the present review is to fill this gap. We survey the available data on the skeletal transformations of functionally substituted heteropolycyclanes in which a heteroatom is replaced by another heteroatom or by a carbon atom, or a carbon atom is replaced by a heteroatom, the initial heteroanalogous framework being retained. The skeletal rearrangements of oxacage compounds giving rise to derivatives with a related oxacage or a stabilomer carbocage structure are also considered.

II. Skeletal transformations with replacement of one heteroatom by another

Transformations of this type accompany some reactions of functional derivatives of 1,3,5,7-tetramethyl-2,4,6,8-tetrathiaadamantane and compounds with the 'bird-cage' structure containing a heteroatom, *i.e.* with the structure of 4-heterohexacyclo-[5.4.1.0^{2,6}.0^{3,10}.0^{5,9}.0^{8,11}]dodecane. These transformations give rise to compounds with the same cage structure but with a different heteroatom. Some functional derivatives of the 'bird-cage' series isomerise under the action of appropriate reagents. The initial number of heteroatoms in the cage as well as the initial carboanalogous structure are retained in all the transformations under consideration.

1. S → O transformations

Solvolysis of 9-bromo-1,3,5,7-tetramethyl-2,4,6,8-tetrathiaadamantane **1** in 50%–92% aqueous acetic acid affords a debromination product, 2-oxa-4,6,8-trithiaadamantane **2** with a different system of heteroatoms. In addition to **2**, the reaction yields a number of compounds in which the initial structure is retained, namely, debromination product **3** and solvolysis product **4**, and derivatives with the protoisomer structure, namely, hydrolysis product **5** and dehydrobromination product **6**.

Uspekhi Khimii **66** (11) 1015–1024 (1997); translated by Z P Bobkova

The proportion of the compound **2** in the product mixture depends on the concentration of acetic acid, the highest content (56%) being attained in 90% acid (Table 1). It is noteworthy that solvolysis of the bromide **1** in 50%–90% formic acid also yields **2**; however, in this case, the proportion of **2** in the product mixture does not exceed 5%.^{10,11}

Table 1. Acid solvolysis of the bromide **1** under various conditions.

Acid concentration (%)	Composition of the reaction products (%)			
	2	3	4	5, 6
MeCOOH				
92	54	37	9	—
90	56	34	6	—
80	40	34	26	—

50	2	36	55	—

A probable scheme for this transformation includes fragmentation with the abstraction of SBr^- and subsequent cyclisation of the unsaturated bicyclic intermediate **7** induced by H_2O and leading to the incorporation of oxygen into the skeleton.

It should be noted that the compound **2** is formed as a side product in the synthesis of 1,3,5,7-tetramethyl-2,4,6,8-tetrathiaadamantane **3** by condensation of acetylacetone with hydrogen sulfide in concentrated HCl. Condensation of these compounds in glacial acetic acid affords **3** as the only product.¹²

Transformations of 4-hydroxy-derivative **9** are also accompanied by skeletal rearrangements in which the sulfur atom is replaced by oxygen (Scheme 1). The compound **9** is prepared from thioketone **8** having a pentacyclo[6.2.1.0^{2,7}.0^{4,10}.0^{5,9}]un-decane structure by reduction with NaBH_4 , which is accompanied by transannular cyclisation. When LiAlH_4 is used instead of NaBH_4 , the reaction gives isomeric thiol **10**, in addition to **9**. The compound **9** does not isomerise to **10** under the action of LiAlH_4 ; however, this isomerisation easily occurs upon sublimation of **9** and upon treatment of **9** with methyl iodide in acetone. In the latter case, thiomethylation product **11** is formed together with the thiol **10**. This isomerisation also occurs during the thermolysis of **9** in acetic acid; this gives a mixture of the thiol **10** and bicae sulfides **12a** and **12b** in a ratio of 2 : 1.

The same skeletal transformation accompanies oxidation of the compound **9** with H_2O_2 (1–10 mol) in MeCOOH leading to bicae disulfide **13**, disulfoxide **14** and sulfone **15**. It is noteworthy that each of these compounds is formed as a mixture of two diastereomers **a** and **b** (Scheme 1).¹³

A possible scheme for the above transformation includes the intermediate formation of an open (with respect to the internal thioacetal **9**) form **16**, which is followed by transfer of the chelating proton from sulfur to oxygen, which might lead to

Scheme 1

13: R = SS; **14:** R = SOSO; **15:** R = SO₂.

intermediate **17**. The 'open' hydroxy-thione **18** thus formed is then converted into the corresponding cyclic form, the thiol **10**.

The bicae sulfide **12** results most likely from the interaction of the intermediate **18** with the thiol **10** accompanied by elimination of H_2S . The formation of the compounds **13**–**15** can be rationalised, in turn, in terms of a scheme including isomerisation of **9** to **10** followed by a series of consecutive oxidation stages, **10** → **13** → **14** → **15**. The formation of the latter compound is accompanied by the abstraction of SO_2 .

2. N → O transformations

Skeletal transformations with replacement of heteroatoms are also typical of compounds with a bird-cage structure containing a nitrogen atom in the cage. For example, isomerisation of hydroxy-derivative **20** into amino-derivative **21** readily occurs in the presence of LiAlH_4 . When the same reagent is used to reduce imino ketone **19**, the reaction is accompanied by transannular cyclisation and also gives rise to the compound **21**, whereas reduction of the imino ketone **19** with NaBH_4 yields only **20** (Scheme 2).^{14–16} Apparently, a transformation of this sort also occurs during reductive amination of some cage diketones (3,6-diones **22**–**24**) under the action of formamide in formic acid, which is accompanied by transannular cyclisation (Scheme 3).¹⁷ These reactions involve one carbonyl group and afford the corresponding bird-cage primary and secondary amines **25**, **27**–**29** with an oxygen atom in the cage. Secondary amine **26**, which contains fragments of the initial structure and which is formed from the diketone **22** when the reaction is conducted under mild

Scheme 2

conditions, provides an exception. The fact that the amines **26** and **27** give rise to the same hydrochloride **30** implies that hydrochlorination of the former compound is accompanied by transannular cyclisation and isomerisation.

Scheme 3

The compounds **25** and **27–29** are internal hemiacetals; the corresponding open derivatives are imino alcohols **25a** rather than amino ketones like **31a**, the formation of which should have been expected in the above reactions.

Using the formation of **25** and **27** as an example, it has been shown that the reductive amination of the 3,6-dione **22** is accompanied by isomerisation; most likely, formamido ketone **32** isomerises to give formimino alcohol **33** (Scheme 4). Apparently, the transformation **32** → **33** occurs similarly to the corresponding isomerisation of sulfur-and-oxygen-containing analogues described above.¹⁷

Scheme 4

The data presented here indicate that cage compounds with an oxa-bridge are formed preferentially under these conditions. Probably, this is due to the fact that oxygen endows lesser strain to the rigid bird-cage structure than sulfur or nitrogen. Hence, the S → O and N → O type transformations discussed here result in the formation of compounds with a less strained heteroanalogous structure.

III. Skeletal transformations with replacement of oxygen by carbon or of carbon by oxygen

Some transformations of heterocage compounds of the O → C and C → O types have been described; these processes give rise to derivatives with carboanalogous structures containing one oxygen atom more or less in the cage than the initial compound.

1. 'Oxadithiaadamantane → dithiaadamantane' transformation

Treatment of 1-hydroxy-3,5,7-trimethyl-2-oxa-4,6-dithiaadamantane **34** with Bu^tONa in pyridine and then with an acid results in its partial isomerisation to give the dihydroxy-derivative of 3,5-dimethyl-2,4-dithiaadamantane **35**. The proportion of this compound in the mixture of reaction products amounts to 20%–25%.

A possible mechanism of this isomerisation includes base-induced ionisation of the compound **34** and subsequent rupture of two bonds; the resulting anion **36** cyclises according to the aldol condensation pattern.¹⁸

2. C → O transformation

The conversion of the C → O type accompanies the transformation of 1,7,8,11-tetrachloro-ketone **37** having the bird-cage structure and containing one oxygen atom in the cage induced by 25% aqueous NaOH into acid **38** having the bird-cage structure with two oxygen atoms in the cage (yield 66.5%). This acid can be regarded as an abnormal product of the Favorsky rearrangement. If the reaction is carried out in an organic solvent (benzene, THF), it gives rise to another abnormal product, namely, tetrachloro-substituted carboxylic acid **39** with the 11-oxapentacyclo[6.2.1.0^{2,7}.0^{4,10}.0^{5,9}]undecane structure (yield 80.2%). The normal product of the Favorsky rearrangement, acid **40** having a substituted bishomocubane structure, is not formed under the conditions studied. When the acid **39** is refluxed in aqueous KOH, it is converted into the acid **38**, while heating of **39** in aqueous methanol gives rise to lactone **41**. When the latter is kept in aqueous KOH, it is also converted into the compound **38** (Scheme 5).

Scheme 5

The **37** → **38** transformation occurs most likely by a mechanism that includes formation of the lactone **41**.¹⁹

Presumably, the C → O transformation under discussion results in the formation of a less strained structure, because the –O– bridge imparts lesser strain to the rigid bird-cage framework than a carbonyl group incorporated into its 'wing'. At the same time, the resulting structure with two oxygen atoms is certainly less strained than the structure of the bishomocubane oxadervative.

According to the above mechanism, the product **38** is formed without participation of the oxygen bridge already present in the cage. This is confirmed by the occurrence of a similar transformation in the series of carbocage α -halo-ketones. For example, ketone **42** with a homocubane, pentacyclo[4.3.0.0^{2,5}.0^{3,8}.0^{4,7}]-nonanone, structure was converted, depending on the reaction conditions, into chloro-derivative of oxacubanecarboxylic acid **43** or chloro-derivative of secocubanecarboxylic acid **44** (Scheme 6). The **44** → **45** → **43** transformations were also accomplished. In this case, too, no normal Favorsky rearrangement product was obtained.²⁰

Scheme 6

Unlike the tetrachloro-ketone **42**, octachloro-ketone **46** with the same structure is converted under similar conditions only into the octachloro-derivative of secocubanecarboxylic acid.²¹

In many other reactions of cage α -halo-ketones, α -halo-diketones and corresponding ketals, no C → O transformation products have also been obtained.^{21–24} The results presented here make it possible to conclude that the C → O type transformation is peculiar only to those pentacyclic α -halo-ketones in which the structure of the cage and the number and arrangement of halogen atoms ensure additional stabilisation of the corresponding anion.

In addition to the cage (oxa)pentacyclanes discussed above, some 2-substituted adamantanes also undergo this type of transformation. For example, when adamantan-2-ol **47** and its 2-methyl-derivative **48** are exposed to UV radiation in CCl₄ or benzene in the presence of an HgO–I₂ mixture, 2-oxaadamantane **49** is formed in a yield of 43%–47%.^{25,26}

R = H (**47**), Me (**48**).

Reactions of these compounds with other oxidants are not accompanied by a skeletal transformation of this type and yield mostly oxahomoadamantane, 4-oxatricyclo[4.3.1.1^{3,8}]undecane, derivatives.^{27–29}

IV. Skeletal transformations of oxacage compounds accompanied by the loss of oxygen and a change in the carbon skeleton

In this Section, we consider reactions of oxacage compounds with electrophiles accompanied by extensive rearrangement of the skeleton. This rearrangement includes opening of the oxygen bridge, loss of the hetero-function and further skeletal transformations resulting in the formation of the corresponding carbocage stabilomer structure.

1. Transformations of the ‘oxahomoadamantane → adamantane’ type

On treatment with H₂SO₄ or hydrohalic acids, compounds of the oxahomoadamantane series with oxygen-containing substituents undergo a skeletal transformation yielding functional-substituted adamantane derivatives: C₁₀-tricyclic stabilomers. This transformation is typical of lactone **50**, 2-hydroxy-lactone **51**, 2-hydroxy-lactam **52** and some other compounds. For example, at 90–100 °C in the presence of 50%–80% H₂SO₄, the lactone **50** isomerises into 2-hydroxyadamantan-4-one **53**, which is formed as a mixture of *syn*- and *anti*-isomers in a ratio of 5 : 1.^{30–33} When this reaction is carried out in CCl₄, it gives the product of isomerisation and chlorination, 2-chloroadamantan-4-one **54** (Scheme 7).³⁰ By treatment with 50% H₂SO₄, the hydroxy-derivative **51** has been converted into adamantane-2,4-dione **55** in 22% yield; the reaction of **51** with 57% HI gives 2-iodoadamantan-4-one **56**.³³ The hydroxy lactam **52** reacts with the above reagents to give the same products but in lower yields than the compound **51**; in addition, compounds with non-rearranged structures are formed.³⁴

X = O (**51**), NH (**52**).

The mechanism of these transformations presumably includes fragmentation and cyclisation stages.

The reactions of individual stereoisomeric 2- and 7-bromo-lactones **57a,b** and **58a,b** with 48% HBr give rise to adamantanone derivatives including stereoisomeric 4-bromides **59a,b**, 4,10-dibromides **60a,b**, 4,8-dibromides **60c,d**, 4a,9e-dibromide **60e**, adamantane-2,4-dione **55** and 4a-hydroxy-10e-bromide **61**. The selectivity of the reaction, the array of reaction products and their proportions in the mixture depend substantially on the positions and spatial arrangement of the substituent in the starting bromo-lactones (Scheme 8).

Scheme 8

These results are due to the fact that fragmentation can follow either a reductive (type A) or non-reductive (type B) pathway as shown for the bromo-lactone **57**. In this case, pathway A predominates. In the case of the bromo lactones **58a,b**, the fragmentation occurs only by pathway B.³⁵

It should be mentioned that the isomeric bromoadamantanones are able to undergo interconversions.³⁶

The transformations under consideration also accompany the reactions of 2-hydroxy-5,5-dimethyl-4-oxahomoadamantane **62** with HBr and HI, which lead to the corresponding 2-halo-4,4-dimethyladamantanes **63** and **64** formed as mixtures of *syn*- and *anti*-isomers.³³

It is noteworthy that the compound **62** undergoes this type of transformation with the loss of oxygen from the cage only under the action of 'hard' reagents. The reactions with 'softer' reagents are accompanied by another skeletal transformation, namely, oxahomoadamantane → oxaadamantane rearrangement. Thus on treatment with 60% H₂SO₄, the compound **62** isomerises into *anti*-4-hydroxy-1-isopropyl-2-oxaadamantane **65**, while the reaction with hydrochloric acid yields a mixture of isomeric chlorides **66** in a ratio of 1 : 1, and the reaction with thionyl bromide gives bromide **67**.³³ This rearrangement also accompanies the reaction of 2-iodo-2-iodomethyloxahomoadamantane **68** with HCl in DMF resulting in the formation of methyl 2-oxaadamantyl ketone **69**^{25–28} and the oxidation of hemiacetal **70** having an oxahomoadamantane structure with the HgO–I₂ system under UV radiation, which gives rise to 2-oxaadamantane.²⁵

2. 'Bird-cage → trishomocubane' skeletal transformation

Treatment of bird-cage compounds containing an oxygen atom in the cage or their homologues with some electrophilic reagents results in an extensive skeletal rearrangement leading to compounds with the structure of trishomocubane, *i.e.* pentacyclo[6.3.0.0^{2,6}.0^{3,10}.0^{5,9}]undecane. This compound is the stabilomer in the series of cage C₁₁-pentacyclanes.⁹ Compound **71** and its 3-substituted derivatives **72**–**74** were converted into polyiodo- and hydroxyiodo-derivatives of trishomocubane by the reaction with Me₃SiI. The reaction affords one of the above derivatives or their mixture depending on the nature of the substituent and the duration of the process. For example, after 12 h, the compound **71** was converted into 7-hydroxy-11-iodo-derivative **75** in a 48% yield, whereas after 150 h, 7,11-diiodo-derivative **76** was obtained in a yield of 73%.³⁷ The same reaction of methyl-substituted compound **72** gave rise to a mixture of 7-hydroxy-11-iodo-1-methyl-substituted product **77** and 7,11-diiodo-1-methyl-substituted derivative **78**; the compound **73** containing a phenyl group was converted only into 7-hydroxy-11-iodo-1-phenyl derivative **79** under the same conditions. Finally, the 2-hydroxyethyl-substituted compound **74** gave 1-(2-iodoethyl)-7,11-diiodo-derivative **80** in 30% yield.³⁸

71, **75**, **76**: R = R' = H;
72, **77**, **78**: R = R' = Me;
73, **79**: R = R' = Ph;
74: R = (CH₂)₂OH; **80**: R' = (CH₂)₂I.

The compounds **71**, **81** and **82** undergo a similar skeletal rearrangement under the action of glacial acetic acid in the presence of a catalytic amount of 98% H₂SO₄. In the case of **71**, 7,11-diacetoxytrishomocubane **84** is formed in 15% yield,³⁹ while **81** has been converted into diacetate **85** with the structure of bismethanotwistane, pentacyclo[7.3.0.0^{2,7}.0^{3,11}.0^{6,10}]dodecane, in 24% yield.⁴⁰ The same transformation of the (–)-6-carboxymethyl derivative **82** leads to (–)-2-carboxymethyl-7,11-diacetoxytrishomocubane **86**.^{41, 42}

71, **84**: R = H, *n* = 1;
81, **85**: R = H, *n* = 2;
(–)-**82**, (–)-**86**: R = CH₂CO₂H, *n* = 1.

Under similar conditions, a mixture of *syn*- and *anti*-epimers of 12-hydroxy-derivative **83** has been converted into a mixture of epimeric 7,11,12-triacetoxytrishomocubanes **87**.⁴³

The mechanism of this rearrangement, which has been discussed in relation to **71**, includes the formation of the protonated ether **88**, which undergoes a nucleophilic attack by MeCOOH to give intermediate **89**. The latter undergoes a skeletal rearrangement with opening of the four-membered ring, similar to the corresponding rearrangement in the series of the carbo-analogue, which results in the formation of the trishomocubane structure (Scheme 9).³⁹

Compounds with the bird-cage structure containing an oxygen atom in the cage and related compounds are formed from derivatives of pentacyclo[6.2.1.0^{2,7}.0^{4,10}.0^{5,9}]undecane and its homologues, as has been shown for the compound **71**. Thermodynamically controlled isomerisation of bird-cage derivatives makes it possible to prepare di- and tri-substituted trishomocubanes the syntheses of which are described in this Section.^{44–50} Of the two alternative routes mentioned above, it is the synthesis based on bird-cage compounds with an oxygen atom in the cage

Scheme 9

(the so-called modified Barborac method) that proved to be more convenient from the preparative viewpoint, because none of its steps yields side products or mixtures of isomers. Therefore, this method has found application in the preparation of key synthons for the syntheses of optically active organic molecules with *T*-symmetry and a known absolute configuration.

For example, by a series of transformations of bird-cage compounds, including preparation of ($\pm$)-hydroxytrishomocubane **90**, the synthesis of (+)-D₃-trishomocubane **91** and (+)-D₃-trishomocubane **92** has been accomplished.^{51, 52}

The compound **86** obtained by this skeletal rearrangement has served as a key intermediate in the synthesis of 2-substituted trishomocubane derivatives, namely, acid chloride (–)-**93** and ethynyl bromide (+)-**94**. The reaction of the former with 1,3,5,7-tetrakis(hydroxymethyl)adamantane **95** has given rise to compound (–)-**96**,⁴² whereas the latter reacts with 1,3,5,7-tetra(ethynyl)adamantane **97** to give compound (+)-**98**.^{53, 54}

Optically active (+)-triketone **99** with the trishomocubane structure was synthesised from a mixture of epimeric 7,11,12-triacetates **87**,⁵¹ while the diacetate **85** was converted into (+)-D₂-bismethanotwistane **100**.⁴⁰

V. Syntheses based on boraadamantanes accompanied by rearrangements involving the boron atom

Cage derivatives of boron can be used as key intermediates in the syntheses of compounds of the adamantane series including aza- and oxa-derivatives.^{55, 56} The transition from bora-containing compounds to other structures is accomplished *via* skeletal rearrangements. Various types of transformations are known, including those in which the boron atom is replaced by a nitrogen or carbon atom or in which the bridging boron atom is displaced from the cage.

The skeletal rearrangement of the B → N type is the key stage in the transformation of compounds **101**–**104** of the 1-boraadamantane series into 1-azaadamantane **109** and its alkyl derivatives **110**–**112**, which are difficult to prepare by any other method. For example, iodination of the tetrahydrofuran complexes **101**–**104** in the presence of NaN₃ followed by oxidation of intermediate compounds by the NaOH–H₂O₂ system gives rise to mixtures of isomeric amino alcohols **105**–**108** with the 3-azabicyclo[3.3.1]nonane structure; cyclisation of these products in the presence of SOCl₂ affords the corresponding compounds **109**–**112** in an overall yield of 15%–40%.^{57–59}

101, 105, 109: $\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{H}$;
102, 106, 110: $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{R}^3 = \text{H}$;
103, 107, 111: $\text{R}^1 = \text{R}^2 = \text{H}$, $\text{R}^3 = \text{Me}$;
104, 108, 112: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{R}^3 = \text{Me}$.

A possible mechanism for this reaction accompanied by a skeletal rearrangement, which is considered in relation to the compound **101**, includes fragmentation with cleavage of one of the B–C bonds and formation of 3-azido-7-iodomethyl-3-borabicyclo[3.3.1]nonane **113**. The latter reacts with excess NaN_3 to give diazide **114**, which undergoes thermal 1,2-anionotropic rearrangement and subsequent cyclisation to give 2-azido-1-aza-2-borahomoadamantane **115**. This is followed by fragmentation accompanied by the loss of boron and yielding the compound **105**.

The B $\rightarrow$ N transformation has also been observed in the amination of 1-boraadamantane with alkylchloroamines. *N*-Alkyl-derivatives of 3-azabicyclo[3.3.1]nonane (**116–119**) were obtained in this way. On treatment with SOCl_2 , the *N*-ethyl-substituted compound **117** cyclises to give quaternary salt **120**; its subsequent fragmentation leads to the 1-azaadamantane **109**.^{60, 61}

$\text{R} = \text{Me}$ (**116**), Et (**117**), Pr (**118**), Bu (**119**).

Carbonylation of 1-boraadamantane derivatives **101, 121** and **122** in the presence of ethylene glycol is accompanied by skeletal transformation in which the boron atom is replaced by a carbon atom. The oxidation of the resulting ethylene glycol ester of 1-adamantylboronic acid **123** (or the corresponding derivatives) affords compounds of the adamantane series. Thus the compound **101** was converted into adamantan-1-ol **124** in 78% yield, the 4-chloro-derivative **121** gave the 4-chloro-1-hydroxy-derivative **125** (in a low yield) and the reaction of etherate **122** resulted in the formation of 1-hydroxy-3,5-dimethyladamantane **126** (yield 95%).^{62, 63} It should be noted that the **101** $\rightarrow$ **124** transformation can also be accomplished using the $\text{KCN} - (\text{CF}_3\text{CO})_2\text{O}$ system.⁶²

$\text{R} = \text{H}$ (**101, 124**), Cl (**121, 125**).

Treatment of the carbonylation products **123** with dichloromethylithium affords chloride **127**. When this product is treated, without isolation, with methylithium, it is converted into compound **128**, oxidation of which yields 1-(1-hydroxyethyl)adamantane **129**.⁶⁴

Based on this skeletal transformation of 1-boraadamantane **101**, a new method for the synthesis of remantadine **130**, a known antiviral drug, has been developed. 1-(1-Aminoethyl)adamantane **131** was obtained in a yield of 38% with respect to the initial boraadamantane **101**. The salt **130** was prepared by treating the free base **131** with HCl in ether.⁶⁴

Complexes of cage boratrimethylsilyl compounds with lithiumalkyls are capable of reducing (by hydride transfer) some types of organic compounds; this reaction is accompanied by rearrangement of the boratrimethylsilyl cage. This rearrangement in which the boron atom is removed from the cage makes it possible to proceed from 2-methyl-2-boraadamantane **132** to 1-hydroxynoradamantane **133**.⁶⁵

VI. Conclusion

It follows from the reactions considered above that skeletal transformations typical of functionally substituted cage heterotricyclanes and heterohexacyclanes are quite diverse and can be induced by various reagents under mild conditions. The reactions of functionally substituted thia- or aza-cage compounds accompanied by cage rearrangements and by replacement of the sulfur or nitrogen atom by oxygen give rise to compounds with the oxacage skeleton, which is less strained than the initial structures. Oxacage derivatives, in turn, can be converted under certain conditions into the corresponding stabilomer carbocage structures.

Thus, the information presented in this review not only considerably supplements the general scheme of known skeletal modifications of cage compounds, but also markedly extends the views about the synthetic potential of the rearrangements of hetero(poly)cyclanes leading to the replacement, introduction or removal of the hetero-function.

VII. Selenacyclophanes and selenium-containing crown ethers	943

Abstract. The literature data, mainly of the last ten years, on the synthesis, reactions, and practical utilisation of selenium-containing heterocycles are analysed, treated systematically, and surveyed. The bibliography includes 516 references.

I. Introduction

Organoselenium compounds have continued to attract the attention of a wide range of investigators owing to a series of their unique properties. At the Second International Symposium on the Chemistry and Biochemistry of Organic Compounds of Selenium and Tellurium, it was noted that the deficiency of selenium in the human and animal organisms constitutes the basis of various chronic diseases, in particular the necrosis of the liver.^{1,2} There are data showing that organoselenium compounds are capable of sensitising processes in the living organism,³ which includes the inhibition of anomalous oxidation processes with the aid of the Se^{2–} containing glutathioneperoxidase active group.¹ Four proteins containing a selenium atom are known among natural products.⁴ Therefore, despite the high toxicity of many selenium compounds,^{5–7} antitumour,^{8–10} anticancer,^{11,12} and other medicinal preparations,^{13–21} as well as biologically active substances exhibiting antiviral,^{22–26} antimicrobial,^{27–30} antiarrhythmic,³¹ and fungicidal^{32–36} activities have been produced on the basis of organic derivatives of selenium. Furthermore, superconducting materials³⁷ as well as dyes,^{38–48} including those suitable for electrophotography,^{49–53} have been prepared on their basis.

Heterocycles containing a selenium atom occupy a special place among organoselenium compounds. Although numerous reviews on various aspects of the chemistry of organoselenium compounds have been published during the last ten years,^{54–74} the survey of literature data on organoselenium heterocycles is restricted to pre-1985.^{74–77} It therefore appears useful to analyse

the data on selenium-containing heterocycles, concentrating attention on studies of recent years.

The size of the heterocycle and not the method of synthesis has been selected as the criterion for the systematic arrangement of data on selenium-containing heterocycles. To achieve a more compact exposition and to eliminate the possibility of duplicating data, the chemical and other properties of the compounds considered are quoted together with the methods of their synthesis.

II. Three-membered heterocycles

1. Seleniranes

Until recently, seleniranes (episelenides) had not been obtained in a pure form, in contrast to their sulfur analogues (thiiranes),⁷⁸ although their formation in the flash photolysis of CSe₂ had been reported,^{79–81} which was confirmed in a mass-spectrometric study.⁸² Later the formation of seleniranes as intermediates was postulated in reactions involving the specific conversion of oxiranes,^{83–86} the cyclisation of *para*-substituted allyl phenyl selenides,⁸⁷ the conversion of bromohydrins into alkenes on treatment with potassium selenocyanate⁸⁸ or of 1,2-dibromethane into ethene in the presence of the selenodithiocarbonate anion,⁸⁹ and in the desulfurisation of thiiranes with 3-methyl-2-selenoxobenzothiazole.⁹⁰ The decomposition of the intermediate seleniranes with liberation of selenium was noted in all the examples quoted above. It was not until the end of the 1990s that reports of the synthesis of substituted seleniranes by the alkylation of heterocyclic selenones **1** and the subsequent transformation of the selenides **2** into substituted seleniranes **3**^{91,92} or by the interaction of the azoles **4** with selenium and epichlorohydrin with formation of the seleniranes **5**⁹³ appeared although without the specification of experimental data.

R = Alk, Ar; R¹ = H, Me; X = CR, N; Y = NR, S; Hal = Br, I.

2. Seleniranium salts

The formation of seleniranium (episelenonium) salts as intermediates has been noted in a series of studies,^{94–104} but it was not until 1986 that data concerning the synthesis of the stable episelenonium salt **6** as a result of the treatment of 1,2-dimethyl-acenaphthylene **7** with PhSeCl in the AlCl₃–SOCl₂–CH₂Cl₂ system at –80 °C were published.¹⁰⁵ According to X-ray (XRD) data, a characteristic feature of the structure of the episelenonium ring in the salt **6** is the appreciable lengthening of the Se⁺–C bond compared with the corresponding bonds in trimethylselenonium,¹⁰⁶ which causes their lower stability. It has also been shown that the benzene and acenaphthene rings in the salt **6** are in the *cis*-position not only in the solid state but also in solution.

III. Four-membered heterocycles

1. Selenetanes

Unsubstituted selenetane was first obtained in a low yield in 1930¹⁰⁷ by treating 1,3-dibromopropane with alkali metal selenides. Selenetane readily polymerises and can be stored only at reduced temperatures in the dark. 3,3-Dimethylselenetane **8** is more stable (up to 140 °C),^{108, 109} whereas its dibromo-derivative **9** is stable only at temperatures below –20 °C; when the temperature is raised, the selenetane ring is opened.^{108, 110}

Selenetan-3-ol **10** is a stable compound. It is formed in 58% yield as a result of the reaction of epichlorohydrin with hydrogen selenide at 60 °C in the presence of tin chloride or toluene-*p*-sulfonic acid¹¹¹ or on decomposition of the salt Hg(II) 1,3-diselenylpropan-2-olate.¹¹² Treatment of the selenetan-3-ol **10** with acetic anhydride leads to the acetate **11**.¹¹⁰

The substituted selenetane **12** is obtained by means of a scheme involving in the first stage the alkylation of the heterocyclic selenone **13** with formation of the selenide **14**, which affords benzimidazo[2,1-*a*]selenazolidine **15** on iodocyclisation. As a result of a series of reactions, involving quaternisation and recyclisation, compound **15** gives rise to the selenetane **12**.¹¹³

The pentacarbonyltungsten complexes of the selenetane **16** are formed when complex **17** is treated with an excess of vinyl ethers.^{114, 115} Complex **16** reacts with an excess of selenocyanate already at –40 °C in the course of several minutes with formation of the diselenolanes **19**. The structure of one of them (R = R' = Me) has been confirmed by XRD data.¹¹⁵

R = H, R' = Et; R = R' = Me.

2. Oxaselenetanes

Four-membered heterocycles containing one oxygen atom and one selenium atom (oxaselenetanes) are known intermediates in the oxidation reactions of exocyclic alkenes by means of SeO₂/H₂O₂.¹¹⁶ The bicyclic 1,3-oxaselenetane derivative **20** was obtained by refluxing 2,2,4,4-tetramethyl-1,5-diphenylpentane-1,5-dione monohydrazone **21** with Se₂Cl₂ in the presence of triethylamine.^{117–119} The reaction proceeds *via* a stage involving the formation of the 1,3,4-oxadiselenolane **22**, the treatment of which with P(NMe₂)₃ or PPh₃ leads to a 1 : 1 mixture of oxaselenetane and benzosuberone derivatives **20** and **23** respectively.

After refluxing the reaction mixture for 10 h, the substituted selenacyclohexane **24** is also formed.¹¹⁹

3. Thiaselenetanes

Among four-membered heterocycles containing sulfur and selenium atoms, the thiaselenetane **25**, formed on treating divinyl sulfone with SeBr_4 , is known.¹²⁰

4. Diselenetanes

Many examples of four-membered heterocycles with two selenium atoms are known. Thus 3,4-bis(trifluoromethyl)-1,2-diselenetane has been obtained in 25% yield on pyrolysis of a mixture of bis(trifluoromethyl)ethyne and selenium.^{121,122} 1,3-Diselenetanes are synthesised by various methods: the pyrolysis of 1,2,3-selenadiazole¹²³ and the reactions of dimethyl malonate with CSe_2 ,¹²⁴ of acetylacetone with SeCl_4 ,¹²⁵ of acetyl chloride with H_2Se and AlCl_3 ,¹²⁶ and of hexafluoroacetone with triphenylphosphine selenoxide.¹²⁷

It has been observed recently that the reaction of the lithium enolate of camphor with selenium and subsequent treatment of the reaction mixture with methyl iodide lead to a mixture of the *syn*-(32%) and *anti*-(10%) isomers of 1,3-diselenetane **26** together with methyl selenide **27** (12%) and the diselenoacetal **28** (15%).¹²⁸ The structure of the *anti*-isomer **26** was confirmed by XRD.

IV. Five-membered heterocycles

The vast majority of studies on the chemistry of selenium-containing heterocycles have been devoted to five-membered heterocycles owing to their relative resistance to the action of various kinds of reagents (by virtue of their aromaticity, the small Bayer strain, and the absence of Pitzer strain) as well as their great practical importance.

Compounds with the properties of semiconductors,^{129,130} polymethine dyes,^{131–134} photosensitisers,^{135–144} as well as substances exhibiting various types of biological activity (antimicrobial,¹⁴⁵ antiviral,¹⁴⁶ antitumour,^{147–150} glutathioneperoxidase,¹⁵¹ spasmolytic,^{152,153} antiallergic,¹⁵⁴ antiherpetic,¹⁵⁵ and fungicidal^{156–158}) are known among derivatives of this class.

1. Five-membered heterocycles with one heteroatom

a. Selenophenes

Selenophene and its derivatives have been most thoroughly investigated among five-membered selenium-containing heterocycles. The continued interest in selenophene has been reflected periodically in published reviews.^{159–162}

Fairly numerous new methods of synthesis of selenophene and its derivatives have been developed during the last decade. One of them involves the interaction of acetylene and its derivatives with elemental selenium. Selenophene has been obtained in this way in 30% yield¹⁶³ together with its derivatives **29** (4%)¹⁶⁴ and **30** (87%).¹⁶⁵

Selenophene may be obtained in 85% yield by the reaction of acetylene with dimethyl selenide in the gas phase¹⁶⁶ and also by treating diacetylene with sodium selenide in methanol (yield 44%).¹⁶⁷ In addition, it has been shown that 2% of selenophene is also obtained on heating dimethyl selenide in a quartz tube at 470 °C.¹⁶⁸

The interaction of sodium hydroselenide with diethynes **31** results in the formation of 2,5-disubstituted selenophenes **32** in quantitative yields.¹⁶⁹

On interaction with selenium tetrabromide, unsubstituted acetylene affords a mixture of bromine-substituted selenides, including selenophene dibromide **33**.¹⁷⁰

Other unsaturated compounds have also found application in the synthesis of selenophenes. Thus buta-1,3-diene reacts with selenium dioxide in the presence of Zeokar 2 as the catalyst with formation of selenophene in 45% yield.¹⁷¹ 3,4-Dimethylselenophene is formed in up to 80% yield from 2,3-dimethylbuta-1,3-diene on interaction with powdered selenium in the presence of sand or glass fragments at 450 °C under a nitrogen atmosphere.¹⁷²

The synthesis of functionally substituted selenophenes **34** on interaction of the nitrile **35** with alkaneselenols **36** has also been reported.¹⁷³

R = Ac, PhCO, CN, NO₂, CHO, COOH, CO₂Et.

The method of synthesis of substituted selenophenes **37** by the dehydration of selenolanediols **38** has been described.¹⁷⁴ The diols were obtained in accordance with the following scheme: the interaction of selenium oxychloride with the ketones **39** to form the chlorinated selenides **40** which are readily reduced by sodium thiosulfate in benzene to the selenide **41**, and subsequent treatment with TiCl₄ and Zn in tetrahydrofuran (THF) at 0 °C.

R¹ = Ar, Het; R² = H, Me.

The transformation of furan and thiophene into selenophene on treatment with hydrogen selenide or elemental selenium, used for the synthesis of 2,3-dihydroselenophene **42**, is well known.¹⁷⁵

The mechanism of this reaction has been investigated relatively recently. It has been established in relation to the interaction of the furans **43** with hydrogen selenide that the reaction proceeds *via* a mechanism involving specific acid catalysis including a stage with a doubly protonated substrate.^{176, 177}

R = H, Me.

3,4-Di(*tert*-butyl)selenophene **44** has been obtained in 21% yield by treating 3,4-di(*tert*-butyl)thiophene 1,1-dioxide **45** with powdered selenium in benzene in an autoclave at 210 °C.¹⁷⁸

b. Selenolanes

A simple method of synthesis of selenolane **46**, by refluxing 1,4-dibromobutane with sodium selenide under a nitrogen atmosphere under the conditions of phase-transfer catalysis, has been developed. Alkyl(C₈–C₁₀)ammonium chlorides were used as the catalysts.¹⁷⁹

2-Methylselenolane **47** has been obtained¹⁸⁰ in two ways. The refluxing of 1,4-dibromopentane with a 1 : 1 mixture of Se and NaI in solution in the monomethyl ether of ethylene glycol leads to the diiodide **48** in 27% yield, which is reduced with NaBH₄ to 2-methylselenolane. The reaction of 1,4-dibromopentane with elemental selenium in alcohol in the presence of sodium tetrahydroborate under an argon atmosphere leads to compound **47** in 78% yield. Certain reactions of 2-methylselenolane have been investigated. Thus, on interaction with bromine in CCl₄, it gives rise to the dibromide **49**, while its interaction with SOCl₂ affords the dichloride **50** in 85% yield. Treatment of 2-methylselenolane **47** with MeI leads to compound **51** which on reaction with NaBPh₄ is transformed into the salt **52**.

The interaction of tetramethyleneselenonium bromide,⁵⁴ obtained from selenolane and bromine, with the alkenes **55** in acetonitrile at 20 °C leads to the β-bromoselenonium salts **53** in yields ranging from 50% to 75%.¹⁸¹ The reaction proceeds in accordance with the Markovnikov rule as stereospecific electrophilic addition with formation of *trans*-adducts.

55: C₅H₁₁CH=CH₂, , , .

The interaction of 3-nonylaluminacyclopentane **57** with elemental selenium on refluxing in benzene has been used in the synthesis of 3-nonylselenolane **56**.¹⁸²

A method based on the interaction of selenocarbonyl compounds **59** with cyclopentadiene has been proposed for the synthesis of bicyclic selenolane derivatives — selenabicycloheptenes **58**.^{183–187}

$\text{R}^1, \text{R}^2 = \text{H, Me, Ph, SiMe}_3$; $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_5$.

The interaction of 2-chloroethyl derivatives of the quinolines **61** with sodium hydroselenide in ethanol has been used in the synthesis of condensed derivatives of the selenolanes **60** containing a quinoline fragment; the yield of the selenolanes **60** then reaches 45%–58%.¹⁸⁸

$\text{R}^1, \text{R}^2 = \text{H, Me, OMe, Cl}$.

c. Condensed selenophenes

Substituted acetylenes, which give rise to both benzo- and naphtho-selenophenes on interaction with selenium tetrahalides, have been used successfully in the synthesis of condensed selenophenes. Thus a preparative method of synthesis of aminomethyl derivatives of benzo[*b*]thio(seleno, telluro)phenes **63** and their hydrohalides **64** has been developed on the basis of the interaction of chalcogen halides with 3-phenylpropynylamines **62**.¹⁸⁹ The reaction proceeds with formation of the intermediates **65**.

$\text{R}^1 = \text{H, Me, Et}$; $\text{R}^2 = \text{Me, Et}$; $\text{R}^1, \text{R}^2 = (\text{CH}_2)_5, (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$;
 $\text{X} = \text{S, Se, Te}$; $\text{Hal} = \text{Br, Cl}$.

The similar treatment of 3-(2-naphthyl) and 3-(1-naphthyl)-propionic acid derivatives with selenium tetrabromide leads to the substituted naphthoselenophenes **66** and **67**.¹⁹⁰

Ethene reacts with alkyl phenyl selenides at high temperatures ($480\text{--}600^\circ\text{C}$) to form benzoselenophene (yield 25%), selenophene, and other organo-selenium compounds.¹⁹¹

2-Biphenyl trifluoromethyl selenide **68** has been used to obtain the dibenzoselenophene salt **69**, which is readily converted into the corresponding dinitro-derivative **70**.¹⁹²

On heating with elemental selenium, 9-mercurofluorene **71** affords dibenzoselenophene **72**, which readily dimerises to the selenurane **73**¹⁹³ and the latter reacts with alcohols, thiols, and selenols in THF at -78°C under an argon atmosphere to form a mixture of products, one of which is dibenzoselenophene **72**.¹⁹⁴

$\text{R} = \text{Me, Et, Pr, Pr}^i, \text{Ph}$;
 $\text{X} = \text{O, S, Se}$.

A method of synthesis of the disubstituted dibenzoselenophene **74** via a scheme involving the oxidation of selenanthrene **75** and the reduction of the resulting selenoxide **76** to compound **77** has also been described. Treatment of the latter compound with sulfuric acid leads to the dioxide **74**. It has been established by NMR that the reaction proceeds via the dication **78**.¹⁹⁵

The Thorpe–Ziegler cyclisation of pyridine-series selenides **80** has been used successfully in recent years for the synthesis of functionally substituted selenopheno[2,3-*b*]pyridines **79**.^{69, 196–221}

R = H, Ar, Het, Alk, NH₂, CO₂Alk, OH, CN;
Z = CN, CO₂Alk, COAr, COHet, CONHAr, CONH₂.

d. Certain properties of selenophenes

The photochemical [2 + 2]cycloaddition of selenophene and 3,4-dimethylselenophene to maleimide with a 1 : 1 reactant ratio leads to the monoadducts **81** in quantitative yields.²²² When a twofold excess of maleimide is used in this reaction, the bisadducts **82** are formed in 60%–70% yields. According to ¹³C NMR data, they exist in the form of three stereoisomers: *syn-anti*, *anti-anti*, and *anti-syn*.

R = H, Me.

On interaction with dithienylmagnesium bromides **84**, the bromoselenophenes **83** afford the oligomeric heteroarylenes **85**.^{223, 224}

R¹, R², R³ = H, Me.

The alkylation of 2,3,5-trimethylselenophene **86** with chloromethyl methyl ether in the presence of zinc chloride has been investigated. The resulting chloromethyl derivative **87** is readily transformed into the nitrile **88**, which dimerises to the substituted ethene **89**. Treatment of the latter with KOH in aqueous EtOCH₂CH₂OH gives rise to the anhydride **90**, which on irradiation in

benzene at 20 °C affords a photostationary mixture with the deeply coloured cyclic form **91** capable of being fully and reversibly converted into the anhydride **90** on irradiation with light at a wavelength $\lambda > 520$ nm.²²⁵

2-Acetylselenophene oxime **93** reacts with ethyne to form a mixture of the bisheterocycles **94** (10%) and **95** (2%).²²⁶

The triene heterocyclic systems **97** have been obtained from 2,5-diacetylselenophenes **96** in 46%–71% yields in accordance with the following scheme:²²⁷

R = Ph,

The selenophene-substituted acrylonitriles **98** have been used successfully in the synthesis of the naphthopyrans **99**²²⁸ and the pyrazolopyrans **100** containing a selenophene ring.²²⁹

Z = CN, CO₂Et, CONH₂, CSNH₂.

2-Methyl-2,3-dihydroselenopheno[2,3-*d*]thiophene **101**, formed *via* the intermediate **102** on heating allyl 2-thienyl selenide **103**, is dehydrogenated to 2-methylselenopheno[2,3-*b*]thiophene **104**.²³⁰

The benzenoid–quinoid tautomerism, which is a thermodynamically controlled process, has been investigated in a series of substituted benzo[*b*]heterocycles **105**. These compounds can be used for the accumulation and transformation of solar energy.^{231, 232}

X = O, S, Se, Te; Y = O, S; R, R' = H, Alk, Ar.

Benzo[*b*]selenopheno[3,2-*d*]-1,2,3-selenadiazole **107** has been obtained in 82% yield by the reaction of benzo[*b*]selenophen-3-one semicarbazone **106** with SeO₂ in glacial acetic acid.^{233–235} Its sulfur analogue — benzo[*b*]selenopheno[3,2-*d*]-1,2,3-thiadiazole **108** — is formed on treatment with thionyl chloride of the semicarbazone **106** (yield 90%) or the ethoxycarbonylhydrazone **109** (yield 75%).^{234, 235} On treatment with an alcoholic solution of alkali, the selenadiazole **107** is converted in 94% yield into dibenzo[*b*]selenopheno[2,3-*b*:2',3'-e]-1,4-diselenine **110**, which is also formed as the sole product in the thermolysis of the selenadiazole **107** at 180 °C. On the other hand, if the selenadiazole **107** is heated at the same temperature in an autoclave in the presence of CS₂, then benzo[*b*]selenopheno[2,3-*d*]-1,3-thiaselenole-2-thione **111** is formed as the main reaction product (25%).^{234, 235}

The dependence of the transfer of the influence of the substituents in the five-membered sulfur- and selenium-containing heterocycles **112** and their annelated derivatives **113–115** on the position of the reaction centre, the nature of the heteroatom, and the type of annelation has been analysed with the aid of quantum-chemical methods and the empirical constants of the substituents.

X, Y = S, Se.

In the series of isomeric selenophenothiophenes **113**, **114** (X = S, Y = Se), and **115** (X = S, Y = Se; X = Se, Y = S), it has been demonstrated by the 'pseudoatoms' method that the increase in the yield of the product of substitution in the α -position of the selenophene fragment with increase in the size of the attacking electrophile is associated with the stabilising interaction, specific to heterocycles, between the heteroatom and the attacking electrophile in the σ -complex formation stage.^{236–238} The ⁷⁷Se chemical shifts in the series of isomeric selenophenothiophenes and thienothiophenes **113–115** have also been subjected to quantum-chemical analysis and correlations have been established between the shifts and the characteristics of the distribution of electron density obtained from quantum-chemical calculations.^{238–240}

2. Five-membered heterocycles with two heteroatoms

a. Selenazoles

A convenient method of synthesis of substituted selenazoles **116** is the interaction of the halo ketones **117** with compounds **118** containing a selenoamide fragment; the yields of the final products are then quantitative.^{241–248}

X = Cl, Br; R = Alk, Ar, Het; R' = NH₂, Alk, Ar.

A method based on the treatment of the phosphonium salts **120** with sodium hydrogen selenide has been used successfully in the synthesis of monosubstituted selenazoles **119**.^{249–253}

R = Alk, Ar, Het; X = Cl, ClO₄.

Sodium hydroselenide reacts with monochloroacetic acid and ethyl isothiocyanate to form the oxoselenazothione **121**. In the presence of a base, it interacts with aldehydes, forming the substituted oxothioselenazoles **122**, which are used in the synthesis of polymethine dyes.²⁵⁴

R = Ph, CH=CHPh, CH=CHC₆H₄NMe₂-4.

The five-membered heterocycle **123**, in which N, Se, and P atoms are present simultaneously, has been obtained in 26% yield as a result of the interaction of chloromethylisothiocyanatophosphonate with hydrogen selenide in benzene in the presence of an excess of triethylamine and subsequent treatment of the intermediate with MeI.²⁵⁵

It has been reported²⁵⁶ that the azoselenazole **125** is formed on oxidation of the hydrazinoselenazole **124** with a 30% solution of H₂O₂ in acetic acid, whilst refluxing in alcohol unexpectedly afforded the selenide **126**.²⁵⁶

The alkylation of 2-acetamidosenazolinones **127** with methyl iodide or dimethyl sulfate in the presence of a 20% KOH solution has been investigated.^{257, 258} When the reaction is carried out in ethanol in the presence of a tenfold excess of the alkylating agent, it involves the nitrogen atom of the selenazolidine with formation of compounds **128**, while in the case where dimethylformamide (DMF) is used as the solvent, only compound **129** is formed regardless of the amount of the initial alkylating agent.

R = H₂, PhCH, 4-NO₂C₆H₄CH, 4-MeOC₆H₄CH, 2-ClC₆H₄CH,

Methyl 4-methyl-2-phenyl-5-selenazolyl ketone **130**, obtained by the reaction of selenobenzamide **131** with 3-chloroacetylacetone, is brominated by *N*-bromosuccinimide with formation of the bromomethyl derivative **132**, which was used to obtain the condensed systems **133** and **134** containing the selenazole ring.²⁵⁹

b. Condensed selenazoles

The benzoselenazoles **135**, which are used in the manufacture of photographic materials and dyes, have been obtained by the reaction of *o*-aminophenols with carbon diselenide.²⁶⁰

R = H, Alk, Ar, Ac, CN, OH, NH₂.

The dioxonaphthoselenazoles **136** have been obtained in 54%–68% yield by the reactions of the corresponding amino-selenolates **137** with aldehydes probably *via* a stage involving the formation of the corresponding azomethines.²⁶¹

R = Alk, Ar, Het.

Among the chemical properties of benzoselenazoles, the ability of the 1,2-dimethylbenzoselenazolium cations **138** to condense with substituted salicylaldehyde to form the spiro-derivatives **139**²⁶² or with carboxylic acid anhydrides to form the selenocarboyanines **140** has been described.^{263, 264}

X = I, ClO₄, BF₄, OTs; R = H, Me, Et, CF₃, C₃F₇, Ph.

A promising method of synthesis of new condensed systems containing the selenazolidine ring **141**, involving the interaction of the selenols **142** with 1,2-dibromoethane, has been described.^{265, 266}

R = Me, R' = H; R-R' = (CH₂)₄.

The condensation of the chloroaminopyridine **143** or **144** with aromatic selenoesters **145** in the presence of BuLi in THF leads to satisfactory yields of the corresponding selenazolopyridines **146** or **147**.²⁶⁷

A general and convenient method of synthesis of selenazolopyridinium salts **148**, consisting in the cyclisation of substituted allyl 2-pyridyl selenides **149** on treatment with the halogens, has been developed.^{268–277} It has been shown that this reaction proceeds *via* an intramolecular electrophilic heterocyclisation mechanism and is a highly stereoselective process: *trans*-quaternisation with formation of a *cis*-junction. The stereoselectivity is ensured by the synchronicity of the interaction in the transition state of the donor (electron pair of the pyridine nitrogen atom) and the acceptor (the halogen molecule) with the multiple bond.

Hal = Br, I; R¹ = H, Alk, Ar, Het, OH, NH₂, CN; R², R³ = H, Alk, cyclo-Alk.

The substituted benzoisoselenazolones **150**, which possess a high antitumour activity, have been obtained in yields ranging from 20% to 60% by treating arylamides with butyllithium and powdered selenium at –40 °C.^{284, 285} On treatment with mercaptans, the benzoisoselenazole heterocycle of compound **150** (R = H) is ruptured with formation of compound **151**.²⁸⁶

The benzoisoselenazolones **152** have been obtained from substituted benzoic acids in accordance with the following scheme:²⁸⁷

Arylbenzoisoselenazoles **153** are formed when compounds **154** are irradiated.²⁸⁸

Irradiation (λ = 330–480 nm) of the pyrazoloselenone **155** leads to a complex mixture of products, from which the condensed isoselenazole **156** was isolated in 40% yield.²⁸⁹

The synthesis of isoselenazolopyrimidines **157** by treating the substituted uracils **158** with selenium dioxide in dioxane at 110 °C has also been reported.²⁹⁰

R¹, R² = Me, Et, Pri, Ph.

c. Oxaselenolanones

Two approaches to the synthesis of substituted 1,2-oxaselenolanones are known: the interaction of acetylene with elemental selenium in aqueous solution in the presence of tin chloride, which results in the formation of a mixture of seven selenium-containing products (one of them is 2,5-dimethyl-4-methylene-1,3-oxaselenolane **159**)²⁹¹ and the reaction of ω-bromoacetophenones with selenoamides leading to 1,3-oxaselenolanones **160**, characterised as the salts **161**.²⁹²

X = H, N(Me)₂, NHPh, OCH₂Ph, SPh; R, R' = H, Alk;
Ar = Ph, 4-MeC₆H₄, 4-ClC₆H₄, 4-BrC₆H₄, 4-PhC₆H₄.

The 1,2-oxaselenolane system **162** has been obtained in accordance with the following scheme: treatment of the selenide **163** with 2.4 equiv. of BuLi (THF, –78 °C, 30 min) and subsequent reaction with a carbonyl compound leads to the β-hydroxyalkyl selenide **164**. The interaction of the latter with 1 equiv. of bromine in the presence of 2 equiv. of triethylamine (CCl₄, 25 °C, 3 h) gives compound **162**.²⁹³ A complex mixture of products is formed in the thermolysis of the oxaselenolane **162**: the selenide **164** (12%), the ketone **165** (55%), the product **166** with an expanded ring (10%), the oxaselenolane **167** (16%), and 35% of a mixture of the selenoxide **168** and the diselenide **169**.

d. Selenafulvalenes

Tetrahetero(S, Se, Te)fulvalenes^{294, 295} as well as their derivatives and analogues²⁹⁶ have attracted much attention by investigators after the discovery of the conductivity²⁹⁷ and superconductivity^{297, 298} of their radical-cation salts and charge-transfer complexes. Cava and coworkers²⁹⁹ described a simple and economical method of synthesis of tetraselenafulvalene **170** by means of the following scheme:

Later^{300, 301} a method of synthesis of tetraformyltetraselenafulvalene **171** from 1,3-diselenole-2-selenone **172**³⁰² was developed. It is based on the thoroughly investigated coupling reaction of 1,3-dithioles or 1,3-diselenoles.^{303–307} Treatment of the fulvalene **171** with hydrazine leads to the bispyridazino-derivative **173**^{300, 308} whilst reduction with sodium tetrahydroborate affords the tetraselenafulvalene **174**.³⁰⁰

Trialkyl phosphites are used fairly widely as condensing agents for the synthesis of asymmetric selenium-containing fulvalenes.^{309–313} Thus the interaction of 4,5-dimethyl-1,3-diselenole-2-selenone **175** with the ketone **176** in boiling toluene in the presence of trimethyl phosphite under an argon atmosphere resulted in the formation of 4,5-dimethyl-2-(4-thioxo-1,3-dithiolan-5-ylidene)-1,3-diselenole **177** in 28% yield.³¹¹

In the absence of the ketone **176**, the interaction of the 1,3-diselenole-2-selenone **175** with trimethyl phosphite in benzene at 18 °C under an argon atmosphere leads to a spiro-compound — 2,3,7,8-tetramethyl-1,4,6,9-tetraselenaspiro[4,4]nona-2,7-diene **178** — the structure of which has been confirmed by XRD data.³¹³

The reaction of 4,5-bis(methoxycarbonyl)-1,3-diselenole-2-selenone **179** with 4-oxoselenane **180** on refluxing in benzene in the presence of triethyl phosphite leads to the cross-coupling product **181** in 23% yield. The product is dehydrogenated on heating in toluene with tetrachlorobenzoquinone (TCBQ).³¹⁴

The substituted tetraselenafulvalenes **183** have been synthesized in 5%–10% yields by the interaction of the dibromocyclopentenes **182**, selenium, and tetrachloroethene in the presence of Bu^tLi.³¹⁰

The preparation of highly conjugated selenatrithiafulvalene derivatives **184** via the following scheme has also been reported:³¹²

Acylation of compound **185** with benzoyl chloride in benzene leads to a 33% yield of the dibenzoyl derivative **186**.³¹⁵

A convenient method of synthesis of the substituted 1,3-diselenole **187** in the form of a mixture of isomers by the interaction of phenylethyne with elemental selenium in the presence of an aqueous KOH solution in both aprotic dipolar solvents³¹⁶ and under the conditions of phase transfer catalysis³¹⁷ has been developed.

It has also been shown that the ethynylselenolates **188** enter into an anionic 1,3-cycloaddition reaction with phenyl isoselenocyanate to form the 1,3-diselenoles **189**, electron-donating substituents accelerating and electron-accepting ones retarding the reaction.^{318–320}

R = C₆H₅, 4-MeC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, 4-NO₂C₆H₄;
X = Li, K.

Changes permitting the synthesis of only monosubstituted tetraselenafulvalenes **191** were subsequently introduced into this reaction. For this purpose, the tetraselenafulvalene **170** is treated at –100 °C with 4 equiv. of lithium diisopropylamide in THF and the resulting tetralithium derivative **192** is then treated with a deficiency of an electrophile.³²¹

R = SPh, SePh, CO₂Me, COOH;
R' = Me, Prⁿ, n-C₁₃H₂₇, n-C₁₅H₃₁.

The metallation of the tetraselenafulvalene **170** with lithium diisopropylamide at temperatures between –80 and –100 °C followed by the addition of an excess of an electrophile (Ph₂S₂, Ph₂Se₂, ClCO₂Me, or CO₂) leads to the corresponding tetrasubstituted tetraselenafulvalenes **190**.³²²

It is of interest that treatment of compound **170** with BuⁿLi leads to the overall degradation of the molecule (only compounds **193** and **194** were detected mass-spectrometrically).³²²

It has been shown by CNDO/CI quantum-chemical calculations with a modified set of spectroscopic parameters that heteroaromatic asymmetric thiones and selenones **195** and **196** as well as the heterofulvalenes **197** and **198** based on them have smaller ionisation potentials and energies of the lowest electronic transitions than their symmetrical isomers. An increase in the size of the thiones and selenones by their annelation to heterocyclic fragments alters the ionisation potentials and the electronic transition energies insignificantly, which can be explained by the small contributions of the atomic orbitals of these fragments to the highest occupied molecular orbital, whereupon the main contribution to the ionisation potentials comes from the $4p\pi$ orbitals of the heteroatoms in the 2,3-positions of the five-membered heterocycle as well as the $2p\pi$ orbitals of the carbon atoms forming the double bond.^{323–332}

X = S, Se.

e. Other five-membered heterocycles with two selenium atoms

In order to obtain 'organic metals' with a high electrical conductivity, a method of synthesis of new types of electron donors — dimethyl- and tetramethyl-anthra[1,9-*cd*:4,10-*c'd'*]bis-1,2-dithioles and the corresponding diselenoles and ditelluroles **199** — *via* the following scheme has been developed.^{333, 334}

X = S, Se, Te; R, R' = H, Me.

Using 7,7,8,8-tetracyanoquinodimethane as well as its 2,3,5,6-tetrafluoro-, 2,5-dimethyl-, and 2,5-dimethoxy-derivatives, 2,5-bis(dicyanomethylene)- $\Delta^{2,2'}$ -di(3-thiolene), and 3,3'-dibromo-5,5'-bis(dicyanomethylene)- $\Delta^{2,2'}$ -di(3-selenolene) **200** as electron acceptors, charge-transfer complexes with electrical conductivities ranging from 8 to $10^{-9} \text{ S cm}^{-1}$ were obtained from compounds **199**.³³³

The synthesis of naphtho[1,8-*c,d*]1,2-diselenole **201** on irradiation of 8,13-dihydrobenzo[*g*]naphtho[1,8-*b,c*]1,5-diselenine **202** has been reported.³³⁵

1,2-Diselenol-3-one **203** is formed in a high yield as a result of the gas-phase reaction of propargyl alcohol with dialkyl diselenides at 400 – 430°C .^{336, 337} The replacement of the dialkyl diselenide by diphenyl diselenide in this reaction lowers the yield of the diselenolone **203** and leads to the formation of selenophene and benzoselenophene together with the latter.³³⁷

R = Me, Et, Prⁱ.

The cyclic five-membered 1,2-diselenides **204** have been obtained in a high yield (76%–98%) as a result of the treatment of 1,3-dibromoalkanes **205** with lithium diselenide in THF.^{338, 339}

R = H, Me.

The bicyclic diselenides **207** have been obtained by treating 3,3-diaryl-2-selenabicyclo[2.2.1]hept-5-enes **206** with elemental selenium and cyclopentadiene in toluene.³⁴⁰

Ar = Ph, 4-MeC₆H₄, 4-FC₆H₄, 4-ClC₆H₄.

A series of studies have been devoted to the reactivity of the salts of the dication **208** obtained by the two-electron oxidation of 1,5-diselenacyclooctane **209** with NOPF₆ (or NOBF₄).^{341–344} The initial biselenide **209** was obtained by treating 1,3-diselenolane **210** with sodium tetrahydroborate and by the subsequent reaction of the resulting sodium propane-1,3-diselenolate with 1,3-dibromopropane in a benzene–ethanol mixture at 40°C under a nitrogen atmosphere using the high dilution technique. The interaction of the dication **208** with aniline or *N,N*-dimethylaniline in anhydrous MeCN at room temperature under an argon atmosphere leads to the corresponding *para*-substituted selenonium salt **211**, whereas the reaction with thiophenol is accompanied by the formation of the disulfide **212** (92%) and 1,5-diselenacyclooctane **209**.^{341, 343} It has also been shown that one-electron reduction with formation of the radical-cation **213** and the ferrocenium cation occurs in the interaction of the dication **208** with ferrocene in anhydrous MeCN at -20°C under an argon atmosphere.³⁴²

X = PF₆, BF₄; R = H, Me.

3. Five-membered heterocycles with three heteroatoms

a. Selenadiazoles

Various methods have been used to synthesise isomeric selenadiazoles.

Thus 1,2,4-selenadiazoles **214** have been obtained in 32%–87% yield by treating selenoamides with *N*-bromosuccinimide in chloroform.³⁴⁵

R = Ph, 4-MeC₆H₅, 4-ClC₆H₅, MeCH₂CH₂, Me(CH₂)₃CH₂, Me(CH₂)₅CH₂, Me₂N, PhCH₂S.

Condensed derivatives of 1,2,4-selenadiazoles — selenatetraazapentalenes **215** — have been obtained by treating selenourea **216** with 2 equiv. of butyllithium in THF at 0 °C under a nitrogen atmosphere and the subsequent reaction of the resulting dianion **217** with phenacyl chloride and alkyl isothiocyanate.^{346–348}

R = Me, Et, CH₂=CHCH₂.

The substituted triselenadiazapentalene **218** has been synthesised in a low yield (4.8%), together with other products, by the interaction of benzoyl chloride, potassium selenocyanate, and diethylamine in acetone at room temperature.³⁴⁹

A convenient method of synthesis of 1,2,3-selenadiazoles has been developed. It consists in the treatment of the semicarbazones of aromatic and carbocyclic ketones with selenium dioxide.^{350–354} Thus treatment of the semicarbazone **219** with SeO₂ in glacial acetic acid results in the formation of 4-(1-naphthyl)-1,2,3-selenadiazole **220** in 65% yield.³⁵⁰

Selenium dioxide is a convenient reagent also in the synthesis of 2,1,3-selenadiazoles from aromatic and heteroaromatic diamines.^{355–358} For example, treatment of the substituted phenylenediamine **221** and 5-bromo-2,3-diaminopyridine **222** with selenium dioxide in dioxane leads to the 2,1,3-selenadiazoles **223**³⁵⁵ and **224**³⁵⁶, respectively.

In the synthesis of condensed 2,1,3-selenadiazoles, H₂SeO₃^{359–361} and SeCl₄³⁶² have also been used as sources of selenium.

In the nitration of 5,6-disubstituted benzo-2,1,3-selenadiazoles with sodium nitrite in H₂SO₄, an increase in the deactivating influence of the substituent on their reactivity is observed in the series Me < Cl < NO₂.³⁵⁷

R¹ = Me, R² = R³ = NO₂; R¹ = Cl, R² = NO₂, R³ = H.

4,5-Diaminobenzo-2,1,3-selenadiazole **225** reacts with acetylacetone in the presence of concentrated HCl to form the hydrochloride of 2,4-dimethyl-1,5-diazepino[5,4-*e*]benzo-2,1,3-selenadiazole **226** in 88% yield.³⁶³

The dimerisation of 2,1,3-selenadiazole **227** to the 14-membered lactone **228** has been reported.³⁶⁴

Photoelectron He(I) spectra of benzo-2,1,3-selenadiazole and its perfluoro-derivatives have been measured and interpreted on the basis of calculations by the MNDO method, the π -fluoro-effect, and the analysis of the vibrational structure and relative

band intensities.³⁶⁵ The reduction of benzo-2,1,3-selenadiazoles with 57% HI³⁶⁶ and NaH,³⁶⁷ as well as the ability of 4- and 5-(β -amino- β -carboxy)ethylbenzo-2,1,3-selenadiazole to form complexes with Cu(II) and Pt(II) salts have been investigated.³⁶⁸

Derivatives of quaternary isomeric selenadiazole — 1,3,4-selenadiazolidines **229** — have been obtained in 70%–80% yields by the interaction of acetylenic alkali metal selenolates with nitrilimines.^{369–375}

M = Li, Na, K; R = Ar, Ac, CO₂Et.

Diazoalkanes **230** react with an excess of carbon diselenide at 80 °C in toluene to form a mixture of substituted 1,3,4-selenadiazolines **231**, which have been separated by thin-layer chromatography (TLC).³⁷⁶ The introduction of selenoketene **232** into the reaction with the diazoalkanes **230** leads to a complex mixture of products, among which substituted 1,3,4-selenadiazolines **233** have been detected.³⁷⁷

R = Bu^t, Ar; X = R₂C, R₂C=NN, RCH;

232 = CH₂=CHCM₂C(SiMe₃)=C=Se.

The 1,3,4-selenadiazolium salt **234** has been obtained by treating the oxadiazolium acetate **235** with alkali metal hydrogen selenides and subsequent acid cyclodehydration of the intermediate.^{378, 379}

On treatment with potassium acetate in acetic anhydride, 1,3,4-selenadiazolium salts recyclise to various derivatives.^{379–382}

X = I, ClO₄, AcO, TsO; R = Alk, Ar, Het.

b. Other five-membered heterocycles with three heteroatoms

The interaction of equimolar amounts of selenium dioxide and epichlorohydrin or epoxyp propane in the presence of boron trifluoride etherate in dioxane at 20 °C under a nitrogen atmosphere is a convenient method of synthesis of substituted 1,3,2-dioxaselenolanes **236**.³⁸³

R = H, Cl.

Benzo-1,2,3-triselenolium chloride **237** has been obtained as a result of the interaction of 1,2-di(chloroseleno)benzene with elemental selenium and also by treating dibenzotetraselenocine **238** with Se₂Cl₂ in dichloromethane.³⁸⁴

Thieno-1,2,3-triselenole **239** has been obtained from 2,5-dichloro-3,4-dilithiothiophene in accordance with the following scheme:³⁸⁵

V. Six-membered heterocycles

Hydrogen selenide or compounds which readily hydrolyse in the reaction medium to hydrogen selenide, as well as alkaneselenols, selenium dioxide, selenium tetrahalides, and, to a lesser extent, elemental selenium are most often used as sources of selenium in the synthesis of six-membered selenium-containing heterocycles.

1. Selenanes

2,2,6,6-Tetramethylselenan-4-one **240** has been obtained by the reaction of phorone with a mixture of aluminium selenide and sodium acetate in 90% ethanol. Its ethynylation under the conditions of the Favorskii reaction in liquid ammonia with powdered potassium leads to the selenanol **241**.³⁸⁶

The interaction of the epoxy ketone **242** with hydrogen selenide in the presence of SnCl_4 or toluene-*p*-sulfonic acid in acetonitrile at 20 °C leads to a mixture of selenane derivatives **243** (55%) and tetrahydroselenophene **244** (12%).¹¹¹

The condensation of the dienone **245** with hydrogen selenide, formed on heating a mixture of aluminium selenide and sodium acetate in 90% ethanol, leads to 2-phenyl-1-selenabicyclo[4.4.0]-decan-4-one **246** as a mixture of four stereoisomers, from which the two individual isomers **246a** and **246b** were isolated by column chromatography on silica gel.^{387–389}

Substituted selenan-4-ones **248** have been synthesised by treating the methiodides of *N*-methylpiperidinones **247** with sodium or lithium hydroselenide in alcohol.^{390–392}

$\text{R}, \text{R}' = \text{H}, \text{Me}$.

The irradiation of a benzene solution of the selenides **249** with light from a tungsten lamp leads to the selenanes **250** in 50%–79% yields.³⁹³

$n = 3–5; m = 1–3$.

On treatment with selenium tetrabromide, compound **251** gives rise to the selenane dibromide **252**.³⁹⁴

Apart from the ethynylation of the selenanone **240** indicated above,³⁸⁶ among the chemical reactions the reduction of 2,5-dimethylselenan-4-one with lithium tetrahydroborate³⁹⁵ as well as the phosphorylation of selenan-4-one with dialkyl phosphites^{396, 397} have been described.

2. Selenopyrans

A convenient method has been developed in recent years for the synthesis of functionally substituted 4-aryl(heteroaryl)-2,6-diamino-3,5-dicyano-(4*H*)-selenopyrans **253**. It consists in the interaction of cyanoselenoacetamide with aryl(heteroaryl)idene-malononitriles at 20 °C in the presence of organic bases.^{398–405} On refluxing in alcohol, the selenopyrans **253** recyclise to the pyridineselenones **254**.

$\text{R} = \text{Ar}, \text{Het}; \text{B} = \text{HN} \begin{array}{c} \diagup \diagdown \\ \diagdown \diagup \end{array} \begin{array}{c} \diagup \diagdown \\ \diagdown \diagup \end{array}, \text{HN} \begin{array}{c} \diagup \diagdown \\ \diagdown \diagup \end{array} \begin{array}{c} \diagup \diagdown \\ \diagdown \diagup \end{array}, \text{Me}-\text{N} \begin{array}{c} \diagup \diagdown \\ \diagdown \diagup \end{array} \begin{array}{c} \diagup \diagdown \\ \diagdown \diagup \end{array} \text{O}.$

Another method of synthesis of substituted (including condensed) selenopyrans **255**, which readily form the selenopyrylium salts **256**, involves the interaction of 1,5-diketones with hydrogen selenide in acid media.^{406–413}

$\text{R}^1-\text{R}^2 = (\text{CH}_2)_3, (\text{CH}_2)_4; \text{R}^1, \text{R}^5 = \text{Ar}; \text{R}^2, \text{R}^4 = \text{H}, \text{Me}; \text{R}^3 = \text{H}, \text{Ar}; \text{X} = \text{Cl}, \text{BF}_4, \text{ClO}_4.$

The cycloaddition of selenocarbonyl compounds to 1,3-dienes has also been used in the synthesis of alkyl(aryl)selenopyrans.^{414–419} Thus the interaction of the selenoesters **257** with 2,3-dimethylbuta-1,3-diene leads to the 3,4-dimethyl-6-phenyl-(2*H*)-selenine **258**,¹¹⁷ while the interaction of selenoaldehydes **259** with cyclic dienes affords the bicyclic adducts **260**.⁴²⁰

$\text{R} = \text{Et}, \text{Bu};$

$\text{R} = \text{CO}_2\text{Me}, \text{COPh}, \text{CN}; n = 1, 2.$

Selenocyanates react with 1,4-dienes, forming dihydroselenopyrans **261** with a small admixture of the selenides **262**.⁴¹⁹

R = CN, COAr.

The synthesis of the selenopyranones **263** by the interaction of the unsaturated ketones **264** with sodium selenide has been reported.⁴²¹

R = Ph, SiMe₃.

It has been demonstrated by ¹H NMR spectroscopy that, depending on the number and nature of the substituents in the heteroaromatic cation, the interaction of selenopyrylium salts **256** with sodium methoxide results in the formation of various reaction products: (4*H*)-selenopyrans, a mixture of (4*H*)- and (2*H*)-selenopyrans with various proportions of the isomers, or 4-methyleneselenopyrans.⁴²²

R, R' = H, Me, Bu^t, Ph, 4-MeOC₆H₄;
X = BF₄, Cl, Br.

The oxidation of the selenopyrans **265** (R³ = H) with selenium dioxide in pyridine leads to the substituted selenophenes **266**.^{423, 424} On the other hand, the oxidation of the selenopyrans **265** (R² = H) with potassium permanganate in acetone or acetonitrile results in the formation of the 4-selenopyranones **267** in a high yield.^{423, 425, 426}

The electrochemical reduction of the selenopyrans **255**^{427, 428} as well as the dimerisation⁴²⁹ and dissociation of the salts **256** in aqueous solutions⁴³⁰ have also been investigated. In addition, a study has been made of the nucleophilic substitution in the series of selenopyrans^{422, 431, 432} and of certain other reactions.^{433–436}

3. Condensed selenopyrans

The spiro-selenopyrans **268**, incorporating a quinoline fragment condensed with the selenopyran ring, are formed when a mixture of 3-formyl-(1*H*)-quinoline-2-selenone **269** and the methylene bases **270** is refluxed in glacial acetic acid in the presence of catalytic amounts of perchloric acid.^{437–439}

X = O, S.

The trisubstituted selenochroman **271** has been obtained by the reaction of α-chlorophenacyl phenyl selenide **272** with *trans*-stilbene in anhydrous CH₂Cl₂ at –20 °C under an argon atmosphere in the presence of zinc chloride and subsequent treatment of the reaction mixture with triethylamine.⁴⁴⁰

In the presence of polyphosphoric acid (PPA), 3-phenylselenopropionic acid affords the selenochroman-4-one **273**, the interaction of which with aromatic aldehydes in the presence of concentrated HCl in methanol leads to 3-arylideneselenochroman-4-ones **274** in 30%–60% yield.^{441, 442}

R = 4-MeC₆H₄, 4-MeOC₆H₄, 4-N(Me)₂C₆H₄, 4-ClC₆H₄,
4-BrC₆H₄, 4-NO₂C₆H₄.

Derivatives of the selenochromanone **273** are also formed from oxo-derivatives of benzo-1,3-selenazine on treatment with iron or zinc in acetic acid.⁴⁴³ The anodic oxidation of the selenochromanone **273** has been studied and it has been shown that the resulting radical-cation **275** can react *via* two parallel routes: deprotonation with formation of selenochromone **276** and homolytic dissociation of the C–Se bond with subsequent dimerisation and formation of the diselenide **277**.⁴⁴⁴

It has also been shown that the reactions of quaternised selenochromans, isoselenochromans, selenochromanones, and isoselenochromanones with Grignard reagents or metallic magnesium are accompanied by the homolytic dissociation of the C–Se bond and the formation of selenides of the benzene series.^{445,446} The intramolecular Friedel–Crafts cyclisation of 2-arylselenobenzoic acids **279** in the presence of PPA has been used for the synthesis of the selenoxanthenones **278**.^{447,448}

R = H, Cl.

Later a series of substituted selenoxanthenones **281** were obtained by the analogous cyclisation of the arylselenobenzoic acids **280** using trimethylsilyl polyphosphate (PPSE) as the catalyst.⁴⁴⁹

R = H, 4-MeO, 5-MeO, 3,4-OCH₂O.

Polyphosphoric acid has been used as a catalyst also in the synthesis of 1,6-diselenapyrene **282**.⁴⁵⁰

Certain properties of selenoxanthenone derivatives have been studied: carboxylation,⁴⁵¹ interaction with nucleophiles,⁴⁵² and electrochemical reduction.⁴⁵³

The reaction of naphthalic anhydride **283** with the zinc salt of *o*-aminophenyl selenide **284** in DMF leads to the anhydride **285**, which is treated, without isolation, with isoamyl nitrite and the anhydride of benzo[*k*,*l*]selenoxanthenone-3,4-dicarboxylic acid **286** is obtained in 60% yield.⁴⁵⁴ A series of imides **287** have been obtained in 64%–94% yield in the interaction of the anhydride **286** with aliphatic amines on refluxing in 2-methoxyethanol.

R = Bu, C₆H₁₁, C₁₈H₃₇, CH₂CH₂COOH.

Benzo[*b*]furan and benzo[*b*]thiophene thio- and selenoaldehydes **288** and **289** react with acrylonitrile to form the condensed thio- and seleno-pyrans **290** and **291** in yields up to 87%.^{455–459}

X = S, Se; Y = O, S; R = Ph, 4-MeC₆H₄, 4-MeOC₆H₄.

The cycloaddition of maleic anhydride to the pyrazoloseleones **292** on refluxing in toluene leads to the anhydrides of 4-arylamino-3-methyl-1-phenyltetrahydroselenopyrano[2,3-*d*]pyrazole-5,6-dicarboxylic acid **293** in yields up to 98%.⁴⁶⁰

R = H, 3-MeC₆H₄, 4-MeC₆H₄, 3-MeOC₆H₄, 4-MeOC₆H₄, 3-NO₂C₆H₄.

The cycloaddition of cyclopentadiene to selenium-containing dienophiles has been used in the synthesis of bicyclic derivatives of 2-selenabicyclo[2.2.1]octene **206**⁴⁶¹ and **294**.⁴⁶²

The selenopyran derivatives **296**⁴⁶³ and **297**⁴⁶⁴ have been synthesised from substituted anthracenes **295** and selenium-containing dienophiles.

$\text{R} = \text{H}, \text{Me}; \text{R}' = \text{Alk}_F$.

4. Six-membered heterocycles with two heteroatoms

Substituted perhydro-1,4-selenazines **298** have been synthesised by the reaction of selenium tetrahalides or phenylselenium trihalides with 1,6-heterodienes **299**.^{465, 466}

$\text{R} = \text{Ph}, 4\text{-MeC}_6\text{H}_4; \text{X} = \text{Br}, \text{Cl}$.

Selenium tetrahalides have also been used to obtain condensed analogues of 1,4-selenazines — 2-halomethylidene-1,4-selenazino[2,3-*gh*]carbazoles **300**.^{467, 468} It has been shown that the reaction proceeds *via* the electrophilic addition of SeX_4 to the triple bond and the subsequent electrophilic attack on the nucleus of the carbazole **301** with formation of the condensed system **300**.

$\text{X} = \text{Br}, \text{Cl}$.

The 1,4-selenazine **303** has been obtained by irradiating the anthraquinone derivative **302**.⁴⁶⁹ Compounds suppressing the biosynthesis of leucotrienes have been detected among its derivatives; preparations based on them have been proposed for the treatment of asthma, inflammatory processes, and cardiovascular and allergic diseases.^{470, 471}

1,5-Bis(alkylamino)-(4*H*)-benzo[*a*]phenoselenazin-4-ones **306**, which absorb in the near infrared and can find application in laser techniques, have been synthesised by condensing the 1,5-naphthoquinones **304** with the zinc salts **305**.⁴⁷²

$\text{R} = \text{Me}, \text{Et}, \text{Pr}^i; \text{R}' = \text{H}, \text{Cl}, \text{OMe}; \text{X} = \text{H}, \text{Br}$.

Heat treatment of compound **307** leads to di(benzoselenazino)quinone **308** in 41% yield.⁴⁷³

Selenium *N,N'*-di(arenesulfonyl)diimides **309** undergo [2 + 4]-cycloaddition to the 1,3-dienes **310** and afford 3,6-dihydro-1,2-selenazines **311** in 88%–94% yields.⁴⁷⁴

$\text{R}^1 = \text{Ph}, \text{R}^2 = \text{R}^4 = \text{R}^5 = \text{H}, \text{R}^3 = \text{Me}; \text{R}^1 = \text{Ph}, \text{R}^2 = \text{R}^3 = \text{Me}, \text{R}^4 = \text{R}^5 = \text{H}; \text{R}^1 = \text{Ph}, \text{R}^2 = \text{R}^3 = \text{H}, \text{R}^4, \text{R}^5 = (\text{CH}_2)_2; \text{R}^1 = 4\text{-MeC}_6\text{H}_4, \text{R}^3 = \text{R}^4 = \text{R}^5 = \text{H}, \text{R}^3 = \text{Me}; \text{R}^1 = \text{R}^3 = \text{Me}, \text{R}^2 = \text{R}^4 = \text{R}^5 = \text{H}$.

The 1,2-selenazine derivatives **312** have been obtained by condensing carboxylic acid selenoamides **313** with 2-(cyclohex-1-enyl)cyclohexanone **314** in the presence of catalytic amounts of naphthalene- β -sulfonic acid.⁴⁷⁵

The substituted 1,4-selenoxane **315** has been synthesised by treating the ester **316** with selenium tetrabromide.⁴⁷⁶

R = H, Me.

The interaction of the disulfide **318** with selenium dioxide afforded 2,3,6,9,10,13-hexamethoxy-5,12-dithia-7,14-diselena-5,7,12,14-tetrahydropentacene **317**, which possesses semiconducting properties.⁴⁷⁷

A method of synthesis of phosphorus-substituted 1,3-diselenanes **319** involving the interaction of 1,2-diselenolanes **320** with dimethyl diazomethylphosphonate in dichloromethane at room temperature in the presence of boron trifluoride etherate has been reported.⁴⁷⁸

R = R' = Me; R = H, R' = Bu^t.

The condensed 1,4-diselenoxane derivative **321** has been obtained by treating 2,3-dichloro-1,4-naphthoquinone with sodium selenide in acetonitrile.⁴⁷⁹

5. Six-membered heterocycles with three heteroatoms

The nitrilimines **323**, obtained by treating *N*-aryl-*C*-chlorohydrazone **322** with an organic base, undergo [3 + 3]-cycloaddition to potassium phenylethyneselenenolate, forming 2,4,5-trisubstituted (4*H*)-1,3,4-selenadiazines **324** in 89% – 100% yields.⁴⁸⁰ The interaction of the nitrilimines **323** with dialkylselenamides of mono-substituted acetic acids also leads to derivatives of 1,3,4-selenadiazines.⁴⁸¹

Ar = Ph, 4-MeC₆H₄, 4-BrC₆H₄; R = COMe, CO₂Et.

The reaction of α-haloketones with selenosemicarbazide, its derivatives, or other compounds containing the selenosemicarbazide fragment has been used fairly successfully in the synthesis of 1,3,4-selenadiazines, including condensed ones.^{482–487}

R¹, R² = H, Alk, Ar, Het; R³ = H, Alk; X = Br, Cl.

The 1,3,4-oxaselenazines **325** have been obtained by the reaction of *N*-aryliminoselenenyl chloride **326** with the alkenes **327** via the [4 + 2]-cycloaddition mechanism.⁴⁸⁸

Ar = Ph, 4-MeC₆H₄, 4-BrC₆H₄, 4-ClC₆H₄, 4-NO₂C₆H₄;
R = H, R' = Ph; R, R' = (CH₂)₄.

A stereoselective method of synthesis of 1,3,5-oxaselenazines **328** by the interaction of selenoamides with aliphatic aldehydes in the presence of boron trifluoride etherate in chloroform at 20 °C has been developed (yields 69% – 97%).⁴⁸⁹

R = Me, C₇H₁₅, Bu^t, cyclo-C₆H₁₁; Ar = Ph, 3-ClC₆H₄, 4-MeOC₆H₄.

VI. Seven – nine-membered heterocycles

The number of publications in recent years on these selenium-containing heterocycles is small and the data presented in them are in most cases of a specific character and they are therefore described in order of increasing ring size of the heterocycle.

The interaction of freshly sublimed selenium dioxide with linalyl acetate **329** in THF at 25 °C leads to the alcohol **330** and the selenepane **331** in proportions of 7 : 3; the yield of the selenepane **331** is then 16%⁴⁹⁰ while in the case where the reaction is carried out in methanol, it is 2%.⁴⁹¹ The structure of the selenepane **331** was established by XRD.⁴⁹²

The analogous treatment of linalool **332** with selenium dioxide in methanol leads to a mixture of compounds containing the

8-oxa-3-selenabicyclo[3.2.1]octane skeleton (compounds **333**–**336**).⁴⁹³ After flash chromatography on silica gel, 22.4% of compound **333**, 7.5% of compound **334**, 2.5% of compound **335**, and 3.1% of compound **336** was obtained.

The synthesis of the tetracyclic selenenpinone **337** by the cyclisation of compound **338** on treatment with a KOH solution in THF has also been described.⁴⁹⁴

Dibenzoselenazocine **340**, the oxidation of which with *m*-chloroperbenzoic acid leads to the selenoxide **341** and the *N*-oxide **342**, has been obtained in 72% yield by the reaction of bis(2-bromomethylphenyl) selenide **339** with methylamine in chloroform at 20 °C under an argon atmosphere using the high dilution technique.⁴⁹⁵ The interaction of the selenoxide **341** with trifluoromethanesulfonic acid anhydride⁴⁹⁵ or thionyl chloride⁴⁹⁶ results in the formation of the stable crystalline salt of the dication **343**, which exists as two conformers according to ¹H NMR data obtained in deuteriochloroform at –50 °C: the boat-boat form (74%) and the boat-chair form (26%).⁴⁹⁷

The analogous reaction of the selenide **339** with sodium sulfide in ethanol at 20 °C leads to a 90% yield of dibenzoselenathiocine **344**, which gives rise to the dication **345** on oxidation with concentrated H₂SO₄ or 2 equiv. of NO⁺PF₆[–].⁴⁹⁸

X = HSO₄, PF₆[–].

It has also been shown that salts of selenuranes **347** are formed on oxidation of dibenzodiselenocine **346** (X = Y = Se), dibenzoselenathiocine **346** (X = Y = S) or dibenzoselenazocine **346** (X = Y = NH, NCH₂Ph) with concentrated H₂SO₄ or 2 equiv. of NO⁺PF₆[–].^{499, 500}

X = Y = S, X = Y = Se; X = Y = NH; X = Y = NCH₂Ph;
X = NH, Y = NCH₂Ph; Z = HSO₄, BF₆[–].

The synthesis of 2,8-dihalomethylperhydro-1,4,6-selenadiazocines **348** by the interaction of the diamide **349** with selenium tetrahalides has been reported.⁵⁰¹

X = Br, Cl.

Nine-membered heterocycles containing two selenium atoms benzodiselenonines **350** — have been obtained by the interaction of 1,2-bis(cyanoselenocarbonyl)benzene **351** with the ditosyl derivatives of 2,2-bis(hydroxymethyl)alkanes or the corresponding cycloalkanes in THF.⁵⁰²

R = R' = H; R, R' = CH₂OCH₂, (CH₂)₂, (CH₂)₄.

An analogous system containing three selenium atoms — 12,13-dimethylbenzo[*d,h*]-1,2,3-triselenonine **352** — is formed in 18% yield as a mixture with 9,10-dimethylphenanthrene **353** (5%) on interaction of (*Z*)-2,3-bis(2-lithiophenyl)but-2-ene **354** with 2–4 equiv. of selenium in ether at –78 °C.⁵⁰³ On thermolysis (180 °C), on refluxing in benzene in the presence of azobisisobutyronitrile, or on photolysis (λ > 290 nm) in THF at 0 °C, the triselenonine **352** recyclises with loss of one selenium atom to 5*a*,10*a*-dimethyldibenzo[*b,f*]seleno[3,2*a*]selenophene **355**. The structures of compounds **352** and **355** were established by XRD.

VII. Selenacyclophanes and selenium-containing crown ethers

The methods of synthesis of various selenacyclophanes are based on the reactions of α,ω -dihaloalkanes or the corresponding cycloalkanes with sodium hydroselenide or potassium selenocyanate *via* α,ω -diselenocyanates, the yields of the final products approaching quantitative yields under these conditions.^{504–510} For example, bis(halomethyl)-substituted aromatic and heteroaromatic compounds **356** interact with 2 equiv. of potassium selenocyanate to form the diselenocyanates **357**, which are converted into the diselenacyclophanes **358** in a high yield as a result of the reaction with the initial halide **356** in THF in the presence of sodium tetrahydroborate.⁵⁰⁸

On heat treatment or photoirradiation in the presence of tertiary phosphines, the diselenacyclophanes lose selenium and are converted into cyclophanes in a high yield.^{504–507, 511, 512} For example, metacyclophane **360** has been obtained in 93% yield as a result of the photodeselenation of diselenacyclophane **359**.⁵¹³

On the other hand, 1,3-dihydro-2-benzoselenophene **362** is formed in 92% yield in the pyrolysis of 2,11-diselena[3.3]-orthocyclophane **361** instead of the corresponding cyclophane.⁵¹³

In conclusion, we shall consider data on crown ethers, cryptands and coronands containing selenium atoms and being of interest from the standpoint of the modelling of involved natural complexes. A simple method of synthesis of sulfur- and selenium-containing cryptands **363** by the interaction of bis(-methylene-epoxy)diaza-18-crown-6 **364** with sodium hydrosulfide or hydroselenide in ethanol under an argon atmosphere has been developed.⁵¹⁴

X = S, Se.

The reaction of α,ω -dihalides with cesium benzenediselenolate leads to the crown ethers **366** containing selenium atoms, in yields up to 40%.⁵¹⁵

n = 1–3; X = Br, Cl.

A new class of coronands, containing selenium atoms, has been obtained in the reactions of the sodium biselenolates **367–369** with dibromoalkanes in THF: tetraselenacyclododecane **370**, tetraselenacyclohexadecane **371**, hexaselenacyclotetracosane **372**, and tetraselenacyclotetradecane **373**.⁵¹⁶

The review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 96-03-32012a).

Abstract. Methods for the synthesis, properties and applications of alkyl 2-cyanoacrylates are surveyed. The reactions of alkyl 2-cyanoacrylates with various nucleophiles (thiols, alcohols, diols, hydrogen sulfide, phosphines, *etc.*) including a new reaction involving insertion of isocyanates and isothiocyanates into the C=C bonds in the adducts of alkyl 2-cyanoacrylates with trialkylphosphines are considered. The prospects for the use of alkyl 2-cyanoacrylates in organic synthesis, in the chemistry of polymers and in the chemistry of adhesives are described. The bibliography includes 117 references.

I. Introduction

Alkyl 2-cyanoacrylates (ACAs) were synthesised for the first time in 1949;¹ as early as 1955, it was proposed to use these compounds as one-component cold-setting adhesives.² Soon after that, industrial production of fast-curing adhesives based on ACAs started, and they appeared on the market.^{3,4}

Adhesives based on alkyl 2-cyanoacrylates are unique materials owing to two specific features. The first of them is an extremely short period needed for setting. At room temperature, surfaces can be cemented together with these adhesives over periods of several seconds, high strengths of the adhesive joints being attained fairly quickly. The second feature is that ACAs can efficiently cement together both living tissues (their use in medicine is allowed) or organic materials (plastics, rubber, wood) and inorganic materials (stones, metals, glass, porcelain, ceramics) in various combinations. Apparently, only Teflon and polyethylene provide exceptions; they can be cemented together only after treatment of their surfaces with special activators (amines, phosphines, *etc.*).^{5,6}

The ability of ACAs to polymerise instantaneously under the action of traces of water and various compounds (and thus to glue materials together) is the main reason accounting for the fact that up to the beginning of the 90s, only polymeric chemistry of ACAs

has developed. In fact, the monographs^{3,4} published in 1980 and reviews (see, for example, Refs 7–9) deal mostly with the polymeric chemistry of ACAs. Among monomeric derivatives of 2-cyanoacrylic acid, only esters have been described.

A new stage in the development of the chemistry of ACAs is associated with the synthesis of cyanoacrylic acid (CAA)¹⁰ and the involvement of this acid and its derivatives in organic synthesis.^{11,12}

II. Methods for the synthesis of alkyl 2-cyanoacrylates

Several methods for the synthesis of ACAs (**1**) are known. One of them is based on the thermolysis of alkyl 3-acetoxy-2-cyanopropionates, which are prepared from the sodium derivatives of the corresponding alkyl cyanoacetates and chloromethyl acetate.¹

However, this method has not been adequately studied. The synthesis of the compounds **1** based on the Knövenagel reaction has been developed in greater detail. This method forms the basis for the industrial manufacture of ACAs, as is illustrated by numerous publications.^{3,13–29}

It is noteworthy that depolymerisation of oligomeric ACAs formed in the first stage must be carried out under rather drastic conditions. This fact largely restricts the synthetic potential of this method (for example, it is fairly difficult to synthesise ACAs with bulky ester groups).

Among the methods developed more recently, syntheses of ACAs from methyl acrylate (**1a**),³⁰ cyanoacetylene,^{31,32} ethyl pyruvate³³ and esters of 2-cyanopropionic acid³⁴ should be mentioned [apparently, the latter method permits preparation of any ester of 2-cyanoacrylic acid, naturally except for those containing basic groups; the initial esters of 2-cyanopropionic acid can be prepared using both various aliphatic alcohols or phenols and polyols (diols, triols, tetraols) including oligomeric

[†] The review is dedicated to William E McEwen on occasion of his 75th birthday.

slightly the standard C–C distance (1.475 Å); this implies that there is no significant conjugation between the C(1)=O and C(2)=C(3) double bonds (the length of the latter bond also coincides with the typical C=C distance equal to 1.321 Å). The lengths of the C(2)–C(4) and C(4)–N bonds are close to the standard values for molecules incorporating a C=C–C≡N fragment; in this fragment, conjugation apparently does occur.

Strong OH...N hydrogen bonds (1.88 Å) join the molecules into zigzag-like chains of the 'head-to-tail' type. The mutual arrangement of the C=C bonds of neighbouring molecules of the acid does not conform to the necessary conditions for the occurrence of topochemical reactions in the crystals of compounds with double bonds. This is in agreement with the fact that crystals of CAA are resistant to light and to prolonged exposure to X-rays.

1-Adamantylmethyl cyanoacrylate and the bis-cyanoacrylate prepared by transesterification of methyl cyanoacrylate with decane-1,10-diol have also been studied by X-ray diffraction analysis.⁴³ It was found that the molecular geometries of 1-adamantylmethyl cyanoacrylate and the bis-cyanoacrylate are similar to that of CAA. However, owing to the presence of strong electron-withdrawing groups, the methylene hydrogen atoms in these ACAs are markedly acidic, and this accounts for the short intermolecular contacts involving CH₂ groups in the crystals of these compounds.

It is possible that it is the acidity of the methylene hydrogen atoms that accounts for the ready polymerisation of ACAs in the presence of nucleophiles and bases by virtue of coordination of the latter to the protons of the methylene group of ACAs.

IV. Chemical properties of 2-cyanoacrylic acid and its derivatives

1. 2-Cyanoacrylic acid

As noted above, no reliable data about the existence of free CAA had been reported until 1985. Only Kadykov and Kochkin⁵³ described the use of CAA (without mentioning the source); however, the procedure presented by these researchers is doubtful.

The presence of the highly electrophilic C=C bond together with the carboxyl and nitrile groups in the CAA molecule accounts for the diversity of its reactions. The preparation of CAA salts is hampered due to the strong tendency of this acid to decarboxylation and polymerisation in the presence of bases. In fact, alkalis, triethylamine and amines with non-branched radicals immediately cause its polymerisation, whereas in the presence of pyridine or diazabicyclooctane, it is rapidly converted into 2,4-dicyanopent-4-enoic acid **4** as shown in Scheme 3.⁴⁰

Obviously, in the first stage, an equilibrium is established, *i.e.* in addition to the formation of the salt, an attack by the amine on the highly electrophilic β -C atom occurs. The zwitter-ion **3** resulting from decarboxylation adds to CAA; when the reaction mixture is treated with a solution of sulfuric acid, the adduct is converted into the acid **4** in a high yield. The correctness of this reaction mechanism was confirmed by trapping the anion **3** as the adduct with 4-nitrobenzaldehyde.

Sterically hindered amines (butyldimethylamine and brucine) react with CAA to give only the corresponding salts, because steric hindrance prevents the attack on the C = C bond.⁵⁴ Conversely, in the case of triethyl phosphite, which is less basic but more nucleophilic than amines, the reaction occurs only at the double bond to give compound **5** containing a strong P – C bond.⁴⁰

Nobody has been able yet to prepare the 2-cyanoacryloyl chloride from the acid by exchange reactions that are used successfully to convert acrylic and methacrylic acids into the corresponding chlorides. For example, CAA does not react with benzoyl chloride even at 200 °C. The reaction of CAA with thionyl chloride occurs with difficulty and stops, apparently, at the stage of formation of the mixed anhydride.⁴⁰ The chloride of CAA can be obtained only by treating the acid with phosphorus pentachloride in a mixture of toluene with xylene.⁴⁰ According to ¹H NMR data, this reaction affords an unstable adduct of the CAA chloride with HCl. When phosphoryl oxychloride and most of the toluene are removed *in vacuo*, hydrogen chloride is eliminated. The solution of 2-cyanoacryloyl chloride thus obtained can be used in various syntheses. For example, ACAs with bulky ester groups^{41,43,45} and thioesters of CAA unknown previously have been prepared from 2-cyanoacryloyl chloride. It has been found³³ that, unlike S-ethyl cyanothioacrylate which polymerises extremely easily, *S*-tert-butyl cyanothioacrylate is fairly stable. To prepare successfully esters of 2-cyanothioacrylic *S*-acid, low-polarity lead thiolate is used, because in the presence of ionic sodium and potassium thiolates, the cyanoacrylate system instantaneously polymerises, evidently, as a result of an attack by the alkali metal thiolate on the β-carbon atom at the double bond.

Like other carboxylic acids, cyanoacrylic acid smoothly reacts with trialkylchlorosilanes⁴⁰ to give the corresponding acyloxysilanes in high yields (see Scheme 2).

Unlike acrylic acid, which adds water only at 100 °C in the presence of alkali, CAA, owing to its high electrophilicity, reacts with water at room temperature. This process has been studied using deuterated water.

Hydration of CAA competes with its polymerisation (according to ^1H NMR spectroscopy, the latter reaction occurs much more slowly). Since the process is reversible, 2-cyano-3-hydroxypropionic acid cannot be isolated in a pure state; removal of excess water affords again free CAA and its polymeric form. Thus, the measured $\text{p}K_{\text{a}}$ value, equal to 2.3 in a 0.01 N aqueous solution, refers to an equilibrium mixture of CAA with 2-cyano-3-hydroxypropionic acid rather than to CAA itself.⁴⁰

Due to its high reactivity, cyanoacrylic acid forms adducts with acid phosphites and thiophosphites without catalysts,⁵⁵ whereas similar adducts of acrylic acid are formed only in the presence of alkaline catalysts.

Cyanoacrylic acid dissolved in dry acetone quantitatively adds ethanedithiol present in excess to give functionally substituted bis-carboxylic acids.⁵⁶

The zwitter-ions **7** cause instantaneous polymerisation of ACAs and are readily alkylated with alkyl halides to give the corresponding phosphonium salts.⁶³ However, their interaction with isocyanates and isothiocyanates follows an unexpected pathway that includes insertion of the iso(thio)cyanate fragment into the C–C bond of the initial zwitter-ion^{62, 64–66} and leads to zwitter-ions **11** *via* intermediates **10a** and probably **10b** (Scheme 5).

Scheme 5

R¹ = Me, Et; R² = R³ = Prⁿ, Prⁱ, Bu, Et₂N;

R⁴ = Me, Ph; X = O, S.

The fact that carbanions containing no phosphonium centres react with iso(thio)cyanates without changes in the carbanion skeleton⁶⁷ suggests that the rearrangement of the intermediate adduct **10a** formed in the first stage into the thermodynamically more stable zwitter-ion **11** is induced by the phosphonium centre. Apparently, its role consists in intramolecular electrophilic assistance to the attack on the carbonyl carbon atom by the nucleophilic nitrogen atom. In the limiting case, this assistance (which can be regarded as intramolecular electrophilic catalysis) gives rise to the unstable phosphorane **10b** the decomposition of which affords the zwitter-ion **11**. The structures of the reaction products (see Scheme 5) have been confirmed by IR and NMR spectroscopy; for the derivatives of methyl and phenyl isocyanate, X-ray diffraction analysis has also been carried out.^{62, 65}

The scheme for the insertion of iso(thio)cyanates includes 'opening' of the carbonyl group by the phosphonium centre. This type of reaction is well known for aldehydes and ketones,⁶⁸ but it rarely occurs for esters.⁶⁹ Therefore, to confirm the above considerations, Gololobov *et al.*⁶⁰ have studied the possibility of converting the phosphonium centre in the zwitter-ions **7** into a phosphorane structure through opening of the carbonyl in the alkoxycarbonyl group. This problem was successfully solved when ACAs were made to react with derivatives of trivalent phosphorus with a specific structure.⁶⁰ It was found that the formation of spiroposphoranes **12** can be facilitated by both steric and electronic factors. The compounds **12** in which the phosphorus atom in the five-membered ring is bound to a branched alkylamine group are the most stable.

R = Bu^t, Hex.

Thus, rearrangement of the adduct **10a** into the zwitter-ion **11** depends on the nucleophilic properties of the negatively charged nitrogen atom. For example, in the case of R⁴ = Me or Ph, this atom is nucleophilic enough to attack efficiently the carboxyl carbon atom. However, when toluene-*p*-sulfonyl isocyanate is introduced into the reaction with the zwitter-ion **7**, the nucleophilicity of the nitrogen atom in the resulting adduct is relatively low and, hence, the attack on the carbon atom of the carboxyl group is inefficient. In this case, adduct **13** is stabilised *via* decomposition to give triisopropylphosphine, the initial tosyl isocyanate and the ACA. The latter rapidly polymerises, while triisopropylphosphine reacts with tosyl isocyanate to yield zwitter-ion **14**.⁶²

The structure of the zwitter-ion **14** was proved by X-ray diffraction analysis.⁶²

Stabilisation of the adducts arising in the reactions of the zwitter-ion **7** with organic azides is also accompanied by the liberation of an ACA molecule and yields phosphinimines **15**.⁶²

b. Reactions of 2-cyanoacrylates with nucleophiles containing active hydrogen atoms

When ACAs react with weak nucleophiles, irrespective of the particular experimental procedure, conditions are created under which ACAs instantaneously polymerise. However, when the nucleophile contains an active hydrogen atom, polymerisation of ACA is suppressed, because the primary adduct **6** is stabilised through self-protonation.

The interaction of ACAs with thiols of diverse structures under conditions when excess thiol is present (which is achieved by adding the ACA to the reactions mixture) apparently gives rise to zwitter-ion **16** in the first stage of the process. Since the proton at the sulfur atom in this zwitter-ion is relatively active, this species is rapidly self-protonated giving sulfide **17**.⁷⁰ Dithio- and thio-acids react with ACAs in a similar way.

R = Alk, Ar, HOCH₂CH₂, HSCH₂CH₂, HCl·NH₂CH₂, HCl·NH₂CH₂CH(COOH), HOOCCH₂, Ac, (EtO)₂P(S), (EtO)₂P(O).

Alcohols can be introduced in this reaction instead of thiols. Normally, alcohols cause only polymerisation of ACAs, because they are less acidic and less nucleophilic than thiols; however, under special conditions (in the presence of an acid the conjugate anion of which is a weak nucleophile), formation of relatively stable adducts of ACAs with alcohols is possible.

Unlike CAA, which reversibly adds water, its esters undergo instantaneous polymerisation in the presence of water. Treatment of ethyl cyanoacrylate with hydrogen sulfide in the presence of 1% of Et₃N gives aminodihydrothiopyran **17** in a quantitative yield.

The interaction of ACAs with phosphites **18a,b** derived from pyrocatechol has been described.⁶⁰ The reaction gives rise to cyclic phosphonates **20a,b** via the corresponding zwitter-ions **19a,b** (Scheme 6).

Scheme 6

In these case, too, the zwitter-ions **19a,b** formed initially undergo self-protonation.⁶⁰ It should be noted that it is the formation of five-membered phosphorus-containing rings that ensures the success of the synthesis of monomeric products according to Scheme 6. When phosphites that cannot be converted into five-membered phosphoranes like **20** are used in this reaction, oligomeric derivatives are formed.

c. Interaction of 2-cyanoacrylates with weak nucleophiles in the presence of acids

The zwitter-ions **6** formed initially in the reactions of weak nucleophiles with ACAs can also be protonated by an acid present in the reaction mixture and forming no strong bonds with the nucleophile. In this case, the reaction yields salt **21**.

In this reaction, the acid not only protonates the zwitter-ion **6**, but also activates ACA molecules. This has been confirmed by the data of IR spectroscopy,⁵⁹ according to which the nitrile and carboxyl groups in ACAs are protonated by acids, and this increases the overall electrophilicity of the ACA molecule.

The activating influence of acids ensures the occurrence of reactions of ACAs with weak nucleophiles, which do not enter into these reactions without acids. Thus 1,3,2-benzodioxachlorophosphole **23** does not react with ACAs in benzene at 20 °C; however, when the reaction mixture contains CF₃COOH, the process yields phosphonate **24** (Scheme 7).⁷¹

Scheme 7

This reaction is an example of conjugate addition of a weak nucleophile and a strong acid to an ACA; the proton of the acid acts as an inductor. Alcohols and other lowly nucleophilic reagents can also enter into these reactions.⁷²

d. Interaction of 2-cyanoacrylates with CH-acids in the presence of bases

In addition to P-, S- and O-nucleophiles, C-nucleophiles (derivatives of CH-acids) can also add to ACAs under certain conditions giving rise to monomeric compounds (Scheme 8).⁷³

Scheme 8

B: — amine;

X = H, COOR (R = H, Et);

Y = NO₂, CN, Ac.

This version of the Michael reaction is possible only for those CH-acids that react with minor amounts of amines (present as catalysts of the reaction) much more rapidly than ACAs react with these amines. Thus, sufficiently basic amines (B) and relatively strong CH-acids with pK_a < 13 (for example, **25**) should be used. The acids should be rapidly converted into the conjugated bases **26**, which would either cause polymerisation of the ACA or react with the ACA to give adduct **27a**. Thus, Scheme 8 reflects a fairly complex system of equilibrium processes, the outcome of which

depends on the acidity of the CH-acid, basicity of amine B, electrophilicity of the ACA, the nature of the solvent, temperature and the order of mixing the reactants.

The results obtained in the study cited⁷³ showed that the Michael reaction involving ACAs can be used as a general method for the synthesis of esters of substituted cyanocarboxylic acids. The method is suitable for the preparation of various functionally substituted compounds.

V. Prospects for the application of 2-cyanoacrylates

Although the intense development of the 'monomeric' chemistry of ACAs has started not long ago, it has led to two important consequences. On the one hand, the chemistry of ACAs has stimulated investigation of the chemical properties of the zwitterions **7** formed by ACAs and trialkylphosphines, and this has resulted in the discovery of the insertion of the carbamide fragment into the C–C bond (Scheme 5). This, in turn, stimulated the development of a new branch of catalysis, namely, intramolecular electrophilic catalysis by a phosphonium centre. On the other hand, even the first studies on CAA and its esters provided grounds to expect that new ACAs would be synthesised, and this would markedly extend the performance characteristics of cold-setting adhesives and open up new ways for their use in industry, medicine and organic synthesis.

1. The ways to extend the temperature range of performance of adhesives based on 2-cyanoacrylates

The strength of gluing surfaces together with an ACA depends on at least two factors, all other factors being the same, namely, the adhesive capacity of the cyanoacrylate itself and on the stability of the adhesive joint under the conditions of its performance (temperature, moisture content and hostility of the medium).

Industrially manufactured methyl and ethyl 2-cyanoacrylates form high-strength adhesive joints at room temperature; however, the stability of these joints at elevated (> 80–100 °C) or low (< –100 °C) temperatures is relatively low (especially in hostile or moist media). At the same time, ample experimental material on this topic implies that the temperature range of operation of cyanoacrylate adhesives have markedly extended, and their performance characteristics have improved.

The relatively low stability of ACA polymers used under rigorous conditions can be explained by the fact that the polymer backbone contains a quaternary carbon atom (see Scheme 4). Polymers incorporating this fragment are known to possess low thermal stabilities.⁷⁴ Therefore, to increase the thermal stability of adhesive joints based on ACAs, the structure of the polymer backbone should be modified by introduction of fragments that would enhance the tolerance of the chain to high temperatures and hostile media (mostly water at various pH). The existing theoretical calculations^{4, 75, 76} provide only general recommendations on the increase in the quality of adhesives based on ACAs.

One of the possible ways of solving this problem is elaboration of cross-linked structures.⁷⁷ Two approaches to the formation of 'cross-linked' structures based on ACAs have been considered in the literature. One of them involves introduction of unsaturated carbon–carbon bonds into the ester fragment of ACAs; subsequently, these bonds ensure cross-linking of the structure.

Allyl and propargyl 2-cyanoacrylates as well as other esters of CAA containing more bulky unsaturated groups have low viscosities; this is a necessary condition for attaining the interfacial contact between the adhesive and the substrate at the first stage of the formation of an adhesive joint.^{22, 46, 78–80} Under the action of traces of moisture or other active reagents, the C=C bond of the acrylate is cleaved on the surfaces being glued together.^{78, 81} Study on the thermodynamics of polymerisation of allyl cyanoacrylate and allyloxyethyl cyanoacrylate⁸² makes it possible to conclude that at room temperature these monomers are completely converted into the corresponding polymers by an anionic mechanism,

and above 100 °C, cross-linked structures are formed as a result of rupture of the multiple bonds in the allyl and propargyl fragments.^{46, 78, 79, 83} It has been noted⁸⁴ that the interfacial interaction between substrate and adhesive is due to van der Waals and dipole–dipole forces. In addition to these adhesive forces, chemical bonds of various natures (adsorption theory of adhesion) contribute to the interaction.⁸⁵ It is noteworthy that, whereas the C=C bond of the acrylate is cleaved by an anionic mechanism, rupture of multiple bonds in the ester fragment of the molecule occurs only with the participation of free radicals.⁷⁸ As a result, an adhesive joint based on unsaturated esters of CAA possesses better performance characteristics than a similar joint based on saturated derivatives.^{46, 86} The main drawback of cross-linked structures based on unsaturated 2-cyanoacrylates (regarding their practical use) is that in this case, strengthening of adhesive joints occurs only at elevated temperatures (> 100 °C). However, it is often necessary that joints be strengthened below 100 °C. In addition, this procedure can yield a rigid cross-linked polymer and, consequently, the adhesion layer can become brittle.⁷⁹ Elastomers can be partly dissolved in ACAs during gluing to give interpenetrating networks⁸⁷ (the process is described in terms of the diffusion theory of adhesion). The second approach to the production of a cross-linked adhesive layer is based on copolymerisation of methyl or ethyl cyanoacrylates with unsaturated compounds of various types. Apparently, by selecting an appropriate comonomer, one can obtain adhesive joints with properties varying over a wide range. This approach is more advantageous, because in some cases, a 'cross-linked' adhesive joint can be obtained at low temperatures. Unsaturated compounds containing electronegative polar groups have been used as comonomers, because, on the one hand, owing to these groups, compounds enter in the copolymerisation with ACAs and, on the other hand, these substituents ensure additional cohesion with the substrate. This line of research has led to impressive progress.^{3, 4, 87–95} Evidently, the structure of 2-cyanoacrylates derived from diols³⁷ and triols⁹⁶ is nearly ideal, because in these cases, a cross-linked adhesive joint is formed rapidly under conditions close to those used for the polymerisation of the main monomer. Unfortunately, at present, it is fairly difficult to produce bis- and tris-cyanoacrylates in large amounts. Some methods proposed for their synthesis^{34, 37} are labour-consuming and expensive; direct esterification of CAA^{41–43} or its chloride as well as transesterification of methyl cyanoacrylate with diols³⁹ can be used only on a laboratory scale.

Judging by several publications,^{77, 97–103} the research aimed at the involvement of esters of 2-cyano-2,4-pentadienoic acid in the copolymerisation with ACAs is proceeding vigorously. The derivatives of ethylene glycol and 2-cyano-2,4-pentadienoic acid are especially efficient.⁷ These esters polymerise at room temperature in the presence of the same catalysts that induce polymerisation of ACA to give a cross-linked structure. It has been shown^{77, 97} that the performance characteristics of ACAs are markedly improved when they are used as mixtures with butadiene derivatives.

These cross-linking reagents are synthesised by the Knövenagel reaction between the corresponding esters of cyanoacetic acid and aldehydes (Scheme 9).^{98, 99}

Scheme 9

R' = H, Me.

A significant feature of the process shown in Scheme 9 is that anhydrous zinc chloride dissolved in dioxane or THF is used as the catalyst. A method for the synthesis of bis-2-cyanopentadienoates derived from diols containing disiloxane units in the chain has been recently described in a patent.¹⁰²

2. The use of 2-cyanoacrylates in medicine

The ability of ACAs to polymerise on the surface of a living tissue over periods of several seconds under very mild conditions without special initiation permits these compounds to be regarded as promising surgical materials.¹⁰⁴ It is of prime importance that the polymer based on an ACA is destroyed relatively quickly in a living organism.¹⁰⁵ Polymers based on isobutyl and isoamyl cyanoacrylates are highly biocompatible. It should also be mentioned that ACAs are relatively non-toxic and possess antimicrobial activities. 1,2-Isopropylidene-glyceryl cyanoacrylates are quite promising in this respect.²⁰ Laboratory and clinical tests on the regeneration of tissue cells and restoration of other characteristics of an organism have shown that ACAs ensure strong and elastic connection of tissues; simultaneously, they exhibit antiseptic properties and pose no harmful consequences.¹⁰⁵ Medical adhesives of this type are used during surgical operations on lungs, brains, heart, kidneys, on organs of digestion, sight and respiration, bone tissue and teeth.^{3, 4, 106–109} Efficient medicinal adhesives of the MK series and SO-9m, SO-9t and SO-57 trademarks prepared using fluorinated methacrylates as comonomers have been developed in the former USSR by Russian, Ukrainian and Azerbaijanian chemists. These formulations are non-toxic and tolerant to disinfectants.¹¹⁰ They possess bacteriostatic and bactericide properties; besides, they are biodegradable in an organism and form no toxic products of decomposition. They also cause no immunological reaction.¹¹¹

The second way of using ACAs in medicine is associated with the development of medical preparations of prolonged action based on them. A procedure has been elaborated for incorporating medical preparations into an ACA-based polymeric matrix. When an ACA is introduced into an intensely stirred solution of a drug, it polymerises to give particles with a size of 170–350 nm containing molecules of the drug sorbed in the polymeric matrix. This procedure was used to obtain immobilised apomorphine¹¹² and oxytocin.¹¹³ The procedure is general and, apparently, it can be used in several variants.

3. Other applications of 2-cyanoacrylates

Polymers based on ACAs are used to produce photo- and electrono-resists. By chemical deposition of perfluoroethyl cyanoacrylate vapour on a support, a photoresist with a sensitivity of 0.2 J cm^{-1} has been obtained.¹¹⁴ Positive electrono-resists have been obtained using homopolymers of ACAs and their copolymers with functionally substituted monomers.¹⁰⁸ Lengthening of the hydrocarbon chain in the ester group of ACAs markedly decreases the adhesive properties of these compounds. Alkyl cyanoacrylates in which the alkyl chain consists of more than six methylene units have found application in the formation of Langmuir–Blodgett monomolecular layers.¹¹⁵ Monolayers are formed by polymerisation of CAA esters (from hexyl to decyl ester) directly on the water surface. Since the energy of interaction of the cyano-group in the polymer with water is relatively low (14.6 kJ), the monolayer can be easily transferred on a solid support. At the same time, monomolecular layers of poly(alkyl cyanoacrylates) exhibit some adhesion both to hydrophilic and to hydrophobic surfaces. The above technology for the preparation of Langmuir–Blodgett films can be used in the production of micro-instruments by the submicron technology.

Cyanoacrylates are readily soluble in liquid carbon dioxide;¹¹⁶ therefore, ACAs packed in aerosol bottles can be used in those cases where a high concentration of ACA vapour is needed. It is clear that the aerosol use of ACAs would help to solve some unexpected problems, because it would permit almost instantaneous production of a polymeric adhesive surface on various objects. ACA vapours deposited on various surfaces polymerise on them and thus fix any traces left there, for example, fingerprints.¹¹⁷

* * *

The data presented in this review provide grounds for believing that at present, a new stage in the development of the chemistry of ACAs has started. This can lead to development of cold-setting adhesives with better performance properties; in addition, new applications of CAA derivatives can appear, and the use of ACAs in organic and organometallic synthesis can become wider.

The review was prepared with the support of the Russian Foundation for Basic Research (Project No. 95-03-08200).

Abstract. The topological disorder, which consists of a set of diverse knots, folds, and entanglements of polymer chains, determines many properties of a polymeric substance. It is manifested in processes involving the sorption of low-molecular substances by the polymer and in the chemical reactions of the substances dissolved in the polymer. The bibliography includes 59 references.

I. Introduction

Zones with a relative degree of order in the disposition of monomer units (short-range order), which alternate with zones where this order is violated, are known to exist in real polymers. The zones with disturbed order arise around topological structures such as loops, folds, various entanglements of the polymer chains (see, for example, Yeh¹), and also at the ends of macromolecules. The majority of zones of short-range order violation [units of disorder (UOD)] are formed in the synthesis of the polymer or during its precipitation from solution and are retained throughout the existence of the given polymer sample, not disappearing even on melting. The set of diverse UOD is referred to as the stable topological disorder, which determines many properties of the polymer.^{2,3} According to the present author, the degree of topological disorder is the missing parameter without considering which it is impossible to describe quantitatively the properties of a polymeric substance.⁴ Examples of the simplest UOD are illustrated in Fig. 1.

There have been numerous studies devoted to the role of entanglements of the macromolecules in the dynamics of melts

and concentrated polymer solutions.^{5–8} The level of disorder must influence the mechanical properties of the polymeric substance, which depend on the nature of the entanglements of the macromolecules.⁹ However, consideration of these questions is outside the scope of the present review, in which attention is concentrated on the relation between the topological disorder and the physicochemical properties of the polymer–low-molecular substance system.

Figure 1. Schematic illustration of the simplest unit of disorder: A—A—fold; B—B and C—C—entanglement.

II. The homopolymer as a two-component system

There exists an extensive class of crystallising polymers, such as polyethylene, polypropylene, poly(vinyl chloride), aliphatic polyamides, *etc.* A characteristic feature of these polymers is incomplete crystallisation. The physical cause preventing the complete crystallisation of the polymeric substance is the presence of a stable disorder in the arrangement of the polymer chains. The ‘crystallinity’, *i.e.* the content of the crystalline substance in such polymers, varies as a rule within wide limits (from 20% to 80%)¹⁰ and may change reversibly with temperature¹¹ and apparently with pressure. It is noteworthy that the absolute value of the ‘crystallinity’ of the same polymer measured in different ways can differ appreciably, so that in speaking of the ‘crystallinity’ of the

Yu A Shlyapnikov Emanuel’ Institute of Biochemical Physics, Russian Academy of Sciences, ul. Kosygina 4, 117977 Moscow, Russian Federation. Fax (7-095) 137 41 01. Tel. (7-095) 939 72 85, (7-095) 939 73 48, (7-095) 939 74 79

Received 29 January 1997

Uspekhi Khimii 66 (11) 1064–1076 (1997); translated by A K Grzybowski

polymer it is always necessary to indicate the method used for its measurement.¹²

Incomplete crystallisation implies that two phases coexist in the individual homopolymer over a certain range of temperatures and pressures: crystalline and amorphous. According to Gibbs' phase rule

$$F + P \leq C + 2, \quad (1)$$

where $F = 2$ is the number of degrees of freedom (temperature and pressure), $P = 2$ is the number of phases (crystalline and amorphous), and C is the number of components which should be at least two. If the disorder units (or the units of disorder) are adopted as the quasi-molecules of a second component, then the degree of disorder can be expressed in concentration units. Taking into account the wide variety of the disorder elements ζ_i , one can write

$$[\zeta] = \sum [\zeta_i] = \frac{1}{VN_A} \sum N_i, \quad (2)$$

where V is the volume of the sample, N_A is the Avogadro number, and N_i is the number of UOD of the i th type in the sample.

Like the species of a low-molecular substance, the quasi-molecules can migrate, although to a limited extent, in the polymer melt; the folds (A–A in Fig. 1) migrate *via* a wavelike motion ('reptation'?), whilst the simplest knots (B–B and C–C) migrate *via* a mechanism in which the monomer units adjoining the knot change places ('sliding' along parallel chains).

Assuming that the complete crystallisation of the polymer is prevented by the osmotic pressure of the solution of the UOD in the noncrystallised part of the polymer, which is $P_{os} = RT[\zeta](1-x)^{-1}$ (x is the degree of crystallinity), the author of the present review² proposed an equation describing the dependence of the degree of crystallinity of the polymer on the concentration of extraneous units ω_i

$$(1-x) = \frac{RT[\zeta]}{-\Delta F_{cr} - \sum_i \kappa_i [\omega_i]}, \quad (3)$$

where $-\Delta F_{cr}$ is the decrease in free energy on crystallisation of the polymer calculated per unit mass of the latter and κ_i are coefficients taking into account the decrease in $-\Delta F_{cr}$ when foreign units of the i th type are incorporated in the crystallite. As can be seen from Eqn (3), for $[\zeta] = 0$ the polymer crystallises fully (*i.e.* $x = 1$) and conversely, above a certain value of $[\zeta]$, the polymer is fully amorphous.

III. Methods for the investigation of the degree of disorder

Any violation of short-range order is associated with a certain excess volume: the density of the polymeric substance in the region of the entanglement of the polymer chains should be reduced. Thus the UOD, or more precisely the structural formations Z_j arising from them, may be regarded as elements of the free volume. Just as one can measure the volume of a vessel by filling it with water or another liquid, the free volume corresponding to the structural formation Z_j is measured by filling it with a low-molecular substance. However, owing to the smallness of the volume of the element Z_j , only those substances the molecular volume of which V_A is not greater than the free volume V_j contained in this element can fill it (or, more precisely, be placed in it):

$$V_A \leq \beta V_j, \quad (4)$$

where β is the coefficient taking into account the lack of correspondence between the shapes of the molecule of substance A and the volume element ζ_j . Thus, by investigating the dissolution (sorption) of various low-molecular substances in the polymer, it is possible to obtain information about the concentration of the UOD and their size distribution for the dissolved (sorbed) molecules.

The density of the polymer or, more precisely, the difference between the theoretical calculated volume of unit mass of the ideally crystallised polymer and the real volume of unit mass of the sample studied (the so-called free volume) might serve as a natural measure of the free volume, but in such an approach we cannot estimate the size distribution of the elements of the free volume. Furthermore, the most sensitive method for the determination of density — hydrostatic weighing — requires the immersion of the sample in a low-molecular liquid the molecules of which partly fill these elements.

Assuming that the sorption of substance A includes a stage involving the formation of a true solution of A in the amorphous part of the polymer with its subsequent permeation into the sorption centres in accordance with the scheme

and that the first stage obeys Henry's law

$$[A] = \gamma_A [A]_m, \quad (6)$$

where $[A]$ is the concentration of truly dissolved molecules of A, $[A]_m$ is the concentration of A in the surrounding medium, and γ_A is Henry's coefficient, it is easy to find the isotherm for the sorption of substance A by the polymer from the formula

$$[A]_p = \gamma_A [A]_m + \sum_j [AZ_j] = \gamma_A [A]_m + \sum_j \frac{\gamma_A K_j [Z_j] [A]_m}{1 + \gamma_A K_j [A]_m} \quad (7)$$

or, neglecting the true solubility of A outside the sorption centres, from the formula

$$[A]_p = \sum_j \frac{\gamma_A K_j [Z_j] [A]_m}{1 + \gamma_A K_j [A]_m}. \quad (8)$$

With increase in the concentration of the molecules of A in the surrounding medium, each term in Eqn (8) tends to $[Z_j]$ and $[A]_p$ tends to $\sum [Z_j] = [Z_A]$ (the overall concentration of the centres sorbing the given substance).

It will be shown below that, even for considerable differences between the sorption constants K_j , the isotherm for sorption on inhomogeneous centres is experimentally indistinguishable from the Langmuir isotherm

$$[A]_p = \frac{a[A]_m}{1 + b[A]_m}. \quad (9)$$

However, for high values of $[A]_m$, this relation may break down. Remaining in the region where the Langmuir Law holds, it is possible to determine the 'Langmuir sorption capacity',^{13,14} *i.e.* the value $[Z_A]$. The type (9) Langmuir relation can be transformed into a straight line in terms of the variables $1/[A]_m$ and $1/[A]_p$, whereupon the intercept made by the straight line on the ordinate axis corresponds to the reciprocal of the concentration of the sorption centres: $b/a = 1/[Z_A]$.

On the simplest assumption that within a certain range $K_1 \leq K_i \leq K_2$ the value of

$$\rho = \frac{\Delta[Z_i]}{\Delta K_i} = \frac{[Z_A]}{K_2 - K_1} \quad (10)$$

is constant and that outside this range it is zero, we arrive at the following expression after substituting the sum (8) by the integral:

$$[A]_p = \rho \int_{K_1}^{K_2} \frac{K \gamma_A [A]_m dK}{1 + K \gamma_A [A]_m} = [Z_A] \left\{ 1 + \frac{1}{(K_2 - K_1) \gamma_A [A]_m} \ln \frac{1 + K_1 \gamma_A [A]_m}{1 + K_2 \gamma_A [A]_m} \right\}. \quad (11)$$

When $[A]_m \rightarrow \infty$, the value $[A]_p$ tends to the limit $\lim [A]_p = [Z_A]$.

Figure 2 presents the curve for the dependence of $[A]_p$, or, more precisely, of the ratio $[A]_p/[Z_A]$, on $[A]_m$, calculated by

Figure 2. The sorption isotherm of a low-molecular substance by a polymer in direct (1) and inverse (2) coordinates: calculation by Eqn (11) with $K_2/K_1 = 10$.

Eqn (11) with $\gamma_A = 1$, $K = 1$, and $K_2 = 10$ in terms of the direct variables and their reciprocals. It is seen from the figure that the curve described by Eqn (11) in inverse coordinates $1/[A]_p$ vs. $1/[A]_m$ is transformed into a straight line, which means that Eqn (11) may be replaced by the simpler expression

$$[A]_p = \frac{[Z_A] K \gamma_A [A]_m}{1 + K \gamma_A [A]_m}.$$

Apparently the majority of the phenomena associated with the role of disorder may be satisfactorily explained by assuming that the UOD can be divided, for any influence, into those participating or not participating in the process and those which respond in different ways to the given influence (in all cases, the quantitative differences within each group are neglected).

In certain cases, it is possible to employ the equilibrium solubility of substance A in the polymer (S_A) as a measure of the concentration of the centres $[Z_A]$. Evidently the value S_A is always smaller than $[Z_A]$, but in some instances, when S_A is close to its theoretical limit $[Z_A]$, one can assume that $S_A \approx [Z_A]$. The closeness of S_A to $[Z_A]$ may be indicated, for example, by a weak temperature dependence of the solubility.

If the substance dissolved in the polymer is an antioxidant, it is possible to estimate the change in the concentration of its mobile part by the method of critical concentrations. This method has been described in detail^{15,16} and here we shall consider only its simplified version.

In order to inhibit a radical chain oxidation reaction occurring in a polymer consisting of RH units, *i.e.*

where R' is a free radical (usually a hydrocarbon), ROOH is the branching product reacting with the initial substance to form new free radicals, α is the yield of hydroperoxy-groups, and σ is the probability of degenerate chain branching, it is necessary to introduce into the reacting substance an inhibitor IH.¹⁷

or a substance Y which reacts with the branching product, *i.e.*

In the former case, the balance of the RO_2' and ROOH concentrations is described by the system of equations

$$\frac{d[RO_2']}{dt} = W_0 + \sigma k_{hp}[ROOH][RH] - k_t[RO_2'][IH], \quad (13)$$

$$\frac{d[ROOH]}{dt} = \alpha k_2[RO_2'][RH] - k_{hp}[ROOH][RH]. \quad (14)$$

Here W_0 is the rate of chain initiation.

Assuming that the RO_2' concentration is stationary, *i.e.* that the rates of formation and consumption of RO_2' are equal, $d[RO_2']/dt = 0$, one can write

$$[RO_2'] = \frac{W_0 + \sigma k_{hp}[ROOH][RH]}{k_t[IH]}.$$

Neglecting the rate of chain initiation W_0 compared with the rate of branching $\sigma k_{hp}[ROOH]$, we find

$$\frac{d[ROOH]}{dt} = \frac{k_{hp}[ROOH][RH]}{k_t[IH]} (\alpha \sigma k_2[RH] - k_t[IH]). \quad (15)$$

As can be seen from the last expression, the value of $d[ROOH]/dt$ is positive, *i.e.* the process is self-accelerated, provided that the expression in brackets is positive, *i.e.*

$$(\alpha \sigma k_2[RH] - k_t[IH]) > 0 \quad (16)$$

or

$$[IH] < [IH]_{cr} = \frac{\alpha \sigma k_2[RH]}{k_t} \quad (17)$$

and, conversely, the rate of the process decreases, tending to a limit, if this expression is less than zero.

The quantity $[IH]_{cr}$, *i.e.* the concentration of the inhibitor (antioxidant) corresponding to the boundary between the two reaction regimes, is called the critical concentration. Compounds which decompose the branching product may displace the critical concentration of the inhibitor but they themselves do not have a critical concentration in the absence of an inhibitor.^{16,17}

The critical concentration of the antioxidant can be determined experimentally comparatively easily as the boundary between the region of the relatively slow stationary process and the fast self-accelerated process.¹⁸ In particular, the induction period, *i.e.* the period during which the fast reaction is suppressed by the antioxidant, does not increase or increases slowly for $[IH] < [IH]_{cr}$ and rapidly for $[IH] > [IH]_{cr}$, which is manifested as a break in the curve for the dependence of the induction period on the initial antioxidant concentration for $[IH]_0 = [IH]_{cr}$.^{16,18}

The antioxidant molecules are divided into those bound into the complexes $Z_i IH$ with the sorption centres and the mobile molecules IH. Mainly the mobile molecules IH participate in the chain termination in the solution in the polymer with participation of the macroradicals M' and MO_2' , the translational mobility of which is close to zero. The concentration of mobile molecules is related to the overall IH concentration in the polymer by the expression

$$[IH] = \frac{[IH]_p}{K_{IH}[Z_{IH}]} \quad (18)$$

where $[Z_{IH}]$ is the concentration of the IH-sorbing centres and K_{IH} is the sorption equilibrium constant; the equation is valid only at low antioxidant concentrations $[IH] \ll [Z_{IH}]$, such as the critical concentrations. Thus the difference between the experimental critical concentrations of the same antioxidant in different samples of a polymer of the same chemical nature is determined by the difference between the concentrations and properties of the sorption centres, *i.e.* the difference in the character of the disorder in the arrangement of the polymer chains. The method of critical concentrations can be used in those cases where the method for the investigation of the sorption isotherm is for one or another reason inapplicable, in particular in the study of polymer melts.

IV. Sorption of low-molecular substances by the polymer

We shall examine the equilibrium sorption of a low-molecular substance — phenyl benzoate (A) — by polyethylene as the simplest example. The curves for the dependence of the concentration of this substance in polyethylene $[A]_p$ on its concentration in the gas phase $[A]_m$ surrounding the polymer are transformed into straight lines when $1/[A]_p$ is plotted against $1/[A]_m$ (Fig. 3)¹⁹ and all the straight lines corresponding to temperatures ranging from 80 to 180 °C, *i.e.* from the solid polymer to its melt, intersect the ordinate axis at the same point corresponding to $[Z_A] = 0.55 \text{ mol kg}^{-1}$. The experimentally observed linear relations of the type

$$\frac{1}{[A]_p} = \frac{1}{[Z_A]} + \frac{K_A \gamma_A [Z_A]}{[A]_m} \quad (19)$$

may be transformed into relations of the 'Langmuir' type

$$[A]_p = \frac{K_A \gamma_A [Z_A] [A]_m}{1 + K_A \gamma_A [A]_m} \quad (20)$$

with $[Z_A] = \text{const.}$

The temperature independence of $[Z_A]$ and the fact that it does not change even on passing through the melting region ($\sim 130^\circ\text{C}$ for polyethylene) agree well with the topological nature of the sorption centres: the folds, knots, and entanglements of the long polymer chains do not disappear on melting the polymer. Many other substances behave similarly to phenyl benzoate on sorption from both the gas phase and from solutions in low-molecular liquids (Fig. 4).²⁰ The limit of the sorption from solutions, *i.e.* the value $[Z_A]$, is as a rule lower than in sorption from the gas phase and depends on the nature of the solvent.²¹ In more complex cases at simultaneous sorption of two different substances from the same solvent, one substance is displaced from solution in the polymer by the other.

Figure 3. The sorption isotherm of phenyl benzoate by high-density polyethylene from the gas phase.¹⁹ Temperature (°C): (1) 80; (2) 90; (3) 100; (4) 110; (5) 120; (6) 130; (7) 140; (8) 150; (9) 160; (10) 170; (11) 180.

Figure 4. The sorption isotherm of phenyl benzoate (1) and diphenylamine (2) by high-density polyethylene from n-hexane at 50 °C in the coordinates $1/[A]_p - 1/[A]_m$.²⁰

Suppose that two substances, A and B, are sorbed by the same centres Z_i . One may then expect that these substances will compete for the sorption centres, *i.e.* the process

will take place. As a result, the solubility of substance A in the polymer will decrease with increase in the concentration of substance B in the surrounding medium. Such a relation has been frequently observed in practice (Fig. 5).^{20, 22}

However, in certain cases a more complex relation holds: maxima appear on the descending curve for the dependence of the solubility of one substance on the concentration of the other (Fig. 6).²⁰ These maxima can be explained by the formation of more complicated complexes ABZ_j on certain sorption centres Z_j .

The solvent can also function as the second substance, which results in a change of the nature of the sorption isotherm. This explains the dependence of the solubility of low-molecular substances on the nature of the solvent from which the given substance is sorbed, which has been observed in a number of experiments.²¹

The sorption centres may be various microcavities the formation of which is not connected directly to the disorder in the

Figure 5. Dependence of the concentrations of α -naphthol (A) (1) and α -naphthylamine (B) (2) in high-density polyethylene on the α -naphthylamine concentration in hexane at 50 °C.²⁰

Figure 6. Dependence of the equilibrium concentrations of α -naphthol $[A]_p$ (1, 2) and diphenylmethane $[B]_p$ (3, 4) in high-density polyethylene (1, 3) and low-density polyethylene (2, 4) on the α -naphthol concentration in isopropyl alcohol at 50 °C {diphenylmethane concentration in solution $[B]_m = 0.2 \text{ M}$ }.²⁰

arrangement of the polymer chains and which vanish when the samples are pressed under high pressure.²³

The sorption is related directly to the diffusion of the dissolved substance. Assuming that only the mobile molecules of A outside these centres participate in the diffusion, it is possible to find the theoretical dependence of the (observed) diffusion coefficient on the overall concentration of substance A in the polymer. According to Fick's first law, the flow of molecules of A through a unit cross-section of the polymer sample, perpendicular to the x axis, is

$$\Phi = -D_r \frac{d[A]}{dx} = -D_r \frac{d[A]}{d[A]_p} \frac{d[A]_p}{dx} = -D_{\text{eff}} \frac{d[A]_p}{dx}, \quad (23)$$

where D_r and D_{eff} are the true and observed diffusion coefficients.

The observed diffusion coefficient of substance A in the polymer is given by $D_{\text{eff}} = D_r \{d[A]/d[A]_p\}$. For low values of $[A]_p$ ($[A]_p < [Z_A]$), we have $[A] = [A]_p / K_A \{ [Z_A] - [A]_p \}$. On differentiating this value with respect to $[A]_p$, we obtain²⁴

$$D_{\text{eff}} = \frac{D_r [Z_A]}{K_A ([Z_A] - [A]_p)^2}. \quad (24)$$

A similar formula has been derived by Fujita.²⁵ In a study²⁶ of the diffusion of 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol), labelled with ^{14}C , into polyethylene containing the same but not radioactive substance at different concentrations, not only was Eqn (24) confirmed but a value of $[Z_A]$ virtually identical with the solubility ($0.034 \text{ mol kg}^{-1}$ at 80 °C) was calculated.

It was later shown with the aid of the NMR method²⁷ that the molecules of ammonia dissolved in polystyrene can be divided into highly and weakly mobile, their mobilities differing by a factor of 20.

V. Formation of sorption centres in the sedimentation of polymers from solution

We shall consider the case where the polymer is formed in sedimentation from solution in a low-molecular liquid.²⁸ Evidently, the sedimentation must be preceded by the sticking together of sections of the polymer chains and the elements of future disturbed-order knots ζ_i^* are then laid down in the polymer.

Suppose that the element ζ_i^* contains a certain volume of the solvent v_i^* . Assuming that the energy of formation of this volume is proportional to the latter and to the difference between the energies of the interaction of the monomer unit of the polymer with another such unit and with the solvent ($q_p - q_s$), i.e.

$\varepsilon_i = v_i^*(q_p - q_s)$, we find that the probability of the formation of the volume element $v_i^* \geq v_A^*$ is

$$p_A = C \exp\left(\frac{-\varepsilon_A}{kT}\right) = C \exp\left[\frac{-v_A^*(q_p - q_s)}{kT}\right]. \quad (25)$$

On sedimentation of the polymer, the structures ζ_i^* are deformed. It is natural to postulate that the greater the volume v_i^* of the element ζ_i^* present in the solution the greater the volume v_i^* of the element ζ_i^* produced from it in the polymeric substance formed. After introducing the proportionality coefficient β , we find an expression for the concentration of the centres $[Z_A]$ in the deposited polymer:

$$[Z_A] = [Z]_0 \exp\left[\frac{-v_A^* \beta (q_p - q_s)}{kT}\right]. \quad (26)$$

The value $[Z_A]$ in Eqn (26) is equal to the concentration of the UOD around which the elements of the free volume may be formed. If it is assumed that such centres are produced around the point of contact between two sections of the same or different polymer chains, then the concentration of these elements is higher, the higher the concentration of the polymer in solution at the instant of sedimentation.

Eqn (26) describes the law of the distribution of the sorption centres with respect to the volume of the molecules sorbed by them. In the sorption of organic substances consisting of C, H, O, and N atoms, the densities of which in the pure state differ little ($\rho_A = 1.1 \pm 0.1 \text{ g cm}^{-3}$), one can assume that $v_A = M_A(\rho_A N_A)^{-1}$, where $N_A = 6.02 \times 10^{23}$ is the Avogadro number. In this case, Eqn (26) transforms into

$$[Z_A] = [Z]_0 \exp(-\kappa M), \quad (27)$$

where

$$\kappa = \frac{\beta(q_p - q_s)}{\rho N_A k T_s}. \quad (28)$$

Here T_s denotes the temperature of the formation of the centre, i.e. the temperature of the sedimentation of the polymer from solution.

As can be seen from Fig. 7,^{28,29} Eqn (28) agrees well with experimental data and the value $q_p - q_s$ found from the slope of the straight line proved to be 51 J cm^{-3} . For comparison, we may note that the heat of melting of polyethylene crystals is 293 J g^{-1} .

Figure 7. Dependence of the logarithm of the concentration of the sorption centres for low-molecular substances $\ln[Z_A]$ in high-density polyethylene on the molecular mass of the sorbed substance (M_A) at 50 °C (solvent — n-hexane).²⁹

VI. Rearrangement of the sorption centres under the influence of the dissolved substance

As shown above (Fig. 3), the Langmuir sorption limit, i.e. the value $[Z_A]$, in most cases remains constant over a wide range of temperatures (from the temperature of the existence of the solid polymer to the melting point). However, when an additive is

Figure 8. Variation of the concentration of phenyl benzoate in isotactic polypropylene in the saturated vapour of this compound at 40 °C. Initial phenyl benzoate concentration in the melt (240 °C) (mol kg⁻¹) (1) 0; (2) 0.34; (3) 0.53; (4) 0.58.³³

introduced directly into the melt, the sorption law may be infringed.^{30–33} The sorption limit may then increase significantly.

Figure 8 illustrates the variation of the concentration of phenyl benzoate, introduced into a melt of isotactic polypropylene at different initial concentrations, when cooled polymer samples are kept in sealed tubes containing an excess of phenyl benzoate. In the course of such experiments, a large proportion of the dissolved substance escapes from the polymer, but its residual concentration exceeds appreciably the solubility in the untreated polymer. If a low-molecular substance A is introduced into the polymer melt at a concentration exceeding the solubility $\{[A]_p > [Z_A]\}$ and the substance is then extracted from the melt with alcohol at a low temperature (40 °C), then its solubility in the treated polymer is found to be appreciably higher than in the untreated polymer.³⁰ When such samples are heated to 80–100 °C, the solubility gradually falls to the initial value. These processes may be represented schematically as follows:

where ζ_k are the elements of disorder, which do not give rise to sorption centres under normal conditions, while Z_k are sorption centres formed around these elements at high concentrations of substance A.

The rearrangement of the elements ζ_k to sorption centres is accompanied by an increase in the free volume contained in them, which requires the consumption of the energy $\Delta\epsilon_k = (q_p - q_A)\Delta v_k$ where q_A is the energy of the interaction of the element of the polymer chain with the additive A referred to unit volume. The dimensions of the values q_p , q_s , and q_A (energy/volume) are identical with the dimension of pressure and in terms of its physical significance q is equal to the osmotic pressure of substance A in the polymer required for the rearrangement of the centres (*i.e.* for the 'fracture' of the polymer structure):

$$RT[A] \approx \frac{RT[A_p]}{[Z_A]K_A},$$

where $[A]$ is the concentration of mobile molecules, while $[A]_p$ is the overall concentration of substance A in the polymer. Since the parameters of the initial elements ζ_k do not enter into the expression for $\Delta\epsilon_k$, this pressure must be identical for all the elements and the rearrangement of all the centres must begin at the same concentration of the given additive. As can be seen from Fig. 9, the solubilities (L) of phenyl- β -naphthylamine and phenyl benzoate in polypropylene begin to increase at the following concentrations of these additives in the melt; ~ 0.15 and 0.25 mol kg⁻¹ respectively.

Figure 9. The solubilities (L) of phenyl- β -naphthylamine (1) and phenyl benzoate (2) in isotactic polypropylene at 40 °C as a function of the initial concentration of the same substance in the melt (240 °C).³⁴

VII. The possibility of varying the degree of disorder on reprecipitation of the polymer

According to Eqns (26) and (27),²⁸ the level of topological disorder, *i.e.* the overall concentration of the elements ζ_i and their size distribution, depend on the conditions governing the formation of the polymeric substance during its sedimentation from solution — on the nature of the solvent, the concentration, and temperature, *i.e.* on the value q_A . All these methods for the variation of the level of disorder have been used in our studies.

It is natural to postulate that the smallest values of q_A will be observed on precipitation of nonpolar polyalkenes from their low-molecular analogues — saturated hydrocarbons, and the highest will be observed on sedimentation from polar aromatic compounds. Indeed, the samples obtained by the reprecipitation of isotactic polypropylene from solutions in *n*-decane and chlorobenzene (5 g per 150 ml) differed appreciably in their properties. The crystallinities of polypropylene reprecipitated from *n*-decane and chlorobenzene, determined by differential scanning calorimetry, were 61.2% and 69.2%, and their densities were 0.9115 and 0.9179 g cm⁻³ respectively. The equilibrium solubilities of antioxidants in the samples of isotactic polypropylene precipitated from solutions in *n*-decane and chlorobenzene at 60 °C were 0.02 and 0.01 mol kg⁻¹ for phenyl- β -naphthylamine and 0.17 and 0.13 mol kg⁻¹ for phenyl benzoate which has the lower molecular weight. The sorption isotherms of phenyl- β -naphthylamine from alcohol by these samples (Fig. 10) differed even more³⁴ while the values of $[Z]_A$ calculated from them differed by a factor of 7.7 (0.30 and 0.039 mol kg⁻¹). It must be emphasised that the powders obtained on reprecipitation of polypropylene were pressed into films at temperatures in the range 200–220 °C, *i.e.* above the melting points of both samples (158.5 and 160.1 °C respectively).

The inhibited oxidation of the polymer samples was investigated at 180 °C, *i.e.* above the melting point. The experiments showed that the critical concentrations of the antioxidant (phenyl-

Figure 10. The sorption isotherms of phenyl- β -naphthylamine by samples of polypropylene reprecipitated from *n*-decane (1) and chlorobenzene (2) (solvent — alcohol, temperature — 40 °C).³⁴

Figure 11. Dependence of the induction period in the oxidation of polypropylene samples on the initial concentration of phenyl- β -naphthylamine (180 °C, oxygen, 300 mmHg): (1) polymer reprecipitated from *n*-decane; (2) polymer reprecipitated from chlorobenzene.³⁰

β -naphthylamine) in these samples differed by a factor of 1.9 (Fig. 11), the higher value corresponding to samples reprecipitated from *n*-decane.³⁴ Thus the difference between the concentrations of the sorption centres arising on reprecipitation of the polymer is preserved also in the melt.

Eqn (28) contains the temperature of the polymer sedimentation T_s . In the study of Kolesnikova and Shlyapnikov,³⁵ a solution of polypropylene in *m*-xylene at a temperature of 130 °C was either mixed with cold alcohol (rapid cooling) or was slowly cooled to room temperature. In the former case, the centres existing at 130 °C (isothermal conditions) were rapidly frozen, while in the latter the sedimentation occurred under nonisothermal conditions (~ 80 °C). The polypropylene samples obtained differed both in the sorption isotherms of phenyl- β -naphthylamine from ethyl alcohol and in the critical concentrations of the phenyl- β -naphthylamine used as the antioxidant in the oxidation of their melts; the latter are $0.055 \text{ mol kg}^{-1}$ (in the samples prepared by rapid cooling) and $0.040 \text{ mol kg}^{-1}$ (in the samples prepared by the slow cooling of the solution).

In the study of Mar'in *et al.*,³⁶ samples of isotactic polypropylene were subjected to a treatment involving repeated 'melting–crystallisation' cycles in accordance with the following scheme: heating to 250 °C, maintenance at this temperature for 90 min, cooling to 150 °C for 120 min, maintenance at this temperature for 120 min, and then cooling to room temperature. It was postulated that, by displacing segments of the macromolecules, the growing crystal facets can 'disentangle' some of their knots. The solubilities of diphenylamine, phenyl benzoate, and phenyl- β -naphthylamine but not the sorption isotherms were used as a measure of disorder. It can be seen from Table 1³⁶ that, as a result of seven cycles, the solubility of diphenylamine (molecular mass $M = 169$) decreased 3.7 fold, that of phenyl benzoate ($M = 199$) fell by a factor of 1.6, while that of phenyl- β -naphthylamine ($M = 219$) decreased by only 15%. Thus the larger the molecule, the greater the volume of its sorption centre and hence the more complex the UOD constituting its basis and the greater its resistance to disentanglement.

Table 1. Variation of the solubilities of low-molecular probe substances as a function of the number of melting–crystallisation cycles of isotactic polypropylene (according to the data of Shlyapnikov and coworkers^{19,36}).

Substance	Molecular mass	Number of cycles			
		1	3	5	7
Diphenylamine	169	0.234	0.208	0.068	0.063
Phenyl benzoate	199	0.162	0.142	0.130	0.102
Phenyl- β -naphthylamine	219	0.0148	0.0138	0.0135	0.0128

VIII. The anomalies in certain equilibria

It follows from Eqn (27) that the value of $[Z]_0$ depends on the concentration of the polymer solution from which the sample has been prepared by precipitation.

The formation of a complex between tetracyanoethylene (TCE) and hexamethylbenzene (HMB) in polyethylene and polypropylene has been investigated.³⁷

In our study of complex formation in the polymer, we were forced to compare the overall concentrations of the individual substances and complexes, *i.e.* to assume that $[\text{TCE}]_p \approx [\text{TCE} \cdot \text{Z}_{\text{TCE}}]$, *etc.*, whereas in fact a series of equilibria of type (21) occur in the polymer. According to Eqn (26), the concentrations of sorption centres decrease rapidly with increase in the molecular mass of the sorbed substance. Since the concentration of the complex under the comparatively mild conditions used in the study of the reaction (20–60 °C) cannot be higher than the concentration of the centres sorbing these complexes, a dependence of the concentration of the complexes, and of the complex formation constant K_c calculated from it, on the concentration of the solution of polyethylene in *n*-decane at the instant of its sedimentation was observed in the experiments (Fig. 12).

Figure 12. Dependence of the apparent equilibrium constant (measured at 22 °C) for the formation of a complex between hexamethylbenzene and tetracyanoethene in polyethylene on the concentration of polyethylene at the instant of its sedimentation in *n*-decane at 120 °C.³⁸

IX. Characteristic features of the kinetics of chemical reactions in polymers

Three types of relatively simple nonchain reactions occurring in polymers have been studied in detail.

Deviations from the regular features of the analogous reactions in the liquid phase were discovered.

A reaction of the first type may take place *via* two mechanisms: within and outside the centres Z_A and the centres can in their turn differ in their sorption energy. In order to simplify the calculations, we shall assume that all the centres are identical and that the reaction can proceed either within the centres or outside them. Denoting the rate constant for the reaction within the centres by k_{AZ} and that outside the centres by k_A , we find the expression for the overall rate of reaction;

$$-\frac{d[\text{A}]_p}{dt} = k_A[\text{A}] + k_{AZ}([\text{A}]_p - [\text{A}]). \quad (33)$$

Since a large proportion of the dissolved substance is usually contained within the sorption centres, *i.e.* $[A] \ll [A]_p$, appreciable deviations of the reactions from first order are observed only in the case where $k_A \gg k_{AZ}$. If compound A decomposes *via* the intermediate reversible formation of a radical pair,

then the volume required for the formation of the pair will be always greater than the volume of the initial molecule and the formation of a 'cage', coinciding with the sorption centre, will require an additional energy. For this reason, the rate of reaction within the centre should be appreciably lower than outside it. In the centres the shape of which corresponds most closely to that of the molecules contained in them, any reactions proceeding with a change in the shape of the reacting molecule will be hindered.

On the basis of general considerations, one may expect that the condition $k_A \gg k_{AZ}$ is obeyed and that the apparent rate constant (the ratio of the rate to the product of the concentrations of the reactants) increases with increase in the initial concentration of the reactant. Indeed, such a relation has been observed in the thermal decomposition of benzoyl peroxide $C_6H_5C(O)-O-O-C(O)C_6H_5$ in isotactic polypropylene (Fig. 13).³⁸ The reaction was catalysed by adding phenyl benzoate, which could substitute the peroxide molecules in the sorption centres. Similarly, the rate of isomerisation of dimethylbenzylsilyl peroxide in the same polymer increased with increase in its concentration.³⁹ It has been shown⁴⁰ that the total yield of the free radicals formed on decomposition of azobisisobutyronitrile in isotactic polypropylene at 80 °C increases nonlinearly with increase in the concentration of this substance: from 0.12 (at an initial concentration of 0.075 mol kg⁻¹) to 0.40 (at a concentration of 0.025 mol kg⁻¹).

Reactions of the second type have been investigated in detail in the interaction of benzoyl peroxide and diphenylethyl hydroperoxide with dibenzyl sulfide⁴¹⁻⁴³ and of benzoyl peroxide with

Figure 13. Dependence of the effective rate constant of the thermal decomposition of benzoyl peroxide (80 °C) in isotactic polypropylene on the initial peroxide concentration: (1) usual polymer; (2) polymer with an increased concentration of sorption centres.³⁸

diphenylamine.⁴⁴ These reactions can proceed *via* several paths:

If the concentrations of the free molecules of A and B are low compared with those of the bound molecules, the first path appears improbable and we shall therefore consider only the three remaining ones.

It was shown above that, despite the diversity of the sorption centres, the sorption isotherms of the individual substances are described satisfactorily by Langmuir isotherms in which K_A and K_B are average values and $[Z_A]$ and $[Z_B]$ are the total concentrations of the centres sorbing the given substance.

On solving the equation $[AZ_A] = K_A[Z_A][A]\{1 + K_A[A]\}^{-1}$ for $[A]$ and substituting $[AZ_A] + [A] = [A]_p$, we obtain a fairly cumbersome expression:⁴⁴

$$[A] = \frac{K_A[A]_p - K_A[Z_A] - 1}{2K_A} + \frac{\sqrt{(1 + K_A[Z_A] - K_A[A]_p)^2 + 4K_A[A]_p}}{2K_A}. \quad (38)$$

The dependence of $[A]/[A]_p$ (the fraction of mobile molecules) on $[A]_p/[Z_A]$ calculated by this formula is presented in Fig. 14 for different values of K_A . As can be seen from the figure, the fraction of mobile molecules increases with increase in the overall concentration of the reactant $[A]_p$, the increase being especially rapid starting from $[A]_p/[Z_A] = 1$.

The concentration of the complexes ABZ_{AB} varies with increase in the concentrations of the reactants in accordance with the equation^{41, 42}

Figure 14. Dependence of the fraction of mobile molecules {of the ratio $[A]/[A]_p$ } on the overall concentration of substance A in the polymer {in units of $[A]_p/[Z_A]$ } [calculation by Eqn (38)].^{41, 43}

$$[ABZ_{AB}] = \frac{K_{AB}[Z_{AB}][A][B]}{1 + K_{AB}[A][B]}. \quad (39)$$

At low concentrations of A and B $\{[A]_p \ll [Z_A]; [B]_p \gg [Z_B]\}$, one may put $[A] = [A]_p/K_A[Z_A]$ and $[B] = [B]_p/K_B[Z_B]$. In this case, Eqn (39) transforms into

$$[ABZ_{AB}] = \frac{K_{AB}[Z_{AB}][A]_p[B]_p}{K_A K_B [Z_A][Z_B] + K_{AB}[A]_p[B]_p}. \quad (40)$$

The rate of reaction (37) is $W_{AB} = k_{AB}[ABZ_{AB}]$, whence the apparent rate constant at low concentrations is

$$k_{AB} = \frac{W_{AB}}{[A]_p[B]_p} = \frac{k_{ZAB}K_{AB}[Z_{AB}]}{K_A K_B [Z_A][Z_B] + K_{AB}[A]_p[B]_p}. \quad (41)$$

According to this equation, the constant k_{AB} decreases with increase in both $[A]_p$ and $[B]_p$.

It is known that the second-order reactions require rapid mixing of the reactants in solution in polymers and they were

therefore investigated in amorphous polymers — atactic polypropylene and polyisobutylene — samples of which, each containing one of the two reactants, were mixed by repeated pressing. The experiments showed that the apparent rate constant for the reaction of benzoyl peroxide with dibenzyl sulfide varies with the concentration of each reactant and passes through a minimum (Fig. 15). This relation can be regarded as the sum of the curves described by Eqns (38) and (41).^{42, 43} In polyisobutylene, in which the solubilities of the reactants {and apparently the values of $[Z_A]$ and $[Z_B]$ } were 1.6 times lower than in polypropylene (the solubilities of benzoyl peroxide in these polymers at 50 °C were $S_A = 0.15$ and 0.23 , whilst those of dibenzyl sulfide were $S_B = 0.32$ and 0.54 mol kg^{-1} respectively), the minimum rate constant was observed at lower concentrations of the reactants.

The existence of two reaction paths [reactions (35), (36), and (37)] has also been confirmed by qualitative experiments: the 'inert' phenyl benzoate, which does not participate in the reaction, substitutes a molecule of benzoyl peroxide in the sorption centres

Figure 15. Dependence of the effective rate constant of the reaction of benzoyl peroxide with dibenzyl sulfide in atactic polypropylene (I) and polyisobutylene (2) on the initial peroxide concentration $[ROOR]_0$ (temperature is 50 °C).⁴³

of both types — $[Z_A]$ and $[Z_{AB}]$ — and lowers the rate of reaction in the region of low concentrations, when the mechanism of the pseudounimolecular conversion of the complexes ABZ_{AB} [reaction (37)] predominates, and accelerates the reaction at high concentrations, displacing the peroxide (and possibly also the sulfide) from complexes of the type AZ_A and BZ_B and increasing thereby the concentrations of the mobile molecules participating in reactions (35) and (36).

It is of interest that the rate of interaction of benzoyl peroxide with dibenzyl sulfide in polypropylene may be higher than the rate of the same reaction in its low-molecular analogue — isooctane, where the rate constant is independent of the initial concentration and is $(13.2 \pm 0.3) \times 10^{-3} \text{ litre mol}^{-1} \text{s}^{-1}$ under the same conditions (50 °C).

The slight increase of the rate constant for the bimolecular interaction of a phenolic antioxidant — 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) — with stearic acid as its concentration in polypropylene increases has been noted.⁴⁵

As an example of reactions of the type $2A + \text{polymer}$ the interaction of substituted *o*-benzoquinones with polyethylene and polypropylene have been studied.^{46, 47}

According to the Scheme (42), the reaction is accompanied by cross-linking of the polymer, the yield of substituted catechol amounting to 50%–60%. Assuming that a reaction of this kind may proceed only in large centres, each accommodating two reactant molecules, and replacing all B by A in Eqn (41), we obtain

$$W = \frac{k_{ZAA} K_{AA} [Z_{AA}] [A]_A^2}{K_A^2 [Z_A]^2 + K_{AB} [A_p]^2} \quad (43)$$

According to Eqn (43), the rate of reaction tends rapidly to the limit $k_{ZAA} [Z_{AA}]$ *i.e.* becomes independent of the concentration of the quinone. On the other hand, as the concentration of the quinone increases, the initial rate of reaction tends to a limit in accordance with Eqn (43) (Fig. 16).⁴⁶

Figure 16. Dependence of the initial rate of reaction between 3,6-di-*tert*-butyl-1,2-benzoquinone (Q) and atactic polypropylene on the initial quinone concentration in the polymer (temperature is 180 °C).⁴⁶

In isotactic polypropylene, the initial rate of reaction is directly proportional to the initial quinone concentration, but a zero reaction order with respect to the quinone is observed in the course of the reaction over a long period of the latter.⁴⁷ Apparently the reaction in this 'rigid' polymer proceeds mainly in the centres formed as a result of the rearrangement of the polymer structure, similarly to the rearrangement described above (see Section V).^{30–32} Apparently the reactions in polyethylene and ethylene–propylene copolymers proceed in accordance with the same law.⁴⁸

X. Displacement catalysis and nonchemical synergism

It has been shown³⁸ that the rate of thermal decomposition of benzoyl peroxide in isotactic polypropylene increases when phenyl benzoate, 'inert' in relation to this reaction in low-molecular media, is introduced into the polymer. Similarly, the rate of isomerisation of dimethylbenzylsilyl peroxide increases in the presence of the isomerisation product.³⁹ This phenomenon, associated with the displacement of the reactant molecules from centres more 'convenient' for them, the filling of which prevents a change in the shape or size of the reactant molecules necessary for the occurrence of the reaction, has been called³⁸ 'displacement catalysis'.

The main reaction on which the inhibition of oxidation is based — chain termination processes by the antioxidant (IH) — proceeds in accordance with the scheme

In polymers, the radicals (more correctly the macroradicals) $\text{RO}_2^\cdot$ cannot move freely and, for the occurrence of reaction (12), it is essential that the molecules of IH should possess translational mobility. Evidently the complexes between the antioxidant and the sorption centres $\text{IH} \cdot \text{Z}_{\text{IH}}$ are also immobile and the chain termination reaction must be preceded by the liberation of the IH molecule from the sorption centre.

Conversely, mobile oxygen molecules participate in the main side reaction — direct oxidation of IH — which leads to accelerated consumption of the antioxidant. Evidently the rate of oxidation of IH molecules in the centres 'convenient' for IH, *i.e.*

is lower than the rate of oxidation of the same molecules outside the sorption centres, *i.e.*

but in all cases the fraction of mobile molecules is small. Subsequently the $\text{I}^\cdot$ and $\text{HO}_2^\cdot$ radicals participate in a wide variety of reactions, most of which reduce the effectiveness of the inhibition of the process, for example $\text{HO}_2^\cdot + \text{IH} \rightarrow \text{H}_2\text{O}_2 + \text{I}^\cdot$. By increasing the fraction of mobile molecules, it is possible to increase selectively the rate of chain termination, altering slightly the rate of the undesirable stages of the process.

According to Eqn (21), substance B, which is relatively resistant to oxidation and reactions with peroxy-radicals but is capable of displacing IH from the centres Z_{AH} , may increase the fraction of mobile IH molecules at the same or even smaller overall concentration of the antioxidant. Assuming for simplicity that all the molecules of B are present in the polymer as complexes with Z_{AH} we find

$$[\text{IH}] = \frac{[\text{IH}]_{\text{hp}}}{K_{\text{AH}}\{[\text{Z}_{\text{AH}}] - [\text{B}]_{\text{p}}\}}. \quad (46)$$

The apparent chain termination rate constant is related to the true constant k_t for the $\text{IH} + \text{RO}_2^\cdot$ reaction by the expression

$$k_{\text{t}} = \frac{k_{\text{r}}}{K_{\text{AH}}\{[\text{Z}_{\text{AH}}] - [\text{B}]_{\text{p}}\}}. \quad (47)$$

Experiments have shown that comparatively 'inert' substances such as phenyl benzoate, octamethylcyclotetrasiloxane, and heptadecane (a low-molecular hydrocarbon) increase appreciably the effectiveness of phenolic antioxidants, distinct maxima appearing on the composition–induction period (*i.e.* the period of the effective retardation of the oxidation reaction) curve obtained at a constant overall concentration of the additives (Fig. 17). In contrast to the similar effect induced by chemically reactive additives, we called this phenomenon 'nonchemical synergism'.^{49–51} At high concentrations, the 'inert' additive disrupts the structure of the polymer and, in contrast to the usual 'chemical' synergism, the effect involving an increase in effectiveness vanishes.⁵²

It is seen from Fig. 18⁵² that, when an 'inert' additive such as octamethylcyclotetrasiloxane (at a variable concentration) is introduced into polypropylene containing phenyl- β -naphthylamine (PNA) as the antioxidant (at a constant concentration), the concentration of substance A in the gas phase initially increases owing to its displacement [Eqn (21)] and then decreases as a result of the rearrangement of the sorption centres {the increase in $[\text{Z}_k]$ } and then again increases owing to the displacement of A but this time from the new centres. This phenomenon is satisfactorily reproduced for various pairs of dissolved substances (see, for example Shlyapnikov *et al.*⁵⁰).

Thus the elements of topological disorder, *i.e.* the various entanglements of monomer chains, behave in polymers as quasi-

Figure 17. Dependence of the induction period in the oxidation of polyamide 12 on the composition of a mixture of 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) (IH) and octamethylcyclotetrasiloxane (OMTS) at 170 °C (1) and 190 °C (2). Overall concentration of additives 0.02 mol kg⁻¹ oxidant — oxygen, pressure — 300 mmHg.⁵¹

Figure 18. molecules differing in their properties and reactivity from the polymeric substance surrounding them.

XI. The zone model of the oxidation of polymers

The presence in the sorption centres Z_i of a free volume sufficient, on the one hand, to accommodate the molecules of low-molecular substances, including oxygen, and, on the other hand, sufficient for the formation of an activated complex in the $\text{RO}_2^\cdot + \text{RH}$ and $\text{R}^\cdot + \text{O}_2$ reactions may lead to a significant difference between the reactivities of the polymeric substance present in the centres Z_i and the surrounding polymeric substance in which short-range order is maintained. It may be postulated that oxidation reactions proceed only in such centres and that a free valence is transferred from centre to centre either as a result of migration along the polymer chain⁵³ or as a result of the diffusion of light radicals.⁵⁴ We shall consider the consequences of this model.^{3,55}

Suppose that a single free valence, responsible for the formation of the radical $\text{RO}_2^\cdot$, enters a zone having a volume v_z with the concentration of monomer units $[\text{RH}]_{\text{z}}$ and a sufficient con-

centration of oxygen, which converts the radicals $R^\bullet$ into $RO_2^\bullet$. The concentration of the radical $RO_2^\bullet$ in the zone is $[RO_2^\bullet]_Z = 1/v_Z$. The consumption of the reactive groups $[RH_Z]$ in the zone is described by the equation

$$-\frac{d[RH]_Z}{dt} = \frac{k_2[RH]_Z}{v_Z}, \quad (48)$$

where

$$[RH]_Z = ([RH]_0) \exp\left(\frac{-k_2 t}{v_Z}\right). \quad (49)$$

According to Eqn (49), the reactive substance is almost fully consumed during the time $\tau \approx 5v_Z/k_2$.

Next there is a possibility of two versions of the development of the process. If the residence time of the free valence in a single zone is $\vartheta \leq \tau$, then the free valence migrates from zone to zone faster than the substance of the zone is consumed. In this case, the rate of reaction is determined by the elementary constants k_1 , k_2 , etc. and the only difference between the kinetics of the reaction and the kinetics of the oxidation of low-molecular liquids is the incomplete consumption of the substance being oxidised: after the consumption of the substance, present in disturbed-order zones, the process is strongly retarded or comes to a complete stop. On the other hand, if $\vartheta \gg \tau$, then the free valence remains in the zone also after the consumption of the reactive substance contained in it and the rate of reaction is given by

$$W = \frac{v_Z[RH]_Z[RO_2^\bullet]}{\vartheta}. \quad (50)$$

The observed chain transfer rate constant $(k_2)_{\text{eff}}$ is described by the expression

$$(k_2)_{\text{eff}} = W[RO_2^\bullet][RH] = \frac{v_Z[RH]_Z}{[RH]\vartheta}, \quad (51)$$

i.e., subject to the assumptions made above, the experimentally observed constant $(k_2)_{\text{eff}}$ does not depend explicitly on the true elementary constants (including the chain propagation constant k_2).

The observed (effective) chain termination rate constant can be determined similarly. The rate of chain termination is equal to the frequency with which two free valences enter a single zone minus the rate of liberation of the unreacted valences from the zone, i.e.

$$W_t = 2 \frac{(1-\chi)[RO_2^\bullet]^2}{[Z]\vartheta} = 2(k_t)_{\text{eff}}[RO_2^\bullet]^2, \quad (52)$$

where $[Z]$ is the concentration of the zones and χ is the probability that a pair of free valences which have entered a single zone will leave it without recombination. If the value χ is sufficiently small, then the effective chain termination rate constant is given by

$$(k_t)_{\text{eff}} = \frac{2}{[Z]\vartheta}. \quad (53)$$

According to the proposed model, the local concentrations of low-molecular substances in the zones (sorption centres) may exceed by a large factor the average concentrations of these compounds in the polymer, which explains the strong influence of antioxidants⁵⁶ and oxygen^{57,58} on the yield of radicals from the 'cage' formed on decomposition of the hydroperoxy-group.

The zone model is illustrated by the scheme shown in Fig. 19.

The characteristic features of the extensive oxidation of a number of polymers may serve as confirmation of the model. Thus the rate of the high-temperature oxidation of polymers is second order with respect to the RH groups being oxidised:⁵⁸

$$W_{O_2} = \frac{k_1 k_2 k_3 [RH]^2 [O_2]}{2k_{3a} k_t} = k_e [RH]^2, \quad (54)$$

Figure 19. Schematic illustration of the propagation of the reaction in the polymer; open circles — zones of order violation before reaction; filled circles — ditto after reaction; A — chain branching site; B — chain termination site.

where k_3 is the rate constant for the decomposition of the radical $RO_2^\bullet$:

Assuming that not the entire polymer but only a proportion of its monomer units $[RH^*] = v_Z[Z][RH]_Z$ participate in the oxidation reaction and that q oxygen molecules are consumed per mole of the groups RH, one can formulate the following equation:

$$-\frac{d[RH^*]}{dt} = k_e [RH^*]^2 = k_e \left([RH^*]_0 - \frac{N_{O_2}}{q} \right)^2, \quad (56)$$

the solution of which gives

$$\frac{1}{[RH^*]_0 - N_{O_2}/q} - \frac{1}{[RH^*]_0} = k_e t.$$

Calculations have shown that, for the transformation of experimental oxygen absorption curves into straight lines in terms of the variables of Eqn (56), it is necessary to assume that $[RH^*]_0 \ll [RH]_0$, i.e. that only a small proportion of the volume of the polymer is oxidised. Under these conditions, q was assumed to be unity, since no other real values of q permit the assumption that $[RH^*]_0 = [RH]_0$. In particular, in the oxidation of polyamide 12 (the concentration of the monomer units is $5.076 \text{ mol kg}^{-1}$ and that of CH_2 groups is $55.8 \text{ g-equiv. kg}^{-1}$) the transformation of kinetic curves requires the assumption that $[RH^*]_0 = 0.6 \text{ mol kg}^{-1}$ (Fig. 20).⁵⁹ As can be seen from the figure, the

Figure 20. Variation of the concentration of the reactive part of the polymer during the oxidation of polyamide 12 (200 °C, oxygen) in coordinates for a second-order reaction (according to data of Monakhova *et al.*⁵⁹) at different pressures (mmHg); (1) 50; (2) 150; (3) 310; (4) 510. In the calculations, it was assumed that $[RH^*] = 0.6 \text{ mol kg}^{-1}$.

straight lines referring to different oxygen pressures intersect at a single point, *i.e.* the fraction of the substance being oxidised $[RH^*]_0$ is independent of the O_2 pressure.

XII. Conclusion

It follows from the data described that there exists a series of processes in which the elements of topological disorder present in the polymeric substance may be regarded as species which differ to some extent in their properties and reactivity from the relatively ordered substance surrounding them and that the distribution of the elements of disorder in the polymeric substance can be regarded as a negative image of its morphological (supermolecular) structure.³ Therefore, if the disorder is not taken into account as a separate component, the properties of the polymer will not be an unambiguous function of its composition and molecular mass distribution.

We believe that purpose-directed formation of topological structures in a polymeric material would be the next natural step in the physical chemistry of polymers and in the technology of polymeric materials.

Abstract. The review deals with the methods of synthesis of deuterium-labelled hydrophobic and hydrophilic synthons of lipid molecules and the routes to selectively and perdeuterated phospholipids and their analogues. Deuterium-labelled lipids are used to study the structural organisation and functioning of biological membranes including NMR studies and neutron diffraction of lipid–lipid and lipid–protein interactions. The bibliography includes 145 references.

I. Introduction

The explosive development of molecular biology, particularly of biomembranology, has stimulated research aimed at the synthesis of deuterated lipids. The preparation of selectively and perdeuterated lipids has permitted studies of structural organisation and functioning of biological membranes. Deuterium can be selectively incorporated into any methyl, methylene, or methine group of the lipid molecule. In these transformations, the properties of lipid molecules remain unchanged, which makes the deuterium label superior to spin or fluorescent labels.

Originally, the deuterium-labelled lipids were used only in mass spectrometry for the analysis of pathways of fragmentation of lipid molecules.^{1,2} In the 70–80's, novel procedures for the study of the structural organisation of membranes were developed, such as solid-state ²H NMR^{3–6} and neutron diffraction.^{7–9}

However, these methods are not very sensitive and require large quantities of lipid samples (tens and even hundreds of milligrams). Thus, the development of convenient (in the preparative sense) methods of synthesis of deuterium-labelled lipids that would permit preparation of these lipids in the amounts required is still urgent.

Another trend in the use of deuterated lipids is related to studies into the structure of membrane proteins. Secondary and tertiary structures of membrane proteins are determined by the

traditional method of high-resolution two-dimensional ¹H NMR spectroscopy.¹⁰ Obviously, such studies require perdeuterated detergents that are 'transparent' for the ¹H NMR method. Organic solvents or micelles obtained from lipid-like detergents are generally used as the membrane environment.^{11–14} Yet no ¹H NMR studies into the structure of membrane proteins in lipid bilayers have thus far been carried out because, in contrast to small-sized micelles, the movement in bilayers is anisotropic, which results in significant broadening of signals in the NMR spectra. The principal conditions for the study of secondary and tertiary structures of proteins in lipid bilayers have now been established. The possibility of obtaining high-resolution two-dimensional ¹H NMR spectra of lipid bilayers using the magic-angle spinning method has been demonstrated.^{15,16} Studies into the structure of intramembrane proteins are being scheduled. The accessibility of perdeuterated lipids is a prerequisite for conducting these studies.

The present review describes the methods of synthesis of deuterium-labelled hydrophobic and hydrophilic precursors of lipid molecules and of selectively perdeuterated phospholipids and their analogues.

The methods for the incorporation of deuterium are based on the use of commercially available deuterium-containing chemical reagents,¹⁷ such as heavy water (D₂O), alcohols (MeOD), acids (D₂SO₄), or bases (NaOD). Enolisable protons of lipids can be specifically exchanged for deuterium under conditions of acid or base catalysis. Molecular deuterium in combination with platinum or palladium catalysts and Raney nickel is mostly employed for conducting a non-specific exchange.

LiAlD₄, NaBD₄ and their derivatives are most often used for the specific reduction of particular functional groups. The use of molecular deuterium has not found wide application in the catalytic reduction of double and triple bonds, since the reduction is often accompanied by a non-selective proton–deuterium exchange.

Bacterial strains that are unable to synthesise certain lipid components and that are grown on media containing these components with deuterium labels are used for specific incorporation of deuterium. Non-specific deuteration is achieved by growing bacteria on culture media in which heavy water is used instead of H₂O.

The final assembly of deuterium-containing fragments into synthons needed for phospholipid synthesis is performed by

methods of organic synthesis. Phospholipids are synthesised by traditional methods employed in lipid chemistry.

II. Synthesis of deuterated fatty acids

The simplest (in the preparative sense) methods for obtaining selectively and perdeuterated fatty acids are based on the reaction of proton–deuterium exchange.¹⁷ A prerequisite for conducting such reactions is the presence of a medium with readily dissociating deuterons and a catalyst enabling the dissociation of C–H bonds of fatty acids.

As a rule, such reactions are carried out at sufficiently high temperatures; fatty acids with C–D bonds are obtained after removal of the catalyst. Under conditions close to physiological ones, they are stable and do not enter into the reactions of reverse exchange. If fatty acid molecules contain functional groups that increase the acidity of vicinal C–H bonds, the exchange can be carried out selectively.

In particular, protons at the α -position to a carbonyl or a carboxyl group can be easily exchanged for deuterium. A tautomeric transformation shown in Scheme 1 is characteristic of carbonyl compounds.

The formation of an enol tautomer occurs either in the presence of bases *via* the enolate anion or in the presence of acids *via* the carbocation.¹⁸ If these transformations are carried out in an excess of a solvent containing readily dissociating deuterons, α -protons exchange for deuterium.

Let us consider some examples of such a selective exchange. The presence of a carboxyl group in palmitic acid **1** increases the acidity of α -protons; selective exchange of α -protons for deuterium gives compound **2** in D_2O (the source of mobile deuterons) in the presence of a base as the catalyst.

In case of long-chain fatty acids, the reaction proceeds under relatively drastic conditions (200 °C, 72 h, 1% NaOD).¹⁹ α -Protons of short-chain carboxylic acids undergo the exchange more readily.²⁰

This approach can be used for the incorporation of deuterium into fatty acids with one double bond without the migration of this bond along the hydrocarbon chain.²¹

Fatty acid esters are more reactive than the acids themselves. Thus equilibrium conditions for the exchange of α -protons of methyl palmitate are reached within several hours of boiling in MeOD in the presence of NaOD.^{22–24} With the same ease, the exchange proceeds with monoalkyl malonates **3**.

Alk = Me(CH₂)₁₃.

The exchange takes place on boiling in D_2O (which is a more readily available reagent than MeOD) in the presence of NaOD as the catalyst.^{24, 25} Decarboxylation of the sodium dicarboxylate **4**

results in a salt of the monocarboxylic acid **2** deuterated at the α -position.

In aldehydes, the exchange of α -protons occurs very readily, which can be used in exchange reactions aimed at deuterium incorporation at the α -position of relatively labile, unsaturated fatty acids. The synthesis of [2,2-²H₂]-oleic acid **9** is an example.²⁶ Methyl oleate acid **5** served as the starting material. It was first reduced to the alcohol **6** which was then oxidised to the aldehyde **7** followed by the exchange reaction in $\text{D}_2\text{O}/\text{Py}$. [2,2-²H₂]-Oleic acid **9** was obtained by the oxidation of the aldehyde **8** with silver oxide.

The multistep character of this approach is its obvious limitation.

Exchange reactions are also used for the substitution of non-enolisable protons for deuterium. Complete non-specific exchange of protons in palmitic acid **1** is achieved at high temperatures and pressure in the presence of Pt and Na₂O₂ as the catalysts.²⁷

Under these conditions, partial decarboxylation of a fatty acid occurs, the yield of the deuterated product **10** is 80%–85%.

Fully deuterated acids can also be obtained by passing gaseous deuterium through a suspension of palladium black in a fatty acid.²⁸ The specificity of the exchange of non-enolisable protons is rather low. However, in some cases selective proton–deuterium exchange can be achieved. If the reaction is carried out under closely controlled conditions, it is possible to exchange predominantly the protons of the terminal methyl group of a carboxylic acid.²⁹ In this case, K₂PtCl₄ is used as the catalyst.

The obvious merit of the above methods is that the synthesis of deuterated fatty acids does not require complex multistage procedures. Moreover, it allows the use of available fatty acids as the initial material. The reactions occur with high yields. The final products are isolated by extraction without recourse to chromatographic purification. The extent of deuteration of a fatty acid depends on the number of repetitions of the exchange procedure, the nature of the deuterating reagent, and its excess. In order to increase the extent of deuteration of the target fatty acids and achieve a more rational use of expensive deuterated solvents, exchange reactions are usually carried out in 2–3 steps.

The preparation of selectively deuterated fatty acids requires the use of more sophisticated procedures. They combine the exchange reactions, selective reduction, and the synthesis of fatty acids from individual synthons. The synthesis of methyl laurate **12** having a deuterated methyl group at the end of the hydrocarbon chain has been described.²⁵ Methyl 12,12,12-trichlorododecanoate **11** was used as the starting material. Zinc dust in D_2O –dioxane specifically reduces the CCl₃ group of the ester **11** to CD₃ resulting in the product **12**.

The methyl ester **12** can be reduced to the corresponding alcohol and used to obtain labelled myristic acid.^{30,31}

Reduction with LiAlD₄ and NaBD₄ is extensively used for the selective incorporation of deuterium labels into different positions of hydrocarbon chains of fatty acids. In this case, deuterium incorporation is carried out in one step and the extent of deuteration of the final products depends exclusively on the extent of deuteration of LiAlD₄ or NaBD₄ used in this reaction. This method has been used for the synthesis of [3-²H₂]-stearic acid **17**^{19,32} from methyl palmitate **13** as the starting compound. It was reduced to the alcohol **14** with LiAlD₄, and then the hydrocarbon chain was elongated by a malonate approach. To this end, the alcohol **14** was activated by its conversion into the mesyl derivative **15**, which was used as the alkylating reagent. The alkylation of the diethyl malonate under alkaline conditions is accompanied by saponification of ester groups; subsequent decarboxylation of the dicarboxylic acid **16** gives the acid **17** with a deuterium label at the β-position.

Apparently, any oxo group in the hydrocarbon chain can be selectively reduced to the CD₂ group.^{19,33} Thus the methyl ester of the oxo acid **18** was selectively reduced with NaBD₄ to the hydroxy ester **19**. The latter was further converted into the tosylate **20** and reduced with LiAlD₄, which resulted in the alcohol **21** deuterated at positions 1 and 17. The oxidation of the alcohol **21** with chromium oxide was accompanied by the removal of deuterium from the position 1, eventually resulting in [17-²H₂]-stearic acid **22**.

The same scheme can be used for the stereospecific incorporation (if required) of one deuterium atom into the fatty acid molecule.³³

In addition to the tosylates of the type **20**, the synthesis of deuterated fatty acids makes use of mesylates and iodides, which are also reduced with LiAlD₄.^{34,35} Primary and secondary bromides are not reduced,^{35,36} which makes it possible to obtain the necessary synthons for the fatty acid synthesis. However, the selectivity of LiAlD₄ is rather low. Therefore, another reducing agent, NaBD₃CN, has been recommended.³⁷ This compound selectively reduces tosylates, mesylates, and iodides in the presence of ester groups in aprotic solvents.

The CD₂ groups are obtained by the Clemmensen reduction of oxo groups (Zn/DCl).^{32,38} However, the presence of mobile deuterons in the reaction medium results in the exchange of the protons at the α-position relative to the oxo group, which leads to the formation of the (CD₂)₃ fragment in the hydrocarbon chain. A versatile procedure has been developed³⁹ for the substitution of the CH₂ group by CD₂ at any position of the saturated fatty acid. This method consists in the reduction of the corresponding ester of

the carboxylic acid **23** with LiAlD₄. The alcohol formed **24** is converted into the bromide, and the bromide is used to obtain the Grignard reagent **25**. The interaction of the Grignard reagent **25** with a salt of a bromo-substituted carboxylic acid **26** in the presence of Li₂CuCl₄ as a catalyst gives the carboxylic acid **27** with a deuterated methylene group. At this stage, the reaction proceeds in high yields (77%–85%) which tend to decrease with the elongation of the hydrocarbon chain in the compound **25**.

By varying the length of the hydrocarbon chain of the ester **23** and the bromo-substituted acid **26**, one can obtain fatty acids with variable lengths of the hydrocarbon chain and variable positions of the CD₂ group.

Lithium dimethylcuprate, LiCuMe₂, was used for the substitution of the tosyl group by the methyl group in the synthesis of methyl [13-²H₂]-myristate.⁴⁰

Vicinally deuterium-labelled fatty acids are synthesised by the reduction of multiple bonds with gaseous deuterium on platinum and palladium catalysts.^{41,42} This method for deuterium labelling is rarely used due to a number of disadvantages, such as the necessity to use a large excess of deuterium, drastic reaction conditions, and, which is the most important, because of the side reactions of isotope exchange. The use of the homogeneous Wilkinson catalyst, [tris(triphenylphosphine)rhodium chloride], allows one to avoid side reactions to some extent.^{43–46} Double and triple bonds can be reduced on a deuterated Raney nickel.^{47,48} However, the most popular procedure for the catalytic hydrogenation of double and triple bonds with molecular deuterium is the deuteration of triple bonds on the Lindlar catalyst. The lower activity of the Lindlar catalyst in comparison with other catalysts makes it possible to selectively deuterate triple bonds. This reaction proceeds with a high degree of stereoselectivity; the content of the *cis*-isomer (the natural isomer in unsaturated fatty acids) in dideuterated alkenes amounts to 98%–99%. This method was used in the synthesis of octadeuterioarachidonic acid⁴⁹ and a series of unsaturated CD=CD-fatty acids.^{49–53} Reduction on the Lindlar catalyst is also used in 'alkyne' syntheses of unsaturated fatty acids with deuterium-labelled methylene fragments, since no reverse deuterium–proton exchange takes place under conditions of catalytic hydrogenation.²¹

Selective deuteration of the double bonds of unsaturated fatty acids is also performed with deuteriohydrazine.^{32,54,55} This reaction is carried out only in the presence of small amounts of an oxidising agent (oxygen, sodium metaperiodate, hydrogen peroxide, copper(II) salts, etc.). First, the diimide DN=ND is formed *in situ* from deuteriohydrazine in the presence of the oxidiser; its *syn*-form ensures the *cis*-addition of deuterium to the double bond.⁵⁶

The synthesis of deuterium-labelled unsaturated acids is based on the use of the Wittig reaction.^{44,57–59} An example of such synthesis is shown in Scheme 2.

According to this scheme, deuterium is incorporated *via* the exchange reaction into the α-position of nonanal **28** upon boiling the aldehyde in a D₂O/pyridine mixture. The second component of the Wittig reaction is obtained by the selective reduction of monomethyl azelate **30** to the alcohol **31**; the hydroxyl group is then consecutively substituted by chlorine (compound **32**) and iodine (compound **33**), and the iodide **33** alkylates triphenylphosphine. The key step in this synthesis is the Wittig condensation of the aldehyde **29** and the phosphonium salt **34**. Initially, it was proposed to use sodium ethoxide in this reaction.⁵⁸ However, very often the condensation proceeded in very low yields.⁶⁰ Later,

Bu^tOLi was recommended as a base.⁵⁹ The latter was obtained by the interaction of equimolar amounts of *tert*-butyl alcohol and hexyllithium. In this case, the condensation of compounds **29** and **34** proceeded with a sufficiently high degree of stereoselectivity, the yield of [11-²H₂]-oleic acid (**36**) and its *trans*-isomer, [11-²H₂]-elaidic acid, reached ~70%. The ratio of *cis*- and *trans*-isomers was 95:5. The formation of *cis*- and *trans*-isomers in the Wittig reaction is a serious limitation of this method, since the separation of geometric isomers of fatty acids requires special chromatographic procedures.⁵⁷ The ratio of *cis*- and *trans*-isomers depends largely on the reaction conditions.⁶⁰ For example, by performing the reaction with potassium bis(trimethylsilyl)amide, one can increase the content of the *cis*-isomer up to 98%⁶¹ which is comparable with the stereopurity of alkenes obtained by hydrogenation of acetylenic compounds on the Lindlar catalyst.

In addition to the above-described methods of elongation of hydrocarbon chains (malonate synthesis, condensation with the use of copper catalysts, the Wittig reaction), other approaches are employed in the synthesis of deuterium-labelled acids that are traditionally used in fatty acid chemistry, such as the 'alkyne' synthesis,^{21, 35, 43, 62, 63} enamine synthesis,^{19, 34, 64} and Kolbe electrolytic synthesis.^{33, 65–67} Synthesis of various deuterium-labelled acids has been considered in a number of reviews.^{30, 31}

III. Synthesis of deuterium-labelled hydrophilic components of phospholipids

The hydrophilic part of phospholipid molecules includes choline, ethanolamine, serine, glycine, inositol, and some other residues.^{68, 69}

To study the structural peculiarities of the polar region of a lipid bilayer, various methods of synthesis of phospholipids with different deuterium-labelled polar portions of phospholipid molecules have been developed.

1. Synthesis of deuterated cholines

One of the most common phospholipids of biological membranes are phosphatidylcholines.⁶⁸ They are the favourite object for biophysical and biochemical studies. This is due to their ability to form stable bilayers within a broad range of temperatures, pH, and ionic strength. The quadrupole splitting of signals of deuterium labels in the ²H NMR spectra of choline is extremely sensitive to changes in the surface electric potential of the lipid bilayer,⁷⁰ which opens new opportunities for the study of electric properties of membranes. It is not surprising therefore that a great deal of attention has been given to the synthesis of deuterated cholines or their chemical precursors.

The developed methods to date permit the incorporation of deuterium into any part of the choline molecule. In order to define

the positions in the choline residue, we shall use the system of designations proposed by Seelig *et al.*:⁷⁰

In order to obtain choline labelled with deuterium at the α-position, the ethyl ester of *N,N*-dimethylglycine (**37**) is reduced with lithium aluminium deuteride, after which the *N,N*-dimethylaminoethanol (**38**) formed is subjected to methylation. This reaction gives [α-²H₂]-choline iodide (**39**),⁷¹ which is then condensed with 1,2-dipalmitoyl-*sn*-glycerophosphodichloridate to give 1,2-dipalmitoyl-*sn*-glycerophospho-[α-²H₂]-choline:

It should be noted that the condensation of phosphatidic acid or phosphodichloridate with choline is an important step in the synthesis of phosphatidylcholines. This reaction is carried out in organic solvents (usually, in pyridine, chloroform, dichloromethane, *etc.*). However, the solubility of choline iodide in organic solvents is very low, which is the reason for low yields at the stage of condensation of the phosphatidic acid and choline iodide. To overcome this problem, it was proposed to use choline acetate.⁷² However, the yields varied within a very broad range and were 40%–60% at best. This is also due to the relatively low solubility of choline acetate in organic solvents and its high hygroscopicity.

The synthesis of perdeuterated phosphatidylcholine was carried out with the use of a complex of choline iodide with iodine.⁷³ The drawback of this approach is the fact that this complex is unstable and loses iodine on storage or drying *in vacuo*. Moreover, after condensation it is necessary to remove the large excess of free iodine, whereas the yield of phosphatidylcholine is as low as 25%–40%.

An effective approach to the synthesis of phosphatidyl choline has been proposed by Harbison and Griffin⁷⁴ who have used choline tetraphenylborate. A salient advantage of this method is that this salt is virtually insoluble in water, and choline can be easily and quantitatively isolated from aqueous solutions. The fact that choline tetraphenylborate is non-hygroscopic and is readily soluble in organic solvents, such as pyridine, allows one to achieve sufficiently high yields in its condensation with phosphatidic acid. [α-²H₂]-Choline tetraphenylborate (**40**) was prepared as follows. After methylation, the organic solvent was removed *in vacuo*, the residue was treated with aqueous alkali, insoluble aluminates were filtered off, and [α-²H₂]-choline was precipitated with an aqueous solution of sodium tetraphenylborate.

The synthesis of β-deuterated choline⁷¹ is based on the method earlier proposed for the synthesis of ¹⁴C-labelled ethanolamine.⁷⁵ According to this method, condensation of sodium cyanide with formaldehyde gives hydroxyacetonitrile (**41**), which is further benzoylated to give the nitrile **42**. The latter is reduced to [β-²H₂]-ethanolamine (**43**). Exhaustive N-methylation of [β-²H₂]-ethanolamine **43** gives [β-²H₂]-choline iodide (**44**):

Yet another approach⁷⁶ consists in the use of the ethyl ester of *N,N*-dimethylglycine (**37**) as the starting compound. The mobile

α -protons of the compound **37** are exchanged for deuterium in MeOD in the presence of sodium methoxide. This exchange occurs at a high rate, and equilibrium conditions are reached within 1 h at room temperature. The deuterium exchange is accompanied by transesterification of the ethyl ester to give the compound **45**. The progress of the exchange reaction is easily monitored by following the disappearance of the signals corresponding to the CH₂ group and the appearance of signals of CHD and CD₂ groups in the ¹³C NMR spectra. The reduction of the methyl ester **45** to the corresponding alcohol **46**, its further methylation, and the preparation of [β-²H₂]-choline tetraphenylborate (**47**) are carried out in much the same way as the synthesis of the compound **40**, except that lithium aluminium hydride is used instead of lithium aluminium deuteride.

Per-C-deuterated choline⁷⁴ is obtained by reduction of ethyl cyanoacetate with lithium aluminium deuteride with subsequent exhaustive N-deuteromethylation of the deuterated ethanolamine **48**. The resulting choline iodide (**49**) can be converted into the acetate,⁷² the complex with iodine,⁷³ or tetraphenylborate (**50**).⁷⁴ The latter seems to be the most convenient form of choline for its subsequent condensation with phosphatidic acid. The total yield of choline tetraphenylborate **50** exceeds 40%.⁷⁴

In addition to this method, per-C-deuterated choline can be obtained by quaternisation of [2-²H₂]-trimethylamine with 1,1,2,2-[²H₄]-2-bromoethanol as in the synthesis of perdeuterated dodecylphosphocholine (see below).⁷⁷ Perdeuterated β-bromoethanol can be used in those schemes of phosphatidylcholine syntheses that envisage the formation of the choline residue at the last stage, by the reaction of bromo(chloro)alkanes with trimethylamine.⁷⁸

Choline with deuterated methyl groups is synthesised by the methods based on methylation of ethanolamine or its partly methylated derivatives. Methylation of ethanolamine followed by precipitation of choline as tetraphenylborate was used to obtain [γ-²H₃]-choline in a practically quantitative yield.⁷⁴ Choline tosylate is yet another convenient derivative for the phosphatidylcholine synthesis.⁷⁹ However, this choline salt is readily soluble in water. Moreover, choline tosylate cannot be obtained by a direct ion-exchange reaction between choline iodide and *p*-toluenesulfonic acid. The conversion of choline iodide into tosylate requires an intermediate synthesis of choline acetate.²⁴ *p*-Toluenesulfonyl chloride is the starting compound in the synthesis of [γ-²H₃]-choline tosylate (**53**).²⁴ Its reaction with CD₃OH yields methyl tosylate (**51**), which is further used for the deuteriomethylation of 2-*N,N*-dimethylethanolamine (**52**). Choline tosylate **53** is obtained in a quantitative yield:

2. Synthesis of deuterium-labelled ethanolamines

Ethanolamine is the structural element of phosphatidylethanolamines, which, like phosphatidylcholines, are zwitterionic phospholipids. However, in contrast to phosphatidylcholines, phosphatidylethanolamines manifest basically different self-organisation properties. Under physiological conditions, phosphatidylethanolamines form in water inverted hexagonal structures rather than an extended bilayer.^{80,81} It is believed that the ability of phosphatidylethanolamines to form non-bilayer structures strongly affects many membrane functions.

To obtain ethanolamines with deuterium labels in different positions, the reduction of glycine derivatives^{82–84} with metal deuterides is generally used. Thus the reduction of glycine ethyl ester (**54**) with lithium aluminium deuteride⁸³ results in ethanolamine (**55**) with a deuterium label at position 1.

An analogous procedure is used to synthesise ethanolamine **43** with a deuterium label at position 2. However, in this case the deuterated ethyl ester of glycine (**56**) and lithium aluminium hydride are used as the starting compounds.⁸³

[2-²H₂]-2-Aminoethanol **43** can also be obtained by the methods employed in the synthesis of deuterated cholines.^{71,75} The ethyl ester of deuterated glycine **56** can also serve as the starting compound in the synthesis of [1,2-²H₄]-2-aminoethanol (**48**).⁸³

The latter was also obtained by the reduction of ethyl cyanoacetate according to the procedure for the synthesis of perdeuterated choline.⁷⁴

In addition to reduction, deuterated ethanolamines can be obtained by proton–deuterium exchange reactions. Thus Raney nickel in D₂O is used as the catalyst in the exchange of protons in ethanolamine (**57**).⁸⁵ This exchange is non-specific despite the higher activity of position 2. The indisputable advantage of this approach is undoubtedly the accessibility of the initial reagents.

The general methodology of the preparation and utilisation of ‘deuterated’ Raney nickel for proton exchange in aliphatic and aromatic compounds has been described by Pojer.⁸⁶

Deuterium-labelled ethanolamines are obtained in the form of water-soluble hydrochlorides and are routinely used in phosphatidylethanolamine synthesis by enzymic transphosphatidylation, which is catalysed by phospholipase D and takes place in aqueous media.

3. Synthesis of deuterium-labelled glycerols

Glycerol (**58**) is a structural element of all glycerophospholipids and a constituent of the polar region of the negatively charged phospholipid phosphatidylglycerol, which, in turn, is the structural component of cardiolipin (diphosphatidylglycerol). The interest in the synthesis of deuterated glycerols is associated not only with their use in the synthesis of labelled lipids, but also with studies of glycerol as a substrate and intermediate of many biosynthetic processes. In this connection, the synthesis of various deuterium-labelled glycerols has become the subject of a large number of publications.^{73,87–95} The methods elaborated to date allow one to obtain glycerols with a deuterium label at any

position of the molecule. Non-protected deuterium-labelled glycerols are used as substrates in enzymic syntheses of phospholipids, and their isopropylidene derivatives are used in chemical syntheses of phosphatidylglycerols. The necessary stereoconfiguration of isopropylidene-glycerols is provided by the original use of specific optically active reagents. Deuterium is introduced into the glycerol molecule by reduction with lithium aluminium deuteride, sodium borodeuteride, or their derivatives,^{73, 87–92} as well as by enzymic methods.^{87, 93, 94}

Let us consider the syntheses of various deuterated glycerols and their isopropylidene derivatives. 1,2-*O*-Isopropylidene-*sn*-[3-²H₂]-glycerol (**64**) has been synthesised by the method traditionally employed in lipid chemistry.⁸⁶ This method is based on the conversion of D-mannitol (**59**) into the 1,2:5,6-di-*O*-isopropylidene derivative **60** followed by scission of the vicinal diol group with lead tetraacetate. To remove the proton remaining at position 1, the protected D-glyceraldehyde **61** is oxidised to the corresponding glyceric acid **62**, which can further be reduced to the alcohol. For more optimal utilisation of the relatively expensive lithium aluminium deuteride, the acid **62** is converted into the methyl ester **63** prior to reduction to obtain 1,2-*O*-isopropylidene-*sn*-[3-²H₂]-glycerol **64** (Scheme 3).⁸⁷

An approach, which is very similar to that described above, was used⁸⁸ in the synthesis of **64**, except that the oxidation of the vicinal diol **60** was performed with sodium periodate, the aldehyde **61** was oxidised with chromic acid, and the resulting acid **62** was directly reduced with lithium aluminium deuteride. Along with D- and L-mannitol, D- and L-serine are also used as the original optically active compounds.^{90, 91}

The synthesis of 2,3-*O*-isopropylidene-*sn*-[1-²H]-glycerol (**66**) has been described.⁸⁷ The aldehyde **65**, an enantiomer of the aldehyde **61**, was prepared from L-mannitol, which, in turn, was obtained by the reduction of L-mannose. The reduction of the aldehyde **65** with sodium borodeuteride gives the isopropylidene derivative **66** containing one deuterium atom at position 1.

Unfortunately, the reduction of the aldehyde **65** is non-stereospecific, and the compound **66** is a mixture of two diastereomers.

The stereospecific incorporation of deuterium into glycerol is carried out by both chemical⁹¹ and enzymic^{87, 93, 94} methods. An original procedure⁸⁷ based on the enzymic reaction of proton–deuterium exchange has been proposed. In the presence of horse alcohol dehydrogenase, one of the protons of 1,2-*O*-isopropylidene-*sn*-glycerol (**67**) is stereospecifically exchanged in D₂O to give 1,2-*O*-isopropylidene-(3*R*)-*sn*-[3-²H]-glycerol (**68**).

Apparently, this reaction is of general character and can be used for stereospecific exchange of one proton for deuterium in any primary alcohol. A combination of chemical and enzymic methods gave (1*R*, 2*R*)-[1,1-²H, ³H]-glycerol stereospecifically labelled with both deuterium and tritium.⁹³

In order to incorporate deuterium into position 2 of the glycerol molecule, the reduction of dihydroxyacetone (**69**) with sodium borodeuteride is used.⁸⁷ When required, glycerol (**70**) can be converted into the isopropylidene derivative by the reaction with acetone in the presence of *p*-toluenesulfonic acid. However, this reaction gives racemic isopropylidene-glycerol (**71**):

Selective incorporation of deuterium into positions 1 and 3 of the glycerol molecule is achieved using the sequence of reactions depicted in the following scheme:⁸⁷

Perdeuterated glycerol **73** (mobile protons of the hydroxy groups are not taken into consideration) is prepared by the reduction of diethyl oxomalonate (**72**) with lithium aluminium deuteride.⁷³ Enzymic phosphorylation of the deuterated glycerol **73** ensures the necessary stereoconfiguration in subsequent intermediates of glycerophospholipid synthesis.⁷³ The introduction of the protecting isopropylidene group into the glycerol **73** gives racemic 1,2-*O*-isopropylidene-*rac*-[1,2,3-²H₃]-glycerol (**74**).⁸⁷

Deuterium-labelled glycerols and their isopropylidene derivatives are used in the synthesis of deuterium-labelled phosphatidylglycerols and perdeuterated phosphatidylcholine. The incorporation of deuterium into position 3 of 1,2-di-*O*-alkylglycerol has been described.⁹² The latter was oxidised to the dialkyl derivative of glyceric acid using the Jones reagent. The resulting acid was reduced with lithium aluminium deuteride to give 1,2-di-*O*-alkyl-[3-²H₂]-glycerol. The diglyceride component can further be used for the synthesis of phospho- or glycolipids. However, this method is inapplicable to the synthesis of diacyl diglycerides due to the reduction of ester groups.

4. Other deuterium-labelled hydrophilic synthons of lipid molecules

Deuterium-labelled [²H₂]-serine is commercially available and can be used in enzymic or chemical syntheses of deuterium-labelled

phosphatidylserines. A synthesis of L-serine stereospecifically labelled with deuterium from labelled asparagine has been described.⁹⁵ A number of publications have been dedicated to the synthesis of glycolipids with deuterium labels in the carbohydrate part.^{92,96–103} Usually, deuteration of carbohydrate fragments is carried out by catalytic exchange in the presence of Raney nickel in D₂O, which results in the exchange of protons geminal to the hydroxyl groups of primary and secondary alcohols.⁹⁶ Glucopyranosides subjected to such exchange accept deuterium labels at positions 2, 3, 4, 6, and 6'. The rate of exchange depends on steric factors and differs markedly for different positions in the carbohydrate moiety. The progress of the proton–deuterium exchange is monitored by ¹³C NMR spectroscopy. In case of glycosyldiglycerides,⁹⁸ dialkyl diglycosyldiglycerides,⁹⁹ and other glycolipids¹⁰¹ devoid of ester groups, the exchange is carried out directly in the glycolipids, which do not undergo destruction. In case of diacyl glycosyldiglycerides, the presence of relatively labile ester bonds precludes the application of this approach. Therefore, deuterium is first incorporated into the carbohydrate fragments, which are further bound to diglycerides by traditional chemical methods.⁹⁷ Deuterium can be incorporated into carbohydrates by reduction with metal deuterides.¹⁰³

IV. Synthesis of phospholipids with deuterated fatty acids

The synthesis of phospholipids with deuterated fatty acids is carried out by traditional methods of lipid chemistry. The synthetic procedures for obtaining phospholipids have been described in manuals,^{69,104} monographs,^{104–106} and reviews.^{107,108} As a rule, original papers dealing with the synthesis and applications of deuterium-labelled phospholipids do not contain the description of experimental techniques, and only references to publications dedicated to the synthesis of non-labelled lipids are given. The experimental procedures that are most commonly employed in lipid chemistry are summarised and reviewed in monographs.^{105,106}

The relatively high cost of deuterium-labelled fatty acids accounts for their incorporation into phospholipid molecules at final stages of the synthesis. The general chemical approaches that are most widely employed for the solution of this task are presented below.

The starting material for the phosphatidylcholine synthesis is *sn*-glycerophosphocholine (**75**) and/or its cadmium adduct. The former is easily prepared by alkaline hydrolysis of natural phosphatidylcholines [most commonly, egg phosphatidylcholine (lecithin)],^{106–108} and is devoid of functional groups that need protection in the acylation. By selecting the deuterium-labelled fatty acids, one can synthesise the desired phosphatidylcholine **6** in one step (Scheme 4):

The acylation is performed with acid chlorides,¹⁰⁷ anhydrides,^{109–112} imidazolides,¹¹³ or other activated derivatives of fatty acids.¹⁰⁴ The acylation of *sn*-glycerophosphocholine **75** can be accompanied by the formation of large amounts of side products, mostly, cyclic phosphate. Therefore, this reaction requires that the preselected experimental conditions were strictly met. Then the

yields at the stage of acylation of *sn*-glycerophosphocholine **75** reach 60%–80% irrespective of the acylating agent used.

The most convenient in the experimental sense are the methods of acylation of *sn*-glycerophosphocholine deuterium-labelled fatty acid with anhydrides and imidazolides. In earlier studies, fatty acid salts have been used as the catalysts for acylation with acid anhydrides;¹¹¹ later, these were replaced by 4-*N,N*-dimethylaminopyridine,¹⁰⁸ sodium methylsulphenylmethanide,¹⁰⁹ and 4-pyrrolidinopyridine.¹¹⁰ Acylation in these cases occurs under milder conditions and is less time-consuming, which is especially important in the synthesis of unsaturated phosphatidylcholines. Fatty acid anhydrides are prepared by treating fatty acids with dicyclohexylcarbodiimide.

Fatty acid imidazolides are obtained upon interaction of the acid with carbonyldiimidazole.^{105,106,113} The imidazolid method is advisable for the synthesis of phospholipids containing expensive labile labelled fatty acids (including spin-labelled ones),¹¹³ since exhaustive acylation with imidazolides requires lesser amounts of the fatty acid than the anhydride method. After acylation has been completed, the excess of the non-consumed fatty acid can be isolated at the stage of chromatographic purification of phosphatidylcholine.

Let us consider the synthesis of phosphatidylcholines with the use of the anhydride method. As can be seen from Scheme 4, in this case phosphatidylcholine synthesis gives only phosphatidylcholines **76** that contain the same fatty acid residues at positions 1 and 2 of glycerol. This is a serious pitfall of this method, since natural phospholipids contain, as a rule, non-identical fatty acids.

The synthesis of these phospholipids rests on the use of lysophosphatidylcholine **78** as the starting compound, which can be easily obtained by enzymic hydrolysis of phosphatidylcholine **77** with phospholipase A₂.^{104,108,114}

Scheme 4

The hydrolysis of phosphatidylcholines does not necessarily require purified preparations of phospholipase A₂. They can be successfully replaced by whole snake or bee venoms. The hydrolysis of phosphatidylcholine with phospholipase A₂ occurs with a high degree of stereoselectivity and can be used for separation of racemic mixtures of synthetic phospholipids.^{104,108,114} The acylation of lysophosphatidylcholines is carried out by the same methods as that of *sn*-glycerophosphocholine, *e.g.*, with a fatty acid imidazolid. By combining various fatty acids in the synthesis of phosphatidylcholines **77** and **79**, one can obtain phosphatidylcholine **79** with any desired set of fatty acid residues including isotopically labelled fatty acids.

These methods of phosphatidylcholine synthesis by acylation of glycerophosphate derivatives have turned out to be very convenient in the preparative sense and they have nearly ousted total chemical synthesis, at least in the case of diacylphosphatidylcholines. The acylation of barium *sn*-glycerophosphate has also been successfully used in the synthesis of perdeuterated

phosphatidic acid, which was further used to obtain perdeuterated phosphatidylcholine.⁷³

However, the synthesis of other phosphoglycerides by acylation of glycerophosphate derivatives is a far more complex problem. Synthesis of such phospholipids as phosphatidylethanolamine, -glycerol, -inositol, and -serine requires that all the functional groups that can be acylated (with the exception of the hydroxy groups of glycerol) be selectively protected and the protecting groups removed in subsequent stages with the preservation of the structure of the synthetic glycerophospholipids. This is rather difficult to accomplish, which is the reason for the low yields of the target product.

A way to overcome this problem is the extensive use of a combination of chemical and enzymic methods and available phosphatidylcholines as the starting material. The phosphatidylcholines **79** with any desired set of fatty acids can be obtained by the above methods and further converted into other glycerophospholipids **80** by the transphosphatidyltransfer reaction catalysed by phospholipase D.^{104–106, 114} A prerequisite for this reaction is a large excess of the alcoholic component (glycerol, ethanolamine, serine, inositol), to which the phosphatidyl group is transferred. The yields of the glycerophospholipids **80a–d** make up to 80%. The only side product of this reaction is phosphatidic acid **80a**. It is impossible to avoid the formation of phosphatidic acid, since this enzymic reaction is carried out in aqueous media, and water competes with an alcohol for the binding with the phosphatidyl residue.

X = H (**a**); $\text{CH}_2\text{CH}_2\text{NH}_3^+$ (**b**); $\text{CH}_2\text{CH}(\text{OH})\text{CH}_2\text{OH}$ (**c**);
 $\text{CH}_2\text{CH}(\text{NH}_3^+)\text{COO}^-$ (**d**).

The experimental procedures based on the use of lipolytic enzymes in lipid chemistry have been considered in detail in some monographs.^{105, 106, 114}

A simple one-step procedure of deuterium incorporation into fatty acid residues of phospholipids is based on the catalytic reduction of double bonds of unsaturated phospholipids.^{115, 116} However, this approach has not found wide use in the synthesis of deuterium-labelled phospholipids, since the reduction of double bonds results in saturated phospholipids the labelled methylene groups of which contain only one deuterium atom. To ensure identical sensitivity in further membrane studies, the content of lipids with CHD labels in the samples must be increased twofold in comparison with lipids containing analogous CD₂ labels.

To obtain lipids with deuterium-labelled hydrophobic substituents, total chemical synthesis is employed.¹¹⁷ Normally, this is applied to obtain lipids of non-natural structure. Thus Sunamoto *et al.*¹¹⁷ described the synthesis of 1,2-[8-²H₂]-dimyristoylamino-1,2-dideoxyphosphatidylcholine, a phospholipid in which ester groups have been substituted by amide ones.

V. Synthesis of phospholipids with deuterium labels in the hydrophilic part of the molecule

As in the case of phospholipids with labelled fatty acids, the synthesis of phospholipids with deuterium labels in the hydrophilic part of the molecule is carried out by traditional methods of lipid chemistry. At the same time, the introduction of deuterium-labelled hydrophilic groups into lipid molecules has a number of distinctive features.

An original procedure for the introduction of a labelled methyl group into the γ -position of choline has been described by Stoffel *et al.*¹¹⁸ In this method one of the methyl groups of choline is selectively removed upon treatment of the phosphati-

dylcholine **81** with sodium thiophenoxide. The *N,N*-dimethylphosphatidylethanolamine **82** formed was alkylated with trideuteriomethyl iodide to give the phosphatidylcholine **83** with one deuteriomethyl group at the γ -position of choline. It should be borne in mind that alkylation with methyl iodide of amino groups of unsaturated phospholipids can be accompanied by modification of double bonds,¹¹⁹ apparently due to the presence of free iodine in the reaction medium.

The incorporation of deuterium labels into phospholipids is also carried out at the stage of formation of the phosphodiester bond. The tetraphenylborate of deuterated choline [$\text{HOCH}_2\text{CH}_2\text{N}(\text{CD}_3)_3\text{BPh}_4^-$, **84**], which is soluble in organic solvents, is phosphorylated with phosphatidic acid **85** in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride as the condensation agent.⁷⁴ The reaction is carried out in pyridine. The yield of phosphatidylcholine **86** is 70%. Reactions with other deuterated cholines, **40** and **50**, occur analogously. Phosphatidic acid **85** is an accessible phospholipid, which can be obtained by phosphorylation of the corresponding diglycerides with phosphorus oxychloride^{79, 120} followed by hydrolysis of phosphodichlorides or by enzymic hydrolysis of phosphatidylcholines with phospholipase D.¹¹⁴ Choline tetraphenylborates with different deuterium labels are obtained according to the schemes described earlier.⁷⁴

R = $(\text{CH}_2)_{12}\text{Me}$; TPS = 2,4,6- $\text{Pr}_3\text{C}_6\text{H}_2\text{SO}_2\text{Cl}$.

Phospholipids of a particular structure or phospholipids having several different deuterium labels are obtained by using procedures based on total chemical synthesis. Chudinov *et al.*²⁴ described the synthesis of a series of diacyl, dialkyl, alkylacyl, and acylalkyl phosphatidylcholines **89a–d**. The synthesis of phosphatidylcholines **89a–d** involved the total chemical synthesis of the deuterium-labelled diglycerides **87a–d** and their subsequent phosphorylation with phosphorus oxychloride; the phosphodichlorides **88a–d** formed in this reaction were directly (without isolation) brought into the reaction with choline tosylate **53** using the method described by Brockerhoff and Ayengar.⁷⁹ The yield of the product at the stage of phosphorylation was 70%–80%.

$R^1 = \text{COCD}_2(\text{CH}_2)_{13}\text{Me}$, $R^2 = \text{CO}(\text{CH}_2)_{14}\text{Me}$ (a);
 $R^1 = \text{CH}_2\text{CD}_2(\text{CH}_2)_{13}\text{Me}$, $R^2 = \text{CO}(\text{CH}_2)_{14}\text{Me}$ (b);
 $R^1 = \text{CD}_2(\text{CH}_2)_{14}\text{Me}$, $R^2 = (\text{CH}_2)_{15}\text{Me}$ (c);
 $R^1 = \text{COCD}_2(\text{CH}_2)_{13}\text{Me}$, $R^2 = (\text{CH}_2)_{15}\text{Me}$ (d).

The chemical synthesis of deuterium-labelled phosphatidylglycerols **91** has been described.^{87,89} The deuterium-labelled glycerol **66** in which two hydroxy groups were blocked by isopropylidene protection was phosphorylated with phosphatidic acid **85** in the presence of a condensation agent. At the last stage, the isopropylidene protecting group in the compound **90** was removed by relatively mild treatment with boric acid. Depending on the structure of the isopropylidene glycerol used for phosphorylation, one can obtain phosphatidylglycerols with labels at any position in glycerol and of any desired stereoconfiguration. However, the yield of phosphatidylglycerols is rather low (30%) (Scheme 5).

Scheme 5

Yet another method for the introduction of deuterium-labelled glycerol into phosphatidylglycerols is based on the use of the transphosphatidyl transfer reaction catalysed by phospholipase D, much as is the case of the compound **80**. The transphosphatidyl transfer is also used to obtain other glycerophospholipids. It should be noted that this reaction requires a large excess of the alcoholic component. Thus in the synthesis of 1,2-dipalmitoyl-*sn*-glycero-3-phospho-[1,1-²H₂]-ethanolamine and 1,2-dipalmitoyl-*sn*-glycero-3-phospho-[2,2-²H₂]-ethanolamine, a 100-fold excess of the appropriate deuterium-labelled ethanolamine relative to 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine was used.⁸³

VI. Synthesis of fully deuterated lipids

It has already been mentioned that perdeuterated lipids can be used as a transparent matrix for structural analyses of membrane proteins by high-resolution two-dimensional ¹H NMR. This has predetermined the interest in the synthesis of these compounds. There is only one publication in the literature that is dedicated to the synthesis of perdeuterated phospholipids.⁷³

1. Synthesis of perdeuterated phosphatidylcholine

The synthesis of perdeuterated 1,2-dimyristoyl-*sn*-glycero-phosphocholine (**95**) was carried out according to Scheme 6.⁷³ Perdeuterated glycerol **73** was obtained by the reduction of diethyl oxomalonate **72** with lithium aluminium deuteride. In order to obtain the desired stereoconfiguration of the substituted glycerol, an original approach has been developed, which was based on the phosphorylation of free glycerol with ATP in the presence of glycerokinase. This reaction results in high yield (66%) of glycerophosphate **92** with the same stereoconfiguration as that of the natural glycerophospholipids. Glycerophosphate **92** was isolated by precipitation from an aqueous solution as the barium salt, further converted into the pyridinium salt by ion-exchange chromatography, and then acylated with a perdeuterated myristic anhydride (**93**) in pyridine in the presence of 4-*N,N*-dimethylaminopyridine. The yield of 1,2-dimyristoyl-*sn*-glycero-3-phosphate (**94**) exceeded 90%. Perdeuterated myristic acid was obtained by the exchange on a platinum catalyst (similar to the compound **10**) and converted into the anhydride with dicyclohexylcarbodiimide. Phosphatidic acid **94** was condensed with perdeuterated choline in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride. To increase the solubility of choline in organic solvents, choline iodide **49** was converted into a complex with iodine by interaction with KI₃. The yield at the stage of the phosphorylation of choline with phosphatidic acid reaches 25%–40%.⁷³

The use of choline tetraphenylborate permits an increase in the yield of the phosphatidylcholine **95** up to 70%.⁷⁴

Scheme 6

2. Synthesis of perdeuterated phospholipid-like detergents

In studies of secondary and tertiary structures of proteins in the membrane environment by two-dimensional ¹H NMR spectroscopy, perdeuterated sodium dodecyl sulfate is mostly used. The use of perdeuterated sodium dodecyl sulfate in these studies is motivated by its commercial availability. Meanwhile, sodium dodecyl sulfate is not a close structural analogue of natural phospholipids. A search for more close structural analogues of phospholipids has stimulated studies aimed at the synthesis of novel detergents.

It was proposed to use dodecyl phosphocholine as a phosphatidylcholine analogue. The structure of its polar region fully corresponds to that of phosphatidylcholine. At the same time, the presence of only one short-chain hydrocarbon residue accounts for the fact that dodecyl phosphocholine forms micelles in water. The critical micelle concentration is 1.1 mmol litre⁻¹,¹²¹ the micelle diameter is about 50 Å, and one micelle comprises 56±5 molecules of dodecyl phosphocholine.¹²²

Dodecyl phosphocholine has been used in membrane studies for simulating the interaction between phospholipase A₂ and the lipid bilayer surface.¹²¹ The synthesis of non-deuterated dodecyl phosphocholine involved the phosphorylation of dodecyl alcohol with 2-bromoethyl phosphodichloride and subsequent reaction of the bromoalkyl derivative with trimethylamine.¹²¹ The first total chemical synthesis of perdeuterated dodecyl phosphocholine (**104**) was carried out in 1979.⁷⁷ The starting compound was lauric acid (**96**), which was subjected to total proton–deuterium exchange by the previously described method.²⁷ Perdeuterated lauric acid (**97**) was reduced to the alcohol (**98**). Perdeuterated dodecanol **98** was phosphorylated with diphenylphosphinoyl chloride. The protecting phenyl groups in the compound **99** were removed by catalytic hydrogenolysis to give dodecyl phosphate (**100**).

The choline component was obtained by quaternisation of perdeuterated trimethylamine with 2-bromoethanol (**101**); the resulting choline bromide (**102**) is converted into the acetate (**103**) in order to increase its solubility in organic solvents. Choline acetate **103** is phosphorylated with the phosphate **100** in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride to give perdeuterated dodecyl phosphocholine (**104**).

This scheme is multistep; the procedure of synthesis of perdeuterated choline was later modified.

Thus Dekker *et al.*¹²³ reduced perdeuterated lauric acid **97** with lithium aluminium deuteride to give the alcohol **98**, which was further phosphorylated with phosphorus oxychloride. The resulting phosphodichloride [CD₃(CD₂)₁₁OP(O)Cl₂, **105**] was hydrolysed with aqueous hydrochloric acid and dodecyl phosphate **100** was precipitated with acetone. Perdeuterated choline in the form of tetraphenylborate **40** was condensed with dodecyl phosphate in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride. The isolation of dodecyl phosphocholine (**104**) was associated with certain difficulties due to its good solubility in water, which excludes extraction. Perdeuterated dodecyl phosphocholine **104** is now commercially available.

Another representative of phospholipid-like detergents is dodecyl phosphoethylene glycol. It represents a structural analogue of the negatively charged phospholipid, phosphatidylglycerol. Together with dodecyl phosphocholine, perdeuterated dodecyl phosphoethylene glycol (**107**) was used to study the effect of lipid environment on the secondary structure of a mitochondrial signal peptide by high-resolution two-dimensional ¹H NMR spectroscopy.¹²⁴ The synthesis of perdeuterated dodecyl phosphoethylene glycol was carried out as described earlier.¹²⁵ Dodecanol **98** was phosphorylated with phosphorus oxychloride and the phosphodichloride (**105**) then reacted with perdeuterated ethylene

glycol to give phospholane **106**. The latter was hydrolysed in the presence of acetic acid to give dodecyl phosphoethylene glycol **107**. All these reactions proceeded in high yields; intermediate products were not isolated. It is necessary to note that dodecyl phosphoethylene glycol possesses chelating properties and after conventional purification procedures it may contain polyvalent cations. It is therefore recommended to convert it into the sodium salt using ion-exchange resins containing chelating groups (*e.g.*, Chelex).¹²⁶

VII. Other deuterium-labelled lipids

In addition to phospholipids, biological membranes of eukaryotic cells contain cholesterol, the content of which can make up to 25% of the total pool of membrane lipids.¹²⁷ Cholesterol plays an important role in the regulation of the phase state of the lipid bilayer.¹²⁸ To study its interaction with phospholipids by the ²H NMR method, cholesterol with deuterium labels at different positions of the molecule and its derivatives have been synthesised.^{129, 130} Syntheses of deuterium-labelled sterols are performed by methods analogous to those used in the synthesis of deuterium-labelled fatty acids.

In some cases, when chemical synthesis of deuterium-labelled lipids is a rather difficult task, microbiological synthesis can be applied. This is exemplified by the synthesis of deuterium-labelled plasmalogens.¹³¹ The incorporation of specifically deuterated glycerols into cardiolipin is achieved by growing *E. coli* cells on culture media containing deuterium-labelled glycerol.^{89, 90, 132, 133}

An analogous approach was used to incorporate deuterium-labelled oleic acid into cardiolipin and phosphatidylglycerol¹³⁴ as well as of deuterium-labelled palmitic acid into the *E. coli* membrane.¹³⁵ To this end, *E. coli* cells were grown on a culture medium containing the fatty acid and a detergent. Depending on the problem to be solved, different strains of *E. coli* were used.^{89, 90, 132–135} Lipids were isolated from the culture mass by conventional methods, which included cell disintegration, extraction, and chromatographic purification. The resulting phospholipid preparations represented mixtures of homologues differing in the length and degree of unsaturation of hydrocarbon residues.

Deuterium-labelled fatty acids that are used as a nutrition source for bacteria can be involved in the biosynthesis of other fatty acids, being converted into other deuterium-labelled acids.^{134, 136} Microbiological synthesis can be used for obtaining perdeuterated lipids. The synthesis of perdeuterated fatty acids by culturing of *Scenedesmus obliquus* cells on a culture medium containing heavy water has been described.¹³⁷

Deuterium-labelled fatty acids of various structures and having labels at different positions of the hydrocarbon chain were incorporated into the membrane of a mycoplasma *A. laidlawii*, which made possible a detailed profile analysis of the order parameter of hydrocarbon chains.^{138–142}

VIII. Analysis of deuterium-labelled lipids

In the synthesis of deuterium-labelled lipids, it is often necessary to monitor the isotopic purity of intermediate and final products and to establish the selectivity of the label incorporation. These

problems can be solved by mass spectrometry, high resolution NMR, gas-liquid, and liquid chromatography.^{30,31}

Mass spectrometry offers a direct and the most sensitive method of analysis of the content of deuterium in organic compounds. The main information about the use of this method in the study of lipids labelled with stable isotopes is given in the review by Rohwedder.¹⁴³ It is suggested that labelled and non-labelled molecules are ionised to the same degree. The measurements have to be performed under conditions that ensure minimum fragmentation of the molecular ion. Prior to analysis compounds with an enhanced tendency for fragmentation (unsaturated acids and alcohols) are converted into silyl derivatives.^{36,49}

The isotopic purity and the position of deuterium labels in the lipids and the intermediates used in the lipid synthesis can be established by ¹H NMR spectroscopy.^{4–6} This method is used for the elucidation of the structure of intermediates and/or lipids that are synthesised. The position and content of deuterium labels is determined from a decrease in the integral intensity of the signal in ¹H NMR spectra corresponding to protons that are replaced by deuterium. However, many signals in the ¹H NMR spectra of lipids overlap, which affects the accuracy of the analysis.

In principle, these problems can be solved with the help of high-resolution ²H NMR. In contrast to ¹H NMR, ²H NMR spectra contain signals from deuterium labels alone, which significantly simplifies the spectra. However, the range of variations of absolute chemical shifts in the ²H NMR spectra is about 6.5 times more narrow (which is in accord with the gyromagnetic proton-to-deuteron ratio) than in the ¹H NMR spectra. Moreover, in the recording of the ²H NMR spectra one cannot use deuterium stabilisation of the magnetic field of the NMR spectrometer, which also diminishes the resolution. It is therefore rather difficult to differentiate signals from several groups with close chemical shifts despite the relative simplicity of the ²H NMR spectra. To some extent, this problem can be overcome by using shift reagents, which made it possible to resolve deuteron signals in the α -, β -, γ -, and δ -positions of a fatty acid.¹⁴⁴

¹³C NMR spectroscopy is devoid of the shortcomings characteristic of ¹H NMR and ²H NMR. The range of variations of the chemical shifts in the ¹³C NMR spectra is one order of magnitude higher than that in the ¹H NMR spectra and, as a consequence, the majority of signals in the ¹³C-NMR spectra of lipids are resolved. Another advantage of the ¹³C NMR method is that the incorporation of deuterium induces a small isotopic upfield shift of the signal.^{30,31,145} As a result, the spectrum simultaneously manifests resolved signals of carbon atoms covalently bound to deuterons and protons, which increases the accuracy of measurements of the isotopic purity. It should be kept in mind that precise measurements of the ratios of deuterated to non-deuterated products is possible only under conditions when ¹³C NMR spectra are recorded under conditions of complete relaxation and in the absence of the Overhauser effect. The signals of carbon atoms bound to deuterium are readily recognised in the spectra because of the characteristic multiplicity caused by the spin-spin interaction with deuterium. The spin of deuterium $I = 1$, that is the signal of the CD-group is observed as a triplet with lines of equal intensity; the spin-spin coupling constant, J_{CD} , is about 20 Hz. A serious pitfall of the ¹³C NMR method is its low sensitivity, which decreases even more upon substitution of protons for deuterium due to the elimination of the Overhauser effect.

Among other methods of analysis of deuterated fatty acids, special mention should be made of gas-liquid chromatography (GLC). The possibility of separation of deuterium-labelled and non-labelled fatty acids has long been known, but it was difficult to perform.³¹ In the study of Rietveld *et al.*,¹³⁴ GLC was successfully used for the separation of fatty acids as methyl esters, including acids with one deuterium-labelled methylene group.

IV. Other syntheses	1010

Abstract. The data on the application of cyclic and acyclic monoterpenoids in the synthesis of optically active insect pheromones are summarised. The bibliography includes 99 references.

I. Introduction

Studies on pheromones have posed many challenging problems to synthetic chemists the solution of which has broadened the range of methods employed in modern organic synthesis. One of these problems is the study of effects of the absolute configuration of chiral molecules on biological activity, since chemical communication in many insect species is mediated by optically active compounds. More than 100 chiral insect pheromones have been identified so far. As the amount of the pheromone produced by each individual species is negligibly small, the accumulation, isolation, and purification of an individual natural substance is a very labourious problem.¹ Therefore, the determination of the absolute configuration of chiral pheromones is based on a stereocontrolled straightforward synthesis of enantiomerically pure compounds rather than on chemical degradation of natural material accessible with difficulty (together with a combination of physicochemical methods). As a rule, the elucidation of the absolute configuration of a natural pheromone requires the synthesis of all of its possible stereoisomers in enantiomerically pure forms and assay of the biological activity of each of them.

Studies of specific responses of insects to each of these possible stereoisomers have demonstrated that the efficiency of attraction of many species increases 2- to 1000-fold if an enantiomer with the absolute configuration of a natural pheromone or a synergistic mixture of enantiomers is used instead of a racemic compound. Obviously, the use of enantiomerically pure or enantiomerically enriched pheromones makes it possible to considerably reduce the

expenditure of materials and the scale of manufacture. However, in order to make the application of these optically active low-molecular-weight bioregulators economically expedient, it is necessary to use the available and inexpensive initial products and simple, practical synthetic schemes.

The currently known chiral insect pheromones are relatively simple molecules (they contain not more than four asymmetric centres and not more than four functional groups). Their structural fragments are sometimes rather peculiar, but the conglomeration of chiral centres and functional groups as in the molecules of carbohydrates, prostanoids, and macrolide antibiotics is not typical of pheromones. Therefore, the 'ideal' chiral building block (CBB) seems to be a moderately functionalised compound devoid of numerous chiral centres. Monoterpenoids, amino acids, and hydroxy acids are the most consistent with this ideal structure. The former are especially suitable for the synthesis of compounds with a branched hydrocarbon skeleton, first of all, of pheromones having an isoprenoid structure. The range of chiral terpenoids is rather wide. All of them are the products of wood-chemical, perfume, food, and pharmaceutical industries.

This review considers the synthetic potentialities of monoterpenoids and the corresponding CBB exemplified in syntheses of optically pure and enantiomerically enriched insect pheromones.

II. Syntheses on the basis of (*R*)-pulegone

Several chiral building blocks can be synthesised from (*R*)-pulegone **1** by simple transformations. Thus the two-step retrocyclisation of pulegone gives citronellic acid **2**. The latter can be converted into methyl ester **3** and reduced to citronellol **4** with diisobutyl aluminium hydride DIBALH. It can also be obtained directly from the acid **2** by reduction with LiAlH₄. The alcohol **4** is easily converted into citronellal **5** or citronellyl acetate **6**.²

Reagents: (a) HCl; (b) NaOH; (c) MeOH/TsOH; (d) LiAlH₄; (e) Bu₂AlH; (f) Py·CrO₃·HCl (PCC); (g) Ac₂O/Py.

A scheme for the synthesis of the both enantiomers of 15-methyltritriacontane **9**, the pheromone of the stable fly (*Stomoxys calcitrans*), from the oxo ester **7a**, which is the product of ozonolysis and reduction of methyl citronellate **3**, has been proposed.³ The (*R*)-**9** enantiomer was synthesised as follows. At the first stage, the aldehyde ester **7a** reacts with C₁₁-phosphorane; then the reaction product is converted in two steps into the aldehyde **8**, which interacts with another phosphorane to give (*R*)-**9** following hydrogenation.

Reagents: (a) O₃/MeOH; (b) Me₂S; (c) Me(CH₂)₉CH = PPh₃; (d) LiAlH₄; (e) PCC; (f) Me(CH₂)₁₄CH = PPh₃; (g) H₂/Pd/C.

In an analogous scheme of the synthesis of (*S*)-**9**, C₁₅- and C₁₂-triphenylphosphoranes have been employed.³

Reagents: (a) Me(CH₂)₁₃CH = PPh₃; (b) LiAlH₄; (c) PCC; (d) Me(CH₂)₁₀CH = PPh₃; (e) H₂/Pd/C.

Pathways for the synthesis of two diastereomers of 2-acetoxy-3,7-dimethylpentadecane **17**, the analogues of diprionyl acetate, the sex pheromone of the sawflies related to the *Diprion* and *Neodiprion* genera, on the basis of the aldehyde ester **7a** and (4*R*)-methyl-5-acetoxypentanoic acid **10**, have been proposed. The C(7)-chiral centre of the target molecule, which has the (*R*)-configuration, was introduced *via* the building block **7a**. Another CBB, the compound **11**, was used for the creation of the C(3)-chiral centre after its conversion into the phosphonium salt **12**. The chiral C(2)-centre is formed in the reduction of the methyl ketone **16** corresponding to the target structure. Thus, the synthesis of the compound **17** was carried out essentially in two steps. In the first step, the alkenoate **13** obtained by alkenation of **7a** was converted into the aldehyde **14** by a two-step procedure.^{4,5} The second part of this synthesis involves the interaction of the aldehyde **14** with the phosphorane prepared from the salt (*R*)-**12** and subsequent selective transformations of the triene **15**: the oxidation of the terminal double bond and borohydride reduction of the methyl ketone **16** into a mixture of diastereoisomers in which the *threo*-isomer predominates (Scheme 1). They were separated by HPLC.

The synthesis of three diastereomers of diprionyl acetate **17** from the aldehyde ester **7b** is based on the coupling of the C₁₂- and C₅-building blocks **18** and **24** of the respective configuration.⁶ The

Scheme 1

Reagents: (a) Pb(OAc)₄/Cu(OAc)₂·H₂O; (b) KOH; (c) BuⁿLi; (d) TsCl; (e) NaBr; (f) PPh₃/14 kbar; (g) BuCH = PPh₃; (h) Bu₂AlH; (i) PCC; (j) **12**/BuⁿLi; (k) O₂/PdCl₂–CuCl; (l) NaBH₄; (m) H₂/Pt; (n) HPLC; (o) Ac₂O/Et₃N/4-dimethylaminopyridine (DMAP).

key stage in the scheme of synthesis of the C₁₂-block of the (*R*)-configuration is the condensation of the aldehyde **7b** with pentylidenephosphorane resulting in the ester **13a**. Its optical antipode, (*S*)-**18**, was synthesised through alkylation of (*R*)-citronellyl tosylate **19**, the ozonolysis of the resulting alkene **20** into the acid **21**, and its conversion into the bromide by the Hunsdiecker reaction.

Reagents: (a) BuCH=PPh₃; (b) H₂/PtO₂; (c) LiAlH₄; (d) TsCl/Py;
(e) LiBr; (f) Me(CH₂)₅MgCl/CuI; (g) O₃/CH₂Cl₂;
(h) H₂O₂/HCO₂H; (i) NaOH; (j) AgNO₃; (k) Br₂.

The synthesis of the C₅-blocks **24** having two chiral centres was carried out by diastereoselective asymmetric reduction of methyl 2-methyl-3-oxobutyrates **22** and subsequent fractional crystallisation of first sodium and then ammonium salts. This rather labourious procedure yielded the hydroxy acids (2*R*,3*S*)-**23** and (2*S*,3*S*)-**23**, which were then converted in four steps into the protected diols (2*S*,3*S*)-**24** and (2*R*,3*S*)-**24** required for the synthesis of target products.

Reagents: (a) H₂/Ni-(*S,S*)-[HO₂CCH(OH)]₂; (b) NaOH;
(c) recrystallisation, H₃O⁺; (d) CH₂N₂;
(e) dihydropyran (DHP)/TsOH; (f) LiAlH₄; (g) TsCl/Py.

Three optically pure diastereomers of diprionyl acetate **17** were obtained by a Wurtz-type reaction by coupling the stereoisomeric C₅-**24** and C₁₂-**18** blocks (Scheme 2).

Scheme 2

Reagents: (a) Mg; (b) (2*S*,3*S*)-**24**/CuI; (c) TsOH/MeOH; (d) Ac₂O/Py;
(e) (2*R*,3*S*)-**24**/CuI.

Dimethyl acetal **25**, another product of ozonolysis and reduction of methyl citronellate **3**, was used in the synthesis of (4*S*,8*R*)- and (4*S*,8*S*)-4,8-dimethyldecanals **29** manifesting attractant activity against *Tribolium confusum* and *T. castaneum* meal worms. The starting acetal **25** was converted by conventional procedures into the sulfone **26** required for the formation of the (4*S*)-chiral centre of the pheromone **29**. The corresponding enantiomeric, selectively protected diols **27** were converted into bromides **28** and used for the introduction of (8*R*)- and (8*S*)-chiral centres.⁷

Reagents: (a) O₃/MeOH; (b) Me₂S; (c) TsOH, MeOH; (d) LiAlH₄;
(e) TsCl/Py; (f) NaI/NaHCO₃; (g) PhSO₂Na;
(h) MeMgI/Li₂CuCl₄; (i) TsOH/MeOH; (j) Br₂/PPh₃.

The alkylation of the sulfone (*R*)-**26** with the bromides (*R*)-**28** or (*S*)-**28** followed by desulfonation of the condensation products and hydrolysis yields the (4*S*,8*R*)- and (4*S*,8*S*)-stereoisomers of the compound **29**, respectively.

Reagents: (a) Bu^nLi ; (b) $(R)\text{-}28$; (c) Na-Hg ; (d) H_3O^+ ; (e) $(S)\text{-}28$.

The allylic alcohol **30**, the product of the Sharpless oxidation⁸ of the compound **3**, was used as the starting material in the synthesis of both enantiomers of $(5E)$ -isopropyl-3,9-dimethyl-deca-5,8-dienyl acetate **39** the (S) -isomer of which is the sex pheromone of the yellow scale (*Aonidiella citrina*).⁹ The building block $(S)\text{-}32$ obtained from the methyl ester **30** via the acetal **31** was used for the creation of the $(3R)$ -centre in the molecule of **39**. Its optical antipode, the aldehyde $(R)\text{-}32$, was obtained from the same allylic alcohol **30** by converting it into a mixture of mono- and di-ethers (**34** and **35**, respectively) via the diol **33**. The ozonolysis and reduction of this mixture gave the monosubstituted diol **36**, which was converted via the benzyl derivative into another key aldehyde ester, $(R)\text{-}32$. Further transformations of (S) - and $(R)\text{-}32$ involved the condensation with the Grignard reagent **40** and a 2,3-sigmatropic rearrangement of the resulting allylic alcohols **37** into the E -homoallylic alcohols **38** via their stannyl derivatives (Scheme 3). The alcohols **38** were further

converted into the corresponding aldehydes; their alkenation gave the target products, (S) - or $(R)\text{-}39$. The synthesis of the biologically active (S) -enantiomer **39** is shown in Scheme 3.

A scheme of synthesis of α -multistriatine **49**, the aggregation pheromone of the elm bark beetle (*Scolytus multistriatus*), on the basis of citronellol **4** has been developed. Thus, pyrolysis of the xanthate **41** gave the diene $(R)\text{-}42$, which was further converted into the diol **43** by chemospecific epoxidation of the trisubstituted double bond with subsequent hydrolysis of the intermediate epoxide. The oxidative cleavage of **43** gave the aldehyde $(R)\text{-}44$. Its α -methylation was carried out via the intermediate Schiff's base **45**. The resulting aldehyde **46** was converted via the ketone **47** into the epoxide **48**; its treatment with SnCl_4 gave a mixture of four stereoisomers from which **49** was isolated chromatographically (Scheme 4).¹⁰

The tetrahydroxypranylic ether of (R) -citronellol **2**, $(R)\text{-}50$, has proved to be a convenient starting material in the synthesis of $(R)\text{-}(+)\text{-}2,3$ -dihydrofarnesol $(R)\text{-}52$, the antipode of terrestrol, the marker pheromone of the male bumblebee *Bombus terrestris*. To this end, $(R)\text{-}50$ was converted into a mixture of the diastereo-

Reagents: (a) MCPBA; (b) LDA; (c) $\text{OEt}/\text{Hg}^{2+}$; (d) 180°C ; (e) $\text{Ph}_3\text{P}=\text{CMe}_2$; (f) H_3O^+ .

meric allyl vinyl ethers **51**. The subsequent Claisen rearrangement and the Wittig alkenation of the intermediate aldehyde gave (R)-**52**.¹¹

The derivatives of citronellol **4** have been used to obtain all the stereoisomeric 4,8-dimethyldecanals **29**.¹² In the synthesis of (4*R*,8*R*)-**29** and (4*R*,8*S*)-**29**, the original benzyl ether **53** underwent the Sharpless oxidation⁸ into the allylic alcohol **54**. Ozonolysis of the latter and reduction gave the monoprotected diol **55**. Its derivatives, the tosylate **56** and the iodide **57**, have found application in the formation of the (4*R*)-chiral centre of **29**. The sulfone **60**, which has been prepared in several steps including the ozonolysis of the compound **30** into the aldehyde ester **58** and Huang–Minlon reduction of the latter into the acid **59**, was used for the formation of the (8*R*)-centre. The reaction of **60** with the iodide **57** and subsequent desulfonation of the condensation product yielded the alcohol (3*R*,7*R*)-**61**; its homologisation into the target aldehyde (4*R*,8*R*)-**29** was performed *via* the corresponding cyanide (Scheme 5).

For the formation of the (8*S*)-centre in the stereoisomer (4*R*,8*S*)-**29**, (2*S*)-methylbutyl bromide **28** has been used. Its reaction with the tosylate **56** gave the alcohol (3*R*,7*S*)-**61**, which was converted into the target product *via* the nitrile (4*R*,8*S*)-**62**.

Reagents: (a) Mg ; (b) **56**/ Li_2CuCl_4 ; (c) $\text{H}_2/\text{Pd/C}$; (d) TsCl/Py ; (e) NaCN ; (f) NaOH ; (g) LiAlH_4 ; (h) PCC .

Electrolysis of a mixture of the acids **59** and **64** (obtained by ozonolysis of homocitronellic acid **63**) in MeONa/MeOH gave a mixture of the corresponding hydrocarbon, bisacetal, and (4*S*,8*R*)-**65**; the latter was isolated chromatographically. Compound (4*S*,8*R*)-**29** was obtained by treatment of (4*S*,8*R*)-**65** with HClO_4 .

Reagents: (a) $\text{Ph}_2\text{Se}_2/\text{H}_2\text{O}_2$; (b) Bu^tOOH ; (c) $\text{O}_3/\text{CH}_2\text{Cl}_2 - \text{MeOH/NaHCO}_3$; (d) NaBH_4 ; (e) TsCl/Py ; (f) NaI ; (g) Me_2S ; (h) $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O/KOH}$; (i) $\text{Pb}(\text{OAc})_4/\text{I}_2$; (j) PhSNa ; (k) MCPBA ; (l) Bu^nLi ; (m) **57**; (n) Li/EtNH_2 ; (o) NaCN ; (p) Bu_2^iAlH .

Reagents: (a) O_3/MeOH ; (b) Me_2S ; (c) MeOH/TsOH ;
 (d) e^- , NaOMe/MeOH ; (e) HClO_4 .

The synthesis of the (*S,S*)-enantiomer **29** is based on the same principle. In this case, the role of chiral building blocks was played by the acids **66** and (*S*)-**68** synthesised from the products of ozonolysis of the acid **2** and tetrahydromyrcene (*S*)-**67**, respectively. The acetal (*4S,8S*)-**65** obtained in the electrolysis of an equimolar mixture of the acids **66** and (*S*)-**68** was further converted into the target product, (*4S,8S*)-**29**.

Reagents: (a) O_3/MeOH ; (b) Me_2S ; (c) MeOH/TsOH ; (d) $\text{O}_3/\text{Me}_2\text{CO}$;
 (e) H_2CrO_4 ; (f) e^- , NaOMe/MeOH ; (g) HClO_4 .

All the four stereoisomers of 3,7-dimethylnonadecane **69**, the sex pheromone of the alfalfa leaf mining beetle (*Agromyza frontella*), have been synthesised on the basis of derivatives of citronellol **6** and **19**.¹³ The key stage in this synthesis was the condensation of the chiral iodide **70** and sulfone **71**.

To obtain sulfone (*S*)-**71**, the alkylation product of the tosylate (*R*)-**19** was successively subjected to the Sharpless oxidation,⁸ ozonolysis, and reduction; the resulting alcohol (*S*)-**72** was converted into (*S*)-**71** by conventional procedures.

Reagents: (a) $\text{Me}(\text{CH}_2)_9\text{MgBr}/\text{Li}_2\text{CuCl}_4$; (b) $\text{Ph}_2\text{Se}_2/\text{H}_2\text{O}_2/\text{Bu}^t\text{OOH}$;
 (c) O_3/CHCl_3 ; (d) NaBH_4 ; (e) TsCl/Py ; (f) PhSNa/MeOH ;
 (g) MCPBA .

The (*R*)-enantiomer of the sulfone **71** was synthesised from the acetoxy aldehyde **73** derived from the compound **6** by ozonolysis and reduction. The Wittig alkenation of **73** and the subsequent hydrogenation of the intermediate alkene gave the alcohol (*R*)-**72**, which was converted into the sulfone (*R*)-**71** in a way analogous to that for the (*S*)-enantiomer.

Reagents: (a) O_3/MeOH ; (b) Me_2S ; (c) $\text{Ph}_3\text{P}=\text{CH}(\text{CH}_2)_7\text{Me}$;
 (d) $\text{LiAlH}_4/\text{CoCl}_2$; (e) TsCl/Py ; (f) PhSNa/MeOH ;
 (g) MCPBA .

The synthesis of the chiral iodides **70** was carried out on the basis of the hydroxy esters **74** via the intermediate, selectively protected diols **27**.

Reagents: (a) DHP/TsOH ; (b) LiAlH_4 ; (c) TsCl/Py ;
 (d) $\text{MeMgBr}/\text{Li}_2\text{CuCl}_4$; (e) H_3O^+ ; (f) $\text{NaI}/\text{Me}_2\text{CO}$.

Reactions of the chiral sulfones **71** and iodides **70** in various combinations and subsequent desulfonation of the reaction products gave all four stereoisomers of the pheromone **69**.

Reagents: (a) BuⁿLi; (b) Na–Hg.

The tosylate (*R*)-**19** has also found application in the synthesis of (2*R*,6*R*,10*R*)-6,10,14-trimethylpentadecan-2-ol **83**, the sex pheromone of the rice moth (*Corcyra cephalonica*) and its analogues having the (2*S*,6*R*,10*R*)-, (2*S*,6*S*,10*S*)-, or (2*R*,6*R*,10*S*)-configuration.¹⁴ The building block **76** obtained from **19** via the alkene **75**, which was subjected to periodate scission in the presence of catalytic amounts of RuCl₃, was used for the formation of the (10*S*)-chiral centre of the two latter compounds.

Reagents: (a) BuⁱMgBr/Li₂CuCl₄; (b) NaIO₄/RuCl₃; (c) I₂/Pd(OAc)₄/hν/CCl₄.

The formation of the (10*R*)-centre of the stereoisomers (2*R*,6*R*,10*R*)- and (2*S*,6*R*,10*R*)-**83** was carried out with the use of the bromide **78** obtained in high yield from dihydrocitronellol **77**, the reduction product of citronellic acid **2**.

Reagents: (a) LiAlH₄/CoCl₂; (b) TsCl/Py; (c) NaBr/DMF.

The (*R*)- and (*S*)-sulfonyl chlorides **79** derived from (*R*)- and (*S*)-hydroxy acids **74** were used in the formation of (6*R*)- and (6*S*)-chiral centres of the corresponding stereoisomers **83**.

Reagents: (a) DHP/TsOH; (b) LiAlH₄; (c) TsCl/Py; (d) NaSPh; (e) MCPBA.

Different versions of alkylation of the chiral sulfonyl chlorides **79** with the iodide **76** or the bromide **78** with subsequent desulfonation of the corresponding condensation products **80**, their conversion into the sulfonyl chlorides **81** and analogous sequences of reactions of the stereoisomers **81** and enantiomeric iodohydrins **82** resulted in the four stereoisomers of the target compounds **83**.

Reagents: (a) BuⁿLi; (b) **78**; (c) Na–Hg; (d) H₃O⁺; (e) TsCl/Py;

(f) NaSPh; (g) MCPBA; (h) (R)-**82**; (i) Li/EtNH₂;

(j) (S)-**82**; (k) **76**.

The obvious structural identity of the portion of 6,10,13-trimethyltetradecan-1-ol **87**, the aggregation pheromone of the predacious beetle (*Stiretrus anchorage*), with that of the above-described pheromone **83** has encouraged their application in the synthesis of its four optical isomers.¹⁵ The chiral building blocks **85** required for this purpose were prepared from citronellyl acetate (*S*)-**6** (following its ozonolysis) and the disubstituted alkene **84** synthesised from (*R*)-**19** by a two-step procedure.

R = OTs [(R)-19], I (100);

X = CO₂Et, R = Et (101); X = R = H (102).

Reagents: (a) CH₂(CO₂Et)₂/BuⁿLi; (b) LiAlH₄; (c) Ac₂O/Py;

(d) MCPBA; (e) HIO₄; (f) [Me(CH₂)₁₄PPh₃]Br/BuⁿLi;

(g) H₂/Pd; (h) TsCl/Py.

The tosylate (S)-96 was obtained from the product of alkylation of the iodide 100 with hexadec-1-ynyllithium. The enyne 105 was oxidised to the aldehyde 106 by cleavage of the double bond. The latter was further converted into the tosylate 107; its homologisation *via* the nitrile 108 completed the synthesis of the tosylate (S)-96.

Reagents: (a) HC≡C(CH₂)₁₃Me/BuⁿLi; (b) MCPBA; (c) HIO₄;

(d) LiAlH₄; (e) TsCl/Py; (f) NaCN; (g) NaOH; (h) H₂/Pd.

The bromide (R)-109 required for the synthesis of the Grignard reagent 97 was obtained from the aldehyde 44 by routine reactions.

Reagents: (a) LiAlH₄; (b) TsCl/Py; (c) LiBr; (d) Mg.

The bromide (S)-109 was prepared from methyl homocitronellate 110. Its ozonolysis and subsequent oxidation gave the acid 111. The methyl bromoalkanoate 112 obtained by the Hunsdiecker reaction was converted into the unsaturated acid 114 *via* the selenide 113. The bromide (S)-109 was synthesised from the acid 114 by standard procedures.

Reagents: (a) O₃/MeOH; (b) Me₂S; (c) CrO₃; (d) Ag₂O-Br₂;

(e) 2-NO₂C₆H₄SeCN/NaBH₄; (f) NaOH; (g) H₂O₂;

(h) LiAlH₄; (i) TsCl/Py; (j) LiBr; (k) Mg.

Reactions of tosylates 96 with the Grignard reagents 97 followed by Markovnikov hydration of the corresponding alkenes and the oxidation of the resulting alcohols gave all the four stereoisomers of the pheromone 99.¹⁹

The methyl bromoalkanoate **112**, one of intermediate products in the scheme presented above, has also been employed in the synthesis of (10*R*)-methyl dodecyl acetate **116**, the minor component of the sex pheromone of the tea leaf rolling moth (*Adoxophyes fasciata*). The formation of the hydrocarbon chain of **116** was carried out by cross-coupling of the tosylate **115** obtained from the bromide **112** and the Grignard reagent **117**.²⁰

Reagents: (a) NaI; (b) LiAlH₄; (c) TsCl/Py; (d) BrMg(CH₂)₆OTHP/(**117**)/Li₂CuCl₄; (e) MeOH/TsOH; (f) Ac₂O/Py.

A formally two-step synthesis of *erythro*-(2*S*,3*S*,7*S*)- and *threo*-(2*R*,3*S*,7*S*)-diprionyl acetates **17** from the tosylate (*R*)-**19** has been carried out.²¹ The aim of the first step was the formation of the structure of the chiral aldehyde **119**; this was accomplished by ozonolysis of the alkene **20** to the aldehyde **117** followed by ozonolysis of the derived enol acetate **118**. The reactions used at the second step of the synthesis of the target acetates (2*S*,3*S*,7*S*)-**17** and (2*R*,3*S*,7*S*)-**17** did not differ from those depicted in Scheme 1 for the enantiomers having the (*R*)-configuration of the C(7) atom.^{4, 5}

Reagents: (a) Me(CH₂)₅MgCl/CuI; (b) O₃/CH₂Cl₂-MeOH; (c) Me₂S; (d) Ac₂O/AcOK/Et₃N; (e) **12**/BuⁿLi; (f) O₂/PdCl₂-CuCl; (g) NaBH₄; (h) H₂/Pt; (i) HPLC; (j) Ac₂O/Et₃N/DMAP.

The retrosynthetic analysis of (2*S*,3*S*,7*S*)-diprionyl acetate **17** suggests that this compound can be obtained by the reaction of the organometallic nucleophile **120** with (*S*,*S*)-2,3-epoxybutane **121**.

Mori *et al.*^{22, 23} have performed the synthesis of the bromide **123**, the chiral building block corresponding to the synthon **120**, by the following scheme. The coupling of the tosylate (*R*)-**19** with lithium dihexyl cuprate and subsequent ozonolysis of the alkene **20** gave the alcohol **122**, which was converted into the bromide by conventional methods. The complementary epoxide **121** was synthesised from the natural L-(+)-tartaric acid **124** in nine steps. The reaction of lithium dialkyl cuprate derived from the bromide **123** with the epoxide **121**, which occurred with high stereoselectivity with respect to all the three chiral centres, gave the target product, diprionyl acetate (2*S*,3*S*,7*S*)-**17**.

Reagents: (a) [Me(CH₂)₅]₂CuLi; (b) O₃/CHCl₃; (c) NaBH₄; (d) TsCl/Py; (e) LiBr; (f) EtOH/H⁺; (g) Me₂CO/H⁺; (h) LiAlH₄; (i) NaI; (j) H₂/Pd/C; (k) HCl; (l) HBr/AcOH; (m) KOH; (n) Li/CuI; (o) **121**; (p) AcCl/Py.

Tetrahydromyrcene **67** obtained by reduction of citronellyl mesylate **125** was used in the synthesis of (6*S*)-methyloctan-3-one, (*S*)-**126**, the component of the alarm pheromone of ants of the *Crematogaster* genus.²⁴

Reagents: (a) LiAlH₄; (b) MCPBA; (c) HIO₄; (d) EtMgBr; (e) K₂Cr₂O₇.

Scheme 6

X = SiMe₂Bu^t.

Reagents: (a) O₃/NaHCO₃; (b) Me₂S; (c) Ph₃P=C(Me)CO₂Et (**128**); (d) LiAlH₄; (e) D-(−)-diethyl tartrate [D-(−)-DET]/Ti(OPrⁱ)₄/Bu^tOOH; (f) (COCl)₂–DMSO; (g) Et₃N; (h) [Pd(dba)₃·CHCl₃]/PPh₃ (dba is dibenzoylacetone); (i) Bu^tMe₃SiCl/imidazole; (j) (MeO)₂P(O)CH₂COOMe/BuⁿLi; (k) SO₃/Py; (l) Bu₄NF; (m) HPLC.

(2*E*,4*E*,6*R*,10*S*)-4,6,10-Trimethyl-2,4-dodecadien-7-one, (6*R*)-**138**, and its (6*S*,10*S*)-isomer, (6*S*)-**138**, the major components of the sex pheromone of the cluster pine scale (*Matsucoccus feytaudi*), have been synthesised using the same building block **67**.²⁵ This synthesis is based on enantioselective epoxidation of the trisubstituted allylic alcohol **130** obtained by a series of transformations from the alkene **67**. The reaction sequence includes ozonolysis and reduction, the Wittig condensation of the resulting aldehyde **127** with the phosphorane **128**, and subsequent reduction of the ester **129** with LiAlH₄. The conversion of the hydroxy group of compound (2*R*)-**131** into the aldehyde group and Wittig alkenation gave the compound **132**; the opening of its epoxide ring resulted in the inversion of the C(4) chiral centre. All subsequent conversions of the compound **133** into the compound (6*R*)-**138** occurred with the retention of the configurations of the carbon atoms. The Horner reaction was used to complete the carbon chain of the compound **133** (Scheme 6).

The use of L-(+)-diethyl tartrate in an analogous scheme at the epoxidation stage gave the (6*S*,10*S*) isomer of **138** via the compound (2*S*)-**131** (Scheme 7).

Scheme 7

Reagents: (a) L-(+)-DET/Ti(OPrⁱ)₄/Bu^tOOH.

Both stereoisomers of 4-methylnonan-1-ol **140** the (*R*)-enantiomer of which is the sex pheromone of the mealworm (*Tenebrio molitor* L.), have been synthesised from citronellyl tosylate (*R*)-**19** and citronellyl bromide **141**.²⁶ The isomer (*S*)-**140** was obtained through oxidative scission of the double bond in the compound **139**, the condensation product of the tosylate (*R*)-**19** with PrⁿMgBr.

Reagents: (a) PrⁿMgBr/Li₂CuCl₄; (b) MCPBA; (c) HIO₄; (d) LiAlH₄.

The synthesis of the enantiomer (*R*)-**140** was carried out according to the scheme that involved the conversion of (*R*)-**141** into methyl homocitronellate **110** and oxidative scission of the double bond to give the aldehyde **142**, which was made to react with Et₂CuLi after conversion into the tosylate **143**. The reduction of the carboxyl group yields the target product.

Reagents: (a) Mg; (b) CO₂; (c) MeOH/H₂SO₄; (d) MCPBA; (e) HIO₄; (f) NaBH₄; (g) TsCl/Py; (h) Et₂CuLi; (i) LiAlH₄.

The bromide **141** has proved to be a convenient starting material in the synthesis of the *Z*- and *E*-isomers of (*R*)-trogodermal **93**.²⁷ The conversion of **141** into the chiral synthon **145** involved the 'malonate' synthesis and ozonolysis with subsequent oxidation leading to the monoester of the dicarboxylic acid **144**. The achiral block **146** was obtained by oxidative scission of aleuritic acid **146**. Successive alkylation of sodium acetylide with the bromide **147** and of the reaction product, with the chiral bromide **145** yielded the alkyne **148**, the precursor of the target pheromones, which were obtained by stereoselective hydrogenation.

Reagents: (a) $\text{NaCH}(\text{CO}_2\text{Et})_2$; (b) $\text{LiCl}/\text{H}_2\text{O}$; (c) O_3/MeOH ; (d) H_2CrO_4 ; (e) $\text{AgNO}_3/\text{K}_2\text{S}_2\text{O}_8$; (f) LiAlH_4 ; (g) $\text{Br}_2 \cdot \text{PPh}_3$; (h) NaIO_4 ; (i) MeOH/HCl ; (j) $\text{HC} \equiv \text{CNa}$; (k) Bu^nLi ; (l) **145**; (m) $\text{H}_2/\text{Ni P-2}$; (n) pyridinium *p*-toluenesulfonate (PPTs)/ H_2O .

The same bromide (*R*)-**141** has been used in the synthesis of all the stereoisomers of 6,12-dimethylpentadecan-2-one **149**, the sex pheromone of the cucumber flea beetle (*Diabrotica balteata* LeConte). The key stage in this synthesis was the alkylation of the sulfone **150** with the iodide **151**.²⁸

The (*R*)- and (*S*)-enantiomers of the iodide **151** were prepared as described.²⁹

In the synthesis of the sulfone (*S*)-**150**, the bromide (*R*)-**141** was first converted into the ketal **152**; its ozonolysis and reduction gave the alcohol **153**. The latter was converted into (*S*)-**150** via the iodide **154**. The (*R*)-sulfone **150** was synthesised from citronellyl bromide (*S*)-**141** by an analogous scheme.

Reagents: (a) $\text{CH}_3\text{CO}_2\text{Et}/\text{NaH}$; (b) KOH ; (c) HCl ; (d) O_3/TsOH ; (e) O_3 ; (f) NaBH_4 ; (g) TsCl/Py ; (h) $\text{NaI}/\text{NaHCO}_3$; (i) NaSO_2Ph .

Different variants of the coupling of the sulfones (*R*)- and (*S*)-**150** with the iodides (*R*)- and (*S*)-**151** gave, after desulfonation of the condensation products, all the four optical isomers of **149**.

Reagents: (a) Bu^nLi ; (b) $\text{Na}-\text{Hg}$; (c) $\text{HCl}-\text{H}_2\text{O}$.

The synthesis of 6-isopropenyl-(3*R*)-methyldec-9-enyl acetate, (*R*)-**157**, the sex pheromone of the California red scale (*Aonidiella aurantii*), from (*R*)-citronellyl acetate **6** has been carried out.³⁰ The key stage in this synthesis was the AlCl_3 -catalysed reaction of methyl propionate with the acetate **6**, which occurred with double bond migration to the terminal position to give the diester **155** (a 1:1 diastereoisomeric mixture). The

selective reduction of the conjugated double bond in **155** and the subsequent building of the butenyl fragment *via* the intermediate hydroxysulfone **156** yielded the target product, (*R*)-**157**. An analogous synthesis from (*S*)-citronellyl acetate **6** gives (*S*)-**157**.

Reagents: (a) $\text{HC}\equiv\text{CCO}_2\text{Me}/\text{AlCl}_3$; (b) $\text{Fe}(\text{CO})_5/\text{NaOH}$; (c) $\text{PhSO}_2\text{CH}_2\text{Li}$; (d) NaBH_4 ; (e) $\text{Ac}_2\text{O}/\text{Py}$; (f) $\text{Na}-\text{Hg}$.

Ozonolysis of the acetate **6** and reduction give the acetoxy aldehyde **73**, which was used in the synthesis of (10*R*)-methyltridecan-2-one **158**, the pheromone of the Western spotted cucumber beetle (*Diabrotica undecimpunctata howardi*). After Wolff–Kishner reduction, the acetoxy aldehyde **73** was converted into the iodide **151**; its coupling with the complementary synthon **159** and conventional procedures gave the target ketone (*R*)-**158**.^{29, 31}

Reagents: (a) O_3/MeOH ; (b) Me_2S ; (c) $\text{NH}_2\text{NH}_2\cdot\text{H}_2\text{O}$; (d) KOH ; (e) TsCl/Py ; (f) NaI ; (g) $\text{LiC}\equiv\text{C}-\text{CH}_2\text{CH}_2\text{CH}_2\text{OTHP}$ (**159**); (h) H_3O^+ ; (i) $\text{H}_2/\text{Pd}/\text{C}$; (j) H_2CrO_4 .

Yet another product of ozonolysis and reduction of the compound (*R*)-**6**, the hydroxyacetate **160**, was converted into the tosylate **161** and used in the synthesis of (14*R*)-methyloctadec-1-ene **162**, the antipode of the sex pheromone of the peach leaf mining beetle (*Lyonetia clerkella*).³² Successive alkylation with lithium dimethyl and di(undec-10-enyl) cuprates completed the synthesis of the enantiomer (*R*)-**162**.

Reagents: (a) O_3/MeOH ; (b) NaBH_4 ; (c) TsCl/Py ; (d) Me_2CuLi ; (e) NaOH/MeOH ; (f) $[\text{H}_2\text{C}=\text{CH}(\text{CH}_2)_9]_2\text{CuLi}$.

In the synthesis of the pheromone (*S*)-**162**, the tosylate **161** was alkylated in the reverse order: at first, the alkene fragment of the molecule was built (Scheme 8) and then the reaction with lithium diethyl cuprate was carried out after the conversion of the acetyl group into the tosyl group.³²

Scheme 8

Reagents: (a) $[\text{H}_2\text{C}=\text{CH}(\text{CH}_2)_8]_2\text{CuLi}$; (b) NaOH/MeOH ; (c) TsCl/Py ; (d) Et_2CuLi .

The allylic alcohol **163** formed by the Sharpless oxidation⁸ of the acetate **6** was used in the synthesis of (2*R*,8*R*)- and (2*S*,8*R*)-stereoisomers of 8-methyldec-2-yl propionate **170**, the pheromone of the Western flea beetle (*Diabrotica virgifera virgifera*), for the introduction of the (8*R*)-chiral centre.³³ To this end, compound **163** was converted into the bromide **164**. The hydroxy ester (*R*)-**166** prepared by hydrolysis of the (*R*)-poly-β-hydroxybutyrate **165** was used as the key compound in the synthesis of the second chiral fragment. Its antipode, (*S*)-**166**, was obtained by enzymic reduction of the oxo ester **167**. Successive alkylation of the dithiane **168**, first with the bromide **164** and then with the (*R*)- or (*S*)-iodides **82** and subsequent desulfonation of the compounds **169a** and **169b** gave the esters (2*R*,8*R*)- and (2*S*,8*R*)-**170**, respectively (Scheme 9).

(5*S*/*R*,9*S*)-Dimethylheptadecane **175** and (5*S*/*R*,9*S*)-dimethylpentadecane **176**, the sex pheromones of *Leucoptera scitella* and *Perileucoptera coffeella*, respectively, have been synthesised from the citronellal **5**. The synthetic schemes involved the Wittig alkenation of the aldehyde **5**, selective allylic oxidation of the reaction products **171** and **172**, and repeated alkenation of the resulting aldehydes **173** and **174**.³⁴

$\text{R} = \text{H}$ (**172**, **174**, **176**, **178**), Et (**171**, **173**, **175**, **177**).

Reagents: (a) $[\text{R}(\text{CH}_2)_4\text{PPh}_3]\text{Br}$ (**177**, **178**)/ NaOMe ; (b) SeO_2 ; (c) PCC ; (d) $[\text{Pr}^n\text{PPh}_3]\text{Br}/\text{NaOMe}$; (e) $\text{H}_2/\text{Pd}/\text{C}$.

Scheme 9

Reagents: (a) $\text{Ph}_2\text{Se}_2/\text{H}_2\text{O}_2$; (b) Bu^tOOH ; (c) O_3/MeOH ; (d) Me_2S ; (e) $\text{NH}_2\text{NH}_2 \cdot \text{H}_2\text{O}$; (f) $\text{KOH}/\text{H}_2\text{O}$; (g) TsCl/Py ; (h) LiBr ; (i) $h\nu/\text{H}_3\text{O}^+$; (j) DHP/TsOH ; (k) LiAlH_4 ; (l) NaI ; (m) baker's yeast; (n) Bu^nLi ; (o) **164**; (p) **(R)-82**; (q) $\text{Raney Ni (Ni-Ra)}/\text{EtOH}$; (r) H_3O^+ ; (s) EtCOCl/Py ; (t) **(S)-82**.

The citronellal **(R)-5** has also been employed in the synthesis of *Z*- and *E*-isomers of trogodermal **(R)-93**. The aldehyde **5** was condensed with malonic acid according to Doebner and then the dienic ester **179** was converted into the *Z*- or *E*-alkenes **93** by a reaction sequence that included the reduction of the double bond conjugated with the ester group, ozonolysis, and oxidation of the acetate **103** as well as stereoselective hydrogenation of the alkyne **92**.³⁵

Reagents: (a) $\text{CH}_2(\text{CO}_2\text{H})_2$; (b) MeOH/TsOH ; (c) $\text{Li}/\text{NH}_3/\text{EtOH}$; (d) $\text{Ac}_2\text{O}/\text{Py}$; (e) O_3 ; (f) CrO_3 ; (g) $\text{K}_2\text{S}_2\text{O}_8/\text{AgNO}_3$; (h) KOH ; (i) $\text{Br}_2 \cdot \text{PPh}_3$; (j) $\text{LiC} \equiv \text{C}(\text{CH}_2)_7\text{OTHP}$; (k) $\text{H}_2/\text{Ni-Ra}$; (l) PCC ; (m) $\text{Na}/\text{NH}_3/\text{EtOH}$.

The citronellal derivative **(R)-180** served as the starting material in the synthesis of 4,8-dimethyldecanal **29**, configurationally homogeneous with respect to the C(8) atom.³⁶ The dehydration of the hydroxy aldehyde **180** gave the rodinal **181**, which was converted by the Wolff–Kishner reaction into the alkene **182**. Homologisation of the bromide **183** derived from the compound **182** by a two-step procedure has opened the way to the target product, **(4R/S,8S)-29**.

Reagents: (a) Al_2O_3 , 350 °C; (b) $\text{NH}_2\text{NH}_2 \cdot \text{H}_2\text{O}/\text{KOH}$; (c) B_2H_6 ; (d) $\text{H}_2\text{O}_2/\text{NaOH}$; (e) $\text{Br}_2 \cdot \text{PPh}_3$; (f) $\text{CH}_2(\text{CO}_2\text{Et})_2/\text{NaH}$; (g) AcOK ; (h) LiAlH_4 ; (i) PCC .

The transformation of pulegone **1** involving the Baeyer–Williger reaction was used in the synthesis of two stereoisomeric 3,7-dimethylnonadecanes, (3*R*,7*R*/*S*)- and (3*R*/*S*,7*S*)-**69**.³⁷ The introduction of the protective ketal group under conditions of acid catalysis was accompanied by a migration of the double bond in the compound **1** to the terminal position. Hydroboration of the resulting α -alkene **184** and subsequent oxidation gave the alcohol **185**, the starting compound for both syntheses.

Reagents: (a) $(\text{CH}_2\text{OH})_2/\text{TsOH}$; (b) B_2H_6 or 9-BBN; (c) $\text{H}_2\text{O}_2/\text{NaOH}$.

To obtain the stereoisomer (3*R*/*S*,7*S*)-**69**, the hydroxy acetal **185** was converted into the ketone **187** via the tosylate **186**. The lactone **188**, prepared from the ketone by a regioselective Baeyer–Williger reaction, was converted into (3*R*/*S*,7*S*)-**69** by a sequence of reactions that involved acid cleavage of **188**, simultaneous reduction of the ester and tosyloxy groups in the compound **189**, and the Wittig reaction between the aldehyde **190** and the phosphorane **191**.³⁷

Reagents: (a) TsCl/Py ; (b) Me_2CuLi ; (c) $\text{HCl}-\text{H}_2\text{O}$; (d) MCPBA ; (e) $\text{MeOH}/\text{H}_2\text{SO}_4$; (f) LiAlH_4 ; (g) PCC ; (h) $\text{Me}(\text{CH}_2)_8\text{CH}=\text{PPh}_3$ (**191**); (i) $\text{H}_2/\text{Pd}/\text{C}$.

In the synthesis of the isomer (3*S*,7*R*/*S*)-**69**, the aldehyde **192** obtained from the alcohol **185** was alkenated with the ylide **193**. The reaction product **194** was converted into the ketone **195**,

which was then oxidised by the Baeyer–Williger reaction. The resulting lactone **196** was converted into the diol **197** and further into the dibromide **198**; its hydride reduction gave (3*S*,7*R*/*S*)-**69**.³⁷

Reagents: (a) PCC ; (b) $\text{Me}(\text{CH}_2)_9\text{CH}=\text{PPh}_3$ (**193**); (c) $\text{H}_2/\text{Pt}/\text{O}_2$; (d) $\text{HCl}-\text{H}_2\text{O}$; (e) MCPBA ; (f) LiAlH_4 ; (g) $\text{Br}_2 \cdot \text{PPh}_3$.

III. Syntheses on the basis of α - and β -pinenes

In the syntheses of pheromones, α - and β -pinenes have also been employed. The methods of their functionalisation can be divided into three groups: (1) reactions without scission of the rings; (2) reactions with the retention of the small (four-membered) ring, and (3) reactions with the opening of both rings.

1. Reactions without scission of the rings

An example of the first type of conversions is the synthesis of *cis*- and *trans*-verbenols **200** constituting the aggregation pheromones of many species of bark beetles of *Ips* and *Dendroctonus* genera. Chiral *trans*-**200** were obtained by allylic oxidation of the corresponding enantiomers of α -pinene **199**,^{38,39} whereas *cis*-**200**, by the Jones oxidation of *trans*-verbenol **200** into verbenones **201** with subsequent reduction with NaBH_4 ^{40,41} or LiAlH_4 .⁴²

Reagents: (a) $\text{Pb}(\text{OAc})_4$; (b) OH^- ; (c) $\text{H}_2\text{Cr}_2\text{O}_7$; (d) NaBH_4 or LiAlH_4 .

The effective cockroach attractants, *cis*-verbenyl acetate **202** and *cis*-verbenyl propionate **203**, have been synthesised by oxidation of α -pinene **199** with lead tetraacetate or tetrapropionate, respectively.⁴³

Reagents: (a) $\text{Pb}(\text{OAc})_4$; (b) $\text{Pb}(\text{OCOEt})_4$.

Nopinone **205**, the product of ozonolysis of β -pinene **204**, has found wide application in the synthesis of insect pheromones.^{44–46} For example, the bicyclic propionate **208** possessing the activity of the sex pheromone of cockroaches, was prepared by transformation of the ketone **205** into apoverbenone **207** via the corresponding monobromide **206**.⁴⁴

Reagents: (a) O_3/MeOH ; (b) Br_2 ; (c) 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU); (d) Me_2CuLi ; (e) $(\text{Pr}^i\text{O})_3\text{Al}/\text{Pr}^i\text{OH}$; (f) $(\text{EtCO})_2\text{O}$.

2. Reactions with the retention of the four-membered ring

The ketone **205** has also served as the starting material in the synthesis of (+)-grandisol **214**, the aggregation-sex pheromone of the boll weevil (*Anthonomus grandis*).^{47, 48} The lactol **209** prepared from the ketone **205** by a five-step procedure was converted by the Wittig reaction into the alkene **210** and then, by a series of simple reactions, into a mixture of alkenes **211**; their allylic oxidation and subsequent hydrogenation gave the ketone **212**. The Norrish photocleavage of this compound followed by deformylation of the resulting aldehyde **213** with the Wilkinson complex and the removal of acetate protection eventually resulted in the target pheromone, (1*R*,2*S*)-**214** (Scheme 10).

The scission of α -pinene **199** with the retention of the small ring was employed in the synthesis of (+)-(1*R*,3*R*)-1-acetoxy-methyl-3-isopropenyl-2,2-dimethylcyclobutane **221**, the sex pheromone of the citrus mealybug (*Planococcus citri*).^{49, 50} This involved the ozonolysis of **199** to yield the oxo aldehyde **215** with the configuration of the chiral centres identical with that of the natural pheromone. The necessary shortening of the side chain was carried out via the enol acetate **216**; its ozonolysis gave a

Reagents: (a) MeMgBr ; (b) NOCl ; (c) $h\nu$; (d) Δ ; (e) H_3O^+ ; (f) $\text{H}_2\text{C}=\text{PPh}_3$; (g) R_2BH ; (h) $\text{H}_2\text{O}_2/\text{NaOH}$; (i) $\text{Ac}_2\text{O}/\text{Py}$; (j) POCl_3/Py ; (k) $\text{CrO}_3 \cdot \text{Py}$; (l) $\text{H}_2/\text{Pd/C}$; (m) $(\text{PPh}_3)_3\text{RhCl}$; (n) LiAlH_4 .

mixture of the acetal **217** and the ester **218**. Treatment of this mixture with methylenephosphorane yielded a mixture of **219** and **220** further converted into the acetate **221** by a three-step procedure. Compound (–)-**221** was synthesised from α -(–)-pinene according to the same scheme.⁵¹

Reagents: (a) O_3/MeOH ; (b) $\text{H}_2/\text{Pd}/\text{CaCO}_3/\text{PbO}$; (c) $\text{Ac}_2\text{O}/\text{NEt}_3$; (d) O_3/SiO_2 ; (e) MeOH/TsOH ; (f) $\text{H}_2\text{C}=\text{PPh}_3$; (g) $\text{PPTs}/\text{H}_2\text{O}$; (h) Bu_2AlH ; (i) $\text{Ac}_2\text{O}/\text{Py}$.

The oxo aldehyde **215** is the key compound in yet another scheme of the synthesis of the compound **221** in which the final stage produced a mixture of acetates **221** and **222** separated chromatographically.⁵²

Reagents: (a) MeMgI; (b) CrO₃; (c) PhCO₃H; (d) POCl₃/Py; (e) SiO₂/AgNO₃.

The pheromone **221** has also been synthesised from the oxo acid **223**, another oxidation product of α -pinene **199**. Irradiation of the product of its reaction with *N*-hydroxy-2-thiopyridine with a tungsten-lamp light gave the intermediate radical **226**; its catalytic oxidation with oxygen and subsequent hydrolysis yielded the alcohol **227**. It was then converted into the target compound **221** by standard procedures.⁵³

Reagents: (a) KMnO₄/(NH₄)₂SO₄/H₂O; (b) SO₂Cl₂; (c) HO-N₂ (225); (d) hv/CH₂Cl₂; (e) O₂/Ph₂SbS(2-MeOC₆H₄); (f) H₂O; (g) Ac₂O/Py; (h) H₂C=PPh₃.

Yet another synthesis of **221** is based on the use of the oxo acid **223**, the product of the oxidative cleavage of (+)-verbenone **201** or *cis*- and *trans*-verbenols **200** with ruthenium chloride in combination with sodium periodate.⁵⁴

Reagents: (a) RuCl₃·3H₂O/NaIO₄; (b) H₂C=PPh₃; (c) LiAlH₄; (d) Ac₂O/Et₃N.

The cyclic aldehyde **228**, the photolysis product of *cis*-(+)-verbanone **227**, has also found application in the synthesis of *cis*-(+)-**221**. The *cis*-(-)-isomer **221** was obtained from *cis*-(-)-verbanone **227** in an analogous way. The *trans*-isomer **221** was

synthesised by conversion of **228** into the *cis*-ester **229** with its subsequent epimerisation into the *trans*-isomer **229**.⁵⁵

Reagents: (a) hv; (b) NaBH₄; (c) Ac₂O/Py; (d) CrO₃; (e) MeOH/H⁺; (f) MeONa/MeOH; (g) LiAlH₄.

3. Reactions with the opening of both rings

An elegant method for the synthesis of both enantiomers of 2-methyl-6-methylenoocta-2,7-dien-4-ol (ipsdienol) **231**, the aggregation-sex pheromone of many *Ips* species, is based on a four-step transformation of the optically active verbenones **201**. β -Verbenols **230a**–**230d** obtained by the reduction of the corresponding non-conjugated ketones were subjected to flash pyrolysis to give the target alcohols **231** with the retention of the absolute configuration of the chiral centre of C(4) in the corresponding alcohols **230** (Scheme 11).⁵⁶

Catalytic hydrogenation of α -(+)-pinene **199** followed by hydroboration and hydrolysis give predominantly *cis*-(+)-pinane **232**.⁵⁷ Its thermolysis yields a mixture of products the main component of which is (*S*)-(+)-dihydromyrcene (*S*)-**42**.⁵⁸

Reagents: (a) H₂/PtO₂ or Ni; (b) B₂H₆; (c) H₂O; (d) 550 °C.

The ketone **233**, the product of the Walker–Tsuji oxidation of the diene (*S*)-**42**, has proved to be a convenient starting material in the synthesis of diprionyl acetate **17** as an equimolar mixture of two diastereomeric pairs having (2*S*,3*S*,7*S*/*R*)- and (2*R*,3*S*,7*S*/*R*)-configurations.⁵⁹ Hydride reduction of the ketone **233** gave a mixture (~1:1) of the *erythro*-(2*S*,3*S*)- and *threo*-(2*R*,3*S*)-alcohols **234** converted into a mixture of diastereomeric diacetoxy alkenes **236** via the corresponding acetates **235**. The latter were obtained in higher yields from the products of allylic oxidation of the ketone **233**. The allylic acetoxy group in **236** was efficiently substituted by alkyl by treatment with the organocuprate reagent. The hydrogenation of the double bond in the thus obtained alkenyl acetate **237** resulting in the formation of the third chiral

Scheme 11

Reagents: (a) NaH; (b) H₃BO₃; (c) LiAlH₄; (d) 550 °C; (e) (PrⁱO)₃Al/PrⁱOH; (f) Li/NH₃.

centre at C(7) occurs in a fully nonstereoselective manner (Scheme 12).⁵⁹

The unsaturated alcohol **238**, the product of selective ozonolysis of the diene (*S*)-**42** at the trisubstituted double bond, has been successfully employed in the synthesis of (3,7*S*)-dimethyloct-(2*E*)-enedioic acid **239** and (3,7*S*)-dimethyloct-(2*E*)-ene-1,8-diol **240**, the components of the sex pheromones of the Chinese bean weevil (*Callosobruchus chinensis*) and the African monarch (*Danaus chrysippus*), respectively. A retrosynthetic analysis of **239** and **240** revealed the efficiency of their syntheses *via* the intermediate diester **241**.⁶⁰

Reagents: (a) O₃/CH₂Cl₂/MeOH; (b) NaBH₄.

To this end, the bromide (*S*)-**109** derived from **238** was introduced into the Grignard reaction with the acetaldehyde; the resulting alcohol **242** was converted into the unsaturated ketone **243** which was further subjected to ozonolysis. The subsequent Horner alkenation of the oxo ester **244** resulted in the diester **241** the hydrolysis or the hydride reduction of which gave the target compounds, **239** and **240**.

Scheme 12

Reagents: (a) O₂/PdCl₂-CuCl; (b) NaBH₄; (c) Ac₂O/NEt₃/DMAP; (d) SeO₂; (e) Ac₂O/Py; (f) Me(CH₂)₆Br/Mg/CuI; (g) H₂/Pd/C.

Reagents: (a) PBr_3/Py ; (b) Mg ; (c) MeCHO ; (d) PCC ;
 (e) $\text{O}_3/\text{CH}_2\text{Cl}_2/\text{MeOH}$; (f) $\text{H}_2/\text{Pd}/\text{CaCO}_3-\text{PbO}$; (g) Ag_2O ;
 (h) CH_2N_2 ; (i) $(\text{MeO})_2\text{P}(\text{O})\text{CH}_2\text{CO}_2\text{Et}/\text{EtONa}$;
 (j) $\text{SiO}_2/\text{AgNO}_3$; (k) NaOH/MeOH ; (l) Bu_2^iAlH .

The aldehyde (S)-44, another product of the ozonolytic cleavage of the diene (S)-42, was used in the synthesis of (6R)-methyloctan-3-one (R)-126, the component of the alarm pheromone of ants of the *Crematogaster* genus.⁶¹ The interaction of the aldehyde (S)-44 with EtMgBr , the catalytic hydrogenation of the double bond in the resulting alcohol 245, and the subsequent oxidation gave the target ketone (R)-126.

Reagents: (a) $\text{O}_3/\text{CH}_2\text{Cl}_2/\text{MeOH}/\text{NaHCO}_3$; (b) $\text{H}_2/\text{Pd}/\text{CaCO}_3-\text{PbO}$;
 (c) EtMgBr ; (d) $\text{H}_2/\text{Pd}/\text{C}$; (e) PCC .

The synthesis of (2S,6)-dimethylhept-5-en-1-ol 248, the alarm pheromone of ants of the *Acanthomyops claviger* genus,⁶¹ required the scission of the vinyl group in the diene (S)-42. For this purpose, the isopropylidene group, which is more sensitive to electrophilic reagents, was protected by conversion into the epoxide 246. Its ozonolysis followed by regeneration of the double bond with AlI_3 resulted in the ester 247, which was converted into the alcohol 248 by standard procedures.

Reagents: (a) $\text{Bu}^t\text{OOH}/\text{Mo}(\text{CO})_6$; (b) $\text{O}_3/\text{CH}_2\text{Cl}_2-\text{MeOH}$;
 (c) $\text{Ac}_2\text{O}/\text{Et}_3\text{N}$; (d) AlI_3/MeCN ; (e) Bu_2^iAlH .

Catalytic hydroalumination of the diene (S)-42 and subsequent hydrolysis gave the alkene (R)-67, which was converted by ozonolysis and reduction into the alcohol 249. The corresponding bromide (R)-89 was used in the synthesis of (R,E)-trogoderma 93.⁶² The regio- and stereo-selective coupling of the magnesium--cuprate reagent derived from (R)-89 with the allylic acetate 250, which occurs as the $\text{S}_{\text{N}}2'$ process, and deprotection gave the target product, (R,E)-93.

Reagents: (a) $\text{Bu}_2^i\text{AlH}/\text{ZrCl}_4$; (b) H_2O ; (c) $\text{O}_3/\text{THF}/\text{MeOH}$; (d) NaBH_4 ;
 (e) PBr_3/Py ; (f) Mg/CuI ;

(S)-Citronellol, (S)-4, is the only oxidation product of the organoaluminium adduct of dihydromyrcene (S)-42.⁶³ This compound and some of its derivatives were used in pheromone syntheses

Reagents: (a) Bu_3^iAl or $\text{Bu}_2^i\text{AlH}/\text{ZrCl}_4$; (b) O_2 ; (c) H_2O .

Thus the tetrahydropyranyl ether of (S)-citronellol, (S)-50, has found application in the synthesis of (14S)-methyloctadec-1-ene, (S)-162, after its ozonolytic conversion into the mono-substituted diol 251. Alkylation of the derived tosylate with MeMgI and the subsequent interaction of the bromo-derivative with undec-10-enylmagnesium bromide completed the synthesis of the pheromone (S)-162.⁶³

Reagents: (a) DHP/TsOH ; (b) O_3/MeOH ; (c) NaBH_4 ; (d) TsCl/Py ;
 (e) $\text{MeMgI}/\text{Li}_2\text{CuCl}_4$; (f) $\text{HCl}-\text{H}_2\text{O}$; (g) PBr_3/Py ;
 (h) $\text{H}_2\text{C}=\text{CH}(\text{CH}_2)_9\text{MgBr}/\text{CuI}-2,2'$ -bipyridyl (bipy).

The methoxyethylmethyl ether of citronellol 252 was used in the synthesis of (3S,6R)-157, the pheromone of the California red scale, and its (3S,6S)-enantiomer. For this purpose, compound 252 was converted into the glycol 253 by epoxidation and subsequent hydrolysis; the glycol was treated with (R)-(+)- α -methoxy- α -(trifluoromethyl)phenylacetyl chloride 256 to give the diester 254 as a mixture of diastereomers readily separable chromatographically. Each of these was reduced to the corresponding diol 255; selective mesylation of the secondary hydroxy group and treatment of the mesylates with an alkali gave epoxides 257 with inversion of the chiral centre at the C(6) atom. The

Reagents: (a) MCPBA; (b) H_3O^+ ; (c) RCl (**256**); (d) HPLC; (e) LiAlH_4 ; (f) MeSO_2Cl ; (g) KOH/MeOH ; (h) $(\text{H}_2\text{C}=\text{CHCH}_2\text{CH}_2)_2\text{CuLi}$ (**258**); (i) Bu^nLi ; (j) $\text{Ac}_2\text{O/Py}$.

reaction of the epoxide with the cuprate reagent **258**, the dehydration of the intermediate alcohols, and the substitution of the methoxyethylmethyl group for the acetate group completed the synthesis of the pheromone **157** (Scheme 13).⁶⁴

The isomeric trogoderms (*R,E*)- and (*R,Z*)-**93** were synthesised by electrolysis of a mixture of (–)-4*R*-methylhexanoic (*R*)-**68** and 12-(2-tetrahydropyranyloxy)dodec-4-ynoic **260** acids with subsequent stereoselective hydrogenation of the resulting acetylenic alcohol **92**.⁶⁵ The chiral acid (*R*)-**68** was synthesised by ozonolysis and oxidation of the alkene (*R*)-**67**, the product of hydride reduction of citronellyl tosylate (*S*)-**19**, whereas the achiral acid **260**, by alkylation of the pent-4-ynoic acid **259** acetylenide with the bromo ester **94**.

Reagents: (a) TsCl/Py ; (b) LiAlH_4 ; (c) O_3 ; (d) H_2CrO_4 ; (e) Bu^nLi ; (f) **94**; (g) e^- ; (h) HCl ; (i) $\text{H}_2/\text{Pd/CaCO}_3\text{—PbO}$; (j) PCC ; (k) Na/NH_3 .

Citronellyl bromide (*S*)-**141** was used as the starting material in the synthesis of an equimolar mixture of the natural (*4R,8R*)- and the synergistic (*4R,8S*)-enantiomers of the mealworm attractants **29**.⁶⁶ The reaction of the bromide (*S*)-**141** with the Grignard reagent from racemic 1-bromo-2-methylbutane **28** gave the alkene **95**; its ozonolysis and the subsequent reduction of the peroxide completed the synthesis of the pheromone (*4R,8R/S*)-**29**.

Reagents: (a) **28**/ $\text{Mg/Li}_2\text{CuCl}_4$; (b) $\text{O}_3/\text{MeOH/CH}_2\text{Cl}_2$; (c) Me_2S .

The mixture (*4R,8R/S*)-**29** was obtained in higher yield according to a scheme involving the interaction of the Grignard reagent prepared from the bromide (*S*)-**141** with allyl bromide and selective carbomagnesation of the resulting diene **261** at the terminal double bond.⁶⁶ The carbomagnesation product **95** contained no more than 5% of the diene **262**, which was converted by ozonolysis into the corresponding dialdehyde, which was readily separated from the target product by chromatography.

Reagents: (a) Mg ; (b) $\text{H}_2\text{C}=\text{CHCH}_2\text{Br/CuI—bipy}$; (c) $\text{Et}_2\text{Mg/Cp}_2\text{ZrCl}_2$; (d) H_3O^+ ; (e) $\text{O}_3/\text{MeOH—CH}_2\text{Cl}_2$; (f) Me_2S ; (g) SiO_2 .

The sex pheromone of *Leucoptera malifoliella* comprises two components: the major component, (5*S*,9*S*)-dimethylheptadecane **175**, and the minor component, (5*S*,9*S*)-dimethyloctadecane **263**. A retrosynthetic analysis of these compounds shows the expedience of their synthesis from the three chiral blocks: **A**, **B**, and **C**.⁶⁷

The iodide **264** corresponding to the fragment **A** was synthesised from the tosylate **27**, while the sulfones **265** and **266** corresponding to the blocks **B** and **C**, from (*S*)-citronellyl acetate, (*S*)-**6**.

Reagents: (a) $\text{PrMgBr/Li}_2\text{CuCl}_4$; (b) H_3O^+ ; (c) TsCl/Py ; (d) NaI ; (e) O_3/MeOH ; (f) Me_2S ; (g) $\text{Ph}_3\text{P}=\text{CHBu}$; (h) $\text{LiAlH}_4/\text{CoCl}_2$; (i) PhSNa ; (j) MCPBA ; (k) $\text{Ph}_3\text{P}=\text{CH}(\text{CH}_2)_4\text{Me}$.

The alkylation of the sulfones **265** and **266** with the iodide **264** and subsequent desulfonation of the products **267** and **268** yielded the target structures, **175** and **263**.

Reagents: (a) Bu^nLi ; (b) **264**; (c) Na-Hg .

The oxidation of the diene (*S*)-**42** by peroxy acids occurs selectively with the formation of the monoepoxide **246**, which is smoothly isomerised into the allylic alcohol **269** employed in the synthesis of an equimolar mixture of *erythro*- and *threo*-diprionyl acetates **17**, which are configurationally homogeneous with respect to the (3*S*)-chiral centre.⁶⁸ The CuI -catalysed coupling of

the acetate **270** with heptylmagnesium bromide, the conversion of the reaction product **271** into the enone **272** by Walker–Tsuiji oxidation, and further simple conversions yielded the target compound, (3*S*,7*R*)-**17**.

Reagents: (a) MCPBA ; (b) LDA ; (c) $\text{Ac}_2\text{O/Et}_3\text{N/DMAP}$; (d) $\text{Me}(\text{CH}_2)_6\text{MgBr/CuI}$; (e) $\text{O}_2/\text{PdCl}_2-\text{CuCl}$; (f) H_2/Ni .

In the synthesis of (10*R*)-methyl dodecyl acetate **116**, the monoepoxide **246** was converted into the saturated alcohol **249** via the diol (*S*)-**43**. Coupling of the derived tosylate **115** with the Grignard reagent **274** completed the synthesis of the pheromone **116**.⁶⁹

Reagents: (a) HClO_4 ; (b) HIO_4 ; (c) H_2/Ni ; (d) TsCl/Py ;

(e) $\text{BrMg}(\text{CH}_2)_5$ (**274**); (f) $\text{HCl}-\text{H}_2\text{O}$;
(g) NaBH_4 ; (h) $\text{Ac}_2\text{O/Py}$.

The bromide (*R*)-**89**, another derivative of the alcohol **249**, was employed in the synthesis of *Z*- and *E*-trogoderms **93** having the (*R*)-configuration. The key stages in this synthesis are the CuI -catalysed cross-couplings of the corresponding Grignard reagent with the primary acetate **275**⁷⁰ and the secondary allylic acetate **276**⁷¹ mediated by the $\text{S}_{\text{N}}2$ and $\text{S}_{\text{N}}2'$ mechanisms, respectively (Scheme 14).

The acid **114** obtained by the Jones oxidation of the diol (*S*)-**43** was used in the synthesis of (+)-(3*S*)-methylheneicosan-2-one **279**, the analogue of the sex pheromone of the German cockroach (*Blattella germanica*). To this end, compound **114** was converted into the tosylate **277** by a two-step procedure; its coupling with the Grignard reagent **278** followed by the Walker–Tsuiji oxidation of the intermediate ketone completed the synthesis of the target ketone **279**.⁷²

Scheme 14

Reagents: (a) H_2CrO_4 ; (b) LiAlH_4 ; (c) TsCl/Py ;
(d) $\text{Me}(\text{CH}_2)_{14}\text{MgBr}$ (**278**)/ Li_2CuCl_4 ; (e) $\text{O}_2/\text{PdCl}_2-\text{CuCl}$.

The diol (*S*)-**43** was used as the starting material in the synthesis of (*4R,8R*)-dimethyldecanal (*4R,8R*)-**29**, another isomer of the mealworm attractant.

The hydrogenation of the diol (*S*)-**43**, the periodate scission of the intermediate saturated analogue, and the oxidation of the resulting aldehyde with Ag_2O gave the saturated acid (*R*)-**68** further converted into the (*R*)-bromide **164** by the Hunsdiecker reaction. The tosylate **281**, the second component required for the synthesis of (*4R,8R*)-**29**, was synthesised from the epoxide **280**. The Wurtz condensation of compound **281** with the bromide **164** resulted, after a series of simple conversions, in the target product, (*4R,8R*)-**29**.⁷³

The synthesis of the sex pheromone of the peach leaf mining beetle, (*14S*)-methyloctadec-1-ene (*S*)-**162**, from the diol (*S*)-**43** was based on the successive reactions of the tosylates **282** and **283** with the corresponding Grignard reagents.⁷⁴

The tosyloxy acetonide **282** has also proved to be a convenient starting material for the synthesis of (*10R*)-methyltridecan-2-one, (*R*)-**158**, which involved the conversion of **282** into the aldehyde **284** and then into the tosylate **285**, which was then coupled with the Grignard reagent **286**.⁷⁵

Yet another scheme of synthesis of the pheromone (*R*)-**158** is based on the interaction of the aldehyde **284** with the achiral organomagnesium compound **287**.⁷⁶

The unsaturated acetonide **288**, which is easily derived from (*S*)-**42**, can be oxidised by peroxy acids into the epoxide **280**, which has been used in the synthesis of 4-methylheptan-3-ol **290**; its (*3S,4S*)-isomer is the aggregation pheromone of the elm engraver (*Scolytus multistriatus*).⁷⁷ The interaction of compound **280** with MeMgI yields the secondary alcohol **289** with a 1 : 1 ratio of the *erythro*- and *threo*-isomers. Further conversions occur without the involvement of the chiral centres. Individual isomers were isolated by HPLC.

Reagents: (a) MCPBA; (b) MeMgI/CuI; (c) Ac₂O/Py; (d) AcOH–H₂O; (e) HIO₄; (f) NH₂NH₂·H₂O/KOH; (g) HPLC.

The stereoselectivity could be increased up to a ratio of 85 : 15 in favour of the *erythro*-isomer **291a** in the synthesis of (4*S*,6*S*,7*S*)-7-hydroxy-4,6-dimethylnonan-3-one (serricornin) **294a**, the sex pheromone of the tobacco beetle (*Lasioderma serricorne*).⁷⁸

Reagents: (a) HIO₄ (b) EtTi(OPrⁱ)₃; (c) Ac₂O/Et₃N/DMAP.

Oxidative cleavage of the dioxolane ring of compounds **291a** and **291b** gave a mixture of *threo*- and *erythro*-acetoxy acids **292a** and **292b**; their alkaline hydrolysis yields a mixture of lactones **293a** and **293b**, which were converted into the target pheromone **294a** containing 15% of the *threo*-isomer **294b**.⁷⁹

Reagents: (a) CrO₃/6N H₂SO₄; (b) KOH/MeOH; (c) HCl/H₂O; (d) MeI, LiN(SiMe₃)₂; (e) EtMgBr.

The regioisomers of dihydromyrcene **42**, 2,6-dimethylocta-1,7-dienes **295** of (*R*)- or (*S*)-configuration are the starting chiral building blocks in the synthesis of (*R*)- and (*S*)-enantiomers of 3,7-dimethyloct-(2*E*)-ene-1,8-diols **240** and 3,7-dimethyloct-(2*E*)-ene-

dioic acid **239**, the secretion product of the Monarch butterfly and, correspondingly, of the sex pheromone of *Callosobruchus chinensis*.⁸⁰ The ozonolysis of the diene (*R*)-**295**[†] results in the chiral oxoaldehyde **296**. Its aldehyde carbonyl group was protected either by selective hydride reduction to give the hydroxy ketone **297** or by conversion into the oxo acetal **299** for the subsequent selective alkenation. The Wittig–Horner reaction of the hydroxy ketone **297** with trimethyl phosphonoacetate gave a mixture of isomeric *E*- and *Z*-hydroxy esters **298**. Their reduction yielded a mixture of the corresponding *E*- and *Z*-diols **240** from which the individual *E*-isomer was isolated chromatographically.

Reagents: (a) O₃; (b) Me₂S; (c) NaBH₄; (d) (MeO)₂P(O)CH₂CO₂Me/NaH; (e) LiAlH₄.

In the second version of this synthesis, the conversion of the oxo acetal **299** into the target diol (*R*)-**240** involved the Wittig–Horner reaction to give a mixture of *E*- and *Z*-esters **300**. Deprotection of the aldehyde function followed by hydride reduction yielded a 4 : 1 mixture of *E*- and *Z*-diols (*R*)-**240**.

Reagents: (a) MeOH/TsOH; (b) (MeO)₂P(O)CH₂CO₂Me/NaH; (c) NaOH/H₂O; (d) LiAlH₄.

Yet another method of synthesis of the pheromone (*R*)-**239** from the oxo aldehyde **296** has been proposed. This method involved the oxidation of the aldehyde function in the oxo aldehyde **296** and the Wittig–Horner coupling of the oxo acid **301** with trimethyl phosphonoacetate. The resulting mixture of monoesters of the dicarboxylic acids **302** (*E*/*Z* ~ 4 : 1) was hydrolysed and the *E*-isomer of (*R*)-**239** was isolated by HPLC.⁸⁰

[†] The Schemes show the transformations for the (*R*)-enantiomers.

Reagents: (a) AgNO₃/EtOH–H₂O; (b) (MeO)₂P(O)CH₂CO₂Me/NaH;
(c) HCO₂H/H₂O.

IV. Other syntheses

Other monoterpenoid compounds have been used in the synthesis of insect pheromones much more rarely so far. These include alkenes (limonene and dihydrolimonene), alcohols (menthol and linalool),⁸¹ and ketones (menthone, carvone,^{82–85} dihydrocarvone, and camphor).

Limonene **303** has proved to be a convenient starting material for the synthesis of pheromones with the isopropenyl group at the chiral centre. The enantiomer (*R*)-**303** was used to synthesise (*6R*)-isopropenyl-3-methyldeca-3,9-dien-1-yl acetate (*R*)-**315**, the sex hormone of the California red scale.⁸⁶ This goal was achieved by partial ozonolysis of (*R*)-**303** which occurred selectively at the endocyclic double bond. The resulting oxo acetal **304** was further converted into the intermediate diethyl phosphate **305**; its treatment with lithium in ammonia gave diene acetal **306**. Deprotection of the carbonyl group and the Peterson condensation of the resulting aldehyde **307** with the silylimine **308** gave the adduct **309**; its hydrolysis gave the conjugated aldehyde **310** further reduced to the allylic alcohol **311** (Scheme 15).

The conversion of the alcohol **311** into the target product, (*R*)-**315**, was carried out in two ways. The first of those involved mild debenzilation under conditions of the Birch reaction, subsequent conversion of the allylic alcohol group of the diol **312** into the allylic chloride, reduction of the chlorohydrin **313**, and acetylation of the alcohol **314**.

Reagents: (a) Li/NH₃; (b) *N*-chlorosuccinimide (NCS)/Me₂S;
(c) LiAlH₄; (d) Ac₂O/Py.

An alternative way of the transformation of the compound **311** into the acetate (*R*)-**315** involved the synthesis of the sulfonate **316** the reduction of which gave the benzyl ether (**317**). The substitution of the benzyl function in this ether for the acetate yielded the target product, (*R*)-**315**.

Reagents: (a) SO₃/Py; (b) LiAlH₄; (c) Ac₂O/HClO₄.

The bifunctional chiral synthon **304** was successfully used in the stereospecific synthesis of (*6R*)-isopropenyl-3,9-dimethyldeca-(3*Z*,9)- and -(3*E*,9)-dien-1-yl propionates **322** of which the *Z*-isomer is the sex pheromone of the white peach scale (*Pseudaulacaspis pentagona*).⁸⁷ In the synthesis of (*E*)-**322**, the dienal **318**, the product of methylenation and subsequent hydrolysis of the oxo acetal **304**, was converted into the trisubstituted intermediate alkene **320** (with the content of the *E*-isomer ≥ 97%) via the intermediate betaine **319** by using a Corey modification of the Wittig reaction. Deprotonation of the betaine formed from MeCH=PPh₃ and the chiral aldehyde **318** and subsequent treatment with ethylene oxide resulted in the *Z*-homoallylic alcohol **324** via the intermediate **323**; the compound **324** was then

Reagents: (a) O₃/MeOH; (b) (NH₂)₂CS; (c) HC(OMe)₃/CeCl₃·6H₂O; (d) LDA; (e) ClPO(OEt)₂; (f) Li/NH₃; (g) HClO₄;

(h) BnOCH₂CH₂CH₂SiEt₂=N^tBu^t (Bn = benzyl) (**308**)/BuⁿLi; (i) (CO₂H)₂/H₂O; (j) PCC; (k) LiAlH₄.

converted into the target component of the pheromone (*Z*)-**322** with the content of the major stereoisomer of $\geq 98\%$.

$R' = \text{H (321, 325); THP (320, 324), EtCO [(E)\text{-}322, (Z)\text{-}322].$

Reagents: (a) $\text{Ph}_3\text{P}=\text{CH}_2$; (b) H_3O^+ ; (c) $\text{Ph}_3\text{P}=\text{CH}(\text{CH}_2)_2\text{OTHP}$;

(d) Bu^nLi ; (e) MeI ; (f) $\text{Ph}_3\text{P}=\text{CHMe}$; (g)

(h) $\text{EtCOCl/Et}_3\text{N}$.

A synthetic procedure based on the ozonolysis of a 1:1 mixture of α - and β -limonene epoxides **326** has been proposed for the stereoisomers **332a** and **332b** of the sex pheromone of the green beetle (*Nezara viridula*).⁸⁸ The reduction of the corresponding ozonides yielded a mixture of the ketones **327a** and **327b**, which were separated chromatographically. To obtain the component **322**, the enantiomer **327a** was converted *via* the terminal alkyne **328** into the corresponding ester **329**. The regio- and stereospecific conjugated addition of Me_2CuLi gave the *Z*-alkene **330**, further converted into the bromide **331** *via* the corresponding alcohol. Its condensation with 1-lithio-2-methylpropene resulted in the target product, *endo*-epoxide **332a**.

Reagents: (a) O_3 ; (b) PPh_3 ; (c) LDA ; (d) $(\text{EtO})_2\text{P}(\text{O})\text{Cl}$; (e) Bu^nLi ;

(f) ClCO_2Me ; (g) Me_2CuLi ; (h) Bu_2AlH ; (i) $\text{CBr}_4 \cdot \text{PPh}_3$;

(j) $\text{Br}-\text{CH}(\text{CH}_3)=\text{CH}_2 / \text{Bu}^n\text{Li}$.

The other component, **332b**, was obtained from the ketone **327b** in a similar way.⁸⁸

The epoxy ketone **327b** has found application as the starting material in an alternative synthesis of the pheromone **332b**. The coupling of **327b** with the sulfone **333** followed by desulfonation gave a mixture of *Z*- and *E*-isomers of the pheromone **332** from which (*Z*)-**332b** was isolated chromatographically.⁸⁹

Reagents: (a) $\text{PhSO}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$ (**333**)/ Bu^nLi ; (b) PhCOCl ; (c) Na-Hg .

(+)-Dihydrolimonene (*R*)-**334** was used as the starting material in the synthesis of (–)-periplanone B (**350**), the sex pheromone of the American cockroach (*Periplaneta americana*).^{90,91} At the first stage of this synthesis, the terpene (*R*)-**334** was subjected to ozonolysis to give the dimethyl acetal **335**, which was further condensed with allyl bromide. The oxidative cleavage of the double bond in the alkene **336** and the reduction of the intermediate oxo aldehyde gave (after acetylation and deprotection) the aldehyde **337**, which was further converted into the unsaturated dihydroxy sulfide **338**. The tosylation of its primary alcohol group and the protection of the secondary hydroxy group gave compound **339**, which was cyclised upon deprotonation. The product **340** was converted into the sulfoxide by a series of simple reactions; its thermolysis yielded the α,β -unsaturated cyclic ketone **346**. The epoxidation of **346** proceeded regioselectively to give predominantly the epoxide **347**. The latter was converted into the diketone **349** *via* the phenyl selenide **348**; the interaction of **349** with ethylene dimethyl sulfide occurred selectively at one of the oxo groups and gave the target diepoxide **350** (Scheme 16).

Scheme 16

Reagents: (a) O_3/MeOH ; (b) $\text{Me}_2\text{S}/\text{TsOH}$; (c) $(\text{MeO})_2\text{CO}/\text{NaH}$; (d) $\text{H}_2\text{C}=\text{CHCH}_2\text{Br}$; (e) KOH/MeOH ; (f) $\text{OsO}_4-\text{NaIO}_4$; (g) LiAlH_4 ; (h) $\text{Ac}_2\text{O}/\text{Py}$; (i) HCl ; (j) $\text{PhSCH}_2\text{CO}_2\text{Me}/\text{LDA}$; (k) $\text{Ac}_2\text{O}/\text{AcONa}$; (l) $\text{MeONa}-\text{MeOH}$; (m) $\text{TsCl}/\text{Et}_3\text{N}/\text{DMAP}$; (n) DHP/PPTS ; (o) $\text{NaN}(\text{SiMe}_3)_2$; (p) $\text{BzCl}/\text{Py}/\text{DMAP}$; (q) $\text{Dowex } 50\text{W} (\text{H}^+)$; (r) $\text{Na}-\text{C}_{10}\text{H}_8$; (s) PCC/NaOAc ; (t) $\text{PhSSO}_2\text{Ph}/\text{LiN}(\text{SiMe}_3)_2$; (u) NaIO_4 ; (v) $\text{CaCO}_3, 110^\circ\text{C}$; (w) $\text{Bu}^t\text{OOH}/\text{KH}$; (x) $\text{PhSeBr}/\text{LiN}(\text{SiMe}_3)_2$; (y) $\text{H}_2\text{O}_2/\text{Ac}_2\text{O}-\text{AcONa}, \text{K}_2\text{CO}_3$; (z) $\text{Me}_2\text{S}=\text{CH}_2$.

$(R)\text{-}(-)\text{-Linalool}$ (**351**) has found application in the synthesis of the cyclic enol ether, 2-isopropyl-(2*R*),5-dimethyl-2,3-dihydrofuran **357**, the sex pheromone of the female beetles *Hylecoetus dermestoides*. Thus hydroperoxide oxidation of **351** gave the epoxide **352** further reduced to the diol **353**. The selective tosylation of its secondary hydroxy group and the subsequent methylation of the tosylate yielded the alcohol **354**; its oxidation with $\text{RuCl}_3-\text{NaIO}_4$ gave the lactone **355** after spontaneous cyclisation of the intermediate hydroxy acid. The latter was converted into the hydroxy ketone **356**; its cyclisation by distillation over CaSO_4 completed the synthesis of the pheromone **357**.⁹²

$(R)\text{-}357$
 Reagents: (a) $\text{Bu}^t\text{OOH}/\text{VO}(\text{acac})_2$; (b) LiAlH_4 ; (c) TsCl/Py ; (d) $\text{Me}_2\text{Cu}(\text{CN})\text{Li}_2$; (e) $\text{RuCl}_3/\text{NaIO}_4$; (f) LiOH ; (g) LiMe ; (h) distillation over CaSO_4 .

$(-)\text{-Dihydrocarvone}$ **358** was used in the synthesis of (3*S*,6*S*)-**157**, the component of the sex pheromone of the California red scale.⁹³ To this end, the ketone **358** was converted into the enol silyl ether **359**; its ozonolysis gave the hydroxy ester **360**. The latter was converted into the target product, (3*S*,6*S*)-**157** via the bromo ester **361**, bromohydrin **362**, iodide **363**, and the corresponding nitrile (Scheme 17).

Another component of the sex pheromone of the California red scale, $(R)\text{-}315$, has been synthesised from (+)-camphor **364** taking advantage of possible cleavage of its 9,10-dibromo-derivative **365** under alkaline conditions to give the unsaturated bromo acid **366** which was converted into the β -bromo-ketone **367** by a series of simple reactions. Its treatment with NaOMe gave the acyclic hydroxy ester derivative **368**. The latter was transformed into the aldehyde **369** the condensation of which with 2-propenylmagnesium bromide gave the allylic alcohol **370**. Its stannyl derivative underwent a highly stereoselective 2,3-sigmatropic rearrangement into the corresponding homoallylic alcohol (Scheme 18).⁹⁴

Scheme 17

Reagents: (a) LDA; (b) Me₃SiCl; (c) O₃/MeOH/CH₂Cl₂; (d) NaBH₄; (e) CH₂N₂; (f) MsCl/Py; (g) Bu₄NBr; (h) Bu₂AlH; (i) H₂C=CHCH₂MgCl/CuI; (j) I₂·PPh₃; (k) NaCN; (l) NaOH; (m) LiAlH₄; (n) Ac₂O/Py.

Scheme 18

R = Bu^tMe₂Si.

Reagents: (a) Br₂/ClSO₃H; (b) Zn/NaOH; (c) KOH/DMSO; (d) HCl; (e) LiAlH₄; (f) O₃/MeOH; (g) Me₂S; (h) Bu^tMe₂SiCl/DMAP; (i) NaOMe; (j) PCC; (k) H₂C=PPh₃; (l) Bu₄NF; (m) CH₂=C(Me)MgBr; (n) Bu₃SnCH₂I/BuⁿLi; (o) Ac₂O/Py.

Scheme 19

Reagents: (a) PCC; (b) C₁₀H₂₁SO₃H; (c) KOH/MeOH; (d) MeOH/TsOH; (e) (CH₂OH)₂/TsOH; (f) Bu₂AlH; (g) BnCl/KOH; (h) HCl; (i) TsCl/Py; (j) Et₂CuLi; (k) H₂/PdCl₂; (l) PBr₃/Py; (m) Mg; (n) CO₂; (o) LiAlH₄.

(3*R*,7)-Dimethyloctan-(6*S*)-olide **373**, the product of regio- and stereo-specific Baeyer–Williger oxidation of (–)-menthone **372** derived from L-(–)-menthol **371** is especially promising in the synthesis of the enantiomerically pure insect pheromones.

The synthesis of the pheromone of the mealworm, (*R*)-**140**, from the key lactone **373** involved the preparation of benzyloxy ketone **378** after a series of simple unambiguous transformations of the compound **374** into the compound **377**; its conversion into the target product involved the formation of the isopropyl ester **379** and the monobenzyl derivative of the diol **380** (Scheme 19).^{95,96}

To obtain the optically pure analogue of the sex pheromone of the German cockroach **279**, the lactone **373** was reduced into the corresponding lactol **381**; its alkenation and hydrogenation of the resulting *Z*-alkene **382** gave the alcohol **383**. The further modification of its hydrocarbon skeleton to that of the target compound, α -methyl ketone **279**, involved the sequence of conversions which did not affect the chiral centre at C(6): viz., the oxidation of **383** to the ketone **384**, which underwent regiospecific Baeyer–Williger oxidation into the isopropyl ester **385** and the oxidative decarboxylation of the corresponding acid and Walker–Tsuiji oxidation of the resulting alkene **386**.^{97,98}

Reagents: (a) Bu_2AlH , -75°C ; (b) $[\text{Me}(\text{CH}_2)_{14}\text{P}^+\text{Ph}_3]\text{Br}^-/\text{Bu}^n\text{Li}$; (c) H_2/Ni ; (d) PCC; (e) MCPBA; (f) KOH/MeOH ; (g) $\text{Pb}(\text{OAc})_4/\text{Cu}(\text{OAc})_2 \cdot \text{H}_2\text{O}$; (h) $\text{O}_2/\text{PdCl}_2-\text{CuCl}$.

The synthesis of (3*S*)-acetoxy-2,6-dimethylhept-6-ene **388**, the analogue of the Comstock's scale (*Pseudococcus comstocki*) pheromone, is also based on the Baeyer–Williger oxidation of the original ketone **372** and subsequent oxidative decarboxylation of the intermediate acetoxy acid **387**.⁹⁹

Reagents: (a) $\text{AcOOH}/\text{H}_2\text{SO}_4$; (b) $\text{Ac}_2\text{O}/\text{Py}$; (c) $\text{Pb}(\text{OAc})_4/\text{Cu}(\text{OAc})_2$.

The present review clearly demonstrates the efficiency of application of optically active monoterpenoids in the syntheses of chiral insect pheromones.

IV. Potential fields of application of carborane-containing organophosphorus compounds	1030
V. Conclusion	1031

Abstract. Published data on the synthesis, chemical properties and practical use of carborane-containing organophosphorus compounds are surveyed. Their properties are compared with those of similar organophosphorus derivatives devoid of carboranyl groups. The bibliography includes 89 references.

I. Introduction

Carborane-containing organophosphorus derivatives constitute an interesting class of compounds that has been insufficiently investigated.

Although a large number of studies devoted to these substances have been published, these publications are not systematic, and this does not make it possible to estimate adequately the influence of carboranyl and phosphorus-containing fragments on the reactivity of these derivatives. In this review, we generalise and describe systematically the published data dealing with carborane-containing organophosphorus derivatives; our consideration has been restricted to dicarba-*closo*-dodecaborane derivatives. The structures and the numbering of atoms in 1,2-, 1,7- and 1,12-dicarba-*closo*-dodecaboranes are presented below.

These isomers are usually represented using the following brief symbols:

We consider methods for the synthesis of carborane-containing derivatives of trivalent and pentavalent phosphorus and discuss their chemical properties and their potential applications.

II. Carborane-containing derivatives of trivalent phosphorus

1. Carboranylphosphines

a. Synthesis of carboranylphosphines

The first representative of carboranylphosphines, namely, bis(diphenylphosphino)-*o*-carborane **1** was synthesised in 1963 by the reaction of dilithio-*o*-carborane **2** with chlorodiphenylphosphine.^{1–3} Subsequently, reactions of lithiocarboranes with trivalent phosphorus acid chlorides have been widely used to prepare various carborane-containing organophosphorus compounds including those with cyclic structures like compound **3**.³

Reactions of the compound **2** and dilithio-derivatives of *B*-bromo-*o*-carborane with chlorodiphenylphosphine⁴ and chlorodiethylphosphine⁵ gave rise to the corresponding bis-phosphines **4**:

R = Et, Ph; *n* = 0, 1.

Monolithiocarboranes **5** substituted at the 1-position have also been introduced into the reactions with chlorophosphines.^{5–7}

Uspekhi Khimii **66** (12) 1125–1140 (1997); translated by Z P Bobkova

R = H (**a**), Me (**b**), Ph (**c**), HC=CH₂ (**d**), MeC=CH₂ (**e**);
R' = Me, Et, Ph.

Bis- and tris-carboranylphosphines have been prepared in a similar way; for this purpose, the lithiocarborane **5b** was made to react with carboranylchlorophosphines. Chloro(2-methyl-*o*-carboranyl)phenylphosphine **7** (R = Me) was converted in this way into bis(2-methyl-*o*-carboranyl)phenylphosphine **8**.⁷

R = Me, Ph.

At the same time, chloro(2-phenyl-*o*-carboranyl)phenylphosphine **7** (R = Ph) does not enter into this reaction. This was attributed⁷ to both steric and electronic influences of the substituent at the second carbon atom of the carborane nucleus. It is of interest that the reaction of chlorobis(2-methyl-*o*-carboranyl)phosphine **9** with the lithio-derivative **5b**, in addition to tris(2-methyl-*o*-carboranyl)phosphine **10**, has given a complex penta-carboranyl compound **11**, the structure of which has been confirmed by X-ray diffraction analysis.⁸

The formation of the abnormal reaction product **11** was explained⁸ by the occurrence of a number of processes including either metallation of a methyl group in chlorobis(methyl-*o*-carboranyl)phosphine **9** and disproportionation of the resulting carboranymethylolithium or transfer of the reaction site in the lithio-derivative **5b** from the carbon atom linked to lithium to the carbon atom of the methyl group *via* a six-centred transition state.⁸

A number of cyclic *o*-carboranylphosphines have been described. For example, phosphines **13** containing a phosphinane ring have been obtained by the reaction of bis(lithiocarboranyl)methane **12** with MePCl₂ or PhPCl₂.⁹

R = Me, Ph.

According to X-ray diffraction analysis, the C–P–C angle in the six-membered ring in the methyl derivative **13** (R = Me) differs only slightly from its normal value, whereas the C–CH₂–C angle is markedly larger than the tetrahedral angle and is equal to 121.8°.¹⁰

Phosphine **15** having a similar structure but containing two phosphorus atoms in the ring has been prepared by treatment of

1,2-bis(chlorophenylphosphino)-*o*-carborane **14** with the dilithiocarborane **2**.³

Synthesis of carboranylphosphines in which the phosphorus atom is separated from the carboranyl nucleus by methylene groups has been reported. Thus the reaction of *o*-carboranymethylmagnesium bromide **16** with chlorodiphenylphosphine has given rise to (*o*-carboranymethyl)diphenylphosphine **17**.¹¹

The compound **11** mentioned above belongs to the same type of derivative. 1,2-Disubstituted *o*-carboranes **18** containing a dimethylphosphino, diphenylphosphino or dimethylarsino group, in addition to the diphenylphosphinomethyl group, have been obtained by treatment of the lithio-derivative of the phosphine **17** with chlorodimethylphosphine, chlorodiphenylphosphine or iododimethylarsine, respectively.¹²

R = Me, E = P (**a**); R = Ph, E = P (**b**); R = Me, E = As (**c**);
Hal = Cl, I.

1-Diphenylphosphino-2-dimethylarsinomethyl-*o*-carborane **19** was prepared by the reaction of chlorodiphenylphosphine with the lithio-derivative of the corresponding carborane.

The reaction of *o*-carboranymethylmagnesium bromide **15** with PCl₃ yields tris(*o*-carboranymethyl)phosphine **20**.¹³

Treatment of bis(bromomagnesiomethyl)-*o*-carborane **21** with Ph₂PCl has resulted in the synthesis of 1,2-bis(diphenylphosphinomethyl)-*o*-carborane **22**.¹²

The reaction of **21** with MePCl₂ or PhPCl₂ affords the corresponding phospholanes **23**.⁶

R = Me, Ph.

Carboranylphosphines **25** in which the phosphorus atom is separated from the carboranyl nucleus by two carbon atoms have been synthesised by nucleophilic addition of Ph₂PLi to the double bonds in 1-vinyl- and 1-isopropenyl-2-substituted carboranes **24**, activated by the presence of the *o*-carboranyl substituent, in a boiling ether–benzene mixture.¹⁴

R = Me, R' = H (a); R = R' = Me (b); R = MeC=CH₂, R' = Me (c).

The resulting phosphines are difficultly crystallisable viscous substances, which have been isolated after treatment with MeI as the corresponding phosphonium salts.

The activation of the double bond in 1-vinyl- and 1-isopropenyl-2-substituted *o*-carboranes **24a–c** towards nucleophilic addition is due to the high electron-withdrawing ability of the *o*-carborane nucleus. In the case of 1,2-diisopropenyl-*o*-carborane **24c**, Ph₂PLi adds only to one double bond. This is due to the fact that the negative charge arising upon the addition of a Ph₂PLi molecule decreases the electronegativity of the carboranyl fragment and thus prevents the reaction at the second isopropenyl group.

For the same reason, a similar derivative of *m*-carborane does not react with Ph₂PLi at all;¹⁴ in fact, *m*-carboranyl is a weaker electron-withdrawing group than *o*-carboranyl.

Synthesis of *o*-carboranylphosphines containing a PH group has required a totally different approach. These compounds have been obtained in 50%–70% yields by reduction of the corresponding chlorophosphines with LiAlH₄ in ether.^{7,11} However, the attempt to reduce chlorobis(2-phenyl-*o*-carboranyl)phosphine failed.

R = Me, Ph; n = 0, 1.

The reduction of the cyclic dichlorophosphine **3** with LiAlH₄ in ether gives diphosphine **26** in 60% yield.⁷

It should be noted that the use of an excess of LiAlH₄ in the reduction of carboranylchlorophosphines leads to the cleavage of the C–P bond giving the corresponding carborane and phosphine. However, in the case of carboranyl(chloro)phenylphosphines, this reaction pathway was not observed.⁷ This indicates that a Ph group at the phosphorus atom increases the stability of the phosphorus–carboranyl carbon bond with respect to nucleophiles.

b. Properties of carboranylphosphines

All the main properties of phosphines containing no carboranyl groups are also characteristic of carboranylphosphines. At the same time, carboranyl groups have a certain influence on the properties of the phosphine group. This effect depends on the number of carboranyl groups and on their structure and also on the nature of substituents in the carborane nucleus and at the phosphorus atom. In the majority of cases, it is difficult to determine whether electronic or steric factors exert the major influence.

Carboranylphosphines are stable with respect to atmospheric oxygen. They are oxidised under relatively drastic conditions. For example, oxidation of methyl- and phenyl-substituted *o*-carboranylphosphines **6b,c** to the corresponding phosphine oxides **27** has been accomplished only by treating them with CrO₃ in acetic acid.¹¹

R = Me, Ph.

The addition of sulfur to tertiary carboranylphosphines occurs with greater difficulty than its addition to ordinary tertiary phosphines, the reaction conditions being dependent both on the substituents in the carborane nucleus and on the distance between this nucleus and the phosphorus atom.¹¹

n = 1, R = H (**17**); n = 0, R = CH=CH₂ (**6d**);

n = 0, R = MeC=CH₂ (**6e**).

Whereas (*o*-carboranymethyl)diphenylphosphine **17** enters into this reaction under mild conditions, namely, in benzene at 60 °C, the same reaction involving the carboranylphosphines **6d** and **6e** requires heating to 180 °C.¹¹

In an alkaline medium, carboranylphosphines are easily cleaved at the P–C(carborane) bond; however, on treatment with pyridine under mild conditions, this bond is retained. In this case, the carborane nucleus is opened to give *nido*-carboranylphosphines.¹⁵

R = Ph, Et, Prⁱ, OEt; R' = Me, PR₂.

c. Transition metal complexes with carboranylphosphines

Soon after the first carboranylphosphines had been obtained, publications dealing with their use as ligands in transition metal complexes appeared. The first carboranylphosphine complexes of nickel, namely, dicarbonyl-1,2-bis(diphenylphosphino)- and -1,2-bis(diethylphosphino)-*o*-carboranylnickel **29** (R = Et, Ph, X = H), were obtained from the corresponding carboranyldiphosphines and Ni(CO)₄ in chloroform or in hydrocarbon solvents at 20 °C.³ Dicarbonyl-1,2-bis(diethylphosphino)-*o*-halocarboranylnickel complexes **29** (R = Ph, X = Cl, Br) are prepared in a similar way under mild conditions.¹⁶

$n = 1-3$; $R = \text{Et, Ph}$; $X = \text{H, Cl, Br}$.

Study of the IR spectra of the complexes **29** shows that the characteristic CO frequencies are markedly greater than those for other complexes of the same type [for example, *o*-(Ph₂P)₂C₆H₄Ni(CO)₂ or (Ph₃P)₂Ni(CO)₂]. The introduction of a halogen atom in the 9-position of the carboranyl nucleus has no substantial influence on the position of the CO band.

These complexes were found to be thermally unstable. On refluxing in high-boiling organic solvents, they lose CO and are thus converted into more stable complexes **30**.^{5,16}

Nickel dihalide complexes **31**, which are prepared by treatment of the corresponding nickeldicarbonyl complexes of halogenated *o*-carboranes with halogens, undergo a similar transformation.^{16,17}

$n = 1-3$; $X = \text{Cl, Br}$; $Y = \text{Cl, Br, I}$.

Based on 1,2-bis(diphenylphosphino)-*o*-carborane **1**, irontricarbonyl **32** and palladium **33** complexes have also been obtained.¹⁸

A large number of complexes with bidentate ligands containing two phosphorus atoms or a phosphorus and an arsenic atom have been synthesised.¹²

These ligands react with Ni(CO)₄ under mild conditions at 20 °C to give the corresponding complexes **34**; however, similar reactions with Mo, W, Cr and Fe carbonyls occur only on exposure to UV radiation.¹²

$R = \text{Me, Ph}$; $E = \text{P, As}$; $M = \text{Ni, Cr, Mo, W, Fe}$; $n = 4-6$.

The bis-phosphine ligands **18** and **22** readily react with NiCl₂ to yield complexes **35** and **36**, which are stable in air but rapidly decompose in alcoholic media.¹²

The reactions of the carboranylphosphine **22** with chromium, molybdenum and tungsten carbonyls occur only on exposure of benzene solutions of the reactants to UV radiation for 5–15 h.¹⁹

$M = \text{Cr, Mo, W}$.

The carboranylphosphines **1** and **18b** react with cyclopentadienylmanganese tricarbonyl in different ways.¹⁹ In the case of **1**, the reaction yields complex **37**. In the latter case, complex **38** with a similar structure is formed together with compound **39** in which the carboranylphosphine **18b** acts as a monodentate ligand.¹⁹

Cp = cyclopentadiene.

o-Carborane derivatives containing one diphenylphosphine group such as *o*-carboranyldiphenylphosphine **6a** ($R' = \text{Ph}$), 1-diphenylphosphinomethyl-2-dimethylarsino-*o*-carborane **18c**, 1-diphenylphosphino-2-methylthiomethyl-*o*-carborane **40** and 1-diphenylphosphino-2-isopropenyl-*o*-carborane **6e** ($R' = \text{Ph}$) react with CpMn(CO)₃ (Cp is cyclopentadiene) with replacement of only one CO group.¹⁹

Diphenylphosphinocarboranes **6d,e** ($R' = \text{Ph}$) containing a vinyl or isopropenyl substituent in the 2-position react with W(CO)₄ and (COD)₂Mo(CO)₄ (COD is cyclooctadiene) to give complexes in which the C=C double bond participates in coordination.¹²

When THF solutions containing *o*-carboranylphospholane **23** ($R = \text{Ph}$) and Cr, Mo or W hexacarbonyl are irradiated by UV light, one CO group is displaced to give complexes **41**.⁶

$M = \text{Cr, Mo, W}$.

All the complexes described above are solids stable in air; however, most of them decompose in the light. In the structures of these complexes, the metal is coordinated by the lone electron pair of the phosphorus atom.

Transition metal complexes with carboranylphosphines containing B–M bonds that involve the boron atom in the 3(6)-position of the carborane ring, in addition to the P–M bonds, have also been synthesised. A complex of this type is formed, for example, when the carboranylphosphine **6a** ($R' = \text{Me}$) is made to react with the iridium cyclooctene complex.²⁰

Other representatives of this type of complexes, for example **41** and **42**, have been prepared by the reactions of (*o*-carboranyl-methyl)diphenylphosphine **17** with iridium and rhodium complexes in the presence of 4-methylpyridine.²¹

$\text{L} = \text{CO}, \text{C}_8\text{H}_{14}$.

The reaction of **17** with $[\text{Rh}(\text{CO})_2\text{Cl}]_2$ (in hydrocarbon solvents at 25 °C) yields a square-planar d^8 -complex of rhodium, *trans*-(*o*-HCB₁₀H₁₀CCH₂PPh₂)₂Rh(CO)Cl, which does not give intramolecular metallation products on heating with excess phosphine or 4-methylpyridine.²¹

Further studies of cyclometallation of carborane-containing phosphines with Rh(I) and Ir(I) complexes have shown that both the structure and the nature of the substituent in the 1-position of the carborane nucleus can have a substantial effect on the reaction pathway and on the nature of the final product.²² It was found that (2-methyl-*o*-carboranyl)diphenylphosphine **6b** ($R' = \text{Ph}$) does not react with Rh(I) complexes but does react with $[\text{Ir}(\text{COD})\text{Cl}]_2$ yielding product **43**.

In addition to *B*-metallated Rh and Ir complexes of carboranylphosphines, a series of Pd, Os and Ru complexes of this type have also been prepared by reductive carboranylation.^{23–25}

$\text{M} = \text{Ru}, \text{Os}; \text{R} = \text{H}, \text{Pr}^i; \text{R}' = \text{H}, \text{Me};$

$\text{L} = \text{N} \begin{array}{c} \diagup \text{C} \diagdown \\ \text{Me} \end{array}; \text{L}_2 = \begin{array}{c} \diagup \text{C} \diagdown \\ \text{N} \end{array}; \text{L}' = \text{R}'\text{C} \begin{array}{c} \diagup \text{C} \diagdown \\ \text{B}_{10}\text{H}_9 \end{array} \text{CH}_2\text{PPh}_2.$

Apart from the *B*-metallated carboranylphosphine ligand, the complexes **44** ($\text{M} = \text{Ru}, \text{Os}$) also contain a carboranylphosphine coordinated to the metal atom through the phosphorus atom and the hydrogen atom in the 9-position of the carboranyl nucleus.²⁵

2. Carborane-containing derivatives of acids of trivalent phosphorus

a. Carborane-containing halophosphines

The main method for the synthesis of carborane-containing halophosphines is based on the reaction of lithio-derivatives of carboranes with halophosphines or with PCl_3 .

The first carboranylchlorophosphines **46a,b** were prepared from 1,2-dilithio-*o*-carborane **2**³ or its *B*-bromo-substituted analogue **45**⁴ and PhPCl_2 .

The carborane-containing chloro(phenyl)phosphines **7** were obtained in a similar way from the lithio-derivatives of 1-substituted *o*-carboranes **5** and PhPCl_2 .⁷

$\text{R} = \text{Me}, \text{Ph}.$

Dilithio-carboranes react with PCl_3 , PBr_3 and PI_3 to give dimeric halodicarboranodiphosphinanes **47**.^{3,4,26}

$n = 0-10; \text{X}, \text{X}' = \text{Cl}, \text{Br}, \text{I}.$

The interaction of the dilithio-derivative of bis-*o*-carborane **48** with PCl_3 affords cyclic chlorophospholane **49** in 94% yield. By treatment with AgSbF_6 , **49** has been converted into the corresponding fluorophospholane.²⁷

The reaction of PCl_3 with the lithio-derivatives **5** results in the formation of bis(*o*-carboranyl)chlorophosphines **51** together with *o*-carboranyldichlorophosphines **50** as an impurity.^{7,28}

$\text{R} = \text{HC}=\text{CH}_2, \text{MeC}=\text{CH}_2, \text{Me}, \text{Ph}.$

1,7-Dimetallated *m*-carboranes react with PCl_3 , PhPCl_2 or AlkPCl_2 to give bis(dichlorophosphino)-, bis[(chloro)phenylphosphino]- or bis(alkylchlorophosphino)-*m*-carboranes **52** together with oligomeric products. No cyclic phosphines have been detected among the reaction products.^{29–31}

$n = 0–10$; $z = 2–10$; $M = \text{Li, Na, K}$; $R = \text{Cl, Ph, Alk}$;
 $X = \text{F, Cl, Br, I}$.

A drawback of the above methods is that some difficulties arise in the purification of the carboranylchlorophosphines. Treatment of carborane-containing phosphamidites **53** with dry HCl in benzene permits preparation of the corresponding carboranylchlorophosphines **54** in yields of up to 95% and in a highly pure state.^{32–34}

$R = o\text{-H, } m\text{-H, } o\text{-Me, } o\text{-Ph, } o\text{-MeC}=\text{CH}_2$; $R' = \text{Me, Et}$.

o-Carboranyl(dialkylamino)chlorophosphines **55**, which can be easily prepared by treatment of lithio-derivatives of the substituted carboranes **5** with (dialkylamino)dichlorophosphines, react with HCl in a similar way.³³

$R = \text{Me, Ph}$.

Carboranyl-containing chlorophosphines are much less reactive than alkyl- or arylchlorophosphines. This may be due both to the steric factors and to the electronic influence of the electron-deficient carboranyl group. They are stable with respect to atmospheric oxygen at room temperature. Carboranyldichlorophosphines and dicarboranylchlorophosphines do not add sulfur under drastic conditions even in the presence of AlCl_3 or FeCl_3 , whereas *o*-carboranyl(chloro)phenylphosphines **7** add sulfur upon heating to 170–180 °C and are thus converted into the corresponding (*o*-carboranyl)phenylphosphinothioic chlorides **57**.^{11, 32}

$R = \text{Me, Ph}$.

The addition of chlorine to carborane-containing chlorophosphines occurs readily and is usually accompanied by an exothermal effect. The addition products have not been isolated; however, it has been assumed that the reaction involves intermediate formation of carboranylchlorophosphoranes, which are readily hydrolysed in moist air or in aqueous dioxane to give the corresponding dichlorides **58**.

$R = o\text{-Me, } o\text{-Ph, } m\text{-H}$.

At the same time, it has been reported but not confirmed experimentally⁷ that the reaction of chlorobis(2-methyl-*o*-carboranyl)phosphine **51** with excess chlorine affords crystalline methyl-*o*-carboranyltetrachlorophosphorane **59** and 2-chloro-1-methyl-

o-carborane **60**, i.e. it is accompanied by cleavage of one phosphorus–carboranyl carbon bond.

Chlorobis(2-phenyl-*o*-carboranyl)phosphine **51** ($R = \text{Ph}$) does not react with chlorine;⁷ this can be explained by steric hindrance caused by the presence of two 2-phenyl-*o*-carboranyl groups at the phosphorus atom.

Carborane-containing chlorophosphines readily react with various nucleophiles, for example, water, alcohols, amines, azides and others. However, these reactions are often accompanied by cleavage of the P–C bond, the reaction pathway depending both on the nature of the attacking nucleophile and on the structure of carboranylchlorophosphine. It was shown that *o*- and *m*-carboranyldichlorophosphines **54** are smoothly hydrolysed at room temperature by atmospheric moisture to give the corresponding carboranylphosphonous acids. According to IR spectral data, these compounds contain pentavalent phosphorus, despite the electron-withdrawing effect of the carboranyl groups.^{33, 34}

$R = m\text{-H, } o\text{-H, } o\text{-Me, } o\text{-Ph}$.

Hydrolysis of *o*-carboranyldichlorophosphines **50** ($R = \text{H, Ph}$) in aqueous dioxane in the presence of hydrochloric acid gives only the products of rupture of the P–C(carborane) bond, whereas dichloro(2-methyl-*o*-carboranyl)phosphine **50** ($R = \text{Me}$) is mostly converted under the same conditions into (2-methyl-*o*-carboranyl)phosphinic acid **61** ($R = \text{Me}$) (yield 75%) and also into the products of rupture of the C–P bond.³² Probably, this reaction pathway is due to the influence of the methyl substituent, which decreases the electron-withdrawing ability of the carboranyl group and increases the strength of the C–P bond.

o-Carboranylchlorophenylphosphine is fairly unstable with respect to hydrolysis, apparently owing to the presence of three electron-withdrawing substituents at the phosphorus atom; it is cleaved into carborane and phenylphosphonous acid even by the atmospheric moisture.⁷

The easy rupture of the C–P bond in the carborane-containing chlorophosphines may be due to the fact that a carboranyl group attached to a phosphorus atom can act as a pseudo-halogen under certain conditions. Similar behaviour has been observed for carboranylphosphinous acids in which the phosphorus–C(carborane) bond is cleaved on heating of their aqueous solutions.³²

Bis(*o*-carboranyl)chlorophosphines are resistant to the action of water; their alkaline hydrolysis gives only products resulting from cleavage of the C–P bond.³²

R = Me, Ph.

The reactions of carboranyl-containing chlorophosphines with ammonia, unlike their reactions with water, occur with replacement of the chlorine atom to give the corresponding amides **62**, the C–P bond remaining intact.⁷

R = Me, Ph.

The dimeric dichlorophosphine **3** reacts with ammonia in a similar way yielding cyclic diamide **63**.³

The interaction of dry ammonia with 1,2-bis(chlorophenylphosphino)carborane **46a** involves both chlorine atoms and gives rise to cyclic imide **64**.

Dialkylamido-derivatives of carborane-containing acids of trivalent phosphorus have been described. These compounds were obtained as intermediates in the synthesis of carboranyl-chlorophosphines; the methods for their preparation were based on the reactions of monolithiocarboranes^{11, 32, 34} or dilithiocarborane³⁵ with chlorobis(dialkylamino)phosphines.

R = *m*-H, *o*-H, *o*-Me, *o*-Ph; R' = Me, Et.

The attempts to prepare bis(carboranyl)dialkylamino-phosphines by treating aminodichlorophosphines with the lithio-derivatives of *o*-carboranes **5** were unsuccessful. In this case, only one chlorine atom was substituted resulting in the formation of dialkylamino(*o*-carboranyl)chlorophosphines **66**. The second chlorine atom was not replaced, apparently, due to steric hindrance.^{11, 33}

R = Me, Ph.

Carborane-containing chlorophosphines readily react with sodium azide. For example, bromo-substituted 1,2-bis(azidophenylphosphino)-*o*-carboranes **67** have been obtained in this way.^{3, 4, 26}

$n = 0-2$.

The bis-azide **67** is unstable and polymerises at 60 °C. Similarly, cyclic bis-halophosphines **47** have been converted into cyclic bis-phosphine azides **68**.^{3, 4, 26}

$n = 0-10$; X = Cl, Br; X' = Cl, Br, I.

These compounds readily react with tertiary phosphines to give the corresponding phosphazo-derivatives. Polymers based on these derivatives possess valuable properties.^{4, 26}

Carborane-containing fluorophosphines and their platinum complexes were synthesised for the first time in the late 70s and early 80s. Various methods have been used for this purpose. Thus treatment of 2-lithio-1-diphenylphosphino-*o*-carborane **69** with PBrF₂ yielded 2-difluorophosphino-1-diphenylphosphino-*o*-carborane **70**.³⁶ A similar reaction involving dilithio-*o*-carborane **2** resulted in the formation of cyclic difluorophosphine **71**.³⁵

Fluoroamides were synthesised by the reaction of PF₅ with 1,2-bis[bis(dimethylamino)phosphino]-*o*-carborane **67** ($n = 0$).³⁵ It was found that this reaction yields initially adduct **72** containing two PF₅ molecules; upon prolonged heating, it is converted into the corresponding fluorophosphine **73**, only one fluorine atom being introduced to each phosphorus atom.

The adduct **72** is a complex containing a P(III)–P(V) bond. It has been assumed³⁸ that in acetonitrile solutions, this compound is ionic. This reaction has also been studied in relation to other compounds.³⁵⁻³⁸

Attempts to replace the NMe₂ group in the carborane-containing aminophosphine **67** by a fluorine atom by treating this compound with PF₃ were undertaken.^{35, 36} This reaction

occurred slowly: only one fluorine atom was introduced into the molecule upon heating the reaction mixture for several days.³⁶

Carborane-containing fluorophosphines are stable in air but are slowly hydrolysed in solution. On treatment with Pt(II) cyanide complexes, they are readily converted into the corresponding *cis*-complexes **74**, their yields ranging from 42% to 85%.³⁹

R¹ = Ph, NMe₂; R² = F, C₆F₆, Ph, NMe₂; R³ = Me, Ph.

b. Carborane-containing esters of trivalent phosphorus acids

Carborane-containing esters of acids containing trivalent phosphorus have been studied in detail. Esters in which the phosphorus atom is either directly linked to the carborane carbon atom or separated from it by other atoms as well as sulfur- and selenium-containing esters in which the phosphorus atom is connected to the boron atom of the carboranyl group *via* sulfur or selenium have been synthesised.

Carborane-containing esters of trivalent phosphorus acids in which the phosphorus atom is directly attached to the carbon atom of the carborane nucleus have been prepared by several methods. The most reliable procedure is based on the reaction of lithiocarboranes with the corresponding phospho- or phosphonochloridites. For example, ethyl bis(*o*-carboranyl)phosphinites **75** have been prepared in yields of up to 70% by the reaction of the corresponding 2-substituted 1-lithio-*o*-carboranes **5** with EtOPCl₂.⁴⁰

R = Me, Ph, MeC=CH₂.

Esters of carborane-containing phosphinous and phosphonic acids **76** have been synthesised in a similar way.^{41–43}

R = *o*-H, *m*-H, *p*-H, *o*-Me, *o*-Ph, *o*-MeC=CH₂; R' = Me, OEt.

The lithio-derivative of the unsubstituted carborane reacts with ethyl phosphodichloridite to give only cyclic diphosphinite **77**.⁴⁰

This may be due to the fact that 1-lithio-*o*-carborane **5a** disproportionates^{44,45} to give 1,2-dilithio-*o*-carborane **2** and carborane, and the dilithio-derivative **2** reacts with ethyl phosphodichloridite. However, it cannot be ruled out that the compound **77** results from metallation of the intermediate bis(*o*-carboranyl)phosphinite **75** by 1-lithio-*o*-carborane **5a** and subsequent interaction of the lithio-derivative with ethyl phosphodichloridite.

Diethyl (*o*-carboranylmethyl)phosphonite **78** has been synthesised by the reaction of diethyl phosphodichloridite with (1-bromomagnesiomethyl)carborane **16**.⁴⁶

Esters of carborane-containing acids of trivalent phosphorus can be obtained by the interaction of alcohols with the corresponding carboranylchlorophosphines. However, this method is inconvenient, because it is difficult to purify the reaction products. It has been reported³¹ that the treatment of 1,7-bis(dichlorophosphino)- or 1,7-bis(chlorophenylphosphino)-*m*-carboranes **52** with methanol gives rise to the corresponding tetramethyl or dimethyl esters of carborane-containing acids of trivalent phosphorus. However, no evidence confirming the structures of the reaction products was presented in the study cited.

Reactions of carborane-containing chlorophosphines with alcohols in the presence of dimethylaniline or sodium ethoxide have been studied. The reaction pathway was found to depend both on the structure of the corresponding chlorophosphine and on the reaction conditions. When 2-substituted *o*-carboranyldichlorophosphines **54** are made to react with methanol or ethanol in the presence of dimethylaniline, the corresponding dialkyl phosphonites **79** are formed in yields of up to 80%.⁷

R = H, Me; R' = Me, Et.

The attempt to carry out the reaction between *o*-carboranyldichlorophosphines **16** and sodium ethoxide has led only to products resulting from the cleavage of the C–P bond.⁷ The reaction involving 2-substituted *o*-carboranylphenylchlorophosphines **6** occurs in a similar way. These substrates are cleaved even by alcohols under mild conditions in the presence of dimethylaniline. This was explained⁷ by the fact that phosphorus carries a phenyl group and a chlorine atom, in addition to the carboranyl group, and this decreases the strength of the C–P bond.⁷

R = Me, Ph.

To synthesise carborane-containing esters of trivalent phosphorus acids and thioacids, carborane-containing alcohols and dithiols have also been used. For example, the reaction of 1-hydroxymethyl-*m*-carborane **80** with PCl₃ leads to the products of replacement of one, two or three chlorine atoms, depending on the ratio of the reactants.⁴⁷ Despite the absence of bases, no hydrogen phosphite was formed in the reaction.

1,2-Bis(hydroxymethyl)-*o*-carborane **81** has also been introduced in the reaction with PCl₃. This gave the corresponding

cyclic phosphochloridite **82**, which was converted into hydrogen phosphite **83** by controlled hydrolysis.⁴⁸

Cyclic carborane-containing phenylphosphonodithioite **85** has been prepared by the reaction of carborane-1,2-dithiol **84** with PhPCl_2 .⁴⁹

The reactivity of carboranyl or carboranylmethyl esters of trivalent phosphorus acids is markedly lower than that of similar esters containing no carboranyl groups. It depends both on the number of carboranyl groups attached to the phosphorus atom and on the character of the substituents in the carborane nucleus.

Carboranyl phosphonites are stable with respect to atmospheric oxygen and are not oxidised even upon heating to 100 °C; however, they are readily oxidised by N_2O_4 .⁵⁰ The addition of sulfur, CuCl and azides to these derivatives as well as the Arbuzov and Perkow reactions occur less readily than those for phosphonites devoid of the carboranyl group.^{41–43}

Bis(carboranyl)phosphinites do not add sulfur, do not form complexes with CuCl , do not react with azides and do not enter into the Arbuzov reaction.⁴⁰ The inertness of these compounds can be due both to the steric hindrance caused by the two carboranyl groups and to the large overall electron-withdrawing effect of these groups.⁴⁰

B-substituted carborane-containing esters of trivalent phosphorus thioacids^{51–53} and selenoacids⁵⁴ have been synthesised from *o*-carborane-9-thiol **86** or *o*-carborane-9-selenol **87**. The reactions were carried out in the presence of triethylamine under an inert atmosphere at –30 °C. When the compound **86** was made to react with EtOPCl_2 , $(\text{EtO})_2\text{PCl}$ and Ph_2PCl , the corresponding thioesters **88** and **89** were obtained in high yields.^{51–53}

R = EtO (**a**), Ph (**b**).

When $(\text{EtO})_2\text{PCl}$ reacts with *o*-carborane-9-selenol **87**, the corresponding selenoester **90** is formed but the researchers have not been able to isolate it in a pure state.⁵⁴

o-Carboran-9-yl esters of trivalent phosphorus thioacids of type **88a,b** add sulfur and selenium; they form complexes with metal carbonyls and enter into the Arbuzov and Perkow reactions. As a rule, these thioesters are quite stable in air; however, the phosphorothioite **88a** is oxidised by atmospheric oxygen to phosphothioate **91** even during chromatography on silica gel.⁵²

On treatment with alkylating reagents, phosphinothioite **88b** is converted into stable quasi-phosphonium salts **92**.⁵⁵

92	R	Hal	Yield (%)
a	Me	I	98
b	PhCH_2	Cl	50
c	$\text{H}_2\text{C}=\text{CHCH}_2$	Br	62

It was shown that treatment of the salt **92b** with sodium ethoxide in ethanol results in the rupture of the P–S bond and gives the thiol **86** in an almost quantitative yield, together with benzyldiphenylphosphine oxide.⁵⁵

The phosphinothioite **88b** forms complexes **93** and **94** with pentacarbonyl tetrahydrofuranotungsten and with dicarbonyl cyclopentadienyltetrahydrofuranomanganese, respectively.⁵³

The phosphinothioite **88b** is fairly stable when heated to 200 °C under an argon atmosphere, whereas the phosphorothioite **88a** decomposes even at 120 °C to give a mixture of products containing the compound **89** (29.9%), *O*-ethyl *S,S*-bis(*o*-carboran-9-yl) phosphodithioate **95** (4.8%), *O,O*-diethyl *S*-*o*-carboran-9-yl phosphothioate **96** (10.6%), *O*-ethyl *S*-*o*-carboran-9-yl ethylphosphonothioate **97** (17.6%), $(\text{EtO})_2\text{PHO}$ (30.5%) and non-identified products (6%).⁵⁵

III. Carborane-containing derivatives of pentavalent phosphorus

Derivatives of pentavalent phosphorus constitute a large portion of all known phosphorus-containing carboranes. These compounds are synthesised by reactions typical of derivatives of both trivalent and pentavalent phosphorus.

1. Carboranylphosphine oxides and sulfides, derivatives of carborane-containing phosphinic and phosphonic acids

Syntheses of some carborane-containing phosphine oxides and sulfides have been mentioned in Section II.1.b. These derivatives were synthesised by addition of oxygen or sulfur to the corresponding carborane-containing phosphines. 2-Diphenylphosphinothiomethyl-*o*-carboranethiol **98** has been prepared using a

different approach consisting in metallation of *o*-carboranylmethylidiphenylphosphine **17** and treatment of the resulting lithio-derivative with sulfur. The reaction product was isolated after acidification by hydrochloric acid.¹²

Bis- and tris-carboranylphosphine oxides have been synthesised by treatment of the lithio-derivatives of 2-substituted carboranes **5b,c** with methylphosphonoyl dichloride or with phosphorus oxychloride.³³

R = Me (**b**), Ph (**c**).

As noted above, carborane-containing esters of acids of trivalent phosphorus are stable against oxidation with atmospheric oxygen; however, they are readily oxidised by N₂O₄ to give the corresponding esters containing pentavalent phosphorus in high yields.⁵⁰ For example, this procedure was used to synthesise compounds **99**.

R = *p*-H, *m*-H, *o*-Me, *o*-Ph, *o*-MeC=CH₂; R' = Me, OEt.

Carborane-containing phosphonothioates and phosphinothioates **100** can be prepared by addition of sulfur, which occurs only on heating to 100–120 °C. The relatively low reactivity of the compounds studied with respect to sulfur is apparently due to the electron-withdrawing effect of the carboranyl group.⁴²

R = *o*-H, *m*-H, *o*-Me, *o*-MeC=CH₂; R' = Me, OEt.

O,O-Diethyl (2-methyl-*o*-carboranyl)phosphonothioate **100** (R = Me, R' = OEt) was also obtained by the reaction of the corresponding carboranylphosphonite **76** with butanethiol under UV radiation.⁴²

On treatment with 4-nitrophenyl azide, carborane-containing esters of acids of trivalent phosphorus **76** are converted relatively easily into imino-derivatives **101**.^{42, 43}

R = H, Me, Ph, MeC=CH₂; R' = Me, OEt.

However, this reaction occurs more slowly than that involving similar esters of acids of trivalent phosphorus devoid of the carboranyl group. It was also found that substituents at the phosphorus atom as well as those in the *o*-carborane nucleus have a substantial influence on the reactivity.⁴³

Based on the dissociation constants of imidophosphinates **101**, the σ^{P} constants for substituted *o*-carboranyl groups were calculated (Table 1).⁴³ The results obtained confirm the electron-withdrawing properties of the carboranyl group.

Table 1. Dissociation constants and σ^{P} values for imidophosphinates **101** (R' = Me).⁴³

R	pK _a	σ^{P}
H	5.48	2.10
Me	6.10	1.79
MeC=CH ₂	5.83	1.92
Ph	5.68	2.00

The Arbuzov reaction can also be used to prepare carborane-containing derivatives of pentavalent phosphorus; however, it also occurs under more drastic conditions than the same reaction for esters of trivalent phosphorus acids devoid of the carboranyl group.

The reaction of diethyl carboranylphosphonite with MeI in acetonitrile carried out by heating the reactants in a tube (100–140 °C) affords the corresponding derivatives of pentavalent phosphorus **99**, their yields ranging from 50% to 73% depending on the character of the substituent at the phosphorus atom. The reaction occurs most readily for the carborane-containing methyl phosphinites **76** (R' = Me).^{42, 43, 50} Ethyl iodide reacts in a similar way.⁴²

R = *m*-H, *p*-H, *o*-Me, *o*-Ph; R' = Me, Et.

The reaction with dimethyl sulfate occurs under substantially milder conditions (at 20 °C) giving rise to compounds **102** in yields of up to 81%.⁴³

R = H, Me.

To carry out a similar reaction with diethyl (*o*-carboranyl)-phosphonites, heating to 110–120 °C is required. Whereas the transformation of diethyl (2-methyl-*o*-carboranyl)phosphonite **76** (R = Me) gave ethyl (2-methyl-*o*-carboranyl)methyl-phosphinate **99** in 78% yield, in the case of *o*-carboranylphosphonites **76** (R = H, MeC=CH₂), the reaction is accompanied by transesterification giving the corresponding methyl (*o*-carboranyl)methyl-phosphinates **103** in yields of up to 56%.⁵⁶

(a) R = Me; (b) R = H, MeC=CH₂.

Transesterification also occurs when ethyl (*p*-carboranyl)-methylphosphinate is heated with excess Me₂SO₄.⁵⁶

When diethyl *o*-carboranylphosphonites are treated with sulfonyl chlorides, the Arbuzov reaction smoothly occurs.^{41, 42} For example, the reactions with butylsulfonyl chloride and 2,4-dinitrophenylsulfonyl chloride in tetrachloromethane gave the corresponding thioesters **104** in yields of up to 90%.

R = Bu, 2,4-(NO₂)₂C₆H₃.

Several examples of the Perkow reaction have been reported. When the compounds **76** have been made to react with a large excess of chloral without a solvent, the corresponding dichlorovinyl carboranylphosphonates and carboranylphosphinates **105** have been obtained in 44% to 90% yields.^{43, 50}

R = *p*-H, *m*-H, *o*-H, *o*-Me, *o*-Ph, *o*-MeC=CH₂; R' = Me, OEt.

(Carboranyl)methylphosphinites enter into this reaction much more readily than carboranylphosphonites. In addition, the ease of this reaction depends on the electron-withdrawing properties of the carboranyl groups, which are determined in this particular case by the nature of the carboranyl nucleus. The substituents present in these nuclei make only a minor contribution to the overall electronic effect of the carboranyl groups but cause substantial steric effects.^{43, 50}

Carborane-containing esters of acids of pentavalent phosphorus in which the carboranyl group is separated from the phosphorus atom by a methylene bridge are also known. These compounds have been prepared by means of standard reactions typical of esters of trivalent phosphorus acids devoid of the carborane group.⁴⁶

Chlorides and bromides of *o*-carborane-containing acids of pentavalent phosphorus **106** have been synthesised by treating the esters derived from carborane-containing acids of trivalent phosphorus **76** with sulfuryl chloride, chlorine or bromine.^{40, 42, 50}

R = Ph, MeC=CH₂; R' = Me, OEt, —C—CH— $\text{B}_{10}\text{H}_{10}$; X = Cl, Br.

Fluorides **107** were prepared by treatment of the corresponding chlorides **106** with antimony trifluoride.⁵⁰

R = Ph, MeC=CH₂; R' = Me, OEt.

The first representatives of carborane-containing acids of pentavalent phosphorus in which the phosphorus atom is linked directly to the boron atom in the 9-position of the carboranyl group were obtained by the reaction of bis(*p*- or *m*-carboran-9-yl)mercury **108** with trimethyl phosphite under UV irradiation. Dimethyl (*p*-carboran-9-yl)phosphonate **109** was synthesised in this way in 60% yield. However, dimethyl (*m*-carboran-9-yl)phosphonate *m*-**109** was obtained by this procedure only in 5% yield, and in the case of bis(*o*-carboran-9-yl)mercury, the reaction did not occur at all.⁵⁷

The σ^Φ constants for 9-*p*- and 9-*m*-carboranyl groups were found to be equal to −1.68 and −1.81, respectively, which points to electron-donating properties of these groups.⁵⁷

Bis(*o*-carboran-9-yl)mercury **108** reacts with PCl₃ on exposure to UV radiation to give the corresponding dichlorophosphine **110** in 5% yield. The *m*-carboranylmercury derivative reacts in a similar way (yield 10%).

m-Carboran-9-yl dichlorophosphine **110** has been oxidised by SO₂Cl₂ to the corresponding phosphonyl dichloride **111**; the latter was converted into dimethyl (*m*-carboran-9-yl)phosphonate **109** by the reaction with methanol in the presence of triethylamine.^{58, 59}

The results of X-ray diffraction and IR spectroscopy studies of dimethyl (*p*- and *m*-carboran-9-yl)phosphonates **109** have shown that their crystals contain hydrogen bonds; *p*-carborane-derivatives were found to form dimers.^{57, 60}

Carborane-containing derivatives of acids of pentavalent phosphorus **112** in which the 9-position of an *o*-, *m*- or *p*-carboranyl group is linked to the phosphorus atom via a mercury atom have been synthesised.^{61, 62}

R = Me, Et, Prⁱ.

Synthesis of (*m*-carboran-9-yl)triphenylphosphonium tetrafluoroborate **113** has been reported.⁶³ The researchers did not succeed in preparing a similar salt derived from *o*-carborane.

2. Derivatives of acids of pentavalent phosphorus containing a carboranyl group in the ester moiety of the molecule

Numerous examples of phosphorus acid esters containing a carboranyl group in the ester moiety of the molecule have been described. In these molecules, the carbon or boron atoms of the carboranyl moiety are linked to the phosphorus atom *via* sulfur or selenium atoms or *via* hydroxyalkyl or thioalkyl groups.

Carboranylalkyl esters of phosphorus-containing acids have been synthesised starting from various hydroxyalkylcarboranes.

The first *o*-carboranyl phosphates **115** were prepared by the reaction of monoacylated 1,2-bis(hydroxymethyl)-*o*-carboranes **114** with H_3PO_4 at 100–120 °C.⁶⁴

R = Alk.

When hydroxymethyl-*o*-carboranes or -*m*-carboranes **80** are treated with PCl_5 , tris(carboranylmethyl) phosphates **116** are formed. The yield of the *m*-carborane derivative is 90%, whereas that of the *o*-carborane derivative does not exceed 26%. This reaction also yields the corresponding chloromethyl derivative **117**.^{65, 66}

The reaction of PCl_5 with the diol **81** gives rise to a mixture of cyclic phosphochloridite **118** and 3,4-(1,2-*o*-carborano)oxolane **119** (yields 22% and 24%, respectively).⁶⁶

The diol **81** can also be used to synthesise cyclic esters of carborane-containing acids of pentavalent phosphorus. For example, the Todd–Atherton reaction involving the phosphite **83** has given carborane-containing amidophosphate **120**. Cyclic heptylphosphonate **121** was synthesised by the addition of the same phosphite to hept-1-ene.⁴⁸

o-Carboranylmethyl phosphates **122** have been described. These compounds are formed in the reaction of hydroxymethyl-*o*-carborane **80** with POCl_3 or with monochlorophosphates in the presence of Mg as a catalyst.⁶⁷

R, R' = Cl, OPh, OCH_2CF_3 .

The reaction of hydroxymethyl-*o*-carborane **80** with diethoxyphosphoryl isocyanate affords carbamate **123**.⁶⁸

A series of *o*-carboranylmethyl esters of acids of pentavalent phosphorus have been synthesised by treatment of propynyl esters of the corresponding acids and thioacids with decaborane in the presence of dimethylaniline.^{69, 70} The yields of the products vary from 50% to 77%.

X, Y = O, S; R, R' = Me, OEt, Ph.

Several methods have been developed for the preparation of *S*-carboranyl esters of dithioacids of pentavalent phosphorus in which the sulfur atom is directly linked to the carbon atom of the carboranyl ring. According to one of these methods, lithiocarboranes **5** are made to react with bis(dialkoxythiophosphoryl) disulfides in benzene or in an ether–benzene mixture.⁷¹

R = Me, Et, Prⁱ; R' = *o*-H, *m*-H, *o*-Me, *o*-Ph, ,

Unexpectedly, the reaction of equimolar amounts of bis(dialkoxythiophosphoryl) disulfides with lithio-*m*-carborane in an ether–benzene solvent mixture resulted in the formation of 1,7-bis(thiophosphorylthio)-*m*-carboranes. Similar transformations in benzene yielded only monosubstituted *m*-carboranyl phosphodithioates.

O-Ethyl *S*-(2-phenyl-*o*-carboranyl) methylphosphonodithioate **124** has been prepared by the reaction of lithium 2-phenyl-*o*-carboranethiolate with *O*-ethyl chlorophosphonothioate.⁷¹

To synthesise esters of thiophosphoric acid containing a 1-methyl-*m*-carboran-7-yl group, 1-methyl-*m*-carboran-7-ylsulfenyl chloride **125** has been introduced into the reaction with triethyl phosphite; this has given *O,O*-diethyl *S*-(1-methyl-*m*-carboran-7-yl) phosphothioate **126**. 7-Ethylthio-1-methyl-*m*-carborane **127** was isolated as a side product.⁷²

A series of *S*- β -carboranylthio(seleno)ethyl esters of thioacids of pentavalent phosphorus **128** have been synthesised by the reaction of *O*-ethyl *S*- β -bromoethyl methylphosphonothioates or *O,O*-diethyl *S*- β -bromoethyl phosphothioates with lithium or ammonium derivatives of carboranethiols or carboraneselenols.^{54, 71, 73}

R = *m*-H, *o*-H, *o*-Me, *o*-Ph; R' = Me, OEt; X = S, Se; M = Li, Et₃NH.

Among carborane-containing acids of pentavalent phosphorus, some *B*-substituted thio- and selenoesters have also been synthesised and studied. Compounds of this type have been prepared from *o*-carborane-9-thiol **86** or selenol **87** using ordinary reactions typical of derivatives of phosphorus-containing acids. For example, treatment of the thiol **86** or the selenol **87** with pentavalent phosphorus acid chlorides in the presence of Et₃N has resulted in the synthesis of thio- or selenoesters containing one (**129**) or two (**130**) carboranyl groups.^{54, 73}

Y = S (**86**), Se (**87**).

Me	OC ₆ H ₄ NO ₂ -4	O	S	74
Ph	Ph	S	S	67
Me	OEt	O	Se	40
Me	OEt	S	Se	71

Other procedures for the synthesis of *B*-substituted derivatives of carborane-containing acids of pentavalent phosphorus are based on reactions of *o*-carboran-9-yl phosphorothioites or phosphoselenoites (see Section II).

O,O-Diethyl *S*-(*o*-carboran-9-yl) phosphinothioite **88a** is readily oxidised even during chromatography on silica gel to give phosphothioate **91** in 70% yield.⁵² The attempt to oxidise the corresponding selenium derivative with atmospheric oxygen gave only decomposition products; however, when furfural has been used as the oxidising agent, the corresponding phosphoselenoate **131** has been obtained in 50% yield.⁵⁴

X = S (**88a, 91**), Se (**90, 131**).

B-Substituted *o*-carborane-containing esters of thio- and seleno-acids of pentavalent phosphorus **132** can also be obtained in 60%–80% yields by the addition of sulfur or selenium to the corresponding thio- or seleno-derivatives of acids of trivalent phosphorus like **88** and **90**.^{51–54}

Y = S (**88**), Se (**90**).

R	R'	X	Y	Yield of 132 (%)
Ph	Ph	S	S	60
Ph	Ph	Se	S	79

OEt	OEt	Se	Se	69
OBu	OBu	Se	Se	68
OEt	9- <i>o</i> -H ₂ C ₂ B ₁₀ H ₉ S	S	Se	93

The reaction conditions depend on the character of substituents at the phosphorus atom. When there are two ethoxy-groups, the addition of sulfur and selenium occurs at room temperature over a period of 36–40 h. Compounds in which two phenyl groups or two *o*-carboranyl groups are attached to the phosphorus atom react only on heating in benzene. In the case of *O*-ethyl *S,S*-bis(*o*-carboran-9-yl) phosphorodithioite **89**, the addition of selenium yields a product mixture that is difficult to separate.^{51, 55}

Several *B*-substituted esters of thioacids of pentavalent phosphorus **132** have been prepared by the Arbuzov reaction from the corresponding *S*-(*o*-carboran-9-yl) phosphorothioites and MeI or EtI.^{51, 52} The reactions involve only the phosphorus atom. No products resulting from the reaction at the sulfur atom were detected. When *Se*-(*o*-carboran-9-yl) phosphoselenoite was made to react with MeI, no Arbuzov products were isolated.⁵⁴ The reaction gave only non-identified phosphorus-containing compounds and bis(*o*-carboran-9-yl) diselenide. When Me₂SO₄ was used as the alkylating agent in the reaction with *O,O*-diethyl *Se*-(*o*-carboran-9-yl) phosphoselenoite **90**, the Arbuzov reaction product was isolated in 45% yield (see Scheme 1).⁵⁴

Scheme 1

OEt	Me	S	I	62
OEt	Et	S	I	65
OEt	Me	Se	SO ₄ Me	40
9- <i>o</i> -H ₂ C ₂ B ₁₀ H ₉ S	Me	S	I	75

Attempts were made to introduce *S*- and *O*-carboran-9-yl esters of acids of trivalent phosphorus into the Perkow reaction.^{51–53, 55} It was found that *O*-ethyl *S,S*-bis(*o*-carboran-9-yl) phosphorodithioite **89** and *S*-(carboran-9-yl) diphenylphosphinothioite **88b** do not react with chloral, whereas *O,O*-diethyl *S*-(*o*-carboran-9-yl) phosphorodithioite reacts with chloral according to Perkow to give *O*-ethyl *O*-(2,2-dichloroethenyl) *S*-(*o*-carboran-9-yl) phosphothioate **133** in a yield of 65%.^{52, 55} *O,O*-Diethyl *S*-(*o*-carboran-9-yl) phosphothioate **91** was also isolated from the reaction mixture. According to GLC analysis, the mixture also contained trichloroethylene and EtCl. This permitted the researchers to suggest that the process involves intermediate formation of quasi-phosphonium compound **134**.^{52, 55}

The reaction of bis(*o*-carboran-9-yl) diselenide or bis(*m*-carboran-9-yl) disulfide with trimethyl or triethyl phosphite is a convenient method for the preparation of *B*-substituted carboranyl esters of phosphothioic and phosphoselenic acids like **132**.^{74, 75}

R	Y	Yield of 132 (%)
Me	Se	68
Et	Se	72
Et	S	71

In the series of *B*-substituted phosphorus-containing carboranes, synthesis of carborane-containing phosphinimine **135** is noteworthy. This synthesis has been accomplished by the reaction of *m*-carboran-9-yl azide with PPh_3 .⁷⁶

In the series of *C*-substituted derivatives, carborane-containing phosphazenes and polyphosphazenes have been synthesised.^{77–82} The reactions of hexachlorocyclotriphosphazene (HCP) with lithio-*m*-carborane and with *m*-carboranethiol in the presence of Et_3N have been described.⁷⁷

$\text{R} = \text{CB}_{10}\text{H}_{10}\text{CH}$, $\text{X} = \text{Li}$; $\text{R} = \text{SCB}_{10}\text{H}_{10}\text{CH}$, $\text{X} = \text{H}$.

The reaction of 1,2-bis(hydroxymethyl)-*o*-carborane **81** with HCP in the presence of Et_3N has resulted in the formation of spiro-compounds. The number of substituted chlorine atoms depended on the ratio of the reactants.⁸¹

The formation of *ansa-o*-carboranylenecyclotriphosphazene has also been observed.⁸²

Synthesis of carborane-containing polyphosphazenes by the substitution of carborane-containing groups for the chlorine atoms in polychlorophosphazenes (PCP) has been reported. The reaction was accomplished by treating PCP with lithio-derivatives of *o*- and *m*-carboranes or with *m*-carboranethiol.^{77, 79} When 2 or 2.5 moles of *m*-carboranethiol, lithium *o*-carboranymethoxide or lithium *o*-carboranymethylphenoxide per mole of PCP was introduced into this reaction, products of replacement of up to 50% of the chlorine were obtained.⁷⁷

The preparation of polymeric carborane-containing phosphazenes by polymerisation of carboranypentahalodicyclopophosphazene has been patented.⁸⁰

In addition to all the carborane-containing organophosphorus compounds listed above, the first, and still the only, derivative of two-coordinate phosphorus **136** has been described. This compound was synthesised by treatment of *m*-carborane-1-carbonyl chloride with tris(trimethylsilyl)phosphine.⁸³

IV. Potential fields of application of carborane-containing organophosphorus compounds

The potential practical use of carborane derivatives is substantially restricted by their high cost. This is completely true for the carborane-containing organophosphorus compounds. Nevertheless, there are several patents dealing with practical use of these substances. First of all, this refers to carborane-containing phosphazenes and polyphosphazenes, which have been proposed as thermally stable and flame resistant materials and also as additives decreasing inflammability of polymers and paper.^{26, 29, 79, 80}

It has been reported that it is possible to use carborane-containing organophosphorus derivatives as biologically active compounds. In this respect, prospects for using these compounds in the neutron-capture therapy of cancer should be mentioned first.^{84–86}

The pesticide, gametocide and bactericide activities of these derivatives have been assayed.^{50, 55, 87–89}

Anticholine esterase activities of various esters, thioesters and selenoesters of phosphorus acids have been studied. In the case of compounds in which the carboranyl group is directly attached to the phosphorus atom, this activity is weak and is much lower than that of similar phosphorus derivatives devoid of the carboranyl groups.^{50, 87}

For derivatives of thioacids of pentavalent phosphorus in which the carboranyl group is incorporated in the ester moiety, the anticholine esterase activity has been found to be higher than that of the corresponding thioesters without carboranyl group.^{55, 88}

The pesticide properties have been tested most extensively for the 2,2-dichlorovinyl carboranylphosphonates. Weak insectoacaricide and relatively low herbicide and fungicide activities have been found.⁵⁰ These derivatives were also found to exhibit high gametocide activities. Good prospects for using them in the production of hybrid wheat seed were shown.⁵⁰

Some *o*-carboran-9-yl esters of phosphorus thioacids have been found to exhibit bactericide activities.⁸⁹

V. Conclusion

The most interesting aspect of the information given above is the properties of carborane-containing organophosphorus compounds and their comparison with the properties of similar compounds devoid of the carboranyl group.

closo-Dicarbododecaboranes are known to be electron-deficient systems with respect to substituents at the carbon atom, the strongest electron-withdrawing effect being observed in the case of the *ortho*-isomer, whereas the weakest effect being typical of the *para*-isomer. The reactivities of these compounds can also be markedly influenced by steric factors caused by the large size of the carboranyl groups.

The above factors influence most crucially reactions of those carborane-compounds in which the carboranyl group is linked directly to a trivalent phosphorus atom. The nucleophilicity of the phosphorus atom in these compounds is substantially decreased; hence, oxidation, addition of sulfur and azides, the Arbuzov and Perkow reactions, *etc.*, occur under more drastic conditions than those for conventional derivatives of trivalent phosphorus. The influence of steric factors also cannot be neglected; however, it is often difficult to distinguish it from the electronic influence. In some cases, a carboranyl group attached to a phosphorus atom can act as a pseudo-halogen atom in reactions with nucleophilic reagents, which occur with rupture of the phosphorus-carborane carbon bond.

B-Substituted carborane-containing organophosphorus compounds in which the phosphorus atom is connected to the carboranyl group *via* a sulfur or selenium bridge are more reactive than similar *C*-substituted derivatives. This is apparently due to the fact that carboranylthio- or carboranylselenio-groups exert an electron-donating effect, and the nucleophilicity of the phosphorus atom thus increases. In this case, steric factors are less significant than for *C*-substituted compounds.

Abstract. The electrochemical properties of thin films of electroactive materials formed on the surface of an electrode by the Langmuir – Blodgett (LB) technique are reviewed. Great attention has been paid to LB films of the charge-transfer materials which may form electroconductive films. This group includes tetrathiafulvalene, tetracyanoquinodimethane, dithiolate complexes of metals, fullerenes, phthalocyanines, conjugated polymers, *etc.* Also, LB films of other redox materials such as ferrocenes, metal bipyridine complexes, viologens and other electroactive LB films are comprehensively reviewed. Structure – property relationships in the experimental voltammetry of LB films and their agreement with theoretical models are examined. Specially organized structures, formed by the LB technique, for the study of the mechanism of electron transfer are of special attention. Potential applications of electroactive LB films in electrocatalysis, electrochromic displays, information storage devices and molecular electronic devices are envisaged. The bibliography includes 163 references.

I. Introduction

For a description of the Langmuir – Blodgett technique see Refs 1–5. For the electrochemical investigations, the LB films (monolayer or multilayer) are transferred onto the surface of an electrode by the conventional vertical dipping or the horizontal touching technique. Indium – tin oxide coated glass (ITO) or gold evaporated onto different supports are usually used as electrodes. Our primary interest in LB films is associated with the LB films of charge-transfer materials, which can give a mixed valence state upon oxidation or reduction. LB films of these materials can exhibit increased electrical conductivity and they may find an application in the molecular electronics (see reviews^{6–11}). Electrochemical techniques can be considered as a method of synthesis and/or method for converting these materials to the conducting state. Moreover electrochemical methods can perform this conversion in a more controllable manner because the desired level of oxidation or reduction can be achieved by passing a certain

quantity of charge. To comply with the principle of electroneutrality, oxidation or reduction is accompanied by the ingress of counter-ions. It is well known from the chemistry of conducting ion-radical salts^{7,9} that a large variety of cations and anions can be inserted in these crystals during electrochemical growth. Similarly applying electrochemical methods to LB films should yield better control of their properties. However, electrochemical doping found only limited application for LB films compared to the vast use of electrocrystallisation to grow conducting crystals and electropolymerisation to produce conjugated polymers.

The electrochemistry of LB films was reviewed by Facci¹² with emphasis on his own work with ferrocene derivatives. Previously we have also discussed the electrochemistry of LB films.¹³ In this review the field is described in more detail taking into the consideration the reports (including ours) published in the last few years.

Other electroactive LB films can serve as models to study the dependence of electrochemical properties on the film structure and the conditions of the LB transfer, *visé versa*. For example phthalocyanine LB films were investigated for their electrochromic properties, but these materials can be also electroconductive. Other potential applications for the electroactive LB films include the formation of ultrathin modified electrodes with the high density of electroactive sites and molecular organisation, which might find application as sensors, photoelectrochemical and information storage devices. LB films can serve as models for molecular rectifying properties in biological systems, electrocatalysis, study of biological membranes, *etc.*

The LB technique is able to create molecularly organised films, advantageous in the preparation of molecular electronic devices. Molecular organisation can also provide new insight on electron transfer reactions at interfaces. Self-assembly (SA) technique also produces molecularly organised films and can be considered as a complimentary approach. Generally, only one type of surface can be used in this technique (for example Au or Pt for thiols and glass or Si for chlorosilanes). This limitation creates difficulties in measuring the electrical properties. The SA technique is not universal and is often limited to monolayer formation.

II. Langmuir – Blodgett films of the charge-transfer materials

The formation of conducting LB films falls into five main groups of materials based on amphiphilic analogues of the following

Chemical oxidation, usually by I_2 vapour, used to be the general method to convert the films to the mixed-valence conducting state. One of its disadvantages is that in these cases the conducting state is not stable as films loose iodine. Several attempts to use electrochemistry can be found in the literature. The electrochemical oxidation during LB film deposition was performed for a TTT derivative **3**¹⁴ using LiClO_4 subphase and for a mixture of compound **1d** and behenic acid¹⁵ using 0.002 M KI subphase. The mixed-valence state in LB film was observed spectroscopically in the latter case. Direct electrochemical oxidation of TTF LB films during deposition was suggested.¹⁵ Alternatively, one could suggest that I^- oxidation takes place under these conditions and then I_3^- oxidises TTF chemically. This oxidation on a live electrode (as well as post-deposition oxidation) conserves the ordering in the LB film in contrast to I_2 vapour oxidation which yields a disordered structure.¹⁴ Recently we deposited LB layers of Ni complex **5** with tetrabutylammonium cation onto the electrode with a gap of 30–50 μm under constant current.¹⁶ We were the first to report electrical conductivity ($10^{-3} \text{ S cm}^{-1}$) using this approach.

Deposition under constant potential was applied to control the adsorption of malachite green, dissolved in the subphase, into LB films of TCNQ derivative **2b**.¹⁷ The adsorption was assigned to the electrochemical reduction of **2b** and the formation of charge-transfer complex between reduced **2b** and malachite green during LB transfer onto ITO electrodes.

It can be suggested that compact LB films may be oxidised or reduced during the process of electrochemical LB deposition, while a similar electrochemical reaction might be inhibited in the preformed LB films.

Postoxidation of preformed LB films is more widely used. To study the electrochemical properties of LB films voltammetric methods with linear sweep of potential, particularly cyclic voltammetry, are usually employed. The theoretically expected response for the surface electrochemical reaction in this technique is a symmetrical cyclic voltammogram (CV) (without peak separation) and a peak half width of ca. 90 mV for the one electron transfer. The best (closer to theoretically expected) stable CV

Figure 1. CV of LB film of mixture of **1f** and 23% molar icosanoic acid on ITO glass, 0.2 M HClO_4 solution. Potentials vs. SCE; (1) monolayer, (2) 5 layers, $v = 200 \text{ mV s}^{-1}$.

response between LB films of the TTF derivatives **1** was registered for the derivative **1f** (Fig. 1).[†] The deviation from the theoretically expected response is manifested in the peak broadening and peak separation. It should be noted that despite the compact structure (the low molecular area¹⁸), the shape of the CV response for the multilayer film was similar to the response of the monolayer. As expected for the surface electrochemical reaction for both monolayer and multilayer films the peak current was proportional to the scan rate. However, the electroactivity of monolayer films was lower than that calculated from the LB transfer and decreased further in the case of multilayer films (Fig. 1).

It was shown spectroelectrochemically^{19,20} that even compact films of TTF derivatives **1a** and **1b** could be oxidised in aqueous electrolyte forming a mixed-valence state. The study of films of **1a** (molecular area close to 0.2 nm^2 , corresponding to the cross-section of the alkyl chain) by cyclic voltammetry has shown that the redox process is quite slow and the oxidation is controlled by diffusion of electrolyte ions through a highly hydrophobic film.¹⁹ For several layers, CV response was highly distorted due to hindered diffusion of ions. Similar behaviour for the LB films of fullerene derivative **4b**²¹ is shown in Fig. 2. Three diffusion controlled reversible or quasi-reversible reduction steps (Fig. 2a) were observed for monolayer film. The CV response was sug-

[†] L M Goldenberg, R Andreu, M Saviron, A J Moore, J Garin, M R Bryce, M C Petty, unpublished results.

Figure 2. CV of a monolayer film (a) and multilayer (b) of **4b** on ITO glass in 0.1 M Bu_4NPF_6 -acetonitrile. Potentials vs. SCE, $v = 10 \text{ mV s}^{-1}$; (1) 3 layers, (2) 11 layers.

gested to be limited by the ion diffusion through well ordered hydrophobic film. The CV shape became severely distorted for multilayer films (Fig. 2b).[‡]

The study of CV response of LB films of other TTF derivatives **1c**,^e ^{18,22} has shown a large influence of the LB film organisation on the electrochemical properties. Films of **1c** have been formed at quite low surface pressure and were not well organised as shown by IR spectroscopy.²² The films possibly contained a sufficient amount of the defects and short S...S contacts between TTF molecules. As a result CV response was unstable, the oxidation peak was shifted anodically and CV response was not changed in multilayer films (Fig. 3). Unstable CV response with peak splitting was also observed for LB films of material **1e**.¹⁸ The more amphiphilic nature of this material resulted in better film properties. Low electrochemical activity of multilayer films was observed possibly due to a more compact structure.¹⁸ The study of the electroactivity of LB films of a number of TTF derivatives^{23–25} resulted in unstable CV responses, often complicated with additional peaks.

Tiecke and co-workers were able to observe a well developed

Figure 3. CV of LB film of mixture of **1c** and 20 mol.% stearic acid on ITO glass, saturated KCl solution.²² Potentials vs. Ag/AgCl; (a): 5 layers, $v = 50 \text{ mV s}^{-1}$, (b): (1) — monolayer, $v = 25 \text{ mV s}^{-1}$, (2) — second scan.

CV response for the multilayer films of **3**.^{14,26,27} It is remarkable, that very thick films (80 layers) exhibited the undistorted response,²⁸ when the films were deposited in the form of radical-cation salt formed on a subphase containing dodecyl sulfate anions. Radical-cation salt formation led to a 70% increase in the molecular area and, possibly, to the formation of the channels for the ion transport. The presence of ions inside LB films may also facilitate the electrochemical reaction.

Nakamura and co-workers²⁹ measured conductivity up to $10^{-3} \text{ S cm}^{-1}$ for LB films of derivative **2a** (15–51 layers) after electrochemical doping at -0.1 V vs. SCE . CV of these films demonstrated large peak separation (about 0.4 V) and prepeaks. However, CVs were improved after electroactive compound in the films was diluted by methyl arachidate probably due to a decrease of repulsive interaction between electroactive sites as predicted by theory.³⁰

LB films of complexes **5**, deposited by the horizontal lifting method,^{31–41} were doped electrochemically. A conductivity as high as $25\text{--}50 \text{ S cm}^{-1}$ for Au complex with tridecylmethylammonium cation (1:1 mixture with icosanoic acid, 20 layers) and in the range of $3 \times 10^{-4}\text{--}5 \text{ S cm}^{-1}$ for other complexes of Ni and Pd was obtained after the constant current oxidation of the LB films

Figure 4. Conductivity as function of temperature for LB films of Au-complex **5** (1:1 mixture with icosanoic acid, 20 layers, after the electrochemical doping) under 0 (1), 2.7 (2), 7 (3), 9.5 (4), 10.9 (5), 11.1 (6) and 9.8 (7) kbar.⁴¹

in LiClO_4 aqueous electrolyte.^{31,32–37} Quasi-metallic character of the conductivity–temperature dependence^{31,32,34–37} (Fig. 4) and the increase of the conductivity with pressure^{38,41} were registered for Au complex. ESR³³ and thermoelectric power^{35–37} measurements also indicated the metallic nature of the films. Very high electrical conductivity of 140 S cm^{-1} was registered at 51 K and 11 kbar.⁴¹

It was previously shown^{37,40,41} that the conductivity was unstable (3-fold decrease in 3 days) and only freshly prepared films showed the metallic conductivity–temperature dependence. In contrast, low-angle X-ray scattering data and thermoelectric power were stable.⁴⁰ All these high conductivity values were calculated assuming the layer thickness of 3 nm^{31,32,41} despite the AFM study,³⁹ which revealed plate-like crystallites with a height of about 18 nm. The blurring of the outline of the crystallites was clearly seen after the electrochemical oxidation. The morphological change was accompanied by an increase of the d -spacing from 1.9 to 2.7 nm.³⁵ The value of the d -spacing in as-deposited film was ascribed to the interplanar distance of Au complex crystallites as the same value was obtained by X-ray structure analysis of a single crystal.^{35,39} This study has been repeated in more detail later³⁴ and the d -spacing of 1.92 nm for as-deposited samples was confirmed. However, this weak pattern was accompanied by stronger peaks corresponding to the d -spacing of 4.88 and 4.43 nm. The latter values were ascribed to the icosanoic acid matrix (Y type bilayer). After the electrochemical doping, a new peak corresponding to the d -spacing of 3.48 nm appeared. It is unclear how the value of 3.48 nm is correlated to an earlier observed value of 2.7 nm.³⁵ Using molecular structure simulation, it was suggested⁴⁰ that the direction of the longest axis in this complex is almost parallel to the surface of the support. In doped films, molecules of the complex are dimerised along the direction normal to the surface. Molecular resolution with the parallelepiped pattern, specified by $1.06 \times 1.31 \text{ nm}^2$, corresponding to molecular area of complex, was observed in AFM images of the monolayer film.⁴⁰ It should be noted, that in this report, AFM was used only for as-deposited samples and possible formation of crystallites was not discussed.⁴⁰ Experimentally observed molec-

[‡] L M Goldenberg, G Williams, M R Bryce, A P Monkman, M C Petty, A Hirsch, A Soi, unpublished results.

ular area was 0.28 nm^2 (Ref. 35), which suggests the multilayer or crystallite formation on the water surface.

Recently we studied a similar Ni complex **5** with the octadecylpyridinium cation.^{42,43} Both single layer and multilayer films were electroactive with CV peak intensity proportional to the number of layers.⁴³ LB films were built-up under different conditions resulting in an electrical conductivity difference of a few orders of magnitude.⁴² Electrochemistry was found to be useful for determining the difference between these films. The CV response revealed that the same chemical compound was transferred on the solid substrate despite the difference in conducting properties. However, film structure influenced the electroactivity and peak separation (indication of difference in electrochemical kinetics). This suggests that the LB films built-up from the true monolayer (non-conducting films) exhibited slower electrochemical kinetics, because according to schematic structure of the film⁴² the molecules of electroactive complex are buried among the hydrophobic chains and are farther from the electrode surface. Electrochemical doping at constant potential of the LB film deposited onto the interdigitated electrode (Fig. 5) exhibited peak shaped current transient (time dependence of current at constant potential). This may be explained by an increase in the effective electrode area due to nucleation of the conducting phase between the fingers of the interdigitated electrode until the film achieves maximum conducting state. The charge consumed in this process corresponds to roughly half of the material being oxidised and consequently to the mixed-valence state. The conductivity value of up to $3 \times 10^{-2} \text{ S cm}^{-1}$ was registered either with KCl or LiClO_4 electrolytes. The conductivity values and activation energy for these films were similar to ones for the films doped with iodine vapours.^{42,43} It should be noted that lower conductivity for these films compared with Au and Pd complexes, studied by Matsumoto group (see above), can be partially explained by using layer thickness measured by profilometry [about 30 nm (Ref. 42)] to calculate the conductivity value, but not the assumed layer thickness of 3 nm.^{31,32,41}

The similar approach was applied to obtain conductive LB

Figure 5. Current transient after application of a potential step for LB film of Ni complex **5** on interdigitated electrode in 3 M KCl solution.⁴³

films from the mixtures of tetrabutylammonium Ni complex **5** and tricosanoic acid.¹⁶ LB films were oxidised at constant potential or constant current in the different electrolyte solutions. In-plane dc conductivity up to $10^{-2} \text{ S cm}^{-1}$ was registered after the electrochemical doping in different electrolytes or chemical doping by iodine vapours.¹⁶ It should be mentioned that samples, doped electrochemically in LiClO_4 or KI electrolyte or by iodine vapour, were more stable than the samples doped electrochemically in KCl or Bu_4NBr electrolytes. The CV response in all electrolytes studied was similar to the one registered for LB films of the amphiphilic Ni complex.⁴² The reversible rapid changes in the visible spectrum were observed under the application of the potential to the LB films (Fig. 6).

Bard and co-workers^{44–46} studied the electrochemical behaviour of LB films of C_{60} **4a**. The first two reduction waves were

Figure 6. Spectroelectrochemistry upon oxidation of tetrabutylammonium Ni complex **5** (40 mol. % of tricosanoic acid) on ITO electrode, 0.5 M Bu_4NBr aqueous solution.

Potentials vs. Ag wire; (1) open circuit, (2) 1 V, (3) -0.3 V .¹⁶

studied in order to avoid dissolution of films. Most probably these films were not true monolayers. Peak current increased and peak half width decreased with the increase of surface pressure used for film deposition. Peak separation was about 210 mV for lower surface pressure and even at higher surface pressure this value was smaller than that for the cast films.

Photoelectrochemical properties of the LB films of C_{60} **4a** and pyrrolidinium derivatives of C_{60} were investigated.⁴⁷ The highest photocurrent quantum yield was observed for the derivative with an electron-donating *o*- Me_2NPh group attached to the pyrrolidine ring.

In conclusion, the electrochemical methods can be used for the fabrication of conducting LB films of charge-transfer materials. The electrochemical doping can be realised either during LB film transfer using the subphase as an electrolyte or after LB deposition for already fabricated films. As a result, highly ordered conducting films can be obtained and different counter-ions can be introduced into the LB films. However, further investigations are necessary to elucidate the counter-ion – property relationship. It should be emphasised that very high conductivity of 50 S cm^{-1} , with partially metallic temperature dependence of conductivity, has been obtained using electrochemical technique.

III. Conjugated polymers

The use of electrochemistry for conducting polymer LB films has been very limited despite the number of such polymeric films prepared to date (see review⁴⁸). The successful application of the electrochemical polymerisation for LB films of amphiphilic pyrrole **6**^{49–51} is one of the few reported. A short length (several mm) of the electrode covered with LB multilayer film is dipped in $\text{LiClO}_4/\text{acetonitrile}$ electrolyte and a coloured area appears when polymerisation proceeds under an applied potential. Then the covered with polypyrrole part of electrode served as a connecting lead for the rest of the LB film.⁸ Multilayer polypyrrole films obtained by this method had highly anisotropic conductivity ($10^{-1} \text{ S cm}^{-1}$ for the direction parallel to electrode surface and $10^{-11} \text{ S cm}^{-1}$ for the direction normal to electrode surface). Low angle X-ray scattering also showed that the part of polypyrrole film which was not immersed in the electrolyte solution kept a highly ordered structure. Thus, this method allows synthesis of highly ordered polypyrrole films, which are impossible to obtain by electropolymerisation of the monomer in solution.

§ It is important that electropolymerisation could not be carried out in aqueous electrolyte, possibly due to hindered diffusion of the water molecules in hydrophobic multilayer films.

Electrically conducting fine lines of polypyrrole in a matrix of icosanoic acid were fabricated by electrochemical polymerisation during LB film deposition.⁵² Pyrrole and icosanoic acid were spread on a LiClO₄ subphase and transfer onto ITO electrode was performed by application of 10 V between the moving ITO electrode and the Pt counter electrode. The resulting low conductivity of the film ($8 \times 10^{-5} \text{ S cm}^{-1}$) may possibly be ascribed to the fact that the concentration of pyrrole in the matrix is low since most of pyrrole would go into the subphase.

Carotenoids are polyenes and are thus related to the simplest conjugated polymer, polyacetylene. Their importance in photosynthesis and possible involvement as photoreceptors are well known. The photoelectrochemistry of LB films of carotenoid **7** was studied on ITO electrodes.⁵³ For films up to five layers thick, the photocurrent was linear with the number of layers. This suggests that there is efficient charge and possibly energy transport between monolayers.

We studied single layer LB films of polyaniline **8** with a thickness of about 6 nm.⁵⁴

We showed that the use of the LB technique for film formation resulted in the improved electrochemical properties (Fig. 7), comparable with those of the best electrochemically polymerised films (high ratio of first oxidation peak current to plateau current). As expected for the surface electrochemical reaction the

Figure 7. CVs of polyaniline **8** on ITO glass in 1 M HCl, $v = 50 \text{ mV s}^{-1}$.⁵⁴ Potentials vs. Ag/AgCl; (a) dip coated film, (b) spin coated film, (c) spin coated film after storage in water, (d) one layer LB film.

peak current was proportional to the scan rate. CV and spectroscopy have shown that LB films are reversibly oxidised (possibly by oxygen) during transfer onto the electrodes. The study of multilayer assemblies of polyaniline⁵⁵ resulted in broad peak CV which were similar to those observed by us for spin-coated films (Fig. 7⁵⁴). The distortion of the CV was attributed to slow electron transfer. In the light of a report⁵⁶ of very fast redox reaction in polyaniline we believe that hindered ion-diffusion through the thick film, but not slow electrochemical kinetics, is responsible for the observed behaviour. To improve film forming properties LB films were produced from polyaniline doped by amphiphilic acids.⁵⁷ A CV response with low peak/plateau current ratio was registered. The films of some substituted polyanilines^{57–60} exhibited less resolved CVs compared to the parent polyaniline. Three redox steps, accompanied by an electrochromic effect, could be observed for an alkoxy-substituted polyaniline derivative.⁵⁸ A comparison of different film forming techniques (electropolymerisation, spin-coating and LB technique) for poly(*o*-ethoxyaniline) showed that the LB technique was not the best in this case (broad peaks on CV).⁶⁰

A CV response with two broad peaks was observed for poly(*p*-phenylenevinylene) **9** films, which were obtained by vacuum heat treatment of a LB film of the precursor polymer.⁶¹

Recently we studied electrochemical properties of LB films of substituted polythiophene oligomers **10**, **11** and alkoxy-substituted polythiophene **12**.⁶²

R = $-(\text{CH}_2\text{CH}_2\text{O})_6-$ (a), $-(\text{CH}_2)_{10}\text{O}-$ (b)

Oligomers of polythiophene exhibited facile electrochemical behaviour with narrow symmetrical peaks on the CV (Fig. 8). Aggregated films of polythiophene **12**, transferred under special conditions, demonstrated molecular recognition of alkali metal cations (the anodic shift of peak potential upon the addition of metal ions), similar to cast films (Fig. 9).[†]

LB films of oligoimides (**13a–d**) closely related to conducting polymers have been obtained by Miller *et al.*^{63, 64}

[†]L M Goldenberg, M Leclerc, M C Petty, unpublished results.

13d: B-A-B-A-B-A-B-A-B-A-B,

These imides are able to form *p*-dimers in solution and stacks in electroprecipitated conducting films. The CV of film **13b** shows a reduction peak and two reoxidation peaks (Fig. 10).⁶³ The films were fully electroactive up to at least 8 layers. Peak current was proportional to scan rate. Even the cathodic peak half width (70–120 mV depending on compound) was rather close to the theoretically expected value (90 mV) for a one-electron surface reaction. Grazing angle IR spectra have shown that the oligomer molecules were oriented with the long axis roughly parallel to electrode surface (tilt angle $\sim 15^\circ$), but after electrochemical cycling the tilt angle increases to $\sim 35^\circ$. That is similar to the value in isotropically oriented evaporated films and thus electrochemical cycling disrupts the original organisation⁶³ in contrast to the films of **3**¹⁴ and polypyrrole **6**.⁴⁹ The doubling of the reoxidation peak and large peak separation can be explained by thermodynamic stabilisation of the radical-anion in the LB films due to possible formation of dimers or stacks, which oligoimides form in solution.⁶⁴ It can also be explained by sufficiently negative interaction energy in a theoretical model.³⁰ That suggests that reduced LB films of **3a–d** could be anisotropic conductors.

Compound **13a** was studied in three possible forms: LB films, an evaporated film and an SA monolayer⁶³ (Fig. 10 for SA and LB films). The cathodic peak was broader in the evaporated film compared to LB film and SA film. The SA film exhibits only one reoxidation peak, which suggests that interactions between molecules are weaker.

Thus, LB technique allows to fabricate high quality conjugated polymer electrodes. Conducting films with the high

Figure 10. CVs of **13a** films.⁶³

Potentials vs. SCE; (a) SA film at 100 (1), 200 (2) and 500 (3) mV s⁻¹ in 0.1 M Ph₄NBF₄-DMF, (b) 6 layers LB film at 20 (1), 50 (2), 100 (3) and 200 (4) mV s⁻¹ in 0.1 M aqueous BaCl₂.

anisotropy of the electrical conductivity were obtained. Electro-polymerisation on the water surface in an LB trough during the film transfer is of interest. Many of conjugated polymers are used for the fabrication of light emitting diodes. Electrochemical light emitting cells can possess the improved characteristics compared to the conventional light emitting diodes. Recently, LB films of conjugated polymers were employed as emitting layers of the light emitting diodes. The electrochemical properties of the films should be further investigated in order to use them in electrochemical light emitting cells.

IV. Coordination compounds

1. Phthalocyanines and related compounds

The main interest in the electrochemical properties of the phthalocyanines (Pc, **14**)

has been related to their electrochromic properties. The LB technique was used as an alternative method to casting for the fabrication of electrochromic films. Electrochromic properties were first reported for LB films of unsubstituted monophthalocyanine;⁶⁵ CV with broad peaks corresponding to a transition from green to red form under oxidation and to purple form under reduction was registered. The detailed paper reported the electrochemical study of alkyloxy-substituted diphtalocyanine Lu⁶⁶ and LB films showed a one-electron reversible oxidation and a one-electron reversible reduction corresponding to a transition from green to orange and blue forms, respectively. The CV response of multilayers was not distorted and well defined peaks were observed. The electroactivity of films under oxidation

corresponds only to 30%–50% of the amount of the deposited material and peak currents are neither proportional to scan rate nor to square root of scan rate. The CV for this compound shows a distinctive diffusion tail. Peak separation was highly dependent on the anion of the electrolyte. Thus, the electrochemical response was at least partially controlled by the diffusion of counter-ions.

The electrochemical properties of a variety of phthalocyanine LB films have been studied.^{65–82} YPc₂ LB films,⁷⁵ mixed with icosanoic acid, showed well developed CV response with peak current proportional to the scan rate. In contrast to the evaporated or cast films, the CV response for LB films was stable upon potential cycling. Three distinct colours (blue, green and red) were observed within the potential range of 1 V. LB films of PrPc₂⁷⁹ also showed better resolved and stable CV response compared to the cast films. Four colour changes were attained and the absorbance decreased by only 35% after 10⁵ electrochromic cycles.

The electrochemical properties of the LB films formed by Cu and Ni monophthalocyanine substituted with short branched chains were studied.⁸¹ Three surface confined redox transitions (electroactivity of about 30%) were observed in acetonitrile solution; electrochromic effect was noted in a 51 layer film. However, the electrochromic response was not stable, particularly in thicker films, due to desorption of the LB film upon potential cycling.

The multilayer assemblies of asymmetrical tetraphenyl substituted LuPc₂ exhibited two or three redox steps,⁸⁰ accompanied by colour changes from blue to green and from blue to red. The spectral peaks were better resolved and the electrochromism was more stable in the LB films than in the cast films.⁸⁰

The first example of phthalocyanine LB films, in which phthalocyanine molecules were not aggregated, has been studied by Lever and co-workers.⁷⁸ Fe bears two long-chain ligands in FePc and these ligands prevent aggregation.⁷⁸ The bilayer film was not electroactive in an aqueous electrolyte. This may be due to blocking of the counterion diffusion by the long chains.⁷⁸ In contrast, well developed electrochemical response was observed for the randomly oriented cast film, indicating a high level of organisation in the LB films. The same group⁷⁷ reported on the assembly of LB films of a new phthalocyanine derivative **15**. A surface electrochemical reaction response with broad peaks was observed at low scan rate for a 10 layer LB film of this amphiphilic Pc.

Recently Wegner and co-workers⁷⁶ reported on the CV and spectroelectrochemical characterisation of highly ordered LB multilayers of 'hairy-rod' polyphthalocyaninosiloxanes **16**. The films showed notable stability in aqueous and nonaqueous electrolytes. Up to 100% one-electron oxidation per phthalocyanine ring was achieved at 1 V vs. Ag/AgCl.

R¹ = Me, R² = C₈H₁₇, C₆H₁₂CH = CH₂

Some of the phthalocyanine LB films showed CVs with peak intensity proportional to the square root of scan rate whose shapes were rather close to a diffusion controlled wave.^{72, 74} In general, we can state that electrochemistry in Pc LB films is quite facile. Multilayer films can be easily oxidised and reduced and improved electrochemical properties were observed compared to cast films in some cases.^{69, 70, 75} An explanation of relatively facile redox reaction in multilayers is that the phthalocyanine ring is large compared to the alkyl tail projected area and thus even in the solid condensed state enough empty space and channels can be present in LB films to allow ion transport.

Electrochromic devices based on LB films exhibit low response time and improved stability upon potential cycling. Bearing in mind that chemical oxidation can be used for the doping to create electroconducting materials (see review¹⁰) and the quite facile electrochemistry of these films, electrochemical techniques can be used for producing electroconducting phthalocyanine LB films.

Porphyrin derivatives were studied with an eye to their biological properties as compounds providing electron transfer in such important biological processes as photosynthesis.

Cytochrome *c* was incorporated in an LB film of phospholipid to prevent denaturation on the electrode surface.⁸³ CV was simulated according to the surface reaction model to yield an estimate of the first-order rate constant of 2 s⁻¹. Such a small value of the rate constant was explained by either a large separation of redox centres from the electrode or nonoptimised orientation of cytochrome *c*.

LB films of Ru hematoporphyrin **17** were studied by CV.⁸⁴

Laviron⁸⁵ presented the theoretical treatment for a surface electrochemical reaction in multilayer modified electrodes. Daifuku *et al.*⁸⁶ extended this treatment to a monolayer. Ueyama *et al.*⁸⁴ suggested a model for Z-type multilayer LB films (when the electroactive heads in all the layers are oriented in the electrode direction). Films were transferred in a solid condensed state with molecular area of 0.83 nm². Even at slow scan rates the peak separation for CVs in the monolayer was 90 mV, which was attributed to rearrangement of porphyrin rings during the redox reaction.⁸⁴ The plots of peak potential vs. ln of scan rate were

linear, starting from about 10 V s^{-1} (irreversible electrochemical reaction), and slopes of these plots gave values of the transfer coefficient of 0.32 and 0.42 for anodic and cathodic reactions respectively. First-order rate constants of 51.1 and 21.1 s^{-1} were obtained for the cathodic and anodic reactions respectively. The simulated and experimental voltammograms for the cathodic wave were not in good agreement, indicating some deviation from the Daifuku model. Two- and three-layer Z-type LB films exhibited complete electroactivity. The peak separation and peak half width increased with an increase of the scan rate. The charge, consumed upon electrochemical cycling, was constant at relatively low scan rates and decreased at high scan rates. This suggests that not all porphyrin rings participated in the electrochemical reaction at higher scan rates. Comparison of experimental and simulated voltammograms⁸⁴ yielded a pseudo-first-order rate constant for interlayer electron transfer of 256 and 128 s^{-1} (and the electron diffusion coefficient of 1.6×10^{-11} and $0.8 \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$) for anodic and cathodic reactions respectively. At higher scan rates (above 12.8 V s^{-1}) disagreement was observed between simulated and experimental voltammograms, which was attributed to slow counter ion transport. In our opinion even the CV at slow scan rate reveals some diffusional tailing.

Thus, LB films of porphyrins can be a good experimental model for the development of a theory of surface electrochemical reaction.

2. Ferrocene derivatives

Bilewicz and Majda incorporated BuFc **18c** in a passivating $\text{C}_{18}\text{H}_{37}\text{SH}/\text{C}_{18}\text{H}_{37}\text{OH}$ mixed monolayer on a gold electrode⁸⁷ and showed that Fc in the matrix was entirely electroactive.

- 18a:** $\text{R}^1 = \text{R}^2 = \text{CONHC}_{18}\text{H}_{37}$;
18b: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{CONHC}_{18}\text{H}_{37}$;
18c: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Bu}$;
18d: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{CH}_2^+\text{NMe}_2\text{C}_{18}\text{H}_{37}$;
18e: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{C}_{15}\text{H}_{30}\text{COOH}$;
18f: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{COCH}_2\text{CH}_2\text{COFc}$ ($\text{Fc} = \text{C}_5\text{H}_5\text{FeC}_5\text{H}_4$);
18g: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{C}(\text{O})\text{OCH}_2\text{CH}_2\text{S}-\text{TTF}$;
18h: $\text{R}^1 = \text{R}^2 = \text{C}(\text{O})\text{OCH}_2\text{CH}_2\text{S}-\text{TTF}$.

A well developed CV with high peak separation about 0.4 V (possibly due to IR drop) was obtained for a densely packed (mean molecular area 0.26 nm^2) eleven layer LB film of an amphiphilic Fc derivative **18b**.⁸⁸

For the Fc derivative **18d** it was shown that the surface pressure used for LB film deposition (and consequently the packing density) did not influence the electrochemical properties.⁸⁹ The CV response corresponded to the surface reaction model with a low peak separation (20–30 mV) and a peak current proportional to the scan rate. An electroactivity fraction of around 55%–80% was observed. Possible reasons for such behaviour could be partial monolayer dissolution, incomplete physical contact of Fc sites with the electrode, reorientation of the film after immersion in the electrolyte solution, hindering of counter ion transport by hydrophobic tails and uncertainty in charge calculation due to high background current. The highest electroactivity (about 80%) was obtained for a surface pressure of 22 mN m^{-1} (mean molecular area 0.37 nm^2). The formal potential for LB film was 0.14 V more positive than for the soluble Fc analogue. It was interpreted as the Fc moiety being more strongly adsorbed to the gold surface than the ferrocenium moiety and the surface wave may be regarded as an adsorption postwave. An SA monolayer of the same compound showed much narrower peaks

Figure 11. CVs of **18d** monolayer in 1 M H_2SO_4 . Potentials vs. SSCE; (1) LB monolayer on Au electrode, (2) SA on Pt/I electrode.⁸⁹

(Fig. 11). Broadness of CVs for LB monolayers have been attributed to repulsive intermolecular interaction according to theory.⁹⁰

There is a wide variation ($0.2\text{--}0.55 \text{ nm}^2$) for reported molecular areas for amphiphilic Fc compounds.⁹¹ The cross-sections of the Fc moiety were determined using molecular modelling to be around 0.5 nm^2 .^{12,91} This value should determine the limiting molecular area for a true monolayer. The staggering of Fc heads is usually suggested¹² in the cases when lower values ($0.2\text{--}0.3 \text{ nm}^2$) have been registered.

Recently we investigated cyanovinyl Fc derivatives **19**:⁹²

$\text{R} = \text{NHC}_{16}\text{H}_{33}$ (**a**), $\text{OC}_{18}\text{H}_{37}$ (**b**), O-cholesteryl (**c**).

The change of the surface pressure–molecular area isotherm with the time that the Langmuir layer was left on the subphase surface before compression is shown in Fig. 12. The monolayer organisation undergoes change from the staggering of Fc heads to the true monolayer. This process can be monitored electrochemi-

Figure 12. The change of surface pressure vs. area per molecule isotherm for compound **19a** with time, monolayer was left on the subphase surface before compression (*a*) and a plot of anodic peak current vs. molecular area at the dipping pressure (35 mN m^{-1}) for monolayers transferred onto ITO electrode after the floating film was left on the subphase surface for different lengths of time before compression (*b*); min: (1) 10; (2) 20; (3) 35; (4) 120.⁹²

Figure 13. CVs illustrating the catalytic oxidation of Fe^{2+} by monolayer of **21a** on SnO_2 electrode in 0.18 M H_2SO_4 . Potentials vs. SCE; $v = 111 \text{ mV s}^{-1}$; (1) LB monolayer, (2) the same with 0.1 M Fe^{2+} , (3) bare SnO_2 electrode with Fe^{2+} .⁹⁵

Electroactive coverage was constant, corresponding to a limiting molecular area in the isotherm surface pressure *vs.* molecular area. An elegant experiment has shown that the monolayer was expanded to the limiting molecular area (owing to repulsive interaction between surfactant molecules) after reimmersion in electrolyte solution. An ITO electrode with a monolayer of **21c** deposited on one half was immersed in electrolyte solution, then dried and another part, where monolayer was not deposited, reimmersed. This part of electrode showed a CV response for the Ru complex. Only the inner monolayer was electroactive in the 2- and 3-layer Y-type LB films. However, a Z-type multilayer, deposited by horizontal lifting technique, showed a CV response which increased with the number of layers.⁹⁹

Thus, LB films of metal complexes (Fc, *etc.*) serve as a good model for the study of the relationship between film transfer conditions and electrochemical properties and for the development of a theory of the surface electrochemical reaction.

V. Miscellaneous materials

Amphiphilic quinone derivatives, coenzyme Q **22** and vitamin K₁ **23**, can be incorporated at a low concentration in a mixed C₁₈H₃₇SH/C₁₈H₃₇OH monolayer.^{87, 100, 101}

These quinone derivatives show complete electroactivity with a nice surface wave response and low capacitive background due to the densely packed C₁₈H₃₇SH/C₁₈H₃₇OH monolayer, enabling low quinone concentrations in the monolayer to be detected. At the surface concentration of **22** below 10⁻¹⁵ mol cm⁻² electrochemistry at single molecule 'gate sites' has been registered.¹⁰¹ These monolayers behave as an array of individually addressed 1 nm diameter disc microelectrodes. An apparent heterogeneous rate constant for the solution redox probe Ru(NH₃)₆^{3+/2+} as high as 80 cm s⁻¹ was calculated. Similarly, high values of the rate constant were obtained only using nanodes (microelectrodes of nm dimensions).¹⁰² This fact proves that ubiquinone molecules in the monolayer film behave as nanodes.

The mediated electroreduction of Ru(NH₃)₆³⁺ and electron tunnelling through ubiquinone were ruled out and a plausible mechanism, where loose conformation of isoprenoid chain in ubiquinone created a channel in LB film, that allows for a direct approach of Ru(NH₃)₆³⁺ ions to the electrode surface, was suggested. An additional confirmation of this hypothesis was found in the dependence of ubiquinone electroactivity on the cation size (Fig. 14). Obviously, the electroactivity of ubiquinone is severely hindered, when only a sufficiently large cation (tetra-butylammonium) is available in solution.

The kinetics (rate constant 80 s⁻¹)¹⁰⁰ has been obtained from CV according to the Laviron theory¹⁰³ and modified theory of Daifuku *et al.*⁸⁶ Compound **22** was also transferred onto a Au electrode by the LB technique¹⁰⁴ and the film exhibited a reversible two electron surface reaction in 0.1 M NaOH. The kinetics were slower at the lower pH. It is noteworthy that the electroactivity of the monolayer is complete and the CV response is symmetrical.

Figure 14. CV of ubiquinone **22** immobilised (1.5 mol.%) in a monolayer of C₁₈H₃₇SH/C₁₈H₃₇OH on a gold surface (a) and schematic representation of monolayer (b).¹⁰¹ Potentials *vs.* SCE: (1) 0.4 M Bu₄NOH; (2) 0.4 M Bu₄NOH + 0.02 M K₂SO₄; (3) 0.4 M Bu₄NOH + 1 M K₂SO₄, $\nu = 50$ mV s⁻¹.

The study of monolayers with the amphiphilic nitroxyl radical **24**¹⁰⁵ has shown that both pure monolayers and monolayers highly diluted with icosanoic acid show a defined 'break-in' effect, where electroactivity increases to a maximum upon voltammetric cycling (Fig. 15).

Both monolayers show responses with peak current proportional to scan rate, but high peak separations (100 mV) and peak half widths greater than theoretically expected 90 mV. Monolayers of pure material show a less symmetric CV response and two peaks were observed for oxidation, which can be explained by interaction between electroactive sites. More difficult to explain is the dependence of the 'break-in' effect on supporting electrolyte concentration, namely that at higher electrolyte concentration more cycles were necessary to achieve the maximum wave. It was suggested¹⁰⁵ that this phenomenon is similar to the 'salting-out effect' at the interface of aqueous solution and a hydrophobic monolayer.

Figure 15. CV of a monolayer film of mixture of **24** and icosanoic acid (1 : 2), 0.18 M H₂SO₄, $\nu = 100$ mV s⁻¹, potentials *vs.* SCE.¹⁰⁵

Using a phospholipid with attached electroactive anthraquinone moieties **25** authors¹⁰⁶ studied the influence of deposition surface pressure, composition of LB layer, nature of supporting electrolyte and the number of layers.

When the monolayers were transferred as a liquid expanded phase a surface wave response was observed and the best shape was observed in the 1:1 mixture with dipalmitoylphosphatidylcholine (Fig. 16a). Electroactivity of the films was complete, but the peak half width was considerably higher (80 and 120 mV) than predicted for a two electron surface wave (45 mV). Film transfer in the solid condensed state results in incomplete reoxidation and a postwave after the main reduction peak. This effect was increased in KCl electrolyte (Fig. 16b). Only the inner monolayer was electroactive in Y-type three layer films consisting of either the same molecules or two nonelectroactive layers. This signifies that the two outer monolayers inhibited charge transfer to the inner monolayer (Fig. 16c). All these observations were consistent with hindered ion transport through LB films. The SA films of the same compound **25**¹⁰⁷ showed low peak separation in KCl solution. However, peak splitting appeared upon potential cycling.

Flavin is one of the typical prosthetic groups of electron transfer proteins. Ueyama and co-workers¹⁰⁸ studied a flavin (**26a**) LB monolayer on a gold electrode.

A surfactant molecule was deposited in the solid condensed state with mean molecular area 0.47 nm². Peak half widths in voltammograms were much larger than the theoretical value and

26a: R¹ = Me, R² = R³ = C₉H₁₉;

26b: R¹ = CH₂SCH₂CO₂H, R² = R³ = C₉H₁₉.

the shape of the response was of a diffusion-controlled type. The dependence on scan rate of peak current was also closer to diffusion controlled behaviour than to surface reaction. Thus a first-order rate constant according to the surface reaction model (about 1.5 s⁻¹)⁸⁶ does not have much validity. In addition electroactivity of the film was not complete even at slow scan rates. Another amphiphilic flavin molecule **26b**¹⁰⁹ showed a better surface wave response for a monolayer film possibly due to higher mean molecular area and consequently more facile ion diffusion.

Bard and co-workers¹¹⁰ studied amphiphilic viologen **27b** in the form of LB and SA monolayers.

27a: R¹ = Et, R² = CH₂CH₂CON(C₁₈H₃₇)₂;

27b: R¹ = Me, R² = C₁₆H₃₃;

27c: R¹ = Et, R² = C₅H₁₀OPhNNPhOC₁₂H₂₅;

27d: R¹ = Me, R² = C₂₂H₄₅;

27e: R¹ = R² = C₁₆H₃₃;

27f: R¹ = R² = C₁₈H₃₇;

27g: R¹ = R² = C₂₂H₄₅.

Figure 16. CVs of monolayer of **25**.¹⁰⁶

Potentials vs. SSCE; (a) in 0.2 M NaClO₄, 50 mV s⁻¹, transferred at 25 mN m⁻¹, molar contents of **25** in monolayer 0.1 (A), 0.5 (B), 1.0 (C); (b) in 0.2 M KCl, $v = 200$ mV s⁻¹, transferred at 40 mN m⁻¹ (A), 31 mN m⁻¹ (B), 25 mN m⁻¹ (C), 15 mN m⁻¹ (D); (c) in 0.2 M KCl, 200 mV s⁻¹, transferred at 25 mN m⁻¹: (A) Y type 3 layer, (B) monolayer of **25**, covered with 2 layers of nonelectroactive surfactant.

The LB monolayers with mean molecular area 0.40 nm² were completely electroactive. Two definitive reduction and oxidation peaks were observed (Fig. 17), which is in agreement with the theoretical model in the case of sufficiently negative interaction energy.³⁰ In contrast, a SA monolayer, which was not as closely packed as the LB monolayer and had more random orientation of molecules, showed only a single peak. In simple chemical terms strong pairing of the dication with the radical-cation results in the mixed valence state exhibiting a different reduction potential compared to the parent dication state. A similar explanation can apply to prepeak observations in LB films of derivative **1c**,²² whose parent compound BEDT–TTF is well known for a strong intermolecular interactions in a mixed valence state, in **2b** LB films,²⁹ and with oligoimides **13**.^{63, 64}

Figure 17. CVs of **27b** monolayer LB films on ITO electrode in 0.2 M NaClO₄.¹¹⁰

Potentials vs. SSCE, scan rate (mV s⁻¹): 100 (1), 200 (2), 500 (3).

The same group studied amphiphilic viologen **27d**, which forms much denser films (molecular area about 0.2 nm²) and demonstrates more stable electrochemical properties.¹¹¹ Better developed splitting of the first reduction peak was observed for these films.¹¹⁰ However, when viologen was sufficiently diluted with icosanoic acid, the monolayer showed only single peaks in CV indicating the absence of the interaction between viologen sites.

For comparison, LB monolayers formed by symmetrical viologen amphiphiles **27e–g** were studied.¹¹² Only single redox peaks were observed. The films were loosely packed as was deduced from the higher molecular area, the contact angle measurements and electrochemical experiments with solution redox probes.¹¹² Thus, the loose structure and, consequently, smaller possibility for intermolecular interactions can account for the single peak behaviour. The reduction potentials for the surface confined viologen in all LB films studied^{110–112} were more positive than for the viologen in solution. This was attributed to the stabilisation of the radical-cation form compared to the dication form in the LB films due to the more hydrophobic environment. The effect is probably similar to the one observed for SA monolayers of Fc substituted thiols on Au.¹¹³

The reduction peak splitting for asymmetrical viologen **27b** depends on the nature of electrolyte.¹¹⁴ The peak splitting was also observed in the response of SA monolayers. However, only CV of LB monolayers with bulky anions displayed double peaks.

Fujihiro and co-workers¹¹⁵ reported on LB films of polyimides **28**. The films were obtained by the thermal chemical reaction of an LB film of the precursor polymer.

A facile electrochemical reaction involving two reduction steps was observed. The electroactivity of the film was proportional to the number of layers (at least up to 30 layers). Unfortunately, the electroactivity decreased upon potential cycling.

The electrochemical technique has been used for detecting methylene green (a water soluble dye) in the LB films, transferred from a mixed monolayer of a phospholipid.¹¹⁶

The study of photosensitised electron injection in xanthene dyes, immobilised into LB films of Cd icosanoate, has been reported.¹¹⁷ The dependencies of current on potential without and with illumination by light of different wavelength (photo-current spectroscopy) were investigated. Similar studies have been done for LB films of halobacterial violet,¹¹⁸ where the effective photocurrent depended on the pH and potential. It was suggested that this phenomenon could be used in the fabrication of a luminance sensor. The photochemistry of the xanthene dyes, immobilised into LB films and deposited onto anthracene crystal, was also investigated.¹¹⁹

The electrochemical properties of LB films of bacterial photosynthetic membranes were also reported.¹²⁰

LB films discussed in this chapter are interesting objects for the study of surface electrochemical reactions, influence of the conditions of LB film transfer on the electrochemical properties of the coated electrodes and modelling of the properties of biological membranes.

VI. Heterolayers

It was suggested^{121–123} that the positively charged viologen amphiphile **27c** forms bilayers with negatively charged poly(1-sulfatoethylene) and other polyelectrolytes. The electroactivity of the films increased with the number of layers, but was not proportional to this number, which means that in a multilayer assembly electrochemistry became more difficult.¹²¹ Peak current

became proportional to the square root of the scan rate for films of more than five bilayers which indicates that electrochemistry is limited by diffusion of ions through the LB film.^{121, 122} Reduction in the first cycle needed higher overpotential and a stable voltammogram was established after a few scans.¹²¹ Quartz crystal microbalance studies indicate ion transport and morphological changes in the films during the electrochemical process.¹²¹ It was also found that the reduction potential for the viologen **27c** is strongly affected by the structure of polyion. The smaller the molecular area of the complex at low surface pressure the lower the reduction potential.¹²² Thus, more compact films required a higher overpotential. For LB films formed with polyacrylic acid¹²³ the reduction potential was found to depend on the pH of the subphase during LB transfer and the pH of the electrolyte in the CV experiment.

Fujihiro and Araki studied a different assembly of LB layer comprised of anthraquinone **29**, viologen **27a** and ferrocene **18a**.^{124, 125}

Multilayers were constructed from an inactive layer of icosanoic acid and electroactive mixed layers (electroactive surfactant + icosanoic acid). All types of anthraquinone-containing multilayer assemblies were electroactive and the proposed mediator for electron transfer through inactive icosanoic acid layers were either electroactive surfactant molecules penetrating through these layers (which seems quite impossible) or traces of oxygen.¹²⁵ The authors estimated a first-order surface reaction rate constant, from peak separations, decreasing with increasing number of inactive layer of icosanoic acid. It seems that electroactivity, as shown by CV,¹²⁵ is at least an order of magnitude smaller relative to the amount of deposited materials. In some cases CV response was not higher than the background current.¹²⁵

On reduction of viologen to its neutral state a gradual decrease of peak current was observed until the redox response completely disappeared. This indicates that the viologen surfactant forms a compact hydrophobic structure in the neutral state, so that reoxidation is blocked owing to hindered diffusion of counterions. For the Fc containing multilayer assembly **18a** no peaks of Fc oxidation were seen. A possible explanation of this fact may be found from a study of a viologen multilayer assembly as Fc containing multilayers are neutral. Facci¹² observed blocking of electron transfer from a Fc monolayer divided by one layer of Cd stearate spacer. A more complicated structure **29**/icosanoic acid/**27a** was then constructed.¹²⁵ This assembly showed anthraquinone reduction and a first viologen reduction. However, if the potential was held at –1.5 V to reduce the viologen layer to the neutral state, the compact viologen layer hindered the reduction of the inner anthraquinone layer. Electroactivity could be recovered at least partially by reoxidation of the film for 5 min at 0 V.¹²⁵

Ueyama and co-workers¹⁰⁸ studied heterojunction multilayers constructed from amphiphilic flavin **26a** and Ru porphyrin **17**. The theoretical model previously developed for multilayers of one compound¹²⁶ was extended to the heterojunction of two monolayers.¹⁰⁸ CVs for flavin, Ru porphyrin and a heterojunction between them are shown in Fig. 18. The shape of the CVs show general agreement with simulated ones. The common features are as follows:

1. Peak potential in the first sweep is similar to Ru porphyrin and no peaks are observed near the flavin peak potential.
2. Anodic peak current in the first sweep is higher than in the subsequent one and charge consumed under the peak corresponds to the sum of the oxidation for flavin and porphyrin.
3. Charge in the second sweep corresponds only to porphyrin oxidation.

Figure 18. CVs for monolayers of **17**, **26a** (a) and Z heterolayer (3 layers of **17** + 1 layer of **26a**) (b, c) electrodes in 0.1 M NaClO₄.¹⁰⁸ Potentials vs. Ag/AgCl; (a) $v = 0.05 \text{ V s}^{-1}$, solid line — **26a**, dashed line — **17**; (b) $v = 0.05 \text{ V s}^{-1}$; (c) $v = 0.8 \text{ V s}^{-1}$; indicated numbers of cycle.

Theoretically this corresponds to the case where electron transfer in one direction from reduced flavin to oxidised porphyrin is much faster than in the opposite direction. Using simulated and experimental CV the electron transfer diffusion coefficient was estimated as $1.9 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$ for the favoured direction and $1.5 \times 10^{-14} \text{ cm}^2 \text{ s}^{-1}$ for the opposite direction. Pseudo-first-order rate constants were estimated as 64 s^{-1} and $\leq 0.25 \text{ s}^{-1}$, respectively.

A bilayer of flavolipid **30** — cytochrome *c* showed similar behaviour.¹²⁷

In this case electron transfer was much faster from flavolipid to cytochrome.

The electrochemical response of the LB heterolayer, consisting of 3 layers of Ru complex copolymer **31**⁹⁴ with an oxidation potential of 1 V vs. SCE and 2 layers of Fc co-polymer **20b** with an oxidation potential of 0.35 V vs. SCE, is shown in Fig. 19.

In the first cycle, no oxidation current was observed at the Fc redox potential of 0.35 V, because Fc could only be oxidised through the reduced inner layer of Ru complex co-polymer **31**. Fc oxidation appears as a sharp catalytic current at the potential, where Ru(II) is oxidised. Upon repeated cycling, only the redox

Figure 19. CVs of the LB films of co-polymers on ITO electrode. Potentials vs. SCE, in 0.1 M NaClO₄, $v = 10 \text{ mV s}^{-1}$; (1) 3 layers of copolymer **20b**; (2) 3 layers of copolymer **20b** + 2 layers of copolymer **31**, first cycle; (3) the same, second cycle.⁹⁴

peaks for the Ru(II)/Ru(III) couple are observed as ferricinium can not be reduced, and the charge is trapped in the outer Fc polymer layers.

It has been suggested earlier¹²⁸ that vectorial electron transfer might be obtained, if redox moieties can be placed in a potential gradient along the polymer chain. This idea has partly been substantiated^{129,130} using two differently substituted *p*-benzoquinone species or *p*-benzoquinone and bipyridyl species immobilised on Au surface by the SA technique. Recently, we suggested a novel approach to this idea by LB technique⁹¹ using multiredox centre molecules **18f–h**. For this, redox molecules **18f–h** were incorporated into an LB array of fatty acid. Direct confirmations of uni-directional electron transfer were not obtained, but electrochemical response of LB arrays differed considerably from that of the randomly oriented cast films suggesting a certain degree of organisation in the LB films. Fig. 20 shows the difference in the CV response for the LB and cast films of the compound **18g**. It is notable that only one peak appears in the LB film of **18g** mixed with fatty acid. An orientation of **18g** with the Fc moiety closer to the electrode surface than the TTF group seems likely.⁹¹ Compound **18f** contains two equivalent Fc redox centres. The experimental observation of the two peaks in CV for the LB films of **18f** mixed with fatty acids led to the conclusion of the ordering of **18f** molecules in an LB array, where two Fc moieties are at a different distance from the electrode surface, and consequently, in a different environment.⁹¹ The peak splitting due to intermolecular interaction³⁰ was ruled out as the dilution of the LB films with fatty acid did not lead to the disappearance of double peaks.

Recently, LB films of amphiphilic diad molecule **32** have been studied.¹³¹

Such porphyrin diads are of interest for modelling of an electron transfer in biological systems. It was shown¹³¹ that a magnetic field in any direction increases the anodic photocurrent at 0 V vs. Ag/AgCl and that electron transfer from the porphyrin onto the electrode is mediated by viologen.

Different bilayer assemblies, containing amphiphile **18d** were studied to understand the possibility of long-range electron transfer.¹² In contrast to the results of Fujihira *et al.*^{124,125} less defective

films of Cd stearate were employed in this work. When one monolayer of a spacer, cadmium stearate, was deposited between Au and the **18d** monolayer, electron transfer was completely blocked (a distance of about 2.5 nm from the electrode). For a bilayer of a mixture of **18d** and Cd stearate, where the electroactive head of the first layer was oriented away from the gold and adjacent to the electroactive head of the second layer, a CV response was observed, but electroactivity was not higher than 10% and an additional reduction peak appeared. If the second layer in such a bilayer consists only of cadmium stearate electroactivity increased to 60%, which signifies that only the inner layer is electroactive. However, in this case both anodic and cathodic peaks were split. Broadening and splitting of the peaks was explained accordingly.³⁰ Other possible explanations include different Fc environments or geometric arrangements.

In more recent reports^{132, 133} the electron transfer at smaller distances was probed. A SA layer of alkanethiol on gold was employed as a spacer to determine the distance for the long range electron transfer. The advantage is that SA monolayers of alkanethiols on gold have smaller defect concentrations than LB films. The electrochemistry of SA monolayer with attached electroactive groups was investigated in several reports.^{134, 135} However, in this case electron transfer could occur through a bond in the alkyl chain. In the case when the LB layer of the amphiphile **18e**¹³³ was deposited on the top of the SA spacer, only through-space electron tunnelling is possible. Preliminary studies with a monolayer of decanethiol¹³² have shown that electrochemistry of **18e** was affected by the composition of the subphase, which was also used as the electrolyte for voltammetry, and the conditions of the film transfer. Two redox couples (0.22 and 0.4 V vs. SCE) were observed for pure **18e** on the 0.1 M NaClO₄ subphase. The diffusion of **18e** to defect sites in the SA monolayer was ruled out as thiol monolayer completely blocked electrochemical reaction of hexacyanoferrate(III) in solution. It was postulated that because of the mismatch between the molecular areas of the head and tail groups in **18e** a high degree of molecular packing was not possible¹³² and the first redox couple is associated with the defects in the LB film, where free counterion transport is allowed. The redox couple at 0.4 V is associated with hindered counterion transport to the Fc sites in a more hydrophobic environment. This corresponds to the report of Creager and co-workers¹¹³ on the increase of the Fc redox potential with increasing hydrophobicity of the environment. White's theoretical treatment¹³⁶ can also explain these results. In the case of **18e** diluted by fatty acid no electrochemical response of Fc was seen. The data of the surface pressure–molecular area isotherm and ellipsometry support the idea that the very densely packed bilayer

structure with alkyl chains of fatty acid filling in the space in the tail groups of **18e** is formed. Such a compact hydrophobic environment completely blocks counterion permeation to the Fc redox sites and consequently electrochemical reaction is inhibited. On the other hand it was shown that **18e** does not form miscible layers on the HClO₄ subphase.¹³² These films are not densely packed and electrochemical reaction could be observed. However, even on the HClO₄ subphase the electroactivity was not complete and it was necessary to transfer films in the expanded state (with molecular area of 3 nm² or even higher, using the horizontal transfer technique). Also if a floating layer was left on the subphase surface for more than 20 min ill-defined CVs were observed. So to ensure a sufficient number of defects in the film for facile counterion transport the floating layer was left on the subphase surface for not more than 5 min. The electron transfer kinetics for SA films of thiols with 10, 12, 14, 15 and 18 carbons were determined according to the Laviron theory.¹⁰³ The dependence of first-order rate constant on the length of alkyl chain in thiol was linear with a decay constant of -0.99 per methylene group. The comparison of these data¹³² with those obtained for the Fc terminated thiols showed that at a distance of 1.4 nm from the electrode surface, electron transfer was almost two orders of magnitude slower. The largest distance was 2 nm (thiol C₁₈H₃₇SH)¹³³ and it is possible that a complete blocking of the electrochemical reaction was not achieved (compared with the previous results,¹² where this distance was about 2.5 nm).

Using a monolayer of Fc amphiphile **18b** on an interdigitated microarray electrode covered with a monolayer of SA film lateral diffusion in a monolayer has been studied¹³⁷ (the transfer on bare electrode was not satisfactory). If all arrays in the interdigitated electrode are connected together the usual surface wave response (Fig. 21 a), with some diffusion tailing due to electroactive material diffusing between the arrays were obtained. Generator–collector voltammograms, shown in the same Fig. 21 b, were obtained when one set of microelectrodes is made oxidising and another is made reducing with respect to the Fc formal potential. Using appropriate theory and steady state collector voltammogram the authors¹³⁷ calculated the lateral diffusion coefficient to be around $(2-4) \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ depending on the surface pressure used for monolayer deposition. It should be mentioned that the diffusion coefficient decreased when the monolayer became more densely packed. These diffusion coefficients were an order of magnitude smaller than for Langmuir monolayers on a water surface. It was explained as a change of fluidity of Fc molecules and it seems it is only possible because the LB films were studied in a liquid expanded state. In the following work¹³⁸ the behaviour of these films was studied in more detail. Since the electrochemical

Figure 21. CV (a) and generator–collector voltammograms of the same system (b) of **18a** on an interdigitated microelectrode array.¹³⁷ (a) Potentials vs. SCE, with both sets of electrodes driven at the common working electrode potential, 1 M aqueous LiClO₄, $\nu = 20 \text{ mV s}^{-1}$; (b) generator electrode scanned from 0 to 0.9 V and the collector electrode held at +0.1 V, $\nu = 20 \text{ mV s}^{-1}$, (I) generator current–voltage curve, (II) collector current recorded at +0.1 V and plotted vs. the potential of generator electrode.

properties were studied using the usual planar electrodes, it implied that electrons are tunnelling over a distance of about 5 nm. This seems impossible in view of the results previously reported.¹² Therefore, it was proposed¹³⁸ that electron transfer occurs by lateral diffusion to defect sites in the LB film. However, it is not proven since the voltammetric response possesses the shape of the surface wave response.¹³⁸ The voltammetric response seems to be very sensitive to the time the monolayer was left on the subphase surface before compression, the compression rate, the surface pressure for the film transfer and the time monolayer was left after compression. For instance, the films transferred at the high pressure (where the staggering of molecules is supposed) postulated the shoulder on the oxidation peak.

The decrease of the electroactivity in the following cycles was explained by the gradual embedding of Fc head groups in the hydrophobic part of monolayer according to the theoretical treatment of White and co-workers.¹³⁶ The electroactive coverage also decreased with the increase of the compression rate and the increase of the time the monolayer was left on the subphase surface before compression. This was ascribed to the two-dimensional reorganisation in the monolayer leading to the burying of Fc head groups in the hydrophobic part of the monolayer. This fact was observed by the AFM (transition from a liquid expanded to a liquid condensed state).¹³⁸

The deposition of ubiquinone **22** on a hydrophobic Au electrode covered with SA monolayer results in only partial electroactivity of ubiquinone. The electroactivity was assigned to the molecules of **22** residing on the defect sites of the SA monolayer.¹⁰⁴ This observation corresponds to the report,¹² where electrochemical reaction was not observed for Fc amphiphile **18d**, when monolayer was deposited onto the top of a passivating monolayer of Cd stearate. Ubiquinone incorporated in a phospholipid bilayer¹⁰⁴ LB film showed distinctive features of diffusion controlled behaviour. This was explained by the diffusion of ubiquinone through the lipid bilayer to the defect sites in the SA monolayer.

VII. Applications

Some of the electroactive LB films showed electrocatalytic properties. A Ni cyclam **33a** LB monolayer on a glassy carbon electrode

was active in the electroreduction of CO₂ in aqueous electrolyte at pH 4.5.¹³⁹

Later,¹⁴⁰ these results were found to be irreproducible and LB films of monosubstituted Ni cyclam **33b** have been prepared. The 1–3 layer films exhibited complete electroactivity, surface wave response and electrocatalytic reduction of CO₂.

The films containing complexes **21a,b**⁹⁵ and bis-Fc¹⁴¹ catalysed some electrochemical reactions. A monolayer containing a Ru complex **21c** electrocatalysed the oxidation of oxalate anions and generated chemiluminescence.⁹⁸

The LB technique was also used for the formation of thin electrocatalytic electrodes loaded with Pt particles.¹⁴² These electrodes had similar activity to smooth Pt electrodes but with a much lower Pt loading level. Catalytic activity in such thin electrodes (~10 nm) cannot be limited by the mass transfer through the film. The electrodes were obtained by LB deposition of the amphiphilic compounds from a H₂PtCl₆ containing sub-phase with subsequent electrochemical reduction of the incorporated PtCl₆²⁻ anion to Pt metal.

Different approaches for the fabrication of electrochemical diodes have already been discussed above. Using a biomimetic approach of electron transfer in biological systems to model the molecular electronic devices Ueyama and co-workers^{108,109,126} fabricated multilayer LB assemblies with uni-directional electron transfer. This device can be considered as a molecular photodiode. Similar behaviour is observed in LB films of flavin with cytochrome *c* in solution,¹⁰⁹ LB heterolayers of flavolipid and cytochrome *c*,¹²⁷ Fc- and Ru-complex co-polymers,⁹⁴ and pyrene **34** and Fc **18a**.¹⁴³

Recently^{144,145} LB films of conjugated molecules **35** were used for rectified electron transfer through a LB monolayer to solution redox species.

The monolayer of **35a** demonstrated a CV response with high peak separation. This might indicate either slow electrochemical kinetics or a diffusion controlled electrochemical reaction. The electrochemical response of [Fe(CN)₆]³⁻ in solution was blocked by a monolayer of compounds **35**. It should be emphasised that it is not easy to fabricate a passivating monolayer by the LB technique. For instance, Bilewicz and Majda⁸⁷ used a monolayer of a mixture of C₁₈H₃₇SH and C₁₈H₃₇OH to achieve good passivating properties on the surface of a gold electrode. This

involves SA of thiol by covalent bonds and decreases, thus, the defect concentration in the monolayer. Therefore the passivating properties of the last monolayer were similar to those of monolayers of SA thiols. The hexacyanoferrate(II) reduction was mediated by the monolayer (an increased peak in the CV response) and the re-oxidation was blocked, which was also confirmed by chronocoulometry. It was suggested^{144, 145} that these amphiphiles with long conjugation might serve as a 'molecular wire'. However, it remains unclear whether the electron transfer occurs 'through space' or 'through conjugated bonds' in the LB film. Mixed monolayers of the compounds **35** displayed an electrochemical response characteristic of the ultramicroelectrode array.¹⁴⁵

Electrochemical photodiodes have been fabricated by a LB technique.¹⁴⁶ Using **29** as an electron acceptor (A), **34** as a sensitizer (S) and **18a** as an electron donor (D) and combining the monolayers into the multilayers as A–S–D or D–S–A, the vectorial current was registered.¹³⁵ The direction of the observed photocurrent was in good agreement with the energy profile of the film components. Subsequent studies have concentrated on the fabrication of similar devices using a monolayer of a molecule containing all components (intra-molecular photodiode).^{146–151} Several triad molecules **36–38** were synthesised:

$n = 11$ (a), 16 (b).

R = H (a), Pr (b).

These triad molecules allow the creation of the structure A–S–D as only the viologen (A unit) is hydrophilic within the triad. Due to the two alkyl chains the compound **37b** allows the fabrication of a film with the opposite orientation D–S–A¹⁵¹ on a hydrophilic support. The direction of the observed photocurrent in all cases considered was in good agreement with the energy diagram of the D, S and A moieties in the film. The highest photoelectric conversion efficiency was registered for photodiodes based on compound **37a**.^{148–150} Also, in order to model the transfer of light energy in photosynthesis, monolayer films of a mixture of compounds **38** and **39** were fabricated.¹⁴⁹

In this case compound **39** worked as a light harvesting antenna and the energy transfer from the pyrene moiety of **39** occurred onto the perylene moiety of **38**. The photocurrent was generated after multistep electron transfer through the monolayer.

Japanese group^{152–155} proposed an interesting photoelectrochemical 'one-way' process based on the difference between the electrochemical reductions of *trans*- and *cis*-isomers of an azo-compound **40** in LB films.

The *cis*-isomer of surfactant azobenzene was much easier to reduce (difference in peak potentials about 400–600 mV depending on pH) than the *trans*-isomer (Fig. 22). However, oxidation of hydrazobenzene yielded only the *trans*-isomer of azobenzene. The *trans*-isomer can be transformed to *cis*-isomer by illumination. This 'one-way' process can be used for high-density information storage either by 'optical writing' (using laser beam) or 'electrochemical writing' (counter electrode probe positioned as in a scanning tunnelling microscope).^{152, 153} Information can be read spectroscopically as well. It has been shown later¹⁵⁶ that to further improve storage density the information can be written and read using linearly polarised UV light. Recently, this material has been deposited by the LB method on Au substrates modified with SA thiol monolayers.¹⁵⁷ The electron transfer distance was changed by varying the length of the thiol molecule and the orientation of molecule **40**. The orientation has been changed by choosing the thiol terminal group. When **40** was oriented with the octyl chain adjacent to the hydrophobic end of the alkyl thiol, the total length of 26 carbon atoms completely blocked electron transfer from the azobenzene moiety (Fig. 23). This corresponds to the results of reports.^{12, 133} In the case of the hydrophobic end of **40** adjacent to the hydrophilic end of HOCH₂CH₂SH the CV response was not observed. This was explained¹⁵⁷ by the change of the azobenzene electrochemistry from irreversible to reversible. The reduction potential of *cis*-azobenzene becomes more anodic than the re-oxidation potential of hydrazobenzene. Owing to this inversion of the redox potentials the reduction of *cis*-azobenzene cannot be observed. This hypothesis was supported by photoelectrochemical studies.¹⁵⁷

Another azo-derivative **41a** also demonstrated well resolved electrochemical properties. It may be used as a memory material through electrochemical means.¹⁵⁸

Figure 22. CV curves of monolayer film of compound **40** on an SnO₂ electrode, $v = 20 \text{ mV s}^{-1}$.¹⁵³ Potentials vs. Ag/AgCl; (1) *trans*, (2) *cis*.

Figure 23. CVs of a monolayer film of **40** transferred onto an SA monolayer of thiol, 0.1 M aqueous NaClO_4 .¹⁵⁷

Potentials vs. Ag/AgCl , $\nu = 20 \text{ mV s}^{-1}$; (a) SA layer of ethanethiol (total length for electron transfer 10 carbon atoms); (b) SA layer of octanethiol (total length for electron transfer 16 carbon atoms); (c) SA layer of octadecanethiol (total length for electron transfer 26 carbon atoms).

41a: $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Me}$, $\text{R}^3 = \text{OH}$;

41b: $\text{R}^1 = \text{Me}_2\text{N}$, $\text{R}^2 = \text{R}^3 = \text{H}$.

Electrochemical properties of the LB films depended on the pH of the subphase and the following illumination of the film. The films transferred from the subphase at pH 3 exist in a *cis*-enol form and undergo the transformation into a *trans*-ketone form upon the illumination with 450 nm light. The last form exists in the LB film transferred from the subphase at pH 6.5. The same group¹⁵⁹ studied photoelectrochemical properties of the LB films of the other azo-derivative **41b**. The occurrence of the photocurrent was attributed to the tautomeric transformation of **41b** upon illumination. In CV this resulted in some change of the peak potentials and decrease of peak separation. It was suggested that these films may be useful for photogenerated information storage and for the fabrication of devices for photoelectric conversion.

A photoalarm based on a photocell using bacteriorhodopsin LB film deposited onto an ITO electrode has been constructed.¹⁶⁰

Amphiphilic azobenzenecrown derivatives¹⁶¹ were designed for the molecular recognition of cations. Monolayers of compound **42** were built up on Au or thin layer Hg electrodes.

While the CV response of the LB film on a gold electrode was unstable, the thin layer Hg electrode modified by the LB monolayer showed perfectly stable surface wave response. The peak separation was increased when the Li^+ cations in the electrolyte solution (peak separation 20 mV) were substituted by Na^+ or K^+ cations (80 and 400 mV respectively). This was attributed to molecular recognition in the LB monolayer due to complexation with the crown ether. Simultaneously the formal potential did not change significantly. We were the first to register electrochemical molecular recognition on the addition of alkali metal cations to films of polythiophene **12** deposited by the LB technique.[†] How-

ever, the electrochemical behaviour of these films did not show any advantages compared with the cast films of the same polymer.

LB films of polyaniline **8**, obtained as described above,^{54,55} were loaded with glucose oxidase during LB film transfer.¹⁶² These electrodes were used as an amperometric biosensor for glucose at the concentration level of 10^{-2} M .

The electrochemical analysis of trace quantities of water-insoluble electroactive compounds by on-trough voltammetry was described.¹⁶³ A specialised microtrough was constructed and water-insoluble compounds were transferred onto ITO or graphite electrodes by the horizontal technique at the low surface pressure. The deposited films were analysed by CV in the same trough. The minimisation of aggregation and the possibility to avoid water-soluble impurities were suggested as potential advantages over the casting of films onto the electrode surface. The application of this technique to the compound **21c** demonstrated linear dependence of CV peak area on the quantity of compound and the possibility of analysing this compound down to 2 pmol. The possibility of the analysis of other non-amphiphilic water insoluble redox active compounds was also demonstrated.

Thus, modified electrodes fabricated by the LB technique can be used in electrocatalysis and electroanalysis. Molecular electronic devices based on electrochemical and photoelectrochemical principles may be constructed.

VIII. Conclusions

LB films exhibit slow redox reactions if they are well ordered and densely packed. This results in a change of mechanism from the surface reaction model to diffusion controlled behaviour. In this case diffusion of the ions through LB film is the limiting process. Hindered voltammetry for multilayer assemblies is usually observed in this case and only the first inner monolayer may be electroactive. When LB films are not as well ordered or the molecule is large, which enables sufficient empty space between the hydrophobic chains, surface reaction response can be obtained. Due to the strong repulsive interaction in highly loaded films this response usually deviates from an ideal surface wave, leading to peak broadening, peak separation, peak doubling and additional peaks. Peak doubling, explained theoretically by sufficiently negative repulsive interaction, can be understood in simple chemical terms as dimerisation of molecules in different redox states in LB films. It is an especially useful explanation when the molecules are known to have strong interaction in crystals and solutions, leading to *p*-dimerisation and stack formation. Such kinds of molecules are often used for conducting charge-transfer complexes and radical-ion salts.

From the theoretical point of view the surface reaction model has been extended for LB monolayer, multilayer and heterolayer films and attempts to calculate *e*-transfer kinetic have been made. First-order *e*-transfer rate constant of 10^0 – 10^2 s^{-1} and pseudo-first-order rate constant for interlayer transfer of 10^2 s^{-1} have been obtained. An electron diffusion coefficient of 10^{-11} – $10^{-12} \text{ cm}^2 \text{ s}^{-1}$ and lateral diffusion coefficients in liquid expanded state of $10^{-8} \text{ cm}^2 \text{ s}^{-1}$ have been obtained. Vectorial electron transfer can be achieved in LB films with electron diffusion coefficients two orders of magnitude higher in the appropriate direction.

Electron transfer distance dependence has been probed using LB films electrochemistry. It can be concluded that electron tunnelling is possible over a distance of about 2–2.5 nm.

Electrochemical techniques can be used for producing electroconducting LB films of charge-transfer materials and LB films of conducting polymers. The electrochemical doping can be realised either on the trough during LB film transfer or as an electrochemical reaction after film deposition (including electropolymerisation in the LB films). Highly ordered conducting films can be

[†] L M Goldenberg, M Leclerc, M C.Petty, unpublished results.

obtained. Different counter-ions can be introduced into the films by this technique. However, further investigations are necessary to understand the dependence of the conductivity and other film properties on the structure of the counter-ion. The films with conductivity as high as 50 S cm^{-1} and a partially metallic temperature dependence have been obtained.

Improvement of film quality for electrochromic devices has been achieved. Interesting molecular electronic devices, especially based on a one-way photoelectrochemical process and vectorial electron transfer, can be fabricated using LB films. LB films have found an application in electrocatalysis.

I wish to thank Russian Foundation for Basic Research (Project 97-03-32268a) for the support of my work with LB films. In particular I thank Profs M R Bryce, M C Petty and Dr. C Pearson, University of Durham for the fruitful collaboration in the LB films studies.

The use of palladium-catalysed cross-coupling for the synthesis of polymers incorporating vinylene and ethynylene groups

A L Rusanov, I A Khotina, M M Begretov

Contents

I. Introduction	1053
II. Synthesis of polyarylenevinylenes	1054
III. Synthesis of polyaryleneethynylenes	1059
IV. Conclusion	1066

Abstract. Methods for the synthesis of polyconjugated polyarylenevinylenes and polyaryleneethynylenes based on polycondensation catalysed by palladium complexes are reviewed. The bibliography includes 134 references.

I. Introduction

Synthesis of new π -conjugated polymers and investigation of their chemical and physical properties have attracted much attention in last decade.^{1–4} In this period polyacetylene,⁵ polydiacetylene⁶ and numerous polyarylenes incorporating aromatic carbo- and heterocycles^{7–10} have been obtained. Among these polymers, of special interest are the so-called polyarylenevinylenes (PARV) and polyaryleneethynylenes (PARE)

These polymers are distinguished by high electrical conductivity,^{1, 11, 12} relatively high non-linear third-order optical activity¹³ and electroluminescence.^{14, 15} Of current interest is the use of these polymers in light-emitting diodes.^{16–20}

Formerly, these polymers were prepared by the Wittig reaction²¹ and condensation according to McMurry.^{22, 23} However, due to the insolubility of polyarylenes, they are usually prepared *via* water-soluble intermediates or *via* products of the metathesis of corresponding cyclic compounds.^{24–26} Both methods include the stage of thermal elimination of low-molecular-weight products, which is not quantitative. As a result, the final products are contaminated with admixtures and this results in reduced electric activity of these materials.^{27, 28}

Hörhold *et al.*^{29, 30} used dehalogenation of *p*-xylylene systems to prepare soluble phenyl-substituted PARV. However, this approach has the same disadvantages as the aforementioned two-stage methods.^{24–26}

Syntheses of PARV or PARE type polymers are largely based on the studies by Heck *et al.*^{31–38} and Sonogashira *et al.*^{39–41}

devoted to the reactions of alkenes with aliphatic or aromatic iodides or bromides in the presence of Pd⁰ or Pd^{II} complexes. Usually, the reaction is performed either in the presence of 1 mol.%–5 mol.% of palladium salt or in the presence of Pd⁰ or Pd^{II} complexes with PPh₃ or other ligands, CuI as a promoter and a base (amine) that is needed to neutralise the hydrogen halide released and for the reduction of Pd^{II} to Pd⁰.

The Heck's reaction generally comprises two principal stages;³⁸ the first one is the formation of an organopalladium salt by oxidative addition, the second is the addition of the salt to alkene or acetylene with subsequent elimination of palladium hydride leading to the product of coupling. The selectivity of this process is determined by the reaction conditions and especially by the catalytic system. Thus when the Pd–AsR₃ system is used, two molecules of aryl halide are coupled; the yield of dimer is ~55%.⁴²

The mechanism of this process was studied in more detail using the formation of diarylacetylene as an example⁴³

Reactions of organometallic compounds (Grignard reagents) with halogen-substituted organic compounds are also widely used for syntheses of PARV and PARE; these reactions are catalysed by Pd or Ni salts.^{44–50}

Received 28 January 1997

Uspekhi Khimii 66 (12) 1162–1179 (1997); translated by T V Vernitskaya

M = Mg, Zn, SnBu₂; M' = Pd, Ni; L = PPh₃;

X, X' = Hal; R = Alk, R' = Alk, Ar, alkenyl, alkynyl.

The mechanism of these reactions is similar to that of reactions (1) and (2). On the first stage, the Grignard reagent and palladium-(or nickel)-phosphine complex form an organopalladium (organonickel) salt, which further yields coupling products in reactions with alkyl, aryl, alkenyl or alkynyl halides.

And finally, PARV and PARE can be prepared by reactions of aryl halides with alkynyl compounds in the presence of Pd complexes and phase-transfer catalysts.^{51–53}

All aforementioned processes have substantial yields of by-products.⁵⁴ Hence these reactions of cross-coupling are far from ideal for polymer synthesis.⁹ Nevertheless, these reactions were used at different times for the preparation of PARV and PARE.

In this decade, one-stage direct reactions of aryl halides with vinyl- or ethynyl-containing compounds, which are catalysed by complexes of transition metals, primarily palladium complexes, are mainly used for synthesis of PARV and PARE.^{7–9}

II. Synthesis of polyarylenevinylenes

The very first reports on the syntheses of PARV by Pd-catalysed cross-coupling^{55–57} considered various possibilities for their implementation, namely, homopolycondensation of 4-bromostyrene,⁵⁶ reaction of *p*-divinylarenes with dihaloarenes,⁵⁵ reaction of ethylene with dihaloarenes.⁵⁷

Homopolycondensation of 4-bromostyrene⁵⁶ according to the following scheme

yields insoluble PARV, this predetermines its low molecular weight. It is possible in principle⁵⁷ to use in this reaction substituted 4-bromostyrenes of the general formula

R¹ = H, R² = Me, Ph, CF₃; R¹ = R² = Me,

which provide a possibility of preparing polymers with improved solubility, however this synthetic procedure for PARV did not find much application.

A method based on the reaction of ethylene with dihaloarenes became more popular; this is due to the availability of the reactants. Heitz *et al.*^{42, 54, 57–60} have systematically studied this reaction. The reaction of ethylene with 2 mol of bromobenzene was used as a model.

This reaction was performed in the presence of a palladium acetate–tris(*o*-tolyl)phosphine–triethylamine catalytic system. It was found that, additionally to the target *trans*-stilbene **1** (75%–95% yield), compounds **2–7** were also formed:

The mechanism proposed by Heck³⁵ explains the formation of these compounds. Styrene (**2**) is formed in side reactions of bromobenzene, when excess of ethylene is used; biphenyl **3** is formed in the arylation of bromobenzene; *cis*-stilbene **4** appears as a result of conformational transformation in the transition complex; 1,1-diphenylethylene **5** is the product of α,β -addition of intermediate Pd–aryl complex with the alkene; triphenylethylene **6** is formed upon additional arylation of stilbene; *trans*-1-phenyl-2-*o*-tolylethylene **7** is a product of the reaction of ethylene or styrene with tris(*o*-tolyl)phosphine, which is used as a cocatalyst.⁵⁴

The side reactions of alkene with the cocatalyst and dehalogenation can result in lower molecular weight of the polymer, whereas formation of diaryls must not block the growth of macromolecules. The presence of triphenylethylene among the reaction products can result in the formation of cross-linked polymers.⁵⁴

The yield of the target *trans*-stilbene can be maximised and the role of side reactions substantially reduced if not suppressed by variation of such factors as the nature of halide and substituents in the haloarenes, composition and quantity of the catalyst, solvent, reaction temperature, pressure of ethylene.⁵⁴

It was shown that (a) bromoarenes are most suitable for the purpose (chloroarenes have low reactivity, whereas iodoarenes sometimes have lower selectivity of the reaction compared to bromoarenes); (b) with bromoarenes, tris(*o*-tolyl)phosphine should be added as a cocatalyst, whereas it is not necessary for iodoarenes; (c) electron-acceptor substituents in haloarenes promote the reaction, while electron-donor ones do not; (d) a lower concentration of the catalyst, palladium acetate, brings about higher yield of the target compound and lower yield of side products (with the exception of 1,1-diphenylethylene); (e) the nature of solvent [acetonitrile, methanol, DMF, *N*-methylpyrrolidone (*N*-MP), *N*-methylcaprolactam, DMSO] affects the yield of the product (the highest yield of *trans*-stilbene was attained with the use of DMF); (f) an increase in the temperature accelerates the main reaction, while selectivity becomes lower (the temperature of 50–100 °C provides the maximum yield of *trans*-stilbene); (g) lower pressures of ethylene favour formation of stilbene and higher pressures, of styrene.

A systematic study of the reactions of non-substituted, mono-, and disubstituted *p*-dibromobenzenes **8** with ethylene, which proceed according to Scheme 1, was reported in Ref. 57.

Table 1. The weight-average molecular weights (M_w), softening temperature (T_s), decomposition temperature (T_d), and composition of PARV **9–13**.⁵⁷

PARV	R^1	R^2	M_w		T_s^c /°C	T_d /°C		Content of Br (%)	
			fraction I ^a	fraction II ^b		fraction I	fraction II	fraction I	fraction II
9	H	H	< 500	—	—	150	200	—	9.87

13	Me	Me	900	2600	—	190	205	—	9.87

^aDetermined by GPC with polystyrene standard. ^bDetermined by GPC with poly(phenylene sulfide) standard. ^cDetermined using polarisation microscope at a heating rate of 10 deg min⁻¹.

$R^1 = H$; $R^2 = H$ (**9**), Me (**10**), CF₃ (**11**), Ph (**12**);
 $R^1 = R^2 = Me$ (**13**).

The synthesis of PARV **9–13** was performed in DMF with the Pd(OAc)₂–P(Tol-*o*)₃–NEt₃ catalytic system at 100 °C for 20 h. In all cases two fractions, DMF-soluble and DMF-insoluble, were isolated from the reaction mixtures. High-temperature gel-permeation chromatography (GPC) of these fractions showed (Table 1) that the DMF-insoluble fractions (with the exception of non-substituted PARV **9**) have higher molecular weight. The fractions insoluble in DMF are soluble in *N*-methylcaprolactam at 140 °C, the molecular weight of the polymer being related to its solubility. Among the polymers synthesised, all substituted PARV **10–13** are more soluble than non-substituted **9**, the phenyl-substituted polymer **12** being the most soluble one. It is well soluble in chloroform and styrene.

Synthesis of PARV according to Scheme 1 was also performed with the reaction time extended to 48 h and chloroform used as a solvent.^{58–60} The reaction employed the 1,4-dibromides **8** with the following substituents $R^1 = H$, $R^2 = H$, Me, Ph, CF₃, F, NO₂; $R^1 = F$, $R^2 = CF_3$. In all cases, the PARV obtained comprised two fractions, a chloroform-soluble one and an insoluble one; the yield of the former was 0%–55%.

Additionally to the synthesis according to Scheme 1, two other approaches were used in order to obtain PARV with improved solubility.^{58–60} The first approach was to use substituted and non-substituted 4,4'-dibromobiphenyls; in the second, at least two haloarenes of different structures were used in the reaction with ethylene.

The former approach is based on the fact that aromatic rings in biphenyl fragments are not coplanar and can rotate with respect to one another.

$R = H$ (**14**), Me (**15**).

The introduction of substituents in dibromobiphenyl monomer results in enhanced non-coplanarity of these rings and, hence, lower length of conjugated segments in PARV chain. This change is reflected in the physical properties of the polymer. Thus the PARV **14** based on 4,4'-dibromobiphenyl does not melt and is insoluble in organic solvents; its colour is light-yellow. At the same time, PARV **15** based on 2,2'-dimethyl-4,4'-dibromobiphenyl is colourless, it is low-melting and dissolves well in chloroform and *N*-MP; its molecular weight measured using GPC is 10 700.

Reduced regularity of PARV structure, which is achieved when ethylene reacts with different substituted dibromobenzenes constitutes the basis of the second approach.

$R = H$ (**16**), Me (**17**), NO₂ (**18**).

Some properties of random copolymers prepared according to the second method⁵⁹ are presented in Table 2. Expectedly, the

Table 2. Some properties of random copolymers based on substituted *p*-dibromobenzenes **16–18** and 2,5-dibromobiphenyl **19**.⁵⁹

copolymers with different substituents in phenylene fragments often have a similar or improved solubility compared to corresponding homopolymers.

Analysis of the properties of copolymers based on dibromide **18** (homopolymer is insoluble) and 2,5-dibromobiphenyl **19** (soluble homopolymer) showed that they all are soluble, the solubility being nonlinearly dependent on the content of nitro-substituted phenylene groups (most soluble is the copolymer containing ~25% of such groups).

Copolycondensation of ethylene with binuclear and condensed dibromoarenes yields PARV **20**, which also have lower structural regularity (Scheme 2).

Scheme 2

The properties of copolymers **20** presented in Table 3 show that irregularity of the distances between vinylene groups does not noticeably affect solubility of copolymers, whereas introduction of alkyl substituents in initial aromatic compounds enhances solubility.

The synthesis of PARV by reaction of haloarenes with divinylaromatic compounds was considered in Refs 61–67.

An attempt was made^{61,67} to obtain anthracene-containing PARV by the Heck's reaction in DMF at 90 °C with a palladium acetate–tris(*o*-tolyl)phosphine–triethylamine catalytic system; the reaction time was 24 h. The reactions of 9,10-divinylanthracene with various dihaloarenes did not produce the desired product, whereas reaction of 9,10-dibromoanthracene with *p*-divinylbenzene gave PARV **21** in nearly quantitative yield.

The solubility of PARV **21** in organic solvents is very low; therefore it precipitates from the reaction mixture in the course of polycondensation. This results in termination of the chain growth and formation of a low-molecular-weight product. This is confirmed by the data on the molecular weight of the polymer **21** (M_w = 1000) and bromine content (15.4%). In order to enhance solubility of PARV, 2-*tert*-butyl-9,10-dibromoanthracene was used as the initial dibromoanthracene. The oligomer based on it had higher molecular weight; the DMF-soluble fraction had M_w = 1300 and insoluble one, M_w = 1500.

Photosetting PARV **22** were obtained by Müllen *et al.*⁶³ by the reaction of 2,2'-divinylbiphenyl with *p*-dibromobenzene (Scheme 3). Upon UV-irradiation of the polymer **22** in solution or in solid it is transformed into polymer **23** that incorporates dihydrophenanthrene and cyclobutane fragments.

Scheme 3

The PARV **24** that incorporates alternating phenylenebisvinylene and alkyl-substituted terphenylene units was prepared by the reaction of 4,4'-dibromo-2,2'',5,5''-tetraoctyl-*p*-terphenyl with *p*-divinylbenzene (Scheme 4).⁶⁴

Scheme 4

According to DSC data, the glass transition temperature of the polymer **24** is -20°C . The polymer is very soluble in THF, chloroform and toluene; this is due to the presence of long aliphatic substituents, which loosen the polymer structure and reduce intermolecular interactions. Previously long alkyl substituents were introduced in initial monomers in order to produce soluble rigid-chain polymers^{68–70} (*viz.* poly-*p*-phenylenes). The GPC measurements of molecular-weight distribution showed that M_w of the polymer **24** is 4500 and polydispersity $M_w/M_n = 1.7$. These data further confirm that the molecular weights depend on their solubility in the reaction mixture; the molecular weight is always higher for the polymers having in their aromatic fragments substituents (*e.g.* aliphatic groups), which enhance their solubility.

Thermogravimetric analysis (TGA) of PARV **24** showed that decomposition of the polymer in N_2 starts at 420°C . The PARV **24** constituted a basic material for efficient light-emitting diodes (blue light).⁵⁹

Polyarylenes **25–27** incorporating side alkoxy groups were obtained in 70%–94% yield by reaction of *p*-divinylbenzene with 2,5-dibromo-1-alkoxybenzenes.⁶⁵

$\text{R} = \text{n-C}_6\text{H}_{13}$ (**25**), $\text{n-C}_{12}\text{H}_{25}$ (**26**), $\text{CH}(\text{C}_5\text{H}_{11})_2$ (**27**).

It has been shown previously that introduction of alkoxy substituents into initial monomers is an efficient means for reduction of glass transition and melting temperatures and enhancement of solubility of rigid-chain polymers.^{71,72} The solubility of alkoxy-substituted PARV depends on the size and

structure of a substituent. Thus PARV **25** is insoluble in organic solvents, the polymer **26** has a limited solubility in tetrachloroethane (TCE), and only PARV **27** ($M_n = 5400$) incorporating 1-pentylhexyl group is well soluble in TCE and chloroform; this is due to reduced (owing to steric hindrance) intermolecular interaction of the polymer chains.⁶⁵

The synthesis of PARV **28**, which incorporate a stilbene chromophore with non-linear optical activity as a substituent (Scheme 5), is also described in Ref. 65. Some properties of the PARV synthesised are presented in Table 4. The polymers containing non-linear optical chromophore and unbranched alkoxy groups are insoluble in organic solvents. Possibly, this is related to the strong intermolecular interaction associated with the presence of large number of polar chromophore groups. Only copolymers containing 50%–70% of $\text{OCH}(\text{C}_5\text{H}_{11})_2$ -groups were soluble in TCE or mixtures of TCE with DMF. Similar to the majority of

Table 4. Some properties of PARV **28**.

^a According to DTGA data. Hereinafter T_d is measured in nitrogen atmosphere at the heating rate of $4^{\circ}\text{C min}^{-1}$.

Scheme 5

$\text{R} = \text{n-C}_6\text{H}_{13}$, $\text{n-C}_{12}\text{H}_{25}$, $\text{CH}(\text{C}_5\text{H}_{11})_2$;

$\text{R}' = -(\text{CH}_2)_6-\text{N}(\text{CH}_3)-\text{C}_6\text{H}_4-\text{CH}=\text{CH}-\text{C}_6\text{H}_4-\text{S}-\text{C}(=\text{O})-\text{OMe}$.

PARV, these copolymers have moderate molecular weights ($M_n = 5000$).

Studies of the physical properties of these polymers showed that they possess photoinduced conduction and electrooptical activity but do not manifest photorefraction.

Some of the homo- and co-polymers synthesised have liquid-crystal properties and form nematic mesophases. This is related⁶⁵ to the rigidity of macromolecular backbones of PARV containing stilbene and distyrylbenzene fragments.^{73, 74}

Soluble and meltable PARV **29** with conjugated chains that have mesomorphic properties were obtained⁶⁶ by reaction of *p*-divinylbenzene with dialkoxy-substituted *p*-diiodobenzenes.

$\text{R} = \text{C}_n\text{H}_{2n+1}$ ($n = 4, 7, 8, 12, 16$).

All the polymers synthesised are well soluble in THF, chloroform, toluene and dichloroethane. This allowed determination of their molecular weight characteristics (Table 5) and some structural studies. The TGA data show that PARV **29** are stable in nitrogen atmosphere up to 430 °C and DSC shows that their glass transition temperatures (second-order transitions) are in the range of 33–46 °C and decrease with shorter side chains (Table 5). All DSC curves exhibit at least two transitions, which are related to melting of the side and backbone chains (Table 6), the distinct melting temperatures decreasing with longer side chains (nematic mesophases form at the temperatures above melting point).

Thermotropic liquid-crystalline PARV **30** incorporating mesogenic groups and spacers in their backbone chain were synthesised by reactions of *m*- and *p*-divinylbenzenes with diiodo-

^a Transition was not observed. ^b The temperature and enthalpy of the transition were not determined due to cross-linking of the macromolecules.

and dibromo-arylenes containing various bridge groups (DMF or pyridine as solvents, 75–120 °C).⁶⁷

Depending on the nature of the monomers used, the polycondensations were either homogeneous or heterogeneous. Iodoorganic compounds proved to be more reactive than bromoaromatics [the latter required higher concentrations of the catalysts and higher temperatures (to 120 °C)]. The properties of PARV obtained are presented in Table 7.

Table 7. Some properties of PARV **30**.⁶⁷

^a $M_w = 14600$, $M_w/M_n = 1.48$. ^b Logarithmic viscosity in *p*-chlorophenol–chloroform solution is 0.51 dl g⁻¹.

The polymers based on *p*-divinylbenzene are insoluble in organic solvents, whereas PARV based on *m*-divinylbenzene and dihaloarenes incorporating ethylene oxide and ester groups are soluble in *p*-chlorophenol and in a mixture of CF₃COOH with CHCl₃; the molecular weights of soluble polymers were measured using GPC (they varied within 1400–14 600).

DSC and optical microscopy showed that PARV **30** manifest thermotropic liquid crystallinity. The mesophases of the polymers based on *m*-divinylbenzene and containing ether and ester groups have the smectic texture.

Reactions of unsaturated bisamides with dihaloarenes belong to the same type of processes.^{75–85} The synthesis of polycinnamamide **31** from bisacrylamide and aromatic diiodide in the presence of palladium complexes is studied in most detail.

The polycondensations were performed in various polar aprotic solvents [DMF, dimethylacetamide (DMAA), *N*-MP, DMSO, hexamethylphosphoramide, 1,3-dimethyl-2-imidazoli-

Table 8. Properties of polycinnamamides **31–36**.

Com- pound	–Ar–	–Ar'–	Yield (%)	$\eta_{\log}$ /dl g ⁻¹	T_g /°C	T_d (10%) /°C	
						N ₂	air
31			99	1.51	–	445	450
32			99	2.60	232	445	445
33			97	1.32	269	395	385
34			94	0.89	238	395	395
35			97	0.26	–	–	–
36			96	0.22	–	–	–

done]; the best results were obtained in DMF. Palladium acetate, palladium chloride and their combinations with triphenylphosphine, tris(*o*-tolyl)phosphine and 1,4-bis(diphenylphosphino)butane were tested as the catalysts. The polymers with highest viscosity were prepared with a Pd(OAc)₂–P(*o*-Tol)₃ (1 : 4) catalytic system in the presence of 1,8-bis(dimethylamino)naphthalene as a base. The reaction was performed at 100 °C for 4 h; when the synthesis temperature was increased to 110 °C, the reaction was accompanied by gelation. Polycinnamamides **31–34** were prepared in homogeneous conditions. High logarithmic viscosities $\eta_{\log}$ of the solutions indicate that the reaction products are high polymers (Table 8). Thus M_n and M_w of polycinnamamide **32** having viscosity of 2.60 dl g⁻¹ are 93 000 and 488 000, respectively. Polycinnamamides **35** and **36** were prepared in heterogeneous conditions and have low logarithmic viscosities.

Polycinnamamides **31–36**, with few exceptions, are soluble in pyridine, DMSO, DMAA, *N*-MP and DMF. Strong transparent films were casted from their solutions in DMF.

According to DTG data, the temperatures of decomposition (10% weight loss) for the polycinnamamides are in the range 380–450 °C, the polymers incorporating ether groups being more heat-resistant than those with isopropylidene groups.

The presence of double carbon–carbon bonds in the backbone chains of the polycinnamamides predetermines their capability of curing when heated (>250 °C) or subjected to UV irradiation.

An attempt was undertaken⁸² to obtain polycinnamamides under conditions of heterophase catalysis using a palladium–graphite catalyst (Pd–Gr). Such catalysts prepared by metal exchange in potassium-intercalated graphite⁸⁴ are known to possess high activity in hydrogenation of alkenes,⁸⁵ Heck's reaction⁸⁶ and nucleophilic substitution *via* π -allyl complexes.⁸⁷

The synthesis of polycinnamamide **32** was performed in the presence of a Pd–Gr–tributylamine catalytic system in DMF at 100 °C for 20–40 h. Under such conditions, even without a cocatalyst, polymers having logarithmic viscosity of 0.9 dl g⁻¹ (which corresponds to the molecular weight of 100 000) can be prepared. Comparison of the results of syntheses of the polycinnamamide on Pd–Gr catalysts and other Pd-containing catalysts is given in Table 9.

Table 9. Comparison of the results of syntheses of polycinnamamide **32** with various palladium catalysts.⁸²

Catalyst	Reaction time /h	Yield (%)	$\eta_{\log}$ /dl g ⁻¹
Pd–Gr	4	90	0.25
	20	95	0.90
Pd–Gr–P(Tol- <i>o</i>) ₃	20	96	0.81
Pd–C	20	94	0.69
Pd(OAc) ₂ –P(Tol- <i>o</i>) ₃	4	95	1.11

According to the results obtained, the heterogeneous catalytic reaction proceeds slower than the homophase reaction in the presence of Pd(OAc)₂. The reaction on a Pd–Gr catalyst not only has the common advantage of heterophase catalysis (*i.e.*, ease of separation of the catalyst from the reaction products) but also yields polycinnamamides with lower polydispersity and lower palladium content, as compared to similar polymers prepared with Pd(OAc)₂.

Generally, the method developed for heterophase synthesis of polycinnamamides^{81,82} is simpler than the conventional procedure⁸⁸ based on the reaction of biscinnamic acids or their derivatives with diamines.

III. Synthesis of polyaryleneethynlenes

The synthesis of PARE is based on the reaction of terminal acetylene groups with a haloaromatic compound.

This reaction is performed in the presence of copper(I) iodide, a base and a palladium salt as a catalyst. Most often PdCl₂(PPh₃)₂ is used as catalyst and DMAA and DMF as solvents, although THF⁸⁹ and pyridine were also successfully used.

The reaction of iodo(or bromo)benzene with phenylacetylene³⁹ catalysed by PdCl₂(PPh₃)₂ complex also gives by-products,⁴² *viz.* diyne, enyne and 1,3,5-triphenylbenzene.

The yields of these compounds, which strongly affect the polycondensation processes, can vary, depending on the reaction conditions;⁴² this necessitates the search for the optimal conditions for each particular polycross-coupling.

Similar to PARV, polyaryleneethynylenes have been prepared *via* three different ways, namely, by reaction of acetylene with dihaloarenes, by homopolycondensation of haloarylacetylenes and by reaction of diethynylaromatic compounds with dihaloarenes.

The reactions of acetylene with dihaloarenes, unlike the corresponding reactions with ethylene, did not find wide application. Thus the reaction of 4,4'-diiodo-3,3'-dimethylbiphenyl with acetylene⁴² yields the product **37** with low molecular weight due to its insolubility in organic solvents. When heated, the oligomer **37** gives a red anisotropic melt.

Homopolycondensation reactions of haloarylacetylenes (AB-type monomers) were studied in detail by Marvel *et al.*^{90–92} Homopolycondensations of 2-ethynyl-5-bromothiophene,⁹⁰ 3-bromophenylacetylene⁹² and 4-bromobiphenylacetylene⁹¹ were performed with the use of a $(\text{Ph}_3\text{P})_2\text{PdCl}_2\text{--PPh}_3\text{--CuI}$ catalytic system; the solvent used was triethylamine–pyridine mixture.^{32, 36, 39, 93–95}

The choice of this catalytic system was based on the high yield of the products of cross-coupling.^{39, 95} Note, however, that this catalytic system increases contribution of a side reaction, because phenylacetylene polymerises efficiently on this catalyst.⁹⁶

Homopolycondensations were carried out at 90 °C for 2.5–46 h and yielded low-molecular-weight PARE **38–40** (Table 10). The IR spectra of PARE **38–40** did not show the absorption maxima corresponding to terminal ethynyl groups. This is believed⁹¹ to result from oxidative coupling of acetylene groups, occurring in parallel with the major reaction. This side reaction has been described previously.^{97, 98}

Table 10. Conditions of synthesis and properties of PARE **38–40**.^{90–92}

Compound	Composition of solvent (NEt ₃ :Py)	Reaction time /h	Conversion (%)	Fraction A ^a (%)	M _w	M _n	Content of Br (%)

	3:22	15	90.6	6.5	3160 ^b	1940 ^b	6.81

^a Fraction A is soluble in chloroform. ^b Determined for soluble fractions.

Thermogravimetric studies of PARE **38–40** showed that they are quite stable up to 300 °C, the weight loss in 20 h was less than 10%. The polymers did not melt at 300–400 °C but they gradually darkened and after 20 h of high-temperature ageing turned into black powders.

Synthesis of PARE **46–50** was also based on homopolycondensation of the AB-type monomers **41–45** incorporating amide groups.⁹⁹

41, 46: X = *p*-Br, Y = *p*-C≡CH; **42, 47:** X = *m*-Br, Y = *p*-C≡CH; **43, 48:** X = *m*-C≡CH, Y = *p*-Br; **44, 49:** X = *m*-C≡CH, Y = *p*-I; **45, 50:** X = *m*-C≡CH, Y = *m*-I.

Depending on the nature of the monomers, the reactions proceeded either heterogeneously or homogeneously and the yield of polyaryleneethynyleneamides was 96%–100% (Table 11). When bromine-containing monomers were used, low-molecular-weight products were obtained ($\eta_{\log}$ = 0.12–0.18 dl g^{–1}), whereas polycondensation of the iodine-containing monomer **45** yielded polymer **50** with logarithmic viscosity of

Table 11. Conditions of synthesis and some properties of polyethynyleneamides **46–50**.⁹⁹

Initial monomer	Reaction temperature /°C	Reaction time /h	Yield (%)	$\eta_{\log}$ /dl g ^{–1}
41	100	4	100	–
42	100	4	99	0.12
43	100	4	100	0.18
44	100	4	100	–
45	100	4	96	0.43
	80	4	95	0.18
	120	4	100	–
	100	1	96	0.16

0.43 dl g⁻¹. This result agrees well with the data of Refs 43, 100, which reported higher activity of aryl iodides compared to aryl bromides in palladium-catalysed reactions of oxidative addition.

Studies of solubility of the polymers synthesised showed that simultaneous introduction of amide and *m*-phenylene groups in PARE results in substantially improved solubility of these polymers. Thus high-molecular-weight polymer **50** dissolves in DMF, DMAA, *N*-MP, DMSO, *m*-cresol and pyridine.

GPC studies of this polymer showed that its M_w is 108 000 and polydispersity $M_w/M_n = 16.4$, in other words, the polymer has broad molecular-weight distribution. According to TGA data, the temperature of beginning of the decomposition and that of 10% weight loss of PARE **50** are 315 and 350 °C, respectively. DSC showed that an exothermic peak is observed near 270 °C; it is related to the polymer curing *via* the ethynyl groups incorporated in the backbone chains of the macromolecules.

The majority of studies considered synthesis of PARE by reactions of dihaloarenes with diethynylarenes. First works in the field were published in the early 90s.^{101, 102} The polyaryleneethynylenes **51** were prepared using two methods.

Method A.

–Ar–	X	Yield of 51 (%)
	Br	79
	I	97
	Br	84
	Br	93
	Br	95

The reactions were carried out for 1–3 h at 80–90 °C in an organic solvent (*e.g.*, toluene)¹⁰² in the presence of CuI and PPh₃. Pd(PPh₃)₄ or PdCl₂(PPh₃)₂ (up to 10 mol.%) were used as catalysts.

Method B.

–Ar–	X	Yield of 51 (%)
	I	97
	Br	82

The reactions were carried out in THF for 2–3 h at 60–70 °C in the presence of Pd(OAc)₂ and PPh₃ or Pd(PPh₃)₃.

All the polymers **51** had high crystallinity but were poorly soluble. Therefore their molecular weights could be estimated only on the basis of halide content, which was substantial; most probably the molecular weights were in the range of 1400–4000.

PARE **52** was prepared by the reaction of *m*-dibromobenzene and *m*-diethynylbenzene;⁹¹ this polymer has the structure close to that of the products of homopolycondensation of *m*-bromophenylacetylene (compounds **39**).⁹⁴

The synthesis of polymer **52** was carried out under the same conditions as those for the homopolycondensation of *m*-bromophenylacetylene. The polymer obtained had somewhat higher molecular weight ($M_w = 3000$). Note that the molecular weight of the polymer determined by means of GPC refers to its soluble fraction (~6%). Generally, this PARE has a very limited solubility. When *p*-dibromobenzene is used as the haloarene, the PARE formed is completely insoluble in organic solvents.

In order to prepare PARE having higher molecular weight and improved solubility, Hergenrother *et al.*¹⁰³ used monomers with bridge groups, the ‘activated’ dibromoaromatic compounds. The solvent used was DMAA. However, virtually all PARE **53–57** (Table 12) precipitated from the reaction solutions after

Table 12. Structure and some properties of PARE **53–57**.

53			see ^d	173	–	355
54			see ^d	–	–	343
55			see ^d	–	–	> 350
56			0.28	143	247	320
57			0.27	–	267	333/375

^a Glass transition temperature determined by DSC at the heating rate of 20 deg min⁻¹; ^b T_{endo} is the melting temperature of crystallites (according to DSC data); ^c T_{exo} is the temperature at which reaction of acetylenic groups starts; ^d PARE are insoluble in TCE, DMAA and *m*-cresol.

several minutes of stirring at 100–120 °C; this is related to the crystallinity of the polymers.

The investigation of PARE **53–57** by means of DSC revealed that they manifest endothermic peaks associated with the melting of crystallites and when the polymers are heated they show exothermic effects related to cross-linking *via* the disubstituted acetylenic groups (Table 12).

The polymers based on 4,4'-diethynyldiphenyl ether and dibromides such as 4,4'-bis(4-bromobenzyl)- and 4,4'-bis(3-bromobenzyl)diphenyl ether have limited solubility in TCE in which their viscosity was examined.

The polyaryleneethynylene **57** yields compound **58**, which contains quinoxal-2,3-diyl fragments, upon treatment with *o*-phenylenediamine in TCE (Scheme 6). According to the data of X-ray diffraction,¹⁰³ the polymer **58** having $T_g = 190\text{ }^{\circ}\text{C}$, had lower crystallinity than the initial PARE and correspondingly was better soluble in DMAA.

PARE of the type,

which have the structure and properties close to those of the compounds described in Ref. 103, have been prepared analogously.¹⁰⁴ The polycondensation was carried out in DMAA at 90 °C (in the presence of triethylamine) or at 120 °C (in the presence of tri-*n*-butylamine) for 4 h with a $\text{PdCl}_2(\text{PPh}_3)_2\text{--PPh}_3$ catalytic system (Table 13).

The PARE obtained are insoluble in organic solvents and decompose in H_2SO_4 ; therefore, their molecular weights were determined from elemental analysis under the assumption that each macromolecule has one terminal bromine atom. The differential thermogravimetry in N_2 shows a small weight loss near 280 °C and less than 5% at 400 °C. The data of DSC indicate that there is a substantial exothermic effect at 250–280 °C; it can be related to thermal cross-linking of the polymer *via* the acetylenic groups.

Similar approach to the preparation of PARE was employed by Rusanov *et al.*^{105–107} In order to enhance solubility and to increase molecular weights of the polymers, the monomers containing various bridge groups or aromatic substituents were employed. Thus reaction of 4,4'-diiododiphenyl ether with *p*-diethynylbenzene, 4,4'-diethynyldiphenyl ether and 1,2-bis[4-(4'-ethynylphenoxy)phenyl]-*o*-carborane in DMF at 100 °C during 4 h yielded predominantly products of cross-coupling.¹⁰⁵

Some properties of the PARE obtained are presented in Table 14. Among the polymers **59–61**, the carborane-containing

compound **61** is the best soluble one; it is soluble in chloroform and amide solvents. This agrees well with the existing notion^{108–110} that carborane groups positively affect solubility of condensation polymers.

Table 14. Some properties of PARE **59–61**.¹⁰⁹

^a According to the data of ebullioscopy in chloroform or sedimentation in *N*-MP. ^b The temperature of 10% weight loss, DTGA.

A much wider variety of dihaloarenes was used^{106, 107} for the synthesis of PARE by reaction of 1,3-diethynylbenzene with various carbo- and hetero-cyclic dibromides.

The reactions were carried out in DMAA at 90 °C for 10 h with the $\text{PdCl}_2(\text{PPh}_3)_2$ – PPh_3 – CuI – Et_3N catalytic system. The data presented in Table 15 show that certain phenyl-substituted PARE are soluble in amide solvents (DMF, DMAA, *N*-MP); this agrees well with the inference¹¹¹ that phenyl substituents have a positive effect on the solubility of polyheteroarylenes. Nevertheless, the degree of polymerisation of these PARE calculated on the basis of Br content did not exceed 2–3. It should be noted that the degree of polymerisation of insoluble PARE obtained from dibromides activated by α -diketone, acetylene, ethylene groups and quinoxal-2,3-diyl fragments is also small (3–5). Apparently, solubility of the target compounds in the reaction mixture is a necessary but

^a Calculated on the basis of elemental analysis.

not sufficient condition for synthesis of high-molecular-weight products.

Amide groups were introduced into PARE macromolecules¹¹² in order to make them soluble in organic solvents; it has been shown previously⁹⁹ that in a number of cases this approach gives the desired result. Synthesis of such PARE was performed under usual conditions. In all cases, a small excess of bisethynylarenes was used; this resulted in formation of polymers with improved viscous properties (Scheme 7).

The course of polycondensation depends on the structure of diiodide **70** used. At 1×10^{-3} mol litre^{−1} concentration, polycondensation of *p*-diiodobenzene (**70a**) and 4,4'-diiododiphenyl ether (**70b**) with bisethynylarenes in DMAA proceeded heterogeneously and at half that concentration, homogeneously. Following isolation, majority of the polymers lost their solubility. The polycondensation of 4,4'-diiododiphenyl sulfone (**70c**) always proceeded homogeneously and the polymers obtained were well soluble in DMAA, DMF, *N*-MP, DMSO, *m*-cresol and *o*-chlorophenol.¹¹² Note that enhanced solubility of diphenyl sulfone-containing polymers, as compared to diphenyl ether-containing, and virtual no effect of diphenylhexafluoroisopropylidene groups on their solubility is quite unusual and falls outside the general structure–solubility dependence in the series of condensation polymers.¹¹³ The properties of the polymers obtained are presented in Table 16. Thus prepared polymers do not show any pronounced glass transition and in TGA experiments in nitrogen atmosphere do not lose weight until 300 °C. At 280 °C, the polymers cross-link *via* acetylenic groups yielding insoluble systems.

The most versatile and reliable method for enhancing solubility of PARE (similar to PARV) is the introduction of long-chain aliphatic substituents into their macromolecules.^{114–122} Schulz *et*

^a Determined by GPC. ^b The temperatures of the start of decomposition and 10% weight loss as determined by DTGA in air at the heating rate of 10 deg min⁻¹.

*al.*¹¹⁴ carried out synthesis of alkoxy-substituted PARE according to the following scheme

$R^1, R^2 = C_4H_9, C_6H_{13}, C_{11}H_{23}, C_{14}H_{29}, C_{18}H_{37}$.

1,4-Diethynylbenzene, 9,10-dibromoanthracene and *n*-alkyl-3,6-dibromocarbazoles were also used for the synthesis of PARE. All the polymers obtained were coloured from yellowish-orange to brown-red and manifested intense fluorescence in aromatic solvents.

The freshly prepared alkoxy-substituted PARE are soluble in boiling toluene, xylene or carbon disulfide. However, after drying *in vacuo* at 30–40 °C only polymers with long side chains ($R^1, R^2 = C_{14}H_{29}$ or $C_{18}H_{37}$) retain solubility. The polymer with $R^1 = R^2 = C_{18}H_{37}$ has the highest solubility (up to 3 g litre⁻¹ in hot toluene). The molecular weight of this polymer determined using GPC and osmometry is 8500–10 000; this corresponds to a degree of polymerisation within the range 9–15. This polymer is a meltable product that forms a transparent viscous melt at ~100 °C. At temperatures ≥170 °C, the polymer cross-links. Films with moderate mechanical properties were prepared from its solution.

DTGA of alkoxy-substituted PARE showed that their decomposition in nitrogen starts at 420 °C. In air decomposition proceeds in two stages, the first stage (70% weight loss) being associated with the cleavage of the side chains and the second, with oxidation of the backbone chains of the polymer.

The alkoxy-substituted PARE **72a–c** with *m*-phenylene groups were obtained by reaction of 1,4-diethynylbenzene with 1-alkoxy-2,4-dibromobenzenes.¹¹⁵

$R = C_{16}H_{33}$ (**a**), $C_{18}H_{37}$ (**b**), $C_{22}H_{45}$ (**c**).

The yields and processibility of the products can be improved through an increase in the length of the substituents. Thus polymer **72c** is soluble in chloroform, benzene, THF, DMF and CS₂; its molecular weight (GPC in DMF) is 40 000; this provides a possibility of casting a good quality film from its chloroform solution.

Synthesis of PARE incorporating heterocycles in their backbone chains was investigated in a number of studies.^{116–119}

73a: X = I, Y = S, $R^1 = H, R^2 = n-C_6H_{13}$;

73b: X = Br, Y = Se, $R^1 = R^2 = H$;

73c: X = Br, Y = S, $R^1 = R^2 = NO_2$;

The syntheses were carried out in anhydrous toluene according to the method described in Ref. 102 (Table 17). The polyaryleneethynyls based on diethynylpyridine **74a** and dihalides **73b** and **73c** are soluble only in HCOOH, whereas based on **73a** polymer incorporating hexylthiophene fragments is soluble in CHCl₃, CH₂Cl₂, THF, DMF and toluene. This indicates that alkyl substituents positively influence the solubility of PARV and PARE. The choice of 2,5-diethynylpyridine was based on the solubilising effect of pyridine-2,5-diyl groups on rigid-chain polymers.^{123, 124}

Table 17. Conditions of synthesis and molecular weights of PARE based on compounds **73** and **74**.

73c	74a	2	2	60	19	86	9.6 ^b

^a Determined using light scattering in chloroform. ^b Light scattering in HCOOH.

Virtually all the PARE obtained had high molecular weights. Strong films with non-linear third-order optical sensitivity $\chi^{(3)} = 5 \times 10^{-11}$ (cgs) were prepared from their solutions. All the compounds have high degrees of depolarisation ($\rho_v = 0.005-0.034$), which, nevertheless, are much lower than $\rho_v = 0.33$ observed for rigid-chain poly(pyridine-2,5-diyl) with the polymerisation degree of 50.^{122, 123} The polymers manifest fluorescence in solutions; $\lambda_{\max}$ in their spectra are shifted to the long-wave region.

Polyaryleneethynylenes incorporating electron-donor (OAlk) or electron acceptor (OCOAlk) substituents were synthesised¹²⁰⁻¹²² using the $\text{PdCl}_2\text{-Cu(OAc)}_2\text{-PPh}_3$ catalytic system in $\text{Et}_3\text{N-THF}$ solution. The use of THF, which is capable of solvating metal complexes (it is poor solubility of intermediate complexes that prevents formation of high-molecular-weight PARE¹²⁵) and the presence of alkyl substituents in the monomers provide a possibility to obtain polymers with molecular weights up to 100 000. The optical properties of these polymers are presented in Table 18.¹²¹

Oligomers (trimers and pentamers), which are better soluble than their high-molecular-weight analogues,¹²² form mesophases when heated. These oligomers are used in preparation of oriented materials for optoelectronics. The oligomers with short side chains show the best non-linear optical properties.

Some studies were devoted to the synthesis of PARE based on monomers incorporating vinylene groups.^{126, 127} Such reactions

usually yield polyenynes. Conjugated polyenynes incorporating thiophene fragments were obtained by reaction of 3,4-didecyloxy-2,5-bis(2-bromoethynyl)thiophene with diethynylbenzenes **76a-c** in the presence of $\text{PdCl}_2(\text{PPh}_3)_2\text{-CuI}$ in $\text{Et}_3\text{N-THF}$ mixture.¹²⁶

The properties of the thus synthesised polyenynes are presented in Table 19. Thin films were casted from solutions of these polymers.

were prepared^{129–132} by a reaction of 1,3,5-triethynylbenzene with 1,3,5-tribromobenzene or monomers of 1,3-diethynyl-5-bromobenzene type. Taking into account that the dendrite polymers are usually much better soluble than their linear analogues (when isolated before the gel point),^{132–134} one may predict that this approach in chemistry of PARV and PARE will find considerable development.
