^a TFPP is tetra(*o*-fluorophenyl)porphyrin; ^b calculated with respect to the substrate; ^c TDCPP is tetrakis(2,6-dichlorophenyl)porphyrin; ^d Im is imidazole; ^e TMP is tetramesitylporphyrin; ^f TPP is tetraphenylporphyrin; ^g calculated with respect to the oxidant consumed; ^h TF₅PP is tetrakis(pentafluorophenyl)porphyrin; ⁱ DCPO is 2,6-dichloropyridine *N*-oxide.

their structures differed from that of $P^+Fe^{IV}=O$ in all cases. According to their absorption spectra, these compounds were characterised either as $PFe^{IV}=O$ ^{103, 139–141} or $(PFe^{IV}-O)L$ ^{142–145} although the presence of the ligand L in the coordination sphere of the metal has not been established. Similarly, for manganese porphyrinates–NaOCl systems, the length of the Mn–O bond in the active species determined by the EXAFS method is more consistent with an Mn–O–Cl structure.¹⁴⁵ As the $PMn^{IV}=O$ and $PFe^{IV}=O$ complexes can oxidise alkenes but are inactive towards alkanes,^{146, 147} their monooxygenase function is usually associated with their ability to generate more reactive intermediates (formally, pentavalent metal oxo-complexes) at room temperature. The latter cannot be detected by physicochemical methods because of their extremely short lifetime under these conditions.

Other active oxygen donors are less suitable for the preparation of high-valent oxo-complexes of metalloporphyrins: anhydrous hydrogen peroxide destroys iron complexes even at $-30\text{ }^{\circ}\text{C}$;¹⁴⁸ *tert*-butyl hydroperoxide generates cationic isoporphyrins with the ROO-group linked at one of the *meso*-positions.¹⁴⁹

Systems with H_2O_2 and ROOH can generate several reactive species, such as hydroxyl or alkoxy radicals and metal oxo-complexes. Homolytic cleavage of the O–O bond in hydrogen peroxide or alkyl hydroperoxide coordinated with metalloporphyrin yields $PM^{IV}=O$ and free radicals ($HO^{\bullet}$ or $RO^{\bullet}$). Heterolytic cleavage generates $P^+Fe^{IV}=O$ and water (or the corresponding alcohol).

In systems based on cumyl and *tert*-butyl hydroperoxides with iron or manganese porphyrins, the kinetic characteristics and the selectivity of the reaction are independent of the nature of the metalloporphyrin; hence it was concluded^{131, 150, 151} that free radicals $RO^{\bullet}$ and $ROO^{\bullet}$ are reactive species in this process.

Introduction of imidazole (Im) into a manganese tetrakis(dichlorophenyl)porphyrinate (TDCPPMn)– H_2O_2 system changes the kinetic features and the composition of the oxidation products. The high activity of this system was explained¹⁵² by the fact that imidazole used as a nucleophilic axial ligand favoured heterolysis of the O–O bond with the formation of PMn^{VO} complexes and facilitated this cleavage as an electrophilic acid catalyst. The effect of axial ligands on the catalytic function of metalloporphyrins (up to complete suppression of epoxide formation) has also been observed in biomimetic systems of alkene oxidation by monopersulfate.^{153, 154} Cleavage of the O–O and one of the O–H bonds in hydrogen peroxide coordinated with metalloporphyrin is the rate-determining step in the reaction of metalloporphyrins with H_2O_2 .^{147, 155} Traylor *et al.*¹⁵⁶ have suggested that the O–O bond in a hydroperoxide coordinated with metalloporphyrin (as in the case of protic solvents) is always cleaved heterolytically to yield $PFe^V=O$, which further reacts with alkenes or hydrogen peroxide. The interaction with peroxides (H_2O_2 , ROOH) gives rise to the radical intermediates ($HO^{\bullet}$, $HO_2^{\bullet}$, $RO^{\bullet}$, $RO_2^{\bullet}$). By increasing the electronegativity of iron porphyrinate (by introducing substituents into the porphyrin ring), Traylor *et al.*¹⁵⁶ succeeded in performing the reaction of $PFe^V=O$ preferentially with alkenes and thus increased the epoxide yield up to 60%–100% with respect to H_2O_2 .

2. Models with molecular oxygen

The use of bound oxygen as the oxidant allows one, as a rule, to carry out the reactions with high selectivity and simplifies the analysis of reactive intermediates. However, the use of halogen-containing oxidants leads to the contamination of the reaction products with organohalogen compounds and other impurities. In this context, molecular oxygen is the oxidant of choice both from the ecological and the economic points of view.

It was found that Mn, Fe, and Cr tetramethylporphyrinates with azide as the axial ligand catalyse isobutane autooxidation to give *tert*-butyl alcohol at $80\text{ }^{\circ}\text{C}$ with a selectivity of 88%–92%.^{157–159} The activity of the catalyst increases abruptly

with a substitution of the hydrogen atoms in the porphyrin ring by halogen atoms.^{160, 161} When iron *meso*-tetrakis(penta-fluorophenyl)- β -octabromoporphyrinate ($FeTPPF_{20}-\beta-Br_8$) was used as the catalyst, isobutane oxidation proceeded with a selectivity of 92% at room temperature; the catalyst turnover number exceeded 13 000 over 70 h and the catalytic activity was retained for 74 h. However, such efficiency was observed only for the alkanes with tertiary C–H bonds. The system is far less efficient for secondary C–H bonds and is completely inactive with respect to primary C–H bonds.

High selectivity and the fact that no co-catalysts are needed have raised great interest in these systems. Analysis of the absorption spectra recorded at room temperature has revealed that $Fe^{II}TF_5PPCl$ and a Fe- μ -oxodimer ($FeTF_5PP$)₂O, which can be isolated from the solution, are formed in a $FeTF_5PPCl-O_2-C_6H_6$ –iso- C_4H_{10} system.^{160, 161} Non-halogenated FeTPP produce inactive μ -oxo complexes that do not catalyse oxidation of saturated hydrocarbons. Ellis and Lyons¹⁶¹ have postulated the generation of $PFe^{IV}=O$ as the reactive species in this system. However, further studies have demonstrated that the reaction of hydroperoxides with Fe^{II} yields free radicals, which further initiate the chain process.¹⁶²

3. Models with molecular oxygen and a reducing agent

Simulation of the key reaction of monooxygenase catalysis, *viz.*, the activation of molecular oxygen by a metal complex in the presence of an electron donor (reducing agent), is undoubtedly of theoretical and practical interest.

Superoxo- and peroxo-ferryl complexes synthesised from O_2 and iron porphyrinate (PFe) in the presence of a reducing agent are relatively stable compounds, which are inert with respect to alkanes. It was only the introduction of an additional component (acetic anhydride) into the system that has resulted in the first complete chemical model of cytochrome P-450 on the basis of PFe that was active towards saturated hydrocarbons.¹⁶³ The role of the effector in this system was played by acetic acid that was present in admixture with acetic anhydride purified using conventional procedures.^{164, 165}

Examples of these model systems are given in Table 3. Hydrogen in combination with colloidal platinum, sodium ascorbate, dihydropyridine, zinc (powder or amalgam), and electrolysis were used for reduction and a mineral or a carboxylic acid or water as the proton donor.^{163–168}

Alkane oxidation in the presence of O_2 and an electron (and proton) source occurs at normal temperature and pressure. The selectivity and the rate of the reaction depend on the nature of the metalloporphyrin as well as on the electron and proton donors. The product yield with respect to the reducing agent is usually low. The best yield (37%) was obtained in the oxidation of hydrocarbons having weak C–H bonds (indane and tetralin) with Zn as the reducing agent.¹⁶⁸ In non-enzymic systems, it is difficult to obtain high yields of the reaction products with respect to the reducing agent, since the reactive oxidant formed in this process reacts with the substrate and the reducing agent with equal ease. Model systems based on molecular oxygen and the reducing agent are usually less selective than the systems in which active oxygen donors play the role of the oxidants.

Nevertheless, the obvious advantage of such systems is a high oxidation rate, which sometimes exceeds that of enzymic reactions by more than one order of magnitude.

As in the catalytic cycle of cytochrome P-450, the generation of reactive intermediates in biomimetic systems based on molecular oxygen and the electron donor occurs in several consecutive steps. The first step, which is usually rate-limiting, is the reduction of metalloporphyrin. The reduced metalloporphyrins add oxygen to yield a dioxygen complex with a rate constant of the order $10^7\text{ M}^{-1}\text{ s}^{-1}$ (see Ref. 169). This reaction is reversible but the $TpivPPFe^{II}(O_2)(Im)$ complex could be isolated if sterically hindered iron tetrakis(*o*-pivaloylaminophenyl)porphyrinate

Table 3. Cycloalkane oxidation in systems with O₂ and a reducing agent.

Substrate	Catalyst	System	Solvent	Products (ratio)	Number of catalytic cycles /min ⁻¹	Ref.
Adamantane (8)	MnTPPCL ^a + MeIm ^b	H ₂ /Pt–HCl–(PhCO) ₂ O	MePh–EtOH	9 + 10 + 12 (15:1.7:1)	0.004	166
		Zn dust–AcOH	MeCN–CH ₂ Cl ₂	9 + 10 + 12 (20:2:1)	0.5	168
		Zn dust–AcOH	MeCN–CH ₂ Cl ₂	cyclooctanol + + cyclooctanone (1.8:1)	0.5	168
Cyclohexane (4)	MnTPPCL	sodium ascorbate	C ₆ H ₆	5 + 6 (1:7.5)	0.006	167
	hemin ^c + NaOH	thiosalicic acid	(Me) ₂ CO–H ₂ O	5 + 6 (1.8:1)	0.4	121
	FeTpivPPCL ^d	Zn dust–AcOH	MeCN	5 + 6 (1.7:1)	2	164
	FeTpivPPCL	Zn dust–AcOH–MV ^e	MeCN	5 + 6 (3.3:1)	50	164
	FeTPPCL	Zn dust–AcOH–MV	MeCN	5 + 6 (2:1)	340	164
	FeTPPCL	Zn dust–PhCOOH–MV	MeCN	5 + 6 (1.5:1)	340	164

^a TPP is tetraphenylporphyrin; ^b MeIm is *N*-methylimidazole; ^c hemin is a natural iron-containing protoporphyrin IX; ^d TpivPP is tetrakis(*o*-pi-valoylaminophenyl)porphyrin; ^e MV is methyl viologen.

(FeTpivPP) and *N*-methylimidazole (MeIm) or 1-tritylimidazole (TrIm) were used.^{170,171}

In the presence of a reducing agent, the addition of oxygen to the reduced metalloporphyrin is followed by the reduction of the oxygen complex. The rate constant for the reduction of TpivPPFe^{II}(O₂)(TrIm) by methylviologen (MV) radical cation is equal to $2.2 \pm 0.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ (Ref. 172).

Protonation of the oxygen atom of the peroxo group results in the homolytic or heterolytic cleavage of the O–O bond depending on the pH of the medium and the polarity of the solvent (similarly to the systems based on hydrogen peroxide).¹⁷³ However, no direct correlation between solvent polarity and the homolysis or heterolysis of the O–O bond in metalloporphyrin intermediates has been found.

The kinetics and the mechanism of generation of reactive species that interact with alkanes have been extensively studied for metalloporphyrin–O₂–carboxylic acid–Zn systems.^{165,174} The configuration of the chiral carbon atom of *cis*- or *trans*-1,2-dimethylcyclohexane is not retained in the catalysis by iron porphyrins. The competitive oxidation of C₆H₁₂ and C₆D₁₂ in this system has a relatively low KIE (2–3). These data permit one to postulate, with an equal probability, both a radical and a molecular mechanism. Analysis of substrate selectivity in the competitive oxidation of cyclopentane and cyclohexane (the so-called 5/6 parameter) was more informative. The dependence of this parameter on the nature of substituents in the phenyl rings of iron porphyrinate, and its magnitude (0.38–0.50), which is characteristic of an electrophilic attack by a positively charged reagent,¹⁷⁵ suggest that the ferryl (P⁺Fe^{IV}=O) or perferryl (PFe^V=O) complexes are the reactive species.

The ratio of the rate constants for the attack at the C–H bond of cyclopentane and cyclohexane (the 5/6 parameter) is being employed more and more often for the study of mechanisms of various reactions of cycloalkanes and alkanes. It is reasoned¹⁷⁵ that this parameter is a measure of the partial charge on the carbon that is attacked in the transition state. The 5/6 ratio is close to unity and does not depend on the reagent charge in reactions where H is detached by a radical or a radical ion. In the case of an electrophilic attack by a positively charged reagent, this parameter is equal to, or less than, 0.5 depending on the reagent charge.¹⁷⁵

In the catalysis by MnTPPCL in an O₂–carboxylic acid–Zn system, the value of the parameter 5/6 (0.7) is close to that observed in the absence of the metalloporphyrin. However, partial retention of configuration (25%) in the oxidation of *cis*- or *trans*-dimethylcyclohexanes shows that the reaction catalysed by MnTPPCL is not, at least partly, a free-radical process. Oxidation of alkenes and the regioselectivity of *n*-heptane oxidation in MnTPPCL–AcOH–Zn–MeIm and PhIO–MnTPPCL–MeIm systems follow the same regularities.¹⁶⁸

The experimental results altogether lead to a conclusion about a single mechanism of the generation of reactive species in the systems based on iron and manganese porphyrins with molecular oxygen and proton and electron donors. The candidates for the reactive intermediates in these systems are high-valent oxo-complexes of metalloporphyrins formed by reductive activation of molecular oxygen in the presence of a proton donor *via* a catalytic cycle that is similar to that of cytochrome P-450. The reactive species in these systems, as well as in the systems with different active oxygen donors may differ from each other depending on the starting reagents. This follows from the differences in the stereoselectivity and KIE in different systems that generate reactive metalloporphyrin complexes.¹²²

4. Models with molecular oxygen and an aldehyde

It was found¹⁷⁶ that cyclohexane can be efficiently oxidised to give cyclohexanol and cyclohexanone by molecular oxygen in the presence of halogenated metalloporphyrins and propionaldehyde at 30 °C. The relative yields of the oxidation products depends on the nature of the central ion and the porphyrin ligand of the catalyst. The maximum turnover number for the catalyst (**24**) and the maximum yield with respect to the substrate (5%) were obtained for manganese *meso*-tetrakis(2,6-dichlorophenyl)-β-octachloroporphyrinate (MnTDCPP-β-Cl₈). The ketone/alcohol ratio varied from 0.8 for FeTDCPP to 4.3 for MnTDCPP-β-Cl₈ depending on the conditions. After completion of the reaction, an appreciable amount of the surviving catalyst was found only in the case of halogenated manganese porphyrinate. This system involves two oxidants, *viz.*, molecular oxygen and a peroxy acid,^{176–178} which is formed according to the scheme:

The aldehyde acts simultaneously as the reducing agent for the metalloporphyrin and the source of an effective oxidant. The peroxy acid reacts with the metalloporphyrin either to form high-valent oxo-complexes [pathway (a)] or to decompose *via* a radical mechanism [pathway (b)].

Thus, according to this scheme,^{176–178} both high-valent oxo-complexes of metalloporphyrin and free radicals are the reactive species in this system. In addition, a possibility of direct inter-

action of a hydrocarbon with metalloporphyrins having a high oxidation potential (*e.g.*, PCo^{111}) can also be considered:

It is noteworthy that this oxidation mechanism is mostly hypothetical and demands further investigation.

5. Photocatalytic models with O_2

Irradiation of cycloalkanes with light of wavelength ~ 350 – 450 nm initiates their oxidation by molecular oxygen (20°C , 200 Torr O_2) in the presence of iron complexes with halogenated tetraphenylporphyrins. In this system, cycloalkanes are oxidised to the corresponding alcohols and ketones. The turnover number of the catalyst does not exceed 230 due to its destruction.

The selectivity of cyclohexene oxidation is distinguished from enzymic processes: epoxides are not produced, while the corresponding alcohol and ketone are formed in high yields (5000 and 4500 reaction cycles for cyclohexenol and cyclohexenone, respectively). Based on these data, a free-radical oxidation mechanism has been proposed for this system. Presumably, hydroxyl radicals generated in the photoactivation of $\text{PFe}^{\text{III}}-\text{OH}$ and peroxy radicals $\text{ROO}^\bullet$ formed in the reaction of alkyl radicals with oxygen are the reactive species.¹⁷⁹

Thus, in models of heme monooxygenases with various oxidants, alkanes can react under mild conditions due to their interaction with active radicals or high-valent metal complexes. The KIE and the stereoselectivity of all biomimetic systems generating high-valent oxo-complexes of metalloporphyrins vary considerably depending on the nature of the metal and the substituents in the phenyl rings of the metalloporphyrins, the nature of the active oxygen donor, and even the properties of the reaction medium.¹²²

There are two viewpoints as to whether the observed variations reflect differences in the structures of reactive intermediates. Some authors^{141,148} believe that it is the $(\text{P}^+ \cdot \text{M}^{\text{IV}}\text{O})$ complex formed in all these systems (*e.g.*, by disproportionation of two ferryl complexes) that is the species that gets alkanes involved in the oxidation. According to Shteinman¹⁸⁰ and Hill¹⁸¹ the reactive complexes that react with alkanes may vary depending on the structure of the original reagents and the reaction conditions. The differences in the stereoselectivity and the magnitude of KIE in systems with different oxygen donors point to differences in the structures of reactive intermediates. Analysis of the experimental data altogether for various types of systems provides a simple explanation for the effects of different factors (polarity, acidity or basicity, the presence of axial ligands in metalloporphyrins, *etc.*) on the structure of the reactive intermediates and, correspondingly, their reactivity with respect to different substrates.

It should be noted that the reactive complexes, $\text{P}^+ \cdot \text{M}^{\text{IV}}\text{O}$, bear a positive charge. Depending on the medium and the nature of the ion, different species can exist in the solution, such as free ions $(\text{P}^+ \cdot \text{M}^{\text{IV}}\text{O})$ (in polar media) and ion pairs $(\text{P}^+ \cdot \text{M}^{\text{IV}}\text{O})^+ \text{L}^-$ (in less polar and non-polar media). Naturally, their activity towards alkanes will also be different. Nucleophilic and electrophilic properties of the complex and the environment are important for the formation of $(\text{P}^+ \cdot \text{M}^{\text{IV}}\text{O})^+$, which is more reactive than $\text{PM}^{\text{III}}\text{OL}$. Axial ligands, such as imidazole, will play the role of nucleophiles, while acids will favour the heterolytic cleavage of the $\text{O}-\text{L}$ bond.

Thus, the model systems based on metalloporphyrins catalyse the oxidation of hydrocarbons in organic solvents; the parameters of this process (temperature, reaction rate) are in many cases similar to those observed in enzymic reactions. In the absence of the stabilising effect of the protein, metalloporphyrins undergo decomposition under the oxidation conditions, which results in the loss of the catalytic activity during the reaction. Analysis of the experimental data accumulated to date demonstrates that halogenation of the porphyrin macrocycles increases the stability and the catalytic activity of metalloporphyrin complexes. Halogenated metalloporphyrins containing halogen atoms both in the

phenyl and the pyrrole rings are superior in this respect. Halogenation enhances the oxidation potential both of the metal centre and of the porphyrin ligand. This, in turn, increases the stability of the complex under the oxidation conditions and the electrophilicity of the metal centre, and, correspondingly, the catalytic activity of the metalloporphyrin complex.

One of the ways of increasing the selectivity of biomimetic systems is the use of porphyrin ligands with bulky groups that create steric hindrances around the active centre. The molecular design of porphyrins is becoming more perfect in this aspect. Recently, a method for the synthesis of a new family of functional models of hemes (the so-called *double picket fence*) with chiral surfaces on both sides of the plane of the porphyrin rings has been proposed.¹⁸² The use of spatially organised porphyrin complexes strongly increases the proportion of primary alcohols and aldehydes in the products of oxidation of linear alkanes, thus simulating ω -hydroxylation, which is a characteristic feature of enzymic catalysis.^{29,183–185}

Another way of increasing the selectivity and the stability of catalysts is the simulation of the microenvironment of the active centre of enzymes through the construction of organised molecular systems. This term refers to multicomponent catalytic systems with an optimum spatial arrangement and energetic and orbital compatibility between the components of the catalytic system and the substrates. Some general principles for the design of organised molecular species, *viz.*, the models of cytochrome P-450, have been formulated in order to achieve optimum rates and selectivity of the monooxygenase reaction.¹⁸⁶ Methods of molecular design are widely employed for enhancement of various characteristics of the chemical models.

6. Metalloporphyrins in microheterogeneous environments and immobilised on supports

a. Micelles

The selectivity of cyclohexane oxidation in an iron tetrakis(*p*-hexadecyloxyphenyl)porphyrinate ($\text{FeTH}-\text{DOPP}$)– PhIO microheterogeneous system is higher than that of the homogeneous analogue (cyclohexanol becomes the only product) but the rate of the reaction decreases.¹⁴²

Different reactive species have different regioselectivities. To estimate it, the parameter $1^\circ/2^\circ/3^\circ$, *i.e.*, the ratio of the products of the attack at the primary, secondary, and tertiary $\text{C}-\text{H}$ bonds with allowance made for the number of bonds of each type, has been proposed.¹⁸⁷ In the case of metal complexes, steric factors can play an important role. Therefore, metal complexes can attack

Table 4. The regioselectivity of *n*-hexane oxidation by metalloporphyrin chemical enzymic systems.

Catalyst	Oxidant	Medium	Selectivity index ^a	Ref.
FeTHDOPPCl^b	PhIO	C_6H_6	0.003	142
	PhIO	$\text{H}_2\text{O}-\text{Triton X-100}$	0.021	
	PhIO	$\text{H}_2\text{O}-\text{DMPC}^c$	0.050	
	PhIO	$\text{H}_2\text{O}-\text{CD}^d$	0.211	
	PhIO	$\text{H}_2\text{O}-\text{MeCD}^e$	0.234	
MnTPPOAc	PhIO	C_6H_6	0.027	150

Cytochrome P-450 (CYP2B4)	O_2	H_2O	0.160	

^a The regioselectivity index is equal to the ratio of the yields of oxidation products of primary and secondary $\text{C}-\text{H}$ bonds taking into account the ratio of these bonds in the hexane molecule; ^b THDOPP is tetrakis(*n*-hexadecyloxyphenyl)porphyrin; ^c DMPC is dimyristoyl phosphocholine; ^d CD is cyclodextrin; ^e MeCD is methylcyclodextrin; ^f TTMP , is tetrakis(2,4,6-trimethoxyphenyl)porphyrin; ^g TTPPP is tetrakis(2,4,6-triphenylphenyl)porphyrin.

a methyl group or an adjacent methylene group more easily than the less accessible methine group or a CH₂ group inside a polymethylene chain.

Table 4 presents data on regioselectivity of hexane oxidation by cyclodextrin (CD) microheterogeneous model systems and (for comparison) enzymes. The regioselectivity with respect to the terminal group increases with an increase in the degree of ordering of the system by nearly two orders of magnitude in comparison with the homogeneous analogue. It is seen that the selectivity of certain microheterogeneous systems is close to that of the most regioselective isoform of cytochrome P-450_{LM2} (CYP2B4). Apparently, the molecules of hydrophobic PFe and alkane in these organised molecular systems are specifically arranged relative to one another in such a way that the reaction at the terminal CH₃ group becomes preferential.

b. Metalloporphyrins in a phospholipid bilayer

Groves and Neumann¹⁸⁹ have developed a system with an optimum spatial arrangement based on membrane-bound Mn tetrakis[*o*-(cholenylamido)phenyl]porphyrin, Mn^{III}(ChP)Cl, which simulates the hydrophobic microenvironment of the active centres of enzymes. Being incorporated into phospholipid vesicles, the catalyst occupies the central position in the lipid bilayer in such a way that the plane of the porphyrin ring becomes parallel to the water surface. Both molecular oxygen in the presence of a reducing agent and sodium periodate can be used as alkane oxidants.

Selective hydroxylation of the C(25) carbon atom of cholesterol, which does not involve the more reactive C(5) = C(6) double bond of the molecule, is the most striking result of the application of molecular design principles to this particular system. Groves and Neumann¹⁸⁹ attribute this effect to the proximity of the tertiary carbon atom C(25) to the metal in the centre of the complex. The selectivity of the process depends on the oxidant. The reaction rate is very low, but the catalyst retains its stability over a long period of time.

c. Metalloporphyrins immobilised on supports

The number of a catalyst's reaction cycles is usually restricted due to the drop of its activity in the course of oxidation. This problem has been solved in Groves' molecular organised systems, but the system itself is extremely complex. Another approach to the

simulation of the catalyst's microenvironment is its immobilisation on a solid support, *i.e.*, the formation of heterogeneous oxygenase systems. Examples of such systems are given in Table 5.

Immobilisation of a metalloporphyrin on porous glass or polyvinylpyrrolidone (PVP) markedly increases the selectivity of alcohol formation. Immobilisation of an iron–porphyrin complex on zeolites¹⁸⁸ and especially on graphite, strongly increases the steric effects, which are observed in hexane oxidation in model systems with active oxygen species.¹⁹² The effect of the matrix is not confined to the increase in the steric hindrances around the active oxidant. It can also be accompanied by a sieve effect, which is well-known for zeolites and accounts for the differences in the substrate specificity.

Heterogeneous systems of alkane photooxidation by oxygen in the presence of iron and manganese porphyrins immobilised on TiO₂-modified montmorillonite have also been developed.¹⁹³

As expected, the heterogenisation of metalloporphyrin catalysts is accompanied by a decrease in the rate of hydrocarbon oxidation. At the same time, heterogeneous systems have significant advantages over their homogeneous analogues. Immobilisation of metalloporphyrins on various supports not only enhances the selectivity of the reactions catalysed by them but also increases their stability in the majority of cases. For example, immobilisation of iron porphyrinate on porous glass¹⁶⁴ increased the number of reaction cycles nearly 200-fold.

It is generally accepted that the reactive species in systems with metalloporphyrins immobilised on supports are similar to those in solution. Apparently, in most cases this conclusion reflects the real situation; however, it should be kept in mind that binding of the catalyst with the support can change its coordination properties and the ability to produce reactive intermediates.

7. The mechanism of alkane oxidation in systems based on metalloporphyrins

The transfer of the oxygen atom by porphyrin complexes to C—H bonds in natural and model systems is a matter for debate. Various types of molecular mechanisms and a crypto-radical oxygen rebound mechanism have been considered in the context of enzymic hydroxylation. In model systems where the yield of radicals into bulk solution is not excluded, an ordinary radical process can also occur *via* the intermediate formation of a hydro-

peroxide; the final products of its conversions are an alcohol and a ketone.

High values of KIE and isomerisation of the molecules subject to oxidation are usually regarded as proofs of the oxygen rebound mechanism both in natural and model systems.¹³² However, despite the seemingly convincing character of these arguments, a careful scrutiny of the experimental data has demonstrated a discrepancy in this concept for biomimetic systems.

Isomerisation observed in the hydroxylation of aromatic compounds (the NIH shift) and in the epoxidation of alkenes (simultaneous formation of aldehydes and epoxides) in chemical and enzymic systems points to the existence of reactive intermediate complexes (rather than free radicals). The effect of radical traps on alkane oxidation may also indicate both the generation of free radicals in parallel and the formation of an intermediate complex in which the alkyl group may acquire sufficient mobility for its reaction with the traps. In addition, the thermodynamic feasibility of radical formation, especially in the case of a strong C–H bond, raises certain doubt. Calculations have shown¹⁹⁴ that if a purely radical mechanism is realised in the first stage, high rates of the reaction of high-valent metal complexes with alkanes can be reached only in the case of weaker tertiary C–H bonds.

The value of the KIE is widely used in the interpretation of mechanisms as the criterion of hydrogen transfer in the form of H^+ , H^- , or $H^\bullet$ in the limiting step as well as in the analysis of the transition state structure.^{100, 195} Small values of KIE ($\sim 1-2$) have been determined for oxidation reactions involving a very reactive (and therefore very non-selective) $^{\bullet}OH$ radical. Higher values of KIE point to the involvement of a more selective intermediate (e.g., metallooxene) as the active oxidant.

For many metalloporphyrins as well as for cytochrome P-450, hydroxylation of C–H bonds in the presence of atomic oxygen donors is characterised by a high isotope effect ($k_H/k_D > 9$). As in the case of natural monooxygenases, for their chemical models^{138, 186, 196} it was assumed that the formation of the ($PMOH + R^\bullet$) pair results from the transfer of the hydrogen atom from the substrate to the reactive intermediate, while the differences in the KIE values are accounted for by a different degree of linearity of transition states. High value of k_H/k_D must correspond to a symmetrical linear transition state for the transfer of the H atom. At the same time, theoretical calculations show that the transition state becomes practically linear after detachment of the hydrogen atom from the methane molecule by H and O atoms or by the $^{\bullet}OH$ radical, but the experimental values of the KIE are small in this case. Moreover, it was established that in some model systems based on metalloporphyrins and active oxygen donors, the experimental values of the KIE substantially exceed the maximum values calculated from the difference in zero point energy levels of the C–H and C–D bonds ($k_H/k_D \sim 7-8$ at 20 °C).¹⁹⁵ The high value of the KIE (> 9 at 25 °C) may indicate a contribution to the mechanism of proton tunnelling (rather than that of the deuteron, which is heavier than the proton and less prone to tunnelling).¹⁰⁰ Obviously, the tunnelling conditions develop gradually but not spasmodically. It is natural to speculate that in all the reactions that occur by this mechanism, the tunnelling effect is present to a greater or a lesser degree, this should be observed for high and narrow barriers.

Hence, a question arises as to why the KIE is so different in the hydroxylation reactions occurring *via* a similar mechanism. It should be noted that in reactions with a high KIE ($k_H/k_D > 6$) its increase is accompanied by an increase in stereoselectivity.¹⁷⁴ At the same time, for systems with a relatively low KIE (about 2), the stereoselectivity varies over a very wide range: from 0% for the $FeTPPCl-O_2-Zn-AcOH$ system to 90% for the $MnTDCPPCl-KHSO_5$ system.

The effect of the medium polarity on the KIE can be accounted for by the lowering of the potential barrier with an increase in ionisation and by the tunnelling effect. In more polar

media, the proton is somewhat 'heavier', being more strongly solvated by the solvent molecule, and the ratios of the masses of the solvated protons and deuterons are smaller than those of the free ones.

Apparently, direct interaction of a high-valent metalloporphyrin complex with the C–H bond of the substrate, which is accompanied by the insertion of the O atom into the C–H bond *via* an intermediate complex with a pentacoordinated carbon is the most probable mechanism for the systems that simulate biological hydroxylation. That the direct insertion is possible follows from the complete retention of the original configuration of the tetrahedral carbon atom observed in some cases, e.g., in the hydroxylation of 1,2-dimethylcyclohexane by an iron–porphyrin complex in a biphasic water–benzene system in the presence of $NaOCl$.^{142–145}

Isomerisation, which is sometimes observed in the oxidation and which is usually considered as evidence in favour of the intermediate formation of radicals, is often in contradiction with the radical mechanism on closer inspection. Thus the hydroxylation of *all-exo*-2,3,5,6-tetradeuterionorbornane using the *meso*-tetrakis(2,6-dichlorophenyl)- β -octabromoporphyrin complex ($Br_8TDCPPFe$) with pentafluoriodosobenzene¹⁹⁷ was accompanied by a partial transfer of deuterium to the *endo*-position. This was interpreted by intermediate formation of a norbornyl radical; however, analysis of the distribution patterns of the hydroxylation products has led to a conclusion that the probabilities of the rotation of the radicals generated by hydrogen detachment from the *exo*- and *endo*-positions of the ring differ drastically (by more than one order of magnitude). If it is assumed that the isomerisation occurred within the intermediate complex in which the carbon atom coordinates the oxygen atom linked with the Fe atom, then it follows from the same data that the rotation leading to the isomerisation is equally probable when the oxygen is added at both the *exo*- and the *endo*-positions. In our opinion, the second mechanism is preferable, especially if one takes into consideration the results obtained for the natural cytochrome P-450.

Hydroxylation of *R*- and *S*-enantiomers of monodeuterio-ethylbenzene with iodobenzene in the presence of a chiral iron–porphyrin complex, which yields all possible isomers of 1-phenylethanol and its deuterioisotopomers, has been studied.¹⁹⁸ It has been found that the main product is formed stereoselectively in both cases and is virtually pure monodeuteriophenylethanol, whereas the deuterium content in the minor product is only 50%. In order to explain these results within the framework of the oxygen rebound mechanism, Groves and Viski¹⁹⁸ had to assume that the intermediate radical formed rotates with a marked probability only in the detachment of H from the *pro-S*-position but does not rotate at all when the detachment occurs from the *pro-R*-position. If one admits the mechanism of oxygen insertion with intermediate formation of a pentacoordinated carbon, the observed results can be easily explained by the isotope effect observed in the insertion of the O atom into the C–H and C–D bonds. If the isotope effect is great, the rate of its insertion into the C–H bond can be much higher than the isomerisation rate, whereas for the C–D bond the rates of the insertion and isomerisation are comparable.

Quantitative estimation of the relative rates of insertion and isomerisation for this reaction¹²⁰ gave a correlation between the rate constants for addition, insertion, and isomerisation. The parameters obtained permit comparison of the experimental and the calculated relative yields of the hydroxylation products (see Table 6). Complete agreement of the experimental and calculated ratios of the reaction products provides evidence for the proposed mechanism. Indeed, the ratio of the reaction products, e.g., for (*S*)-deuterioethylbenzene, can be predicted from the parameters calculated for the *R*-isomer without any additional postulates, and the calculated and the experimental values coincide.

Table 6. The relative yields of the isomers and the deuterioisotopomer of 1-phenylethanol during the oxidation of (*R*)- and (*S*)-(1-deuterioethyl)benzene.¹²⁰

Substrate	Isomer ^a	Relative yield (%)	
		experimental ¹⁹⁸	calculated ¹²⁰
(<i>R</i>)-(1-Deuterioethyl)benzene	<i>R</i> _H	23	22.9
	<i>R</i> _D	19	19.1
	<i>S</i> _H	1	1.1
	<i>S</i> _D	57	56.9
(<i>S</i>)-(1-Deuterioethyl)benzene	<i>R</i> _H	2	1.7
	<i>R</i> _D	87	87.3
	<i>S</i> _H	6	6.0
	<i>S</i> _D	5	5.0

^a The H and D indices are related to the products of oxidation of the C—H and C—D bonds, respectively.

It can be noted that theoretical calculation¹⁹⁹ shows that triprotonated methane, CH₃³⁺ (*i.e.*, heptacoordinated carbon) can, in principle, exist; other authors^{200,201} have succeeded in obtaining complexes of penta- and hexa-coordinated carbons as stable crystalline salts, $\{[(C_6H_5)_3PAu]_5C\}^+$ and $\{[(C_6H_5)_3PAu]_6C\}^{2+}$.

Thus, the non-radical mechanism of oxidation, which involves the attachment of the oxygen atom at the C—H bond and its subsequent insertion into this bond, provides quantitative characteristics for the rationale of the unusual distribution of the reaction products and the isotope effects of hydroxylation of isotopically modified molecules in enzymic and biomimetic systems in which H and D atoms interchange in the course of hydroxylation. Analysis of the rates of the separate stages of this reaction calculated for the new mechanism has revealed interesting and unusual dynamics of the hydroxylation process. The kinetic parameters give a noncontradictory pattern of the reaction dynamics without any recourse to improbable statements, which distinguishes it favourably from the oxygen rebound mechanism employed so far.

Thus, the systems based on metalloporphyrins discussed above not only represent functional models of heme monooxygenases. Many of them simulate the natural process both as regards the reactive species and the oxidation mechanism. Recent data demonstrate significant advances in the design of novel systems based on metalloporphyrins and shed additional light on the mechanisms of reactions occurring in them, although the proposed oxidation schemes are often hypothetical. Further investigations are necessary in order to create more efficient systems and gain a deeper insight into their mechanisms.

IV. Models of non-heme monooxygenases

1. Mononuclear models of non-heme monooxygenases

The systems in which alkane hydroxylation is concomitant with the oxidation of low-valent metals by molecular oxygen can be regarded as the simplest functional models of non-heme monooxygenases. The concomitant oxidation of cyclohexane in systems with FeCl₂ and SnCl₂ in acetonitrile, which is a rather efficient process, can serve as an example.^{202–204} The yield of the alcohol (calculated with respect to the metal) can be increased by lowering the concentration of the complex. Under optimum conditions, it can reach 20% with SnCl₂ and 30% with FeCl₂. The system with SnCl₂ manifests high selectivity (under certain conditions the alcohol is formed as the only product). Thus with an excess of the substrate, the SnCl₂:O₂:ROH ratio is 1:1:1, *i.e.*, it is the same as for the monooxygenase reaction. However, a detailed kinetic analysis has shown that this reaction proceeds *via* a

branched radical-chain mechanism, which involves the [•]OH radical.¹

A great number of analogous systems including simple salts (FeCl₂, FeBr₂, FeI₂, MnCl₂, MnBr₂, VCl₂, CuCl₂, NiCl₂) in which cyclohexane is oxidised to give the alcohol and the ketone, have been described; the yields are nearly identical for different salts.²⁰⁵ The oxidation of cyclohexene does not yield the epoxide, cyclohex-2-enol being the main product. The regioselectivity of hydroxylation of 2-methylbutane (*i.e.*, the ratio of yields of the tertiary, secondary, and primary alcohols formed, is in accord with the regularity that is characteristic of the [•]OH radical: 3°/2°/1° = 13:5:1. Toluene is oxidised to both benzyl alcohol and isomeric cresols (predominantly the *ortho*- and *para*-isomers). These systems are usually characterised by a low value of KIE in the oxidation of C₆H₁₂ and C₆D₁₂,²⁰² which is also typical of the hydroxyl radical.

One of the few proofs of the participation of non-radical intermediates in such systems has been found in the study of alkane oxidation in the Ph₂Sn—O₂ system.²⁰⁶ Partial stereospecificity (20%) observed in the oxidation of *trans*-dimethylcyclohexane is suggestive of the oxenoid reaction that occurs as a background to the radical process. It has been assumed²⁰⁶ that the peroxo complex Ph₂SnO₂ is the reactive intermediate in this reaction.

The system discovered in 1954 by Udenfriend *et al.*²⁰⁷ was one of the first functional models of non-heme monooxygenases based on iron complexes. This system was made up of ascorbic acid and an Fe^{II} complex with ethylenediaminetetraacetate (EDTA) and could hydroxylate aromatic compounds by molecular oxygen. Later, Hamilton⁸⁸ found that this system could also hydroxylate cyclohexane (although in low yield) and epoxidise cyclohexene. In further studies, numerous systems containing non-heme complexes of bi- and tri-valent iron together with oxygen and a reducing agent or a source of active oxygen in various solvents have been proposed and analysed (Table 7).

As can be seen from Table 7, these systems simulate many reactions of atomic oxygen transfer catalysed by monooxygenases, such as aliphatic and aromatic hydroxylation, oxidation of heteroatoms, and epoxidation of alkenes. It is also evident that the characteristics of model systems (selectivity, isotope effect) strongly depend on the nature of the ligand, the source of active oxygen, and the presence of water.

Peroxides or molecular oxygen as oxidants together with various reducing agents are generally used in non-heme models. There is little or no data on the non-heme complexes (other than with cyclam²¹⁴ and cyclidene¹⁹⁷) that can hydroxylate alkanes by atomic oxygen donors, such as iodosobenzene. Peroxides as oxidants simulate more completely molecular oxygen activation by monooxygenases including the stages of peroxo complex formation and O—O bond cleavage. However, difficulties emerge because free radicals generated simultaneously with the ferryl species initiate radical-chain oxidation.²¹⁷ Most papers devoted to this problem are aimed at the search for new ways of estimating the non-radical contribution to the overall oxidation.

One first proof of the non-radical hydroxylation catalysed by iron salts was found in cyclohexanol oxidation by hydrogen peroxide in the presence of Fe^{II}(ClO₄)₂ in acetonitrile.²⁰⁸ It was found that the main oxidation product was *cis*-cyclohexane-1,3-diol obtained in a more than 70% yield. Such selectivity was attributed to the formation of a complex between the active oxidation intermediate, Fe^{IV}=O, and the OH group of the original alcohol. The nearest C—H bond, which is accessible for the attack, is that at the C(3) atom. Later, it was shown that this system can hydroxylate methane (*k*_H/*k*_D = 5) and ethane and oxidise dimethyl sulfoxide to dimethyl sulfone with a selectivity of about 96%.^{209,218} The data obtained have led to a conclusion about the involvement of oxoferryl in the hydroxylation of light alkanes at a low (below 1.5 M) concentration of H₂O₂ in solution.

It has been found that the selectivity of hydrocarbon oxidation concomitant with the activation of H₂O₂ on iron complexes in

aprotic solvents ^{219, 220} differs markedly from the selectivity of the radical-chain oxidation initiated by ·OH radicals. ²⁰² This can be accounted for by the possibility of heterolytic cleavage of hydrogen peroxide with the formation of high-valent iron oxo-complexes, Fe^{IV}=O and Fe^V=O, as the active oxidation intermediates.

The system based on the Fe^{II} complex with 1,4,8,11-tetraazacyclotetradecane (cyclam) and H₂O₂ (Table 7) is specific in that it can effectively epoxidise alkenes and hydroxylate alkanes. ²¹⁴ It was suggested that this system contained an iron peroxo-complex stabilised by a hydrogen bond with the nitrogen of the ligand as the reactive epoxidising agent.

Various tripodal ligands have been used to control the coordination sphere of iron ²¹⁶ (Table 7). By applying Me₂S as the oxene trap, Leising *et al.* ²¹⁶ have demonstrated that the formation of the alcohol and the ketone in the cyclohexane oxidation by *tert*-butyl hydroperoxide occurs *via* a pathway which is different from that operating in the formation of dialkyl peroxide: the former two are apparently generated through an oxoferryl intermediate, while the latter is formed under the action of radicals. The results obtained earlier for heme models were also confirmed: electron-donor ligands at the Fe atom favour heterolytic dissociation of the peroxide and provide the stabilisation of the high-valent state of iron in the oxo-complex.

2. The Gif systems

The so-called Gif systems (named after the French town Gif-sur-Yvette) the first variant of which was proposed by Barton *et al.* ²²¹ can also be related to the above-described model systems. In the decade that followed, these systems were intensely investigated, ^{222–226} and several versions were proposed (Table 8).

In all these versions, the Gif systems had a similar composition analogous to that of the above-mentioned mononuclear models. A characteristic feature of these systems is that they employ a pyridine–carboxylic (usually, acetic) acid mixture in various proportions (as a rule, 10 : 1) as the solvent. The majority of Gif systems utilise iron complexes as the catalyst with various ligands that strongly influence the rate of the reaction. Thus, the addition of picolinic acid to FeCl₃·6H₂O increases the reaction rate by a

Table 8. Gif systems.

^a The nomenclature of the Gif systems was proposed by Barton. ²²³

factor of tens, whereas pyridine-2-phosphoric acid fully inhibits this process. ²³⁹

The Gif systems have attracted the attention of investigators owing to their unusual selectivity in alkane oxidation. It was believed at first that secondary C–H bonds are oxidised more efficiently than tertiary ones (the 2°/3° ratio in the oxidation of adamantane reached 22, and for *trans*-decalin it was 36), the ketone being the main product. Later, it was found that in addition to the oxidation products, tertiary adamantyl radicals also yield coupling products with pyridine the content of which increases with a decrease in the oxygen concentration. At the same time, secondary adamantyl radicals do not form coupling products with pyridine irrespective of the oxygen concentration. ²²⁷ The regioselectivity of adamantane oxidation in these systems is 2°/3° = 1.0 : 1.1 taking into account coupling products. Although the tertiary C–H bond does react several times faster than the secondary one, the selectivity of this reaction still differs markedly from that observed in ordinary radical processes.

Gif reactions can be conducted in *tert*-butyl alcohol and even in water at the corresponding pH values. ^{228–230} The predominance of a ketone among the reaction products, which is characteristic of the Gif systems, is determined by the solvent

(pyridine–acetic acid), which plays the role of a buffer by maintaining the pH at 6.5 which favours the catalytic dehydration of alkyl hydroperoxide to ketone.

The oxidation of alkyl-aromatic compounds in Gif systems yields the corresponding aldehydes and the ketones. The oxidation involves predominantly the secondary C–H bonds, but not the aromatic ring.²³¹ In the case of terminal disubstituted alkenes, the cleavage of the C=C bond yields a ketone and formaldehyde.²³² The presence of readily oxidisable substrates, such as alcohols, thiols, PPh₃, *etc.*, does not produce any inhibitory effect on the alkane oxidation in these systems.^{228, 233, 243}

The detection of an alkyl hydroperoxide as an intermediate product of the cyclohexane oxidation was an important stage in the study of the mechanism of action of the Gif systems.²³⁴ In these systems, cyclohexyl hydroperoxide is nearly completely converted into cyclohexanone (the ketone/alcohol ratio reaches 10). Alkyl hydroperoxides are intermediate products in the alkane oxidation in all the versions of the Gif systems including copper-containing ones.²⁴³ Experiments with ¹⁸O₂ have shown that it was molecular oxygen (but not H₂O₂) that was the donor of the oxygen atoms in the alkyl hydroperoxide.²²⁸

It is natural to suppose that alkyl radicals are the precursor of hydroperoxides. This assumption has been confirmed by experiments with radical traps (Ph₂Se₂, Ph₂S₂, CCl₄, *etc.*), which generate the corresponding monosubstituted alkanes instead of the ketone.^{234, 244} At low pressure (down to 40–10 mm Hg), where the concentration of O₂ and the yields of the oxidation products are minimal, a paramagnetic trap, 2,2,6,6-tetramethylpiperidine-*N*-oxyl (TEMPO), yields the corresponding derivatives with secondary and tertiary adamantyl radicals, the yield and the selectivity index (2°/3°) being the same as those for the oxidation products at normal pressure.²²⁸

At the same time, some experimental data, particularly the absence of coupling products of secondary adamantyl radicals with pyridine even at low concentrations of O₂ is a serious argument against the generation of free secondary alkyl radicals. Some other data are also in contradiction with the formation of free-radical alkyl intermediates.^{245, 246}

Barton *et al.*²²⁹ have interpreted the data concerning the selectivity of Gif systems in a framework of a reaction mechanism that included the generation of a complex of highly oxidised iron with oxygen, Fe^V=O. Its reaction with the secondary C–H bonds of an alkane gives a metal-alkyl complex, HO–Fe–R, with an Fe–C bond. The insertion of molecular oxygen or other reagents into this bond yields an alkyl hydroperoxide or different alkane derivatives. However, it was understood that this hypothesis fails to explain the whole body of evidence obtained with the Gif systems, particularly the lack of an obvious dependence of the reaction parameters on the nature of the metal.

Sawyer *et al.*,^{220, 247} who paid much attention to the study of hydrogen peroxide activation on metal complexes suggested that such oxidative intermediates as LFe^{II}OOH and LFe^{IV}(OH)OOH (the latter is formed when the peroxide is in an excess over iron), which interact with alkanes to give intermediate complexes with Fe–C or FeOO–C bonds, can be generated in Gif and related systems. The simultaneous presence of radical and non-radical reactive intermediates in this reaction is also possible.

3. Functional models of methane monooxygenase

The selective oxidation of methane is a most serious problem because of the high strength of its C–H bond. Very few chemical systems known thus far can oxidise methane to methanol simulating enzymic oxidation under mild conditions.

The chlorides of some metals can promote hydroxylation of light alkanes concomitant with autooxidation in organic solvents.²⁴⁸

Recently, several systems for methane oxidation by hydrogen peroxide in trifluoroacetic acid under relatively mild conditions have been proposed. Methyl trifluoroacetate is formed in the presence of Pd(II) and can further be hydrolysed to methanol.²⁴⁹

Catalysis by Ru(II)²⁵⁰ gives methanol and formaldehyde in a 4:1 ratio. These systems can catalyse the transfer of the oxygen atom from H₂O₂ to the C–H bond of methane, although metal-complex activation of the methane itself should not be ruled out.

A system for methane and ethane oxidation by oxygen in aqueous media in the presence of a metal catalyst (Pd/C) and a reducing agent (CO)²⁵¹ for which 1000 catalytic cycles were obtained at 85–100 °C is an interesting example of a heterogeneous analogue of methane monooxygenase (MMO). In this system, ethane is oxidised to CH₃CO₂H, HCO₂H, and CH₃CH₂OH in the 221:50:15 ratio. It is assumed that the 'OH radical does not take part in a hydrocarbon oxidation despite the intermediate formation of hydrogen peroxide.

Apparently, one of the best functional models of MMO is the oxidation of methane, carbon monoxide, and benzene by nitrous oxide on the so-called α -centres of iron-containing zeolites, ZSM-5.²⁵¹ These centres result from iron release from the crystalline lattice of the zeolite upon thermal treatment. Their nature still remains obscure. It is believed^{252, 253} that they represent surface iron hydroxide clusters.¹³ The dissociation of N₂O on α -centres results in the addition of the oxygen atom to yield the active oxidant **14**, which oxidises methane stoichiometrically at room temperature:

The use of functional models has made it possible to carry out mild homogeneous oxidation of methane; however, structural factors, such as the binuclear nature of the active centre of MMO, have not been taken into consideration.

4. Binuclear model systems

Binuclear iron complexes with one μ -oxo- or μ -hydroxo-bridge of the (L_nFe)₂O(H) type are the simplest models of the active centre of MMO.²⁵⁴

One of the first attempts to use a binuclear μ -oxo complex, iron hydro(tris-1-pyrazolyl)borate, {Fe[HB(pz)₃]}₂O, in alkane hydroxylation by oxygen in the presence of a reducing agent (zinc) and an effector (acetic acid in CH₂Cl₂) was undertaken in 1988.²⁵⁵ This work did not raise the problem of the preservation of the binuclear structure during functioning of the complex. However, further studies have shown that most of the binuclear complexes with a single μ -oxo bridge were unstable in the presence of reducing agents.²⁵⁴ Later, Kitajima *et al.*²⁵⁶ improved this system by introducing an additional stabilising ligand (hexafluoroacetylacetonate) into the binuclear complex; the excess of the ligand simultaneously fulfilled the role of an effector instead of acetic acid.

The Fe₂O(DTBC)₂Cl₄ complex, where DTBC is di(*tert*-butyl)catechol, catalyses the oxidation of alkanes (including methane) by molecular oxygen in the presence of a reducing agent (hydrazobenzene).²⁵⁷ The binuclear complex proved to be stable under reaction conditions. The mononuclear complex is one order of magnitude less active than the binuclear one. The change in the regioselectivity of the hexane and adamantane oxidation as the binuclear complex is substituted for the mononuclear one shows that the iron complex is involved in the reaction with alkanes. It is concluded from these data that the binuclear oxoferryl intermediate plays the role of the active species. However, the structure of the hypothetical intermediate remains obscure.

The catalytic activity of a series of complexes of the [Fe₂OL₄X₂](ClO₄)₂ type, where L is 2,2'-dipyridyl (bipy), 4,4'-dimethyl-2,2'-dipyridyl or phenyl, and X is a labile ligand (H₂O,

Cl^- , CH_3CO_2^- , CF_3CO_2^-), was studied in the reaction of alkane oxidation by peroxides.^{258,259} It was shown that the efficiency of these complexes depends on the lability of the ligand X. The rate of the reaction drops with an increase in the basicity of the ligand L. The best results in the cyclohexane oxidation by *tert*-butyl hydroperoxide (the yield of the oxidation products is > 50%, the reaction rate is 17 cycles per min) were obtained for the $\text{Fe}_2\text{O}(\text{bipy})_4(\text{H}_2\text{O})_2(\text{ClO}_4)_4$ complex in alkane oxidation (involving methane) by peroxides. The catalytic activity of the binuclear iron complex, $[\text{Fe}_2\text{OL}_4(\text{H}_2\text{O})](\text{ClO}_4)_4$, was found to depend on the nature of the substituent in the ligand.²⁶⁰ The dependence of the selectivity of hydroxylation of a series of alkanes and epoxidation of limonene on the nature of the ligand substituent and the effect of oxygen on the selectivity and the yield of the reaction products demonstrated that these processes occur not only by a radical mechanism, but also by a molecular mechanism, *i.e.*, with the transfer of the oxygen atom from the peroxide to the hydrocarbon mediated by the metal complex.²⁶¹

Cyclohexanol is the single product of cyclohexane oxidation by *tert*-butyl hydroperoxide catalysed by $[\text{Fe}_2\text{O}(\text{TPA})_2(\text{H}_2\text{O})_2]^{4+}$, where TPA is tris(2-pyridylmethyl)amine, under conditions where the concentration of the hydroperoxide exceeds that of the catalyst by more than one order of magnitude. The peroxo complex $\text{Fe}^{\text{III}}\text{OOR}$, which can oxidise alkanes and the excess of the hydroperoxide by initiating radical-chain oxidation, has been assumed to be the reactive intermediate. The relative contribution of each of these mechanisms is determined by the concentration of the peroxide.²⁶²

Cyclohexane is also oxidised in high yield but at a much lower rate in the presence of two-bridge complexes of the $(\text{L}_n\text{Fe})_2\text{O}(\text{OAc})$ type with μ -oxo- and carboxylate (OAc) bridges.^{258,263} The reactive intermediate in alkane oxidation by *tert*-butyl hydroperoxide in MeCN involving the binuclear complex, $[\text{Fe}_2(\text{TPA})_2\text{O}(\text{OAc})](\text{ClO}_4)_3$, was shown to be a metallocomplex compound. The substitution of TPA in the complex for analogous tetradentate ligands alters the KIE in the alcohol formation reaction, which provides direct evidence in favour of the involvement of the iron complex in the transfer of oxygen. Addition of Me_2S completely inhibits the formation of the alcohol and the ketone without any effect on diperoxide production. It is suggested²⁵⁸ that the alcohol and the ketone are formed by the oxenoid mechanism, whereas the diperoxide is formed by the radical-chain reaction. The KIE of the diperoxide formation ($k_{\text{H}}/k_{\text{D}} = 7.7$) does not depend on the nature of the complex used. This fact is an additional proof that the metal complex intermediate does not take part in the diperoxide formation.^{264,265}

Three-bridge binuclear complexes structurally closely resemble the active centre of MMO. The first models **15** containing the nucleus, $(\text{LFe})_2\text{O}(\text{OAc})_2$, were developed by Wieghardt *et al.*²⁶⁶ in Germany and by Lippard *et al.*²⁶⁷ in the USA who employed terminal tridentate ligands.

A number of analogous complexes with different terminal and bridge ligands have been obtained. All these complexes efficiently simulate the spectral and magnetic properties of hemerythrin and ribonucleotide reductase (but not MMO), but do not possess any functional activity due to the lack of vacant sites for O_2 binding in their coordination spheres.

L is $\text{C}_6\text{H}_{15}\text{N}_2$,²⁶⁶ 1,4,7-triazacyclononane;²⁶⁶ $\text{HB} \left(\text{N} \begin{array}{c} \diagup \diagdown \\ \text{---} \text{---} \end{array} \right)_3$.²⁶⁷

The methods for preparing iron binuclear complexes with labile coordination sites have been elaborated in the past decade;

some of these are based on the self-assembly from simple molecules:^{268–270}

Solv is the solvent molecule.

This reaction can yield binuclear or tetranuclear complexes depending on the conditions.

The catalytic activity of such three bridge binuclear complexes in alkane oxidation is usually low.²⁷¹ The oxidation of methane and other alkanes by hydrogen peroxide catalysed by $[\text{Fe}_2\text{O}(\text{bipy})_2(\text{OBz})_2\text{Solv}_2](\text{ClO}_4)_2$ (where OBz is benzoate and Solv is H_2O or MeOH) in acetonitrile has been studied.²⁷⁰ The solvent molecule in these complexes represents a labile ligand and can apparently be substituted by H_2O_2 . The KIE for the oxidation of C_6H_{12} and C_6D_{12} ($k_{\text{H}}/k_{\text{D}} = 3.0$), the selectivity of hexane oxidation, and the 5/6 parameter for cyclopentane and cyclohexane oxidation suggest the involvement of the $\text{Fe}=\text{O}$ formed by the splitting of the FeOOH intermediate. It has been shown that such complexes with a labile coordination sphere are more active in alkane oxidation than complexes with a closed coordination sphere.

In a recent study²⁷² it has been shown that the $[\text{LFe}_2\text{O}(\text{OAc})_2](\text{ClO}_4)_2$ complex, where L is the tetradentate hexapyridine ligand, efficiently catalyses alkane oxidation by *m*-chloroperbenzoic acid. If dichloromethane and dibromomethane were used as the solvents, the products of oxidation of cyclohexane (**4**) contained chlorocyclohexane (**7**) and bromocyclohexane, respectively. Radical traps completely inhibited the oxidation. These results together with the regioselectivity data and the KIE led the authors²⁷² to conclude that alkane oxidation in this system occurs *via* a radical mechanism with the formation of an alkyl radical.

As new information about reactive intermediates of the catalytic cycle of binuclear monooxygenases became available, attempts were undertaken to synthesise the corresponding model compounds.^{273–276}

Early studies on simulation of peroxo intermediates were based on the reactions of binuclear complexes of trivalent iron with hydrogen peroxide.^{274–276} Later, a series of Fe_2^{II} complexes with an open coordination sphere and the ability to bind O_2 have been synthesised.²⁷³ The ligands able to bind two metal centres that have been prepared on the basis of 1,3-diaminopropan-2-ol and the carboxylate bridge provide the appropriate ligand environment (N_3O_2) for each Fe^{II} atom. In addition, one molecule of water is sometimes coordinated to one of them. Reversible²⁷⁷ and irreversible^{278,279} binding of molecular oxygen to these and related complexes is observed at low temperatures. An increase in temperature results in the formation of oxidised Fe_2^{III} (see Refs 278 and 279). The oxygen adducts have been characterised as $(\mu\text{-}1,2\text{-peroxo})\text{Fe}_2^{\text{III}}$ complexes on the basis of their Raman and Mössbauer spectra.

The factors that enhance the stability of peroxo complexes have been established. They include the presence of bulky substituents in the tetradentate ligand that attenuate the electron-donor properties of nitrogen and form simultaneously a hydrophobic environment for the peroxo-centre.^{277,278} The peroxo-intermediate, $\text{Fe}^{3+} - \text{O}_2^{2-} - \text{Fe}^{3+}$ on the basis of the $[\text{Fe}_2(\text{Ph-bimp})(\text{C}_6\text{H}_5\text{COO})](\text{BF}_4)_2$ complex (where Ph-bimp is 2,6-bis-{bis[(1-methyl-4,5-diphenylimidazol-2-yl)methyl]aminomethyl}-4-methylphenoxide) is stable even at room temperature.²⁸⁰ The introduction of donor substituents into the bridge ligand accelerates the decomposition of the peroxo complexes. This is accounted for by an increase in the electron density at the metal, which facilitates the cleavage of the O—O bonds and simultaneously stabilises the highly oxidised state.²⁷³ The stabilising effect of polar solvents on peroxo intermediates has also been reported.^{277,279,280}

The parameters of the optical and the Raman spectra of model peroxo complexes are in good agreement with the corresponding parameters of the intermediate P formed in the catalytic cycle of MMO.^{76, 281}

The catalytic systems based on binuclear iron complexes are rather unstable. In the course of the reaction, such complexes either decompose into mononuclear complexes or are destroyed due to ligand oxidation. Moreover, reductive activation of O₂ can be accompanied by nonproductive reactions between the oxidised and reduced forms of the iron complexes, which decreases the activity of the homogeneous systems. Immobilisation of complexes on solid supports favours their stabilisation and decelerates nonproductive bimolecular reactions.

5. Immobilised binuclear complexes

The synthesis of an iron complex on the surface of silica gel modified by imidazole derivatives has been reported.^{282, 283} The structure of a binuclear complex has been proposed on the basis of UV, EPR, and Mössbauer spectroscopic data. This heterogeneous catalyst induces the oxidation of methane and other alkanes by molecular oxygen at room temperature in the presence of a reducing agent (zinc dust), an effector (acetic acid), and an electron carrier (methyl viologen) in acetonitrile. The regioselectivity of hexane oxidation suggests that the [•]OH radical is the reactive species in this system. A recent report²⁸⁴ deals with cyclohexane oxidation by an analogous heterogeneous complex which, in contrast to the former, has two μ -oxo bridges and a dimethylamino group instead of imidazole, but no carboxylate bridges. This complex effectively hydroxylates cyclohexane (57 cycles per catalyst), but does not oxidise methane at an appreciable rate.

6. The mechanism of alkane oxidation and reactive intermediates in non-heme model systems

Fish *et al.*^{285, 286} have concluded that alkane oxidation in all the systems having a composition $LFe^{II/III} + H_2O_2 - O_2$ yield an alkyl hydroperoxide or its complex with iron, FeOOR, as the intermediate product, which, in turn, points to the formation of the substrate-derived radical R[•] as the intermediate. This conclusion was confirmed by the detection of diperoxides in the systems based on mono- and bi-nuclear iron complexes with *tert*-butyl hydroperoxide as the oxidant.^{262, 287}

Evidence that alkane oxidation in the

$[Fe_2O(bipy)_4(H_2O)_2](ClO_4)_4 - H_2O_2$,²⁶¹ $[Fe_2O(tmima)(OAc)_2](ClO_4)_2 - H_2O_2$ ²⁸⁶

[tmima is tris(1-methylimidazol-2-yl)amine],

$[Fe_2O(TPA)_2(H_2O)_2]^{4+} - Bu^tOOH$, and

$[Fe(TPA)Cl_2]^+ - Bu^tOOH$ ²⁷²

systems involves alkyl radicals is provided by the dependence of the concentration and composition of oxidation products on the concentration of molecular oxygen in the reaction medium.

Presumably, radical oxidation is initiated by the oxygen radicals generated either by activation of peroxides on metal complexes^{288, 289} or in the oxidation of the excess of peroxide by oxenoid intermediates.^{156, 262} The possibility of generation of the alkyl radicals R[•] through detachment of hydrogen from the hydrocarbon by reactive peroxo- or oxo-iron complexes has also been considered.^{252, 272, 286} Redox potentials for the formation of radicals from hydrocarbons with the general formula $HCH_{3-n}(CH_3)_n$ varies from 1.60 to 2.25 eV;¹⁹⁴ therefore, the detachment of H by oxenoid intermediates occurs apparently only in the oxidation of the less stable (tertiary or activated) C—H bonds.

Although short-living oxenoid intermediates have been detected in systems with non-heme iron, they have not been adequately characterised. The intermediate $Fe^{IV}=O$ has been effectively generated by laser photolysis of a Fe^{II} salen complex (salen is 1,2-disalicylideneaminoethane) with molecular oxygen.²⁹⁰ It was shown that iron complexes with EDTA, like their

porphyrin analogues, can transfer an oxygen atom from peroxy acids and peroxides by splitting the latter *via* a heterolytic mechanism.²⁹¹ The formation of a non-heme ferryl complex has been observed in aqueous solutions by spectral methods.²⁹²

The ability of binuclear Fe^{II} complexes with 1,2-bis(2-hydroxybenzamido)benzene to transfer the oxygen atom from a peroxy acid and PhIO to cyclohexene *via* the intermediate formation of $Fe=O$ has been established.^{293, 294} In the absence of the substrate, the spectroscopically identified $Fe=O$ intermediate (its lifetime is 1.5 h at $-78^\circ C$) was converted into the μ -oxo complex.

A reactive oxidative intermediate generated in the reaction of a binuclear iron μ -oxo complex, $[Fe_2O(TPA)_2](ClO_4)_4$, with H_2O_2 , in a system that hydroxylates alkanes and epoxidises alkenes, has been characterised in the most detail.²⁹⁵ Analysis of the EPR, Mössbauer, and Raman spectra, together with the data from the elementary and mass-spectrometric analyses,²⁹⁶ suggest that the reactive intermediate has an $Fe_2(\mu-O)_2$ nucleus with a delocalised electron. In its characteristics it is similar to the reactive intermediate X in the catalytic cycle of ribonucleotide reductase.²⁹⁶

Obviously, these are only the first steps on the way to the simulation of non-heme monooxygenases. On the whole, this problem is still far from being finally solved. There are relatively few systems for which the involvement of well-characterised binuclear complexes in alkane oxidation has been confirmed experimentally. There are practically no reliable data on the nature of the reactive intermediates. At the same time, the experimental results altogether suggest that the construction of efficient analogues of MMO is a task of the nearest future. One important problem on the way is the stabilisation of binuclear complexes during the catalytic cycle. Preliminary data show that a major breakthrough can be expected from the application of complexes immobilised on solid supports. A strong impetus for the construction of adequate models of MMO is the X-ray determination of MMO structure. However, the design of efficient structural and functional analogues will also require great skills of synthetic chemists because the modelling of the protein environment of the active centre is fraught with considerable difficulties. Apparently, the design and synthesis of more complicated models that reproduce, with a great degree of accuracy, the structure of the iron complex and its environment in the protein globule will play a prominent role in both the simulation of cytochrome P-450 and the construction of analogues of non-heme monooxygenases.

V. Conclusion

The results presented in this review allow one to make a conclusion about the increasing interest in the enzymic oxidation of alkanes and the construction of chemical models of these reactions. Special interest of investigators has recently been focussed on the relatively poorly investigated enzyme, methane monooxygenase, as well as on the biomimetic systems based on non-heme binuclear iron complexes. Studies of cytochrome P-450 and its chemical models for which many fundamental problems still remain unsolved are also very important.

Undoubted progress in the field of natural and biomimetic monooxygenase systems should be mentioned. The use of modern physical methods permits the prediction, with an increasing degree of reliability, of the structure of reactive species involved in the transfer of the oxygen atom to the substrate. The formulation of a hypothesis about the intermediate formation of species with pentacoordinated carbon during the insertion of the oxygen atom into the C—H bond has been important for the understanding of the mechanism of monooxygenation. This hypothesis, which allows prediction of the quantitative distribution of the oxidation products in some cases has eliminated the contradictions evolved in the analysis of the two earlier proposed mechanisms, namely, the oxenoid mechanism, which entails direct

insertion of the O atom into the C—H bond, and the cryptoradical (oxygen rebound) mechanism.

The progress in the chemical simulation of monooxygenases demonstrates that novel efficient, highly selective catalytic systems for alkane oxidation will hopefully be created based on them in the nearest future.

Abstract. In 1994, the superconductivity of intermetallic borocarbides (IBC) of composition $\text{LnM}_2\text{B}_2\text{C}$, where Ln is a rare-earth metal and M is Ni or Pd, was discovered. This discovery stimulated numerous works on the synthesis of new quaternary borocarbide phases and solid solutions based on them and studies of their crystal chemistry and magnetic, superconducting, and transport properties. Almost simultaneously, investigations of the fundamental electronic properties of IBC and specific chemical bonding in this new class of materials have been initiated. The results of theoretical and experimental investigations in these fields are summarised. The bibliography includes 179 references.

I. Introduction

The year 1994 was marked by a discovery in the physical chemistry of a poorly studied class of multicomponent intermetallic compounds, *viz.*, intermetallic borocarbides (IBC): the superconductivity effect was observed in the Y–Pd–B–C and Lu–Ni–B–C systems. Superconducting transitions at $T_c \approx 23$ K and $T_c \approx 16$ K for a heterophase specimen with the composition $\text{YPd}_3\text{B}_3\text{C}_{0.3}$ and a single-phase specimen of borocarbide $\text{LuNi}_2\text{B}_2\text{C}$, respectively, were reported.¹³

The attention of researchers was immediately drawn to IBC since they appeared to be the first superconducting quaternary intermetallic systems known which are devoid of copper and oxygen ions. The above phases had nickel and palladium as components. At the same time, it was well known that the presence of ferromagnetic nickel in compounds resulted in suppression of their superconducting properties, whereas very few superconductors studied contained appreciable quantities of palladium (for instance, PdH_x , metallic palladium saturated with boron and carbon ions, and several hydrogenated Pd alloys with *d*-metals (Cu, Ag, Au, Nb, Mo, and W)).⁴

The observation of superconductivity in nickel-containing IBC stimulated an active search for other multicomponent phases containing magnetic transition-metal ions. Currently, information on the synthesis of superconducting intermetallic silicides and carbides, namely, LaNiSi , LaNiC_2 , $\text{La}_{1-x}\text{Th}_x\text{NiC}_2$, and $\text{Tm}_2\text{Fe}_3\text{Si}_5$ is available.^{5–8}

The initial stage of experimental studies of IBC was characterised by a quest to extend the class of known quaternary phases of the $\text{LuNi}_2\text{B}_2\text{C}$ type by replacing Lu by magnetic rare-earth metal ions and to determine the critical temperature of superconducting transition (T_c) for compounds produced. This kind of study was carried out for IBC containing Tm ($T_c \approx 10.8$ K), Er ($T_c \approx 10.5$ K), Ho ($T_c \approx 8.5$ K), and Dy ($T_c \approx 6.2$ K).^{9–14} Similar attempts to 'chemically modify' the superconducting properties were made by changing the type of the transition metal. In particular, it has been established that for $\text{YNi}_2\text{B}_2\text{C}$ ($T_c \approx 15.6$ K)² such substitutions appreciably affect the T_c value, which is equal to 10.0, 23.0, and 0.0 K for Pt,¹⁵ Pd,^{16,17} and Co,¹⁸ respectively.

One more remarkable discovery was made at the same period. It has been established in studies of the properties of IBC containing magnetic rare-earth metal ions (Pr, Dy, Ho, Er, Tb, *etc.*)^{19–25} that these compounds form a unique class of superconducting materials with close-lying temperatures of magnetic ordering, namely, the Neel temperature (T_N) and the temperature of superconducting transition. In this regard, no other analogues of IBC are known so far.

The current stage of investigations of IBC is characterised by both a search for new quaternary phases, in which the metallic sublattice is composed of actinides [for instance, phases in the UMBC systems (M = Ni, Pd, and Pt)],^{26–29} and attempts to synthesise intermetallic boron nitrides^{30,31} as well as by a tendency to perform more flexible variation of the composition and properties of IBC by doping their sublattices with a finite (variable) concentration of dopants. Transition metals (M'), as a rule, play the role of dopants. The concentration dependences of physicochemical characteristics of solid solutions (SS) of the type $\text{Ln}(\text{M}_{1-x}\text{M}'_x)_2\text{B}_2\text{C}$ ^{32–35} or $\text{Ln}(\text{M}_{1-x}\text{M}'_x)\text{BC}$ ^{36,37} are being studied intensively. Thermobarochemistry techniques are also used to affect the crystal structure.³⁶ Attention is focused on the effect of possible processing conditions (for instance, annealing) on the properties of the specimens. On the whole, the majority of

experiments deal with the studies of the nature of superconducting, magnetic, and kinetic properties of IBC and the ways of their targeted control.

Each group of superconducting materials [high-temperature superconducting (HTSC) cuprates, fullerites, Chevrel's phases, A-15 compounds, *etc.*] is characterised by its individual crystal structure and the structure of the energy bands. Therefore, it is natural that a set of experiments on studying the specific character of the electron states in IBC were initiated almost simultaneously with the discovery of superconductivity in borocarbide phases.

The information on the electronic energy spectra (EES) and the nature of chemical bonding in IBC obtained to date using computational methods of solid state quantum chemistry and experimental spectroscopic techniques is analysed in the present review. Attempts aimed at interpreting the observed physico-chemical properties of IBC from the viewpoint of their electronic structure are considered.

II. Phase relationships in Ln–M–B–C systems

No detailed studies of phase equilibria in Ln–M–B–C systems have been reported to date; information on phase relationships in these systems and plausible structures of compounds that formed is scarce and is of tentative character so far.³⁸

In the first papers,¹³ the $\text{LuNi}_2\text{B}_2\text{C}$, $\text{YNi}_2\text{B}_2\text{C}$, and $\text{YPd}_2\text{B}_2\text{C}$ phases as well as the related LuNiBC phase were identified as superconducting ones. The efforts of chemists were focused on obtaining a series of isostructural compounds in analogous systems. To date, the $\text{LnNi}_2\text{B}_2\text{C}$ phases for most 4f-elements, Y, and Sc have been synthesised.^{1–3, 9–14, 39, 40} Substances obtained by complete substitution of Ni by Pd, Pt, Rh, or Ir appear to be thermodynamically stable only for early lanthanides.^{1, 15, 40} As to borocarbides with the composition LnMBC , the attempts to synthesise isostructural phases corresponding to various combinations of rare-earth and transition metals made it possible to establish reliably the existence of only borocarbides LuNiBC and YNiBC , whereas the attempts aimed at obtaining stable single-phase specimens with La, Ce, Ni, Co, and Cu failed.^{9, 36, 41, 42}

The crystal structure of the borocarbides $\text{LuNi}_2\text{B}_2\text{C}$ and LuNiBC was first studied by Schmidt *et al.*⁹ The fragments of these structures are shown in Fig. 1 and some of the crystallographic parameters are listed in Table 1. The structure of $\text{LuNi}_2\text{B}_2\text{C}$ can be considered as a modified 'filled' variant of the body-centred tetragonal (BCT) structure of the ThCr_2Si_2 type (see Ref. 38) with the space group $I4/mmm$ composed of alternating Ni_2B_2 layers (with tetrahedral coordination of Ni atoms) and plane LuC nets, where the atomic ordering is of the rock salt type.

The Ni_2B_2 layers in LuNiBC borocarbide are separated by two LuC nets; however, several interatomic distances appear to be very close for both phases (see Table 1).

Figure 1. The crystal structures of borocarbides.⁹ (a) $\text{LuNi}_2\text{B}_2\text{C}$; (b) LuNiBC .

Table 1. Crystallographic parameters of $\text{LuNi}_2\text{B}_2\text{C}$ and LuNiBC .

Ni–B	2.10	2.11
Ni–Ni	2.449	2.474
B–C	1.47	1.52

In accordance with the classification suggested by Gangopadhyay *et al.*,³⁷ the $\text{LnM}_2\text{B}_2\text{C}$ phases have the simplest (for this series of compounds) structure with alternating M_2B_2 and LnC layers (the so-called 'one-layered' phases) and can be described by the general formula $(\text{LnC})_n(\text{MB})_m$, where $n = 1$, and $m = 2$. Compounds with the composition LnMBC belong to the 'two-layered' phases ($n = 2$, $m = 2$). Schmidt *et al.*⁹ and Gangopadhyay *et al.*³⁷ assumed that the systems in question may exist as extended homologous series with the compositions $(\text{LnC})_n(\text{MB})_2$ and $(\text{LnC})(\text{MB})_{m+2}$ with variable content of the nets of the LnC and M_2B_2 phases, respectively, and their combination, the $(\text{LnC})_n(\text{MB})_{m+2}$ phase. No experimental confirmations of the existence of such compounds are available to date.

Analysis of the structure of the $\text{LnNi}_2\text{B}_2\text{C}$ phases has shown⁹ that the constants *a* and *c* of the BCT lattice change almost linearly depending on the lanthanide radius $r(\text{Ln})$ ^{43, 44} (Fig. 2) in contrast to the expected effect of conventional lanthanide compression according to Vegard's rule. The only exception is $\text{CeNi}_2\text{B}_2\text{C}$, which is explained by variable (or mixed) valence of cerium ($\text{Ce} \sim 3.75$) due to hybridisation of its 4f shell with the states of the valence band of the crystal.^{45–47}

Figure 2. Dependence of the BCT lattice parameters of $\text{LnNi}_2\text{B}_2\text{C}$ phases on the ionic radius of the lanthanide.

Note. Atomic positions in the unit cell: Ln (0, 0, 0), Ni (1/2, 0, 1/4), B (0, 0, z), C (1/2, 1/2, 0), B_i (x , y , z), B_{ii} (1/2 + x , 1/2 + y , 1/2 – z).

The most detailed study of crystallochemical properties of the $\text{LnNi}_2\text{B}_2\text{C}$ (Ln = Y, Ce, Pr, Nd, Tb, Dy, Ho, Er, Tm, and Yb) phases (Table 2) was carried out by the neutron diffraction technique.⁴⁷ The interatomic Ln–C and Ln–B distances increase appreciably with the lanthanide radius, which results in a decrease in the thickness of the Ni_2B_2 layer and distortion of NiB_4 tetrahedra it is composed of. Since the Ni–B distances are little changed, the most pronounced changes occur in the bond angles of the NiB_4 fragments (Table 2). The interatomic B–C distances appear to be the least ‘sensitive’ to the $r(\text{Ln})$ values, which is explained⁴⁷ by the strongest interspecies interactions in the C–B–C groups (see below).

It should be noted that the strongly anisotropic quasi-two-dimensional (2D) structure of IBC can indicate at first glance the similarity in the nature and mechanism of superconductivity in these phases and in 2D high-temperature superconducting cuprates. Such a similarity seems to be real, in particular, taking into account the assumptions by Disalvo⁴⁸ and Geballe⁴⁹ that partial replacement of copper atoms in cuprates by atoms of other transition metals and that of oxygen atoms by more electro-positive ions (N, C, B) can be considered in several cases as the factor that prognostically favours superconductivity. However, it should be immediately noted that all information concerning the specificity of the electronic structure of IBC available to date rules out the possibility of the above analogy.

III. Electronic structure of nonmagnetic superconductors $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$

The first numerical calculation of the electron states of $\text{LuNi}_2\text{B}_2\text{C}$ was carried out by Mattheiss⁵⁰ in the framework of the local electron density formalism (LEDf) by using the scalar relativistic linearised augmented plane waves (LAPW) method.^{51,52} The exchange-correlation effects were taken into account by the use of Wigner’s interpolation formula.⁵³

The dispersion dependences $E(\mathbf{k})$ are shown in Fig. 3. The lowest energy band is formed by the $\text{C}2s$ states. The allowed states in the interval from –10 eV to the Fermi level are composed of contributions of the $\text{B}2s$, $\text{B}2p$ – $\text{C}2p$, and $\text{Ni}3d$ states (in order of increasing energy). The Fermi level cuts the $\text{Ni}3d$ bands partially ‘seizing’ the bottom of the $\text{Lu}(d_{x^2-y^2})$ subband (at the point Γ). The major contribution to the maximum near the Fermi level [$N(E_F)$] comes from the $\text{Ni}3d$ states: 2.4 states per eV for a transition metal, which is approximately twice as large as the corresponding value for copper in the case of HTSC cuprate La_2CuO_4 (see Ref. 54) and is close to $N(E_F)$ for vanadium in the ‘conventional’ A-15 superconductor V_3Si .⁵⁵ Hence, Mattheiss⁵⁰ has come to the conclusion that $\text{LuNi}_2\text{B}_2\text{C}$ must be considered as a ‘conventional’ superconductor with the known T_c vs. $N(E_F)$ (or T_c vs. γ , where γ is the electronic heat capacity) dependence.⁵⁶

Experimental measurements of γ for $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{LaPt}_{1.7}\text{Au}_{0.3}\text{B}_2\text{C}$ have been performed⁵⁷ almost simultaneously with

**Figure 3.** The band structure of $\text{LuNi}_2\text{B}_2\text{C}$.⁵⁰

Mattheiss’ calculations,⁵⁰ with γ values being close to those of A-15 compounds.

Analysis of the distribution of the valence s , p , and d states of lutetium (Fig. 4) shows⁵⁰ that their contributions to the formation of $N(E_F)$ cannot be neglected, in contrast, for instance, to the case of HTSC lanthanum cuprate.⁵⁴ The near-Fermi region of the spectrum of $\text{LuNi}_2\text{B}_2\text{C}$ contains all five $\text{Ni}3d$ subbands.⁵⁰ The contributions of the d_{xy} and $d_{yz,zx}$ states to $N(E_F)$ exceed those of the $d_{x^2-y^2}$ and $d_{3z^2-r^2}$ states only by 16% and 6%, respectively. The inclusion of Lu $4f$ levels into the valence basis set has nearly no effect on the shape of the curve of the total density of states (TDOS). In this case, the shapes of TDOS for $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$ appear to be similar (Fig. 4). The latter was calculated by Schmidt *et al.*⁹ using the values 3.53 and 10.57 Å for the lattice parameters a and c , respectively.

Judging from the results obtained, the energy-band spectra of Lu and Y borocarbides do not satisfy the criterion for that of promising HTSC phases,⁵⁸ which requires that the σ^* band formed as a result of interaction between the degenerate anionic and cationic levels be half-filled. Unlike cuprates, where the corresponding bands are in the immediate vicinity of E_F , the $\text{Ni}3d$ – $\text{B}2s$ or $\text{Ni}3d$ – $\text{C}2p$ bands of borocarbides have different energetics owing to a specific character of interatomic σ -bonds in the NiB_4 tetrahedra.

Data on the energy band structure of $\text{LuNi}_2\text{B}_2\text{C}$ obtained by the LAPW method⁵⁹ in the LEDf parametrisation^{60–63} using the lattice constants $a = 3.464$ Å and $c = 10.631$ Å, and $z/c = 0.1379$, where z characterises the position of the B atoms above the Lu–C plane, coincide in general with those obtained by Mattheiss *et al.*^{58,64} The shape of the Fermi surface determined by Pickett *et al.*⁵⁹ appeared to be rather complicated: the $\text{Lu}d$ and $\text{Ni}d$ – $\text{B}2p$ type spheroids that form the Fermi surface are centred at the centre of the Brillouin zone. The fact that the dispersion of the

Figure 4. The energy distribution of the total densities of states for $\text{LuNi}_2\text{B}_2\text{C}$ (a), $\text{YNi}_2\text{B}_2\text{C}$ (b), and partial (s - f) Lu states in $\text{LuNi}_2\text{B}_2\text{C}$ (c); calculations by the LAPW method.⁵⁰

corresponding energy bands is comparable in the atomic planes and along the c axis, as is the case in Mattheiss' calculations,⁵⁰ is an unambiguous evidence for the three-dimensional (3D) nature of the electronic energy spectra of IBC.

Particular attention was given to the analysis of the structure of bands near the Fermi level responsible for the formation of the DOS maximum at the Fermi level. Its presence is associated with the formation of plane energy bands in the (110) direction (the Γ - X direction in Fig. 3), which include antibonding ($\text{Ni}d_{z^2}$ - $\text{Ni}d_{z^2}$), bonding (Bp - $\text{Ni}d$), and impurity ($\text{Lu}d_{xz,yz}$) states. Taking into account an appreciable contribution of the $\text{Ni}d$ states to $N(E_F)$, one can assume that (by analogy with the known ferromagnetic behaviour of metallic nickel or nickel films) this peak in IBC is unstable according to Stoner. However, no ferromagnetic instability of this type was shown in calculations⁵⁹ carried out with consideration of the spin moments.^{65,66}

Pickett *et al.*⁵⁹ emphasised that the appearance of the near-Fermi $3d$ -like band of Ni separated from all the other filled $\text{Ni}d$ bands is one of the most remarkable features of the $\text{LuNi}_2\text{B}_2\text{C}$ electronic spectrum and studied its genesis in detail. To this end, the sublattices of the 'empty' BCT phase were progressively 'filled' with the corresponding atoms. Calculations of isolated Ni and Ni_2B_2 monolayers that retained their atomic geometry in the bulk of $\text{LuNi}_2\text{B}_2\text{C}$ did not result in splitting of the $\text{Ni}d$ subband; only the addition of bridging carbon atoms made it possible to detect a resonance DOS peak of the $\text{Ni}3d$ type separated from the main d band of nickel. However, the energetics and structure of the near-Fermi maximum characteristic of a superconducting IBC is formed finally in the presence of the Lu atoms, *i.e.*, when Ni-C interactions are corrected taking account of the carbon-lutetium bonds.

Such analysis not only confirms the 3D nature of IBC,[†] but is of importance from the viewpoint of methodology. It shows that the local models that take into account only the closest environment of the transition-metal atom cannot be used for interpreting the superconductivity effects in IBC, which was the usual practice in the first stages of the description of electronic energy spectra of

HTSC cuprates (for a review, see Ref. 67). Therefore, one should be extremely careful when applying cluster quantum-chemical methods to the class of intermetallic borocarbides; in particular, the chosen fragments must be balanced with respect to the stoichiometric composition of real IBC materials. Analogous conclusion was drawn by Kim *et al.*⁶⁸ who have calculated the energy band structure of $\text{LuNi}_2\text{B}_2\text{C}$ by the *ab initio* pseudopotential method.⁶⁹

The energy band structure of the BCT borocarbide $\text{YNi}_2\text{B}_2\text{C}$ was studied by Mattheiss,⁵⁰ Coehoorn,⁷⁰ Lee *et al.*,⁷¹ Ravindran *et al.*,⁷² and Zeng *et al.*⁷³ The dispersion dependences $E(k)$ and DOS distributions for the $\text{YNi}_2\text{B}_2\text{C}$ phase found by these authors are in good agreement with each other despite certain deviations in numerical estimates of EES inevitable if different methods and approximations are used for the accepted models. For this reason, the results obtained by Lee *et al.*⁷¹ will be used in the subsequent description of characteristic features of the electronic structure of $\text{YNi}_2\text{B}_2\text{C}$. The calculations were performed by the self-consistent linearised muffin-tin orbital (LMTO) method with the lattice parameters $a = 3.527 \text{ \AA}$ and $c = 10.5427 \text{ \AA}$.⁷⁴

The structure of the energy bands of $\text{YNi}_2\text{B}_2\text{C}$ is shown in Fig. 5, several parameters of the electron states are listed in Table 3. Lee *et al.*⁷¹ draw attention to the composition of the bands near the Fermi level, which consist mainly of the $\text{Ni}3d$ contributions and appreciable admixtures of the $\text{Y}4d$, $\text{B}2p$, and $\text{C}2p$ states. The flat band crossed by the Fermi level at the point Γ results in the appearance of the van Hove-like singularity on the TDOS curve. Cross-section of the Fermi surface by the $k_z = 0$ plane of the Brillouin zone is shown in Fig. 6. Its topology (see Fig. 5) is formed with participation of the bands that determine the combination of the electron and hole states. An appreciable energy dispersion of the $\text{C}2p$ -like bands in the Γ - Z direction was noted.⁷¹ It was also emphasised that it is carbon that plays the crucial role in the formation of the 3D nature of the given phase, whereas a quasi-2D behaviour is expected for a hypothetical IBC with an 'empty' C sublattice.

The nature of chemical bonding in IBC has not been analysed in detail.^{50, 59, 64, 68, 70–73} Certain qualitative conclusions on the dominance of one or another type of interaction were based on the energy distributions of the local densities of states (LDOS) considered in Refs 75 and 76.

IV. Chemical bonding in intermetallic borocarbides

The nature of the formation of chemical bonds in IBC and the role of particular atoms and atomic groups were considered by Zeng *et al.*⁷³ and Halet.⁷⁷ The main attention was given to calculations of the indices of local interatomic interactions such as the overlap integrals (OI) of effective atomic orbitals.

A semiquantitative analysis of chemical bonding for $\text{LuNi}_2\text{B}_2\text{C}$ was performed by Halet⁷⁷ in the framework of the tight-binding method,^{78, 79} which is the energy-band version of the extended Hückel method.

The molecular orbital (MO) diagram of the isolated B_2C^{2-} group (Fig. 7) illustrates the character of the interaction between the boron and carbon atoms, which form the corresponding sublattices in IBC. Hybridisation of $2s$ and $2p$ atomic orbitals (AOs) of the B and C atoms results in the formation of six σ -type MOs, two of which are bonding, two are nonbonding (σ_g and σ_u), and two are of pronounced antibonding nature. In addition, the MO system includes degenerate π -type orbitals corresponding to bonding ($1\pi_u$), nonbonding (π_g), and antibonding ($2\pi_u$) interactions of the p - p states.

**Figure 7.** The molecular orbital (MO) diagram of $(\text{B}_2\text{C})^{2-}$ group for an IBC with the BCT structure of the ThCr_2Si_2 type.

The energy interval (the ‘forbidden gap’) between the highest nonbonding (π_g) and the lowest antibonding ($2\pi_u$) MO depends⁷⁷ on the formal charge ascribed to the B_2C group and diminishes sharply on going from $(\text{B}_2\text{C})^{3-}$ to $(\text{B}_2\text{C})^{2-}$. The subsequent decrease in the ‘forbidden gap’, which is absent in a real IBC material, is associated with the formation of metal–nonmetal covalent interactions.

Numerical estimates of OI and effective atomic charges (q_{ef}) are listed in Table 4. Interactions of a complex, ionic-covalent type, which differ considerably for particular intervals of the energy spectrum, have been found in IBC. In particular, the hybridised σ -bonding $\text{Ni}-\text{B}_2\text{C}$ states and the nonbonding (π_g and σ_u) states of the B_2C group with admixture of the antibonding π states of $\text{Lu}-\text{C}$ participate in the formation of states near the Fermi level.

Table 4. Overlap integrals (OI) and effective charges (q_{ef}) of the atoms and groups in $\text{LuNi}_2\text{B}_2\text{C}$.

Atomic pair	OI /e	Atom, group	q_{ef} /e
Ni–Ni	0.138	Lu	+1.48
Ni–B	0.304	Ni	–0.50
B–C	1.023	B	+0.35
Lu–B	0.072	C	–1.18
Lu–C	0.157	B_2C	–0.48

Zeng *et al.*⁷³ discussed the nature of the formation of individual interatomic bonds in $\text{YNi}_2\text{B}_2\text{C}$ using the discrete variational^{80–82} embedded-cluster approach in the framework of the local electron density functional. According to this model, the interaction between the chosen 71-atomic fragment $[\text{Y}_{12}\text{Ni}_{15}\text{B}_{32}\text{C}_{12}]$ with D_{2d} symmetry and the crystalline environment was calculated using a scheme developed by Ellis and co-workers.^{83–85} The von Barth–Hedin exchange-correlation potential⁸⁶ was used, and the numerical basis set included the following AOs: $4s$, $4p$, $4d$, $5s$, and $5p$ of Y; $3s$, $3p$, $3d$, $4s$, and $4p$ of Ni; and $1s$, $2s$, and $2p$ of B and C.

The AO populations and OIs for this cluster in the $\text{YNi}_2\text{B}_2\text{C}$ structure are listed in Table 5. According to these data, the metal and nonmetal atoms in $\text{YNi}_2\text{B}_2\text{C}$ are in the cationic and anionic states, respectively, while the largest charge transfer is believed to occur in the plane nets from Y to C. As to the covalent component of the bond, the pair B–C bonds appear to be the most populated, as in $\text{LuNi}_2\text{B}_2\text{C}$. The Ni–B bonds are much less populated, whereas the Y–C interactions should be considered to be antibonding ones. It is clearly seen on the contour plots of the electron density distribution $\rho(r)$ ⁷³ that the electron density is concentrated along the lines of the Ni–Ni bonds (in the xy plane), that the bonding states are formed between the atomic Ni and Y layers, and that the interactions of the Ni– B_2C type arise in the yz plane.

Table 5. Orbital populations, effective atomic charges, and overlap integrals for the 71-atomic cluster in the structure of $\text{YNi}_2\text{B}_2\text{C}$ according to discrete variational calculations.

Atom	Orbital population			q_{ef}	Type of the bond	OI
	d	s	p			
Ni(1) ^a	9.06(3d)	0.38(4s)	0.52(4p)	+0.11	Ni(1)–B	0.64
Ni(2) ^b	9.11(3d)	0.41(4s)	0.39(4p)	+0.16	Ni(2)–B	0.66
Y	0.54(4d)	0.06(5s)	0.05(5p)	+2.49	Y–C	–0.18 ^c
B		0.82(2s)	2.53(2p)	–0.35	B–C	1.14
C		1.40(2s)	4.35(2p)	–1.75		

^a The central nickel atom in the cluster. ^b Peripheral nickel atoms in the cluster. ^c The ‘minus’ sign corresponds to antibonding.

V. The effect of the composition of metal and metalloid sublattices on the energy band structure of the $\text{LnM}_2\text{B}_2\text{C}$ phases and their solid solutions

The study of the effect of the composition of metal and metalloid sublattices on the electronic energy spectra of IBC became a natural continuation of investigations into determination of the energy band structure of $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$, where either a complete replacement of one or several types of ions were by ions of another type was performed or a variable concentration of possible impurities was considered in the framework of the initial BCT structure.

1. Phases of composition $\text{LnM}_2\text{B}_2\text{C}$ ($\text{M} = \text{Co}, \text{Cu}, \text{Pd}$, and Pt)

Mattheiss and co-workers⁶⁴ performed LAPW calculations of the EES for a series of BCT intermetallic borocarbides of composition $\text{LnNi}_2\text{B}_2\text{C}$ ($\text{Ln} = \text{La}, \text{Pr}, \text{Pm}, \dots, \text{Tm}, \text{and Lu}$). The energy band structures of these IBC appeared to be similar to those of $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$ discussed above. For all the phases under study, the valence band (of width ~ 14 eV) contains 18 filled energy bands, including 10 $\text{Ni}3d$ bands. The latter can be arbitrarily combined into two subbands located immediately near and below the Fermi level. Figure 8 presents the band structure of $\text{LaNi}_2\text{B}_2\text{C}$ as an example. For this phase, the free $4f$ states are localised $\sim 3\text{--}4$ eV higher than E_F .

Special emphasis was placed by Mattheiss and co-workers⁶⁴ on the dispersion of the sp band (Γ_{2-} , indicated by the solid line in Fig. 8) near the Fermi level depending on the specific features of the structure of the individual phases, in particular, on the geometry of the NiB_4 tetrahedra. Calculations (in accordance with the experimental data discussed above) show that the lattice constants a and c in the $\text{LnNi}_2\text{B}_2\text{C}$ series change in different manner. A progressive distortion of the NiB_4 tetrahedra occurs

with increase in radius of the lanthanide atom. Thus, the bond angles α change from 108.7° (Lu) to 102.1° (La), which results in the sharp (by ~ 2 eV at the Γ point, see Fig. 8) change in the energetics and dispersion of the sp band and in a decrease in its contribution to the Brillouin zone and the degree of its filling. In turn, this affects the energy and character of filling of the $\text{Ni}3d$ band (along the $\Gamma-X$ direction).

Mattheiss and co-workers⁶⁴ argue that these distinctions in subtle features of the energy distribution of the bands near the Fermi level are determined not by the type of the rearrangement of interatomic interactions resulting from the $\text{La} \rightarrow \text{Lu}$ substitution, but first and foremost by the structural factor, namely, by the degree of distortion of the NiB_4 tetrahedra, which increases with the lanthanide ionic radius. A trial calculation has been performed for a hypothetical 'ideal' compound $\text{LaNi}_2\text{B}_2\text{C}$ containing layers formed by regular NiB_4 tetrahedra ($\alpha = 109.5^\circ$, $d(\text{Ni}-\text{B}) = 2.33$ Å). Its band structure appeared to be close to that of $\text{LuNi}_2\text{B}_2\text{C}$ ($\alpha = 108.5^\circ$, $d(\text{Ni}-\text{B}) = 2.11$ Å). The $N(E_F)$ value for the 'ideal' $\text{LaNi}_2\text{B}_2\text{C}$ increases substantially (by $\sim 90\%$), thus approaching the $N(E_F)$ value for superconducting $\text{LuNi}_2\text{B}_2\text{C}$. It has been assumed⁶⁴ that the degree of distortion of the NiB_4 tetrahedra in the $\text{LnNi}_2\text{B}_2\text{C}$ phases as well as that of MB_4 tetrahedra ($\text{M} = \text{Pt}, \text{Pb}, \text{Ru}, \text{and Ir}$) in other known IBC can be deliberately controlled by using high-pressure techniques. In this case, the experiments on the hydrostatic or axial compression of IBC can result in revealing nontrivial T_c dependences on the lattice parameters for each particular material.

A comparative analysis of the energy band structure of $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{LaPt}_2\text{B}_2\text{C}$ was carried out by Singh.⁸⁷ The energy spectra of these compounds calculated by the LAPW method were found to be similar. The distribution of the near-Fermi states has a pronounced 3D character and is close to an isotropic one, which means that the superconductivity of $\text{LaPt}_2\text{B}_2\text{C}$ ($T_c \simeq 11$ K)⁴⁰ can be considered in the framework of conventional Bardeen–Cooper–Schrieffer (BCS) mechanism by the analogy, for instance, with transition metal B1 carbides and nitrides.^{88,89} The main specific features of the energy spectrum of $\text{LaPt}_2\text{B}_2\text{C}$ are associated with the position of the flat $\Gamma(110)$ band about 0.4 eV above the Fermi level. We remember that the corresponding band in $\text{LuNi}_2\text{B}_2\text{C}$ is in the immediate vicinity of the Fermi level and crosses it. As a result, the DOS maximum of the near-Fermi bands for $\text{LaPt}_2\text{B}_2\text{C}$ appears to be shifted toward the region of unfilled states. This leads to an appreciable decrease in $N(E_F)$ for $\text{LaPt}_2\text{B}_2\text{C}$ as compared to that for $\text{LuNi}_2\text{B}_2\text{C}$ despite the fact that the contributions of the d states of Ni and Pt to $N(E_F)$ for both phases are comparable in magnitude. Singh⁸⁷ explained the distinctions indicated above by the increase in the width of the $\text{Pt}5d$ band (as compared to the $\text{Ni}3d$ band) due to enhanced hybridisation of the platinum d states with metalloids (increased splitting of d states), which, in turn, is determined by greater extension of the d orbitals of Pt and La compared to those of Ni and Lu, respectively. Using the concepts of a relationship between T_c and $N(E_F)$ and the rigid band model,^{4,88,89} Singh⁸⁷ assumed that an increase in the concentration of valence electrons (CVE), for instance, due to partial substitution of carbon atoms by those of more electronegative metalloids or the introduction of another 'electron donor' will have a favourable effect on the change of T_c of $\text{LaPt}_2\text{B}_2\text{C}$. For this phase, the optimum concentration of the 'excess' electrons, at which E_F coincides with the DOS maximum, is equal to ~ 1.2 electrons per cell.⁸⁷

Coehoorn⁷⁰ performed a detailed analysis of the composition of energy bands near the Fermi level for yet another representative of BCT borocarbides, *viz.*, $\text{YPd}_2\text{B}_2\text{C}$, using the scalar relativistic version⁶⁹ of the augmented spherical waves (ASW) method. It was found for this compound that E_F coincides with the local DOS peak $N(E_F) = 3.26$ eV⁻¹ and the maximum contributions to $N(E_F)$ come from $\text{Pd}4d$ and $\text{Y}4d$ states (Table 6), as in nickel-containing Y and Lu borocarbides. It can be seen from the data in Table 6 that an appreciable filling of $d_{xz,yz}$ and d_{xy} orbitals occurs for yttrium and palladium, respectively. In the bulk of the crystal,

Figure 8. Dispersion of energy bands near the Fermi level for $\text{LaNi}_2\text{B}_2\text{C}$ (a), 'ideal' $\text{LaNi}_2\text{B}_2\text{C}$ (b), and $\text{LuNi}_2\text{B}_2\text{C}$ (c).

The band of nonmetal sp states near the Fermi level is indicated by solid line.

Table 6. Occupation numbers (state per 1 eV) of valence orbitals in the region $-0.2 \leq E_F \leq 0.2$ eV for $\text{YPd}_2\text{B}_2\text{C}$; calculations by the ASW method.

Atom	Occupation numbers							
	s	p_x, p_y	p_z	d_{xy}	$d_{xz, yz}$	$d_{3x^2-y^2}$	$d_{x^2-y^2}$	total value
Y	0.02	0.01	0.05	0.09	0.26	0.09	0.15	0.67
Pd	0.03	0.08	0.31	0.19	0.15	0.13	0.14	1.03
B	0.06	0.07	0.13	0.00	0.00	0.00	0.00	0.26
C	0.02	0.07	0.10	0.00	0.00	0.00	0.00	0.19

the Y atoms occupy the centre of the unit cell, the Pd atoms occupy positions $(0, 1/2, 1/4)$ and $(1/2, 0, 1/4)$; one of the ‘blades’ of the Y $d_{xz, yz}$ AOs is oriented along the Y–Pd bond, whereas the Pd $4d_{xy}$ AOs are directed towards neighbouring Pd atoms. Considerable concentration of these states near E_F is due to their splitting into bonding and antibonding ones as a result of interatomic (and interlayer) interactions. This splitting is an additional indication of the 3D nature of the electron distributions in BCT intermetallic borocarbides.

Coehoorn⁷⁰ was the first who attempted to take into account the role of the magnetic order in the formation of energy spectra of IBC in ASW calculations of ferromagnetic $\text{GdNi}_2\text{B}_2\text{C}$. The major effect was the splitting of the DOS peak near the Fermi level by ~ 0.2 eV due to the direct intraatomic $4f$ – $5d$ exchange interaction on Gd atoms. In the first approximation, the exchange splitting for all ferromagnetic compounds $\text{LnNi}_2\text{B}_2\text{C}$ is assumed to be proportional to the local magnetic moment. Then, the magnitude of this splitting for each Ln atom will be much larger than the width of the superconducting energy gap, which can be estimated as $\Delta E \approx 0.05$ eV for $\text{LnNi}_2\text{B}_2\text{C}$ in the framework of the BCS theory; this indicates that the superconductivity is only possible in the case of antiferromagnetic spin ordering.

With the aim of elucidating the tendencies in the filling of the near-Fermi states, Coehoorn⁷⁰ calculated hypothetical ideal BCT crystals $\text{LuCo}_2\text{B}_2\text{C}$, $\text{LuCu}_2\text{B}_2\text{C}$, and $\text{LuCo}_2\text{B}_2\text{B}$; the interatomic distances in the above compounds were assumed to be identical and equal to those for $\text{LuNi}_2\text{B}_2\text{C}$ ($a = 3.4639$ Å and $c = 10.6313$ Å). It was concluded on the basis of calculations that the rigid band model will give reasonable results for the description of $N(E_F)$ changes in the case of chemical modification of IBC composition.⁷⁰

2. Phases of composition $\text{YNi}_2\text{B}_2\text{X}$ ($\text{X} = \text{B}, \text{C}, \text{N}$, and O)

The effect of variable concentration of the valence electrons on the filling of the near-Fermi states and the position of the Fermi level for BCT intermetallic borocarbides due to substitution of carbon atoms by other atoms was considered using $\text{YNi}_2\text{B}_2\text{X}$ as an example. Calculations of hypothetical $\text{YNi}_2\text{B}_2\text{B}$, $\text{YNi}_2\text{B}_2\text{N}$, and $\text{YNi}_2\text{B}_2\text{O}$ phases were carried out by the LMTO method.

It was established⁷¹ that the structure of valence bands is strongly dependent on the composition of the X sublattice. The binding energies of quasi-core $\text{X}2s$ bands increase in the series $\text{B} < \text{C} < \text{N} < \text{O}$ and are equal to 10, 13, 17, and 21 eV, respectively. The $\text{X}2p$ -like subbands fall into a similar sequence on the energy scale. Lee *et al.*⁷¹ paid the major attention to the relative position of E_F and the DOS maximum near the Fermi level. It was shown that the position of the Fermi level for $\text{X} = \text{B}$ is lower, whereas that for ‘boron oxide’ and, especially, for ‘boronitride’ is higher than the maximum of the DOS peak. The obtained estimates of $N(E_F)$ for $\text{YNi}_2\text{B}_2\text{X}$ are 1.7, 4.40, 2.8, and 1.0 states per eV for $\text{X} = \text{B}, \text{C}, \text{N}$, and O , respectively. Lee *et al.*⁷¹ believe that this indicates the maximum superconductivity of the borocarbide.

Naturally, the assumptions accepted⁷¹ (first of all, the identity of the lattice parameters for all phases) make it possible to consider the results obtained as purely qualitative ones, especially with account of the data on the substantial role of B–C interactions in the formation of the crystal structure of IBC (see

above). Obviously, the formulation of the problem of simulation of the effect of doping the nonmetal IBC sublattice on their energy band structure and, all the more, on their properties requires performing correct calculations of the energy parameters for substitution processes of such kind, estimates of the stability of solid solutions formed, and direct calculations of the values of their lattice constants.

3. Substitution solid solutions of composition $\text{Y}(\text{Ni}_{1-x}\text{M}_x)_2\text{B}_2\text{C}$ ($\text{M} = \text{Fe}, \text{Co}, \text{Ru}$)

Specific features of the electronic structure of the ‘ideal’ quaternary BCT $\text{LnM}_2\text{B}_2\text{X}$ phases depending on the composition of their sublattices were considered above. Corresponding sites in such sublattices were occupied by atoms of rare-earth or transition metals, or by $2p$ atoms of the same sort.

A much more subtle effect on the properties of IBC can be exerted in the case of partial substitution of the atoms of a sublattice by ‘related’ atoms of another sort with the formation of quinary (and more complex) substitution solid solutions.

The first calculations of similar systems were carried out by Zeng *et al.*⁷³ in 1996 in the framework of the embedded-cluster approach. Before turning our attention to the results of these calculations, let us briefly consider experimental studies of the properties of the solid solutions mentioned above, in which the parameters of electronic spectra of multicomponent alloys are discussed.

It has been shown in the first numerical calculations of IBC that the d states of transition-metal atom play the determining role in the formation of the near-Fermi band, whereas the DOS of the conduction electrons genetically related to the rare-earth ions is rather low. Hence, the doping effects of a transition-metal sublattice will be the most ‘impressive’; for this reason, fairly well studied $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$ phases were mainly used as matrices and $3d$ and $4d$ transition metals (Co, Cu, Fe, Rh, Pd, *etc.*) were used as dopants.

Schmidt and co-workers⁹⁰ have synthesised single-phase specimens of $\text{Y}(\text{Ni}_{1-x}\text{Co}_x)_2\text{B}_2\text{C}$ ($0 \leq x \leq 1$) and studied the T_c dependences of these alloys on the concentration of impurity (Co). It was established that a sharp decrease in T_c (from ~ 15 K for the original $\text{YNi}_2\text{B}_2\text{C}$ to ~ 1.2 K for $x \approx 0.2$) occurs with an increase in x . Coehoorn⁷⁰ and Lee *et al.*⁷¹ explained this effect qualitatively within the framework of the rigid band model taking into account the results of band calculations for the matrix, where a decrease in CVE upon introduction of cobalt will induce a decrease in $N(E_F)$.

Another interpretation can be given from the viewpoint of Kaiser’s theory of nonmagnetic resonance states.⁹¹ According to this theory, the change in T_c should be correlated with the resonance scattering of the conduction electrons and Coulomb interaction between localised d states. In this case, the dependence of T_c on the concentration of impurity (x) can be written as follows:⁹²

$$T_c(x) = T_c(0) \exp\left(-\frac{Ax}{1-Bx}\right),$$

where coefficients A and B are functions of the LDOS at the Fermi level for the matrix and impurity [$N_{\text{im}}(E_F)$], respectively, of the parameter of the electron–phonon interaction λ , and effective interatomic Coulomb repulsion U_{ef} . The experimental dependence of T_c can be reproduced if $U_{\text{ef}} = 0.09$ eV, $N_{\text{im}}(E_F) = 11.8$ states per eV atom spin, and the ‘critical’ concentration of impurity (20%) can be found taking $N_{\text{im}}(E_F) = 0.2$ states per eV atom spin and $\lambda = 2.6$ (see Ref. 59). The values of $N(E_F)$ and λ are close in order of magnitude to those of mixed $\text{Lu}_2(\text{Fe}_{1-x}\text{Co}_x)\text{Si}_5$ alloys.⁹³

The effect of Ni substitution by Co and Cu on T_c of $\text{Y}(\text{Ni}_{1-x}\text{M}_x)_2\text{B}_2\text{C}$ was studied by Goldman *et al.*¹⁸ The specimens synthesised contained $\sim 95\%$ of a BCT phase with small amounts of Y_5C_6 , YB_2C_2 , YNi_2 , and Ni_3C . It has been noted that copper possessed limited solubility in the original borocarbide. The lattice parameters (the initial values $a = 3.526$ Å and $c = 10.538$ Å coincide with those found by Schmidt *et al.*⁹⁴ and

Chakoumakos *et al.*⁹⁵) increase or decrease as copper and cobalt, respectively, are introduced as dopants into $\text{YNi}_2\text{B}_2\text{C}$.

The introduction of Co or Cu into $\text{YNi}_2\text{B}_2\text{C}$ results in a decrease in T_c , the effect being more pronounced for Co ($dT_c/dx = -45$ K for Co and $dT_c/dx = -19$ K for Cu in the region $x \leq 0.2$). At high concentrations of dopants the dependence of T_c is affected by multiphase composition of the specimens synthesised.

Several possible reasons for such a strong difference in the dopant effect on T_c of the alloys have been considered, *viz.*, the presence of carbon vacancies; local magnetism of cobalt ions; 'asymmetry' of the shape of the near-Fermi $N(E)$ peak of the matrix, and, finally, the role of the electron–phonon interaction. The assumption of an appreciable concentration of carbon vacancies was based on the presence of a stable boride YCo_2B_2 phase (see Ref. 96). In this case, the number of carbon defects in $\text{Y}(\text{Ni}_{1-x}\text{Co}_x)_2\text{B}_2\text{C}$ must increase with temperature, and the lattice constants should be appropriately changed. However, annealing of borocarbide specimens did not result in noticeable changes in a and c .

The increased dT_c/dx value for Co can be due to its magnetic properties; however, special experiments^{16,90} indicate a nonmagnetic behaviour of Co. Therefore, a relationship between the $T_c(x)$ dependence and the parameters of its electronic spectrum and/or electron–phonon interaction is most probable.

As to the role of the electron states, it should be noted that according to calculations,^{70–72} the E_F value for $\text{YNi}_2\text{B}_2\text{C}$ coincides with the LDOS maximum, *i.e.*, the introduction of either Co or Cu will shift the E_F value along the energy scale favouring an increase in $N(E_F)$ and, correspondingly, suppression of superconductivity. However, the sharp (more than twofold) difference in the effect of Co and Cu impurities on T_c cannot be explained in this case. An attempt to explain the observed effect by the change in the constant of the electron–phonon interaction (λ) cannot be considered as sound, since in this case the 'loosening' of the crystal structure upon introduction of Cu (the increase in the lattice parameters of the solid solution) will determine the increase in λ , whereas the cobalt impurity will have an opposite effect on λ .

Despite the contradictions mentioned above, the experiment confirms directly the principal results of calculations,^{70–72} namely, that E_F coincides with the DOS maximum, which indicates that any attempts to 'chemically modify' the borocarbide composition aimed at increasing its superconducting characteristics¹⁸ are not promising.

Gangopadhyay *et al.*³⁴ and Hoellworth *et al.*⁹⁷ discussed the changes in $N(E_F)$ and the role of the electron–phonon interaction in the formation of superconducting properties of $\text{YNi}_{2-x}(\text{Co}, \text{Cu})_2\text{B}_2\text{C}$ alloys taking into account the results of experimental investigations of magnetic susceptibility (χ)

$$\chi = \chi_P + \chi_L + \chi_{VV} + \chi_c + \chi_i = \chi_{\text{intr}} + \chi_{\text{imp}}, \quad (1)$$

where χ_P , χ_L , χ_{VV} , and χ_c are the Pauli paramagnetic, diamagnetic (of conduction electrons), van Vleck, and diamagnetic (of core electrons) contributions, respectively; χ_i is the contribution of paramagnetic impurities; and χ_{intr} and χ_{imp} are the intrinsic and impurity susceptibilities, respectively.

Gangopadhyay *et al.*³⁴ discussed the role of χ_{intr} and χ_{imp} for $\text{YNi}_2\text{B}_2\text{C}$ doped with cobalt and copper. Assuming that χ_{intr} is independent of temperature and χ_{imp} obeys the Curie–Weiss law, one can write

$$\chi(T) = \chi_{\text{intr}} + \frac{C}{T - T_K}. \quad (2)$$

It turned out that this dependence is valid for a narrow temperature range (see also Refs 97, 98) and appreciably decreases as temperature increases. Similar $\chi(T)$ dependences were also found in the studies of poly- and mono-crystalline specimens of $\text{YNi}_2\text{B}_2\text{C}$.^{99,100}

Assuming that the contributions of the orbital paramagnetism and atomic core diamagnetism are constant, the observed³⁴ $\chi(T)$

dependence can be explained first of all by temperature changes in the Pauli paramagnetism of the conduction electrons χ_P resulting from either rearrangement of the band spectrum or spin fluctuations.^{99,100} The presence of antiferromagnetic spin fluctuations was postulated^{101,102} for $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$ to account for abnormal temperature dependences of ^{11}B spin-lattice relaxation times and the Knight shift. In a more recent study,¹⁰⁰ the temperature dependence of the magnitude and the sign of χ_P has been interpreted on the basis of the electronic energy spectrum. The results of the experiments on neutron scattering,²¹ NMR,¹⁰⁰ spin relaxation,¹⁰³ and heat capacity¹⁰⁴ also provide no information on spin fluctuations for $\text{YNi}_2\text{B}_2\text{C}$.

The dependence of T_c on the effective DOS calculated for $\text{YNi}_{2-x}(\text{Co}, \text{Cu})_2\text{B}_2\text{C}$ solid solutions from experimental data using the following equation

$$\begin{aligned} \chi_P &= N_A \mu_B^2 S N(E_F) = \\ &= 0.3233 \cdot 10^{-4} S N(E_F) \text{ (states per 1 eV per formula unit),} \end{aligned} \quad (3)$$

where N_A is the Avogadro constant, μ_B is the Bohr magneton, and S is the Stoner parameter, is shown in Fig. 9.

Figure 9. Correlation dependence of T_c on the reduced DOS at the Fermi level $[SN(E_F)]$ for solid solutions $\text{YNi}_{2-x}(\text{Co}, \text{Cu})_2\text{B}_2\text{C}$.

Thus, the reconstructed $T_c[SN(E_F)]$ dependences for Co and Cu impurities are substantially different. The only possible rationale for this fact can be relative strengthening of the electron–phonon interaction in alloys with the $\text{Cu} \rightarrow \text{Ni}$ type of substitution. The results of the investigation of the effect of the uniform compression on T_c for the systems in question¹⁰⁵ can be considered as indirect evidence in favour of the participation of both the electronic and electron-phonon mechanisms in the formation of superconducting properties of intermetallic borocarbides.

The effect of other impurities (Fe, Co, Ru, and Pd) on the superconducting properties of $\text{YNi}_2\text{B}_2\text{C}$ has been considered by Bud'ko *et al.*³² Linear suppression of the superconductivity effect with an increase in x was found in all cases. The data of Mössbauer spectroscopy and experiments on the magnetic susceptibility show that the dopants in the bulk of the initial phase have no local magnetic moments and their effect on the magnitude of the superconducting gap and thermodynamic properties is of local character.¹⁰⁶ Then T_c will be mostly affected by the $N(E_F)$ value, for which the change rate is proportional to the difference between the number of the valence electrons (z) of nickel and that of a substituting element.

Studies of the effects of sublattice doping on the electronic properties of IBC carried out by numerical quantum-chemical methods were started taking the $\text{Y}(\text{Ni}_{1-x}\text{M}_x)_2\text{B}_2\text{C}$ ($\text{M} = \text{Fe}, \text{Co}$, and Ru) solid solutions as an example.⁷³ Solid solutions with two different impurity concentrations ($x = 0.07$ and 0.47) approximated in the framework of the cluster approach by 71-atomic $\text{Y}_{12}(\text{Ni}_x\text{M}_{1-x})_{15}\text{B}_{32}\text{C}_{12}$ fragments with D_{2d} symmetry have been analysed.

The 'cluster' densities of the d states of Ni and substituting elements (Fe, Co, and Ru) in the $\text{Y}(\text{Ni}_{1-x}\text{M}_x)_2\text{B}_2\text{C}$ alloys for

Figure 10. The ‘cluster’ densities of states for Ni (*a, b*) and substituting elements (*M* = Fe, Co, and Ru) (*c, d*) in $Y(Ni_{1-x}M_x)_2B_2C$ alloys for $x = 0.07$ (*a, c*) and 0.47 (*b, d*).

$x = 0.07$ and 0.47 are shown in Fig. 10 and the electronic configurations and atomic charges are listed in Table 7.

As should be expected from the rigid band model, doping the matrix with the *d* elements mentioned should decrease the E_F value and result in partial ‘devastation’ of the near-Fermi $Ni3d$ states with the corresponding reduction of their populations. However, the populations of the $Ni3d$ orbitals remain virtually unchanged, whereas the corresponding cluster LDOS become somewhat broadened. The local densities of states for Ni and dopants differ substantially. Thus, the high-energy region of the subband of *d* states for Fe and Co is vacant. In contrast to $3d$ impurities, the $Ru4d$ states form a broad diffuse subband for all ruthenium concentrations. A low-energy peak (with an energy at the maximum of about -0.4 Ry) corresponding to localised $Ru-B$ bonds in the NiB_4 tetrahedra and a three-peak structure of delocalised states can be seen on the LDOS profile. Additionally, one more LDOS peak appears at the Fermi level. A change in the effective charge of the Ni atoms occurs in the $Y(Ni_{1-x}M_x)_2B_2C$ alloys (Table 7); it is primarily due to breaking down the symmetry of the crystalline environment of these sites upon introduction of dopants and to the change in the population of the extended $4s$ and $4p$ orbitals of nickel.

It is of interest to follow the change in the extent of overlap of the wave functions for individual atoms (the covalent component of the bond) upon doping of YNi_2B_2C . The corresponding bond populations are listed in Table 8. The $B-C$ interaction, which is the strongest in the original crystal, becomes weakened by $\sim 1\% - 4\%$ upon introduction of impurities. The antibonding $Y-C$ state remains almost unchanged, being localised in the plane nets. The $N-B$ bond order is constant in the presence of Fe

and Co; however, it decreases (by $\sim 3\%$) upon introduction of Ru. The overlap integrals for $M-B$ bonds are larger than those for the $Ni-B$ bond.

The considered processes of rearrangement of the electron states in doped borocarbide alloys are illustrated by the contour plots of the difference charge density.⁷³ These contour plots show that both the covalent $B-C$ bond and the charges on the yttrium atoms weakly ‘respond’ to the change in the composition of the *M* sublattice. The major effects of the electron density perturbation are localised near the substitution centre (in the bulk of the MB_4 tetrahedron). On the whole, the calculations⁷³ make it possible to interpret the chemical bonding in the $Y(Ni_{1-x}M_x)_2B_2C$ solid solutions as a combination of covalent-ionic-metallic interatomic

Table 8. Bond populations (e) in $Y(Ni_{1-x}M_x)_2B_2C$ solid solutions ($M = Fe, Co, \text{ and } Ru$) according to discrete variational embedded-cluster calculations.

^a The negative value corresponds to antibonding of the Y—C bond.

interactions with a substantial spatial anisotropy, where the Y—C interaction in the plane nets and the interaction in M—B layers result from ionic and covalent binding, respectively, and the ‘interlayer’ (YC)—(MB) interactions are due to hybridisation of B and C atomic states. The doping of the M sublattice predominantly modifies the charge states and interspecies bondings in the M—B layers.

It is natural that the applicability of the cluster approach to the correct description of changes in subtle features of the TDOS (especially, near the Fermi surface, *viz.*, in the region of strongly delocalised states), interpretation, and prognosis of superconducting and magnetic properties of multicomponent solid solutions is limited. Band calculations of borocarbide solid solutions of variable composition are needed.

VI. The energy band structure of ‘two-layered’ $LnNiBC$ borocarbides and solid solutions based on them

In addition to the quaternary $LuNiBC$ phase, a series of isostructural solid solutions of variable composition of the general formula $Ln(Ni_{1-x}M_x)BC$ ($Ln = Lu, Y; M = Cu, V$) have been synthesised to date.^{36, 37, 42}

The energy band structure of $LuNiBC$ was calculated by Mattheiss,⁵⁰ Kim,⁶⁸ and Coehoorn.⁷⁰ Let us discuss it in the framework of LAPW calculations.⁵⁰ The character of the $E(k)$ dependence for the near-Fermi bands is the most remarkable when comparing the valence band structures of $LuNi_2B_2C$ (Fig. 3) and $LuNiBC$ (Fig. 11). The flat regions of the $Ni3d$ bands ($G-X$), which virtually coincide with E_F for $LuNi_2B_2C$, appear to be shifted towards higher energies on the energy scale for $LuNiBC$. This results in the formation of the $Ni3d$ resonance in the region of nonbonding states and the DOS at the Fermi level appears to be low ($N(E_F) \sim 1$ electron per cell). The E_F position in the region of the local DOS minimum in the electronic energy spectra of $LuNiBC$ is reproduced in calculations performed by the ASW⁷⁰ and *ab initio* pseudopotential⁶⁸ methods.

**Figure 11.** The band structure of $LuNiBC$.⁵⁰

These peculiarities of the position of the Fermi level in the region of local DOS maximum ($LuNi_2B_2C$) and minimum ($LuNiBC$) are crucial for the explanation of distinctions between the superconducting properties of ‘one-layered’ and ‘two-layered’ IBC having similar crystalline structures and close interatomic distances. If the calculations^{50, 58, 70} of electronic spectrum of $LuNiBC$ are correct, one should expect that the $N(E_F)$ values of solid solutions will be increased as compared to that of an ‘ideal’ crystal (with the corresponding changes in properties) for any change in CVE (for instance, due to the doping of sublattices).

This assumption was tested by Qiu *et al.*^{36, 42} and Gangopadhyay *et al.*³⁷ Thus, YBC , YB_4 , and several other phases were present in the specimens of synthesised $LnNi_{1-x}Cu_xBC$ solid solutions ($Ln = Y, Lu; 0 \leq x < 1$), the amount of tetragonal $YNi_{1-x}Cu_xBC$ phase decreased sharply with an increase in the copper concentration.³⁷ It was thus suggested that compounds $YCuBC$ and $LuCuBC$ are unstable.³⁷ The effect of dopant on the lattice constants of $YNiBC$ ($a = 3.579 \text{ \AA}$, $c = 7.570 \text{ \AA}$) and $LuNiBC$ ($a = 3.495 \text{ \AA}$, $c = 7.663 \text{ \AA}$) is worth noting. The value of parameter a increases most rapidly in the initial stage of doping (up to $x \approx 0.2$), while a linear increase in the parameter c is observed at higher concentrations of copper. The rates of changes in the concentration (c) $d \ln c / dx$ for Y and Lu solid solutions are equal to 0.032 and 0.038, respectively, which is very close to that for $YNi_{2-x}Cu_xB_2C$ ($d \ln c / dx \approx 0.03$).⁴² This indicates a common nature of the observed effect, which can be related to the weakening of covalent M—B interactions upon partial $Cu \rightarrow Ni$ substitution due to the filling of the $Ni3d$ orbitals by an additional electron of copper. The reason for considerable differences in the solubility limits of copper in ‘one-layered’ and ‘two-layered’ IBC, which amount to $\sim 50\% - 60\%$ and 20% , respectively, remain unclear.

An increase in the content of copper results in the increase in T_c of $LnNi_{1-x}Cu_xBC$ solid solutions, the effect for yttrium compounds being more pronounced than that for lutetium compounds. The maximum T_c for $YNiBC$ doped with copper is 8.9 K (at $x > 0.6$) is determined by tetragonal IBC and cannot be ascribed to impurities of other phases [YB_6 ($T_c = 6.0 \text{ K}$), YB_{12} ($T_c = 4.7 \text{ K}$), YC_2 ($T_c = 3.8 \text{ K}$), YB_2C_2 ($T_c = 3.0 \text{ K}$)] found in the specimens.¹⁰⁷ Gangopadhyay *et al.*³⁷ also pointed to the fact that T_c is dependent on the dispersity of the specimens; for instance, annealing of $YNi_{1-x}Cu_xBC$ specimens (for $x > 0.6$) considerably increases their T_c .

Extrapolation of the $T_c(x)$ dependence to $x = 1$, which corresponds to a hypothetical ‘ $YCuBC$ ’, gives $T_c \approx 10 \text{ K}$, which is lower than for ‘ $LuCuBC$ ’. Presumably, the electronic structures of $LuNiBC$ and $YNiBC$ are similar and the $N(E_F)$ value for both compounds must increase upon introduction of copper atoms.

The inverse effect, namely, a decrease in CVE, upon partial substitution of nickel by vanadium in $LuNiBC$, was discussed by Qiu *et al.*³⁶ A series of single-phase $LuNi_{1-x}V_xBC$ solid solutions has been prepared and the solubility limit of vanadium is $x = 0.25$. The temperature dependence of electrical resistance has been measured and it has been found that $T_c(LuNiBC) = 2.96 \text{ K}$ and $T_c(LuNi_{0.8}V_{0.2}BC) = 2.60 \text{ K}$, *i.e.*, $d \ln T_c / dx = -0.5$. Thus, E_F for the matrix does not coincide with the local DOS minimum and the $N(E)$ shape is more complex, since the Fermi level in $LuNiBC$ can be intermediate in energy between the minimum and local

maximum of $N(E)$, hence, $dN(E)/dE > 0$. The study of the effect of external pressure on T_c shows that $dT_c/dP = -0.17 \pm 0.03$ K GPa⁻¹ for both the original and doped IBC. From the viewpoint of the band theory, the effect of external pressure is equivalent either to broadening of the bands (at $E_F = \text{const}$) or to the E_F shift towards the lower-energy region. Hence, if E_F for LuNiBC coincides with the DOS minimum, then the $dN(E_F)/dP$ should be positive for both LuNiBC and LuNi_{1-x}V_xBC. The negative value of dT_c/dP can indicate either a more complex shape of the DOS distribution near E_F than was obtained from the one-electron band calculations or the impossibility to describe the effect of hydrostatic pressure on T_c by a simple correlation with the change in $N(E_F)$.

VII. Electronic structure and some physicochemical properties of intermetallic borocarbides

The nature of IBC is determined by (or is closely related to) their electronic structure and can be rationalised from the viewpoint of theoretical models of EES for intermetallic borocarbides.

1. Superconductivity

The superconductivity of IBC is the property that attracted attention to this class of compounds and gave rise to numerous experimental and theoretical studies. The first calculations of EES of LuNi₂B₂C, LuNiBC, and YNi₂B₂C (see Refs 50, 59, 64, 70, and 71) made it possible to place the IBC with certainty into the class of conventional superconductors with the BCS type of conductivity, to determine specific features of the structure of the near-Fermi energy bands for one- and two-layered IBC, and to relate their conducting properties to specific electron states on the Fermi surface. These concepts are widely used for qualitative interpretation of the results obtained. As has been noted above, the attempts were made to extend them (using the rigid band model) to multicomponent solid solutions. It was assumed, in the simplest case, that $T_c \sim N(E_F)$, which, in turn, is determined by the degree of filling the valence band depending on CVE for the compound of a given composition.

An attempt to find correlations between the parameters of the one-electron energy spectra of solid solutions Y(Ni_{1-x}M_x)₂B₂C (M = Fe, Co, and Ru) (these parameters were obtained in the framework of the cluster approach) and T_c has been undertaken by Zeng *et al.*⁷³ The integrated density of the d states of transition-metal atoms (N_d) in solid solutions of variable composition, which is used in the theory of paired electron correlations and associated with the conditions for the formation of superconducting state, was considered as the 'electronic factor' of superconductivity. The N_d value can be calculated using the following formula

$$N_d = \int_{-\infty}^{E_F} D_d^q(\varepsilon) d\varepsilon, \quad (4)$$

where $D_d^q(\varepsilon)$ is the sum of partial populations of the d states of the q -type atoms

$$D_d^q(\varepsilon) = \sum_i P_{d,i}^q \frac{\delta\pi}{(\varepsilon - \varepsilon_i)^2 + \delta^2}. \quad (5)$$

Here, $P_{d,i}^q$ is the Mulliken population of the atomic orbital d in the cluster orbital ϕ_i with the energy eigenvalue ε_i , δ is the half-width ($\delta = 0.136$ eV) of the Lorentzian function employed to simulate the energy broadening of the discrete cluster levels in the crystal, and summation is performed over all occupied orbitals i .

In the rigid band model, the integrated density of d states for a binary alloy of variable composition A_{1-x}B_x can be written as

$$N_d^{\text{AB}} = (1-x)N_d^{\text{A}} + xN_d^{\text{B}},$$

where N_d^{A} and N_d^{B} are populations of the d states for 'pure' metals A and B. Thus, the corresponding populations for the Ni_{1-x}Fe_x

alloy are usually assumed to be ~ 9 e⁻ (Ni) and ~ 7 e⁻ (Fe). This primitive scheme for the solid solutions under consideration (for instance, Y(Ni_{1-x}Fe_x)₂B₂C) can be refined using formula (6)

$$\bar{N}_d = 9(1-x) + 7x + N_d^0, \quad (6)$$

where N_d^0 describes the effects of hybridisation of the transition metal (Ni), that is substituted, with the nearest environment (Ni–B₄).

Comparison of N_d values obtained from self-consistent calculations on selected clusters and the values of $\bar{N}_d$ parameters of a given model found from Eq (6)[‡] allows one to test the rigid band model.

Calculations performed by Zeng *et al.*⁷³ showed that the N_d and $\bar{N}_d$ values are fairly close for low impurity concentrations ($x = 0.07$) and the T_c vs. N_d correlation dependence is clearly observed. The difference between the parameter of the model $\bar{N}_d$ and the self-consistent N_d value increases substantially as the M content increases.

Direct estimates of T_c based on the results of calculations of the energy band structure of IBC were made by Mattheiss *et al.*,^{50, 64} Pickett *et al.*,⁵⁹ Kim *et al.*,⁶⁸ and Ravindran *et al.*⁷² The constant of the electron–phonon interaction (λ) was found to be approximately equal to 2.6 and the frequency of the Ba_{1g} phonon mode for LuNi₂B₂C is 850 cm⁻¹.⁵⁹ It is assumed that the soft modes of heavier atoms also make contributions to the superconductivity. Taking into account a mixed character of highest filled bands, it is emphasised that the multicomponent nature of the phase is one of the main factors that determine the superconductivity of IBC.

The electron–phonon mechanism of superconductivity in LuNi₂B₂C owing to the interaction between an isolated sp band near the Fermi level and high-frequency Ba_{1g} phonons modulating the angles of NiB₄ tetrahedra was discussed by Mattheiss *et al.*⁶⁴

The T_c value (≈ 15 K) found for YNi₂B₂C using $\lambda = 0.9$, the experimental Debye temperature ($\Theta = 573$ K),⁷⁴ and the calculated $N(E_F)$ value is in good agreement with the experiment.⁷¹

Kim *et al.*⁶⁸ estimated the λ value from the data on measurements of low-temperature electronic heat capacity γ (see Ref. 56) and band calculations using the McMillan formula⁴ and found that $\lambda \approx 0.8-1.1$. The relatively high T_c value for LuNi₂B₂C is primarily determined by considerable contributions of the Ni3d states to $N(E_F)$ ⁶⁸ and the assumed mechanism of the interaction between the high-frequency a_{1g} mode and sp nonmetal bands⁶⁴ cannot play the decisive role, since the contributions of the boron and carbon atomic states to $N(E_F)$ are small. Then, an estimate of the T_c value for the related borocarbide LuNiBC using a rough approximation $T_c \approx N(E_F)$ can be made and the results obtained ($T_c \sim 0.7-2.6$ K) are close to the experimental data.

Despite the above disagreement on the relative role of the electron and vibrational states of individual atoms and atomic groups in the formation of superconducting properties of IBC, all calculations^{50, 59, 64, 68, 71} allow one to consider these compounds as the 3D systems with an intermediate type of the electron–phonon interaction and superconductivity described by the BCS theory.

In this connection the studies of the isotope effect¹⁰⁸ and some electronic properties of IBC¹⁰⁹ should be mentioned. They suggest rather strong electron–phonon interactions in these systems. The phonon anomalies similar to those found in superconducting 3D carbides were found in borocarbides.¹¹⁰ An additional phonon mode associated with the formation of superconducting state was reported by Kawano *et al.*¹¹¹

A progressive suppression of the real part of optical conductivity $\sigma_1(\omega)$ in the far IR region, as should be expected in accord with the BCS theory in the case of appearance of a superconducting gap (Δ), was observed for YNi₂B₂C and LuNi₂B₂C in the

[‡] In this case, the N_d^0 value for the original matrix ($x = 0$) is obtained from the condition $N_d = \bar{N}_d$.

Figure 12. The PCS function of the electron–phonon interaction for $\text{HoNi}_2\text{B}_2\text{C}$ (a), $\text{YNi}_2\text{B}_2\text{C}$ (b), and $\text{LaNi}_2\text{B}_2\text{C}$ (c).¹¹⁴

studies of the temperature dependence of $\sigma_1(\omega)$ at $T < T_c$.¹¹² At $T \approx 6$ K and frequencies 5.6 meV ($\text{LuNi}_2\text{B}_2\text{C}$) and 6.9 meV ($\text{YNi}_2\text{B}_2\text{C}$), the $\sigma_1(\omega)$ values are equal to zero. This makes it possible to estimate the $2\Delta/k_B T_c$ value as ~ 3.9 – 5.2 . Hence, the effect of the formation of the Cooper pairs is assumed to occur with participation of the low-frequency phonon modes (optical phonons).¹¹³

The electron–phonon interaction in a number of IBC was studied by the point contact spectroscopy (PCS),¹¹⁵ which makes it possible to observe directly the interactions of the conduction electrons with elementary excitations in the crystal.

The PCS functions $g(\omega)$ for $\text{HoNi}_2\text{B}_2\text{C}$, $\text{YNi}_2\text{B}_2\text{C}$, and $\text{LaNi}_2\text{B}_2\text{C}$ are shown in Fig. 12. It can be seen that the function $g(\omega)$ for $\text{HoNi}_2\text{B}_2\text{C}$ has two distinct maxima with energies corresponding to the DOS peaks of soft phonons. A similar structure of the function $g(\omega)$ is observed for $\text{YNi}_2\text{B}_2\text{C}$, which indicates an electron-phonon interaction with low-energy phonons ($h\nu \approx 4$ – 9 meV). On the contrary, the corresponding interaction was not observed for nonsuperconducting $\text{LaNi}_2\text{B}_2\text{C}$ in the soft mode region of the phonon spectrum. Bommeli *et al.*¹¹² explain the above distinctions by specific features of the electronic structure (in particular, by the nesting effect on the Fermi surface) of the considered representatives of IBC homologous series.

2. Superconductivity and magnetism

The relationship between superconductivity and magnetism is one of the central problems of modern physical chemistry of crystals. For ternary intermetallic borides, this problem has been discussed in detail in a monograph.¹¹⁶ It has been noted in early studies of the properties of IBC that most $\text{LnM}_2\text{B}_2\text{C}$ phases are magnetic superconductors;^{1–3, 19} therefore, the problems of coexistence and mutual influence of magnetism and superconductivity were considered first in numerous experimental studies.

The results obtained to date make it possible to state that IBC are a unique class of magnetic superconducting materials. It is known that the onset of a magnetic order leads to an abrupt suppression of superconductivity and in the case of coexistence of both effects they are observed at appreciably different temperatures (energies). In this case, the temperature of magnetic ordering (the Neel temperature, T_N) is, as a rule, much lower than T_c for all the known groups of magnetic superconductors. Thus, T_c in Chevrel's phases is higher than T_N (~ 1 K) by an order of magnitude.¹¹⁶ The differences between T_c and T_N for HTSC cuprates containing rare-earth metal ions are even larger.¹⁰⁷

On the contrary, in the case of IBC the magnetic and superconducting states exist in the same temperature range and T_c can be either higher or lower than T_N .

T, K	$\text{ErNi}_2\text{B}_2\text{C}$	$\text{GdNi}_2\text{B}_2\text{C}$	$\text{DyNi}_2\text{B}_2\text{C}$
T_N	6.8	19.0	10.6
T_c	11.0	2.0	6.0

If T_N and T_c values are comparable, then the energy effects of the magnetic ordering and electron–electron interaction through the lattice phonons (formation of the Cooper pairs), *i.e.*, the energies of formation of magnetic structures and the energies of superconducting states, will also be close. Such a unique feature caused an ever increasing number of publications devoted to the investigation of relationship between the magnetism and superconductivity of IBC.

The greatest progress in this line has been achieved in the studies of magnetic structures of IBC. The investigations were mostly carried out by X-ray or neutron diffraction techniques for $\text{PrNi}_2\text{B}_2\text{C}$ and $\text{DyNi}_2\text{B}_2\text{C}$,^{14, 19, 20, 23, 100, 117–132} $\text{ErNi}_2\text{B}_2\text{C}$ and $\text{TbNi}_2\text{B}_2\text{C}$,^{21, 22, 47, 133–135} $\text{TmNi}_2\text{B}_2\text{C}$,^{11, 47, 136–138} $\text{GdNi}_2\text{B}_2\text{C}$,^{25, 45–47} and $\text{CeNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$.^{47, 139}

As a result, a wide variety of magnetic IBC structures was found; some of them are listed in Table 9. Thus, an antiferromagnetic ordering was found for $\text{LnNi}_2\text{B}_2\text{C}$ ($\text{Ln} = \text{Pr}, \text{Dy}, \text{and Ho}$) at low temperatures. The antiferromagnetic structure is formed due to alternation of antiferromagnetically oriented rare-earth metal layers with ferromagnetic type of intralayer ordering of magnetic moments along the z axis. The magnetic structure of $\text{ErNi}_2\text{B}_2\text{C}$ can be described by the spin density waves (SDW) with the wave vectors $\mathbf{q}(001)$ or $\mathbf{q}(110)$. Several magnetic structures were found for $\text{HoNi}_2\text{B}_2\text{C}$ ($T_c \approx 8$ K). At $T_N \approx 8.5$ K, a helical incommensurate antiferromagnetic structure appears, in which the plane nets of vectors of ferromagnetically oriented moments of are rotated by an angle of $\sim 17^\circ$ with respect to the original antiparallel packing. The wave vector of this incommensurate spin structure is $\mathbf{q}(0, 0, 0.91)$. Another type of incommensurate structure modulated along the x axis by the wave vector $\mathbf{q}(0.55, 0, 0)$ exists at $T_N \approx 6.5$ K (in the region of the reentrant superconducting transition with $T_c \approx 5$ K). The helical structure is destroyed with the formation of a conventional antiferromagnetic order as the temperature decreases. It is important that the magnetic structures are extremely sensitive to the IBC composition.^{140, 141}

Currently, there is no general microscopic theory of superconductors having incommensurate magnetic structures. Only assumptions on the nature of coexistence and relationship between the superconductivity and magnetism have been made.^{10, 14, 23, 47, 117–139}

Table 9. Types of magnetic structures, magnetic moments (μ), the Neel temperatures (T_N/K) critical temperatures (T_c/K), and magnetic wave vectors ($\mathbf{q}$) for several IBC.⁴⁷

Phase	Type of magnetic structure	T_N	T_c	μ, μ_B	$\mathbf{q}$
$\text{PrNi}_2\text{B}_2\text{C}$	AF	4.0	—	0.81	(0, 0, 1)
$\text{NdNi}_2\text{B}_2\text{C}$	AF	4.8	—	2.10	(1/2, 0, 1/2)
$\text{GdNi}_2\text{B}_2\text{C}$	ISS(x)	19.0	—	7.0	(0.55, 0, 0)
$\text{TbNi}_2\text{B}_2\text{C}$	ISS(y)	15.0	—	7.78	(0.555, 0, 0)
$\text{DyNi}_2\text{B}_2\text{C}$	AF	10.6	6	8.47	(0, 0, 1)
$\text{HoNi}_2\text{B}_2\text{C}$	ISS(z)	8.5	8	6.7	(0, 0, 0.91)
	ISS(x)	6.3	—	—	(0.55, 0, 0)
	AF	5.0	5	8.62	(0, 0, 1)
$\text{ErNi}_2\text{B}_2\text{C}$	SDW(x)	6.8	11	7.19	(0.553, 0, 0)
$\text{TmNi}_2\text{B}_2\text{C}$	SDW(z)	1.5	11	3.78	(0.093, 0.093, 0)

Note. The following designations are used: AF is antiferromagnetic structure, ISS(x, y, z) is incommensurate spin structure with the wave vector modulated along the (x, y, z) directions, and SDW(x, y, z) is spin density waves along the (x, y, z) directions.

Thus it has been shown in one of the first studies of $\text{LnM}_2\text{B}_2\text{C}$ ($\text{Ln} = \text{Tm}, \text{Er}, \text{Ho}, \text{and Dy}$)¹⁰ that their properties are similar to those of magnetic superconductors LnRh_4B_4 and LnMo_6S_6 .^{142, 143} In the latter compounds, the high density of local magnetic moments (the long-range spin order) and superconductivity ‘coexist’ owing to the spatial separation of magnetic rare-earth metal ions and transition-metal ions, a weak exchange interaction between the states of these sites, and a low density of the conduction electrons at the sites occupied by the $4f$ elements.

The vast majority of theoretical investigations of EES are devoted to IBC containing nonmagnetic rare-earth metal atoms (Y and Lu) and carried out for a spin-restricted (nonmagnetic) version. Quantitative calculations of the electron states taking into account the spin order were performed only for $\text{GdNi}_2\text{B}_2\text{C}$ assuming the ferromagnetic ordering of magnetic moments.⁷⁰ The first attempt to explain the magnetic order from the viewpoint of one-electron band structure calculations of IBC has been undertaken by Greenwood *et al.*¹⁴⁴ The ordering of magnetic moments was assumed to occur due to an indirect interaction (of the Ruderman–Kittel–Kasuga–Yoshida type) of $4f$ electrons of the rare-earth metal atoms. Then, the onset of magnetic order can be correlated with the maxima of magnetic susceptibility $\chi(\mathbf{q})$ of the conduction electrons, which, in turn, are determined by the distribution of states on the Fermi surface (in particular, by the nesting effect). The calculations¹⁴⁴ showed that the $\chi(\mathbf{q})$ peaks appear near the wave vectors $\mathbf{q} = (0.6, 0, 0)$ and $(0, 0, 0.9)$ along the $\mathbf{a}^*$ axis and near the wave vectors $\mathbf{q} = (0, 0, 0.3)$ and $(0, 0, 0.9)$ along the $\mathbf{c}^*$ axis. These wave vectors correspond to the observed incommensurate SDW for $\text{HoNi}_2\text{B}_2\text{C}$.¹⁹

It should be noted again that most of the problems of the fundamental theory of superconducting magnetic IBC remain unexplored to date. They include, in particular, the problems of the onset of the magnetic order in superconducting materials, conditions of compatibility of and competition between these phenomena, the nature of the exchange interaction between magnetic ions and the conduction electrons, the role of the spin-orbital interaction, *etc.*

3. The electric field gradient

The electric field gradient (EFG) reflects the asphericity of the charge density distribution near the nucleus in question and is directly related to the electron density distribution in the crystal, the nature of the chemical bond, and the symmetry of the nearest environment of the nuclei. It is possible to determine the EFG value by studying the quadrupole effects in NMR spectra¹⁴⁵ and the Mössbauer effect.¹⁴⁶ Experimental estimates of EFG for compounds in question were performed for the ^{155}Gd nuclei in $\text{GdNi}_2\text{B}_2\text{C}$ and $\text{GdCo}_2\text{B}_2\text{C}$ (see Ref. 70) and ^{57}Fe for $\text{Y}(\text{Ni}_{1-x}\text{Fe}_x)_2\text{B}_2\text{C}$ alloys.⁷³

The electric field gradient at the ^{155}Gd nuclei reflects first of all the asphericity of the $6p$ electron density distribution within a radius of $\sim 2 \text{ \AA}$.¹⁴⁷ The positive contributions to the V_{zz} EFG obtained for $\text{GdNi}_2\text{B}_2\text{C}$ and $\text{GdCo}_2\text{B}_2\text{C}$ points to considerable contribution of the $6p_x, p_y$ orbitals localised in the plane of $\text{Gd}-\text{C}$ nets to the charge density.

A quantitative EFG analysis was carried out using ASW calculations of the low-temperature $\text{GdNi}_2\text{B}_2\text{C}$ phase under the assumption of ferromagnetic spin order.^{70, 148} The values of local magnetic moments at the Gd , Ni , B , and C atoms were 7.27, 0.03, 0.00, and $-0.01 \mu_B$, respectively. The contributions of the populations (n_i) of the $\text{Gd } 6p$ and $5d$ orbitals to the EFG and the radial charge densities $\langle r^{-3} \rangle_i$ were calculated using the following equations¹⁴⁸

$$V_{zz}(6p) = 7.74 \left[\frac{1}{2} (n_x + n_y) - n_z \right] \langle r^{-3} \rangle_{6p}, \quad (7)$$

$$V_{zz}(5d) = 5.54 \left[\frac{1}{2} (n_{x^2-y^2} + n_{xy}) - \frac{1}{2} (n_{xx} + n_{yy} - n_{3z^2-r^2}) \right] \langle r^{-3} \rangle_{5d}.$$

Table 10. Orbital populations (n_i), radial charge densities ($\langle r^{-3} \rangle_i$), and EFG components (V_{zz}) at ^{155}Gd nuclei for ferromagnetic $\text{GdNi}_2\text{B}_2\text{C}$ according to the ASW calculations.

Parameter	Spin ‘up’	Spin ‘down’
$n_x = n_y / e$	0.173	0.165
n_z / e	0.147	0.132
$n_{z^2-y^2} / e$	0.216	0.148
n_{xy} / e	0.304	0.278
$n_{xz} = n_{yz} / e$	0.235	0.178
$n_{3z^2-r^2} / e$	0.285	0.227
$\langle r^{-3} \rangle_{6p} / e a_0^{-3}$	25.9	29.0
$\langle r^{-3} \rangle_{5d} / e a_0^{-3}$	1.83	1.44
$10^{21} V_{zz}(6p) / \text{V m}^{-2}$	5.21	7.41
$10^{21} V_{zz}(5d) / \text{V m}^{-2}$	0.0	0.16

The values obtained are listed in Table 10. It can be seen that the $\langle r^{-3} \rangle_{6p}$ values are much larger than $\langle r^{-3} \rangle_{5d}$, *i.e.*, that the V_{zz} values are determined mainly by the asphericity of the $6p$ charge density. The calculated V_{zz} value ($12.8 \times 10^{21} \text{ V m}^{-2}$) virtually coincides with the experimental one ($11.9 \times 10^{21} \text{ V m}^{-2}$) obtained from the analysis of the Mössbauer spectra.¹⁴⁸

Mulder *et al.*¹⁴⁸ emphasise that the V_{zz} value for $\text{GdNi}_2\text{B}_2\text{C}$ is comparable to the EFG value for the known magnetic materials $\text{Ln}_2\text{Fe}_{14}\text{B}$, $\text{Sm}_2\text{Fe}_{17}\text{N}_3$, and LnCo_5 (see Refs 149–151) and is remarkable in connection with the macroscopic magnetic anisotropy of IBC. However, the V_{zz} contribution of isostructural BCT phases ($\text{GdNi}_2\text{Si}_2\text{C}$, $\text{GdCo}_2\text{Si}_2\text{C}$) is small and negative.¹⁴⁷ It is suggested¹⁴⁸ that carbon atoms filling the vacancies of ThCr_2Si_2 -like sublattice play the key role in the formation of IBC. The role of the carbon atoms is thought to be analogous to that of the nitrogen atoms, whose insertion into the bulk of intermetallic $\text{Sm}_2\text{Fe}_{17}$ results in redistribution of the electron density around the samarium nucleus in such a way that the EFG in the formed nitride $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ increases by $\sim 100\%$.¹⁵²

The EFG values at the nuclei of transition-metal atoms in alloys of composition $\text{Y}(\text{Ni}_{1-x}\text{M}_x)_2\text{B}_2\text{C}$ ($\text{M} = \text{Fe}, \text{Co}, \text{and Ru}$; $x = 0.07$ and 0.47) were calculated in the framework of the cluster approach;⁷³ the following individual components responsible for the formation of the EFG tensor at the nuclei were estimated: V_{zz}^{val} , *i.e.*, the EFG dependent on the asymmetric distribution of valence electrons of the atom under consideration,

$$V_{zz}^{\text{val}} = \left\langle \frac{\rho(3z^2 - r^2)}{r^5} \right\rangle, \quad (8)$$

and V_{zz}^{nuc} , which includes the contribution of point charges Q_v and polarisation of inner shells

$$V_{zz}^{\text{nuc}} = \sum_v \frac{Q_v(3z_v^2 - r_v^2)}{r_v^5}, \quad (9)$$

where the summation is performed over the atoms of the calculated fragment.

Generally, one should also take into account the contribution of V_{zz}^{host} , which describes the effect of the crystal ‘residue’ (‘external’ with respect to the cluster selected) and whose nature is similar to that of V_{zz}^{nuc} . In several studies (see, for instance, Ref. 70), the V_{zz}^{host} value is assumed to be negligible by analogy with the results of calculations of ionic compounds.¹⁵³ The V_{zz}^{val} , V_{zz}^{nuc} , and V_{zz} values are listed in Table 11.

The EFG for transition metals is known to be determined by the asphericity of the distribution of d and p electrons.¹⁵⁴ The positive V_{zz}^{val} values (see Table 11) show that the contributions of $d_{x^2-y^2}$, d_{xy} , p_x , and p_y orbitals of transition metals (in the xy plane) dominate over those of d_{z^2} , d_{xz} , d_{yz} , and p_z orbitals oriented along the z axis. The small concentration differences in V_{zz}^{val} indicating the local nature of the EFG formation also worth noting. Estimates of the quadrupole splitting value proportional to the

Table 11. The EFG components ($e a_0^{-3}$) at the transition-metal nuclei in $Y(Ni_{1-x}M_x)_2B_2C$ ($M = Fe, Co,$ and Ru) alloys according to discrete variational calculations.

Central atom in the cluster	x	V_{zz}^{val}	V_{zz}^{nucl}	V_{zz}	$10^{17} V_{zz}$ / $V \text{ cm}^{-2}$
Ni	0.00	0.74	-0.65	0.09	0.87
Fe	0.07	0.61	-0.65	-0.04	-0.39
Fe	0.47	0.50	-0.63	-0.13	-1.26
Co	0.07	0.27	-0.65	-0.37	-3.59
Co	0.47	0.24	-0.64	-0.40	-3.89
Ru	0.07	1.96	-0.65	1.31	12.7
Ru	0.47	1.95	-0.63	1.32	12.8

EFG value for iron in $Y(Ni_{1-x}Fe_x)_2B_2C$ alloys appeared to be in reasonable agreement with those obtained by Mössbauer spectroscopy.³³

4. Atomic properties

Physicochemical characteristics of the solids determined by the total energy of their electron–nuclear system (E_{tot}) or by their cohesion energy (E_{coh}) are usually considered as their atomic properties. Direct calculations of E_{tot} and E_{coh} using modern quantum-chemical methods make it possible to determine many of the properties of crystals, namely, the equilibrium volumes and lattice parameters, bulk moduli, critical pressures (breaking stress of a chemical bond), and a number of thermodynamic parameters.^{155, 156}

To date, these parameters have been calculated only for YNi_2B_2C in the framework of the LMTO approach.⁶⁹ Thus, calculation of the contributions of the atoms of different types (the so-called structural energies ΔE)⁷² makes it possible to understand, in particular, the role of individual elements in the formation of the crystal structure of IBC. It has been found that ΔE values for Y and Ni are negative, whereas they are positive for the metalloid atoms (with respect to E_{tot} of neutral atoms), which implies that metallic components play the key role in the phase formation of IBC. Despite the destabilising (positive) energy of carbon, its incorporation into the structure results in an appreciable increase in the bonding energy of yttrium, *i.e.*, in the overall stabilisation of the phase. This is confirmed by calculations of the heat of formation of YNi_2B_2C : $\Delta H = -153.82$ Ry per formula unit.

Ravindran *et al.*⁷² reported the solution of the equation of state for YNi_2B_2C (which makes possible studying the P – V dependences^{157, 158}) as a universal relationship between the volume of the crystal and its total energy. Theoretical values of the bulk modulus ($B_0 = 1.071$ kbar) and its first derivative have been obtained. Their comparison with the corresponding values for YRh_3B indicates a greater plasticity of YNi_2B_2C , which is likely associated with its layered structure.⁷² Unfortunately, thermomechanical characteristics of IBC have not virtually been studied.

In our opinion, systematic calculations of the atomic characteristics of IBC of different composition and structure must be an effective method of attacking the problems of thermobarochemistry and theoretical material science of IBC and related compounds.

VIII. Spectroscopic studies of the electronic structure of intermetallic borocarbides

Spectroscopic methods make it possible directly to investigate the distribution of partial and total densities of filled and free states in a wide energy interval using X-ray emission, X-ray absorption, and X-ray photoelectron spectra (XES, XAS, and XPES, respectively). It is natural that the first band structure calculations were followed by spectroscopic studies of IBC. The main problems of such studies were testing the correctness of suggested theoretical

models and determining specific features of the distribution of the electron states in excited electronic subsystems.

1. X-Ray photoelectron spectra

The XPES method was first used in studies of the distribution of the YNi_2B_2C electron states (Fig. 13).^{159, 160} As can be seen, the XPES contains a peak of maximum intensity (~ 1.4 eV lower than the Fermi level) corresponding to the distribution of the $Ni3d$ states, and local maxima with energies (E) 4.6, 6.2, 9.2, and 13 eV corresponding to s and p energy bands of boron and carbon. The doublet structure of the $Y4p$ core level is detected at $E \approx 25$ eV. The edge structure of the near-Fermi photoelectron emission matched to the YNi_2B_2C DOS obtained from LAPW calculations^{50, 59} and corrected for the effective cross-sections of photoionization of the individual states¹⁶¹ is shown in the inset. The calculations reproduce the spectral structure sufficiently well. The narrowing of the width of the experimental peak (of the $Ni3d$ type) and the shift of its maximum (by ~ 0.25 eV) towards lower bonding energies are the most pronounced differences between the calculated and experimental spectra. In addition, the DOS peak with an energy equal to E_F , predicted by quantum-chemical calculations, is not detected in the experiment.

The discrepancies between the results of calculations of the nonexcited states of YNi_2B_2C and its XPES can be explained using the resonance emission experiments.¹⁵⁹ The XPES were studied in the range of photon energies $h\nu = 64 - 74$ eV, *i.e.*, near the excitation threshold of $Ni3p$ core levels. In this case, a satellite peak with energy $E \approx 8$ eV is clearly seen on the high-energy side of the main spectral maximum.

This phenomenon, which is known for many metals, alloys, and compounds as resonance photoemission,^{162–166} is accounted for by excitation of the $Ni3p$ core level and interference of direct processes of excitation of $3d$ photoelectrons and the processes involving super-Kronig–Coster transitions $3p^63d^{10}4s \rightarrow 3p^63d^84s + e$, where e is a free electron.

Thus, the experimentally measured width of the $3d$ band for metallic nickel is by about 30% smaller than that obtained from LEDF calculations of the ground state, and a satellite is observed in the spectrum (~ 6 eV lower than E_F) due to the effects of electron correlation in the d band.^{162, 163} The reason for the appearance of the satellite for NiO (~ 10 eV lower than E_F)¹⁶⁵ is analogous. Thus, the indicated discrepancies between the calculations and XPES of YNi_2B_2C can be associated with the redistribution of the ‘spectral’ density between the energy interval of localisation of the band of nonexcited states and lower-energy region (the appearance of the satellite due to the effect of electron correlation).

Figure 13. X-Ray photoelectron spectra of YNi_2B_2C ($h\nu = 60$ eV). The high-energy near-edge structure of photoemission ($h\nu = 20$ eV) is shown in the inset. Solid lines correspond to the theoretical XPES spectra obtained from the band LAPW calculations.

Peculiarities of the distribution of free states near the Fermi level in $\text{YNi}_2\text{B}_2\text{C}$ were studied¹⁶⁰ by the inverse XPES method also known as X-ray bremsstrahlung (isochromat) spectroscopy (XBIS). The XBIS spectrum obtained¹⁶⁰ corresponds mainly to the $\text{Ni}3d$ conduction band shifted by ~ 1.5 eV with respect to E_F and to a partially unfilled $\text{Y}4d$ band with its centre ~ 6 eV above the E_F . For both XPES and XBIS, the suppression of spectral intensity near E_F is observed. This can be connected with narrowing of the near-Fermi conduction bands due to the interaction with low-energy excitations (the appearance of a pseudogap as a result of electron–phonon interactions,^{167,168} the interaction of electrons with spin fluctuations¹⁶⁹).

The main reason for discrepancies between the results obtained by the XPES method and the band theory, namely, redistribution of ‘spectral’ density towards higher bonding energies near E_F for $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$, is discussed by Fujimori *et al.*¹⁷⁰ It has been suggested to explain the transfer of the ‘spectral’ density from the near-Fermi region of coherent quasi-particle excitations to the region of incoherent excitations (more distant from the E_F) by renormalisation of the mass of the conduction band; the macroscopic description of this effect should take into account the electron–electron interactions.

2. X-Ray emission spectra

The XES studies of the partial DOS distribution were carried out for $\text{YNi}_2\text{B}_2\text{C}$ and LuNiBC (see Ref. 171) and for $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LaNi}_2\text{B}_2\text{C}$ (see Ref. 172).

The BK_α and CK_α emission spectra of $\text{YNi}_2\text{B}_2\text{C}$ and LuNiBC and the LDOS of B and C atoms calculated by Mattheiss⁵⁰ are presented in Fig. 14. As can be seen, the positions of the main spectral peaks are in agreement with the distribution of the $\text{B}2p$ and $\text{C}2p$ states. The contributions from low-energy bands (mainly of the $2p$ type) of nonmetals are not detected in K_α XES, since they are forbidden by the dipole selection rules; the spectra exhibit the presence of a density of boron and carbon $2p$ states near E_F for $\text{YNi}_2\text{B}_2\text{C}$, and their presence in this region is associated with the effect of $\text{B}2p$ – $\text{Ni}3d$ – $\text{C}2p$ hybridisation.¹⁷¹

Figure 14. The BK_α (a) and CK_α (b) X-ray emission spectra of LuNiBC (1) and $\text{YNi}_2\text{B}_2\text{C}$ (2). Solid lines correspond to local DOS of the B and C $2s$ and $2p$ AOs according to the LAPW calculations.⁵⁰

Fluorescence (B, C) K_α XES of polycrystalline specimens of $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LaNi}_2\text{B}_2\text{C}$ have been analysed by Shin *et al.*¹⁷² After comparing the parameters of the BK_α and CK_α spectra of both IBC, the authors have noted that the BK_α lines appeared to be more sensitive to structural distortions on going from $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LaNi}_2\text{B}_2\text{C}$, which implies that the metal–nonmetal hybridisation occurs mainly due to the $\text{B}2p$ states. Comparison of intensities of the BK_α XES of IBC near E_F shows that this value for the superconducting $\text{YNi}_2\text{B}_2\text{C}$ is $\sim 10\%$ larger than that for $\text{LaNi}_2\text{B}_2\text{C}$ and, hence, $\text{B}2p$ states play an important role in the formation of superconducting properties of IBC.

3. X-Ray absorption spectra

Pellegrin *et al.*¹⁷³ studied the structure of the bottom edge of the conduction band of polycrystalline $\text{LnNi}_2\text{B}_2\text{C}$ ($\text{Ln} = \text{Y}, \text{Sm}, \text{Tb}, \text{Ho}, \text{Er}, \text{Tm}, \text{Lu}$) specimens by $\text{BK}(1s \rightarrow 2p)$ and $\text{NiL}_{2,3}(2p_{2/3} \rightarrow 3d, 4s)$ XAS. It has been found that the shape of the NiL spectra is nearly the same for all IBC studied, *i.e.*, that the degree of filling of $\text{Ni}3d$ and $4s$ bands is independent of the nature of the Ln atoms. Hence, the observed differences in T_c for these phases are not related to the position of E_F with respect to the centre of the $\text{Ni}3d$ band, but are determined by the effect of the magnetic unpairing of the Cooper pairs. The lines of the NiL XAS of IBC were found to be shifted (by ~ 1 eV) toward the high-energy region relative to metallic nickel, which is accounted for by the chemical shift of the $\text{Ni}2p$ level in borocarbides due to a partial $\text{Ni} \rightarrow \text{B}, \text{C}$ charge transfer, which also involves the density of $\text{Ni}4s$ electrons.

For BK XAS, on the contrary, pronounced distinctions depending on the lanthanide type were observed between spectral lines in the region 4–7 eV above E_F , which might be due to the lanthanide effect on the degree of distortion of the NiB_4 tetrahedra.

Matching the BK and $\text{NiL}_{2,3}$ absorption spectra using a unified scale (Fig. 15) indicates an appreciable covalent overlap of Ni – B outer states. Thus the four clearly seen extrema of the $\text{NiL}_{2,3}$ spectrum (see Fig. 15, points *b*, *c*, *d*, and *e*) have their isoenergetic analogues in the structure of the BK spectrum and reflect a rather strong $\text{Ni}3d$ – $\text{B}2p$ interaction. The peak of the BK spectrum corresponds to the $\text{C}2p$ – $\text{B}2p$ covalent interaction.

Comparison of the absorption spectra and partial densities of unfilled states indicates¹⁷³ that the one-electron methods of the band theory reproduce the electronic energy distributions in this spectral region fairly well. An appreciable broadening of XAS spectral bands as compared to the results of calculations can be due to the electron–photon interaction.

The XAS method was also used for the determination of cerium valence in $\text{CeNi}_2\text{B}_2\text{C}$ and solid solutions $\text{Y}_{1-x}\text{Ce}_x\text{Ni}_2\text{B}_2\text{C}$.¹⁷⁴ As has been mentioned above, in its crystallographic

Figure 15. The near-edge structure of the BK (1) and NiL (2) absorption spectra of $\text{ErNi}_2\text{B}_2\text{C}$.

characteristics $\text{CeNi}_2\text{B}_2\text{C}$ is an exception to the morphological series of IBC, namely, its lattice constant a is larger, whereas the lattice constant c is smaller than those expected from the lanthanide compression rule. Presumably, the above anomaly is associated with the variable valence of Ce; an indirect confirmation of this assumption was obtained in the experiments on magnetic susceptibility in the series of phases $\text{CeNi}_2\text{B}_2\text{C}$, $\text{NdNi}_2\text{B}_2\text{C}$, and $\text{GdNi}_2\text{B}_2\text{C}$.^{175, 176}

X-Ray absorption spectra of $\text{Y}_{1-x}\text{Ce}_x\text{Ni}_2\text{B}_2\text{C}$ alloys ($x = 0, 0.05, 0.1, 0.25$, and 1.0) were obtained in the energy region $5680\text{--}5820\text{ eV}$ corresponding to the L_{III} edge of Ce absorption at 300 and 10 K . The absorption spectrum contains two resolved peaks at $E \approx 5723$ and 5731 eV assigned to the $\text{Ce}4f^1$ and $\text{Ce}4f^0$ configurations, respectively. The relative intensities of these maxima change with temperature, which directly indicates a fluctuation of the valence state of cerium. Decomposition of spectral lines into individual components according to the procedure suggested^{177, 178} makes it possible to estimate the averaged cerium valence ($\langle v \rangle$). The $\langle v \rangle$ values obtained 3.15 and 3.21 (at $T = 300\text{ K}$ and 10 K , respectively) are smaller than 3.33 , which is usually obtained for the ions with a formal valence of 4 by the XAS method. The standard underestimation of $\langle v \rangle$ as compared to the value of the formal valence is due to the final state effect.¹⁷⁹ In $\text{Y}_{1-x}\text{Ce}_x\text{Ni}_2\text{B}_2\text{C}$ solid solutions, cerium also has a variable valence ($\langle v \rangle = 3.18$). It is of interest to note that the $\langle v \rangle$ value decreases at elevated temperature and increases at low temperature ($T = 10\text{ K}$) as the cerium concentration in the solid solution increases. Allen *et al.*¹⁷⁴ explained the distinctions in the temperature dependence of $\langle v \rangle$ for Ce in $\text{CeNi}_2\text{B}_2\text{C}$ and $\text{Y}_{1-x}\text{Ce}_x\text{Ni}_2\text{B}_2\text{C}$ solid solutions diluted with respect to Ce by co-operative effects.¹⁷⁷

Additional information on the valence states of Ce can be obtained using the X-ray fluorescence spectroscopy of core levels.

IX. Conclusion

Over a rather short period elapsed from the beginning of intensive studies of IBC, a considerable body of information on the physicochemical properties of this group of compounds has been accumulated. The available data are dissimilar. Intermetallic borocarbides are a unique class of multicomponent superconducting magnetic materials. For this reason, their low-temperature electrophysical and magnetic characteristics have been studied in most detail.

Much less information on phase equilibria and phase diagrams of IBC is available, while their thermodynamic and thermomechanical properties have not virtually been studied. The latter is also true for the problems of targeted synthesis of IBC and the effect of various structural defects on the properties of these compounds. A systematic accumulation of information on the above lines is required to develop the fundamentals of material science of IBC.

Only the principal results of the studies of the electronic structure of intermetallic borocarbides have been covered in this review. Currently, prominent specific features of electron distributions and chemical bonding in IBC have been reliably established. The mechanism of the formation of several physicochemical properties of these compounds has been explained from the viewpoint of their electronic structure.

It should be noted that most of the available data refer to nonexcited electronic subsystems of ideal quaternary phases in the nonmagnetic state. Taking account of a swift increase in the experimental information on the properties of IBC, particular attention of theoreticians in the near future will most likely be drawn to describing the microscopic nature of the origin of magnetic order, conditions of its coexistence with superconductivity, relationship between the superconductivity and the valence state of lanthanides, possible external effects (pressure or temperature) on the spin subsystems.

Setting up research in the field of theoretical material science of IBC associated with problems of constructing phase and magnetic phase diagrams, computer simulation of new multicomponent phases, their solid solutions, studies of the influence of various impurities and structural defects on the properties of IBC appears to be no less urgent.

VI. Conclusion	390

Abstract. A systematic account is given of the current ideas about atomic and group electronegativities and the trends in the development of the concept of electronegativity are analysed. Attention is concentrated on the latest approaches to the definition of electronegativity — the concept of 'orbital' electronegativities and the density functional theory. A procedure is proposed for the determination of 'inductive' electronegativities, which permits a correct theoretical calculation of the electronegativity of a substituent from the electronegativities of individual atoms and the steric structure. It is shown that the approach developed has a series of important advantages — for example, it makes it possible to calculate the group electronegativities of isomeric substituents avoiding the principle of the equalisation of electronegativities. A survey of literature data and generalisation of the method proposed by the authors have made it possible to formulate the concept of electronegativity as an unchanging fundamental immanent characteristic of a chemical element. The bibliography includes 222 references.

I. The electronegativity of atoms

The history of the study of electronegativity (EN) has been described in a series of theoretical, methodological, and retrospective communications.^{1–6} The concept and the term 'electronegativity' itself were introduced in 1932 by Pauling, who characterised it as the force with which an atom in a molecule attracts electrons. In Pauling's studies, the electronegativity of atoms was determined on the basis of thermodynamic data from the energies of the single bonds in which they are involved:⁷

$$\Delta E(AB) = E(AB)_{\text{exp}} - \frac{1}{2}[E(AA) + E(BB)], \quad (1)$$

where $\Delta E(AB)$ is the additional energy of the interaction of the atoms A and B above the additive covalent contribution. Pauling observed that atomic additivity is characteristic of the function $\Delta E^{1/2}$ and that it may serve as a characteristic of the difference between the electronegativities (χ) of the atoms involved in the formation of the bond

$$|\chi_A - \chi_B| = 0.208 \Delta E^{1/2} \text{ (eV)}.$$

Having adopted EN for hydrogen as $\chi_H = 2.1$, Pauling calculated the values of χ for a large number of atoms. The data which he obtained served as the basis for the first electronegativity scale. Virtually the same scale may be obtained by using in Eqn (1) the geometrical mean value of the covalent component of the bond energy.⁸

The fruitfulness of Pauling's idea and the practical importance of his scale were convincingly confirmed in studies by various investigators who published the results of thermochemical studies (see, for example, Batsanov's communication⁸ and the literature quoted therein).

Later some investigators modified the computational scheme itself, whilst others redetermined the values of EN found by Pauling on the basis of their own experimental data and found new values of χ . As a result, Pauling's scale was significantly expanded and, what is particularly important, the EN for atoms in different valence states were determined. One of the most significant gaps in Pauling's original concept, which postulated a single value of χ for each atom regardless of its hybridisation, was thus abolished. Nevertheless, none of the subsequent studies introduced fundamental changes into Pauling's system of EN and into the method for their determination.

Furthermore, the main cause of the appearance of other approaches to the calculation of χ from physical characteristics of atoms and molecules was believed for a long time to be the impossibility of a thermodynamic description of the values of EN for all the elements in all the their chemical manifestations owing to the lack of the energies of individual bonds.⁸

Pauling's EN scale came to be generally employed and became a kind of reference standard for new methods of calculation of χ , many of the newly created scales being adjusted to Pauling's scale.⁹ Furthermore, some of the modern investigators believe that Pauling's original EN scale is not only the most successful but is also adequate¹⁰ and that his method is still one of the fundamental ones for the determination of EN.

Another no less familiar approach to the determination of electro-negativities was developed in 1934 by Mulliken,¹¹ who determined 'absolute' electronegativities, having expressed them in terms of half the sum of the ionisation energies of a neutral atom:

(first ionisation potential I) and a negative ion

(electron affinity F) in the absence of the overlap of the electron shells of the interacting atoms:

$$\chi_M = \frac{I + F}{2}. \quad (2)$$

Mulliken considered two neutral systems X and Y having identical electronegativities. In this case, the energy changes in the two disproportionation reactions

should be identical. The energies of the first and second reactions are $I_X - F_Y$ and $I_Y - F_X$, so that, after recalculation for a single valence electron, one obtains Eqn (2) in which EN is expressed in energy units.

Pauling's and Mulliken's scales proved to be linearly related (different workers give different parameters of the corresponding linear regression),^{9, 12–15} although the dimensions of the EN are in fact not the same. Furthermore, as already mentioned, the EN of atoms on Pauling's scale are regarded as unchanging, whereas the EN on Mulliken's scale should depend on the hybridisation of the atom (like the ionisation potential and the electron affinity). This factor served subsequently as a basis for the creation of scales containing the EN for atoms in different valence states.⁸ At the same time, some workers have noted that Mulliken's system does not have a rigorous theoretical basis.^{3, 9} The use of ionisation potentials and electron affinities makes the Mulliken EN not only easy to obtain but also readily explicable, reflecting the average power of the atom to retain its own valence electron (described by I) and to attract the electron of its partner involved in the bond (described by F).

However, in a series of subsequent studies, only one of the parameters of the Mulliken equation was employed. For example, Vereshchagin¹⁵ assumed that the EN of an atom is expressed directly by its electron affinity F , because EN reflects the 'tendency' of the atom in the molecule to attract electrons. On the other hand, in practice, procedures for the calculation of EN involving the use of the ionisation potential (IP) of the atom came to be most widely used.¹⁶ Thus the employment of average IP for the calculation of EN by the equation

$$\chi = -\frac{I_n}{n} + F,$$

where I_n is the ionisation potential of an n -valent atom and F its electron affinity, made it possible to find the values of χ satisfactorily correlated with the EN found by Pauling.¹⁷

Martynov and Batsanov¹⁸ put forward the hypothesis that, from the physical standpoint, EN could be usefully determined as the average energy per valence electron and expressed in terms of the arithmetical mean of all the IP of all the valence electrons

$$\left(\sum_{i=1}^m I_i \right) / m. \quad \text{Allen}^{19} \text{ identified the average energy of a single}$$

valence electron with the weighted mean of the energies of s and p electrons (ε_s and ε_p respectively):

$$\chi_{\text{spec}} = \frac{m\varepsilon_s + n\varepsilon_p}{m + n},$$

where χ_{spec} is the 'spectroscopic' EN.

In a later review,³ he notes that the ionisation potential of a valence electron should in fact be regarded as an objective physical characteristic reflecting the EN of an atom and formulates the equation quoted above as

$$\chi_{\text{spec}} = \frac{mI_s + nI_p}{m + n},$$

where I_s and I_p are the IP for s and p electrons respectively.

The employment of the first IP of atoms (in Mulliken's procedure the values of I averaged in a certain way) or of the last IP for the calculation of EN^{20, 21} leads to results which agree with those obtained by Pauling.⁸ This situation can be evidently accounted for by the fact that both the electron affinity and different IP functions and hence EN itself are determined by the same factor — the individual electronic structure of the atom.

This idea constitutes in essence the basis of another widely employed procedure for the determination of EN — χ is found from geometrical relations of the type

$$\chi = aZR^{-n} + b, \quad (3)$$

where a , n , and b are constants, Z is the effective nuclear charge, and R is the covalent atomic radius.

The 'geometrical' EN scale was first put forward by Gordy,²² who identified EN with the electrostatic potential generated by the effective nuclear charge Z on a covalent sphere with a radius R :

$$\chi = 0.62 \frac{Z}{R} + 0.5. \quad (4)$$

The effective nuclear charge Z is the charge of a nucleus partially shielded by electrons:

$$Z = Z^* - \sigma,$$

where Z^* is the formal nuclear charge and σ is the shielding constant.

There are several ways of determining σ , among which Slater's semi-empirical method is the most familiar. According to this method, the electron shells have their own values of σ_i , the sum of which determines the shielding constant of the atoms σ .

According to Gordy,²² $\sigma = 1$ for inner electrons and 0.5 for valence electrons. Thus Eqn (4) assumes the form

$$\chi = 0.31 \frac{n+1}{R} + 0.5, \quad (5)$$

where n is the number of valence electrons.

The calculation of EN by Gordy's procedure is simple; it is also quite important that this method makes it possible to express electronegativity in terms of fundamental characteristics of the atom — Z and R , demonstrating the 'periodic' character of χ which distinguishes EN, according to the view of many investigators, from other quantitative characteristics of intramolecular interactions.¹⁵ Even within the framework of the same 'geometrical' system, different parameters a and b in Eqn (3) are characteristic of elements belonging to different Periods.

The fact that in Gordy's method the electrostatic potential was first employed to calculate EN must be included among its undoubted advantages. This idea subsequently proved very fruitful.⁹

Allen¹⁹ proposed that the Periodic Table be considered in a three-dimensional form and that the spectroscopic electronegativities of the elements be introduced as the third dimension. In Allen's view, this will make it possible to rationalise the diagonal subdivision of the Periodic Table into metals and nonmetals. With the aid of $\Delta\chi_{\text{spec}}$, it is possible to arrange systematically the properties of an extensive range of familiar materials: ionic crystals, covalent compounds, metals, minerals, inorganic and organic polymers, semiconductors, etc.

An ideologically similar approach has been used by Sproul,^{23, 24} who proposed a simple graphical procedure for the determination of the nature of bonds in binary two-component molecules A_nB_m . By plotting the electronegativity difference $\chi_A - \chi_B$ against the average value $\bar{\chi}$ for a wide range of compounds A_nB_m , Sproul observed that the points on the resulting plot form three different regions corresponding to the ionic, metallic, and covalent nature of the bonds between A and B. Regardless of the EN scale employed, the nature of the distribution and separation of the points was reproduced every time.

Strictly speaking, the conclusion that the electronegativities of partner atoms involved in the bond determine the nature of the latter followed from the work of Pauling himself. However, on the basis of empirical data, Sproul showed that the best graphical separation is achieved when Allen's¹⁹ and Nagle's²⁵ scales are employed. Nagle considered the ratio $(n/\alpha)^{1/3}$, where n is the number of valence electrons and α the polarisability of the isolated atom, as a measure of the polarisability of isolated atoms. Since it is known that $\alpha^{1/3}$ for an isolated atom is proportional to its radius,^{26,27} Nagle's EN scale, like that of Gordy, can be assigned to the class of 'geometrical' scales.

There are quite a few approaches to the determination of χ in which the number of valence electrons²⁸ or directly the number of the Group^{14,29} are used.

Returning to the history of the development of 'geometrical' systems, we shall consider the widely familiar study by Pritchard and Skinner,³⁰ who devised a more rigorous approach to the calculation of the parameter Z in Eqn (4) and obtained, within the framework of Gordy's method, an EN scale which agrees well with Pauling's scale.

Luo and Benson³¹ identified EN with the energy of attraction of a valence electron at a distance equal to the covalent radius from the nucleus;

$$\chi_{LB} = \frac{m+n}{R},$$

where m and n are the numbers of s and p electrons respectively and R is the covalent radius. They created a scale of χ_{LB} values, which they called 'covalent potentials'. The Luo–Benson scale is one of the most familiar and frequently employed in the interpretation of experimental EN data.³² On the basis of the results of the analysis of the frequency distribution of elements with respect to a range of values of χ , Filippov and Gorbunov³³ isolated from the set of known EN data the 'covalent potential' scale and recommended it as the most convenient for practical use.

Neng and Guo³⁴ proposed another modern EN scale reflecting the properties of the outer valence electrons of isolated atoms. They defined EN as the average nuclear potential of the last valence electron:

$$\chi = \frac{Z^*}{\langle r \rangle_{nl}}.$$

Here $\langle r \rangle_{nl}$ is the average radius, which serves as a specific measure of the distance from the valence electron to the nucleus (the averaging was carried out not only with respect to the orbital radius but also with respect to the possible effects of the nuclear core) and Z^* is the nuclear charge acting on the valence electron separated by the distance $\langle r \rangle_{nl}$ from the nucleus and strictly speaking not identical with Slater's nuclear charge. The EN scale introduced by these investigators³⁴ for free atoms is correlated with Mulliken's scale.

The relation

$$\chi_A - \chi_B = k(f_{AB} - 0.5),$$

where k is the scaling factor, f_{AB} is the orbital factor determined by the distances from the atoms A and B to the centre of the bond orbital (r_A and r_B respectively), i.e.

$$f_{AB} = \frac{r_A}{r_A + r_B}$$

and $f_{AB} - 0.5$ is a measure of the difference between the forces of attraction of electrons by atoms, serves as the basis for the creation of the first nonempirical scale within the framework of the quantum-mechanical FSGO (floating spherical Gaussian orbital) method.³⁵

It is noteworthy that the nonempirical FSGO method yields reasonable and reliable values of EN, which are correlated with those on Pauling's scale, but a lot of calculation is then necessary.

The method for the estimation of EN in terms of electron density is very close to the FSGO method:³⁶ the scale obtained on this basis takes into account the topological properties of the electron distribution density in the molecule. The H–X systems (where X is an atom or group of atoms) with the distances r_H and r_X to the bond critical point (BCP) are considered within the framework of this method. The parameter F_X may serve as an equivalent of the EN of the atom X:

$$F_X = \frac{r_H}{n_X \rho(r_i) r_{HX}},$$

where n_X is the number of valence electrons given up by the atom X to the molecule HX and $\rho(r_i)$ is the electron density at the BCP. If the values of F_X are adjusted to the scale with the boundary values $\chi(\text{Li}) = 1.0$ and $\chi(\text{F}) = 4.0$, then χ_X can be found from the equation

$$\chi_{\tilde{X}} = 1.938 F_X^{-0.2502}.$$

The values obtained in this way are correlated both with those calculated by Pauling and with the χ_{FSGO} .

We may note that, in systems analogous to H–X the electronegativity of the atom X is expressed in terms of the change in the H–X bond length on ionisation.³⁷ Marriott *et al.*³⁸ considered derivatives of HX and showed that the charge density on the hydrogen atom, obtained within the framework of *ab initio* calculations, may be used as a simple measure of the electronegativity of X.

The study of Allred and Rochow³⁹ initiated the overall direction of the development of the 'geometrical' methods for the calculation of EN. They were the first to represent EN as the force of the interaction of an unshielded atomic nucleus and a valence electron separated by a distance corresponding to the covalent radius R :

$$\chi = 0.36 \frac{Z_{\text{ef}}}{R^2} + 0.74.$$

The value of Z_{ef} is determined in accordance with Slater's rule. Numerical coefficients adjust χ to Pauling's scale.

Evidently the method for the description of EN as a 'force' corresponds best to its initial definition by Pauling and comparison of the values found by Allred and Rochow with those derived for other systems demonstrated the high quality of their approach.^{8,9} The Allred–Rochow EN system is one of the best known and most frequently employed. For example, Allen identifies it, together with Pauling's system, as the best founded and most acceptable at the present time.³ Employment in the Allred–Rochow equation of experimental values of Z_{ef} obtained from X-ray diffraction data makes it possible to put forward an EN scale⁴⁰ which agrees with Pauling's scale.

The 'force' approach to the determination of EN was later developed in many investigations.^{8,41,42} Boyd and Markus⁴³ proposed a theoretical method for the calculation of EN based on a nonempirical electrostatic model, according to which electrostatic forces, which determine χ , act between the effective nuclear charge and electrons at a certain distance r from the nucleus:

$$\chi = c N r^{-2} \left[1 - \int_0^r D(r) dr \right],$$

where c is the normalising coefficient which adjusts the EN to Pauling's scale, N is the atomic number, and $D(r)$ is the radial density function. Application of the Hartree–Fock wave function enabled the authors to obtain electro-negativities which are satisfactorily correlated with the values on empirical scales.⁹

The force acting on an electron (and hence EN) can be determined⁴² within the framework of the inverse quadratic dependence on the radius R using the ionisation potential of the valence electron I and the effective principal quantum number n^* :

$$\chi = 0.241 \frac{n^*(I/R)^{1/2}}{r^2} + 0.775$$

(R is the Rydberg constant).

Sanderson's 'geometrical' system,^{44–54} based on the inverse cubic law, relates the EN of an atom to its volume electron density (ED), which is determined by the atomic number N and the covalent radius R :

$$\text{ED} = \frac{3N}{4\pi R^3}.$$

Sanderson suggests that a dimensionless quantity, which he called the 'stability ratio' (SR), be used as a measure of ED. It is obtained by dividing the ED for the atom by the ED for the inert gas in the given Period (the value of R for the latter is interpolated). The stability ratios thus obtained, characterising according to Batsanov⁸ not isolated atoms (as postulated by Sanderson himself) but atoms in molecules, form an intrinsic electronegativity scale (SR), which can be adjusted to Pauling's scale by means of the following equation:^{8,9}

$$\chi = (0.21\text{SR} + 0.77)^2.$$

The values of SR are correlated satisfactorily with experimental data.⁹

More than 20 different 'geometrical' EN systems are known.⁵⁵ It is assumed that the increase in the accuracy of such systems is associated with the increase in the power exponent n in Eqn (3). However, Batsanov⁸ has noted that the accuracy increases also with increase in the constant term b . The increase is caused by the parallel increase in the difference between the dimensionalities of the thermochemical and geometrical EN.

In order to reduce this difference to a minimum, Batsanov proposed a new geometrical EN system. Having adopted as a basis the Cottrell–Sutton formula

$$\chi = 0.5 \left(\frac{Z}{R} \right)^{1/2} + 0.2$$

(one of the earliest geometrical systems), he put forward the following relation whereby the maximum approach of the values of χ to Pauling's scale is achieved:

$$\chi = \alpha \left(\frac{Z^*}{R} \right)^{1/2},$$

where α is a correction factor:

$$\alpha = \frac{1 + 0.1n}{1 + 0.01(n^*)^3},$$

n being the number of the Group of the element in the Periodic System.

By modifying this equation, it is possible to calculate the EN of atoms in the crystalline state, which is necessary for the interpretation of the nature of the bonds in binary and complex compounds.

As noted above, several tens of EN scales, based on different properties of atoms and molecules, which are not always identical, are known. As a rule each scale is satisfactorily correlated with several other EN scales. This apparently reflects the identity of their nature despite the fact that the values of EN proposed by different workers may differ both in dimensionality and in the methodology of their determination and even in the physical significance attributed to them.

We may note that the criteria of the validity of a particular approach to the determination of EN are lacking, which is perhaps the principal problem as regards the concept of EN. For this reason, investigators test the correctness of any new EN system by comparing it with the scales already available. The necessary correspondence can be achieved with by no means all the scales and investigators have to be satisfied as a rule by a more or less acceptable reproduction of a proportion of them.

Indeed the question arises which physical (or chemical) characteristic or property should be regarded as the most adequate expression of χ , how should EN be measured, and what is its dimensionality. In order to answer these questions, it is essential to understand what EN actually is. Paradoxically, despite the more than adequate, from the scientific point of view, age of the concept of EN, controversy as to 'what is electronegativity' has not been resolved even now. The majority of investigators tend to adopt Pauling's original treatment: 'EN is the force with which an atom in a molecule attracts electrons'. However, the current content of this concept is much wider. Since EN is undoubtedly an individual atomic characteristic, the question naturally arises what individual property of the atom determines its power to attract electrons in the molecule. Finally, is this property additive and to what extent? Evidently the property must be characteristic of an individual free atom (the majority of approaches are based precisely on this idea), but at the same time it can remain unchanged or vary in proportion to the initial value on formation of bonds. It has to be said that an exact unambiguous answer has not been obtained to the majority of these questions to this day.

II. The electronegativity of groups

The development of the concept of EN has inevitably led to the appearance of the idea of the EN of a group (substituent).

In 1951, Sanderson put forward the postulate according to which the EN of a molecule is equal to the EN of any atom in it and proposed a method for the averaging of the EN on the basis of their geometrical mean.⁹ Sanderson's total equalisation principle initiated the overall direction of the development of the concept of EN and made it possible to calculate the EN of groups and substituents from the atomic χ .

If EN is a characteristic not only of an atom but also of a group, the question of the quantitative determination of the group EN is legitimate. According to Pauling's classical definition, the latter is the force with which the group attracts valence electrons in the molecule.

The EN of groups of atoms were first calculated by Pritchard and Skinner³⁰ in a study of the thermochemical characteristics of disproportionation reactions of mercury derivatives.

Finemann⁵⁶ later modified Pauling's classical method for the determination of the EN of hydrocarbon radicals:

$$\Delta E = E(\text{AR}) - \frac{1}{2}[E(\text{AA}) + E(\text{RR})],$$

where A is an atom and R a radical. The quantity $\chi_{\text{Me}} = \chi_{\text{C}}$ was adopted as the standard.

Subsequently this thermodynamic approach was developed and partially applied in practice. The results of the analysis of the thermodynamic parameters of various reactions and experimental bond energy data have been described in detail in a monograph.⁸

When Pauling's method is employed, account is frequently taken of the results of other physicochemical studies. Thus the following equation has been employed:^{57,58}

$$D(\text{AB}) = [D(\text{AA})D(\text{BB})]^{1/2} + k|\chi_{\text{A}} - \chi_{\text{B}}|^2.$$

Here the force constant k is optimised on the basis of the values of χ_{B} obtained from the parameters of NMR spectra. Examples of a similar use of hydrolysis⁵⁹ and basicity constants, oxidation potentials, *etc.*¹⁵ are known.

1. Determination of electronegativity from correlations with physical properties

The concept of EN is directly related to ideas concerning bond energies. The energy of chemical bonds determines in its turn many physical characteristics of compounds, for example spectroscopic characteristics. Thus the numerous correlations between EN and various spectroscopic parameters, frequently employed in finding new values of χ , have a physical justification.

It has been noted^{8,15} that it is most useful to employ bond force constants, which are determined solely by the energies of the interactions between atoms. Such a relation was first established by Gordy,⁶⁰ who expressed the force constant k as a function proportional to the product of the EN of the atoms involved in the bond. Furthermore, the force constant k_{AB} of the A–B bond can be expressed, as in Pauling's method, in terms for the corresponding values for homogeneous bonds, k_{AA} and k_{BB} , and the difference between the EN of the atoms A and B:⁶¹

$$k_{AB} = (k_{AA}k_{BB})^{1/2} + (\chi_A - \chi_B)^2.$$

However, since the force constants are difficult to obtain, correlations between EN and the vibrational frequencies of atoms have come to be most widely employed.

As early as 1954, Bell *et al.*⁶² found a linear relation between the vibrational frequency of the P=O bond in the compounds ABCP(O) and the sum of the EN of the groups A, B and C. Subsequently this approach was extended⁶³ to the carbonyl derivatives ABC=O.^{64,65}

Relations between the vibrational frequency of a functional group and not only the EN of the substituents but also the EN of the atom attached to the group are widely known. Thus it has been shown⁶⁶ that there is a linear relation for the compounds CH₂=CHX between the frequencies of the out-of-plane deformation vibrations of the CH₂ groups and the Pauling EN of the atoms X. A similar dependence on the EN of a halogen atom is characteristic of the $\nu(\text{H}-\text{Hal})$ stretching vibrations.

Subsequently similar relations were discovered not only for the compounds HR^{67,68} but also for the methyl derivatives CH₃X.⁶⁹ Correlations between the EN and the vibrational frequency of the OH,⁷⁰ CN, CH, *etc.*¹⁵ groups have also been obtained. It has been shown⁷¹ that the vibrational frequencies of the –CH₂– fragment in the molecules A–CH₂–B are directly related to the sum of the electronegativities of A and B. On the other hand, a dependence of ν on χ^2 has been found for these systems.⁷² Similar relations have been noted also in a series of other investigations (see, for example, a monograph¹⁵ and the literature quoted therein). Relations between ν and $\chi^{1/2}$ have been established for the vibrational frequencies of the C–Si bonds in silane derivatives.⁷³ Vereshchagin¹⁵ has noted that the correlations between the parameters of vibrational spectra and EN can be extended to compounds of any complexity.

A large number of studies have been devoted to relations between the EN of atoms and groups and NMR spectroscopic data. Spin–spin coupling constants, particularly for olefinic derivatives, are used to calculate the unknown values of χ .^{74,75} Numerous linear relations between EN and vicinal constants have been discovered.¹⁵ The chemical shifts of protons have also been considered as characteristics of EN. For example, an expression relating the difference between the proton shifts of methylene and methyl groups to the EN of the substituent X has been established:⁷⁶

$$\chi = 1.71 + 0.02315[\delta(\text{CH}_3) - \delta(\text{CH}_2)].$$

Inamoto and coworkers^{77,78} have shown that the chemical shifts in the ¹³C NMR spectra of certain aliphatic (EtX) and aromatic (PhX) derivatives reflect the influence of the EN of the corresponding substituent X. In order to account for experimental NMR data, a new 'inductive' parameter of the substituents has been proposed. It is calculated by a formula similar to Gordy's equation [Eqn (4)]:

$$i = \frac{Z_{\text{ef}} + 1}{n_{\text{ef}}}.$$

The relations describing the influence of the EN of the substituent on the shielding of the nuclei continue to be used widely even to this day in ¹H,⁷⁹ ¹³C,^{80–82} ¹⁹F,^{83,84} ¹³P,⁸⁵ ¹¹⁹Sn,^{15,86} *etc.* spectroscopy.

Correlations between EN and the shifts of the absorption maxima of compounds in UV spectra, ³⁵Cl NQR spectroscopic frequencies, and other physicochemical parameters are known.

2. Theoretical approaches to the quantitative estimation of group electronegativities

The experimental methods described above have undoubtedly played and continue to play an important role in the quantitative estimation of Group EN. At the same time, it is evident and reasonable that procedures for the calculation of EN of groups using the EN of their substituent atoms are theoretically of greatest interest among all the diverse approaches to the solution of this problem.

The majority of studies in this field may be assigned to two principal aspects. The first identifies the donor–acceptor properties of the substituent with the nature of its central atom (CA). Thus the problem of the determination of the group EN (χ_g) reduces to finding a value of the EN at the first (central) atom of the group modified depending on the environment:

$$\chi_g = \chi(\text{CA}) + \delta\chi(\text{CA}).$$

Thus, in Gordy's method,²² on passing from the calculation of the EN of atoms to that of the EN of groups the number of valence electrons n in Eqn (5) is replaced by the effective quantity n^* , reflecting the 'electron atmosphere' of the first atom. The latter is calculated from the EN of the first atom and a series of independent parameters introduced by various investigators in a fairly arbitrary fashion.^{87,88} The corresponding equation has the form

$$\chi = a \frac{n^* + 1}{R} + b$$

A similar 'geometrical' approach to the determination of the EN of the central atom as a measure of the EN of the group is used in the Luo–Benson method of 'covalent potentials' (U_X):^{31,88–92}

$$U_X = \frac{n_X}{R_X}$$

where n_X is the number of valence electrons of the central atom and R_X is its covalent radius.

The fundamental difference between this method and others consists in the fact that the covalent radius of the central atom (R_X) is considered as the variable. Since this experimental physical quantity characterises the size of the atom in the 'covalent' molecule, *i.e.* the atom in the energetically optimal valence state and not the free state, one can postulate that the calculated values of R_X are reliable. This hypothesis has been confirmed by the satisfactory correlation between U_X and the results of other workers.^{91–93}

The contribution of the environment of the central atom to the overall EN of the group is calculated within the framework of certain approaches on the basis of a kind of similarity of the additive scheme, which admittedly does not have a rigorous physical and mathematical justification. Thus the following equation has been proposed for the calculation of the EN of the group AX_m.⁹⁴

$$\chi(\text{AX}_m) = \chi(\text{A}) + \frac{m}{6}[\chi(\text{X}) - \chi(\text{A})].$$

If the substituents at A were different, similar relations were employed. For example, the EN of the group CX¹X²X³ (Refs 64, 65) was calculated by the equation

$$\chi(CX^1X^2X^3) = 0.5\chi(C) \sum \frac{\chi^2(X)}{12\chi(H)}.$$

The other aspect, developed in Sanderson's studies,^{44–54} is based on the principle of the equalisation of electronegativities which he postulated. In this approach the group EN is considered as a function of the averaging of the EN of all the atoms constituting the substituent. Apart from the geometrical-mean function, proposed by Sanderson himself,^{95,96} the arithmetical-mean^{8,15} harmonic-mean,⁹⁷ *etc.*⁹⁸ functions were examined.

All the theoretical methods specified above for the determination of the group EN are linked by the idea that the EN of a free atom changes when the latter forms a covalent bond. Thus an internal electronegativity, equalised *in situ*, is attributed to the 'bound' atom. It can be determined also by its environment, among other factors. The *in situ* EN of atoms determine in their turn the donor–acceptor properties of the group itself.

A logical development of the entire EN theory consisted in the fact that an intrinsic and unique value of EN was assigned to each atom, as had been done in the original study by Pauling, after which the EN of the atom in different valence states were introduced, and finally there arose the concept of the *in situ* EN of the bound atom, which depends on its environment, *i.e.* on the state of the atom in the molecule.

Consequently any attempt to designate the relation between the 'free' EN and the EN *in situ* involves the principal problem in chemistry — what is an atom in a molecule? In practice the consideration of the EN of chemical groups and the atoms in them makes it necessary to take into account the distribution of electron density.

III. The concept of 'orbital' electronegativities and the equalisation principle

As noted above, Mulliken's definition of EN¹¹ postulates the dependence of EN on the valence state of the atom, which made it possible to abandon the idea of the existence of a unique EN for each atom regardless of its hybridisation. The need to take into account the orbital in which the valence electron is located then arises.

While studying this problem Hinze and Jaffe^{99–101} introduced the concept of the 'orbital' EN and developed a semi-empirical method for the calculation of the ionisation potential (I_v) and the electron affinity (F_v) for any valence state v . This made it possible to find the EN by Mulliken's method taking into account the corresponding valence states of the atoms:

$$\chi_M = \frac{I_v + F_v}{2}. \quad (6)$$

The calculated values proved to be linearly related to those determined by Pauling's method.

It is noteworthy that quantum-mechanical calculations are used to evaluate the orbital EN for pure s , p and d states. In order to obtain the EN of an atom, they are added together in conformity with the degree of hybridisation of the atom:¹⁵

$$\chi = n_s\chi_s + n_p\chi_p + n_d\chi_d + \dots$$

The orbital EN (χ_l) may be expressed¹⁰² also in terms of the radius of the valence shell and the quantum number l :

$$\chi_l = \frac{l}{R}.$$

If χ_1 , χ_2 , and χ_3 are the EN of the s , p , and d orbitals respectively, then the atomic EN is expressed as follows:

$$\chi_a = 0.43 \sum \chi_l + 0.24.$$

It has also been suggested that the orbital EN be calculated by Mulliken's method with the aid of the modified Eqn (6):^{103–107}

$$a = \frac{I_v + F_v}{2} = \frac{I_0 + P_0 + P^+ + P^-}{2},$$

where I_0 and P_0 are respectively the ionisation potential of the free atom and the energy of the transition of the free atom to the given valence state and P^+ and P^- are the energies of the promotion of the cation and anion formed from the atom in the valence state v .

Special mention should be made of the study of Iczkowski and Margrave,¹⁰⁸ which to a large extent determined the subsequent development of the ideas about the orbital EN. In 1961, these workers first represented the energy of an isolated atom (E) as a function of the filling of the electron shell:

$$E(\delta) = E_0 + a\delta + b\delta^2 + c\delta^3 + d\delta^4, \quad (7)$$

where E_0 is the energy of the ionised core, δ is the partial charge of the atom, and a , b , c , and d are empirical coefficients, which depend on the nature of the atom and its valence state.

According to the authors themselves, it is sufficient to restrict Eqn (7) to second-order terms (at least for s and p elements):

$$E(\delta) = E_0 + a\delta + b\delta^2. \quad (8)$$

If it is assumed that $E_0 = 0$, $E(1) = I$, and $E(2) = I + F$, then the values of a and b expressed in Mulliken terms are obtained:

$$a = \frac{3I - F}{2}, \quad b = \frac{F - I}{2}.$$

Iczkowski and Margrave regarded $E(\delta)$ as a continuous and differentiable function of δ and identified the EN of an isolated atom with the first derivative of the energy with respect to the occupation number of the valence orbitals:

$$\chi = \frac{dE}{d\delta}. \quad (9)$$

In this representation, the EN of an atom may be expressed as a linear function of δ :

$$\chi(\delta) = a + 2b\delta. \quad (10)$$

It was subsequently proposed that a more rigorous three-term equation be employed:¹⁰⁹

$$\chi(\delta) = a + b\delta + c\delta^2$$

with empirical coefficients differing markedly from those in Eqn (10) (here the contribution of the quadratic terms is relatively small). Nevertheless the linear Eqn (10) has in fact come to be most widely used and has become best known. On substituting into it the parameters a and b expressed in the Mulliken form, it is possible to obtain the following expressions for the EN of a cation, a neutral atom, and an anion respectively:

$$\chi(0) = \frac{3I - F}{2}, \quad \chi(1) = \frac{I + F}{2}, \quad \chi(2) = \frac{3F - I}{2}.$$

On the one hand, the identity of the equation for the EN of a neutral atom $\chi(1)$ with the Mulliken expression served, according to Iczkowski and Margrave, as confirmation of the correctness of their approach. On the other hand, Mullay⁹ noted that such results yielded an additional theoretical justification of Mulliken's scale itself, which may possibly make it the best among all others.

It is noteworthy that Iczkowski and Margrave were not the first to relate the *in situ* EN of an atom to its partial charge δ . As early as 1951, Sanderson⁹⁵ suggested, on the basis of the principle of the total equalisation of electron density, a simple scheme for the calculation of δ . Here the *in situ* χ was calculated as the geometrical mean.

Nevertheless, it was in fact Eqns (9) and (10) that became the 'starting' point for the further development of the theory and methods for the calculation of EN.

Hinze *et al.*¹¹⁰ developed ideas concerning orbital EN and identified the donor–acceptor properties of an isolated atom with the EN of its valence orbital. Having adopted as a basis the definition of Iczkowski and Margrave, who expressed the EN of an isolated atom in terms of the potential acting on the valence orbital [Eqn (9)], the authors suggested that similar relations be used for the orbital EN (χ_{aj}):

$$\chi_{aj} = \frac{\partial E_a}{\partial n_j}, \quad (11)$$

where E_a is the energy of the atomic orbital j and n_j is its population.

Next, having postulated that the function $E_a(n)$ is continuous and differentiable and having restricted it to the quadratic dependence on n , they obtained a linear equation relating the EN of the orbital to its population:

$$\chi_{aj} = a_a + 2b_a n_{aj}. \quad (12)$$

This equation is analogous to Eqn (10). According to the data of Whitehead *et al.*,¹¹¹ the parameters a_a and b_a may be expressed, as in Eqn (10), in terms of the ionisation potential and the electron affinity, but in this case not of the atom but of the corresponding orbital j . Furthermore, Whitehead showed that the parameters a_a and b_a can be determined by using the parameters of the population of all the valence orbitals of the atom other than j .

As mentioned above, Eqns (10) and (11) identify the EN (the EN of an isolated atom and the orbital EN) with the potential, which possesses *a priori* the equalisation property. This factor reasonably led the creators of the theory of orbital EN to the idea of their equalisation. In conformity with Meek's hypothesis,¹⁰⁵ the orbital EN of the atoms A and B are equalised on formation of the bond A–B:

$$\frac{\partial E_A}{\partial n_A} = \frac{\partial E_B}{\partial n_B},$$

hence the functions of the charges on each of these atoms also become equal:

$$a_A + 2b_A n_{Aj} = a_B + 2b_B n_{Bj}.$$

Thus, bearing in mind that two electrons participate in the formation of the bond, *i.e.* $n_{Aj} + n_{Bj} = 2$, the equation obtained can be used to establish the charge distribution. On the basis of the foregoing, an iterative method for the calculation of the EN of haloalkyl groups has been developed;¹¹⁰ with its aid, it has been possible to calculate certain group χ .

Subsequently Huheey^{112, 113} proposed a simple scheme for the determination of the EN of groups based on the Iczkowski–Margrave Eqn (10), but in this instance operating with the values of a_A and b_a taken from the studies of Hinze, Whitehead, and Jaffe. On the basis of Sanderson's study, Huheey postulated the equality of the EN of the group and its constituent atoms. Thus the following expression was obtained for the substituent AB_n :

$$\begin{aligned} \chi_{AB_n} = \chi_A = \chi_{B_1} = \dots = \chi_{B_n} &= a_A + 2b_A \delta_A = \\ &= a_B + 2b_B \delta_{B_1} = \dots = a_B + 2b_B \delta_{B_n}. \end{aligned}$$

Having solved these equations, it is possible to obtain, as in the method of Hinze, Whitehead, and Jaffe, the charges and the group EN. The solutions can then be found for a neutral group, a cation, and an anion (subject to the condition that $\delta_g = \Sigma \delta = 0, +1$, and -1 respectively). Having applied his approach, Huheey calculated the EN of almost 100 substituents and, what is no less important, analysed the significance of the coefficients in the equation relating the EN of a group (atom) to the charge and identified a_A with the intrinsic value of the EN of the atom and b_A with the sensitivity of the EN to a change in the charge.

A similar approach, based on the hypothesis of the equality of a_A and b_A , *i.e.* $\chi_a = a_a + b_a \delta_a = a_a(1 + \delta_a)$, and the principle of

the total equalisation of the EN, made it possible to obtain the following expression for the group EN:⁹

$$\chi = (N + \delta_g) / \sum_1^N \frac{n_i}{\chi_{ai}}, \quad (13)$$

where $N = \Sigma n_i$ is the total number of atoms, n_i is the number of atoms in the group, and χ_i is the EN of the i th atom on Pauling's scale before the formation of the molecule.

Subsequently Mullay¹¹⁴ established another relation between the coefficients a_a and b_a , namely $b_a = 1.5a_a$, and expressed the *in situ* orbital EN in the following manner:

$$\chi_{aj} = a_a(1 + 1.5 \sum \sigma_a). \quad (14)$$

The EN of a chemical group AB is then determined as the EN of its central atom on which an effective charge $d_j \ll 0$ is accumulated at the expense of the orbital j , ensuring a bond between the central atom and the rest of the molecule. Subject to the condition of the conservation of electroneutrality ($\delta_A + \delta_B = 0$) and the equalisation of the orbital EN ($\chi_A = \chi_B$), it is possible to obtain an expression for the calculation of group EN analogous to Eqn (13):³

$$\chi_g = \frac{N + 1.5 \sigma_g}{\sum_1^N n_i / \chi_i}.$$

The group EN obtained within the framework of this method, which takes into account the hybridisation of the valence orbital and the effective charge on the group, have reasonable values.

Subsequently this approach was improved: a term taking into account the interatomic electronic repulsion of the valence orbitals was added to Eqn (14):^{115, 116}

$$\chi_{aj} = a_{aj}(1 + 0.5 \sum \delta_{ai} + 1.5 \sum \delta_{aj}).$$

Thus the concept of orbital EN became the basis of the modern concept of EN, with the aid of which not only have the new easy methods for the calculation of EN been created but its physical nature has been to a large extent elucidated. Certain principal postulates of this concept of EN have been subjected to serious criticism at various times;³ the very legitimacy of identifying the EN solely with orbitals has been questioned;⁹ in some investigations, it has been shown that the idea of using orbitals in discussing EN is not always necessary.¹¹⁷ The arbitrary nature of the assumption of the continuity and differentiability of the relation between the energy of the system (atom, molecule) and the number representing the filling of the orbitals by valence electrons [the function $E(q)$], the assumption constituting the basis of the theory of orbital EN, has also been noted.⁶ This hypothesis is strictly speaking invalid for an isolated atom: in this case, the values of the argument q can only be discrete.

Slater¹¹⁸ emphasised that in the fundamental equations of the X_α SCF method there are no limitations associated with the requirement that q is integral because atomic and electronic systems obey Fermi statistics, a characteristic feature of which is fractional energy level occupation numbers. At the same time, he justified the expansion of the function $E(q)$ in the series

$$E(q) = E(0) + \left(\frac{\partial E}{\partial q}\right)q + \frac{1}{2!} \left(\frac{\partial^2 E}{\partial q^2}\right)q^2 + \frac{1}{3!} \left(\frac{\partial^3 E}{\partial q^3}\right)q^3 + \dots \quad (15)$$

Eqn (15) is analogous to the empirical Iczkowski–Margrave Eqn (7). Comparison demonstrates the correspondence between the coefficients a and b in the Iczkowski–Margrave equation and the first and second derivatives of the energy with respect to the occupation number in the Slater formula.

Klopman^{119–121} also showed that it is possible to expand the energy in a series analogous to the series in Eqn (7). Within the

framework of the theory of atomic spectra, he expressed the energy of a free atom by the equation

$$E_a = \sum_i B_a^i + \frac{1}{2} \sum_{ij} A_a^+ \delta_{ij} + \frac{1}{2} \sum_{ij} A_a^- (1 - \delta_{ij}), \quad (16)$$

where B_a^i is the energy of the i th electron in the atomic spin-orbital in the electron shell with the quantum number l , A_a^+ and A_a^- are the energies of the interaction of electrons with identical and opposite spins respectively, and δ_{ij} is the Kronecker parameter.

If the electrons are in the same orbital, $A_a^+ = A_a^- = A_a$ and Eqn (16) assumes the form

$$E_{a_j} = n_{a_j} B_a^j + \frac{1}{2} n_{a_j} (n_{a_j} - 1) A_a. \quad (17)$$

Having put $a_a = B_a^j - A_a/2$ and $2b_a = A_a/2$, we obtain from Eqn (17) an expression for EN:

$$\chi_{a_j} = \frac{\partial E_{a_j}}{\partial n_{a_j}} = B_a^j - \frac{A_a}{2} + \frac{A_a}{2} n_{a_j},$$

which corresponds fully to the Hinze–Jaffe formula (12).

Later Mullay¹¹⁴ showed that the relation between the Klopman parameters B_a^j and A_a is linear. This enabled him to express the orbital EN by employing only one of the parameters:

$$\chi_{a_j} = A_a(0.5 + 0.15N s_j).$$

Here N is the number of valence electrons and s_j is the fraction of the s character of the orbital j .

From this expression, the author obtained a formula whereby a series of values of EN on Pauling's scale were determined:

$$\chi_{a_j}^0 = 1.67 \frac{G_j Z_{\text{ef}}^2}{n_{\text{ef}}^2} + 041,$$

where G_j is a function which depends linearly on the p character of the orbital j and Z_{ef} and n_{ef} are the effective nuclear charge and the effective principal Slater quantum number.

Furthermore, it should be noted that Klopman confirmed within the framework of his approach the validity of the equalisation principle for orbital EN, having described them not only in atomic but also in molecular terms:¹²²

$$\frac{\partial E_m}{\partial n_j^i} = \frac{\partial E_m}{\partial n_k^i},$$

where E_m is the energy of the molecule, n_j^i the electron density of the orbital j corresponding to the i th electron, and n_k^i the electron density of the orbital k corresponding to the i th electron. Thus Klopman concluded that all the orbitals in the molecule are equipotential and actually proposed the term 'molecular orbital EN'.

The total equalisation principle, which became an indissoluble component of the concept of orbital EN, has been subjected to a many-sided criticism.^{3, 9, 15} One of its main deficiencies is the impossibility of a differentiated determination of the EN of isomeric groups, although their donor–acceptor properties should undoubtedly differ. Some investigators have noted that the equalisation principle, possessing undoubted simplicity, does not reflect a series of fundamental chemical ideas, for example the resonance electrostatic effects.^{15, 112, 1113, 123, 124} There exists also the view that, under conditions where the electron density is displaced, the total equalisation principle does not work at all because the electrostatic potential arising under these conditions inhibits further displacement of electron density and at best one can only speak of a partial equalisation of the EN.

Thus Pritchard¹²³ suggested that the real difference between the electronegativities of bound atoms, taking into account the overlap of the orbitals, reaches $\sim 10\%$ of the initial difference $\Delta\chi$.

Quantum corrections for this overlap were subsequently introduced,¹⁵ which permitted an additive calculation of the electron distribution in a series of fluoromethane derivatives.

Whilst modifying this method for the determination of EN, Huheey¹²⁵ proposed 80% equalisation of electron density and introduced a corresponding coefficient of 0.8 into the calculation.

The method involving the incomplete equalisation of the EN has also been developed in other investigations^{126, 127} based on the electrostatic model postulating the expansion of the energy in a power series. The authors multiplied the atomic charges (obtained by minimising the total energy) by an arbitrary constant, which takes into account the potential arising when electrons are displaced and also the influence of remote atoms. The iterative procedure for the calculation of EN was performed until constant values of the latter called the 'residual' EN were obtained. A rigorous determination of such EN became possible only subject to the removal of the condition involving the restriction of the dependence of E on q to the quadratic term.¹²⁸

Thus the concept of orbital EN undoubtedly promotes the development and understanding of the problem of EN as a whole, permitting the theoretical justification and the binding into a single whole of many general ideas and postulates (for examples, Mulliken's definition of EN, Sanderson's principle of the equalisation of EN, the dependence of EN on the valence state of the atom, the dependence of the energy of the atom on the charge, *etc.*). At the same time, one cannot fail to mention also a whole series of important problems remaining open to discussion, such as the possibility of the continuous expansion of E in terms of q for an isolated atom, the legitimacy of the total equalisation of EN and the specific equalisation algorithm (geometrical mean, arithmetical mean, *etc.*), the physical significance of the *in situ* EN of an atom in a molecule, and certain others, which have not so far received an adequately rigorous justification.

Many of these problems have been solved within the framework of the density functional theory (DFT), which has recently appeared and has undergone an extremely dynamic development. It permitted the current interpretation of many facts which have been insufficiently rigorously justified and treated.

IV. Electronegativity and the density functional theory

Any property characterising the state of a molecule is a function of parameters the values of which manifest the individuality of the given compound. The density functional theory considers a molecule as a set of nuclei and electrons. The parameters employed are the number of electrons N and the energy of the interaction of the nuclear core with the i th electron $v(r)$ at any point in the molecular system (its nuclear potential):¹²⁹

$$v(r) = \sum_n \frac{Z_n}{r_{n_i}},$$

where n is the index of the nucleus, Z_n is the nuclear charge, and r_{n_i} is the distance from the nucleus n to the i th electron.

If $N = \text{const}$, the energy of the system is determined as the functional $E[N, v(r)]$, and the task of describing the interaction between the nuclei and electrons consists in finding an analytical expression for the energy E as a function of the independent parameters N and $v(r)$.

The function of the distribution of electron density of the ground state $\rho(r)$, simultaneously determining N and $v(r)$ and hence containing all the information about the system itself and its energy, is introduced within the framework of the DFT in accordance with the Hohenberg and Kohn theorems:¹²⁹

$$E(N, v) = E(\rho) = \int \rho(r) v(r) dr + F(\rho).$$

By applying the variational principle to the functional $E_{\text{el}}[\rho(r)]$ (E_{el} is the electronic energy of the system), it is possible to obtain

the Euler equation, which is analogous to the Schrodinger equation:

$$v(r) + \frac{\partial F(r)}{\partial \rho(r)} = \mu,$$

where $F(r)$ is the sum of the electron kinetic energy and the electron repulsion energy, $\rho(r)$ is the electron density functional, and μ is the Lagrange multiplier, called the electron chemical potential, which has the same value throughout the entire system and is determined as the partial derivative of the energy E with respect to the number of electrons N at a constant external potential v :

$$\mu = \left(\frac{\partial E(r)}{\partial \rho(r)} \right)_{v(r)} = \left(\frac{\partial E}{\partial N} \right)_{v(r)}.$$

Thus $\mu[Nv(r)]$ is a global characteristic, which, together with the energy, is a fundamental property of the ground state of the system.

The development of the ideas of both the DFT and of the entire modern concept of EN has to a large extent been determined by the studies of Parr and Pearson and coworkers.^{130–136}

Parr and coworkers¹³¹ made the fundamentally important assumption that the negative chemical potential and the EN are identical:

$$\chi = -\mu = \left(\frac{\partial E}{\partial N} \right)_v. \quad (18)$$

Subsequently Parr and Pearson¹³² determined the second derivative of the energy with respect to the number of electrons as the absolute hardness (η)

$$\eta = \frac{1}{2} \left(\frac{\partial^2 E}{\partial N^2} \right), \quad (19)$$

reflecting the ‘resistance’ of the chemical potential μ (or the electronegativity χ) to a change in the number of electrons:

$$\eta = \frac{1}{2} \left(\frac{\partial \chi}{\partial N} \right) = \frac{1}{2} \left(\frac{\partial \mu}{\partial N} \right). \quad (20)$$

Correspondingly the softness of the system is defined as the reciprocal of the hardness:

$$S = \frac{1}{2\eta}. \quad (21)$$

Having postulated a quadratic dependence of the energy of the system on the number of electrons (in the absence of overlap of the valence orbitals), the electronegativity of the atom χ^0 and its hardness η^0 can be expressed in terms of the ionisation potential I and the electron affinity F :

$$\chi^0 = \frac{I + F}{2}, \quad \eta^0 = \frac{I - F}{2}. \quad (22)$$

Thus the definition of EN within the framework of the DFT agrees with Mulliken’s ideas about the ‘absolute’ EN, while the parameter η , defined by Eqn (20), is³² the ‘absolute’ hardness.

1. The principle of hard and soft acids and bases

The concepts of chemical hardness and softness were first introduced in the study of the properties of Lewis acids (electron acceptors) and bases (electron donors). Pearson^{133–135} divided them into soft (readily polarisable) and hard (poorly polarisable). He also formulated the principle of ‘hard and soft acids and bases’ (HSAB), according to which hard acids combine preferentially into complexes (react) with hard bases, whilst soft acids combine similarly with soft bases.^{133, 134} This principle has been widely applied in various branches of chemistry, but a quantitative

characteristic of the ‘hardness’ of acids and bases was lacking for a long time.⁶ The definition of hardness η within a framework of the DFT readily elucidates the physical significance of this parameter. According to the Klopman theorem, the ionisation potential I and the electron affinity F can be expressed in terms of the energy of frontier orbitals: the highest occupied (HOMO) and the lowest unoccupied (LUMO):^{134, 136, 137}

$$-E_{\text{HOMO}} = I, \quad -E_{\text{LUMO}} = F.$$

Thus the hardness of the system is determined by half the difference between the energy levels:

$$\eta = \frac{E_{\text{HOMO}} - E_{\text{LUMO}}}{2}. \quad (23)$$

Clearly a ‘hard’ molecule should have a large energy gap between the LUMO and the HOMO, while a ‘soft’ molecule should have a small gap, which in fact explains the difference between their polarisabilities.

Another important postulate put forward by Pearson¹³⁸ is the principle of maximum hardness, according to which the system tends to acquire the maximum hardness. This principle, like the HSAB principle, was initially based on experimental relations and only then received a mathematical justification within the framework of DFT.^{136–140} According to Eqn (22), the quantity η increases with increase in ionisation potential and with decrease in electron affinity. Thus the system endeavours not to give up its electrons and not to accept extraneous ones, *i.e.* to remain stable.

Pearson’s principle of maximum hardness combines a whole series of familiar empirical relations, rules, and concepts: the octet principle postulated by Lewis and Langmuir, the 18 electron rule. Hückel’s $(4n + 2)$ aromaticity rule for organic systems, and the Wade–Mingos $(2n + 2)$ rule for inorganic systems, as well as the concept of the maximum thermodynamic stability of the molecule in the case where all its bonding orbitals are fully occupied whilst the antibonding orbitals are unoccupied.¹³⁷ The view that chemical hardness is a quantitative characteristic of the stability of electronic systems and can be used instead of the overall energy has been generally established in the literature.^{141–151}

Together with the chemical potential (EN) and hardness, yet another parameter, playing an important role in the modern studies of reactivity and selectivity, namely the Fukui function $f(r)$, defined by Parr and Yang¹⁵² (see also Refs 148–153),

$$f(r) = \left(\frac{\partial \mu}{\partial v(r)} \right)_N = \left(\frac{\partial \rho(r)}{\partial N} \right)_{v(r)},$$

has been introduced within the framework of the DFT.

Yang *et al.*¹⁵⁴ established that a high local reactivity corresponds to a large Fukui function at a point r in the molecule. This means that $f(r)$ is an important reactivity index. The Fukui function is an intramolecular characteristic which can be used to determine intramolecular reactivity indices, in particular the local hardness and the local softness $s(r)$. The latter is defined as follows:

$$s(r) = \left(\frac{\partial \rho(r)}{\partial \mu} \right)_{v(r)} = \left(\frac{\partial \rho(r)}{\partial N} \right)_{v(r)} \left(\frac{\partial N}{\partial \mu} \right)_{v(r)} = f(r)S,$$

where S is the global softness [see Eqn.(21)], which can be calculated in terms of the local softness $s(r)$ values:

$$S = \int s(r) dr.$$

Evidently the local characteristics of the molecule should determine the selectivity of the reactions involving it.^{155–158} Thus in the interaction with a hard reagent, a ‘locally hard’ atom should serve as the preferred reaction centre, whilst in a reaction with a soft reagent a ‘locally soft’ atom should be used for this purpose.

Thus the DFT yields a satisfactory qualitative justification of Pearson's HSAB principle and leads to the possibility of a quantitative estimation of the corresponding parameters.

2. The density functional theory and the electronegativity equalisation principle

The density functional theory justifies not only the continuity of the expansion of the energy E in a power series in terms of the charge q but also confirms the validity of the total equalisation of the EN, which follows from the variational principles for the electron density of the ground state.^{159, 160} Furthermore, the DFT identifies EN with the chemical potential μ , which is characterised, by definition, by the equalisation property, like any other potential.

The mathematical formalism of the principle of the total equalisation of EN, based on the ideas of the DFT, has become the basis for the creation of a wide variety of approaches, which makes it possible to calculate the partial charges on atoms,^{161–167} to model the chemical bond,^{6, 168–170} to interpret the reactivities of various compounds,^{164, 171–176} etc. We shall examine the approaches concerning the mathematical interpretation of the principle of the equalisation of EN and the method for the determination of the EN of atoms and groups based on it.

Thus using the mathematical procedures of the DFT, Parr and Bartolotti¹⁷⁷ justified not only the principle of the total equalisation of EN proposed by Sanderson but also his method of averaging EN on the basis of the geometrical mean.

In describing a bound atom, the authors examined its valence state as the ground state perturbed by the environment and proposed the following scheme for the formation of a molecule.

The initial hypothetical molecule AB, consisting of an atom A with the parameters μ_A^0 , ρ_A^0 , N_A^0 , and v_A^0 and an atom B with the parameters μ_B^0 , ρ_B^0 , N_B^0 , and v_B^0 , possesses intrinsic values of μ_{AB}^0 , ρ_{AB}^0 , $N_{AB}^0 = N_A^0 + N_B^0$, and $v_{AB}^0 = v_A^0 + v_B^0$. Before charge transfer, the atoms A and B are in the valence states A* and B* characterised by the parameters μ_A^* and μ_B^* , ρ_A^* and ρ_B^* , N_A^0 and N_B^0 , and v_A^* respectively. After charge transfer, the atoms A and B are in states to which the parameters μ_A , ρ_A , N_A and μ_B , ρ_B , N_B correspond. Under these conditions, one can write for the molecule (in accordance with the total equalisation principle)

$$\begin{aligned}\mu_{AB} &= \mu_A + \mu_B, \\ \rho_{AB} &= \rho_A + \rho_B, \\ N_{AB} &= N_A + N_B = N_A^0 + N_B^0.\end{aligned}$$

Thus $\Delta N_A - N_B^0 = N_B - N_B^0$, which is proportional to $\mu_A^* - \mu_B^* = \mu_A^0 - \mu_B^0$ corresponds to the charge transfer. Under these conditions, the equalised EN is determined as the geometrical mean of the EN of the neutral atoms before charge transfer:

$$\mu_{AB}^2 = \mu_A^2 = \mu_B^2 = \mu_A^* \mu_B^* \simeq \mu_A^0 \mu_B^0.$$

Bearing in mind that the chemical potential μ is identified with EN, we obtain for the molecule AB

$$\chi_{AB} = (\chi_A \chi_B)^{1/2}.$$

At the same time, according to the definitions of the chemical potential (EN) and the absolute hardness within the framework of the DFT [Eqns (18)–(20)], one can formulate the following expression for the *in situ* EN:

$$\chi = \left(\frac{\partial E}{\partial N} \right)_{v(r)} = \chi^0 + 2\eta^0 \Delta N, \quad (24)$$

where χ^0 is the intrinsic orbital EN of the atom, η^0 is its absolute hardness, and ΔN is the number of electrons participating in the charge transfer. Thus it is easy to show that the charge transfer along the bond AB is determined by the values of EN and of the hardness of the atoms A and B:

$$\Delta N = \frac{\chi_A^0 - \chi_B^0}{2(\eta_A^0 + \eta_B^0)}. \quad (25)$$

Eqns (24) and (25) were first obtained already by Huheey and Watts,^{178, 179} who used instead of the hardness η the charge capacity parameter $k = 1/2\eta$, characterising the power of the atom to delocalise the partial charge, *i.e.* the 'softness'.

The stabilisation energy corresponding to the given charge transfer can be expressed in terms of the same parameters:¹³²

$$\Delta E = \frac{(\chi_A^0 - \chi_B^0)^2}{4(\eta_A^0 + \eta_B^0)}. \quad (26)$$

Like Pauling's original formula, Eqn (26) demonstrates the proportionality of the polar component of the energy to the square of the difference between the EN of the partner atoms involved in the bond.

Komorowski *et al.*¹⁸⁰ identified ΔE with the power of the atoms A and B to effect charge transfer [they introduced the CTA (charge-transfer affinity) parameters] and emphasised that the polarity of the bond is determined not only by the EN of the atoms A and B but also by their hardnesses and it is not permissible to neglect them, as had been done in Eqn (26). Furthermore, whilst considering the pair interactions of the substituents with the reference reaction centre, the authors found an interesting linear relation between the inductive constants (σ_F) of the substituents and the corresponding CTA parameters. On the one hand, this makes the latter adequate characteristics of the groups and, on the other, it demonstrates the impossibility of a direct (disregarding the hardness) comparison of the inductive constants σ and the electronegativities χ . In their description of the *in situ* polarity of the bond AB, Allen and coworkers^{3, 181, 182} neglected the hardnesses of A and B and introduced the bond polarity index BPI, directly related to the difference between the EN. Komorowski and coworkers^{180, 183} find in the BPI a contradiction both with Pauling's original concept and with its DFT-based justification.

On passing from a simple diatomic molecule AB to a system comprising atoms Yang *et al.*¹⁸⁴ obtained the following expression for the averaging of atomic EN taking into account the electroneutrality principle ($\sum \Delta N_i = 0$) and the total EN equalisation condition ($\chi_i = \chi$):¹⁰

$$\chi = \frac{\sum_i \chi_i^0}{\sum_i \eta_i^0} \bigg/ \frac{1}{\sum_i \eta_i^0}. \quad (27)$$

This equation may be formulated also using the values of the softness of atoms:¹⁷⁶

$$\chi = \frac{\sum_i \chi_i^0 s_i}{\sum_i s_i}. \quad (28)$$

Similar relations of type (27) and (28) have been obtained independently by different workers in the study of equalised EN based on the DFT-justified approaches.^{185–188} At the same time, in describing the EN of bound atoms, many investigators indicate the need to take into account their interaction and to introduce the corresponding corrections.

Mortier and coworkers^{161–163, 173} proposed a scheme for the equalisation of the *in situ* EN taking into account the influence of the charge on the neighbouring atom q_B on the electronegativity χ_A :

$$\chi_A = \chi_A^0 + \Delta \chi_A + 2(\eta_A^0 + \Delta \eta_A) + \sum \frac{q_B}{r_{AB}}.$$

The last term (the Madelung potential) includes the interatomic distance parameter r_{AB} , which takes into account the influence of the geometrical parameters of the molecule on the equalisation of the EN of its constituent atoms.

The interaction of the atomic charges is taken into account within the framework of the Rappe–Goddard model¹⁶ by

introducing into Eqn (18) an additional parameter containing the Coulombic integral J_{AB} , which describes the potential between A and B:

$$\chi_A = \chi_A^0 + 2\eta_A^0 + \sum J_{AB}q_B.$$

A similar additional term has also been used by Wells.¹²

As already mentioned, Eqn (25) makes it possible to calculate the charge transfer in the bond. Such a calculation is frequently used to determine the ionicity parameters, but the values thus obtained are lower by approximately a factor of two compared with the traditional estimates by Pauling's method.⁶ This is associated with the failure to take into account the interaction between the atoms. Urusov⁶ therefore proposed an approach, called the 'model of interacting spheres' according to which the electron density of the molecule is regarded as a superposition of the electron densities of atoms with the effective charges $q+$ and $q-$. This approximation makes it possible to some extent to take into account the repulsion between the electrons of different atoms and their attraction to the 'foreign' nucleus. Within the framework of this method, an expression has been obtained for the ionicity parameter:

$$\Delta N = \frac{\chi_A^0 - \chi_B^0}{\eta_A^0 + \eta_B^0}.$$

It yields values twice as high as those found by Eqn (25). Furthermore, in Urusov's view,⁶ the EN equalisation principle can be applied more accurately and correctly in the model of interacting spheres than in the DFT.

Special mention should be made of a study¹⁸³ the authors of which developed a quantum-chemical method for expressing the *in situ* EN and the hardness without the direct employment of the EN equalisation principle. They assumed that the EN of a molecule χ_m can be divided into the additive contributions of its constituent atoms χ_a :

$$\chi_m = -\frac{dE_m}{dN} = -\sum \frac{dE_m}{dN_a} \frac{dN_a}{dN} = \sum \chi_a K_a, \quad (29)$$

where $\chi_a = -(dE_m/dN)$ is the EN of the bound atom and $K_a = dN_a/dN$ is the index of the Fukui function.¹⁸⁹

On passing to group EN, one can write¹⁸⁰

$$K_g = -\frac{dN_g}{dN} = \sum \frac{dN_a}{dN} = \sum K_a;$$

since $\sum N_a = N$, it follows that

$$\chi_g = \frac{\sum \chi_a K_a}{\sum K_a}. \quad (30)$$

Evidently this expression is virtually identical with Eqns (27) and (28) based on the EN equalisation principle; the Fukui index K_a is related to the softness s_i in Eqn (28) by the expression $s = K_a/\eta_m$,¹⁸³ where η_m is the hardness of the molecule. Furthermore, the authors showed that the *in situ* χ_a can be replaced in Eqn (30) by χ_a^0 — the EN of free atoms (groups):

$$\chi_g^0 = \frac{\sum \chi_a^0 K_a}{\sum K_a}.$$

Evidently on passing to a molecule, *i.e.* for $\sum K_a = 1$, the expression obtained reproduces formula (29).

As noted by Komorowski *et al.*¹⁸⁰ themselves, the approach presented presupposes any level of additivity — the EN of the molecule can be divided not only into the contributions of atoms but also into those of groups or even into 'mixed' contributions:

$$\chi_m = \sum \chi_a K_a + \sum \chi_g K_g.$$

An orbital additive level of representation of formula (29) is also possible.

We may note that Liu and Parr,¹⁹⁰ who examined the chemical potential (EN) at the orbital level, arrived at analogous conclusions and relations, but they employed the classical DFT apparatus (and evidently the principle of the total equalisation of EN).

Together with the methods based on the DFT postulates, it is necessary to point out another remarkable approach — Bader's quantum topological model, which also operates with the electron density function $\rho(r)$ and the concepts of EN and hardness but is characterised at the same time by a series of fundamental differences and characteristic features.^{191–194}

Bader's concept of topological atoms is based on the subdivision of molecular space into nonoverlapping atomic regions separated by boundary surfaces corresponding to zero electron density flux.

This procedure also presupposes the classification of the interatomic interactions (chemical bonds) in terms of types of the so called 'bond critical points' (BCP) at which the condition presented above holds. It was then found that the position of the BCP and the electron density at this point reflect the polarity of the corresponding bond and make it possible to determine the EN for both atoms and groups.^{36, 195, 196} One of the most significant arguments in support of this approximation is the fact that the atoms in the given valence state and the molecular fragments frequently retain an unchanged form, volume, polarisability, and other characteristics as part of the composition of various compounds. This in fact determines their chemical individuality.

Using atomic characteristics obtained on the basis of Bader's method (atomic volumes and the BCP parameters) combined with classical DFT equations, Komorowski *et al.*¹⁹⁷ calculated the EN and hardnesses for a large number of chemical groups.

In concluding this Section, we may emphasise that the DFT, supported by a single theoretical basis, integrates the methods for the quantitative expression of the donor–acceptor properties of chemical systems and combines Mulliken's ideas concerning absolute EN,¹¹ the Iczkowski and Margrave expansion of the energy of an isolated atom,¹⁰⁸ the Hinze–Jaffe concept of orbital EN,^{99–101, 110} Sanderson's principle of the total equalisation of EN,⁹⁵ the HSAB concept, *etc.* The global and local characteristic parameters introduced within the framework of the DFT (hardness, softness, Fukui index, *etc.*) permit an adequate description of quantitative data on the reactivities and selectivities of the interaction of diverse compounds.

At the same time, the different interpretations involved in the determination of the *in situ* EN on the basis of the OFT-justified approaches have been attributed by Allen³ to the deficiencies of the DFT definition of EN given by Parr and Pearson. Furthermore, he subjected to a well argued, in our view, criticism Mulliken's expression for EN, which has become the criterion of the validity of a whole series of approaches, including the DFT. Furthermore, Allen believes that it is illegitimate to identify EN with the chemical potential and he therefore does not accept the idea of the equalisation of EN. Parr postulates in his turn that Allen's criticism has arisen mainly from a discrepancy in the understanding of the electronic state of a bound atom.¹⁹⁰

In our view, the essential feature of the contradictions has a deeper origin. One is not dealing with deficiencies in the Mulliken definition of EN and with the disagreements of various workers as regards the state of an atom in a molecule. Both in the beginning and now there is no clear idea as to what EN is (and hence as to what is the exact mathematical form of its description). Indeed the entire data described in the previous Sections indicate that the authors of different concepts of EN have no unanimous view concerning its nature even at the atomic level. Strictly speaking, the current state of this question does not even allow one to consider EN as a physical quantity. It is merely a qualitative and, in a certain sense, a conceptual notion more in the nature of a 'property' or a 'capacity' and having no rigorous dimensionality and mathematical expression. Despite this initial contradiction,

the ideas concerning EN have developed and the concepts of the EN of first a group and later of a molecule appeared. Indeed, if EN is identified with the energies of HOMO and LUMO, the EN (chemical potential) of a molecule can be easily calculated. However, it does not then become in any way better founded and more unambiguous.

The chemical potential of a molecule is known to depend on external factors such as the solvent,^{198, 199} the external field,¹⁵⁹ *etc.* Consequently one should not speak of the EN of a molecule as a characteristic individual quantity. And, whereas in relation to Lewis acids and bases the molecular EN together with hardness can be used for the interpretation of the properties of complex formation, in the general case its physical significance is not entirely clear. Even hardness itself, used together with EN as an independent parameter, is evidently not such a parameter because both χ and η are expressed with the aid of the same parameters — the ionisation potential I and the electron affinity F .

Another piece of evidence for the ambiguity of the parameters χ and η is the interrelation (and in a series of approaches also the identity), mentioned in this review, of the parameters a and b in the quadratic equations relating E and q , subsequently identified with EN and hardness. Furthermore, it is logical to postulate (and this has already been noted above) that the parameters I and F are themselves determined by identical factors involving the elementary structure of the atom and constitute merely one of the many manifestations of EN as a more fundamental property.

In our view, EN has received an unduly extensive and hence diffuse treatment, which does not reflect its initial physical significance. The reason is that, as a fundamental characteristic determining the electronic properties of atoms and molecules, EN cannot be measured in a way other than through these (measured) properties, *i.e.* cannot be determined directly. This is in fact why fundamental importance is frequently attributed to a measured parameter (for example, the ionisation potential).

We believe that the vital problem at the present stage of development of EN is that of the ‘return to sources’: it is necessary to restrict the concept of EN as a fundamental unchanging property of a chemical element and to create on this basis simple and understandable methods for the quantitative determination of the electronic properties of atomic-molecular *ensembles* (substituents, groups, molecules, *etc.*). The next Section of the review is devoted to one of such possible approaches.

V. The concept of ‘inductive’ electronegativities

A wide variety of numerous methods for the estimation of EN have been developed (the main ones were described in previous Sections of the review). Several tens of EN scales have been created on their basis and these are widely employed in the analysis of physicochemical properties and reactivities of compounds.

At the same time, the general methods for the estimation of EN from reactivity data have been scarcely employed. In our view, such direct approaches are in fact the most interesting and promising for the estimation of the electronic properties of atoms and groups, just as inductive, steric, and other constants of substituents are determined on the basis of the principle of the linearity of free energies.^{14, 15, 200, 201}

The view that the values of EN and inductive constants reflect a general fundamental property, determining the distribution of electron density in the molecule, has been firmly established in the literature.¹⁵ This is confirmed by the existence of numerous correlations of inductive constants and EN with the same parameters. Furthermore, numerous examples of the employment of EN of atoms and groups for the quantitative interpretation of the reactivities of molecules, especially in the chemistry of organo-metallic compounds, are known.¹⁵

In this connection, attempts have frequently been undertaken to relate the quantities σ and χ , but the correlations obtained were

of a local character, which rules out the establishment of a functional interrelation between these parameters.²⁰²

1. A new model of the inductive effect

In a series of communications^{203–206} we proposed a new method of determining the EN of ‘inductive’ atoms and groups from the inductive constants of substituents, which are directly related to the reactivity of molecules.

The method has been developed on the basis of a new model of the inductive effect, which makes it possible to calculate with a high degree of accuracy the inductive constants of various substituents at any reaction centres. The calculated Taft inductive constants for 427 substituents are linearly related to the corresponding experimental data with a correlation coefficient of 0.99.²⁰⁶

Using the model of the inductive effect, it is possible to solve a series of important theoretical problems associated with that of inductive interactions, such as the inductive influence of alkyl substituents,²⁰⁷ the inductive effect in the chemistry of organoelement compounds,²⁰⁸ *etc.*, which cannot be done within the framework of any other approaches. Some of the rules derived in the new model made possible a new look at the problem of the quantitative determination of EN and of its physical significance.²⁰⁹ The principal results obtained by means of the approach which we have developed have been surveyed in a review.²⁰²

The fundamental postulate of the model of the inductive effect involves the consideration of inductive constants at the atomic level of additivity:

$$\sigma^* = \sum_i^n \frac{(\sigma_a)_i}{r_i^2}, \quad (31)$$

where σ^* is the inductive constant of the substituents on Taft’s scale, n is the number of atoms in the substituent, $(\sigma_a)_i$ is an empirical quantity, which we introduced, defining the inherent power of the i th atom of the substituent to exhibit the inductive effects and depending on the chemical nature of the element and its valence state, and r_i is the distance from this atom to the reaction centre for which a tetracoordinate carbon atom was chosen in constructing the model.

Evidently this approach is in essence formal. However, the high quality of the correlations between the calculated inductive constants and experimental data shows that the constants σ_a really reflect the ability of atoms to exhibit the inductive effect. As a consequence of this, the question of the factors responsible for such ability, *i.e.* the physical significance of the elementary constants σ_a , is of current interest.

In order to solve this problem, we investigated the quantitative dependence of the constants σ_a on various physical and geometrical parameters and established in this connection a series of important rules.

In particular, an expression relating the quantity σ_a to the difference between the EN of the given element and carbon (the reaction centre) and the square of the covalent radius of the element in the corresponding valence state was obtained:

$$\sigma_a = 7.840(\Delta\chi + 0.45)R^2. \quad (32)$$

This relation explains satisfactorily both the magnitude and the sign of the inductive constants.

In order to eliminate the systematic correction of 0.45 from Eqn (32), we adopted a value of 2.1 for the ‘inductive’ EN of the carbon atom. Eqn (32) then assumes a simpler form:

$$\sigma_a = 7.840\Delta\chi R^2. \quad (33)$$

This value of the ‘inductive’ EN of carbon ($\chi_C = 2.1$) differs appreciably from the corresponding value on Pauling’s scale ($\chi_C = 2.55$), which is not fortuitous. The value which we proposed reflects the real donor–acceptor properties of carbon manifested in its reactivity. An argument in support of this claim is the fact

that the data obtained are based on concrete characteristics of the reactivity of molecules — inductive substituent constants. That the EN of carbon on Pauling's scale are somewhat too high is indicated also by the fact that the quantity $\chi_C = 2.55$ presupposes the existence of electron-accepting properties in carbon in relation to iodine ($\chi_I = 2.4$) and phosphorus ($\chi_P = 2.2$) and this is not the case. Furthermore, the insignificant polarity of the C–H bond indicates the similarity of the electronegativities of carbon and hydrogen atoms, which is also inconsistent with their values on Pauling's scale ($\chi_H = 2.1$).

By analysing Eqn (33), it is possible to understand the physical significance of inductive interactions. The constant σ_a , reflecting the ability of the atom to exhibit the inductive effect, depends not only on the EN — the driving force of the shift of electron density — but also on the area of its valence shell (R^2), *i.e.* its ability to delocalise the charge generated. Thus the inductive effect of a particular element (substituent) is determined by the 'difference between the potentials' ($\Delta\chi$) of this element and the reaction centre and by the 'capacity' of the latter.

We may also note that Eqn (33) makes it possible to express the EN of the element in terms of its constant σ_a and the square of the covalent radius.

$$\Delta\chi = a\sigma_a R^{-2}$$

Evidently this method of expressing EN is in essence identical with the 'geometrical' EN systems, while the empirical constants σ_a are similar, in terms of their physical nature, to the effective nuclear charges of atoms. Furthermore, we obtained a correlation, with a similar significance, between the constant $\sigma_a(C)$ of the element E, linked to a carbon atom as the reaction centre, and the dipole moment μ of the C_{sp^3} –E bond:²⁰³

$$\sigma_a(C) = 9.370 R^2 \frac{\mu}{l}, \quad (34)$$

where l is the bond length.

Since $\mu/l = q$, one can postulate that the superposition of relations (33) and (34) will 'disclose' the correspondence of the difference between the EN of the partner atoms in the formation of the bond ($\Delta\chi$) to the partial charge q arising on them:

$$q = 0.836\Delta\chi.$$

We have already mentioned analogous relations between the atomic charges in the X–H and X–Me systems, calculated by quantum-chemical methods, and the EN of the element χ quoted by Marriott *et al.*³⁸ Relations between q and χ are also known for alkali metal halides.⁸

The fact that Eqns (31) and (33) make it possible to express the inductive constant of the substituent via the fundamental physical and geometrical parameters of its constituent atoms in accordance with the additive scheme

$$\sigma^* = 7.840 \frac{\sum \Delta\chi_i R_i^2}{r_i^2} \quad (35)$$

is particularly remarkable. This method of determining inductive constants permits the solution of many theoretical problems concerning the quantitative determination of the inductive effect (for a more detailed system, see the relevant review²⁰²).

It is remarkable that Eqn (35) relates two terms — the driving force for the displacement of electron density (EN) and the ability to delocalise the charge generated (R_i^2/r_i^2 , actually the softness). However, these parameters are frequently used as independent parameters for the description of reactivity within the framework of the DFT (see, for example, Langaenaeker and coworkers^{210–213}). Thus an analogy may be traced in which the parameter R_i^2/r_i^2 acquires the significance of an 'effective softness'.

Furthermore, the reproducibility and stability of the solutions indicate the constancy of the physical nature of the additive model of the inductive effect. This permits the analysis of the physical significance of the established rules on the basis of fundamental

physical laws. Thus the evident analogy between the mathematical procedures of the model under discussion and the familiar equations of the theory of electrostatic induction is noteworthy. In particular, within the framework of this theory the flux of the electrostatic induction vector $\vec{N}$ through a spherical surface is defined as follows:

$$\vec{N} = \frac{q}{4r^2} R_s^2, \quad (36)$$

where R_s is the radius of the sphere, q is the point charge, and r is the distance from the centre of the sphere to this charge.

If the inductive influence of the substituent is considered within the framework of the fundamental equation (31) taking into account Eqn (34) obtained, then, for the inductive constant of a monatomic substituent on Taft's scale, it is defined by

$$\sigma^* = 9.370 \frac{q}{r^2} R^2, \quad (37)$$

where q is the charge arising on the atom when the latter forms a covalent bond, r is the distance from the atom to the reaction centre, and R is the covalent radius of the atom.

The similarity of Eqns (36) and (37) imparts to the inductive constant of a monatomic substituent the physical significance of the flux of the electromagnetic induction vector, passing through the surface of the corresponding atom and generated by the charge on the reaction centre. The physical significance of the inductive effect has been analysed.²⁰⁹ Without going into the details of this investigation, we shall only mention that the following expression has been established for the calculation of the charge arising on the i th atom in a nonconjugated molecule:

$$q_i = 0.172 \sum_j \frac{\Delta\chi_{i-j}(R_i^2 + R_j^2)}{r_{i-j}^2}, \quad (38)$$

where the values of q_i are expressed in units of the elementary charge e , while the distances r_{i-j} between the i th and j th centres and the radii of the atoms i and j are expressed in Å.

We may note a clear analogy between the relation obtained and Eqn (25) expressing the charge in terms of the EN and the hardness of the partner atoms involved in the bond. In the model of the inductive effect, the charge and its inductive constant are directly proportional to $\Delta\chi$ and the ability of the system to delocalise the charge [the ratio $(R_i^2 + R_j^2)/r_{i-j}^2$]. In the DFT, the quantity q is also directly proportional to $\Delta\chi$ and inversely proportional to the sum of the hardnesses $\sum\eta$, *i.e.* actually to the ability to delocalise the charge mentioned above.

We shall demonstrate by the following example the possibility of calculating the partial charges in the molecule on the basis of the relations which we have obtained. Table 1 presents the effective atomic charges (δ) in the molecules of hydrogen halides obtained by Sanderson's method,²¹⁴ the reduced dipole moments of the hydrogen halide molecules μ/l , and the charges q calculated by Eqn (38). Evidently δ and q are fairly close. Furthermore, the reduced dipole moments of the H–Hal molecules and the distribution of their electron density are correlated with the calculated value of q :

$$\frac{\mu}{l} = (-1.351 \pm 0.071) + (19.523 \pm 0.645)q.$$

Table 1. The charges on the atoms in the molecules of hydrogen halides calculated by Sanderson's method and within the framework of the new model of the inductive effect together with the reduced dipole moments.

Molecule	δ / e	q / e	$(\mu/l)/\text{\AA}$
HF	0.16	0.177	2.09
HCl	0.09	0.108	0.81
HBr	0.06	0.099	0.56
HI	0.04	0.084	0.26

Thus one may say that the empirical rules established within the framework of the model developed permit a fairly adequate estimation of the shift of electron density in molecules.

2. Determination of the 'inductive' electronegativities of atoms and groups

The results of our investigations have shown that the model developed elucidates to a considerable degree the nature and physical significance of the inductive effect, relating it to the fundamental laws of electrostatics and electromagnetic induction. This leads in its turn to new possibilities for the quantitative theoretical estimation of the intramolecular distribution of electron density and of the reactivities of organic and organoelement compounds.

Furthermore, the expressions obtained for the inductive constant [Eqns (33)–(35)] permit the converse procedure involving the calculation of the group 'inductive' EN.^{215–217}

Thus we found the values of χ for a series of the commonest atoms in different valence states by a converse recalculation based on Eqn (33). We created in this way a scale of 'inductive' EN. The values obtained reproduce Pauling's scale with an adequate accuracy (with the exception of the carbon atom) and are quite well correlated with a series of other familiar scales.²¹⁵

Proceeding to the determination of group EN on the basis of Sanderson's total equalisation principle, we postulated that the $\Delta\chi_i$ in Eqn (35) for the atoms of the substituent is a constant quantity reflecting the EN of the entire substituent. One can then write

$$\Delta\chi = \frac{\sigma^*}{7.84 \sum R_i^2/r_i^2}.$$

Comparison of this expression and Eqn (33) yielded the final formula for the calculation of group 'inductive' EN.

$$\Delta\chi_g = \frac{\sum_i^n \Delta\chi_i R_i^2/r_i^2}{\sum_i^n R_i^2/r_i^2}. \quad (39)$$

It is remarkable that an evident analogy with Eqn (33) for the group EN in the DFT is observed in this case too. This confirms yet again the legitimacy of identifying the parameter R_i^2/r_i^2 with the effective softness of the atom.

Equation (39) permits the calculation of the group EN for any groups, substituents, or ligands at any reaction centres from the fundamental characteristics of their constituent atoms. At the same time, it is evident that this expression for the group EN has a series of undoubted advantages.

Firstly, it makes it possible to reveal in an analytical form, other conditions being equal, the decisive role of the central atom of the substituent. It is in fact in this instance that the parameter r_i is a minimum and the contribution of the corresponding term is the most significant. Furthermore, the expression presented makes it possible to obtain the values of EN of both groups and individual atoms on a single scale, because the latter can be regarded in this case as monatomic substituents.

Secondly, the 'inductive' EN of the most diverse nonconjugated substituents,²¹⁶ calculated in terms of the approximation of a carbon reaction centre within the framework of Eqn (39), are correlated satisfactorily with the known scales based on the principle of the total equalisation of EN (for examples, the scales of Mullay,¹¹⁵ Sanderson,²¹⁸ and De Proft *et al.*²¹⁹). A fairly good qualitative correspondence is observed with other χ scales (correlation coefficients of 0.91–0.95).²¹⁶ In contrast to other equations, Eqn (39) takes into account the steric structure of the substituent, which permits a correct calculation of the group EN for isomeric fragments, avoiding one of the most significant deficiencies of the principle of the equalisation of EN.

Thirdly, in analysing the expression for the group EN one cannot disregard the question of the dependence of the EN of the substituent on its conformation. The existence of this dependence for the inductive effect has been frequently noted and is not open to doubt.¹⁵ Electronegativity has never been considered in this context, although the EN of the substituent and its inductive influence have the same physical nature.

Fourthly, Eqn (39) makes it possible to discover the relation between the three principal characteristics of substituents — the inductive (σ^*) and steric (R_s) constants and the group EN (χ_g).

The following expression defining the steric constant has been proposed within the framework of the model of the frontal steric effect which we have developed:^{220–222}

$$R_s = 30 \lg \left(1 - \sum_i^n \frac{R_i^2}{4r_i^2} \right), \quad (40)$$

where R_i is the radius of the i th atom of the substituent and r is the distance from this atom to the reaction centre.

The scale of the constants R_s thus obtained is satisfactorily correlated with various experimental scales (for example, E_s , E_s^0 , and V), describing adequately the steric effects of various substituents. The model permits the calculation with a high degree of accuracy of the steric effect of any substituent at any reaction centre.

Equation (40) may be simplified by taking into account the fact that, for low values of x , the function $\log(1-x)$ is linear. For the vast majority of substituents (with the exception of unduly bulky ones), the sum in brackets is small and one can therefore write

$$R_s = \text{const} \sum_i^n \frac{R_i^2}{r_i^2}. \quad (41)$$

Since the difference between the atomic and covalent radii of the elements (used respectively in the steric and inductive models) is as a rule insignificant, the following final formula relating the fundamental physical parameters of the substituent is obtained from Eqns (35) and (41):

$$\sigma^* = A \Delta\chi_i R_s, \quad (42)$$

where $A = \text{const}$.

In order to confirm the correctness of this expression and to determine the normalised value of the multiplier, we calculated the group EN also for a series of other groups frequently encountered in organic and organoelement compounds and not containing multiple bonds. Within the framework of regression analysis, all the values of $\Delta\chi_i$ obtained were compared with the corresponding constants σ^* and R_s . The theoretical values of the latter for substituents at a carbon reaction centre were taken from Cherkasov *et al.*²⁰² This yielded a relation²¹⁶ confirming the validity of the above considerations at an experimental level and indicating the universality of relation (42):

$$\sigma^* = (0.067 \pm 0.034) + (0.435 \pm 0.024) \Delta\chi_i R_s \quad (43)$$

(the correlation coefficient is 0.9868 for 64 points).

The exact value of the normalising coefficient in expressions of type (43) can vary somewhat on passing from one reaction series to another depending on the nature of the specific reaction centre.²¹⁷

The existence of relation (43) makes it possible to justify Eqn (39), avoiding the direct employment of the equalisation principle.

Since the steric constant R_s , defined by Eqn (41), is additive, we can write

$$R_{si} = B \frac{R_i^2}{r_i^2}, \quad (44)$$

where $B = \text{const}$ and R_{si} is a parameter describing the shielding of the reaction centre by the i th atom of the group.

Using Eqns (44) and (45), it is possible to express the inductive constant of the substituent in the following form:

$$\sigma^* = \text{const} \sum_i^N \Delta\chi_i R_{si}.$$

However, bearing in mind Eqn (43), the inductive constant of the substituent can be expressed in terms of the EN of the group and its steric shielding constant:

$$\sigma^* = \text{const} \Delta\chi_g R_{sg}. \quad (45)$$

Thus, taking into account Eqns (35) and (45), we obtain an expression for the group EN, more correctly for the difference between the EN of the substituent and the reaction centre $\Delta\chi_g = \chi_g - \chi_{RC}$, which agrees fully with Eqn (39), but this time does not involve the employment of the principle of the total equalisation of EN:

$$\Delta\chi_g = \frac{\sum_i^n \Delta\chi_i R_i^2 / r_i^2}{R_{sg}} = \frac{\sum_i^n \Delta\chi_i R_i^2 / r_i^2}{\sum_i^n R_i^2 / r_i^2}. \quad (46)$$

It is remarkable that Eqn (45) is analogous also to the relation between the principal characteristics of the substituent — the inductive constant σ , the group EN, and the steric shielding constant R_s — obtained on the basis of the total equalisation principle.

Taking into account the relations obtained, one may conclude that the mathematical principle of the total equalisation of the EN of all the atoms constituting the substituent is capable of yielding correct results as a computational method. The problem consists only in the need to establish the optimum algorithm for the averaging of the atomic EN, taking into account the chemical nature of the atoms and the steric structure of the substituent. Evidently, our approach is fully consistent with these requirements.

3. The 'inductive' electronegativities of substituents at different reaction centres

In the expression which we obtained for the 'inductive' EN, there are parameters which depend on the choice of the specific reaction centre — the distance from the i th atom of the substituent to this centre and the difference between their EN. It therefore appeared logical and useful to calculate using Eqn (39) the values of $\Delta\chi_g$ for the commonest nonconjugated substituents at different reaction centres.²¹⁷

We compared them with the corresponding 'inductive' EN [$\Delta\chi_g(C)$] which we had obtained earlier in terms of the approximation of a carbon reaction centre²¹⁶ using a linear regression of the type

$$\Delta\chi_g(E) = a\Delta\chi_g(C) + b. \quad (47)$$

This made it possible to show that there is a rigorous linear relation between the $\Delta\chi_g$ for substituents at different reaction centres; the correlation coefficients are 0.98–0.99. The coefficients a then proved to be virtually unity and the coefficients b were found to be equal to the difference between the EN of carbon and the element E ($\chi_C - \chi_T$), whence it follows that χ_g is a constant quantity. This leads to the unambiguous conclusion that the 'inductive' EN of the substituents χ_g are constant regardless of the nature of the reaction centre, which is consistent with the established view concerning the universal nature of the concept of 'electronegativity'.

The method which we have developed takes into account the evident dependence of the difference between the EN of the group and the reaction centre $\Delta\chi_g$ on the nature of the latter, but the 'inductive' EN themselves do not vary under these conditions, in contrast to the constants σ characterising the electronic pair interaction between the substituent and the reaction centre.

In analysing the relations obtained, the question arises of the universality of the relation between the inductive constant, the group EN, and the steric constant [Eqn (45)] and of its dependence on the nature of the reaction centre. Thus, we showed previously²⁰² that, on passing from one reaction centre to another, the constants R_s vary in proportion, but the inductive constants are not linearly related in the general case. Furthermore, the linear relation established in the above investigation between the $\Delta\chi_g(E)$ presupposes the existence of a significant constant term in relations of type (47). In order to estimate the universality of Eqn (45) and to determine its normalising multiplier, we tested experimentally the validity of Eqn (45) on a wide range of different reaction centres E. The constants σ and R_s were taken from Cherkasov and coworkers.^{202, 220}

Analysis of the data obtained demonstrated the validity of a rigorous linear relation between the parameters investigated and the constancy of the slopes in all the correlation equations. Consequently Eqn (45) is universal and valid regardless of the choice of the reaction centre. Having averaged the values of a obtained, it is possible to formulate the following final expression:

$$\sigma^* = -2.1\Delta\chi_g R_s.$$

Thus the methods for expressing the steric (R_s) and inductive (σ) constants as well as EN in terms of fundamental physical and geometrical parameters [Eqns (35), (40), and (46)] which we have proposed not only permit a correct theoretical calculation of these characteristics but also reveal their genetic interrelation.

The possibility of a simple description of the electronic steric influence of substituents within the framework of the models developed is determined by the fact that they are based on extensive experimental data — inductive and steric constants. This 'extremely empirical' basis of the theoretical approaches which we have developed constitutes a significant argument in support of their adequacy. This is also indicated by the agreement between the experimental substituent constants and their values calculated by Eqns (35) and (44).

The concept of 'inductive' EN revealed a series of new aspects of the application of group EN: its interrelation with conformations, the absence of a dependence on the nature of the reaction centre, and 'the genetic relationship' with the inductive and steric constants. The quantitative interrelation of the 'inductive' EN and the partial atomic charges, which we have discovered, as well as consistency with other known methods for the calculation of EN must be specially emphasised. This makes it possible to throw light on certain controversial questions and to emphasise new aspects in the concept of EN.

Thus the expression for group EN [Eqn (46)] has been obtained within the framework of the approach which we have developed by two independent procedures, one of which presupposes the equalisation of the EN of the substituent atoms. On the one hand, this makes it possible to explain the existing diversity of the views on the principle of the equalisation of EN. As a mathematical computational procedure, it undoubtedly 'works', although Eqn (46) presupposes a more complex equalisation formula than simple geometrical, arithmetical, *etc.* averaging. On the other hand, the existence of an expression which permits the calculation of the EN of the group from the EN of its constituent atoms taking into account the geometry of the system throws doubt on the usefulness of employing the principle of the equalisation of EN. We agree with the criticism by Allen,³ who pointed out that the equalisation of the *in situ* EN conflicts with the constancy of the chemical nature of the atom and who rejected the identification of EN with the chemical potential.

We have already emphasised that the 'inductive' EN have been obtained from the corresponding empirical atomic constants σ_a . This suggests that the calculated 'inductive' EN of atoms reflect their real electron-donating (electron-accepting) properties. However, since σ_a is an inherent unchanging atomic characteristic (this in fact permits its employment in additive calculations), we arrive inevitably at the conclusion that EN

should also be a constant quantity for an atom, regardless of its environment (and, incidentally, regardless of any external factors in general).

$$\chi = \frac{\sigma_a}{R} = \text{const.}$$

Thus one may conclude that the transition from the set of accumulated methods for the determination of χ (including also procedures within the framework of our approach) and also of procedures for the treatment of the term 'electronegativity' itself to a qualitatively new representation of its essential nature, not as a concept but as a property determined solely by the nature of the element and its valence state, has been achieved.

VI. Conclusion

Within the limited space of a review article, we were unable to cover the entire wide variety of the studies carried out in the field of the quantitative determination of EN and its practical employment.

From our point of view, the entire experience gained in the course of the historical development of the concept of EN has shown that it is a universal property of a chemical element, which depends solely on its nature and valence state and remains unchanged on formation of a molecule. Indeed, in all the existing scales, with all their diversity, the EN of chemical elements are constant quantities within the limits of each scale, differing only as regards the valence state. They describe satisfactorily the physical and chemical properties of diverse molecular systems. On the other hand, the majority of the scales, which have been frequently created on the basis of significantly (sometimes also fundamentally) different approaches, are satisfactorily correlated, emphasising the universality of EN as a property of a chemical element.

On the other hand, all the known methods for the 'averaging' or equalisation of EN when the donor — acceptor properties of groups and molecules are considered nevertheless operate in one way or another with 'intrinsic' (or 'null') values of the EN of their constituent chemical elements. Thus the basic sets of EN are entirely sufficient for an adequate quantitative description of the electronic properties of any atomic ensembles, while the equalisation principle (whatever the specific algorithm on which it is based) is only a successful instrument for such description. The attribution to it of a real physical significance actually leads to the blurring of the concept of EN and to its replacement by other (perhaps similar) concepts.

One should add to the foregoing that electronegativities are introduced methodologically as constants: an intrinsic unchanging value of χ is assigned to each abstract atom or substituent; their sets constitute EN scales.

Thus EN is a fundamental property of an atom — its power to attract electrons, which is manifested on formation of a molecule. We suggest that it is just as fundamental and unchanging as the chemical nature of an element and its nuclear charge and mass are constant in any molecules. As a fundamental property in a similar category, EN should be regarded, in our view, as a characteristic of a chemical element which depends on its nature and valence state. In its turn, EN generates the remaining electronic properties of atoms and molecules — ionisation potential, electron affinity, chemical potential, charge distribution, hardness, softness, etc, (the group EN should be included here also), which are determined by the balance of the EN of the chemical elements constituting the given system.

These properties may vary and may be equalised, but EN itself should remain unchanged. As soon as we allow a dependence of the EN of the element on its environment in the molecule, its charge, etc, we inevitably blur the very concept of EN, replacing it by other derived quantities (for example, the chemical potential) which are perhaps logically non contradictory. Yet another important cause of such 'mixing' of concepts is the fact that EN may be measured only in terms of measured properties, as a

consequence of which an unjustifiably great importance is attributed to the measured parameter. Pauling's definition of EN is most correct in this connection: 'EN is the force with which an atom in a molecule attracts electrons'.

However, when account is taken of the postulate, described above, of the constancy of EN as a fundamental property of a chemical element in a given valence state, we tend to understand by the term 'atom in a molecule' in Pauling's formulation the state of the atom in the initial instant of the interaction. From our point of view, such an interpretation is simpler, logical, and rational if only because it is definite and unambiguous. Pauling's definition, which is essentially correct, therefore requires refinement in each specific instance. We believe that it can be formulated as follows: 'EN is the ability of an element to attract electrons on formation of chemical bonds, which depends on its nature and valence state'.

This revised definition of EN is the most complete and unambiguous and makes it possible to distinguish it from other similar parameters characterising the electronic state of atomic-molecular systems, and implies the constancy of EN as a fundamental property of an element in the given valence state.

Abstract. Published data on the methods for synthesis of carbo- and heterocyclic compounds based on reactions of α,β -unsaturated nitriles with carbonyl compounds and activated phenols are surveyed. It is demonstrated that all these reactions occur *via* nucleophilic addition of the carbanion generated from a carbonyl compound to the double bond of an unsaturated nitrile (the Michael reaction). The main routes of transformation of the adducts into carbo- and heterocyclic compounds are considered. The methods for regioselective preparation of fused 4*H*-pyrans or 1,4-dihydropyridines by varying conditions of cyclisation of Michael adducts are discussed. The bibliography includes 249 references.

I. Introduction

Reactions of carbonyl compounds with α,β -unsaturated nitriles can yield carbo- and heterocycles that are difficult to synthesise by other methods. Unsaturated nitriles activated by electron-withdrawing substituents react with carbonyl compounds under mild conditions; in some cases, this makes it possible to isolate intermediate compounds and to conduct highly regio- and stereoselective reactions that require simple experimental equipment. The use of initial compounds with various substituents in the molecules permits the synthesis of a broad range of heterocyclic derivatives including substituted 4*H*-pyrans, pyridines, 2-pyridones, and pyridine-2-thiones. It should be noted that the compounds produced in this way contain easily modifiable functional groups, and, therefore, they present interest for fine organic synthesis and for the chemistry of pesticides and medicines. The reactions of carbonyl compounds with ylidene derivatives of malononitrile, cyanoacetamide, and ethyl cyanoacetate have been considered in several reviews^{1–6} and monographs.^{7–9} How-

ever, due to the vigorous development of this field of organic chemistry, the information available from these sources needs to be supplemented. In this review, we generalise and describe systematically the data on the methods for the synthesis of carbo- and heterocycles based on reactions of carbonyl compounds with unsaturated nitriles.

II. General regularities and classification of the reactions

Reactions of carbonyl compounds **1** with α,β -unsaturated nitriles **2** occurs most often as the Michael nucleophilic addition of the methylene group of the carbonyl compound to the activated double bond of the nitrile. The reaction involves a base, the role of which is to generate the corresponding carbanion. In addition, the base stabilises the resulting adduct as salt **3**. This process is generally illustrated by Scheme 1.¹⁰

The resulting salt **3** or **4** can undergo a number of subsequent transformations, their routes depending on the structures of the initial reagents and on the particular conditions. Thus, the reaction in question possesses great synthetic potential, because its regioselectivity can be modified by varying the substituents and reaction conditions. In some cases, the process follows pathway (*a*) with elimination of nitrile derivative **5** and formation of α,β -unsaturated dicarbonyl compounds **6**, *i.e.* **1** and **5** exchange their methylene fragments. This reaction is reversible, and heterocyclic compounds can be synthesised both by reaction of **1** with **2** and **5** with **6**. If one of the substituents (for instance M) is a good leaving group, it is eliminated giving rise to a multiple bond [path (*b*)]. The alkene **7** thus formed, depending on its structure, is either removed from the reaction area or undergoes intramolecular cyclisation to give carbo- or heterocyclic compounds. Acidification of the salt **3** gives adduct **8**, which can be converted into the nitrile **7** upon elimination of MH.

The most frequently encountered variant of the subsequent transformations of the compounds **3** and **8** is intramolecular cyclisation.¹¹ Depending on the natures of substituents X, Y, and Z, this can afford diverse, as a rule six-membered, carbo- and heterocycles. Some of the adducts **3**, **7**, and **8**, can be isolated, especially those derived from cyclic dicarbonyl compounds or tetracyanoethylene, which cyclise under more rigorous conditions. These adducts can also eliminate a nucleofugal fragment.

III. Synthesis of Michael adducts

In this Section the formation of stable Michael adducts in the reactions of carbonyl compounds with unsaturated nitriles is described, the conditions and stereochemical aspects of these reactions are generalised, and decomposition of these adducts with elimination of nucleofugal groups is considered. The Michael adducts derived from carbonyl compounds and tetracyanoethylene (TCE) are the most stable.^{3,4} It has been found that reaction of TCE **9a** with ketones **10** catalysed by 'molecular silver' or alcohols occurs selectively involving the methyl group and yields acyclic adducts **11**.¹² To activate the methylene group and obtain the isomeric product **12**, the reaction needs to be conducted with heating in the presence of acetic or trichloroacetic acid.¹² The structures of the adducts **11** and **12** were confirmed by their cyclisation into pyridines and pyrans under the action of acids.¹³

Acetylacetone **13a** reacts with TCE in the presence of silver in benzene at room temperature to give easily cyclisable adduct **14a** in 70% yield.¹⁴ When the same compounds react in ethanol without a catalyst, the yield of **14a** is 88%.¹⁰ Dicyanofumarate **9b** gives similar adducts **14b**.¹⁰

Data on isolation of stable products of addition of cyclohexanone **15** to TCE in the presence of SO₂ have been reported; the yield of adduct **16** reaches 95%.³

4*H*-Thieno[3,2-*b*]pyrrol-4-one **17** reacts with TCE in boiling benzene giving rise to stable adduct **18**, which has been reported¹⁵ not to undergo subsequent cyclisation.

Tautomeric forms of cyclic 1,3-dicarbonyl compounds, such as 4-hydroxycoumarin **19**, 4-hydroxy-2-quinolinone **20**, and (4-hydroxy-2,5-dioxo-2*H*,5*H*-pyrano)[3,2-*c*][1]benzopyran **21**, also react with TCE to give stable Michael adducts. The adduct **22** was prepared in ethanol, while compounds **23** and **24** were synthesised in glacial acetic acid.¹⁶

The reaction of the dicyanofumarate **9b** with dimedone **25** results in the formation of adduct **26** existing in the enol form.¹⁰

Under the Michael reaction conditions, the ketones **10** are cyanoethylated by acrylonitrile at the methylene group yielding stable compounds **27**, which are intermediates in the synthesis of cyclic diketones (see Section IV).¹⁷ The addition of dimedone **25** to acrylonitrile in boiling dioxane gives rise to stable Michael adducts **28** and **29** and acid **30**, the latter being the major product. However, variation of the reaction conditions permits the adduct **28** to be prepared in 85% yield. Alkaline hydrolysis of this adduct in a 10% solution of potassium carbonate affords the acid **30** in 74% yield.¹⁸ The reaction of cyclohexanone **31a** or its methyl analogue **31b** with acrylonitrile affords adducts **32** in yields of more than 60%.²⁰ The structure and chemical properties of these products, in particular, cyclisation to give pyridines, have been studied.^{19, 20}

R = H (a), Me (b).

Ethyl acetoacetate **33a** adds to ethyl 1-cyanoacrylate in the presence of highly basic secondary amines yielding adduct **34**.²¹ Ethyl cyanoacetate **33b** and ethyl nitroacetate **33c** behave in a similar way.

X = AcO (a), CN (b), NO₂ (c).

Arylidene derivatives of malononitrile and its analogues are widely used in reactions with carbonyl compounds. The Michael adducts formed in these reactions are normally unstable and readily undergo intramolecular cyclisation. However, the reaction of methyl acetoacetate **35** with 2-cyano-3-(3-nitrophenyl)acrylamide **36** in methanol in the presence of piperidine affords stable Michael adduct **37** in 88% yield.²² Similar open-chain products are formed when unsaturated ketone **38** is made to react with malononitrile **39**; adduct **40** does not cyclise even in sodium alkoxide solutions.²³

Apparently due to steric rigidity, heterocyclic carbonyl compounds are more readily converted into Michael adducts than acyclic 1,3-dicarbonyl compounds. The reaction of N-substituted 3-methyl-5-pyrazolones **41** with arylidenemalononitriles **42** can serve as an example of a well studied reaction of this type. A large number of adducts **43** with various aryl substituents have been synthesised in this way.^{11, 24–27} It was found that in DMSO solutions these compounds exist mostly in the enol form **43b**.²⁵

The adducts **43** have also been obtained by condensation of aromatic aldehydes **44**, malononitrile **39**, and pyrazolones **41**²⁷ and by the addition of malononitrile **39** to 4-arylidene-3-methyl-5-pyrazolones **45**.^{25, 27}

In addition, adducts of the type **43** are formed upon interaction of benzylidenemalononitrile **42** with 3-hetaryl-substituted 5-pyrazolone derivatives.²⁸

Stable Michael adducts are also produced when oxindole **46** reacts with arylidene derivatives of malononitrile **42** or cyanoacetamide **47**.²⁹ The adducts **48** do not cyclise into the corresponding pyrans even on treatment with strong bases; this was attributed²⁹ to the low degree of enolisation of the indoline fragment.

Z = CN (**42**, **48a**); Z = CONH₂ (**47**, **48b**).

Apparently, this also accounts for the fact that adducts **51a–d** formed from ketones **49** and 3-cyanomethylidene derivatives of oxindole **50** are quite stable and do not cyclise to pyrans without preliminary reduction.³⁰

Z = CO₂Et, R = Ph (**a**); Z = CN, R = Me (**b**);
Z = CO₂Et, R = Me (**c**); Z = CN, R = Ph (**d**).

The reaction of dicarbonyl compounds with arylidene derivatives of cyanothioacetamide also possesses great synthetic potential. In this case, the presence of several reaction centres ensures the existence of various routes for cyclisation of the intermediate Michael adducts and, as a consequence, the possibility of regio-controlled synthesis of a number of oxygen-, nitrogen-, and sulfur-containing heterocycles. Arylidene cyanothioacetamides **52** are prepared by reactions of the aromatic aldehydes **44** with cyanothioacetamide **53**^{31,32} or by reactions of the corresponding amides **47** with phosphorus pentasulfide in pyridine.³³ They tend to dimerise according to the Diels–Alder reaction pattern to give 2H-thiopyrans **54**, which exist in solutions as a ring–chain equilibrium with the compounds **52**; this equilibrium shifts to the left on increasing the temperature.³² Some thioamides **52** have been reported to exhibit tuberculostatic activities.³³

The reaction of dimedone **25** with arylidene cyanothioacetamides **52** in the presence of an equimolar amount of secondary amines in anhydrous ethanol at 20–25 °C affords Michael adducts, which are isolated from the reaction mixture as poorly soluble enol salts **55**.^{34–36} The corresponding aromatic aldehydes **44** and cyanothioacetamide **53** can be used in this reaction, instead of the compounds **52**, under the same conditions.³⁶ On treatment with hydrogen chloride in ethanol at 0 °C, these salts are reversibly converted into free adducts **56**, which exist solely in the enol form.³⁶

4-Hydroxycoumarin **19** reacts with arylidene cyanothioacetamide **52** in a similar way. When the reaction is carried out in ethanol in the presence of equimolar amounts of secondary amines at 20–25 °C, salts **57** are formed; these salts are also produced when 4-hydroxycoumarin **19** reacts with the aromatic aldehydes **44** and cyanothioacetamide **53**.³⁷ When gaseous hydro-

gen chloride is passed through an ethanolic solution containing the salts **57**, they are reversibly converted into compounds **58**.³⁷

When 4-hydroxycoumarin **19** is made to react with ethyl arylidene cyanoacetates **59** in the presence of an equimolar amount of morpholine, a mixture of enolates **60** and the products of their subsequent cyclisation, 4H-pyrans **61**, is formed; according to the data of NMR spectroscopy, the salts **60** predominate in this mixture. The free enol **62b** was prepared by treatment of the compound **60b** with hydrogen chloride.³⁷

Mor is morpholine; Ar = C₆H₅ (**a**); 4-BrC₆H₄ (**b**).

Meldrum's acid (isopropylidene malonate **63**), which is formally a cyclic 1,3-dilactone and a structural analogue of dimedone, is widely used in organic synthesis.³⁸ Being a relatively strong CH acid ($pK_a = 4.97$),³⁹ Meldrum's acid is not enolised in the solid state or in solution.^{40,41} Like dimedone, it reacts with arylidene cyanothioacetamides **52** to give enolates **64**.⁴²

Unlike the salts **55** and **57**, which can be converted into the free enols **56** and **58** by acidification, compounds **64** decompose on treatment with hydrogen chloride in ethanol at 0 °C or on heating in acetic acid to give the initial thioamides **52**. However, in the case of the morpholinium salt **64** (Ar = Ph), free Michael adduct **65** has been prepared.⁴² Heating of the same salt in acetic acid affords thiopyran **54** resulting from dimerisation of benzylidenecyanothioacetamide.³²

The compounds **64** react with phenacyl bromide according to the Hantzsch reaction pattern with elimination of Meldrum's acid and formation of thiazole derivatives **66**. The same compounds have been synthesised by treatment of the thioamides **52** with phenacyl bromide.⁴²

Arylthiazolylcyanoethylenes **66** have previously been obtained by reactions of 2-cyanomethylthiazoles **67** with the aromatic aldehydes **44**,⁴³ or phenacyl bromide with 4-amino-6-aryl-5-cyano-1,3-dithiacyclohexenes **68**.⁴⁴ The latter reaction has served as evidence for the intermediate formation of the thioamides **52** during thermal decomposition of dithiacyclohexenes **68** (see Section VII).^{45, 46}

The reaction of Meldrum's acid **63** with arylidenemalononitriles **42** in ethanol in the presence of secondary amines also gives rise to Michael adducts formed as salts **69**.⁴² A similar reaction of dimedone and 4-hydroxycoumarin affords fused 4*H*-pyrans (see Section VI).

When cyclic 1,3-dicarbonyl compounds are made to react with arylidenecyanothioacetamides, the Michael adducts are usually isolated as enol salts of secondary amines. In the case of acyclic 1,3-dicarbonyl compounds, the intermediate adducts cyclise without isolation to the corresponding pyridines (see Section VII).

Based on the spin-spin coupling constants, $^3J = 11.5 - 12.5$ Hz, of the methine protons in the compounds **55–58**, **60**, **62**, **64**, **65**, and **69**, it was found that the dihedral angles ϕ between these protons are 158–165°, which corresponds to the antiperiplanar conformation.^{36, 37, 42}

It is known that the selectivity of any reaction is determined by the symmetry of the transition state; therefore, when diastereoisomeric activated complexes are formed, they react at different rates.⁴⁷ The Michael addition of dicarbonyl compounds to unsaturated nitriles of the types **42**, **47**, **52**, or **59** results in the appearance of two asymmetric centres; thus, the reaction system is diastereotopic. Since the attack on the diastereotopic sides of the molecule could give unequal amounts of diastereoisomers, due to the difference between the free energies of the corresponding transition states, this reaction is, in principle, diastereoselective and can afford two pairs of diastereoisomeric adducts, **70a,b** and **70c,d**. The substituent Z is usually represented by ester, amide, thiocarbamoyl, and other similar groups, which, according to the succession rule, are senior with respect to the cyano group. In this case, the stereoisomers **70a** and **70b** constitute an enantiomeric pair of the *erythro*-type (*parf*) diastereoisomers, whereas the isomers **70c** and **70d** belong to the *threo*-type (*pref*).^{48, 49} The predominant formation of one or another stereoisomer depends on the particular conditions.

The addition of a dicarbonyl fragment to the double bond in the compounds **52** existing as *E* isomers^{32, 50} gives intermediate carbanions **71** and **72**. It is known that the inversion of configuration in carbanions occurs relatively easily⁵¹ and that the *E/Z* isomerisation of arylidenecyanoacetates occurs exactly at this stage.⁵² Apparently, the carbanions **71** and **72** are also able to isomerise to each other. The protonation of the carbanions **71** and **72** gives isomers represented by projections **73** and **74**, respectively. Evidently, the course of cyclisation depends not only on thermodynamic factors but also on the spatial structure of the adducts. Therefore, intramolecular cyclisation of *erythro*- and *threo*-diastereoisomers yields different compounds: pyrans or pyridines (see Sections VI and VII, respectively, Scheme 2).

It is known that pyridinium ylides are good reagents for transferring the methylenecarbonyl function to an activated C=C bond.⁵³ When pyridinium ylides **75** react with the unsaturated nitriles **59**, or the nitriles **5** react with unsaturated ketones **76**, Michael adducts **77** are formed.^{53–55}

Z = CN, CO₂Et.

Based on conformational analysis using the magnitudes of the spin-spin coupling constants of methine protons, $^3J = 11.2$ – 11.8 Hz, it was shown that the adducts **77** also exist only in the antiperiplanar conformation. The reactions of unsaturated nitriles with pyridinium ylides have been considered in more detail in a review.⁵⁶

A possible route for subsequent transformations of Michael adducts is decomposition accompanied by elimination of an easily leaving group⁵⁷ [Scheme 1, pathway (a)] and resulting in various rearrangements and exchange of methylene components.^{57–59} The Michael adducts derived from unsaturated nitriles also tend to undergo retro-reactions, and, consequently, the reactions of ylide derivatives of cyanoacetic acids with nucleophiles typically involve dynamic equilibria of the type $1 + 2 \rightleftharpoons 3 \rightleftharpoons 4 \rightleftharpoons 6 + 5$ (see Scheme 1).⁶⁰ These transformations have been considered in detail.⁶¹

The adducts formed from cyclic carbonyl compounds and TCE tend to eliminate malononitrile **39**. Thus on treatment with pyridine, the adduct **18** is cleaved to afford compound **78**.¹⁵

Benzo[*b*]thiophen-3-one **79** reacts with TCE giving rise to unsaturated nitrile **80** without intermediate isolation of the Michael adduct.¹⁵ The reaction of the pyrazolone **41a** with TCE also results in the formation of the corresponding dicyanomethylidene derivative **81**.⁶² 2-Indolinone **46** reacts with TCE in a similar way and gives dicyanomethylideneindolinone **82**.⁶³

TCE is tetracyanoethylene.

The behaviour of imides **83** in the reaction with TCE depends on the nature of the substituent at the nitrogen atom. For R = H, the reaction occurs according to the Michael pathway followed by elimination of malononitrile **39** to give compound **84a**. However, in the presence of an alkyl substituent, the nucleophilic methylene group in the compound **83** attacks the electrophilic carbon atom of a cyano group in TCE giving rise to the Thorpe reaction products **85a,b**.⁶⁴

R = H (**83a**), Me (**83b**, **85a**), Et (**83c**, **85b**).

Cyclic diketones such as 4,5-dichlorocyclopent-4-ene-1,3-dione **86**⁶⁵ and 1,3-indanedione **87**⁶⁶ also react with TCE according to the Michael pathway. The products **88** and **89** thus formed contain an electron-deficient double bond. The compound **88** has been used to prepare charge-transfer complexes.⁶⁵ The reaction of indanedione **87** with 3-nitrobenzylidenemalononitrile **90** gives rise to unsaturated diketone **91**.¹¹

The reaction of 4-nitrobenzylidenemalononitrile **92** with indolinone **46** affords compound **93a**.²⁹ When other arylmethylidenemalononitriles are introduced into this reaction, stable Michael adducts **48** are produced;²⁹ one of them (**48a**) is converted into non-substituted unsaturated ketone **93b** on treatment with ammonia.²⁹

Ar = 4- $\text{NO}_2\text{C}_6\text{H}_4$ (**a**), Ph (**b**).

The reactions of thiazolidine derivative **94** with furylidene- and thienylidene-malononitriles **95a,b** giving unsaturated ketones **96a,b** have been reported.⁶⁷

X = O (**a**), S (**b**).

3-R-2-Thiohydanthoins **97** having a similar structure and 3-methyl-1-phenylpyrazolone **41a** react with **95a,b** and **98a,b** to give products **99** and **100**. It has been suggested⁶⁸ that during this reaction, the reactants exchange their methylene components.

X = O, Z = CN (**95a**); X = S, Z = CN (**95b**);
X = O, Z = CO_2Et (**98a**); X = S, Z = CO_2Et (**98b**).

It has been shown that on refluxing in ethanol with barbituric acid **101a** and triethylamine, substituted furylidene-malononitriles **95a,b** are converted into compounds **102**.⁶⁹ By varying reaction conditions, one can obtain 2-aminopyrano[2,3-*d*]pyrimidines (see Section VI).

X = O (**a**), S (**b**).

An interesting reaction occurs between arylidenemalononitriles **42** and 1,1,1-trifluoro-3-(2-thenoyl)acetone **103**. The Michael adducts **104** formed intermediately undergo acidic cleavage with elimination of trifluoroacetic acid and are thus converted into substituted dicyanopropanes **105**,^{11,70} which can be used to synthesise substituted pyridines.⁷⁰

It has been mentioned above that the salts of adducts formed by Meldrum's acid and arylidenecyanothioacetamides **64** enter into a retro-reaction induced by acids and resulting in regeneration of the thioamides **52**. This is in agreement with the known data indicating that Michael adducts are stabilised by bases.⁶⁰ On heating in ethanol, the dimedone and Meldrum's acid derivatives are finally converted into derivatives of hydrogenated pyridine (Section VII). In the case of the salts **57** prepared from 4-hydroxycoumarin the cyclisation is hampered, and, as a result, the retro-reactions prevail. Prolonged refluxing of the salts **57** in ethanol followed by acidification has given aryl-substituted dicoumarins **106**;³⁷ these compounds have also been synthesised by the reaction of 4-hydroxycoumarin **19** with aromatic aldehydes **44**.^{71,72} The chemical properties of the compounds **106** and their analogues have been studied.^{73,74} It was found that they possess a moderate anticoagulant activity and inhibit oxidative phosphorylation in liver mitochondria.⁷⁵ The structure of a dicoumarin **106** (Ar = Ph) has been studied by X-ray diffraction analysis.⁷⁶

IV. Synthesis of carbocyclic compounds

Carbocyclic compounds are formed in those cases where at the stage of cyclisation of the adducts **7** and **8** (see Scheme 1), the carbon atom of the methyl, methylene, or methine group, activated by electron-withdrawing substituents, acts as the nucleophilic centre, while the carbonyl or nitrile carbon atom acts as the electrophilic centre.⁷ The reactions of 1,3-dicarbonyl compounds **13a** and **33a** with substituted nitriles **107** occur *via* cyclisation of the intermediate Michael adducts **108** at the aryl group and afford compounds **109**.^{23, 77}

R = Me (**13a**), OEt (**33a**).

The dicarbonyl compounds **33a, d–f** react with ethoxymethylidenemalononitrile **110** to give substituted anilines **111**.^{78–80} When the compounds **33g–i** with R = (CH₂)_nCO₂Et, n = 1, 2, 3, are introduced into this reaction, subsequent condensation is possible, resulting in the formation of fused heterocyclic compounds **112**.⁸⁰

R = H (**a**), Me (**d**), Et (**e**), Ph (**f**), EtO₂CCH₂ (**g**), EtO₂C(CH₂)₂ (**h**), EtO₂C(CH₂)₃ (**i**).

In some cases, the intermediate Michael adducts can add to a second molecule of the starting unsaturated nitrile, and the resulting bis-adduct can undergo Thorpe cyclisation. This route is realised, for example, in reactions of dibenzoylmethane **13b** with 1,1-dicyanoethylene¹ and oxindole **46** with benzylidenemalononitrile **42a**.²⁹ The resulting compounds **113** and **114** contain six-membered carbocycles.

Cyclopentanone **115** also adds two molecules of an unsaturated nitrile giving rise to fused anilines **116**.⁸¹

On treatment with hydrogen peroxide in methanol, the adducts **27** are converted into esters **117**, refluxing of which in the presence of sodium methoxide leads to their cyclisation yielding substituted cyclohexanediones **118**.¹⁷

Unsaturated nitriles **119** react with substituted acetophenones **120** or with acetylacetone **13a** to give arylated 2-aminobenzonitriles **121** and **122**, respectively.⁸²

V. Synthesis of five-membered heterocycles

With an appropriate arrangement of the reaction centres, Michael adducts like 1,4-dioxo nitriles cyclise to give five-membered heterocycles, furans and pyrroles. Thus the adduct **14a** is converted into substituted 2-iminofuran **123** even during recrystallisation from a mixture of acetone and petroleum ether. The reaction of acetylacetone **13a** with TCE **9a** in benzene in the presence of pyridine affords immediately the imine **123**.¹⁴

On heating, 2-iminofuran **123** undergoes rearrangement accompanied by migration of the dicyanomethyl group to give dihydropyrroles **124**. The pyrroles **124** are also produced when ethyl acetoacetate **33a** or various acyclic 1,3-diketones **13b–f** (except for acetylacetone) react with TCE in the presence of piperidine. No furans **123** were produced in these reactions.¹⁴

$\text{R}^1 = \text{R}^2 = \text{Me}$ (**13a**, **14a**); $\text{R}^1 = \text{R}^2 = \text{Ph}$ (**13b**);
 $\text{R}^1 = \text{R}^2 = \text{Et}$ (**13c**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Ph}$ (**13d**);
 $\text{R}^1 = \text{CHMe}_2$; $\text{R}^2 = \text{Me}$ (**13e**), CHMe_2 (**13f**); $\text{R}^1 = \text{OEt}$, $\text{R}^2 = \text{Me}$ (**33a**).

It has been reported⁸³ that during the reduction with sodium tetrahydroborate, acyclic adducts of the type **12** cyclise to substituted tetrahydrofuro[2,3-*b*]pyrroles **125**.

When the adduct **22** is refluxed in an alkaline solution, two cyano groups are substituted to give intermediate **126**, which cyclises with simultaneous hydrolysis of one more cyano group giving rise to furobenzopyranone **127**.¹⁶

Pyrans **128**, obtained by the interaction of dimedone **25** or cyclohexanedione **31a** with TCE, react with alkali with opening of the pyran ring to give intermediates **129**, which are then converted into fused furans **130** in a similar way.⁸⁴

$\text{R}^1 = \text{R}^2 = \text{Me}$ (**25**), H (**31a**).

2-(Dicyanomethylidene)-1,3-indanedione **89** reacts with alkyl acetoacetates **33a,j** on refluxing in ethanol. This results in the formation of propellanes **131** in moderate yields.⁸⁵

$\text{R} = \text{Et}$ (**33a**), Bu^t (**33j**).

The reactions of isoquinolinedione **132** with unsaturated nitriles **133** containing an easily leaving group R^1X ($\text{X} = \text{O}, \text{S}$) result in the formation of pyrrolo[1,2-*b*]isoquinolinediones **134**.

Cyclisation occurs under mild conditions without isolation of intermediate adducts. The compound **134** was found to possess antiproliferative activity.⁸⁶

3-Phenyl-2-thiohydantoin **97a** reacts with a large number of ylidenemalononitriles **135** giving rise to substituted pyrrolo[1,2-*c*]imidazoles **136**.⁸⁷ However, for unsaturated nitriles containing a benzoyl group, for example, for **107a**, the cyclisation was reported⁸⁷ to involve the CO group instead of CN and to yield pyrrolo[1,2-*c*]imidazole **137**.

VI. Synthesis of pyrans

Cyclisation of the Michael adducts of the type **7** and **8** (see Scheme 1) giving a pyran ring occurs in those cases where the oxygen atom in δ -hydroxy or δ -oxo nitriles acts as the nucleophilic centre.⁷ As a rule, this affords 4*H*-pyrans. A carbonyl fragment can serve as the electrophilic centre in place of the nitrile group. Depending on the structures of the initial compounds, the formation of pyrans in the reactions under consideration can occur without intermediate Michael reaction between the reactants. The mild conditions needed for these reactions, high yields of products, and also potential biological activities of the resulting 4*H*-pyrans account for the considerable interest aroused by these objects and for the large number of publications on this topic, which have been surveyed in monographs and reviews.^{1,7,88}

There are two main approaches to the synthesis of the compounds in question, namely, interaction of nitriles with α,β -unsaturated ketones^{23,88} and interaction of carbonyl compounds with α,β -unsaturated nitriles. This section is devoted to the latter approach. However, in each particular case, the most efficient preparative method can be chosen for the synthesis of pyrans, because the above structures can occur in equilibrium ($\text{5} + \text{6} \rightleftharpoons \text{3} \rightleftharpoons \text{1} + \text{2}$ in Scheme 1)^{10,60,61} and these reactions have common intermediates.

The acyclic adducts **14a,b**, prepared by the addition of acetylacetone to TCE or dicyanofumarate, readily cyclise to the corresponding 4*H*-pyrans **138** on refluxing in petroleum ether.¹⁰ The same products are formed when acetylacetone **13a** reacts with nitriles **9a,b** in acetonitrile.

$\text{Z} = \text{CN}$ (**a**), CO_2Et (**b**).

The adduct **12a** synthesised from acetone and TCE cyclises into the 2*H*-pyran **139** under the action of hydrogen chloride.¹³

The compounds **12**, which are formed when ketones add to TCE (see Section III), can react with aldehydes at the terminal dicyanomethyl group; this yields bicyclic compounds with the pyran structure **140**.⁸³

Refluxing of pyrazolones **41** with TCE in ethanol results in the formation of pyrano[2,3-*c*]pyrazoles **141**. This reaction carried out without heating yields bis-adducts **142**.⁸⁹ Apparently, in this case, the rate of elimination of malononitrile from the intermediate Michael adduct is higher than the rate of cyclisation.

When dimedone **25**^{10, 84} reacts with TCE **9a**, or indanedione **87**¹⁰ reacts with dicyanofumarate, fused pyrans **143** and **144** are formed.

Barbituric acids **101a,b** react with TCE in boiling THF to give fused 4*H*-pyrans **145**.⁸⁹ It is of interest that the same reaction carried out in ethanol results in the formation of bis-adducts **146**.⁸⁹

R = H (a), Me (b).

4-Hydroxycoumarin **19** and 4-hydroxy-2-quinolinone **20** can be regarded as completely enolised cyclic 1,3-dicarbonyl compounds. As noted above, they form Michael adducts **22** and **23** upon reactions with TCE.¹⁶ Later, it has been found that the reaction of the substituted coumarins **147** (X = O) and quinolinones **147** (X = NR) with TCE permits the synthesis of fused pyrans **148** in one step without isolation of the adducts of the type **22** and **23**.⁶³ Like 4-hydroxycoumarin, triacetic acid lactone **149** also reacts with TCE giving rise to fused pyran **150**.⁸⁹

The reactions of carbonyl compounds with dicyanomethylidene derivatives of carbo- and heterocyclic compounds make it possible to synthesise spiro-derivatives of pyrans, which are difficult to obtain by other methods. Thus reactions of 3-dicyanomethylidene-1-methylisoquinoline-2,8-dione **84b** with acetylacetone **13a**, ethyl acetoacetate **33a**, and ethyl benzoylacetate **33k** gave spiropyrans **151**.⁹⁰ When dibenzoylmethane **13b** or benzoylacetone **13d** is used as the dicarbonyl compound, the reaction starts with elimination of malononitrile from the compound **84b** giving homophthalimide **83b**. The latter reacts with excess **84b** to yield spiropyran **152**.⁹⁰

X = CO; R = R¹ = Me; R = OEt; R¹ = Me, Ph.

2-Dicyanomethylidene-1,3-indanethione **89** reacts with acetylacetone **13a** and ethyl benzoylacetate **33k** giving rise to substituted 2*H*-pyrans **153a,b**.⁸⁵

R = R¹ = Me (**13a**, **153a**); R = Et, R¹ = Ph (**33k**, **153b**).

Unlike acyclic dicarbonyl compounds, dimedone adds to the unsaturated nitrile **89** according to Michael; this is followed by cyclisation to fused *4H*-spiropyran **154**.⁸⁵

The reactions of 3-cyanomethylidene **50** with a broad range of dicarbonyl compounds of the types **13** and **33** lead to the synthesis of substituted spiropyrans **155** without isolation of intermediate Michael adducts.⁹¹ Similar results have been obtained in another study.⁸⁵

R = Alk, Ar; R¹ = Alk, Ar, OAlk; X = CO; Z = CN, CO₂Et.

On reduction with sodium tetrahydroborate, the adduct **51a** cyclises giving rise to substituted hydrogenated spiropyran **156**, which has been isolated as a mixture of two diastereoisomers in a ratio of 3 : 1.³⁰

Cyclic 1,3-dicarbonyl compounds — substituted 1,3-cyclohexanediones **25**, **32** and indanedione **87**⁹² — react with 3-cyanomethylidene-2-oxindoles **157** to give spiropyrans **158** and **159**, respectively.

The addition of the pyrazolone **41a** to substituted 3-cyanomethylidene-2-oxindole **157** results in the formation of spiropyrans **160**.^{91,93} Some fluoro-substituted derivatives of **160**, for example, those with R² = 5-F or 4-CF₃, exhibit herbicide properties.⁹³

Z = CN, CO₂Et.

Barbituric acids also react with 3-cyanomethylideneindolones **157** to give spiropyrans.^{91,94} In the case of 1-phenylbarbituric acid **101c**, the reaction with fluorine-containing **157** gives rise to spiro compounds **161**.⁹⁵

Z = CN, CO₂Et; X = CO.

3-Dicyanomethylidene-2-oxindoles **157** with 4-hydroxycoumarin **19** afford the corresponding spiropyrans **162**.⁹²

X = CO.

Arylidene derivatives of malononitrile and ethyl cyanoacetate smoothly react with 1,3-dicarbonyl compounds containing a highly reactive methylene group yielding 2-amino-4*H*-pyrans. In this case, the intermediate Michael adducts immediately undergo intramolecular cyclisation. The reaction is normally carried out in ethanol at room temperature using catalytic amounts of organic bases. The simplicity and convenience of this route to substituted 2-amino-4-aryl-4*H*-pyrans **163** have been demonstrated in relation to the interaction between ethyl acetoacetate **33a** and the unsaturated nitriles **42**.⁹⁶ Later, ethyl oxaloacetate **33l**⁹⁷ and other acyclic dicarbonyl compounds such as acetylacetone **13a** and dibenzoylmethane **13b**¹¹ were also introduced in the reactions with the unsaturated nitriles **42** and **59**. The aromatic aldehydes **44** and functional derivatives of malonic acid (Z = CN, CO₂Et) can be used instead of the nitriles **42** and **59**; in many cases, this results in simpler preparative procedures.⁹⁶

R = R¹ = Me (**13a**); R = R¹ = Ph (**13b**); R = OEt: R¹ = Me (**33a**), R¹ = CO₂Et (**13l**); Z = CN (**42**), CO₂Et (**59**).

This reaction has been extended to hetaryl-substituted derivatives of the unsaturated nitriles **42** and **59**. In particular, 1,3-dicarbonyl compounds have been made to react with thiophene⁹⁸ and pyridine⁹⁹ derivatives and with quaternised pyridines.¹⁰⁰ The structure of the pyrans obtained in this way, namely, 3-(2-amino-

3,5-dicarbethoxy-6-methyl-4(4*H*)-pyranyl-1-methylpyridinium iodide, was studied by X-ray diffraction analysis.¹⁰⁰ It was found that the pyran ring has a boat conformation in which the O and C atoms emerge from the plane of the boat 'bottom'.

The formation of furyl-substituted pyrans **163** upon interaction of 2-furylidenemalononitriles with ethyl 4-chloro-3-oxobutylate¹⁰¹ or acetylacetone^{102,103} has been reported. In several studies,^{104–108} syntheses of pyrans based on reactions of the unsaturated nitriles **42** and **59** with ethyl acetoacetate or acetylacetone have been reproduced.

The use of optically active esters of acetoacetic acid in the reactions with arylidenemalononitriles was a step forward on the way to the synthesis of chiral 4*H*-pyrans. Thus reaction of esters derived from acetoacetic acid and (1*R*,2*S*,5*R*)-(-)-menthol, (1*S*)-endo-(-)-borneol, or ethyl (*S*)-(-)-lactate with benzylidene- and *m*-nitrobenzylidene-malononitriles **42a** and **90** affords the pyrans **163** containing an optically active substituent. The yields of the mixture of diastereoisomers was 73%–98%;¹⁰⁹ however, the diastereoisomeric excess was no more than 10% and the mixture could not be separated. The reactions of the arylidenemalononitriles **42** with chiral acetoacetylsulfamide **164** are much more stereoselective. Thus pyrans **165** are formed as mixtures of diastereoisomers with a diastereoisomeric excess of 60%–70%. In some cases, this mixture has been separated into individual isomers, and it turned out that all the major isomers are characterised by the same configuration at the newly formed C(4) chiral centre in the pyran fragment. X-Ray diffraction study has shown that in the minor isomer of **165** (Ar = Ph), this atom has the *S*-absolute configuration.

A much higher degree of asymmetric induction has been observed for the reactions of the unsaturated nitriles **42** and **59** with β-oxosulfones and sulfoxides yielding 5-*R*-sulfinyl- and 5-*R*-sulfonyl-substituted pyrans.¹¹⁰ The reaction of the optically active β-oxo sulfoxide **166** with 4-chlorobenzylidenemalononitrile **42b** gives the single enantiomer **167** in 86% yield. According to X-ray diffraction analysis, the C(4) and S atoms in this compound have the (*R,R*) absolute configuration. In 5-sulfinyl-substituted analogues of the pyran **167**, the oxygen atoms and the proton of the RSOC(5)C(4)HAr structural fragment are always *syn*-arranged.

The researchers¹¹⁰ believe that this high degree of asymmetric induction is due to the fact that the electron-withdrawing reaction centre approaches from the side opposite to the *p*-tolylsulfinyl substituent. However, thermodynamic control of the stereoselectivity in this process also cannot be ruled out.

Apart from 1,3-dicarbonyl compounds, α-cyano ketones can also serve as convenient synthons for the synthesis of pyrans. The

reaction of 2-thenoylacetonitrile **168** with the nitriles **42** and **59** giving rise to 5-cyanopyrans **169** provides an example.¹¹¹

Z = CN (**42**), CO₂Et (**59**).

Sodium pyruvate **170** possesses sufficient CH acidity to be involved in the Michael reaction with the arylidenemalononitriles **42**. Refluxing in ethanol for 3 h in the presence of sodium ethoxide results in the formation of derivatives of 4*H*-pyran-2-carboxylic acids **171**.¹¹²

The possibility of synthesising 6-phenyl-substituted 4*H*-pyrans **173** from alkyl aryl ketones has been demonstrated by performing the reaction of the propiophenone **172** with the nitriles **42** and **59**.¹¹³ Some of the compounds **173** have been reported to exhibit antibacterial, including antistaphylococcal, activities.¹¹³

Z = CN (**42**), CO₂Et (**59**).

Acetyl derivatives of heterocyclic compounds can be involved in the Michael reaction as CH acids. A study of the reaction of 5-acetyl-substituted pyrimidines **174** with benzylidenemalononitrile **42a** has shown¹¹⁴ that despite the fact that **174** are polyfunctional compounds, the reaction is highly chemoselective and results in the formation of pyrans **175** in 50%–55% yields.

Cyclic ketones serve as the starting compounds for the preparation of fused pyrans. To obtain substituted tetrahydrobenzo[*b*]pyrans **176** from cyclohexanone and the nitriles **42**, it is sufficient to reflux the reactants in ethanol in the presence of triethylamine for 10 min.¹¹⁵ 2-Benzylidenecyclohexanone **177** enters into this reaction under similar conditions to give pyrans **178**.¹¹² When substituted tetrahydrocinnolin-5-one **179** is made to react with benzylidenemalononitrile **42a**, polyfused pyran **180** is produced.¹¹⁶

Five-membered heterocyclic carbonyl compounds also react with unsaturated nitriles giving rise to fused 4*H*-pyrans. Thus thiazolone **181** reacts with benzylidenemalononitrile **42a** upon refluxing in ethanol for 6 h in the presence of triethylamine. It has been noted¹¹⁷ that this reaction is accompanied by hydrolysis of the cyano group and affords 3-carbamoyl-substituted pyran **182**.

The reaction of compound **183a** with furylidenemalononitrile **95a** affords pyran **184a**.¹¹⁸ Compound **183b** reacts in a similar way giving rise to thiopyran **184b**.¹¹⁸

Y = O (a), S (b).

Thiazolone derivatives **185** react with ethyl arylidenecyanoacetates **59** with the formation of 2-aminopyrans **186**.^{119, 120}

Among the reactions of carbonyl compounds with unsaturated nitriles, the transformation of 3-methylpyrazol-5-ones **41** yielding pyranopyrazoles **187** deserves special attention. The simplicity of the experiment and the high yields and the potential biological activity of the reaction products^{28, 121} account for the large number of publications dealing with this topic. The synthetic capacity of the reactions of the pyrazolones **41** with arylidenemalononitrile **42** giving stable Michael adducts **43** was considered in Section III. On treatment with bases, the resulting adducts cyclise to pyrans **187**. The latter have also been isolated when the compounds **41** have been heated with **42** in the presence of morpholine.^{11, 24–27} The aromatic aldehydes **44** and unsaturated ketones **45** react with malononitrile **39** or with the pyrazolones **41** under conditions described by the researchers cited above^{24, 27} to give aminopyrans **187**. 3-Trifluoromethylpyrazol-5-ones react with the nitriles **42** in a similar way; on boiling in ethanol with

piperidine, they are converted into 5-trifluoromethyl-substituted pyrans **187b**.¹²²

R¹ = Me (a), CF₃ (b).

The use of 1-heteryl-substituted pyrazolones **188** in the reaction with benzylidenemalononitrile **42a** permits the synthesis of 1-heterylpyrano[2,3-*c*]pyrazoles **189**, which exhibit antimutagenic activity.²⁸ In the absence of bases, it is possible to isolate intermediate Michael adducts of the type **43**.

R = Me, Ph; X = O, S.

The reaction of arylidenenitroacetone nitriles **190** with the pyrazolone **41a** results in the formation of difficultly accessible 4-aryl(hetaryl)-3-nitro[2,3-*c*]pyrazoles **191** exhibiting antiallergic properties.¹²³

It has been reported⁶⁸ that 3-aminopyrazolone **192** reacts with 2-furyl- and 2-thienyl-substituted derivatives **95a,b** to give 5-aminopyrazolo[2,3-*c*]pyrans **193**.

Y = O (a), S (b).

Pyrazoline-3,5-dione **194** reacts with aryl-substituted unsaturated nitriles **42** similarly to the pyrazolone **41** to yield fused 2-amino-4*H*-pyrans **195**.^{68, 124} Acrylonitrile forms bis-adduct **196**.¹²⁴

Cyclic 1,3-diketones are strong CH acids and are substantially enolised.¹²⁵ Enolisation is important for the formation of the pyran ring,⁷ and cyclic 1,3-dicarbonyl compounds are widely known as convenient reagents for the synthesis of fused 4*H*-pyrans. Thus a number of fused 4*H*-pyrans **197** containing a nitro group have been obtained by reactions of dimedone **25** with aryl (or hetaryl) derivatives of nitroacetonitrile **190**.^{123, 126–128} Some of them were found to exhibit antiallergic properties.¹²³ When dimedone **25** reacts with 5-bromofurfurylidene malononitrile **198** in the presence of secondary amines, substituted pyran **199** is formed in 95% yield.⁹⁷

Z = NO₂.

Oxalacetate **331** does not react with the nitrile **198** under these conditions; in this case, only the bromine atom is substituted by a secondary amine residue. The rate of nucleophilic substitution in the furan nucleus in this system proves to be higher than the rate of Michael addition and, hence, the nitriles **200** are formed.

These findings are consistent with the available data on nucleophilic reactions in the series of furylidene derivatives **201**.¹²⁹ It was shown that hard nucleophiles (Nu) enter into the addition reaction to give adducts **202**. In the case of soft nucleophiles (Nu'), the halogen in the furan ring undergoes nucleophilic substitution, and this gives furylidene derivatives **203**.

Numerous representatives of substituted tetrahydro-4*H*-benzo[*b*]pyrans **197**^{11, 26, 130–132} have been prepared by interaction of 1,3-cyclohexanediones with the aryl(or hetaryl)-substituted α,β -unsaturated nitriles **42** and **59**. It was found that some compounds of the type **197** possess fungicidal activities.¹³⁰

R¹ = R² = Me (**25**); R¹ = R² = H (**31a**); R¹ = Ph, R² = H (**31c**); Z = CN (**42**), CO₂Et (**59**).

Fused pyrans of the type **197** can also be obtained by the reaction of dimedone with aromatic aldehydes and malononitrile.¹³³ The reaction of dimedone with the substituted acetophenones **120** and malononitrile affords 4-methyl-substituted pyrans **204**.¹³³

1,3-Indanedione **87** reacts with arylidenemalononitriles **42** to give fused pyrans **205**. The reaction requires a 20-min heating in ethanol in the presence of triethylamine.¹¹²

It has been mentioned above that the reaction between barbituric acid and arylidenemalononitriles in boiling ethanol affords the compounds **102** resulting from elimination of malononitrile. However, at room temperature in dioxane, barbituric acid **101a** reacts with the nitriles **42** or **59** giving rise to substituted 2-aminopyrano[2,3-*d*]pyrimidines **206**.^{134, 135} The compounds **206** are also formed in the reaction with 2-thiobarbituric acid **101d**¹¹⁹ and 1,3-diphenyl-2-thiobarbituric acid **101e**.¹³⁶

R = H: X = O (**a**), S (**d**); R = Ph, X = S (**e**); Z = CN (**42**), CO₂Et (**59**).

In this Section, we also present numerous examples of reactions of unsaturated nitriles with phenols, which can be regarded as completely enolised ketones.¹²⁵

It is known that interaction of activated phenols (resorcinol, *m*-aminophenol, phloroglucinol) with α,β -unsaturated nitriles under the conditions of the Hoesch reaction¹³⁷ does not involve the cyano group. The phenols add to the double bond giving β -arylpropionitriles or products of their subsequent cyclisation ('anomalous Hoesch reaction'¹³⁸). Thus in the presence of acid catalysts, cyanoethylation of substituted resorcinol derivatives results in the formation of 3,4-dihydrocoumarins.^{138–141} Arylidene derivatives of malononitrile **42** and the cyanoacetate **59** react with phenols **207** under conditions of basic catalysis on short-term heating in ethanol. This affords substituted 4*H*-benzo[*b*]pyrans

208 in 65%–90% yields.^{142, 143} On refluxing in ethanol for 15 min in the presence of piperidine, non-substituted phenol also gives pyrans **208** ($R = R' = H$).¹⁴⁴

$R = OH, NH_2$; $R' = H, Alk$; $Z = CN$ (**42**), CO_2Et (**59**).

Under similar conditions, 2-naphthol **209** reacts with the nitriles **42** and **59** to give substituted 4*H*-naphtho[2,1-*b*]pyrans **210**.^{143, 145} In this case, the arylidenemalononitriles **42** can be replaced by a mixture of the corresponding aromatic aldehydes and malononitrile.¹⁴⁶

$Z = CN$ (**42**), CO_2Et (**59**).

1-Naphthol **211** reacts with the nitriles **42** and **59** on a short-term heating in ethanol in the presence of a base giving rise to the corresponding fused pyrans **212** in 65%–85% yields.^{144, 147, 148} 8-Hydroxyquinoline **213** behaves in a similar way and upon the reaction with **42**, it is converted into pyrans **214** in yields of up to 80%.¹⁴⁴ When 2-aminosulfo-derivatives of 8-hydroxyquinoline **213b** are made to react with the nitriles **42** and **59**, the corresponding aminosulfonyl-derivatives **214b** are produced.¹⁴⁹ Under similar conditions, 4-hydroxy-1-methyl-2-quinolinone **215** reacts with the nitriles **42** and **59** affording fused pyrans **216**, their yields ranging from 80% ($Z = CO_2Et$) to 90% ($Z = CN$).¹⁴⁴

$R = H$ (**a**), R_2NSO_2 (**b**); $Z = CN$ (**42**), CO_2Et (**59**).

Dihydroxynaphthalenes are capable of condensing with two molecules of **42** or **59** to give naphthodipyran. Thus 1,5-dihydroxynaphthalene **217** was converted into naphtho[1,2-*b*:5,6-*b'*]dipyran **218**,^{147, 150} 1,6-dihydroxynaphthalene **219** into naphtho[1,2-*b*:6,5-*b'*]dipyran **220**,¹⁵⁰ while 2,3-dihydroxynaphthalene **221** and the nitriles **42** and **59** form naphtho[1,2-*b*:3,4-*b'*]dipyran **222**.^{150, 151}

$Z = CN$ (**42**), CO_2Et (**59**).

The reaction of ethyl 3,5-dihydroxynaphthalene-2-carboxylate **223** with 3-nitrophenylmethylidenemalononitrile **92** occurs selectively giving rise to naphtho[1,2-*b*]pyran **224**.¹⁵²

Among fused pyrans — derivatives of 2-naphthol, dihydroxynaphthalenes, hydroxyquinolines, and hydroxyisoquinolines, — compounds with high antiproliferative activities have been found.¹⁵³ Some of them have been recommended for treatment of immune disorders and also for a number of diseases such as rheumatoid arthritis, atherosclerosis, cirrhosis, cancer, *etc.*^{152, 153}

On refluxing with benzylidenemalononitrile **42a** in pyridine¹⁵⁴ or water,¹⁵⁵ 4-hydroxycoumarin **19** is converted into 4*H*-pyran **225**, which undergoes acid hydrolysis being thus converted into compound **226** serving as the intermediate in the synthesis of a rodent poison, warfarin. The pyran **225** is also formed when benzylidenemalononitrile **42a** is made to react with 4-hydroxycoumarin **19** in ethanol at room temperature in the presence of an equimolar amount of a base; Michael adducts were not isolated in this reaction.³⁷

The reactions of *C*-acetyl-derivatives of phenols with unsaturated nitriles involve the methyl group of the acetyl fragment. For example, 2-hydroxyacetophenone **227** reacts with the nitriles **59** giving 2*H*-pyran-2-ones **228**, which result from intramolecular cyclisation of the intermediate Michael adduct at the ethoxycarbonyl group.

To the contrary, the reaction of 3-acetyl-4-hydroxy-1-methyl-2-quinolinone **229** with the nitriles **42** and **59** yields only 2-amino-4*H*-pyrans **230**,¹⁴⁹ i.e. cyclisation involves the cyano group.

Z = CN (**42**), CO₂Et (**59**).

The formation of the pyrans **61a,b** upon the reaction of 4-hydroxycoumarin with arylidenecyanoacetates **59** has been considered previously (see Section III).

Arylidenecyanothioacetamides **52** can also serve as convenient intermediates in the synthesis of 4*H*-pyrans and their derivatives. It has been reported¹⁵⁶ that the reaction of the phenyl-substituted pyrazolone **41a** with thioacetamides **52**, like the reaction with the nitriles **42**, affords the pyrans **187**. However, when the thioamides **52** are made to react with the pyrazolone **41b** or with isoxazolone **231**, thiapyrans **232** and **233**, respectively, are produced.

As has been noted in Section III, the interaction of cyclic 1,3-dicarbonyl compounds (dimedone, 4-hydroxycoumarin, and Meldrum's acid) with arylidenecyanothioacetamides results in the formation of Michael adducts, which can cyclise according to various pathways depending on the reaction conditions. Thus on refluxing in benzene with a catalytic quantity of triethylamine, the adducts are converted into fused 3-thiocarbamoyl-4*H*-pyrans **234**. However, reaction of the arylidenecyanothioacetamides **52** with dimedone **25** under the same conditions is a more convenient

route to the pyrans **234**.^{36,157} The thiocarbamoyl group in the pyrans **234** can be modified according to the Hantzsch reaction pattern on treatment with phenacyl bromide in DMF. Substituted 3-(4-phenylthiazol-2-yl)-4*H*-pyrans **235** were synthesised in this way.

Evidently, a necessary condition for the intramolecular cyclisation to occur is close arrangement of the reaction centres, the OH and CN groups. Consideration of the projections presented in Section III (**71–74**) shows that conditions favourable for the cyclisation to pyrans are realised in the conformation **74**. Since the yields of the pyrans **234** in this reaction reach 90%,³⁶ it is assumed that under these conditions, the conformers **73** undergo the reverse reaction with regeneration of the initial compounds **25** and **52**.

The adducts **58** prepared from 4-hydroxycoumarin cyclise to fused 2-amino-3-thiocarbamoyl-4*H*-pyrans **236** on boiling in benzene with triethylamine. Higher yields of the pyrans **236** (up to 73%) can be attained when the reactants **19** and **52** react directly with each other.³⁷

Treatment of the pyrans **236** with α -haloketones resulted in the synthesis of the corresponding 3-(4-phenylthiazol-2-yl)-4*H*-pyrans **237**.³⁷ The pyran ring in the compounds **236** can be cleaved by secondary amines; this gives the acyclic salts **57**, which are converted into the pyrans **237** on treatment with phenacyl bromide.³⁷

Reactions of arylbenzothiazolylcyanoethylenes **238** with ethyl acetoacetate **33a** afford benzothiazolyl-substituted pyrans **239**.¹⁵⁸

The synthesis of pyrans based on alkylidene derivatives of malonic acids has not been adequately elaborated yet. A three-component reaction between benzoylacetonitrile **240**, formaldehyde, and malononitrile **39** in ethanol in the presence of triethylamine should be mentioned.¹⁵⁹ Apparently, this reaction involves intermediate formation of 1,1-dicyanoethylene, which then reacts with the ketone **240** to give pyran **241** having no substituent at the 4-position.¹⁵⁹

In some cases, unsaturated nitriles contain easily leaving groups such as methylthio, halo, or trichloromethyl groups. As has been noted in Section II, the products of addition of carbonyl compounds to these nitriles can eliminate a readily leaving fragment and then cyclise. Several syntheses of pyrans based on this approach have been reported. Thus the 2,2-di(methyl-thio)methylidene derivatives of malononitrile or cyanoacetate **242a,b** react with the acetophenones **120** with elimination of the methylthio group to give pyran-2-ones **243**.^{160–162}

Z = CN (a), CO₂Et (b).

Substituted *m*-aminophenols (or resorcinol) **207** react with β -chloro-substituted unsaturated nitriles **244** (Z = CN¹⁶³ or CO₂Et¹⁶⁴) yielding coumarin dyes **245**.

R = OH, Me₂N, Et₂N; Z = CN, CO₂Et.

The reaction of pyrazoline-3,5-dione **194** with trichloro-substituted nitrile **246** is accompanied by elimination of chloroform and gives rise to substituted 6-iminotetrahydropyrano-[2,3-*c*]pyrazole **247**.¹²⁴

Although the phenyl-substituted acetylacetonitrile **248** is formally also an α,β -unsaturated nitrile, it does not enter into the Michael reaction with carbonyl compounds. The addition of the pyrazolone **41b** involves the carbonyl group of **248** and results in the formation of fused 2*H*-pyrans **249**.¹⁶⁵

VII. Synthesis of pyridines

The reactions of carbonyl compounds with α,β -unsaturated nitriles opens the way to the synthesis of pyridine derivatives that are difficult to obtain by other methods. It is clear that pyridines can be formed if the intermediate adducts undergo cyclisation involving a nucleophilic nitrogen atom, in particular, the nitrogen of the nitrile group. A more widely used variant is incorporation of the nitrogen atom from ammonium acetate or enamine. The method for the synthesis of pyridones and pyridine-thiones with participation of amides and thioamides seems promising. The reactions resulting in the synthesis of 2-aminopyridines have been considered in detail and systematised in a monograph.⁸ Published data on the synthesis of 3-cyano-2(1*H*)-pyridones, -pyridine-thiones, and -pyridineselenones have been surveyed in a review.¹⁶⁶ In this Section, we consider the characteristic features of the preparation of pyridines based on reactions of carbonyl compounds with unsaturated nitriles.

The reduction of the nitrile group in the adducts **32** by lithium aluminium hydride results in the generation of an amine and, as a consequence, in the formation of hydrogenated quinolines **250**.¹⁹ The cyano group in the adduct **32b** is hydrolysed with subsequent cyclisation giving rise to hydrogenated quinoline **251**, which has been used as the starting compound in a 14-stage synthesis of 12-epilycopodine.²⁰

R = H (a), Me (b).

On treatment with acids, the adducts **12** cyclise to substituted 3,4-dicyano-2(1*H*)-pyridones **252**. The reaction includes hydrolysis of the cyano group followed by cyclisation of the resulting amide.¹³ Treatment of the compounds **12** with hydrogen halides affords 2-halopyridines **253** according to the known mechanism of dinitrile cyclisation.^{13, 83}

The adduct **51b** has been converted into spiro-compound **254** upon the reaction with hydroxylamine.³⁰

Sodium acetylacetonate **255** reacts with the chloro-substituted derivative of malononitrile **244a** giving rise to the *cis*-isomer of the substitution product **256**, which transforms into the *trans*-isomer on exposure to UV radiation in methanol; the latter cyclises *in situ* to 3-cyano-2(1*H*)-pyridone **257**.¹⁶⁷

The formation of pyridines **258** upon cyclisation of intermediates **259** resulting from interaction of 2-hydroxyacetophenone **227** with the nitriles **42** has been reported.¹⁴⁹

Ammonia can also be used as the source of nitrogen needed to close a pyridine ring. Thus treatment of the adducts **12** with ammonia yields either 2-aminopyridines in the betaine form **260** or bicyclic pyridine derivatives **261**, depending on the nature of the substituents *R*.⁸³

Among the numerous methods for the synthesis of 2-aminopyridines,⁸ we would like to mention interaction of the unsaturated nitriles **42** with carbonyl compounds in the presence of ammonium acetate. The aromatic aldehydes **44** and malononitrile

39 can be used instead of **42**.¹⁶⁸ It has been reported¹⁶⁹ that the interaction between these compounds yields the nitrile **42**, to which carbonyl compounds then add. Treatment of Michael adducts **262** with ammonia induces their cyclisation to pyridines **263**. Among this series of reactions, the synthesis of alkyl-substituted pyridines **263** ($\text{R}^1, \text{R}^2 = \text{H}, \text{Alk}$) from the nitriles **42** and aliphatic ketones has been studied.¹⁷⁰ Substituted acetophenones ($\text{R}^1 = \text{Ar}'$, $\text{R}^2 = \text{H}$) have also been used;¹⁶⁹ in this case, the reactions were conducted with heterocyclic derivatives of malononitrile such as 5-methoxy-2,3-diphenylbenzo[*b*]furan-6-ylidenemalononitrile¹⁷¹ and 5-nitrobenzo[*b*]thiophen-2-ylidenemalononitrile.¹⁷² The compounds **263** containing a bipyridine fragment ($\text{Ar} = \text{pyridyl}$) and possessing cardiotonic properties have been prepared from pyridinecarbaldehyde, the appropriate ketone, and ammonium acetate.¹⁷³

Refluxing of sodium pyruvate **170** with the nitriles **42** and ammonium acetate in acetic acid affords derivatives of α -picolinic acid **264**.¹¹²

It has been shown for propiophenone **172** that alkyl aryl ketones react with the nitriles **42** forming either the pyrans **173** (Section VI) or 2-aminopyridines **265**. The latter are formed when the reactants are refluxed in acetic acid with ammonium acetate.¹¹³

Cyclopentanone **115** and cyclohexanone **15** react with the nitriles **42** yielding the corresponding pyridines **266** ($n = 1, 2$).¹⁶⁹

$n = 1$ (**115**), 2 (**15**).

When 1,3-indanedione **87** is refluxed with benzyldenemalononitrile **42a** and ammonium acetate in acetic acid, fused 2-aminopyridines **267** are produced.¹¹²

The introduction of aryl(alkyl)idene derivatives of ethyl cyanoacetate into reactions with carbonyl compounds and ammonium acetate makes it possible to synthesise substituted 3-cyano-2(1*H*)-pyridones. When cyclopentanone **115** reacts with

arylidene derivatives of the cyanoacetate **59** in the presence of ammonium acetate, 7-arylidene-2-pyridones **268** are formed. Evidently, in this case, a second molecule of the cyanoacetate is cleaved under the reaction conditions,⁶⁰ and the aromatic aldehyde formed *in situ* enters into the condensation. The alkyl-derivatives **59** do not undergo this cleavage and form pyridones **269**.¹⁷⁴

The condensation of the cyanoacetate **33b** and compounds **270** — 3-formyl-2(1*H*)-pyridones ($Z = \text{O}$), -pyridinethiones ($Z = \text{S}$), and -pyridinoselenones ($Z = \text{Se}$) — with cyclohexanone **15** and the substituted acetophenones **120** in the presence of ammonium acetate gives rise to bipyridine derivatives **271**.¹⁷⁵ Substituted 2-chloro-3-formylquinolines have also been used as the aldehyde constituent for the preparation of hetarylpyridines of the type **271**.¹⁷⁶

$\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4$ (**15**); $\text{R}^1 = \text{Ar}$, $\text{R}^2 = \text{H}$ (**120**); $Z = \text{O}$, S , Se .

Refluxing 3-pyridyldienemalononitrile **272** ($Z = \text{CN}$) or ethyl 3-pyridyldienecyanoacetate ($Z = \text{CO}_2\text{Et}$) with 3-acetylpyridine **273** and ammonium acetate affords derivatives of the alkaloid nicotelline **274** or **275**, respectively.¹⁷⁷

The formation of a pyran ring upon intramolecular interaction of hydroxy and cyano groups is reversible.⁷ Therefore, under

certain conditions, for example, under the action of nucleophiles, the pyran ring can be cleaved. Thus 2-aminopyridines **264**¹¹² and **265**¹¹³ are formed when the pyrans **171** and **173** are treated with ammonium acetate in boiling acetic acid.

$\text{R}^1 = \text{H}$, $\text{R}^2 = \text{CO}_2\text{H}$ (**171**, **264**); $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Ph}$ (**173**, **265**).

It has been reported¹³² that the fused pyrans **197** ($Z = \text{CN}$), prepared from dimedone and arylidenemalononitriles, recyclise in a similar way giving rise to 2-amino-3-cyano-6-hydroquinolines **276**. 3-Ethoxycarbonyl-substituted pyrans **197** ($Z = \text{CO}_2\text{Et}$) are converted under these conditions into 3-carbamoyl-6-hydroquinoline-2(1*H*)-quinolinone derivatives **277**.¹³²

The fused pyrans **176** recyclise on treatment with ammonium acetate to give tetrahydroquinolines **266**. Formamide can also act as a nucleophile in this reaction. When **176** are heated in formamide in the presence of formic acid, pyrido[2,3-*d*]pyrimidine derivatives **278** are produced *via* the intermediate quinolines **266**.¹¹⁵

It has been noted¹¹⁰ that treatment of the 5-ethoxycarbonyl-pyran derivatives **163** with hydrazine hydrate results in their recyclisation to 1-amino-1,4-dihydropyridines **279**.

Treatment of 2-aminopyrans with nucleophilic reagents, for example, alkoxides, may lead to opening of the pyran ring followed by cyclisation to pyridine with participation of the

amino-group nitrogen. This provides a route from fused pyrans **280** to pyridine derivatives **281**,¹⁷⁸ which are converted into pyridones **282** in acid media.¹⁷⁹

The pyrans **243** are capable of recycling to pyridones **283** in the $\text{CH}_3\text{COOH}-\text{HBr}$ system [pathway (a)]. Apparently, this process begins with the hydrolysis of the cyano group to an amide group with the intermediate formation of pyran **284**. The yields of the pyridones **283** are 24%–32%. It should be noted that the yields of the pyridones **283** in the alkaline recycling of compounds **284** obtained preliminarily by treating the nitrile **243** with polyphosphoric acid (PPA) [pathway (b)] are considerably higher (66%–81%).¹⁶⁰

(a) $\text{CH}_3\text{CO}_2\text{H}/\text{HBr}$; (b) 1. PPA, 2. NaOH.

The reactions of acetone, cyclohexanone, or acetophenone with the dithioacetal **242a** involve intermediate formation of pyrans **285**.¹⁶⁰ However, whereas in the case of acetophenone, the imino group in the intermediate is hydrolysed, and this yields the pyran **243a**, in the case of acetone and cyclohexanone, the iminopyrans **285** undergo nucleophilic opening of the ring followed by transformation into the pyridones **286a,b**.

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$ (**10a**, **286a**); $\text{R}^1 = \text{R}^2 = (\text{CH}_2)_4$ (**15**, **286b**);
 $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$ (**120a**, **243a**).

The reaction between the compounds **287** and **110** occurs in a similar way and involves the formation and recyclisation of the pyran **288**. This procedure is used to prepare the cardiotonic preparation milrinone **289**.¹⁸⁰

The nucleophilic nitrogen atom needed to close a pyridine ring can also be provided by enamines, prepared from mono- and dicarbonyl compounds. It is known that enamines add to an activated double bond more readily than the corresponding ketones.¹⁸¹ The interaction of enamines **290** and **291** with TCE **9a** occurs as substitution of the cyano group and subsequent cyclisation of the intermediate products to fused pyridines **292**⁸⁴ and **293**.⁸⁹

The dicyanofumarate **9b** reacts regioselectively with enamines **294**, prepared from indanethione, giving rise to *N*-substituted fused 1,4-dihydropyridines **295**.¹⁸²

The reactions of some cyclic enamines with unsaturated nitriles containing a nucleofugal group follow a different pathway. In these cases, the activated $\text{C}=\text{C}$ bond of the nitrile undergoes nucleophilic attack by the enamine nitrogen atom. In some cases, acyclic substitution products have been isolated. Subsequently they can cyclise forming fused pyridines. Thus aminouracils **296** react with TCE or the nitriles **242a** to give the corresponding substitution products **297**⁸⁹ and **298**.¹⁸³ On heating in diphenyl ether, the latter cyclise to pyridopyrimidines **299**.¹⁸³

The reaction of 4-aminocoumarin **300** with the nitriles **242a,b** occurs in a similar way.¹⁸⁴ The cyclisation of the substitution products **301a,b** to fused compounds **302a,b** occurs upon heating in DMSO. The enamine **290** prepared from dimedone reacts with isomeric benzoylacrylonitrile **303** to give tetrahydroquinoline **304**.¹⁸⁵ In the case of *trans*-**303**, the reaction is conducted by refluxing in toluene, whereas for the *cis*-isomer, it is carried out in acetic acid.

Z = CN (a), CO₂Et (b).

The unsaturated nitriles **305** and **110** contain groups that can be easily replaced by nucleophiles. The reaction of these compounds with the substituted 6-aminouracil derivatives **296** occurs as the substitution of the dimethylamino or ethoxy group by the heterocycle followed by cyclisation to fused pyridines **306**¹⁸⁶ and **307**,¹⁸⁷ respectively. Compounds of the type **306** are of interest as potential dihydrofolate reductase inhibitors.¹⁸⁶

The arylidenemalononitriles **42** undergo Michael reactions with the enamines **308** and **290** derived from acetoacetate and dimedone, and also with the compounds **296**; the reaction is followed by cyclisation to pyridines **309**,¹⁸⁸ 1,4,5,6,7,8-hexahydroquinolines **276**,¹³² and substituted pyrido[2,3-*d*]pyrimidines **310**.¹⁸⁹

Methods for the synthesis of pyridines based on amines are widely used. In this case, the nitrogen atom of the amide group of one of the reactants participates in the formation of a pyridine ring. This method permits the synthesis of 2(1*H*)-pyridone derivatives. An amide group can be contained both in the carbonyl and the nitrile component. The former type of reaction is represented by the addition of malonodiamide **311** or acetoacetanilide **312** to the unsaturated nitriles **107** and **42**. The intramolecular cyclisation of the intermediate adducts affords hydrogenated pyridones **313**¹⁹⁰ and **314**.¹⁹¹

It has been shown¹⁹² that the reaction of cyanoacetylhydrazine **315** with the arylidenemalononitriles **42** gives rise to 1-amino-2(1*H*)-pyridones **316**.

Amidine **317** reacts with nitriles **318** similarly to amides, giving rise to hydrogenated 2,6-diaminopyridines **319**, which possess diuretic and cardiotonic activities.¹⁹³

The second type of reactions proceeds in the case of unsaturated nitriles containing an amide group. It was mentioned in Section III that the addition of methyl acetoacetate **35** or oxindole **46** to arylidenecyanoacetamides yields stable Michael adducts. In some cases, they can be subsequently cyclised. Thus the adduct **37** was converted into 3,4-dihydro-2(1*H*)-pyridone **320** in 95% yield by treatment with sulfuric acid in acetic acid.²²

Similar *cis*-3,4-dihydro-2-pyridones **321** were synthesised by the reaction of the amides **47** with the enamine **308**.¹⁸⁹

Arylideneacyanoacetamides **47** are transformed into acids **322** upon interaction with sodium pyruvate **170**. This reaction is completed when the reactants have been refluxed in ethanol in the presence of sodium ethoxide for 3 h.¹¹² The reaction of the amides **47** with propiophenone **172** under similar conditions affords the corresponding 5-methyl-6-phenyl-substituted 2(1*H*)-pyridones **323**.¹¹³

The pyridinium ylides **75** react with arylidenecyanoacetamides **47** yielding the betaine pyridiniumolates **324**.¹⁹⁴ The same products are formed when the arylidenecyanoacetates **59** are made to react with ylides **325** containing an amide group.^{194–196} In all cases, only *trans*-isomers of the betaines **324** were isolated.

The amidonitriles **242c** react with a broad range of carbonyl and 1,3-dicarbonyl compounds in the DMSO–KOH system at room temperature. The reaction occurs as the nucleophilic vinylic substitution of the methylthio group followed by cyclisation to 2(1*H*)-pyridones **286a–g**.¹⁶⁰

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$ (a); $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_4$ (b); $\text{R}^1 = \text{Ar}$, $\text{R}^2 = \text{H}$ (c); $\text{R}^1 = \text{Ph}$; $\text{R}^2 = \text{Me}$ (d), CO_2Et (e); $\text{R}^1 = \text{Me}$; $\text{R}^2 = \text{Ac}$ (f), CO_2Et (g).

The reactions of arylidenecyanothioacetamides with carbonyl compounds afford the corresponding pyridine-2(1*H*)-thiones, methods for the synthesis of which (as well as their oxygen and selenium analogues) have been described in a review.¹⁶⁶ Here we consider the characteristic features of this reaction in more detail. The interest in this reaction was aroused after the discovery of recyclisation of 2,2-dialkyl-4-amino-6-aryl-5-cyano-1,3-dithiacyclohex-4-enes **68** to 4-aryl-3-cyano-2(1*H*)-pyridine-thiones.^{45, 197, 198}

Previously, it was known that 1,3-dithianes, analogous to the compounds **68**, undergo thermal decomposition giving rise to thioketones and ylidene derivatives of cyanothioacetamides.¹⁹⁹ In the molecules of the dithianes **68**, there occurs intramolecular conformationally rigid conjugation, as has been established by X-ray diffraction analysis for the compound with $\text{Ar} = \text{Ph}$, $\text{R}^1 - \text{R}^2 = (\text{CH}_2)_5$.²⁰⁰ Therefore, heat treatment of **68** induces cleavage of the ring at the weakest C–S bonds. The products **52** and **326** thus formed undergo the Michael reaction followed by cyclisation to give 4-aryl-3-cyano-2(1*H*)-pyridinethiones **327**.

Study of the regularities of recyclisation made it possible to offer a convenient method for the synthesis of substituted pyridinethiones **327**.^{46, 200, 201} This method consists in interaction of arylidenecyanothioacetamides **52** with a broad range of carbonyl compounds such as aliphatic ketones,^{35, 46, 201, 202} substituted acetophenones,^{202, 203} and cyclic ketones,^{35, 46, 200, 201} and also enamines. Due to the high reactivity of enamines, it is better to use them in this reaction.

Later, the pyridinethiones **327** were also obtained by the reaction of the arylidene derivatives **52** with acetone and acetophenone on refluxing in ethanol.²⁰⁴ The fused pyridinethiones **327** in which $\text{R}^1 - \text{R}^2$ are polymethylene chains were prepared by the reaction of arylmethylenecyanothioacetamides **52** with cyclic ketones in boiling dioxane.^{205–207} In addition, the interaction of the 2-thienyl- and 2-furyl-derivatives **52** with cyclic ketones resulted in the synthesis of 4-hetaryl-substituted fused pyridine-thiones of the type **327**.²⁰⁸

Arylideneacyanothioacetamides **52** react with malononitrile **39** to give 6-amino-4-aryl-3,5-dicyano-4*H*-thiopyrans **328** (Scheme 3). The same compounds can be prepared by coupling of arylidenemalononitriles **42** with cyanothioacetamide **53**.²⁰⁹ This reaction is reversible, the thiopyrans **328** being formed at room temperature.

When the compounds **328** are refluxed in ethanol in the presence of bases, they recyclise to give pyridinethiolates **329**.^{209, 210} The same products **329** are also formed when the initial reactants **42** and **53** or **52** and **39** are refluxed in ethanol in the presence of bases. Presumably the intermediate Michael

Scheme 3

adduct **330** cyclises under mild conditions to the thiopyran **328**, while in the presence of bases, intermolecular interaction of thioamide and nitrile groups occurs, resulting in irreversible formation of pyridinethiolates **329** (see Scheme 3). A similar recyclisation has been found for selenium analogues of **328** and **329**.^{211–213}

Refluxing the thiopyrans **328** in benzene with various ketones (acetone, acetophenone, cyclohexanone, cyclopentanone) affords the pyridinethiones **327** in 64%–85% yields.²¹⁴ Apparently, since both the thiopyrans **328** and the intermediate Michael adducts **330** are thermodynamically unstable, under the reaction conditions, the ring in the thiopyrans **328** is cleaved and the adduct **330** undergoes reversible decomposition to give the initial compounds **52** and **39**. When a carbonyl compound is added, its addition to the nitrile **52** becomes the predominant process, because it results in the irreversible formation of the pyridinethione **327**, which is assumed²¹⁴ to be thermodynamically the most stable compound in this system.

The overall process can be represented as exchange by the methylene components with elimination of malononitrile and incorporation of the ketone carbon skeleton in its place.²¹⁴ Thus, the interaction of ketones with the thiopyrans **328** occurs similarly to their interaction with arylidenecyanothioacetamides **52**.

The reaction of arylidenecyanothioacetamides **52** with acyclic 1,3-dicarbonyl compounds such as acetylacetone **13a**^{202, 215, 216} or ethyl acetoacetate **33a**^{202, 217, 218} follows a somewhat different pathway. The electron-withdrawing carbonyl group at the 5-position stabilises the intermediate dihydropyridine owing to conjugation with the π -system of the pyridine ring.²¹⁹ In the presence of organic bases, such as piperidine, morpholine, *etc.*, substituted 3-cyano-1,4-dihydropyridine-2-thiolates **331** have been obtained. The same products are formed when the corresponding enamines **332** are introduced in the reactions with the nitriles **52**^{202, 215, 217, 220} and also in the multicomponent condensation of the aromatic aldehydes **44**, cyanothioacetamide **53**, and a dicarbonyl compound in the presence of excess piperidine (Scheme 4).^{221–223}

Scheme 4

The pyridinethiolates **331** have also been obtained by reactions of unsaturated dicarbonyl compounds **333** and cyanothioacetamide **53**.^{217, 224}

In the case of non-symmetrical dicarbonyl compounds such as benzoylacetone **13d** or 3-benzoyl-1,1,1-trifluoroacetone **13g**, the reaction occurs regioselectively and gives benzoylated pyridinethiolates **331** ($R^1 = \text{Ph}$).²¹⁸ The enamines **332** derived from non-symmetrical diketones **13d**, **g** react in a similar way.²¹⁸ 2-Furylidene-²¹⁸ and 3- and 4-pyridylidenecyanothioacetamides^{35, 218, 225} as well as mixtures of the corresponding aldehydes **44** and the thioamide **53**^{35, 218} also react with the dicarbonyl compounds **13a** and **33k**, **m** to give the corresponding derivatives of 4-hetaryl-1,4-dihydropyridine-2-thiolates **331** (see Scheme 4).

When the aryl substituent contains an electron-withdrawing substituent²²² or when the reaction is carried out with ethyl benzoylacetate,²²³ it is possible to isolate 6-hydroxy-substituted pyridinethiolates **334**, which are dehydrated on heating in an acid medium giving rise to compounds **335**.^{222, 223}

The structure of the pyridinethiolates **331** was studied by X-ray diffraction analysis.²²⁶ The dihydropyridine ring in morpholinium 5-acetyl-3-cyano-6-methyl-4-(2-nitrophenyl)-1,4-dihydro-2-pyridinethiolate was found to exist in a flattened-boat conformation. The negative charge is mostly localised on the sulfur atom. The latter accounts for the high regioselectivity of alkylation reactions of the thiolates **331**. They react with haloalkanes or dimethyl sulfate exclusively at the sulfur atom yielding the corresponding 2-alkylthio-derivatives.^{35, 202, 218, 223, 225, 227, 228}

Protonation of 4-aryl(furyl)-substituted derivatives **331** affords 3,4-dihydro-2(1*H*)-pyridinethiones **336**.^{202, 215–218, 220–223, 228} Upon acidification, the 4-(3- and 4-pyridyl)pyridine-thiolates **331** are converted into the corresponding betaines **337**.^{35, 218, 225, 227}

(a) $R^3 = \text{Ar}, \text{O-C}_6\text{H}_4$; (b) $R^2 = \text{N-C}_6\text{H}_4$.

Since 3,4-dihydropyridines are markedly less stable than their 1,4-dihydro-analogues,²¹⁹ it should be expected that they would be readily dehydrogenated. In fact, on storing at room temperature or on heating in ethanol or acetic acid, the thiones **336** are dehydrogenated to give pyridinethiones **338**, disulfides of 1,4-dihydropyridine-2-thiols **339**, or mixtures of these products, depending on the reaction conditions and the structures of the initial compounds.^{35, 202, 215, 217, 218, 223}

The pyridinethiones **338** were synthesised by interaction of the thiopyrans **328** with the acyclic dicarbonyl compounds **13a** and **33a**.²¹⁴ The addition of dimedone **25** to the system causes exchange by methylene components accompanied by elimination of cyanothioacetamide, which results in the formation of the fused pyrans **197**.²¹⁴

$R^1 = R^2 = \text{Me}$ (**13a**); $R^1 = \text{OEt}$, $R^2 = \text{Me}$ (**33a**);
 $Z = \text{CN}$ (**39**), CO_2Et (**33b**).

The non-fused 4-hetaryl-substituted pyrans **163** recyclise on treatment with cyanothioacetamide to give the pyridines **338**.⁹⁹ The formation of a pyran ring is reversible; this ring can open on treatment with nucleophiles. The acyclic intermediate **340** thus formed undergoes retro-decomposition^{10, 60} to the initial components **33b** (or **39**) and **341**. The addition of cyanothioacetamide **53**, introduced in the reaction medium, to unsaturated ketone **341** shifts the equilibrium towards the stable thione **338**. Synthesis of the pyridines **338** by direct interaction of arylidenecyanothioacetamides **52** with the dicarbonyl compounds **13a** and **33a** has been reported.²²⁹ The reaction requires refluxing in ethanol for 3 h in the presence of a catalytic amount of piperidine.

$R^1 = R^2 = \text{Me}$ (**13a**); $R^1 = \text{OEt}$, $R^2 = \text{Me}$ (**33a**);
 $Z = \text{CN}$ (**39**), CO_2Et (**33b**).

The reaction of ethyl malonate with *ortho*-substituted arylidenecyanothioacetamides results in the corresponding 2(1*H*)-oxo-3,4-dihydropyridine-6-thiolates **342**.²³⁰

$\text{Ar} = 2\text{-ClC}_6\text{H}_4$, $2\text{-IC}_6\text{H}_4$, $2\text{-NO}_2\text{C}_6\text{H}_4$; $\text{B} = \text{O-C}_6\text{H}_4\text{-N-Me}$.

Acetoacetanilides **312** react with the aryl(hetaryl)idenecyanothioacetamides **52** or with arylidenecyanoselenoacetamides **343**, synthesised recently, to give the corresponding 1,4-dihydropyridine-2-thiolates and -selenolates **344**.²³¹ A method for preparing the thiolates **344** ($\text{X} = \text{S}$) from the aldehydes **44**, cyanothioacetamide **53**, and *N*-acetoacetylaniline **312a** has been developed.²³²

$\text{X} = \text{S}$ (**52**), Se (**343**).

The Michael adducts **56**, derived from dimedone and arylidenecyanothioacetamides, or their salts can cyclise to either the pyran derivatives **234** (see Section III) or substituted quinolines

Scheme 5

345, depending on the reaction conditions.^{36, 158} The interconversion of the adducts **56**, the salts **55**, and the pyran derivatives **234** are presented in Scheme 5. The Michael adduct salt **55**, produced from arylidenethioacetamides and cyclic 1,3-dicarbonyl compounds in ethanol at room temperature, cyclise on heating giving rise to quinolinethiolates **345**. Refluxing of the adducts **56** in benzene gives rise to the 3-thiocarbamoyl-4*H*-pyrans **234**, which are also converted into the quinolinethiolates **345** on treatment with morpholine followed by refluxing of the reaction mixture. However, if the pyrans **234** are treated with secondary amines at room temperature, it is possible to isolate the intermediates **55**.^{36, 157, 158} Thus, recyclisation of the pyrans **234** to quinoline-2-thiolates **345** occurs *via* a stage of formation of the acyclic salts **55**, the formation of the pyrans **234** from the compounds **56** being a reversible process.

The interaction of the compounds **56** with morpholine in ethanol followed by refluxing of the salts **55** formed *in situ* was also found to yield quinolinethiolates **345**.^{34, 36, 158} The cyclisation to the quinolines **345** should be realised for the *threo*-isomers of the intermediates **55** represented by the projection **73** (Section III).

Yet another recyclisation route of 3-thiocarbamoyl-4*H*-pyrans **234** is their transformation into 3-cyano-4*H*-pyrans **197** on refluxing in benzene in the presence of malononitrile and triethylamine.¹⁵⁸ The compounds **197** are also formed when dimedone **25** reacts with arylidenemalononitriles **42**¹³¹ or the thiopyrans **329**.²¹⁴

As was shown in Section VI, opening of the 4*H*-pyran ring under the action of secondary amines is also typical of analogous 4-hydroxycoumarin derivatives **236** and thus, it is a common feature of 3-thiocarbamoyl-derivatives of pyrans.

Convenient preparative methods for the synthesis of the quinolinethiolates **345** have been developed consisting of the interaction of dimedone **25** with arylidenethioacetamides **52** or directly with the aromatic aldehydes **44** and cyanothioacetamide **53**.²³³ On treatment with acids, the thiolates **345** are converted into compounds existing as thiones **346** in the solid state and entirely passing into the tautomeric thiol form **347** in solution (DMSO, trifluoroacetic acid, or acetone).^{36, 233}

It should be noted that all the thiols **347** formed exist as mixtures of two stereoisomers, although the initial thiolates **345** contain only one isomer.

The quinolinethiones **346** are more stable to dehydrogenation than their non-fused analogues **335**. The regioselective dehydrogenation of the compounds **346** and **347** to give 3,4-dehydroderivatives **348** was accomplished by heating them in DMSO at 80–100 °C.²³³ Oxidation of **346** and **347** by atmospheric oxygen or by nitrobenzene results in the formation of a mixture of dehydrogenated quinolinethiones **348** and disulfides **349**. The latter have been obtained in preparative yields by treating the compounds **347** by iodine in an alkaline alcoholic solution.²³³

(a) I₂, KOH, EtOH; (b) O₂, PhNO₂.

The interaction of quinolinethiolates **345** with alkyl halides occurs regioselectively giving 2-alkylthio-derivatives of quinolines **350**; when these products contain electron-withdrawing substituents, they cyclise in the presence of excess base to 4,5,6,7,8,9-hexahydrothieno[2,3-*b*]quinolines **351**.^{34, 35, 158, 234}

X = Cl, Br; Z = C₆H₅, CN, CO₂Et.

The reactions of 1,4-dihydropyridine-2-thiolates **331** and hexahydroquinolinethiolates **345** with allyl bromide involve the sulfur atom, like reactions with other alkyl halides. However, the 2-allylthio-1,4-dihydropyridine derivatives **352** thus formed undergo regioselective [3 + 3]-sigmatropic rearrangement on heating without a solvent or in a DMSO or ethanol solution giving rise to substituted 3-allyl-3-cyano-1,2,3,4-tetrahydropyridine-2-thiones **353** in high yields.²³⁵

$R^1 = \text{Me, EtO}$; $R^2 = \text{Me}$ (**337**); $R^1 - R^2 = \text{CH}_2\text{C}(\text{Me})_2\text{CH}_2$ (**345**).

The structures of the initial compounds and the products were studied and proved by IR and ^1H and ^{13}C NMR spectroscopy^{236, 237} and also by X-ray diffraction analysis.²³⁸ A thermal rearrangement of this type is also typical of substituted 2-allylseleno-3-cyano-1,4-dihydropyridines;^{237, 238} apparently this is a common property of compounds of the 2-allylthio(seleno)-1,4-dihydropyridine series.

The reactions of arylidenecyanothioacetamides **52** with cyclic 1,3-dicarbonyl compounds have also been studied in relation to indane-1,3-dione **87**. It was found that this reaction affords fused 3,4-dihydropyridine-2-thiones **354**.²³⁹ Three-component condensation of cyanothioacetamide **53**, the aldehydes **44**, and the indanedione **87** and the subsequent treatment with iodoalkanes give rise to fused 2-alkylthio-9*b*-hydroxy-1,4-dihydroindano-[1,2-*b*]pyridines **355**.^{239, 240} Similar products are formed from the compounds **52** and **87** in the presence of iodoacetamide.²³⁹

Pyridobenzothiazole **356** reacts with the arylidenecyanothioacetamides **52** on refluxing in ethanol or pyridine. The structure **357** has been assigned to the reaction product.²⁴¹

As has been mentioned in Section III, pyridinium ylides react with unsaturated nitriles giving the betaines **77**, which cyclise on treatment with hydrogen sulfide to the corresponding pyridine-thiolates **358** with retention of the *trans*-pseudoaxial arrangement of the C(3)H and C(4)H protons.⁵⁴ The same thiolates have been obtained by reaction of pyridinium ylides **359** with arylidenecyanothioacetamides **52** or by a three-component reaction of the ylides **359** with the aldehydes **44** and the thioamide **53**.^{54, 242} The ylide **75** and the compounds **52** form betaines **360**.^{194, 196}

Some stereochemical aspects of the synthesis of pyridine betaines have been surveyed in a review;⁹ the atropo- and the stereo-selectivity of formation of these compounds have been discussed.²⁴³ Nucleophilic reactions of pyridinium ylides have been considered in greater detail in another review.⁵⁶

On heating in acetic acid with ammonium acetate, all the hydrogenated pyridinethiolates **358** eliminate pyridine yielding the corresponding pyridinethiones **361**.^{54, 242, 244, 245}

Based on the interaction of the pyridinium ylide **359** ($\text{Ar}' = 3\text{-pyridyl}$) with 3-pyridylmethylenecyanothioacetamide, a method for the synthesis of the tobacco alkaloid nicotine and its analogues has been developed.²⁴⁶

Pyridinethiones having no substituents at the 4-position can be synthesised using reactions with formaldehyde. Thus three-component condensation of formaldehyde, malononitrile **39**, and cyanothioacetamide **53** gives ¹⁵⁹ 2(1*H*)-pyridinethione **363**, which is produced *via* a stage of recyclisation of 4*H*-thiopyran **362**. The compound **363** has been obtained previously as the product of interaction of cyanothioacetamide **53** with ethoxymethylenemalononitrile **110**.²⁴⁷

Three-component condensation of aliphatic aldehydes with carbonyl compounds and cyanothio(seleno)acetamides opened up way to 4-alkyl-substituted 2(1*H*)-pyridinethions and -selenones, which had been difficult to synthesise before. The reaction of the anilide of acetoacetic acid **312a** with propionaldehyde **364** and cyanothioacetamide **53** yields 4-ethyl-substituted pyridine **365**.²⁴⁸

Dimedone **25** reacts with aliphatic aldehydes and the cyanoamides **53** or **366** to give compounds **367** similar to the aryl derivatives **55** described previously. The compounds **367** can be regarded as adducts of dimedone and alkylidenecyanothio(seleno)acetamides, which are apparently formed *in situ* in this reaction. When the temperature is increased, the compounds **367** cyclise to 4-alkyl-substituted hexahydro-2(1*H*)-quinolinethiones(-selenones) **368**.²⁴⁹

Y = S (**53**), Se (**366**).

Under these conditions, Meldrum's acid **63** forms analogous salts **369**; at higher temperatures, they cyclise with destruction of the 1,3-dioxane ring, being thus converted into hydrogenated pyridones **370**.²⁴⁹

Y = S (**53**), Se (**366**).

The use of compounds **371**, resulting from condensation of cyclic ketones with cyanothioacetamide, in the reactions with the dicarbonyl compounds **25** and **63** permitted the synthesis of spiroderivatives of hydrogenated quinolines **372** and pyridones **373**, which are of interest from the stereochemical viewpoint.²⁴⁹

Analysis of the published data indicates that reactions of carbonyl compounds with α,β -unsaturated nitriles is a quite promising field of research. Studies along this line make it possible to synthesise a large number of diverse organic compounds possessing useful practical properties and also make a substantial contribution to the development of theoretical problems of organic chemistry.

III. Homolytic reactions of thiocyanogen and thiocyanogen halides with alkenes	430
IV. Conclusion	432

Abstract. Data on the reactions of thiocyanogen and thiocyanogen halides with unsaturated compounds are systematised. The kinetic, stereo-, and regiochemical regularities of these reactions are analysed. The bibliography includes 81 references.

I. Introduction

Reactions of thiocyanogen and thiocyanogen halides with alkenes belong to the important methods used for the preparation of organic isothiocyanates and thiocyanates. The presence of several reaction centres in these compounds^{1,2} opens up wide prospects for their application in the synthesis of diverse heterocyclic compounds.^{3–14} Organic isothio- and thiocyanates and compounds based on them possess fungicidal and bactericidal activity,^{15–17} manifest properties of optically active crystals¹⁸ and organic superconductors.¹⁹

The ability of thiocyanogen to add to a double bond served as a basis for the development of a method for the quantitative determination of the degree of unsaturation of individual organic compounds, fats, and oil²⁰ (the thiocyanogen value).

Despite the practical importance of alkene thiocyanation, its mechanism remained poorly studied for a long time. It was stated that the chemical properties of thiocyanogen, (SCN)₂, and thiocyanogen halides are similar to those of halogens; in view of this, they are often called pseudo-halogens.²¹ In the middle of the 1960s, the first studies on the stereochemistry and mechanism of reactions of thiocyanogen and thiocyanogen halides with alkenes appeared. To date, a large body of experimental data have been obtained; they require systematisation and reviewing.

We have made an attempt to generalise the data available on the reactions of thiocyanogen and thiocyanogen halides with unsaturated compounds both under conditions of electrophilic addition and under UV irradiation.

II. Reactions of thiocyanogen and thiocyanogen halides with alkenes under heterolytic conditions

Thiocyanogen was first isolated in an analytically pure form in 1919.²² It is a very unstable compound with m.p. –2 °C, but its

solutions in organic solvents are stable for rather long periods of time.^{22–24}

IR Spectra of thiocyanogen in carbon disulfide and pentachloroethane²⁵ are in favour of its disulfide structure (structure 1)

However, the main absorption band in the IR spectra recorded in ether is somewhat shifted towards lower frequencies, whence a conclusion was made²⁵ that the isothiocyanate form (structure 2) of thiocyanogen in ether is preferred

This assignment is doubtful. For example, a similar shift of the absorption band in the IR spectra of thiocyanogen iodide was explained²⁶ by the formation of a charge-transfer complex of thiocyanogen iodide with ether as a low-basic solvent.

The coincidence of the heat of formation of thiocyanogen found experimentally with the theoretical value calculated assuming the disulfide structure^{27–29} is in favour of structure 1. It was confirmed by UV spectroscopic data for thiocyanogen in the gas phase and by theoretical calculations.³⁰

Thiocyanogen chloride can be obtained quantitatively by the reaction of chlorine with (SCN)₂²⁵ or with AgSCN³¹ in the gas phase or in organic solvents. However, it decomposes rapidly in solutions.^{25,32} Mass spectrometric studies showed that the potential for formation of the SCN⁺ particle from thiocyanogen chloride is lower than the potential for its formation from (SCN)₂.²⁹

According to the data of IR,^{25,33} microwave,³⁴ and photoelectron spectroscopy,³⁵ structure 3 is preferable for thiocyanogen chloride to structure 4.

The data available to date indicate that the S–Cl bond in the thiocyanogen chloride molecule is polarised under heterolytic reaction conditions.

1. Main pathways of the reaction of thiocyanogen and thiocyanogen chloride with alkenes

Benzene, chloroform, and other non-nucleophilic solvents, as well as acetic acid, are the most common solvents used in reactions of alkenes with thiocyanogen. As a rule, these reactions result in a mixture of adducts, *i.e.*, dithiocyanates 5 and isothiocyanatodithiocyanates 6; in solutions in acetic acid, solvato-adducts 7 are also formed.

E V Skorobogatova, V R Kartashov Nizhnii Novgorod State Technical University, ul Minina 24, 603600 Nizhnii Novgorod, Russian Federation. Fax (7-831) 236 23 11. Tel. (7-831) 236 93 57

Received 1 July 1997

Uspekhi Khimii 67 (5) 474–485 (1998); translated by S S Veselyi

It was shown^{36,37} that the reaction rate increases with an increase in the solvent polarity and in the electron-donating properties of the substituent at the double bond of the alkene.

It was found in a study of the reaction of styrenes with thiocyanogen in AcOH that the second-order reaction constants correlate with the Brown–Okamoto constants (σ^+) of substituents. The reaction constant ρ^+ is -5.3 .³⁸ These data indicate the electrophilic character of the reaction and a considerable polarity of the transition state.³⁸

The products of the reaction of styrenes **8a–f** with thiocyanogen in acetic acid include 1-(aryl)ethane-1,2-diylthiocyanates **9a–f**, 2-(aryl)-2-isothiocyanatoethyl thiocyanates **10a–f**, and products of the conjugate addition of acetic acid, *i.e.* 2-(aryl)-2-acetoxyethyl thiocyanates **11a–f**. The yields of the latter depend on the electron-donating properties of the aryl substituent (Table 1).^{38,39} Thus, the introduction of electron-withdrawing substituents into the benzene ring of styrene increases the yields of thiocyanates **11a–f**, whereas electron-donating substituents decrease the yields.

The adducts **10** and solvato-adducts **11** are formed regioselectively. Similar regiochemistry of the formation of compounds **10** is observed in the reaction of $(\text{SCN})_2$ with styrene **8c** in benzene (Table 1).⁴⁰

The high polarity of the transition state (the limiting step of the reaction of thiocyanogen with alkenes) is evident from the greater effect of LiClO_4 on the overall reaction rate in comparison with the effect of this salt on the sulfonylhalogenation of alkenes.³⁹ In reactions with styrene³⁹ and cyclohexene,⁴¹ the second-order reaction constants depend linearly on the LiClO_4 concentration according to Eqn (1)

$$k_{\text{exp}} = k_0 (1 + b[\text{LiClO}_4]), \quad (1)$$

where k_{exp} and k_0 are the observed reaction rate constants in the presence and in the absence of the salt, respectively. The b parameter varies from 17 to 38 depending on the reaction temperature and the alkene structure,³⁹ whereas for sulfonylhalogenation, it varies from 4.5 to 8.^{39,42–44}

The formation of adducts **6** with isothiocyanate groups is undoubtedly related to the ambidentate properties of the thio-

cyanate anion. The table below lists the charge distributions in the SCN^- anion calculated by MO LCBO (method A)⁴⁵ and by MO LCAO in the Wolfberg–Helmholtz (method B)⁴⁶ and Hückel approximations (method C).⁴⁷

Method	Charge distribution on atoms		
	S	C	N
A	-0.7108	$+0.1934$	-0.4826
B	-0.24	$+1.00$	-1.76
C	-0.31	$+0.09$	-0.79

It was shown⁴⁰ that increasing the number of substituents at the alkene double bond increases the fraction of the adduct of type **6** containing the isothiocyanate group. For example, a comparison of the results of reactions of $(\text{SCN})_2$ with 2-methylbut-2-ene **12a** and 2,3-dimethylbut-2-ene **12b** in benzene shows that the yield of isothiocyanate **14b** is considerably higher than that of thiocyanate **14a**.

R = H(a), Me (b).

Under similar conditions, hex-1-ene gives hexane-1,2-diyl dithiocyanate **15** in 42% yield as well as 2-isothiocyanatohexyl thiocyanate **16** and 1-isothiocyanatohexane-2-yl thiocyanate **17** in 27% overall yield.

The observed ratio of the reaction products **15**:(**16**+**17**) is explained⁴⁰ by the effect of steric and electronic factors of the substrate and the thiocyanate anion in the step of the formation of reaction products.

It was found⁴⁸ that the reaction of *trans*- and *cis*-hex-3-enes with $(\text{SCN})_2$ gives *erythro*- and *threo*-4-isothiocyanatohexane-3-yl thiocyanates **18** and hexane-3,4-diyl dithiocyanates **19**, respectively, as the main reaction products. The ratio of products **18**:**19** depends substantially on the properties of the solvent. In aprotic solvents, this ratio decreases with an increase in the polarity of the solvent, *e.g.*, it is 2.15 in benzene and 0.46 in acetonitrile.

The product ratio of this reaction in low-polar solvents is affected substantially by the addition of iron powder. For example, the ratio of isomers **18**:**19** changes to 0.03 in benzene. The observed ratio of the reaction products was explained⁴⁸ in terms of the HSAB concept.⁴⁹ In the opinion of Maxwell *et al.*,⁴⁸ the ambident thiocyanate anion in non-polar solvents is mostly solvated at the soft sulfur atom (interaction involving charge transfer). This results in charge-controlled attack of the intermediate carbocation by the nitrogen atom. As the dielectric constant of the solvent increases, the direction of the reaction of the SCN^- anion with the intermediate changes from charge-controlled to frontally-controlled with attack by the sulfur atom. A decrease in the fraction of product **18** in acetonitrile can also be explained by an association of the thiocyanate anion with the solvent similar to dipole-dipole interaction.

Table 1. Yields of the products of the reaction of styrenes **8a–f** with thiocyanogen in acetic acid.

Compound	R	Product yields (%)		
		9	10	11
a	4-OMe	78	—	—
b	4-Me	59	~20	21
c	H	36 (44) ^a	~20 (22) ^a	42
d	4-Cl	36	~20	44
e	3-Cl	—	—	85–90
f	3-F	—	—	85–90

^a The numbers in parentheses indicate the yields of the products in benzene.

The preferential (84%) formation of dithiocyanate **19** in acetic acid is explained⁴⁸ by the coordination of the solvent with the thiocyanate anion with the formation of hydrogen bonds mainly with the nitrogen atom.

Reactions of alkenes with thiocyanogen chloride in acetic acid generally result in products of addition of ClSCN to the alkene double bond and solvato-adducts of the type **7**. For example, the reaction of ethylene with thiocyanogen chloride gives 2-chloroethyl thiocyanate and 2-acetoxyethyl thiocyanate in 64% and 6% yields, respectively.⁵⁰ The addition of thiocyanogen chloride to asymmetric aliphatic alkenes occurs both according to and against the Markovnikov rule, whereas solvato-addition always occurs according to the Markovnikov rule. For instance, the reaction of propene with ClSCN in AcOH gives a mixture of adducts: 2-chloropropyl thiocyanate **20** (54%), 1-chloropropane-2-yl thiocyanate **21** (27%), and 2-acetoxypropyl thiocyanate **22** (18%).⁵¹ The ratio of thiocyanates **20**:**21** is the same if the reaction is carried out in chloroform.⁵² The reaction of hex-1-ene with ClSCN in AcOH occurs similarly to give 2-chlorohexyl thiocyanate (49%), 1-chlorohexane-2-yl thiocyanate (28%), and 2-acetohexyl thiocyanate (15%).⁵¹ The addition of ClSCN to styrene **8c** obeys the Markovnikov rule to give 2-chloro-2-phenylethyl thiocyanate and 2-acetoxy-2-phenylethyl thiocyanate in 41% and 50% yields, respectively.⁵¹

2. Stereochemistry of alkene thiocyanation

The reaction of (SCN)₂ and ClSCN with cyclohexene occurs stereoselectively. The reaction of (SCN)₂ with cyclohexene in benzene gives *trans*-isomers of cyclohexane-1,2-diyl dithiocyanate **23** and 2-isothiocyantocyclohexyl thiocyanate **24**. The reaction in acetic acid gives *trans*-2-acetoxycyclohexyl thiocyanate **25** in addition to the above products **23** and **24**.⁴⁰

Compound	R	Yield (%)	
		in C ₆ H ₆	in AcOH
23	SCN	32	48
24	NCS	16	22
25	OAc	—	24

The reaction of cyclohexene with ClSCN in acetic acid results in *trans*-2-chlorocyclohexyl thiocyanate **26** (77%) and a solvato-adduct **25** (15%).⁵⁰

Similar results were also obtained in the reaction of (SCN)₂ and ClSCN with 4-methylcyclohexene.^{40,50} The reaction with (SCN)₂ gave *trans*-isomers of 4-methylcyclohexane-1,2-diyl dithiocyanate, 5-methyl-2-isothiocyantocyclohexyl thiocyanate, and 4-methyl-2-isothiocyantocyclohexyl thiocyanate.⁴⁰ The reaction with thiocyanogen chloride gave a mixture of regioisomeric *trans*-adducts (2-chloro-4-methylcyclohexyl thiocyanate and 2-chloro-5-methylcyclohexyl thiocyanate) and *trans*-solvato-adducts (2-acetoxy-4-methylcyclohexyl thiocyanate and 2-acetoxy-5-methylcyclohexyl thiocyanate).⁵¹

Reactions with conformationally rigid and conformationally fixed alkenes give products in which the functional groups formed upon the addition of the reagent occupy the *trans*-diaxial positions. For example, the reaction of ClSCN with 5 α -2-cholestene in acetic acid results in 2 β -chloro- and 2 β -acetoxy-3 α -thiocyanato-5 α -cholestanes in 82% and 11% yields, respectively.⁵¹

The reaction of thiocyanogen with *trans*- Δ^2 -octalin **27** in benzene affords *trans*-decalin-2a,3a-dithiocyanate **28** (yield 10%) and *trans*-3a-isothiocyantodecalin-2a-thiocyanate **29** (yield 5%). If the reaction is carried out in acetic acid, *trans*-3a-acetoxycyclohexyl-2a-thiocyanate **30** is formed in addition to the adducts **28** and **29**. The yields of decalins **28**–**30** are 40%, 18%, and 21%, respectively.⁴⁰ Solvato-adduct **30** and *trans*-3a-chlorodecalin-2a-thiocyanate **31** were isolated in 25% and 69% yields, respectively, from the reaction mixture of octalin **27** with thiocyanogen chloride.⁵⁰

R = SCN (**28**), NCS (**29**), OAc (**30**), Cl (**31**).

The reaction of 4-*tert*-butylcyclohexene with thiocyanogen in acetic acid gives products **32a**–**c**,⁴⁰ while the reaction with thiocyanogen chloride gives compounds **33a,b** and **34a,b**.⁵¹ The functional groups in compounds **32a**–**c**, **33a,b**, and **34a,b** have a *trans*-diaxial configuration.

The rule of *trans*-addition of thiocyanate-containing reagents also holds for such highly strained alkenes as cyclopropenes.^{52,53} The reactions of 3,3-dimethylcyclopropene with thiocyanogen chloride and thiocyanogen in CHCl₃ and AcOH afford adducts with *trans*-configuration, namely, *trans*-2-chloro-3,3-dimethylcyclopropyl thiocyanate (80%) and *trans*-3,3-dimethylcyclopropyl-1,2-diyl dithiocyanate (20%), respectively.⁵²

The reaction of (SCN)₂ and ClSCN with stereoisomeric acyclic alkenes is *trans*-stereospecific.⁵⁰ Thus, the reaction of thiocyanogen chloride with *cis*-but-2-ene gives 3-chlorobutane-2-yl thiocyanate (81%) and 3-acetoxybutane-2-yl thiocyanate (15%) with *threo*-configurations. The same compounds but with *erythro*-configurations are formed in the reaction with *trans*-but-2-ene. They were isolated in 89% and 8% yields, respectively.

Similar results were obtained in the reaction of thiocyanogen with *cis*- and *trans*-2,5-dimethylhex-3-enes in benzene.⁵⁰ In this case, ($\pm$)- and *meso*-2,5-dimethylhexane-3,4-diyl dithiocyanates, as well as *threo*- and *erythro*-2,5-dimethyl-4-isothiocyantohexane-3-yl thiocyanates, respectively, are formed.

The observed stereochemical features agree with the stepwise reaction scheme and the cyclic structure of the intermediate.^{54–56}

The stereoselectivity of addition is violated in reactions with alkenes containing aryl substituents at the double bond. For example, the reactions of *cis*- and *trans*-stilbenes with ClSCN afford a mixture of *threo*- and *erythro*-2-chloro-1,2-diphenylethyl thiocyanates and *threo*- and *erythro*-2-acetoxy-1,2-diphenylethyl thiocyanates. The yield of the adducts was ~50% with predominant formation of the *trans*-isomer. The solvato-adducts are also predominantly of the *trans*-type (the *trans*- and *cis*-isomer ratio was 9:1; the total yield was ~40%). A mixture of adducts with *threo*- and *erythro*-configuration is formed in dichloromethane, chloroform, and benzene.⁵⁷ The reaction of *trans*-1-phenylpropene with (SCN)₂ in benzene is also non-stereospecific.⁴⁰ However, in this case the total yield of the reaction products does not exceed 20%.

The stereochemistry of the addition of thiocyanate-containing reagents to aryl-substituted alkenes is close to the stereochemistry

observed in reactions of the latter with bromine and its analogues,⁵⁸ but differs substantially from the stereochemistry of the addition of sulfonyl halides where high *trans*-stereoselectivity is a typical feature.^{54–56}

It was assumed^{40,57} that the intermediate **35** with an open structure is formed in the rate-limiting step of the reaction of (SCN)₂ and ClSCN with aryl-substituted alkenes.

X = SCN, Cl.

This assumption agrees well with kinetic data obtained for the reaction of styrenes with thiocyanogen in AcOH.³⁸

The reactions of thiocyanogen and thiocyanogen chloride with indene and acenaphthylene are not stereoselective, either. Indene **36** reacts with (SCN)₂ in benzene to give *cis*- **37a** and *trans*-indane-2,3-diyl dithiocyanates **38a** as well as *cis*- **37b** and *trans*-3-isothiocyanatindane-2-yl thiocyanates **38b**.⁴⁰

The reaction with thiocyanogen chloride in acetic acid gives 22% of a mixture of *trans*- **39** and *cis*-3-chloroindane-2-yl thiocyanates **41** (in the 15:7 ratio) and 70% of *trans*- **40** and *cis*-3-acetoxyindane-2-yl thiocyanates **42** in which the *trans*-isomer predominates.⁵¹

R = Cl (**39**, **41**), OAc (**40**, **42**).

Acenaphthylene reacts with thiocyanogen chloride in AcOH to give a mixture of *cis*- and *trans*-2-chloroacenaphthenyl thiocyanates in 21:79 ratio (total yield 61%) and a mixture of *cis*- and *trans*-2-acetoxyacenaphthenyl thiocyanates in 12:88 ratio and in 35% total yield.⁵⁷

3. Molecular rearrangements and proton elimination in reactions of thiocyanogen and thiocyanogen chloride with alkenes

Reactions of thiocyanogen and thiocyanogen chloride with alkenes commonly involve skeletal rearrangements. This was first discovered in a study of a reaction of 2-aryl-3-methylbut-3-en-2-ols **43a–f** with thiocyanogen in a mixture of AcOH with Ac₂O.⁵⁹ The main reaction products are thiocyanatoketones **44a–f** formed due to the aryl group migration. The yield of 3-aryl-3-methyl-4-thiocyanatobutan-2-ones **44a–c** is close to quantitative. The yields of ketones **44d–f** were 72%, 60%, and 46%, respectively. The reactions of alkenes **43d–f** give the adducts, namely, 3-aryl-3-hydroxy-2-methylbutane-1,2-diyl dithiocyanates, in addition to thiocyanatoketones **44d–f**.

R = 4-OMe (**a**), 4-Me (**b**), 3-Me (**c**), H (**d**), 4-Cl (**e**), 3-Cl (**f**).

The second-order reaction rate constants (first-order with respect to each reagent) correlate with the Hammett constants of substituents. The reaction constant is negative, $\rho = -2.35$.⁵⁹

The addition of thiocyanogen to benzonorbornadiene **45** in chloroform and acetic acid gives exclusively products of the Wagner–Meerwein rearrangement:⁶⁰ 2-*exo*-7-*anti*-dithiocyanato-5,6-benzobicyclo[2.2.1]hept-5-ene **46** and 2-*exo*-isothiocyanato-7-*anti*-thiocyanatobenzobicyclo[2.2.1]hept-5-ene **47**. The total yield of the products is 90%. The relative content of compounds **46** and **47** is 51% and 49% in chloroform and 75% and 25% in acetic acid, respectively.

Rearrangement is the only direction of the reaction of benzonorbornadiene with ClSCN. When the reaction was carried out in chloroform, compound **48a** was isolated in 95% yield. In acetic acid, 2-*exo*-chloro- **48a** and 2-*exo*-acetoxy-7-*anti*-thiocyanato-5,6-benzobicyclo[2.2.1]hept-5-ene **48b** are formed in 83:17 ratio in 80% overall yield.⁶⁰ It is assumed that an ion pair **49** is formed as an intermediate without substantial manifestation of a dative bond.⁶⁰

Rearrangement is also possible in the thiocyanation of allylbenzenes **50**. It was found^{42,61} that, in addition to the usual 1,2-addition products **51–53**, these reactions give rearrangement products **54, 55**.

R = 4-OMe (**a**), 4-Me (**b**), H (**c**).

The reaction of thiocyanogen with alkene **50a** in a mixture of anhydrous AcOH with acetic anhydride (4:1, v/v) gives a product of 1,2-migration of the aryl group, viz., 2-(4-methoxyphenyl)propane-1,3-diyl dithiocyanate **54a** in 70% yield.⁶¹ The fraction of rearrangement products decreases abruptly with a decrease in the electron-donating properties of the aryl substituent.^{42,61}

The proportion of rearrangement products formed in the reaction of alkenes **50** with ClSCN is much larger than in the reaction with (SCN)₂. For example, the reaction of alkene **50a** with ClSCN in AcOH results only in products of 1,2-shift of the aryl group, i.e. 2-(4-methoxyphenyl)-3-chloropropyl thiocyanate (**56a**) and the solvato-adduct **56b**, in the 9:1 ratio.⁴²

R = Cl (**a**), OAc (**b**).

In addition to the main addition product **57**, the reaction of thiocyanogen chloride with (*Z,Z*)-cycloocta-1,5-diene in AcOH also gave products of a *trans*-annular reaction, *i.e.* bicycles **58** and **59**.²¹ Conversely, the reaction of the same diene with thiocyanogen gives only an adduct, namely, cyclooct-5-ene-1,2-diyl dithiocyanate.²¹

The reactions of (SCN)₂ and ClSCN with 1-methylcyclopropane in chloroform and acetic acid have been studied.^{52, 62, 63} The reactions occur in several directions to give a mixture of products. In addition to the corresponding adducts and solvato-adducts, addition products with cyclopropane ring opening were isolated.

The reaction of (SCN)₂ and ClSCN with *gem*-disubstituted alkenes occurs with considerable peculiarities. For example, isobutene reacts with (SCN)₂ in acetic acid to give an addition product, methallyl isothiocyanate **60a**, and a solvato-adduct, 2-acetoxy-2-methylpropyl thiocyanate **61**, in a 1:4 ratio in 60%–70% total yield instead of adducts. It is believed⁶⁴ that the formation of isothiocyanate **60a** is the result of allyl rearrangement of the thiocyanate **60b** formed initially.

R = NCS (**a**), SCN (**b**).

Thiocyanation of 3-aryl-2-methylprop-1-enes **62a, b** afforded solvato-adducts (2-acetoxy-3-aryl-2-methylpropyl thiocyanates **63a, b**), addition products (**64a, b** and **64a, b** as a mixture), and products **66a, b** and **67a, b**. The ratio of the sum of unsaturated products **64a–67a** to the acetate **63a** is 1:1, and the ratio of compounds **64b–67b** to compound **63b** is 1:2.⁶⁴

R = H (**a**), 4-Cl (**b**).

Unsaturated compounds are also formed in the reaction of thiocyanogen with 2-methylbut-2-ene in acetic acid.⁶⁴

Similarly, the reaction of isobutene⁶⁴ and 2-ethylbut-1-ene⁵¹ with ClSCN in AcOH affords the corresponding unsaturated compounds **60a** and 3-ethylbut-3-en-2-yl isothiocyanate **68** in addition to the adducts and solvato-adducts.

The reactions studied show again that (SCN)₂ resembles halogens and interhalogen electrophilic reagents.⁵⁸

It was assumed⁵¹ that unsaturated compounds are formed due to the elimination of a proton from intermediate **69**.

However, an alternative scheme may be suggested for these reactions according to which unsaturated compounds may be formed from a cyclic intermediate through a highly polar intermediate **70**. The stabilising effect of substituents at the β-carbon atom in the carbocationic centre on the intermediate state probably favours such a transformation of the cyclic intermediate.⁶⁵

X = SCN, Cl.

Unsaturated compounds are also formed in reactions of ClSCN with phenyl-substituted alkenes. The reaction with 1,1-diphenylethylene afforded a product of the β-proton elimination, *viz.*, 2,2-diphenylvinyl thiocyanate, in 10% yield. 1,1-Diphenyl-2-thiocyanatoethanol was also isolated from the reaction mixture. It is believed⁵¹ that this compound is formed as a result of hydrolysis of the adduct formed initially, 2-chloro-2,2-diphenylethyl thiocyanate. The reaction of ClSCN with triphenylethylene gave a β-proton elimination product, 1,2,2-triphenylvinylthiocyanate, in 75% yield.⁵¹

This reaction is assumed⁵¹ to occur through the formation of the intermediate **71**.

Finally, let us consider the data that allow one to deduce the structure of the intermediate formed in the thiocyanation of alkenes. According to some data,⁶⁶ the intermediate may have a structure of a π-complex **72** with two electron-deficient S–C bonds without noticeable overlapping of the 3*p*-orbital of the sulfur atom with the π-antibonding orbital of the alkene (dative bond) or of a three-membered cyanosulfonium ion **73** with two ordinary two-electron S–C bonds.

X = SCN, Cl.

Intermediates of the type **73** are assumed to be formed in the sulfonylhalogenation of alkenes.^{54, 67, 68} From the formal structural point of view, ClSCN and (SCN)₂ can be regarded as sulfonyl chlorides (ClSR) and sulfonyl thiocyanates (NCSSR) in which the hydrocarbon group is replaced by the cyano group. In this case, one should expect a similarity in the chemical behaviour of these two types of electrophilic reagents and formation of intermediates with similar structures.

However, as can be seen from the above data, despite the formal similarity, the thiocyanation of alkenes differs substantially in many respects from the reaction of alkenes with sulfonyl

halides. The formation of rearrangement products and unsaturated compounds, as well as transannular cyclisation and the cyclopropene ring opening, are in better agreement with the assumption that the intermediate in the thiocyanation of alkenes has the structure **72**. In the absence of the dative bond or if it manifests itself insignificantly, the carbon skeleton of π -complex **72** can be largely deficient in electron density. This stimulates the processes described above.

It follows from stereochemical data that in reactions of $(\text{SCN})_2$ and ClSCN with aryl-substituted alkenes, the intermediate **35** with an open structure is more stable than the cyclic one. The sulfonylation of such alkenes occurs *trans*-selectively.^{54–56} The difference between thiocyanation and sulfonylation can be explained by the smaller bond strength in the cyclic intermediate **72** than in the episulfonium ion due to the absence of overlapping of *p*- and π^* -orbitals. Therefore, the reaction occurs through a non-cyclic intermediate in the presence of substituents capable of noticeable conjugation with the electron-deficient carbon atom.

Taking into consideration the properties of the media in which these reactions are usually carried out (aprotic and protic solvents with low dielectric constants), one can assume that, irrespective of the exact structure of its cation, the intermediate exists as a tight ion pair, which is possibly in equilibrium with a solvate-separated ion pair.^{42, 50, 53, 57, 59, 69} It was assumed^{38, 39} that the interaction between the sulfur atom of the cation and the counter-ion exists.

4. Addition of thiocyanogen bromide and thiocyanogen iodide to alkenes

Thiocyanogen bromide has been obtained both in solution^{25, 70} and in gas phase.³⁵ Like ClSCN , it is an unstable compound. The reaction of BrSCN with alkenes has been little studied. The procedure for the preparation of the reagent affects considerably the result of the reaction. In one study,⁷¹ it was prepared by the reaction of bromine with lead thiocyanate in CCl_4 . Its subsequent reaction with oct-1-ene resulted in a mixture of 1,2-dibromooctane and 2-bromooctyl thiocyanate. The reaction products were not separated. The conclusion on their structures was done on the basis of GLC and elemental analysis data. It was also assumed that a small amount of 1-bromooctane-2-yl thiocyanate was present in the reaction mixture.

Several procedures were attempted⁷² with the aim of obtaining vicinal bromothiocyanates. It was found that the optimum conditions are those where an alkene is treated with an equimolar amounts of bromine and thallium thiocyanate in moist CCl_4 or CHCl_3 . The reaction of these reagents with cyclohexene gave *trans*-2-bromocyclohexyl thiocyanate **74** as the main product (50%) and small amounts (3%–5%) of *trans*-1,2-dibromocyclohexane **75** and thiocyanates **23** and **24**.

When lead thiocyanate was used, the yield of thiocyanate **74** decreased to 20%.

The reaction of 1-methylcyclohexene with the same reagents gave similar *trans*-addition products **76**–**78** and an unsaturated compound, 2-methylcyclohex-2-enyl isothiocyanate **79**. The structure of *trans*-2-bromo-*cis*-2-methylcyclohexyl thiocyanate **76** indicates that the sulfur atom is the electrophilic centre in the BrSCN molecule.

The reaction with hex-1-ene is less regioselective. Isomeric products are formed in this case, namely, 2-bromohexyl thiocyanate **80** (44%), 1-bromohexane-2-yl thiocyanate **81** (9%) and compounds **15**–**17** (total yield 18%).

Styrene **8c** reacts under the conditions specified above to give 2-bromo-2-phenylethyl thiocyanate **82** (44%) and compounds **9c** (18%) and **10c** (12%). The yield of adduct **82** increases to 77% upon the addition of KBr to the reagent.

Unlike in the reactions mentioned above, the reaction of the system bromine–thallium thiocyanate with 2-phenylpropene does not give a vicinal bromothiocyanate. In this case, 2-phenylpropane-2-yl isothiocyanate **83**, 2-phenyl-2-isothiocyanatopropyl thiocyanate **84**, 2-phenylpropane-1,2-diyl dithiocyanate **85**, and 2-phenylpropane-1,2-diyl diisothiocyanate **86** were obtained.

Under the same conditions, the reactions of *trans*- β -methylstyrene result in *threo*- and *erythro*-1-bromo-1-phenylpropane-2-yl thiocyanates **87** in 11% and 8% yields, respectively, *threo*-1-isothiocyanato-1-phenylpropane-2-yl thiocyanate **88** (11%), and a mixture of *threo*- and *erythro*-1-phenylpropane-1,2-diyl dithiocyanates **89** (total yield 20%).⁷²

It is assumed⁷² that, depending on the alkene structure, either *S*-cyanosulfonium ion of the type **73** ($\text{X} = \text{Br}$) or a cation with an open structure (for aryl-substituted alkenes) are formed as intermediates.

Reactions of alkenes with thiocyanogen iodide are of considerable interest as a method for the synthesis of vicinal iodothio- and iodoisothio-cyanates that can be used efficiently in the synthesis of heterocyclic compounds.^{6, 11–14} It is a problem to establish a procedure for the preparation of the reagent that would ensure the selective synthesis of these adducts.

By analogy with thiocyanogen chloride and bromide, ISCN was obtained using the reaction of iodine with thiocyanogen. It should be noted that there is no common viewpoint regarding the position of equilibrium in this system. For example, it was reported²⁶ that thiocyanogen iodide was formed in a solution in CCl_4 ; conversely, the formation of a substantial amount of thiocyanogen iodide was considered unlikely in other papers.^{35, 73} Nevertheless, although the data presented above are controversial, the use of a solution of iodine and thiocyanogen leads rather smoothly to the formation of iodothio- and iodoisothio-cyanates in many reactions with alkenes.

In another method, a system consisting of iodine or iodine-containing electrophiles and salts with the thiocyanate anion were used as the source of ISCN . The advantage of this method is the possibility of varying the reaction conditions over a wide range by changing the properties of the medium and the nature of the salt.

The reaction of *cis*- and *trans*-hex-3-enes with the $\text{I}_2-(\text{SCN})_2$ system has been studied.⁷⁴ It was found that in benzene, *threo*- and *erythro*-4-iodohexane-3-yl isothiocyanates **90**, respectively, are

formed along with a small amount of the addition product **18**. The same reaction in AcOH results in compounds **18**, **19**, and **91**. It was concluded on this basis⁷⁴ that ISCN was not formed in acetic acid. However, a study of the reactivity of the $I_2-(SCN)_2$ system with *trans*-hex-3-ene⁶ showed that the *erythro*-adduct **90** and *erythro*-4-iodohexane-3-yl thiocyanate **92** are the main products in benzene, dichloromethane, chloroform, and acetic acid. The ratio of compounds **90**:**92** in AcOH is ~2:1 and the total yield is ~60%. In other solvents studied, their ratio changes from 3.5 to 6.0 and the total yield varies from 70% to 80%. Compounds **18**, **19**, and **91** are formed in small amounts.

It was assumed⁶ that in all solvents ISCN is the actual electrophile, and, according to the expected polarisation of the reagent, the reaction involves the intermediate **93**.

For comparison, the reaction of *trans*-hex-3-ene with the KSCN– I_2 system was studied. In chloroform, the ratio of products **92**:**90** is 4:1, which differs markedly from that (1:6) obtained in the reaction described above. It is believed⁶ that the reaction pathways are different.

The $I_2-(SCN)_2$ system reacts with unsymmetrical aliphatic alkenes to give regioisomeric iodothio- and iodoisothiocyanates. The main reaction products with 4-methylpent-1-ene in benzene are 2-iodo-4-methylpentyl thiocyanate **94**, 1-iodo-4-methylpentane-2-yl thiocyanate **95**, 2-iodo-4-methylpentyl isothiocyanate **96**, and 1-iodo-4-methylpentane-2-yl isothiocyanate **97**.⁷³ The total yield and ratio of the reaction products depend on experimental conditions, in particular on the quality of lead thiocyanate used for the preparation of thiocyanogen solutions. The highest yield of the reaction products (72%) and satisfactory selectivity are observed when the process is carried out in the dark in oxygen-free nitrogen. Iodothiocyanates **94** and **95** were isolated in 17% yield (ratio 3:1) and the yield of iodoisothiocyanates **96** and **97** was 51% (ratio 1:2).

Similar results were obtained in the reaction with oct-1-ene and 3,3-dimethylbut-1-ene. The reaction with oct-1-ene gives a mixture of 2-iodooctyl thiocyanate **98** and 1-iodooctane-2-yl thiocyanate **99** in 18% total yield (ratio 1.5:1) and a mixture of 2-iodooctyl isothiocyanate **100** and 1-iodooctane-2-yl isothiocyanate **101** in 55% total yield (ratio 1:2). The reaction with 3,3-dimethylbut-1-ene affords 3,3-dimethyl-2-iodobutyl thiocyanate **102** (10%), 3,3-dimethyl-2-iodobutyl isothiocyanate **103** (40%), and 3,3-dimethyl-2-iodobutane-2-yl isothiocyanate **104** (2%).

In this case, the formation of a iodonium ion of the type **93**, which is attacked by a nucleophile from the less sterically hindered side, is also assumed.⁷³

It is noteworthy that with an $I_2-(SCN)_2$ system as the reagent, the proportion of vicinal iodoisothiocyanates in the reaction products exceeds significantly that of iodothiocyanates. It was noted⁶ that the fraction of iodothiocyanates formed is substantially larger when the I_2 –KSCN system is used. This tendency is also confirmed by the results of the reaction with 4-*tert*-butylcyclohexene in chloroform. Iodothiocyanates **105** and **106** in the 5:4 ratio were obtained as the main products (total yield 65%), and the yield of iodoisothiocyanates **107** and **108** was only 12% (ratio 5:4).⁶

105: R = SCN, R' = I; **106**: R = I, R' = SCN;
107: R = NCS, R' = I; **108**: R = I, R' = NCS.

It is assumed that the reaction products mentioned above are formed as a result of diaxial opening of *cis*- and *trans*-iodonium ions. The regioisomeric ratio indicates that the reaction pathway via a *cis*-iodonium ion is slightly preferred (5:4).⁶

The reaction with 3-*tert*-butylcyclohexene gives *trans*-adduct **109a** and unsaturated compounds **110** and **111**.⁶

Syntheses of vicinal iodothiocyanates and iodoisothiocyanates were carried out^{75,76} using the ICl –KSCN, I_2 –KSCN, and I_2 –TISCN systems in organic solvents and in a water–organic solvent system in the presence of phase transfer catalysts. Methyltrialkyl(C_8 – C_{10})ammonium chlorides (Adogen 464) or 18-crown-6 ether were used as catalysts. The structure and yields of the reaction products depend considerably on the reaction conditions. The reaction of cyclohexene with the KSCN– I_2 system in a chloroform–sulfolane mixture or in chloroform gives almost exclusively *trans*-2-iodocyclohexyl thiocyanate **112** (96%).

The use of the I_2 –TISCN system in a chloroform–sulfolane mixture at 0–3 °C was found to be optimum for the synthesis of *trans*-2-iodocyclohexyl isothiocyanate. In this case, the yield of isothiocyanate **113** was 60%. In addition, up to 15% of thiocyanate **112** was formed.

In the reaction with styrene **8c**, the highest yield (72%) of 2-iodo-1-phenylethyl thiocyanate **114** was obtained with the use of the KSCN– ICl system in a chloroform–sulfolane mixture (1:9) at 0–3 °C. The selectivity decreases abruptly under different conditions, and 2-iodo-2-phenylethyl thiocyanate **115**, 2-iodo-1-phenylethyl thiocyanate **116**, and products **9c** and **10c** are formed in addition to adduct **114**. Treatment of iodothiocyanate **114** with boron trifluoride etherate in chloroform gives iodoisothiocyanate **116** in 89% yield.

The reaction of β -methylstyrene with the TISCN– I_2 system in the presence of boron trifluoride etherate occurred most efficiently in $CHCl_3$. In this case, 2-iodo-1-phenylpropyl isothiocyanate (74%) and the product **89** (15%) were isolated.

Thus, performing the reaction in the presence of BF_3 etherate was one of the methods for the selective synthesis of iodoisothiocyanates in the studies cited above.^{75,76} Its addition favours the isomerisation of iodothiocyanates into iodoisothiocyanates. However, this method is not always efficient. For example, such a treatment of thiocyanate **109a** gave compound **117** (26%) instead of the expected isothiocyanate **109b**; the formation of

compound **117** was explained⁶ by the migration of the methyl group in the intermediate carbocation.

If the reaction is carried out in a chloroform–sulfolane mixture (1:9) in the presence of the ICl–KSCN system, the adduct **109b** (yield 51%) is formed along with a small amount (3%) of the product **117**. Performing the reaction under different conditions did not increase the selectivity of the process.

In order to perform selective iodoisothiocyanation of α -methylstyrene, the reaction was carried out either in a chloroform–water mixture (10:1) in the presence of the phase transfer catalyst Adogen 464 using the KSCN–I₂ system or in sulfolane with the TISCN–I₂ system with an addition of boron trifluoride etherate. In these cases, 1-iodo-2-phenylpropane-2-yl isothiocyanate was formed in 71% and 76% yields, respectively.⁷⁶

Iodoisothiocyanation of indene **36** in sulfolane results in *trans*-2-iodoindan-3-yl isothiocyanate **118** and *trans*-2-iodoindan-3-yl thiocyanate **119**. When the reaction mixture was kept for 2 h, compounds **118** and **119** were isolated in 43% and 26% yields, respectively, while after 23 h, adduct **118** was formed preferentially (88%).⁷⁶ If the reaction was carried out under different conditions, a more complex mixture of products was formed.

5 α -Androstene **120** reacts very slowly with the systems considered above. The degree of conversion of this steroid was small when it was treated with I₂–KSCN in chloroform in the presence of a phase transfer catalyst. After 92 h, a mixture of products was isolated from the reaction mixture: 3 α -iodo-2 β -isothiocyanato- **121** and 2 β -iodo-3 α -isothiocyanato-5 α -androstanes **122** in the 7:1 ratio (total yield 23%); 3 α -iodo-2 β -thiocyanato- **123** and 2 β -iodo-3 α -thiocyanato-5 α -androstanes **122** in the 5:1 ratio (total yield 34%), as well as 3 α -iodo-2 β -chloro- **125** and 2 β -iodo-3 α -chloro-5 α -androstanes **126** in the 2.4:1 ratio (total yield 2%).⁷⁶

The effect of the metal ion in the system iodine–metal thiocyanate on the reaction with alkenes was studied.⁷ In the reaction of this system with cyclohexene, the maximum yield (88%) of the products **112** and **113** and a high selectivity (**113**:**112** = 91:9) of the process was observed when Hg(SCN)₂ was a component of the system. With TISCN or AgSCN, the total yield and the selectivity decrease dramatically. The reaction does

not occur in the presence of Ni(SCN)₂ and Pb(SCN)₂. The highest selectivity of the formation of the adduct **112** was achieved with KSCN (**113**:**112** = 3:97; total yield 78%). Similar results were obtained for cyclopentene, cycloheptene, and *trans*-hex-3-ene. The reaction with Hg(SCN)₂ gives the corresponding iodoisothiocyanates in 65%–70% yield, and iodothiocyanates are mainly formed (60%–70%) in the reaction with KSCN. It is assumed⁷ that alkenes react with ISC⁺ through a iodonium ion, which reacts with the I(SCN)₂[−] complex ion to give iodoisothiocyanates and with [−]SCN to give iodothiocyanates.

The regioselective synthesis of 2*e*-aryl-2*a*-iodocyclohexyl 1*a*-thiocyanates **127** by the reaction of 1-arylcyclohexenes with a complex system KSCN–Al₂O₃–I₂ in chloroform was carried out.⁷⁷ The yield of thiocyanates **127** was ~40%. In addition to thiocyanates **127**, 2-arylcyclohex-2-enylthiocyanates **128** were obtained in ~60% yield. The formation of the latter is explained⁷⁷ by the elimination of a HI molecule from adducts **127**.

Ar = Ph, 4-MeC₆H₄, 3,4-Me₂C₆H₃, 4-Bu^tC₆H₄, 4-MeOC₆H₄.

III. Homolytic reactions of thiocyanogen and thiocyanogen halides with alkenes

Homolytic reactions of thiocyanogen and thiocyanogen halides are initiated by ultraviolet irradiation. Under these conditions, thiocyanogen and its halo-derivatives exhibit high reactivity in addition reactions. For example, CISCN reacts with vinyl chloride, 1,1-dichloroethylene, *cis*- and *trans*-1,2-dichloroethylenes, and other similar compounds under UV irradiation; no reaction occurs without UV irradiation.⁷⁸ The yields of reaction products depend on the solvent and the intensity of irradiation. In the reaction of CISCN with *cis*- and *trans*-1,2-dichloroethylenes, the maximum yield of 1,2,2-trichloroethyl thiocyanate (60%) was obtained in acetic acid in a nitrogen atmosphere; the distance of the reactor from the source of irradiation was 1 cm, and the reaction time was 1 h. Under these conditions, tetrachloroethylene was more inert, and the yield of 1,1,2,2,2-pentachloroethyl thiocyanate was only 11% after 12 h.

Tetraphenylethylene and *trans*-ethylene 1,1-dithiocyanate appeared to be inert under these conditions; the latter was transformed into an equilibrium mixture of *cis* and *trans*-isomers.

The reaction of CISCN with vinyl bromide affords a mixture of 1-bromo-2-chloro- and 2-bromo-2-chloro-ethyl thiocyanates in 61% and 9% yields, respectively.

Regioisomeric products are also formed in reactions of CISCN with 1,1-dichloro- and trichloroethylenes. In this case, 1,1-dichloroethylene gives a mixture of adducts **129a** (55%) and **130a** (4%), and trichloroethylene forms products **129b** and **130b** in 52% and 6% yields, respectively.

R = H (a), Cl (b).

A comparison of the results of reactions of thiocyanogen with aliphatic and alicyclic alkenes under homolytic⁷⁹ and heterolytic⁴⁰ conditions was carried out. The yields of the products are higher in a radical reaction even after shorter reaction times. The reaction with many alkenes is completely selective, e.g., the reactions of alkenes **131** and **132** gives only α,β -dithiocyanates in 70%–98% yields.⁷⁹

R = H, Me, Bu, Bu^t, Me(CH₂)₇, Me(CH₂)₁₇, Cl, Br, Ph.

R = R' = Me; R = R' = Et; R = Ph, R' = Me.

The reaction of thiocyanogen with 3-methylbut-1-ene is less selective. In addition to 3-methylbutane-1,2-diyl dithiocyanate (63%), unsaturated compounds, viz., 2-methylbut-3-ene-2-yl isothiocyanate and 3-methylbut-2-enyl isothiocyanate, are formed.

As could be expected, the stereochemistry of the radical reaction differs from that of the heterolytic reaction. *trans*-β-Methylstyrene reacts with (SCN)₂ to form adducts **89** with *threo*- and *erythro*-configurations in 14% and 80% yields, respectively. The reaction with *cis*- and *trans*-but-2-enes is not stereoselective. A mixture of (±)- and *meso*-diastereomeric adducts **133** is formed from both isomers. The yields of the adducts are 37% and 57% for the *cis*-alkene and 39% and 60% for the *trans*-alkene.

The reaction of thiocyanogen with *cis*- and *trans*-stilbenes is also non-stereoselective. The products of this reaction will be discussed later.

The reaction with *cis*- and *trans*-hex-3-enes occurs in a more complex way. In addition to the adduct **19** (21%), (*E*)-hex-3-en-2-yl isothiocyanate **134** (48%) is formed as a mixture of (±)- and *meso*-diastereoisomers.⁷⁹ A somewhat different ratio of the products of this reaction is given by Maxwell *et al.*⁴⁸ Compounds **134** and **19** were isolated in 45% and 39% yield, respectively, upon thiocyanation of a *cis*-alkene, and in 60% and 33% yields upon thiocyanation of a *trans*-alkene. In addition, insignificant amounts of adducts with the isothiocyano group were obtained (6.5% and 14.5%, respectively, for *trans*- and *cis*-hex-3-enes).

The reaction of *cis*- and *trans*-2,5-dimethylhex-3-enes resulted only in products of the substitution of hydrogen at the allylic position, *trans*-2,5-dimethylhex-3-en-2-yl isothiocyanate and 2,5-dimethylhex-4-en-3-yl isothiocyanate, in ~29% total yield.⁷⁹

Unsaturated compounds of the type **135a–c** are formed as the main products in reactions of (SCN)₂ with cyclohexene and 4-methyl- and 4-*tert*-butylcyclohexenes (yields 40%–50%).⁷⁹ Compounds **135b,c** were obtained as a mixture of isomers, and their structure was not fully determined.⁷⁹ The reaction with *trans*-Δ²-octalin **29** occurs similarly to give a mixture of isomeric compounds of the type **136** (the structure was not determined, yield 45%) and the adduct **30** (40%).

R = H (**a**), Me (**b**), Bu^t (**c**).

The reactions occur much more slowly in the presence of oxygen and other inhibitors of radical processes. A mechanism

presented in Scheme 1 was suggested on the basis of stereochemical data.⁷⁹

Scheme 1

Allylic isothiocyanates are probably formed according to Scheme 2.⁷⁹ The primary reaction products include allylic thiocyanates, which isomerise rapidly into more thermodynamically stable isothiocyanates.

Scheme 2

An alternative scheme was suggested⁷⁹ according to which allylic isothiocyanates are formed directly through the reaction of the allylic radical with the nitrogen atom of thiocyanogen, which is more readily accessible sterically.

An increase in the number of methyl groups at the carbon atom of the double bond increases the time required for the reaction. This also leads to a considerable increase in the fraction of adducts of the type **6** in the reaction mixture.⁸⁰ This trend also holds for alkenes with phenyl substituents. For example, the reaction of *trans*- and *cis*-1,2-diphenylethylenes gives products with the isothiocyanate groups in 16%–18% yields as a mixture of *erythro*- and *threo*-1,2-diphenyl-2-isothiocyanatoethyl thiocyanates **139a**. However, the main reaction direction is the formation of 1,2-diphenylethane-1,2-diyl dithiocyanates **139b** (a mixture of (±)- and *meso*-forms) in 73% yield. The reaction of (SCN)₂ with 1,1-diphenylethylene and triphenylethylene gave 2,2-diphenyl-**140a** and 1,2,2-triphenyl-2-isothiocyanatoethyl thiocyanates **140b**, respectively;⁸⁰ α,β-dithiocyanates were not found in the reaction mixture.

Abstract. Chemical approaches to the elucidation of DNA template biosynthesis using DNA polymerases and reverse transcriptases, predominantly DNA polymerase I from *E. coli* and reverse transcriptase from HIV-1, are considered. Special attention is paid to the comparison of chemical modification and X-ray structural analysis data as well as to quantitative aspects of the interaction of DNA polymerases with templates, primers, and nucleoside 5'-triphosphates. New versions of a catalytically competent labelling method developed in the course of investigation of these enzymes are described. The data obtained in the analysis of replication complexes using primer analogues with photoreactive groups are presented. The bibliography includes 98 references.

I. Introduction

Some general problems concerning the application of chemical approaches to the study of the mechanism of template biosynthesis of nucleic acids and the main results obtained in the study of enzymes that catalyse RNA biosynthesis (transcription) by chemical methods have been reviewed.¹ The present review is devoted to the application of chemical methods to the study of DNA biosynthesis, namely, its replication and reverse transcription.²

The main chemical event in this process, *viz.*, the elongation of the polynucleotide chain, in the case of DNA polymerases is fully identical with that for RNA polymerases considered previously.¹ A nucleoside triphosphate (pppN_i) complementary to the translatable element pN_i of the template (its role is played by single-stranded DNA) phosphorylates the 3'-OH group of the 3'-terminal nucleotide residue of the growing DNA chain. It is in this way that the nucleotide residue is transferred from the triphosphate to

the 3'-OH group of the growing polymeric chain; therefore the enzyme represents a nucleotidyl transferase.

where p is the orthophosphate residue; N_i and N_i are the nucleoside residues in the product and the template, respectively, and *i* is the ordinal number of the residue in the polynucleotide chain starting from the 5'-end of the product and the 3'-end of the template, respectively.

However, this is virtually the last point where the similarity between DNA polymerases and RNA polymerases ends. RNA polymerases interact with double-stranded DNA, which are temporarily unwound under the action of this very enzyme to form a non-extended unwound region (protrusion). One of the unwound strands (on which transcription occurs) becomes involved in the selection of a substrate in the active centre. If the replication is accomplished by DNA-dependent DNA polymerases, the double-stranded DNA is first unwound by a special system mentioned below. DNA polymerase is not directly involved in DNA unwinding.

Transcription begins at a predetermined site of the template and requires preliminary binding of the enzyme in the region where the transcription begins (the promoter region). Following the formation of a complex with an enzyme and specific transcription factors at the required region of DNA subject to transcription the process is initiated, *i.e.*, the synthesis of a dinucleotide occurs. It should be noted that the first dinucleotide residue retains a triphosphate group. Initiation of DNA synthesis in living organisms always begins with the synthesis of a ribooligonucleotide primer the 3'-terminal OH group of which serves as an acceptor of deoxyribonucleotide 5'-phosphate. It is not until this process has been completed that the synthesis of a new DNA chain begins. The 3'-terminal deoxyribonucleotide fragment now acts as a primer. A special enzyme, primase, in prokaryotes and eukaryotes is responsible for the synthesis of a ribooligonucleotide

D G Knorre, N V Kudryashova, O I Lavrik Novosibirsk Institute of Bioorganic Chemistry, Siberian Branch of the Russian Academy of Sciences, prosp. Akad. Lavrent'eva 8, 630090 Novosibirsk, Russian Federation. Fax (7-383) 235 16 65. Tel. (7-383) 235 64 61 (D G Knorre)

primer; therefore the primary product is a hybrid oligonucleotide, which has a ribooligonucleotide at its 5'-end.

The region where the direct chemical conversion takes place contains a complex of the 3'-terminal nucleotide of the primer with a complementary nucleotide of the template, the protruding single-stranded fragment of the template and the selected substrate. Therefore, it makes no difference whether we deal with an exogenous primer or the terminus of a newly synthesised strand.

In the case of RNA polymerases, the product is a single-stranded RNA fixed by complementary interactions to the strand of the template subjected to transcription only at its 3'-end. In the case of DNA polymerases, a duplex is formed, which is preserved in biological systems up to the beginning of the next replication cycle. In this context, the range of problems that can be solved by chemical methods in respect of DNA polymerases differs from that for RNA polymerases described in the review cited.¹ It is also noteworthy that X-ray data about the spatial structure of DNA polymerases and their complexes with templates and substrates are now more abundant. Therefore, it is expedient to consider the large body of experimental results concerning the chemical (including affinity-based) modification of DNA polymerases in relation to the X-ray data available. Much of the above can be said of the enzymes responsible for reverse transcription, *i.e.*, to RNA-dependent DNA polymerases (reverse transcriptases).

While considering DNA polymerases, special mention should be made of two groups of enzymes differing in their biological functions. One of them is responsible for the synthesis of new DNA molecules, which occurs *via* separation of strands of the parent DNA and the formation of daughter replicas on each of the separated strands. This results, with the accuracy of inevitable errors, in the formation of two double-stranded structures that are identical with the original one. However, this process requires the participation of several additional enzymes and proteins. The unwinding of the double helix is effected by enzymes called helicases. They function in the branching region of the original double helix, namely, in the replication fork. The recombination of the two strands is prevented owing to their binding to a special protein, most commonly referred to as the SSB (single strand binding) protein. Continuous synthesis of a complementary chain towards the replication fork takes place on one of the strands with a 5' → 3' orientation from the replication fork. This strand is usually named the leading strand. The synthesis on the second strand can proceed only in the direction away from the replication fork, and a new initiation must take place at certain intervals of time with the liberation of the template. In other words, the synthesis of a new RNA primer, which is further elongated in the direction away from the replication fork, takes place. Thus, the fragments of the daughter strand with a ribonucleotide at the 5'-end (Okazaki fragments) are the products of synthesis on this lagging strand. A hybrid DNA-RNA duplex is formed at the primer site. Its RNA fragment must be removed from the final replication product. This is achieved, at least partly, with a special enzyme, RNase H, which catalyses the hydrolysis of ribooligonucleotides within this hybrid duplex. The preceding Okazaki fragment can then be elongated with DNA polymerase to reach the 5'-end of the second chain. As a result, the lagging daughter strand is formed with ruptures called nicks. Linking of 5'-phosphate with the 3'-OH group of the preceding fragment requires yet another enzyme, DNA ligase, which catalyses the formation of a phosphodiester bond between these two groups. Thus, a minimum set of replication enzymes and auxiliary proteins includes DNA polymerase itself, helicases, the SSB protein, RNase H, and DNA ligase.

As a matter of fact, this set is even greater. An important feature of the replication process is its processivity. After elongation, the 'template-elongated primer' system is not separated from the enzyme. Instead, a new encoding element of the template and the 3'-end of the elongated primer are transposed relative to the enzyme in such a way that they appear in the active centre of the enzyme. There is a large body of evidence that the processivity is

provided by special auxiliary proteins that consolidate the enzyme complex with the template-primer duplex. These proteins are called 'clamps'.³

The second group of DNA polymerases cannot synthesise complete daughter replicas, but they are necessary to fill short gaps that often appear on one of DNA strands. The classical example of such gaps is the excision of damaged regions of one of DNA strands by special enzymes that play an important role in restoring injured sites (DNA repair). Therefore, DNA polymerases pertaining to this group are often regarded as DNA repair enzymes, although their functions are hardly confined to repair. DNA polymerase I from *E. coli* and human DNA polymerase β are the most well-studied enzymes of this group. The spatial structure of these two enzymes has been established by X-ray structural analysis.

II. The main types of affinity reagents used for the study of replication and reverse transcription

Application of affinity-based modification to the study of enzymes is particularly efficient in two cases. First, when it is necessary to determine the position of a site(s) of modification of an enzyme by a reactive substrate or effector analogue, which points either to a subunit or a region in the protein molecule that interacts with the substrate or the effector. Second, when it is necessary to determine the affinity of a substrate or a cofactor for the protein from the data on the competition between the reagent and the substrate (or the cofactor).⁴ The second case will be considered in more detail in Section V.

DNA polymerases and reverse transcriptases interact with the template, the primer, and deoxynucleoside 5'-triphosphate (further referred to as dNTP). In the case of DNA polymerases, the strands of a double-stranded DNA are first unwound by helicases. Thus, single-stranded DNA serves as a template for replication. There is every reason to believe that reactive derivatives of DNA modify the enzyme at the binding site of the template.

One of the strands in double-stranded structures corresponds to the template, and the other one to the primer. If a complex of two DNA fragments has both a double-stranded and a hanging one-stranded element and the shorter fragment at their junction has a free 3'-OH group, it is this fragment that functions as a primer. Complex 1 is an example which can be useful for further consideration:

1

Apparently, it is the upper strand in this complex that plays the role of a primer. However, the situation with dNTP analogues is not so unambiguous. Even in the framework of a simplified scheme implying the existence of distinctly separated binding sites for a template, a 3'-terminal fragment of the template, and a dNTP, a dNTP analogue will not necessarily form a complex with the binding site of the substrate. It will be shown later (see Section V) that dNMP and dNDP also possess affinity for the binding site of the template. As a result, modification of an enzyme by such an analogue will not allow the unambiguous assignment of the modified region of the protein to the binding site of dNTP because it may be the binding site of the template as well.

Introduction of reactive groups into dNTP can be easily carried out at the γ -phosphate⁵ *via* nucleoside 5'-trimetaphosphate. Using this route, derivatives containing 4-(*N*-2-chloroethyl-*N*-methylamino)benzylamine,^{6,7} imidazole,^{8,9} and *p*-azidoaniline residues¹⁰ were obtained. In the case of alkylating and phosphorylating derivatives, the inactivation proceeded only in the presence of a template-primer complex. This can be regarded as evidence in favour of analogue binding in the substrate-binding site.⁶⁻⁹ In the case of a photoaffinity reagent (*p*-azidoaniline derivative), inactivation was also observed upon irradiation in the absence of the complex, but its presence enhanced inactiva-

tion.¹⁰ A wide variety of dNTP analogues with a photoreactive group in the heterocyclic base have been recently synthesised. Derivatives containing a photoreactive group at position 4 of cytosine, at position 5 of uracil (dTTP analogues), and at positions 2 and 8 of adenine have been described and tested.^{11–20} Table 1 lists the presently known dNTP containing reactive groups in their heterocyclic bases. It is important to mention that some of these

compounds can act as substrates for DNA polymerase. This property makes it possible to use these analogues for specific photoaffinity-based modification of DNA polymerases.

Photoreactive analogues must possess good photochemical characteristics that allow their irradiation at the wavelengths that cause no photoinactivation of proteins and nucleic acids.¹¹ At the same time, these analogues manifest good substrate properties in

Table 1. Derivatives of dNTP containing photoreactive groups in the heterocyclic base.

Photoreactive group	Position of the group in the heterocycle	Substrate properties	Modification (inactivation)
N ₃	Ade-8	–	Modification of Ile765 and Tyr766 in DNA polymerase I from <i>E. coli</i> in the absence of a template–primer duplex ¹⁷

reactions catalysed by DNA polymerase α from human placenta,²¹ reverse transcriptase from HIV,^{13–16} and DNA polymerase β .¹² These substrates can act as terminators by preventing further elongation of α primer after being incorporated into its 3'-end. In other cases, the presence of a modified residue at the 3'-end does not prevent the addition of the next unit, *i.e.*, further elongation of the chain. These derivatives can be used for conducting the polymerase chain reaction (PCR), which yields a duplex with a large number of reactive groups.²² The corresponding characteristics of reactive dNTP derivatives are listed in Table 1.

Despite the apparent similarity of analogues containing reactive groups at the same positions, their properties as affinity reagents may vary substantially. Thus three dATP analogues containing 4-N₃C₆H₄CH₂S, 4-N₃C₆H₄SS, and 2-NO₂-4-N₃C₆H₃S groups at position 2 of adenine have been described.¹⁹ It was found that only the first of them could inactivate the Klenow fragment of DNA polymerase I upon irradiation (see Section III.1). It should be noted that inactivation does not require the presence of a template–primer duplex. Modification reaches saturation when one residue is incorporated into the enzyme. Although the modifying reagent is based on dATP, its competitive substrate is dTTP. Moreover, this modification is inhibited by the poly(dA)–oligo(dT) duplex, which may attest to the binding of the analogue in the template region of the enzyme.¹⁸

Among other nucleotide analogues having a reactive group in their carbohydrate fragment, 2',3'-epoxyATP has been studied in more detail. In the presence of the duplex **1**, the enzyme was inactivated in accordance with the classical law of affinity-based modification;⁴ its K_d was 21 μ M and the inactivation rate constant was 0.021 s^{−1}. The 2',3'-epoxyAMP residue was incorporated into the primer simultaneously with inactivation. Naturally, the residue incorporated played the role of a terminator. It was shown²⁵ that the duplex carrying this residue at its terminus did not modify the enzyme; its inhibitory effect is due to the enhanced stability of a triple complex with the enzyme.

Sometimes, DNA derivatives designed for modification of DNA-binding sites of an enzyme can be obtained by direct introduction of a reactive group into the DNA molecule or its fragment. Thus the decanucleotide d(pT)₂pC(pT)₇ modified at the N(3) atom of the cytosine residue with *cis*-aquahydroxodiammineplatinum, *i.e.*, containing the *cis*-{(NH₃)₂Pt[N(3)-dC](OH)} fragment, was used as an affinity reagent for the matrix site of DNA polymerase α from human placenta and the Klenow fragment of DNA polymerase I.^{26–28} Incubation of this decanucleotide with the enzyme results in gradual inactivation of the latter. This inactivation is competitively inhibited by deoxyoligonucleotides of various lengths and structures.

Since both the template and the primer have sufficiently extended contacts with the enzyme, when used as the affinity reagents (DNA analogues), it is especially desirable to obtain a series of derivatives with a reactive group at different predetermined positions of DNA. Two main approaches to the synthesis of these derivatives have been developed. One of them is based on the introduction of a reactive group during the synthesis of the corresponding oligonucleotide. Naturally, this approach can be used only for derivatives with a reactive group in their heterocycles. One can also synthesise DNA or an oligonucleotide derivative containing a group where the reactive residue will be introduced in the final stage of the synthesis. As an example, we can mention the synthesis of a series of primer analogues with a photoreactive group at different positions relative to the 3'-end of the growing chain.²⁹ Thus a thymidine analogue containing a (CH₂)₃NHCOCF₃ residue at position 5 of uracil was introduced instead of thymidine into a specific position of the primer during the synthesis.²⁹ After removal of the trifluoroacetyl group by mild alkaline hydrolysis, the primer was treated with 5-azido-2-nitrobenzoic acid *N*-hydroxysuccinimide ester. Then the modified primer was hybridised with DNA from phage M13 used as a template and elongated by one unit with DNA polymerase from

phage T4 using [α -³²P]ddATP as a substrate. The final procedure sharply diminishes the risk of cleavage of the 3'-terminal residue due to 3' → 5' exonuclease activity inherent in the enzyme and allows simultaneous introduction of the radioactive label into the primer. This step is essential for the affinity-based modification with this compound. Using this approach, primers with a photoreactive arylazide group at positions 3, 9, 13, 18, 22, 27, and 46 relative to the 3'-terminal fragment have been obtained.²⁹ When the corresponding template–primer duplex is used, the reactive residues can be introduced into the specific positions of the primer by the enzymic method using dNTP analogues bearing a reactive group as DNA polymerase substrates.^{12, 14, 15, 23}

The second approach to the synthesis of DNA with a predetermined position of the label can be exemplified by the synthesis of a series of derivatives of oligonucleotide primers with different positions of the fluorescent label relative to the 3'-end of the primer. A set of such derivatives were obtained³⁰ from one oligonucleotide with a thymidine analogue U* at a definite position; this analogue contained the fluorescent 5-dimethylaminonaphthalene-1-sulfonyl group at position 5 instead of the methyl group. The starting duplex had the structure **2**.

2

The structure of the template allowed the elongation of the primer in the presence of DNA polymerase, by one unit (compound **3**) with dCTP, by three units (compound **4**) with dCTP + dATP, and by six units (compound **5**) with dCTP + dATP + dGTP. The fluorescent label was translocated at a certain distance from the enzyme active centre.

3

4

5

In some experiments, it was possible to use a hairpin structure with a hanging single-stranded fragment instead of a template–primer duplex. Such a structure mimics the template–primer duplex and the short fragment of the hairpin stem can be elongated in the presence of DNA polymerase. When photoreactive dNTP are used for elongation, a photoreactive stem mimicking the photoreactive duplex can be obtained.

This approach was used in particular for the synthesis of a hairpin containing several residues of bromodeoxyuridine (compound **6**).³¹

6

*A is the radiolabelled dAMP residue,

B is 5-bromodeoxyuridine;

(a) DNA polymerase, [α -³²P]dATP + BrdUTP (BrdUTP is 5-bromodeoxyuridine triphosphate).

This hairpin structure has been used for photoaffinity-based modification of DNA polymerase γ (mitochondrial DNA polymerase) from frog (*Xenopus*) and DNA polymerase ϵ from calf thymus.³²

III. Study of the interaction of DNA polymerases with templates, primers, and nucleoside 5'-triphosphates using group-specific and affinity-based chemical modification. Structural aspects

1. DNA polymerase I from *E. coli* and the Klenow fragment

This enzyme is made up of one polypeptide chain (M_r is 103 kDa, 928 amino acid residues) and forms three domains. The N-terminal domain (1–330) comprises an active centre for 3' → 5' exonuclease activity and catalyses stepwise hydrolysis of nucleotides from the 5'-end. The central domain (residues 331–514) contains an active centre for 5' → 3' exonuclease activity and catalyses the cleavage of the 3'-terminal nucleotide from the growing polynucleotide chain. It is noteworthy that this cleavage is directed predominantly against the residue that is not complementary to the template and thus prevents preservation of an erroneously incorporated monomer. The 515–928 domain contains the DNA polymerase centre itself.³³ Mild treatment of the enzyme with a protease (subtilisin) results in the splitting of the 5' → 3' exonuclease domain to form the so-called Klenow fragment, which retains only two activities and which is now the subject of the most active studies.³⁴

X-Ray structural analyses of the Klenow fragment and of its complexes with a model DNA duplex and with dCTP have been carried out with a resolution of 3.9 Å (Fig. 1).^{35,36} This figure clearly demonstrates the presence of both domains. The N-terminal 5' → 3' exonuclease domain is formed by seven α -helices A–G and four β -structures 1–4. The C-terminal polymerase domain of the Klenow fragment is formed by three subdomains, which have been termed the 'palm', the 'fingers', and the 'thumb' by anatomic analogy with the right hand (Fig. 1). The 'palm' domain consists

of six β -structures 7–9 and 12–14, the 'thumb' domain comprises four α -helices H–K, and the 'fingers' domain is made up of five α -helices L–P. The regions of the other two subdomains that are the most remote from the 'palm' come together to form a cleft where DNA binding takes place. The bottom of this cleft contains carboxy groups of two aspartic acid residues (Asp705, Asp882) and one glutamic acid residue (Glu883) (Fig. 2), which are supposed to coordinate the triphosphate group of the substrate through Mg^{2+} ions. Magnesium ions play an important role in the main catalytic process, being responsible for the transfer of the monophosphate residue to the 3'-OH group of the primer. Similar triads of dicarboxylic acid residues were also detected in other DNA polymerases the spatial structures of which have been studied. Special mention should be made of DNA polymerase β ; its structure in the complex with a dCTP and dATP was established with high resolution both in the presence and in the absence of a template–primer complex.^{37,38} The most detailed information about the contact sites of the template–primer complex with the enzyme was obtained by Modak *et al.*³⁹ These authors performed direct photo-cross-linking of two [5'-³²P]-labelled oligonucleotides, containing 25 and 37 monomeric units the 3'-termini of which formed a hairpin structure with the enzyme. The stem of the hairpin mimicked the template–primer complex. The main modification involved the peptide fragment corresponding to the DNA polymerase fragment 759–775 at Ile765, Tyr766, Ser769, and Phe771 residues in the O helix of the 'fingers' domain.

To obtain information about the binding site for the substrate, a series of investigations were carried out using reactive derivatives of dNTP. These studies began with direct photo-cross-linking of the enzyme with dTTP by irradiation of the enzyme–substrate complex with light at $\lambda = 254$ nm.⁴⁰ It was shown that photoaddition occurred at the His881 residue. As can be seen from

Figure 1. A scheme of the three-dimensional structure of the Klenow fragment of DNA polymerase I from *E. coli*. The α -helical regions of the polypeptide are shown as cylinders; the β -pleated sheet, as ribbons, with arrows indicating the direction of the chain in the folds from the N- to the C-end. The arrows indicate the amino acid residues detected by affinity-based modification.

Fig. 1, this residue is localised between the 12th and 13th β -structures of the 'palm' subdomain. When the Klenow fragment was modified with 8-azido-dAMP, photoaddition occurred predominantly at Tyr776 localised in the α -helix of the 'fingers' subdomain.¹⁷ It is interesting to note that the same tyrosine residue was modified upon irradiation of the enzyme in the complex with the template and the primer analogue 7.⁴¹

3' d(AGCGTCGGCAGGTTCCCAA)
5' d(TCGCAGCCGU*)

7

U* is the residue of the dTMP analogue containing a 5-azido-2-nitrobenzoyl group linked *via* a spacer, (CH₂)₃NH, at position 5.

This coincidence shows that Tyr766 is localised directly in the catalytic centre. Evidence in favour of the presence of a tyrosine residue in the catalytic centre can also be derived from the results of chemical modification of the Klenow fragment by *N*-acetylimidazole, a specific reagent for the OH group of tyrosine. This modification was accompanied by a loss of the enzymic activity. The enzyme could be protected from inactivation only in the presence of a complete template–primer–dNTP complex. The latter must be complementary to the template used.^{4,42}

Even this example shows that chemical modification data do not fit into a simplified pattern of statistical distribution of substrate binding sites. Comparison of these data with the spatial structure of DNA polymerase obtained from X-ray analysis shows that the distance between the Tyr766 residue modified by 8-azido-dAMP and the His881 residue modified by dTTP is rather large (9 Å). This suggests that the orientation of the latter is different in different nucleotides, at least in the binary enzyme–dNTP complex.

In addition to dNTP analogues, other reagents, such as pyridoxal 5-phosphate (which often behaves as a nucleotide analogue) and 5'-*p*-fluorosulfonylbenzoyl adenosine (the size of the FSO₂Bz-fragment of which is close to that of the triphosphate group), were used for modification of DNA polymerase (the Klenow fragment). In the former case, the modification affected Lys758,⁴³ in the latter case, Arg682.⁴⁴ It should be noted that the latter modification was performed in the presence of a template–primer complex modelling the complex of the Klenow fragment with the template–primer and dNTP.

If one assumes that the residues thus revealed are directly related to the active centre of the enzyme, it would be reasonable to suppose that the positively charged residues of both Lys758 and Arg682 will interact with the triphosphate fragment of dNTP. However, this interpretation, too, is inconsistent with the enzyme structure obtained from X-ray analysis. Indeed, Lys758 is localised in the *O* helix pertaining to the 'fingers' domain, while Arg682 is located in the 'thumb' domain, *i.e.*, in the opposite side of the cleft (Fig. 1). At the same time, the triad of amino dicarboxylic acid residues localised in the 'palm' domain is the most probable participant in the binding of the triphosphate fragment. Moreover, these assumptions are at variance with the results obtained by photo-modification of the Klenow fragment with 2-(4-azidophenacylthio)-dATP.¹⁸ It was found¹⁸ that the modification affected the Asp732 residue localised in the helix *N*.

When conducting a simultaneous analysis of the X-ray and chemical or affinity-based modification data, one should bear in mind that these results may not be adequate from the theoretical standpoint. X-Ray analysis is carried out on crystalline preparations and gives an optimised structure. It is obvious, however, that the conformation of the protein backbone may fluctuate to some extent, and the crystal conformation deduced from X-ray analysis will not necessarily be optimum for the binding of dNTP or its triphosphate fragment. In an even greater degree this applies to the results of chemical modification. It was found⁴⁵ that the thermodynamically optimum structure of an affinity reagent–enzyme complex will hardly provide the optimum mutual orientation of the reactive fragment and the amino acid residue of the target. The use of the molecular mechanics method for the analysis

of the process occurring in the duplex formed by complementary oligonucleotides one of which carries the *N*-2-chloroethylamino group showed⁴⁶ that the energetically optimum conformations do not provide sufficient approximation of the heterocycle to be alkylated and the intermediate ethyleneimmonium cation that formed from the original alkylating group. To provide the transition from the thermodynamically optimum to the kinetically optimum structure, it is necessary to overcome a certain energetic barrier. The term 'store-conformation' has been introduced to describe energetically minimised structures able to pass (easily but not freely) to a kinetically optimum conformation.⁴⁶ Therefore, a small inconsistency between the X-ray and chemical data, which does not exceed several Angström, can only reflect the conformational differences between the structure of the enzyme with the optimum arrangement of the substrate and of the modifying agent.

It was shown⁴⁷ that the treatment of the Klenow fragment with [7-¹⁴C]phenylglyoxal, which specifically reacts with the arginine residues, inactivates the enzyme. Incorporation of four residues of the reagent into the protein gives a 95% inactivation. Since each arginine residue can react with two phenylglyoxal molecules, this implies that the inactivation occurs upon modification of two arginine residues. Only the template–primer complex can protect the enzyme from inactivation by phenylglyoxal. The main site of modification is Arg841. This residue is localised in the *Q* helix near Tyr766, Lys758, and His881, which, as mentioned previously, take part in the interaction with dNTP or their analogues. The position of amino acid residues within the three-dimensional structure of the Klenow fragment of DNA polymerase I from *E. coli* revealed by affinity-based modification is shown in Fig. 1. The triad of dicarboxylic amino acid residues is marked by black circles in Fig. 2.

Figure 2. The position of the triad of dicarboxylic amino acids in a three-dimensional structure of the Klenow fragment of DNA polymerase I from *E. coli*.

An unexpected result was obtained in the study of the structure of the Klenow fragment of DNA polymerase I. It was found that the active centre where the elongation of the primer takes place and the site of the 3' → 5' exonuclease activity are at a large (about 30 Å) distance from one another. According to the generally accepted and well-rationalised experimentally viewpoint concerning the centre of the 3' → 5' exonuclease activity, the newly attached 3'-terminal fragment must undergo 'testing' in the exonuclease centre after each elongation act. This requires the translocation of the terminal fragment of the primer by several units. This problem was studied using a template–primer duplex 8 with covalently cross-linked chains as a model.⁴⁸

Here, the amino groups of the two cytosine residues are linked through an ethylene bridge. Such a cross-linking is achieved by introducing a cytidine analogue (instead of cytidine) containing a highly reactive three-membered ethyleneimine ring at position 4 into a matrix oligonucleotide. This analogue easily alkylates an opposite amino group of the primer chain. It was found that only the 5th (starting from the cross-linking site) dTMP residue of the primer can be split off by exonuclease. Splitting of the 4th residue is strongly hindered (the rate constant for this reaction is two orders of magnitude lower than that for the 5th residue). At the same time, this shortened cross-linked primer, the 3'-OH group of which is at a distance of four nucleotides from the cross-linking site, is still a good substrate for elongation. Hence, the difficulty in separating the strands affects only one of the enzyme activities. This result can be regarded as an experimental proof that the 3'-terminal fragment of the strand that is synthesised should be translocated at a large distance for correction.⁴⁸

Some data about the contact sites of the enzyme and nucleic acid components were obtained with the use of fluorescent methods. A series of duplexes 2–5 were used to study the contact sites of a template–primer duplex with the enzyme.³⁰ These duplexes contained a dTMP analogue with the fluorescent 5-dimethylaminonaphthalene-1-sulfonyl group (instead of the methyl group) at position 5 introduced into a predetermined position of the primer component. Thus the fluorescent label was set aside at a certain distance (which was different for different duplexes) from the enzyme active centre. The fluorescence lifetime and the inner rotation correlation time measured for all the samples showed that at least six primer residues interact with the enzyme. The label becomes more remote from the 3'-end of the primer, some changes in its fluorescent properties were observed, which reflect the changes in both the label accessibility for the solvent and its closeness with the protein.

Introduction of fluorescent labels into the protein, DNA, and dNTP was used to calculate the distances between the specific site in the enzyme, DNA, and dNTP using the Förster theory based on the resonance energy transfer. 4-Amino-7-nitrobenzo-2,1,3-oxadiazole can be introduced into the Klenow fragment as an energy acceptor at Cys907 through the CH₂C(O)OCH₂CH₂ spacer. A similar acceptor can be introduced into position 5 of uracil through the trimethylene spacer, and a DNA fragment can be synthesised on the basis of the thymidine fragment thus obtained. The fluorescent 5-aminonaphthalene-1-sulfonate group can be introduced as an energy donor into position 5 of uracil through the SCH₂C(O)NHCH₂CH₂ spacer. This can serve as a basis for obtaining a mononucleotide, a nucleoside triphosphate, and a DNA fragment carrying a donor group. This study made it possible to determine the distances between dNMP, dNTP, DNA, and Cys907 as well as the distance between DNA and dNMP.⁴⁹

Studies of the active centres of other DNA polymerases by affinity-based modification are still in their infancy. Human DNA polymerase β for which high resolution X-ray data are now available seems to be a tempting object of investigation.^{37,38} An attempt was made to localise the dNTP-binding site by modification with 8-azido-ATP and 5-azido-dUTP.⁵⁰ However, these experiments were carried out in the absence of the template–primer complex. This may account for the modification of the 8 kDa subdomain involved in the interaction with single-stranded DNA.⁵⁰ Recently, catalytically competent labelling of DNA polymerase β was performed using FAB-dCTP.¹² Given that the site(s) of modification are established, they can be more reliably associated with the dNTP-binding site.

2. Reverse transcriptases

Enzymes responsible for reverse transcription, *i.e.*, catalysing template biosynthesis of DNA on RNA templates, are characteristic of a large group of viruses called retroviruses. Some investigations based on the use of chemical methods were carried out with reverse transcriptases of the avian myeloblastosis virus (AMV) and the Moloney murine leukemia virus (MuLV). Identification of reverse transcriptase in the human immunodeficiency virus (HIV-1) has given a strong impetus to intensive studies of these enzymes. Reverse transcriptase is regarded as a promising target in the fight against AIDS; therefore this section will largely deal with the HIV-1 enzyme.

Normally, reverse transcriptase is made up of two subunits designated according to their molecular weights (in kDa) as p66 (555 amino acid residues) and p51 (446 amino acid residues). The smaller subunit (p51) represents a shortened subunit of p66 devoid of the fragment 447–555.^{51–53} This enzyme catalyses several reactions. Its functioning begins with reverse transcription of genomic viral RNA expressed in the virion by two molecules, 9750 nucleotides each.⁵⁴ Like all other DNA polymerases, this enzyme requires the presence of a primer. Host-cell tRNA is a natural primer and human tRNA^{Lys,3} is a primer for the HIV-1 enzyme. In a definite (final) stage of reverse transcription, which results in the formation of a minus-replica of DNA, the enzyme begins to function as an ordinary DNA polymerase by forming a plus-strand of DNA from the information contained in the minus-strand. The formation of the minus-strand is accompanied by gradual destruction of the genomic viral RNA under the action of another activity inherent in the enzyme, namely, that of RNase H. It is this enzymic activity that is present in the 447–555 domain, which is absent from the p51 subunit.^{53,55} In principle, homodimers made up of identical subunits can be obtained under special conditions instead of the p66/p51 heterodimer.

X-Ray structural analysis of the heterodimer revealed⁵⁶ that the p66 subunit consisted of several subdomains. They form a structure similar to that of the Klenow fragment of DNA polymerase I represented by the 'fingers', 'palm', and 'thumb' subdomains. The residues corresponding to these subdomains, which are linked to the C-terminal subdomain responsible for the RNase H activity through a linker subdomain, were identified in the primary sequence of reverse transcriptase.⁵⁶ The 'palm' subdomain contains three Asp residues (110, 185, 186) that seem to play the same role as the corresponding triads in DNA polymerases I and β.

The first three domains form a polymerase domain which, like the Klenow fragment, has a cleft for the binding of the template–primer duplex. However, unlike the Klenow fragment, the polymerase domain is formed by the N-terminal part of the polypeptide chain but not by its C-terminal part.⁵⁷

The contact site of the duplex with the enzyme was studied in most detail using footprinting with the •OH radicals.⁵⁸ Several probes were prepared on an artificial template–primer duplex (its central part is shown below) by elongation of the primer with the corresponding dNTPs and one ddNTP.

Using this approach, a series of duplexes with the terminating fragment at a distance of 1, 4, 10, and 19 units from the original fragment were obtained. For example, the 10-nucleotide-shift was achieved by adding dATP, dGTP, and ddCTP to the duplex--enzyme mixture. Since the incorporation of the terminator occurs in the active centre of the enzyme, complexes with the duplex at the same position relative to the active centre but with different nucleotide environment were formed in all the cases studied. In all these cases the enzyme protected the sites from +3 to -15 on the template strand and the primer residues from -1 to -15 (the numbering is given relative to the terminator incorporation site). At the same time, the sites from -9 to -11 of the template and the sites from -8 to -10 of the primer are not protected. In addition, a pair with a strongly enhanced sensitivity to modification neighbours (with respect to the 5'-end of the primer) the sequence protected from the $\cdot\text{OH}$ radicals (Fig. 3). The dark area designates the regions in the primer and the template between positions +3 and -15 protected by the enzyme from free radicals. The hypersensitive spot is the site of enhanced cleavage of the template chain induced by changes in the template structure owing to the interaction of the HIV-1 reverse transcriptase heterodimer with the RNase H domain. The region of the duplex where this conformational change takes place is near the contact site for RNase H. It is therefore probable that it is the RNase H domain that induces a conformational transition in this region of the duplex. Similar, although not identical results were obtained in enzymic footprinting studies. Irrespective of the site where the synthesis is stopped by the terminator, the template residues from +7 to -23 and the primer residues from -1 to -25 are protected from DNase I. This site becomes accessible for the DNase attack at the junction of the regions forming the polymerase and RNase H centres (nucleotides -20 of both the template and the primer).⁵⁹

Figure 3. A scheme of footprinting with the hydroxyl radicals of the template and the primer chains.

One of the most intriguing properties of reverse transcriptases is the use of definite host-cell tRNAs as primers for reverse transcription. The 3'-terminal sequences of these tRNAs are always complementary to the site of the primer binding with genomic RNA. However, some other domains of this tRNA are also involved in the binding with both genomic RNA and the enzyme itself. Studies with *trans*-Pt[(NH₃)₂Cl₂] as a bifunctional cross-linking reagent⁶⁰ revealed that the anticodon loop of tRNA^{Lys,3} appears to be linked to reverse transcriptase of HIV-1. Using the same reagent, it was shown that cross-linking of the anticodon loop with reverse transcriptase of HIV-1 also takes place when tRNA is synthesised by transcription of the encoding gene by RNA polymerase from phage T7, which does not contain modified heterocycles, *viz.*, 5-methoxycarbonyl-

methyl-2-thiouracil and *N*-(2-methylthiopurin-6-yl)threonine. This implies that this interaction is not due to the presence of specifically modified heterocycles in the anticodon loop.⁶¹

In order to identify tRNA^{Lys} fragments that make contact with the enzyme, tRNA analogues with specifically incorporated 4-thiouridine residues were used.⁶² In most cases, irradiation of the enzyme-tRNA complex with light at $\lambda = 365$ nm resulted in the cross-linking of tRNA with the protein. It was found that in the case of tRNAs containing a photoactive residue at positions -1 and +16, *i.e.*, within the acceptor stem and the dihydrouridil loop, the cross-linking occurred exclusively with the p66 subunit. If the thiouridine residue was at position 36 (the anticodon loop), the cross-linking occurred with both subunits, although the reaction with p66 was predominant. When the thiouridine residue was at position 43 (the anticodon stem), no photo-cross-linking of tRNA with the enzyme took place. These results give an idea of which regions in the tRNA primer are in a direct contact with the enzyme.

Chemical modification with reagents specifically interacting with single-stranded sites of nucleic acids, *viz.*, dimethyl sulfate, *N*-cyclohexyl-*N'*-[2-(*N''*-methylmorpholinium)ethyl]-carbodiimide, diethyl pyrocarbonate,⁶³ made it possible to carry out a detailed analysis of the interaction of the primer binding site (PBS) of genomic RNA of HIV-1 and tRNA^{Lys}. The absence of or a drastic decrease in the level of modification of some particular sites of genomic RNA suggest their involvement in the formation of complementary nucleotide pairs. It was found that 18 nucleotide residues at the 3'-end of tRNA form a double helix with the 179-196 site of genomic RNA. The results obtained with the use of simpler unnatural systems, *e.g.*, poly(rA)-oligo(dT) duplexes, indicate that reverse transcription does not require such a complicated and specific primer. Nevertheless, the 3'-end of this primer not only corresponds to a definite site in viral genomic RNA, *i.e.*, fulfils the function of a primer, but also forms a complex with other fragments of tRNA and the template. The hexanucleotide fragment 33-39 of this primer, which forms an anticodon loop, is linked to the complementary 162-167 site of the template with a fall-out of one minor nucleotide from the two-helical site of the loop. The 40-47 site forms duplexes with the 140-143 and 158-160 sites of viral RNA.⁶³

Thus, the use of chemical methods for the study of reverse transcriptase of HIV-1 has made it possible to identify the regions of the template and the product located on the enzyme in the vicinity of its catalytic centre as well as the sites of the natural primer interacting with the enzyme and genomic RNA. The regions interacting with the primer were also established for genomic RNA.

The information obtained from the analysis of functionally important protein regions by chemical methods was more scarce and sometimes controversial. Of undoubted interest are the results obtained with affinity reagents and related to the distribution of modification sites between the subunits. Direct photo-cross-linking of dTTP with the enzyme occurs only on the p66 subunit.⁶⁴

The same results were obtained by photoaffinity labelling of the enzyme in the template (18-, 21-meric oligomers)-primer (12 units) complexes elongated with 4-thiouridine triphosphate⁶⁵ and with poly(dA)-oligo(dT) used as the primer-template and 2',3'-dideoxy-(5*E*)-[4-(3-trifluoromethyl-3*H*-diazirin-3-yl)styryl]UTP as a dTTP analogue.²⁰ Direct photo-cross-linking was performed⁶⁶ for the duplex formed by a 40-meric 5'-terminal fragment of genomic RNA and a 20-meric DNA primer. In this case, the primer was added exclusively to the p66 subunit. At the same time, after elongation of the primer to 40 nucleotides, the cross-linking occurred also with the p51 subunit. Presumably, this indicates the presence of a common pocket, which binds the primer and which is formed by both subunits of the enzyme.⁶⁶ In any case, it is obvious that the p51 subunit begins to interact with the primer at a sufficiently large distance from the enzyme active centre.

Similar results were obtained by Lavrik *et al.*⁶⁷ In these studies, the enzyme was irradiated with light at $\lambda = 266$ nm in the presence of [^{32}P]d(pT)₁₀ with or without a complementary template [poly(rA)] added; radioactivity was found only in the p66 subunit. At the same time, when the d(pT)₁₀ derivative containing a photoreactive residue of 2-nitro-5-azidobenzamide or β -alanyl-lamidoethidium linked by a phosphamide bond with the 5'-terminal phosphate was used, the photoinduced binding occurred with the both subunits. This can be interpreted as a result of remoteness of the photoreactive group from the enzyme active centre where the opposite 3'-terminal residue of the nucleotide has to be localised. At the same time, introduction of a dCTP analogue residue with a photoreactive azidoperfluorobenzoyl group linked with C(5) of cytosine through the spacer $\text{CH}=\text{CH}-\text{CH}_2-\text{NH}$ (AlFAB-dCTP), or with the amino group of cytosine through the spacer $\text{CH}_2-\text{CH}_2-\text{NH}$ (FAB-dCTP) to the 3'-end of the primer also results in cross-linking of the primer with both subunits upon irradiation.¹⁴

This change in the distribution pattern upon introduction of a relatively small fragment separating the photoreactive group and the primer shows that the p51 subunit is located near the catalytic site of p66. X-Ray data for an HIV-1 reverse transcriptase–DNA complex together with computer simulation suggest the involvement of the p51 subunit in the interaction between revertase and the template–primer complex.^{56, 57, 68}

Studies of reverse transcriptase of the avian myeloblastosis virus, which is also made up of two subunits, show their non-equivalence. This enzyme is used as a natural primer for tRNA^{Trp}. It was found⁶⁹ that tRNA^{Trp} oxidised with periodate at the 3'-terminal *cis*-diol group inactivates the enzyme. When the modification is not brought to completion, all the tRNA^{Trp} appears to be bound with only one of the two subunits designated as α . The latter is probably a p66 analogue of the HIV-1 enzyme because it contains all the activities inherent in this enzyme including that of RNase H.

Some studies provide evidence about the sites or regions of reverse transcriptase of HIV-1 that either interact with affinity reagents or are essential for manifestation of catalytic functions. In the above experiment with direct photo-cross-linking of the enzyme with dTPP, the main modification point was determined to be a Lys73 residue localised in the 'fingers' subdomain.⁶¹ In contrast, in the template (18–21 units)–primer (12 units) complex elongated with 4-thiouridine triphosphate, photoaffinity-based labelling was restricted to the peptide fragment 313–423.⁶² This fragment corresponded to the lower part of the 'thumb' subdomain and the linker domain. It was found also that modification with phenylglyoxal, which is specific for arginine, results in complete inactivation of the enzyme.⁷⁰ The presence of a template–primer complex prevents the inactivation; the Arg277 residue appears to be protected from modification. This residue is also present in the 'thumb' subdomain, but at its opposite end (relative to the peptide), and is modified with 4-thiouridine.

To establish the binding site for the primer, (pdT)₁₆ was directly cross-linked with a homodimer made up of two p66 subunits.⁷¹ Analysis of tryptic hydrolysates revealed that a peptide 288–307 localised in the upper part of the 'thumb' subdomain is the main binding site for oligo(dT). Fragments Leu289–Thr290 and Leu295–Thr296 were identified as the most probable sites of modification. This region also comprises a polynucleotide-binding domain for the homodimer of reverse transcriptase of HIV-1.⁷²

It should be noted that some photoactivated groups in the primer modify both the protein and the template DNA, which results in the cross-linking of the primer and template chains. This phenomenon was observed in enzyme–template–primer systems of reverse transcriptase of HIV-1 and of a DNA polymerase α complex with primase when primers with a FAB-dCTP residue were used.^{13, 14, 21}

IV. Catalytically competent labelling of DNA polymerases

The method of catalytically competent labelling of template enzymes was first actively applied to the study of DNA-dependent RNA polymerases. The main principle of this method consists in chemical modification of the enzyme by some unlabelled reactive analogue followed by elongation of a covalently attached substrate with a second substrate bearing a radioactive label. In this case only those residues of the first substrate analogue will contain the radioactive label the orientation of which allows them to take part in subsequent catalysis due to covalent binding. These residues are usually referred to as 'catalytically competent'.^{1, 73}

For the first time, this principle was applied to DNA polymerase I.⁷⁴ Oligothymidylate analogues with an alkylating group linked to the 5'-terminal phosphate were used as affinity reagents (Fig. 4). Affinity-based modification of DNA polymerase I was carried out by covalent binding of a reactive thymidylate analogue in the presence of a poly(dA) template. After covalent binding, a radioactive label was introduced by elongation of oligothymidylate with [α - ^{32}P]dTTP. This approach made use of the catalytic competence of the oligonucleotide primer covalently attached at its 5'-end. The most intense labelling was observed in the peptide Asn832–His928 located in the polymerase region of the enzyme. As the 3'-OH group of the primer must be in the active centre of the enzyme during catalytically competent labelling, more detailed localisation of the binding site at the 5'-end of the primer might allow establishing of the orientation of the primer relative to the enzyme. The orientation of the primer complex with DNA polymerases is currently a matter of vivid discussions.^{38, 75}

Figure 4. A scheme of highly efficient affinity-based modification of DNA polymerase I from *E. coli*: p^* is the radiolabelled phosphorus atom; X–pTpTpTpT is the affinity reagent; X is the affinity reagent residue covalently bound with the enzyme; E is the enzyme.

An analogous approach was used⁶⁷ in a study of the contribution of revertase subunits to the interaction with the template–primer complex. It is interesting to note that covalent binding of the primer at its 5'-end did not prevent subsequent attachment of at least four thymidine residues to the growing chain. Therefore, one should not rule out the possibility of translocation of the enzyme relative to the template–primer duplex. This system appears to be an interesting model for translocation studies. The same result was obtained for primase from *E. coli*⁷⁶ where the covalent attachment of adenosine trimetaphosphate followed by elongation with [α - ^{32}P]GTP was used for competent labelling. Elongation with [α - ^{32}P]GTP, together with other dNTP, yielded tetra- and pentanucleotides.

In this case, too, the covalent binding did not prevent several elongation acts to be accomplished.

A new version of catalytically competent labelling was carried out using photoreactive analogues of dNTP with arylazido groups linked with a heterocyclic base of the nucleotide through spacers. In contrast with the above-described versions of catalytically competent labelling where immobilisation was carried out at the 5'-end of a monomer or an oligonucleotide, the triphosphate group of dNTP does not take part in substrate immobilisation on the enzyme and thus remains unmodified. Hence, it can participate in the reaction with the 3'-OH group of the primer added.

This possibility was studied using a series of photoreactive analogues the substrate activity of which had been tested beforehand (see Table 1, Refs 11, 12, 14–16, 23). It was found that in all the cases studied the dNTP analogues covalently linked to DNA polymerase through a heterocyclic base could interact with the template–primer complex. In the presence of [^{32}P] phosphate at the 5'-end of the primer, this resulted in competent labelling of the binding site of the dNTP analogue. In other studies, a non-labelled template–primer complex was added to a DNA polymerase conjugate with a dNTP analogue followed by addition of [$\alpha\text{-}^{32}\text{P}$]dNTP corresponding to the template. In this case labelling of the conjugate also took place. Thus, the template–primer complex immobilised through a heterocyclic base can participate in the elongation of the primer.^{12, 14, 21, 23}

According to some data, binding of such reagents can increase the selectivity of modification. Modification of HIV-1 reverse transcriptase with a template–primer complex carrying a FAB-dCTP or AIFAB-dCTP residue at the 3'-end of the primer is described in Section III.¹⁴ In these studies, the photoreactive group was introduced into the primer enzymically, *i.e.*, with the help of a free substrate. This resulted in modification of both subunits. In analogous experiments, the same photoreactive groups were introduced into the primer with the help of preimmobilised analogues of dNTP. In this case, modification was more selective and affected only the p66 subunit. In the case of NAB-dUTP, the use of this approach did not increase the selectivity. The label was detected in the subunits both after preliminary immobilisation and without it.¹⁵ This provides additional evidence for the close localisation of the p51 subunit and the active centres of the p66 subunit.

That the triphosphate group of an immobilised dNTP retains substrate activity may be of considerable interest in the study of an enzyme centre involved in the catalysis of the nucleotidyl-transferase reaction. It is therefore important to preserve at a maximum the ability of the immobilised dNTP to take part in the elongation of the primer. One of the approaches has been checked for the example of FAB-dCTP and reverse transcriptase of HIV-1.¹² To this end, photoaddition of the reagent was carried out in the presence of a template–primer complex with the corresponding dideoxynucleotide at the 3'-end of the primer component. A fragment of this system is shown below:

The duplex used could not undergo elongation due to the absence of the OH-group at the 3'-end of the primer. In other features, it fully mimicked the functional duplex. After irradiation, the dideoxy analogue of the primer was replaced with an excess of an ordinary ^{32}P -labelled primer. The level of catalytically competent binding of the enzyme in the presence of a template and a primer was determined by the amount of the label bound with the enzyme. It was found that the level of labelling of the p66 subunit increased substantially (severalfold) in comparison with that observed upon photo-cross-linking of the same analogue in the absence of the other components. It is interesting to note that analogous experiments with human DNA polymerase β did not reveal any increase in the level of FAB-dCTP binding with the

enzyme. This may indicate a lesser dependence of the interaction of dNTP with the active centre of this enzyme on the template.¹² The primer (both covalently attached to the 3'-end by catalytically competent elongation and containing a photoreactive group in the 3'-terminal unit after covalent attachment) can be further elongated with an [$\alpha\text{-}^{32}\text{P}$]dNTP.^{12, 14} This approach can also be used for the analysis of the translocation mechanism of DNA polymerases.

V. Study of interactions of DNA polymerases with templates, primers and nucleoside 5'-triphosphates by affinity-based chemical modification. Quantitative aspects

As mentioned above, affinity-based modification of biopolymers, *i.e.*, modification by reagents with a specific structure that is recognised by a biopolymer and carrying a reactive group, is widely used for selective modification of those groups of a biopolymer that are localised at the site of its interaction with the ligand. In other words, affinity-based modification is used as a tool for the study of the structural organisation of active centres of enzymes. The kinetics of affinity-based modification can be studied by measuring either the degree of the reagent binding with the biopolymer or a decrease in the biopolymer activity in the course of the reaction. Kinetic data provide information about the reagent affinity for the biopolymer. The measurements performed in the presence of a ligand competing with the reagent for the binding to the enzyme active centre allow one to determine the affinity for the competing ligand. The methods used to estimate the dissociation rate constants (K_d) for the ligands competing with affinity reagents have been generalised in the reviews.^{4, 77} In the simplest form, the affinity-based modification of an enzyme (E) by a reagent (X) in the presence of a competing ligand (Y) can be represented as follows:

where EX is the enzyme–reagent complex; EZ is the modification product; EY is the enzyme–Y complex; k is the rate constant for the conversion of EX into EZ; K_X is the rate constant for the dissociation of the EX complex, and K_Y is the rate constant for the dissociation of the EY complex.

At a sufficiently large excess of the affinity reagent X, modification occurs as a first-order reaction. The values of apparent rate constants for the modification (k_{app}) at various concentrations of the reagent and the competing ligand can be determined from the dependence of the degree of modification or the residual activity of DNA polymerase on the time of its incubation with a reactive analogue of an oligonucleotide. The dependence of k_{app} on the initial concentration of the reagent X_0 and the concentration of the competing ligand Y_0 can be written as equation (1):

$$\frac{1}{k_{\text{app}}} = \frac{1}{k} + \frac{K_X}{[kX_0(1 + Y_0/K_Y)]}, \quad (1)$$

where k_{app} is the apparent rate constant for the modification, k is the rate constant for the conversion of EX into EZ, K_X is the rate constant for the dissociation of the EX complex, and K_Y is the rate constant for the dissociation of the EY complex.

Using this anamorphosis, it is not difficult to obtain the constant K_Y from the dependence of k_{app} on Y_0 at constant X_0 .

This method was used to study the interaction of DNA polymerases with templates, primers, and deoxynucleoside 5'-triphosphates. The affinity reagent (pdT)₂p((NH₃)₂Pt[N(3)-

Figure 5. Dependence of ΔG^0 for the complex of the Klenow fragment with oligocytidylate (1), oligothymidylate (2), oligoguanylate (3), and oligoadenylate (4), and for the complex of DNA polymerase α from human placenta with oligothymidylate (5) on the length of the oligonucleotide.

dC(OH)}(pdT)₇ was used to study the binding site of the template. Its reaction with the enzyme was followed by monitoring the changes in the activity of DNA polymerase.⁷⁴ A broad array of oligonucleotides of various lengths and composition were used as competitive inhibitors. The values of the dissociation constants for the DNA polymerase α complex and the Klenow fragment with oligonucleotides and the corresponding standard free energies of binding (ΔG^0) were established.^{28, 78, 79} The dependence of ΔG^0 on the length n was determined for a series of homooligonucleotides (Fig. 5). This dependence is linear up to about $n = 20$. This suggests that the length of the region in which the template binds with the enzyme is about 20 nucleotide residues. For decathymidylates this dependence is described by equation (2).

$$\Delta G^0 = -6.0 - 0.32n \text{ (kcal mol}^{-1}\text{)}. \quad (2)$$

This means that the contribution of each nucleotide unit is 0.32 kcal mol⁻¹. For other types of nucleotide units these values are different. Thus for the most hydrophilic pdC, this value is -0.28 kcal mol⁻¹, whereas for more hydrophobic pdA and pdG it is -0.40 kcal mol⁻¹ (see Ref. 74). The linear dependence (2) makes it possible to calculate the value of ΔG^0 for the interaction of DNA polymerase with an oligonucleotide with a random sequence of the monomers (Table 2). The calculated values are in good agreement with those obtained experimentally.

Table 2. K_d values for the complexes of the Klenow fragment of DNA polymerase I from *E. coli* with oligonucleotides of various lengths and structures.²⁸

Oligonucleotide	K_d / μ M	
	calculated	experimental
d(pTpApApTpApCpGpA)	0.140	0.170
d(pCpTpGpCpGpTpTpApC)	0.120	0.130
d(pApApTpCpApTpGpGpTpCpApT)	0.013	0.015
d(pCpA) ₅	0.070	0.060
d(pGpA) ₅	0.024	0.015
d(pGpA) ₃	0.400	0.450
d(pGpT) ₆	0.011	0.009

The correlation between the nature of the oligonucleotide and its role in the interaction with the enzyme suggests that this interaction is hydrophobic rather than electrostatic. It is interesting to note that according to direct photo-cross-linking data, the 759–774 region of the Klenow fragment, which interacts directly with the DNA duplex, does not contain charged amino acid

residues,³⁹ but has eight highly hydrophobic residues (Ile760, Phe762, Leu764, Ile765, Tyr766, Met768, Phe771, and Leu773).

This finding was confirmed in experiments with oligothymidylates esterified (ethylated) at internucleotide phosphates, *i.e.*, devoid of the negative charge.²⁶ The dissociation constants (K_d) for the complex of human placenta DNA polymerase α with the octanucleotide d(Tp)₇T and the octanucleotide d[Tp(C₂H₅)Tp]₃Tp(C₂H₅)T ethylated at four internucleotide phosphates are 0.4 and 0.33–0.39 μ M, respectively (depending on the configuration of the chiral phosphorus atoms). In other words, elimination of four charges in the oligonucleotide molecule does not affect its affinity for the enzyme. At the same time, on complete esterification of the octanucleotide d[Tp(C₂H₅)]₇T the affinity drops by one order of magnitude ($K_d = 2.8 \mu$ M).²⁶

It is noteworthy that this dependence is not extrapolated to zero at $n = 0$. This implies that the free energy ΔG^0 of the interaction of the enzyme with orthophosphate is -6.0 kcal mol⁻¹. This was also confirmed by direct experiments where enzyme inactivation by the reagent was inhibited in the presence of orthophosphate. Moreover, neutral triethyl phosphate ($\Delta G^0 = -4.5$ kcal mol⁻¹) acted as a competitive inhibitor of the inactivation reaction. This fact illustrates the role of hydrogen bonds in the interaction of the phosphate fragment with DNA. The experimental data altogether allow a conclusion to be made about the significant contribution of only one internucleotide phosphate in the formation of a template–DNA polymerase complex.

In studies of the interaction of DNA polymerase with a primer to form a complex, the Michaelis constant, K_m , was used to characterise the primer affinity for the complex. In preliminary affinity-based modification experiments, it was shown that K_m differed slightly from the dissociation constant of the primer complex. A series of experiments was performed aimed at the enzyme inactivation by 2',3'-anhydroATP.⁸⁰ This was shown⁸⁰ to inactivate the enzyme in the presence of a template–primer [(poly(dT)–oligo(dA))] complex, the rate of inactivation being dependent on the concentration of this complex. Since the latter depends on the concentration of the primer, one may calculate the value of the dissociation constant for the primer complex. The equation used for calculation (3) was obtained on the assumption⁸⁰ that the primer and 2',3'-anhydroATP bind independently with the dissociation constants K_Y and K_X , respectively, but the reaction proceeds only when both the primer and the reagent are present simultaneously:

$$\frac{1}{k_{app}} = \frac{(1 + K_X/X_0)(1 + K_Y/Y_0)}{k}. \quad (3)$$

Table 3 gives the values for several oligodeoxyadenylates and human placenta DNA polymerase α . As is seen, the differences between these constants are small. This suggests that the Michaelis constant can be used as a measure of the primer affinity. For the Klenow fragment this coincidence is even better. Therefore, the main regularities of the interaction of DNA polymerases with the

Table 3. The K_d and K_m values for the complexes of human DNA polymerase α and the Klenow fragment of DNA polymerase I from *E. coli* with primers.

Primer	DNA polymerase α		Klenow fragment

d(pA) ₁₂	0.2	0.37	—	—

primer were analysed preferentially for the poly(dA)-oligo(dT) system using the K_m values.^{78,81} The latter were determined conventionally from the dependence of the rate of the primer elongation on its concentration. The dependence of $-\log K_m$ on the primer length (the number n of the nucleotide residues) was found to be linear up to $n = 9-12$. The K_m values for a series of oligothymidylates ethylated at internucleotide phosphates were compared. It was shown that the primer affinity for the enzyme--template complex strongly depends on the presence of a charged phosphate group at the 3'-terminal nucleotide residue. Ethylation of all the other internucleotide phosphates has practically no effect on K_m . The presence of the OH group at the 3'-end of the primer is a crucial factor. The oligonucleotide d(pT)₉p(ddT), which carries a 2',3'-dideoxythymidylate residue at its 3'-end and is devoid of the OH group, is a noncompetitive inhibitor of the primer. In these experiments with variable concentrations of the template, the oligonucleotide d(pT)₉p(ddT) behaved as a typical competitive inhibitor. This result testifies to its binding to the matrix site of the enzyme.^{81,82}

The dependence of $-\log K_m$ on the length of the primer is extrapolated to ~ 4 at $n = 1$. This suggests that the mononucleotide, too, can serve as a primer for DNA polymerase. This was demonstrated in direct experiments on human placenta DNA polymerase α where poly(dT) was used as a template, dATP as a substrate, and [³H]dAMP as a primer. As was shown by reversed phase chromatography of the reaction mixture, the dinucleotide d(pA)₂ was predominantly formed together with smaller analogues of longer oligomers. The substantial predominance of the dimer over longer oligomers attests to the distributive character of the synthesis. Similar results were obtained when [³H]dATP was used as a primer. This implies in fact that DNA polymerases can initiate DNA synthesis *in vitro*, although as has already been mentioned, in all cases studied the initiation of DNA synthesis *in vivo* begins with the synthesis of a ribooligonucleotide primer.⁸¹ These results are in favour of general regularities in the interaction of a DNA duplex with prokaryotic and eukaryotic DNA polymerases and fit well into a nonspecific sequence-independent model of DNA recognition. Indeed, the contribution of hydrophobic interactions of bases is crucial for single-stranded sites, whereas the interaction of the sugar-phosphate backbone is a critical factor in the case of DNA duplexes. It is noteworthy that the number of electrostatic interactions of both template and primer chains with the enzyme is limited. X-Ray data for the complexes of the Klenow fragment of DNA polymerase I with DNA³⁶ and of DNA polymerase β with DNA³⁸ are consistent with the conclusion about the limited number of contacts between the charged amino acid residues and DNA. For example, only one charged residue, *viz.*, Arg254, was found in DNA polymerase β . Presumably, this residue forms a hydrogen bond with the phosphate of a 3'-terminal dNMP newly introduced into the primer.³⁸ Simulation of the interaction of a DNA duplex with reverse transcriptase of HIV-1 carried out on the basis of X-ray data also revealed a limited number of electrostatic contacts, *viz.*, one or two lysine residues in the binding site of the 3'-end of the primer and several (but no more than 5-6) residues in the template region.⁶⁸ These data are consonant with the idea about the electrostatic nature of the DNA-binding site of DNA polymerases and the presence of a strong electrostatic field in this region.⁸³ This structure may be necessary for primary diffusion of DNA; however, the number of genuine 'strong' contacts can be restricted in order to provide the 'mobility' of DNA during the translocation and dissociation of the products.

The mechanism of interaction of dNTP with DNA polymerases was analysed by affinity-based modification of enzymes with γ -P-imidazolides of deoxynucleoside 5'-triphosphates and P-imidazolides of deoxynucleoside 5'-monophosphates.^{79,84,85} It is noteworthy that these reagents inactivated DNA polymerases only in the presence of both the template and the primer and only when the template was complementary to the reagent base. This suggests that the reagents bind to the site where the substrate is

selected for subsequent transfer of the nucleotide residue to the 3'-terminal hydroxy group of the primer. Quantitative estimation of nucleotide binding with a different number of phosphate groups was carried out on the basis of the protective effect of poly(dA) and oligo(dT)₁₅ on enzyme inactivation by dTMP-imidazolide. The values of dissociation constants for the complexes of dNMP, dNDP, and dNTP with human DNA polymerase α determined by this method are given in Table 4.⁸⁵ According to these data, the K_d values for different dNMP and dNDP are very similar, which suggests that β -phosphate hardly contributes much to the formation of dNTP complexes with DNA polymerase.

Table 4. K_d Values for the complexes of human DNA polymerase α with nucleotides in the presence of a template [poly(dA)] and a primer [d(pT)₁₅].⁸⁴

Base	$K_d (K_i \text{ or } K_m)/\mu\text{M}$				
	dNMP	dNDP	dNTP	NTP	γ -methylamide dNTP
C	15	11	7(15)	3	—
T	9 (28)	7	0.06(3.1)	0.05	0.03
G	7 (6)	6.0	0.3(0.64)	0.3	—
A	3 (7.8)	—	0.8	0.7	0.3

The affinity of dNMP for the enzyme increases in the following order: dCMP < dTMP < dGMP < dAMP. There was a linear correlation between ΔG^0 for dNMP binding and the retention time of the corresponding nucleosides on a reversed-phase adsorbent. Hence, the α -phosphate group of various dNMP makes an equal contribution to the total efficiency of complex formation with the enzyme. The difference in the affinity of both dNMP and dNDP for the active centre of DNA polymerase is largely due to the difference in the efficiency of hydrophobic interactions of their bases with the enzyme and does not reflect their complementarity to the template. At the same time, the situation is quite different for triphosphates. The base of dTTP is complementary to that of the template in the enzyme-poly(dA)-oligo(dT) complex and this nucleotide possesses the highest affinity for the complex. The affinity of all of the dNTP is higher than that of di- and mono-phosphates. This leads to a conclusion that the integrity of the triphosphate group of dNTP is required to enable the complementary interaction of nucleotides with the template.

Similar results were obtained for the Klenow fragment.⁸⁶ It should be emphasised, however, that the integrity of the triphosphate group is also important for the formation of a nonspecific complex between dNTP and DNA polymerases; this follows from the above data, especially for dATP and dGTP. The conclusion about the essential role of the triphosphate group for the recognition of dNT was confirmed by X-ray data, according to which the catalytic centres of DNA polymerases contain three carboxy groups that determine the Mg^{2+} -mediated orientation of the triphosphate fragment of dNTP.^{37,87}

VI. Chemical methods for the study of replicative complexes

As mentioned earlier, the functioning of the enzymes catalysing replication occurs within complicated multisubunit structures. The two main problems currently arising in this respect are concerned with the detection of contacts between the polynucleotide components and individual polypeptides of the complex, on the one hand, and between individual polypeptides, on the other hand.

In this context, replicating DNA polymerase from *E. coli* (DNA polymerase III), which actually represents a replicative complex, has been studied in most detail. This enzyme is made up of ten subunits, *viz.*, α , ϵ , β , τ , γ , δ , δ' , χ , ψ , and θ .⁸⁸ Partial

dissociation of the total complex usually takes place during its isolation; therefore, studies are carried out with intermediate incomplete complexes, *viz.*, complex III, which includes α , ϵ , and θ subunits; complex III', which contains additionally the subunit τ , and complex III*, which contains all subunits except for β . Complex III represents the nucleus of the total DNA polymerase. It comprises DNA polymerase α , 3',5'-exonuclease ϵ , and the subunit θ the function of which has not been finally established. These subunits are responsible for the two most important functions, *i.e.*, the binding of complex III' at the initiation site including the 3'-end of the primer bound with the template, and subsequent migration of the enzyme along the template without any dissociation of the enzyme–template complex.

In order to determine the subunits to which DNA binds in the course of elongation, a series of primers with a photoreactive group at different positions relative to the 3'-end of the growing chain were synthesised and assayed.²⁹ Their synthesis is described in Section II. Primers with a photoreactive arylazide group at positions 3, 9, 13, 18, 22, 27 and 46 relative to the 3'-terminal fragment were used for this purpose. After formation of the enzyme–template–primer complex, this was irradiated. This resulted in the cross-linking of a definite nucleotide residue with the enzyme. Analysis of subunits of the irradiated complex showed that the presence of a photoreactive group at positions 3 and 9 resulted in labelling of the α -subunit; at position 13, of the α - and γ -subunits; at position 18, of the γ -subunit alone, and at position 22, of the γ - and β -subunits. Primers with a photoreactive group at positions 27 and 46 from the 3'-end did not cross-link with any of the subunits. Assuming that in all these complexes the 3'-end of the primer is at the same position relative to the enzyme, the results obtained can be interpreted as evidence in favour of translocation of the product relative to the components of the complete enzyme.

The second system more or less thoroughly characterised was DNA polymerase in a complex with auxiliary proteins of bacteriophage T4. Bacteriophage T4 contains about 150 genes including those encoding proteins of the replicative complex. They are usually marked by numbers corresponding to the gene number and by the symbol gp (gene product). An efficiently functioning system contains DNA polymerase gp43 itself and the auxiliary proteins gp44, gp62, and gp45. Moreover, it requires the presence of a protein that binds single-stranded DNA (gp32). The auxiliary proteins fulfil the function of a clamp. The prerequisite for the formation of a stable complex between the 3'-end of the template–primer complex and three auxiliary proteins is the presence of ATP γ S, a non-hydrolysable analogue of ATP that contains the S atom at the γ -atom of P. It should be noted that DNA polymerase does not bind with this complex; its binding takes place only when a normal, hydrolysable ATP is added to the system.⁸⁹

This system was studied by determining direct photo-cross-links upon powerful laser irradiation (one or several 8 ns pulses, irradiation power was $5-8 \times 10^{16}$ photons). The most intense cross-linking was observed for the protein gp32. In this case, (dT)₁₀ is cross-linked with a far greater efficiency than (dC)₁₀. Direct photo-cross-linking of (dT)₁₀ occurs also with the individual proteins gp43 and gp45, although less intensely; no modification of gp44 and gp62 takes place. At the same time, in a system comprising an ensemble of all the three auxiliary proteins, photomodification affects only gp62. It is worth noting that its modification requires the presence of ATP.⁹⁰

A strong effect of ATP was also established in studies using a template–primer complex with a photoactive analogue of thymidine (NAB-dTTP) at several predetermined positions relative to the 3'-end of the primer.⁹¹ Addition of ATP and DNA polymerase resulted in significant changes in the contacts between the auxiliary proteins and the primer. For example, the binding of gp62

with the primer in the presence of all of the other auxiliary proteins was much stronger in the presence of ATP γ S, but not of ATP. This suggests that the addition of ATP results in its hydrolysis, which initiates a conformational transition, which either displaces gp62 to a larger distance from the primer or completely displaces it from the system.

In the case of eukaryotes, the fragment of a replicative complex containing DNA polymerase α and primase was studied first. Each of these enzymes consists of two subunits, which can be easily isolated as a single complex composed of four subunits, *viz.*, a 180 kDa subunit (DNA polymerase itself, or sometimes as a 165 kDa subunit formed upon partial proteolysis), a 72 kDa subunit (its function is unknown), and 60 and 50 kDa subunits (γ - and δ -subunits of primase). After direct photo-cross-linking of [α -³²P]ATP with a complex from yeast, the label is detected only in the δ -subunit.⁹² After modification of the complex with adenosine triphosphate *P*-*p*-formylphenyl ester followed by identification of modification points by catalytically competent labelling, the radioactive label was found in both subunits. Modification of an analogous complex from human placenta with adenylate *P*-*p*-formylphenyl esters with subsequent introduction of the radioactive label using [α -³²P]ATP revealed that the ATP ester was bound exclusively with the δ -subunit in the presence of poly(dT) and with both subunits of primase in the absence of poly(dT).⁹³

In studies of a DNA polymerase–primase complex from human placenta, a template–primer duplex (25 and 10 units, respectively) was elongated with FAB-dCTP. It was found that the primer was photoadded not only to the 165 kDa subunit of DNA polymerase but also to primase subunits. However, the 72 kDa polypeptide was not labelled under these conditions. Photoaddition of FAB-dCTP to the complex with subsequent attachment of the primer (catalytically competent labelling) resulted in modification of only the 165 kDa subunit of DNA polymerase and the minor (50 kDa) subunit of primase.²¹ Similar results were obtained for a DNA polymerase–primase complex from calf thymus. However, in the latter case the use of catalytically competent labelling did not result in labelling of the primase subunits at all.²³ These results suggest that photoaffinity modification can be used for gaining information about the role of various subunits of the complex in the formation of active structures and the change-over from the primase function to elongation of a newly synthesized DNA.²¹

Photoaffinity modification was also used to study the interaction of a eukaryotic replication factor (RPA) with DNA. RPA is made up of three subunits with molecular weights of 70, 32, and 14 kDa. Its functions are to stabilise the configuration of denatured DNA and to establish specific interactions of DNA with other proteins involved in replication, repair, and recombination of DNA.⁹⁴ The interaction of RPA subunits with a DNA duplex having an extended template chain, was studied by introducing a photoreactive group into the 3'-end of a radiolabelled primer using DNA polymerases α or β with 5-(5-azido-2-nitrobenzoyl)-deoxyuridine 5'-triphosphate as a substrate.⁹⁵ The p32 and p70 subunits underwent the most intense labelling upon UV irradiation. The minor (p14) subunit was not modified under these conditions. Based on the results obtained, a model for the interaction of RPA subunits with the DNA duplex was proposed (Fig. 6). It is supposed that the p70 subunit interacts with the single-stranded site of the DNA duplex, the p32 subunit is near the 3'-end of the primer, while the p14 subunit is remote. This scheme is very efficient for the studies of DNA interaction with other replication factors, such as PCNA and RFC, as well as for the study of formation of the whole replicative ensemble in the course of DNA synthesis.

Figure 6. The interaction of the eukaryotic replication factor (hRPA) with a DNA duplex containing a photoreactive residue, dNMP(U*), introduced into the 3'-end of the primer by DNA polymerase; p70, p32, and p14 are the RPA subunits.

VII. Conclusion

Chemical approaches to the study of the mechanism of action of enzymes are not confined to the use of chemical modification for the analysis of template biosynthesis of DNA. Various substrate analogues obtained mostly by chemical methods have found wide use in enzymological studies. With respect to DNA polymerases, this approach has been successfully developed in studies by Kraevsky.^{96,97}

The data presented in this review demonstrate that the use of chemical (particularly, affinity-based) modification to elucidate the nature of active centres of DNA polymerases is a very practicable approach. However, the results obtained by this method must be analysed together with X-ray data. Analysis of these data together with the results obtained by site-directed mutagenesis is no less important. Most recent studies resort to methods of computer simulation more and more often because they allow a more detailed interpretation of information obtained by experimental methods.

The processes catalysed by DNA polymerases are characterised by a high degree of dynamism. The same can be said of the stage of the monomer selection where the monomer is tested for complementarity to the encoding element of the template prior to the nucleotidyl transferase reaction), to the translocation stage, where the template-elongation product complex migrates relative to the active centre of the enzyme, and to the repair stage involving 3' → 5'-exonuclease where the 3'-end of the synthesised chain is translocated from the polymerase to the exonuclease centre. These events occur over milliseconds; one of the few possible ways to monitor these transient changes in the contact sites of enzymes, templates, and products is fast photochemical labelling of the enzyme by photoreactive analogues of the substrate or the primer. This can be done for a millisecond interval using pulse irradiation. Although these experiments have just begun, a considerable chemical ground for this method including the synthesis of photoreactive analogues of dNTP and introduction of photoreactive nucleotide residues into definite positions of the primer chain has been created.

An important and very promising result of the most recent investigations is the elaboration of new techniques for catalytically competent labelling of enzymes with dNTP derivatives carrying a reactive group in their heterocyclic base. These derivatives retain their triphosphate fragment after covalent cross-linking with the enzyme and can sometimes act as donors of the nucleotide residue. This opens up interesting possibilities for the study of the mechanism of the nucleotidyl transferase reaction catalysed by the enzyme. Studies of elongation of primers covalently immobilised on the enzyme also seem to hold much promise. Since this system allows simultaneous realisation of several elongation acts and, as a consequence, of several translocation acts, it remains to be hoped that a convenient model for the study of the translocation mechanism will be developed despite limited mobility of the primer.

One of the peculiarities of studies of nucleic acid polymerases by the chemical modification method is the simultaneous presence in the system of single- and double-stranded nucleic acids and a protein (or a group of proteins). As mentioned above, simulta-

neous modification of the enzyme and the template was observed for primers carrying an azidoperfluorobenzoyl group linked to a heterocyclic base.^{14,21} In some cases, this can impede the interpretation of results of affinity-based modification, *e.g.*, due to the impossibility of separation of DNA chains or because simultaneous binding of two or more photoreactive groups of the primer with the template and the enzyme yields products that cannot be easily identified. Therefore, preference may be given to reagents endowed with the ability to selectively modify proteins without any cross-linking of the primer with the matrix, *e.g.*, when the primer contains NAB-dUMP residues.¹⁵ Studies on a model system in which the amino acid residue and the photoreactive group (azidoperfluorobenzoyl, 5-azido-2-nitrobenzoyl or *p*-azidoanilide) are artificially converged by addition to the 3'- and 5'-terminal phosphates of complementary oligonucleotides, respectively, showed that only in the former case can the cross-linking also take place in the absence of the amino acid residue at the 3'-end.⁹⁸ Therefore, among other arylazides used for protein modification, derivatives with a 5-azido-2-nitrobenzoyl or *p*-azidoanilide groups are more preferable.

Chemical approaches, in the first place, covalent cross-linking of reactive primer-template complexes with reactive fragments at predetermined positions of these complexes are an indispensable tool in the study of both RNA polymerases and transcription complexes, on the one hand, and replicative complexes, on the other hand. In particular, they are used for the study of the mutual arrangement of individual components of the above complexes (*e.g.*, eukaryotic DNA polymerase and auxiliary proteins, such as SSB, PCNA, RFC) and their translocation relative to the template-primer complex in the course of elongation.

Abstract. Second-order nonlinear optical properties in polymeric media and the mechanisms of generation and relaxation of the second harmonic of a polarised laser beam are discussed. The relationships between the chemical structures of the polymeric systems and the transport characteristics of the charge carriers are considered and the influence of the captured charges on the parameters of the second harmonic relaxation are analysed. It is shown that the kinetics of second harmonic relaxation in the polymeric systems of the host–guest type is determined entirely by the decay kinetics of the surface potential. The bibliography includes 98 references.

I. Introduction

Optical second harmonic generation (SHG) consists in the medium assisted transformation of two photons with the frequency ω into one photon with the frequency 2ω . The generation of the second harmonic (SH) results from the dispersion of light in the medium and occurs under the action of polarised laser radiation, as a rule, in the spectral range of polymer transparency where both single- and multi-photon absorption by the medium are absent. This range corresponds to the radiation of the near-IR lasers. Physicochemical basis of SHG is considered in detail in several monographs^{1–4} and reviews^{5–8} and numerous papers. Preparation of polymeric systems with nonlinear optical properties that are used for SHG requires first of all that an oriented molecular structure was formed. These structures are produced under the action of an external electric field. The charges left after the electric field is switched off determine in some cases kinetic characteristics of SHG.

Uspekhi Khimii 67 (6) 507–522 (1998); translated by L M Goldenberg

This review is devoted to the analysis of the influence of captured charges in polymers on the characteristics of the SH relaxation. Some general information on the mechanism of the SH generation and relaxation in polymeric media is considered at the beginning of the paper.

The SHG phenomenon is caused by the nonlinear polarisability of conjugated molecules containing donor and acceptor *para*-substituents when the electric field is applied. It is known that a dipole moment is induced in a molecule placed in the electric field E

$$\vec{p} = ex = \alpha E \cos \theta, \quad (1)$$

where e is the electronic charge, x is the displacement of a bound electron in the electric field, α is the polarisability, θ is the angle between the direction of the electric field and the induced dipole moment. In the rectilinear coordinates, the projections of the vector $\vec{p}$ are equal to

$$p_i = \alpha_{ix}E_x + \alpha_{iy}E_y + \alpha_{iz}E_z, \quad i = x, y, z, \quad (1a)$$

where α_{ij} is the coefficient of linear polarisation along the axis i with electric field acting along the axis j ; this is a second rank tensor or the tensor of linear polarisability

$$\alpha_{ij} = \begin{vmatrix} \alpha_{xx} & \alpha_{xy} & \alpha_{xz} \\ \alpha_{yx} & \alpha_{yy} & \alpha_{yz} \\ \alpha_{zx} & \alpha_{zy} & \alpha_{zz} \end{vmatrix}$$

Macroscopic polarisation (P) per unit volume of a substance containing N chromophore molecules along the direction of the applied field is the sum of the projections of dipole moments for each individual molecule onto this direction under conditions of dipole–dipole interaction. Under the action of the laser radiation, nonlinear effects along with linear dependence $P = \chi^{(1)}E$ take place in donor–acceptor systems

$$P = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE + \dots \quad (2)$$

Here $\chi^{(1)}E$, $\chi^{(2)}EE$, and $\chi^{(3)}EEE$ are the polarisations, and $\chi^{(1)}$, $\chi^{(2)}$, $\chi^{(3)}$ are the susceptibilities of the first, second, and third order, respectively. The nonlinear terms, $\chi^{(2)}EE$ and $\chi^{(3)}EEE$, are also called hyperpolarisabilities of the second and third orders.

Under the action of a monochromatic electromagnetic wave $E(\omega) = E_1 \cos(\omega t) = 0.5E_1(e^{i\omega t} + e^{-i\omega t})$, dipoles oscillating with a frequency ω in small fields appear provided $P(\omega) \approx \omega^{(1)}E_1 \cos(\omega t)$. The donor–acceptor systems discussed below exhibit nonlinear

response to laser radiation, which is caused by the nonlinear electronic polarisation

$$P(\omega) = \chi^{(1)}E(\omega) + \chi^{(2)}E(\omega)E(\omega) + \chi^{(3)}E(\omega)E(\omega)E(\omega) + \dots (3)$$

or

$$P(\omega) = \chi^{(1)}E_1\cos(\omega t) + 0.5\chi^{(2)}E_1^2\cos(2\omega t) + \dots (3a)$$

$$+ 0.5\chi^{(2)}E_1^2 + \frac{\chi^{(3)}}{4}E_1^3[\cos(3\omega t) + 3\cos(\omega t)] + \dots$$

The expressions for the nonlinear polarisation in media with symmetrical polarisability with respect to the inversion centre, where $P(+E) = -P(-E)$, cannot contain even terms, i.e., $\chi^{(2)} = 0$ in Eqns (3) and (3a). In such media, nonlinear effects are caused by the third order polarisation. The second-order polarisation is induced in noncentrosymmetrical systems, where $P(+E) \neq -P(-E)$. According to the formula (3), the nonlinear response of a centrosymmetrical system causes the generation of the third harmonic (3ω) of the fundamental frequency of the laser radiation. In a noncentrosymmetrical medium, the radiation spectrum of the assembly of the oscillating dipoles contains a second harmonic caused by the second order nonlinear polarisation

$$P(2\omega) = 0.5\chi^{(2)}E_1^2\cos(2\omega t). (3b)$$

The anharmonic character of the polarisation induced by the polarised light $E(\omega)$ is illustrated in Fig. 1.^{1,8} The polarisation along a donor–acceptor molecule D–B–A (D is the donor fragment, B is the bridging spacer group with the system of conjugated π -bonds, A is the acceptor fragment) is caused by the fact that the charge displacement from A to D is smaller than in the opposite direction. In this case, an expression for the polarisation is represented by a Fourier series. The terms of the series possess the frequencies $\omega, 2\omega \dots 0$ (see Fig. 1).

Figure 1. Polarisation (P) in a molecule D–B–A induced along the direction from A to D by the electric field $E(\omega)$ of a light wave (upper x axis) and the expansion of $P(\omega)$ as a Fourier series with the frequencies $2\omega, \omega$, and 0 (bottom x axis).

$$P = P(\omega) + aP(2\omega) + \dots + \epsilon P(0).$$

The dipole oscillations with the frequency 2ω (second term of the series) induce the generation of the second harmonic 2ω under the action of the fundamental frequency ω .

II. The relationship between microscopic and macroscopic polarisation

The dipole polarisation of an isolated chromophore molecule in a linear range can be written as follows [see formula (1a)]

$$p_i(\omega) = \alpha_{ij}(\omega)E_j(\omega).$$

Here i and j are the molecular coordinates that fix the orientation of the induced dipole moment $p_i(\omega)$ and the direction of the electric field $E_j(\omega)$, respectively. In the range of the appearance of the nonlinear effects, the expression for the dipole polarisation takes the form

$$p_i(\omega) = \alpha_{ij}(\omega)E_j(\omega) + \beta_{ijj}(-2\omega, \omega, \omega)E_j(\omega)E_j(\omega) + \gamma_{ijjj}(-3\omega, \omega, \omega, \omega)E_j(\omega)E_j(\omega)E_j(\omega) + \dots (4)$$

Here $\beta_{ijj}(-2\omega, \omega, \omega)$ and $\gamma_{ijjj}(-3\omega, \omega, \omega, \omega)$ are the polarisabilities of the second and third orders or hyperpolarisabilities of the second and third orders (the coefficients β_{ijj} and γ_{ijjj} are the tensors of the third and fourth rank), respectively.

In the macroscopic coordinates XYZ , the macroscopic polarisation of a dielectric, e.g., in the direction Z , is determined by the local internal field $F_Z(\omega)$, which is linked with the external field by the expression

$$F_Z(\omega) = E_Z(\omega) + \frac{4\pi}{A}P_Z(\omega) = E_Z(\omega) \left[1 + \frac{4\pi}{A}\chi_{ZZ}^{(1)}(\omega) \right],$$

where A is a coefficient depending on the system geometry: for sphere $A = 3$, for ellipsoids of polarisation this factor is tabulated and can be found in the reference books. Using the relationship between the dielectric constant $\epsilon_Z(\omega)$ and the susceptibility

$$\epsilon_Z(\omega) = 1 + 4\pi\chi_{ZZ}^{(1)}(\omega),$$

the expression in square brackets can be written in the form⁵

$$f_Z(\omega) = 1 + \left[\frac{\epsilon_Z(\omega) - 1}{A} \right] (5)$$

and

$$F_Z(\omega) = f_Z(\omega)E_Z(\omega). (5a)$$

If $A = 3$, then

$$f_Z(\omega) = \left(\frac{\epsilon_Z(\omega) + 2}{3} \right), (5b)$$

where $\epsilon_Z(\omega) = n^2(\omega)$, and $n(\omega)$ is the refractive index for the fundamental frequency. It thus follows that the linear polarisation can be represented by the relation [see also formula (1)]

$$P_Z(\omega) = N\alpha_{ij}f_Z(\omega)E_Z(\omega)\langle \cos\theta_{Zi} \rangle.$$

Thus, the first-order susceptibility is linked with the linear polarisability of an individual molecule α_{ij} by the relation

$$\chi_{ZZ}^{(1)}(\omega) = N\alpha_{ij}f_Z(\omega)\langle \cos\theta_{Zi} \rangle. (6)$$

Consequently, the second-order macroscopic polarisation is linked with β_{ijj} by the relation

$$P_Z(2\omega) = N\beta_{ijj}E_Z(\omega)f_Z(\omega)\langle \cos\theta_{Zi} \rangle E_Z(\omega)f_Z(\omega)\langle \cos\theta_{Zi} \rangle f_Z(2\omega)\langle \cos\theta_{Zi} \rangle,$$

where $f_Z(2\omega)$ is determined according to the formula (5b) at the frequency 2ω .

The second-order polarisability along the direction of the macroscopic axis Z , which is averaged along all orientations of the individual molecules D–B–A, is determined by the expression

$$\beta_i = \beta_{iii} + \frac{1}{3}[\sum(\beta_{ijj} + \beta_{jji} + \beta_{jji})].$$

The molecules D–B–A are chromophores, since they contain donor and acceptor groups, and a conjugated chain; they absorb visible light. Below we call these molecules nonlinear optical NLO-chromophores or just chromophores.

A component of the second-order susceptibility along the direction Z is determined by the polarisability β_i according to the relation

$$\chi_{ZZZ}^{(2)} = N\beta_i(-2\omega, \omega, \omega)f_Z(\omega)\langle\cos\theta_{Zi}\rangle f_Z(\omega)\langle\cos\theta_{Zi}\rangle f_Z(2\omega)\langle\cos\theta_{Zi}\rangle,$$

i.e., in a quasi one-dimensional molecule (in which dipole moment is directed along the axis of symmetry and the β_{iii} dominates)

$$\chi_{ZZZ}^{(2)} = N\beta_{iii}(-2\omega, \omega, \omega)f_Z^2(\omega)f_Z(2\omega)\langle\cos^3\theta_{Zi}\rangle, \quad (7)$$

$$\begin{aligned} \chi_{ZXX}^{(2)} &= \chi_{ZYY}^{(2)} = \\ &= \frac{1}{2}N\beta_{iii}(-2\omega, \omega, \omega)f_Z^2(\omega)f_Z(2\omega)(\langle\cos\theta_{Zi}\rangle - \langle\cos^3\theta_{Zi}\rangle). \end{aligned} \quad (7a)$$

III. The polarisability of polymeric donor-acceptor systems

Doubling of the laser radiation frequency was observed for the first time for quartz crystals⁹ ($d_{33} = 0.5 \text{ pm V}^{-1}$)[†]. Nowadays, a large number of inorganic crystals that generate the SH of the fundamental frequency of the laser radiation are known. However, of special interest are polymeric systems as that it is in these media the maximum intensities of the SH corresponding to $d_{33} = 200 \text{ pm V}^{-1}$ are obtained. Organic polymers are processable and blend well with integrated film optical systems.

Polymeric matrices containing low-molecular-weight chromophores and polymers containing chromophores in the side groups or in the main chain belong to the polymeric media that include D–B–A chromophores.^{1,5} It is essential that these molecules possess dipole moments in the ground state. As a rule, the initial polymeric films are disordered and, consequently, are centrosymmetrical systems. Intensive studies of the second harmonic generation in the polymeric donor–acceptor systems began after 1979,^{10–12} when an earlier developed rather simple method for transformation of the centrosymmetrical systems into noncentrosymmetrical ones due to predominant orientation of the dipole chromophore molecules under the action of a constant electric field at the glass transition temperature T_g was applied to the polymers (see references cited in the Ref. 6). A decrease in the temperature of such orientational poling in a constant field down to 20 °C and below can be achieved if the polymer layer is plasticised by the introduction of the CO₂ under high pressure. After polarisation the CO₂ is removed by the evacuation, and the polymer is restored its to initial glassy state that is now polarised.¹³

When the constant field E is applied, the potential energy of a molecule with the dipole moment μ is changed by the quantity

$$U(\theta) = -\mu F \cos\theta,$$

where $F = Ef(0)$, $f(0) = (1/3)(\epsilon + 2)$ [cf. formulas (5) and (5a)] and ϵ is the dielectric constant of the polymeric matrix. According to the Boltzmann distribution law the number of particles oriented at an angle θ to the direction of the field E is proportional to $\exp(-U(\theta)/kT)$ and the mean values of $\langle\cos^n\theta\rangle$ are determined according to the formula

$$\langle\cos^n\theta\rangle \equiv L_n\left(\frac{\mu F}{kT}\right) = \frac{\int_0^\pi \left\{ \exp\left[\frac{-\mu F \cos\theta}{kT}\right] \cos^n\theta \cdot \sin\theta \right\} d\theta}{\int_0^\pi \left\{ \exp\left[\frac{-\mu F \cos\theta}{kT}\right] \sin\theta \right\} d\theta},$$

[†] The second harmonic nonlinear coefficient $d_{ZZ} = 0.5\chi_{ZZZ}^{(2)}$ is often used as the SHG characteristics in equations (3a) and (3b). In the studies that are aimed at practical application, the symbols 123 are used, as a rule, instead of XYZ for the designation of the nonlinear coefficient coordinates; i.e., $d_{ZZ} \equiv d_{33}$.

representing the Langevin functions $L_n(\mu F/kT) \equiv L_n(u)$. This function is represented¹ in the form of the Legendre polynomial $L_n(u)$, where $u = \mu F/kT$ when the mean values of $\langle\cos^n\theta\rangle$ are calculated. For $n = 1$,

$$L_1(u) = \frac{u}{3} - \frac{u^3}{45} + \dots \simeq \frac{u}{3},$$

Hence, in the first approximation $\langle\cos\theta\rangle \approx \mu F/3kT$ in the relation (6). For $n = 3$,

$$\begin{aligned} L_3(u) &= \left(1 + \frac{6}{u^2}\right)L_1(u) - \frac{2}{u} + \dots = \\ &= \left(1 + \frac{6}{u^2}\right)\left(\frac{u}{3} - \frac{u^3}{45} + \dots\right) - \frac{2}{u} + \dots \simeq \frac{u}{5}, \end{aligned}$$

i.e., $\langle\cos^3\theta\rangle \approx \mu F/5kT$ in the relation (7).

Thus,

$$\chi_{ZZZ}^{(2)} = N\beta_{iii}(-2\omega, \omega, \omega)f_Z^2(\omega)f_Z(2\omega)f_Z(0)\frac{\mu E}{5kT} \quad (7b)$$

and

$$\chi_{ZXX}^{(2)} = \chi_{ZYY}^{(2)} = \frac{1}{3}\chi_{ZZZ}^{(2)}.$$

If a constant electric field E is applied the second harmonic may contain a contribution of the third-order nonlinearity

$$\Delta P(2\omega) = N\gamma(-2\omega, \omega, \omega, 0)f_Z(2\omega)E_Z^2(\omega)f_Z^2(\omega)Ef(0),$$

where $N\gamma(-2\omega, \omega, \omega, 0)f_Z(2\omega)f_Z^2(\omega)f(0)$ is the contribution of the third-order susceptibility.

In this case, the constant electric field E excites rather than orients the molecule. Thus,¹⁴

$$\begin{aligned} \chi_{ZZZ}^{(2)} &= NEzf(0)f_Z(2\omega)f_Z^2(\omega)[\beta_{iii}(-2\omega, \omega, \omega)\frac{\mu E}{5kT} + \\ &+ \gamma(-2\omega, \omega, \omega, 0)]. \end{aligned} \quad (7c)$$

The contribution of the third-order nonlinearity expressed by the term $\gamma(-2\omega, \omega, \omega, 0)$ appears and disappears simultaneously as the constant electric field E is switched on and off irrespective of the degree of orientation of the chromophores.

Considerable attention is paid to the D–B–A chromophores such as *para*-substituted stilbenes, where B is $-\text{C}_6\text{H}_4-\text{CH}=\text{CH}-\text{C}_6\text{H}_4-$, for example, 4-dimethylamino-4'-nitrostilbene (DANS),

arylamines, where B = $-\text{C}_6\text{H}_4-$, polyconjugated systems with B = $-\text{C}_6\text{H}_4(\text{CH}=\text{CH})_n-\text{C}_6\text{H}_4$ ($n \geq 2$), $\text{C}_6\text{H}_4-\text{N}=\text{CH}-\text{C}_6\text{H}_4$ or $\text{C}_6\text{H}_4-\text{N}=\text{N}-\text{C}_6\text{H}_4$, etc. J-Aggregates of dyes are also effective chromophores.¹⁵

For the molecules D–B–A it is established^{16,17} that the second-order polarisability β can be represented in the form of two terms

$$\beta = \beta_{\text{ad}} + \beta_{\text{ct}},$$

where β_{ad} is the additive part resulting from the interaction between the substituents and the systems of conjugated bonds, and β_{ct} is the contribution for which the donor–acceptor interaction is responsible. As the molecular structure in the case of full charge transfer from D to A corresponds to the structure of the excited molecule then according to the concepts developed in the publications^{5–8, 16–24}

$$\beta_{\text{ct}} = \frac{3e^2\hbar^2}{2m} \frac{W}{[W^2 - (2\hbar\omega)^2][W^2 - (\hbar\omega)^2]} f\Delta\mu_{\text{ex}}, \quad (8)$$

Table 1. β Values for the chromophores with different relationships between μ_e and μ_g .

Chromophore	Relationship between μ_e and μ_g	μ_g/D	μ_e/D	$10^{-30}\beta/\text{cm}^5\text{C}^{-1}$
	$\mu_e > \mu_g$	+ 9.85	+ 23.5	+ 73
	$\mu_e \approx \mu_g$	+ 7.84	− 10.5	− 12
	$\mu_e < \mu_g$	+ 22.6	+ 13.7	− 100

Note. Signs + and − denote the direction of the vectors $\vec{\mu}$ and $\vec{\beta}$ in chromophore.⁸

where h is the Planck constant, m is the mass of an electron, W is the distance between the ground-state level and the first excited level of an intramolecular DA-complex, ω is the fundamental frequency of the laser radiation, f is the oscillator strength for the transition from the ground state to the excited state, $\Delta\mu_{ex} = -\mu_e - \mu_g$ is the difference in dipole moments of the DA-complex in the ground state and excited state, respectively.

It follows from formula (8) that weak ($\mu_e \gg \mu_g$) and weak ‘reverse’ complexes ($\mu_e \ll \mu_g$), where the electron transfer is only possible in one direction from D to A or from $A^{-\cdot}$ to $D^{+\cdot}$, respectively should exhibit the highest nonlinearity. On going to the molecules $D^{\delta+}A^{\delta-}$ with the degree of transfer $\delta \approx 0.5$, $\mu_e \approx \mu_g$, the charge displacement in both directions is possible where upon application of the electric field, one should expect the weakening of nonlinear characteristics. Indeed, when the weak complexes ($\mu_e < \mu_g$) are replaced by molecules with close values of μ_e and μ_g , the contribution of β_{ct} decreases drastically, but on going to the reverse complexes ($\mu_e > \mu_g$) this contribution increases considerably (Table 1).

The oscillator strength f is proportional to $(eRV_{01})^2/W$, where R is the distance between the groups D and A, V_{01} is the energy of the exchange interaction between D and $A^{-\cdot}$: $V_{01} = V(R_0)\exp[-(R-R_0)/\zeta]$, R_0 is the sum of Van der Waals radii of D and $A^{-\cdot}$, ζ is the parameter of damping of the wave functions.^{20,21} Taking this into account, one can represent formula (8) as follows

$$\beta \propto (eRV_{01})^2 \frac{\Delta\mu_{ex}}{W^2}$$

[in a static approximation, $h\omega = 0$ (see Ref. 8)]. The parameter ζ decreases if delocalised π -electrons of the bridging group B in the molecule D–B–A take part in the exchange interaction

$$V_{01} = V_{01}(D, M^{-\cdot})V_{01}(M^{-\cdot}, A^{-\cdot}).$$

The parameter ζ is determined by the structure of the bridging group. Weakening of the exchange interaction at a large distance between D and A leads to the decrease in β_{ct} .

It is seen from the formula (8) that the contribution of β_{ct} increases with a decrease in the distance between the ground and excited levels, which determines the longwave optical absorption of the intramolecular DA complex. The experimental data showing the increase in $\log \beta_{ct}$ with the increase in the wavelength of the optical absorption for *para*-substituted benzenes and stilbenes are presented by Kanis *et al.*⁸

The charge displacement from D to A in the D–B–A molecules in the ground state is determined by the difference in the Hammett constants (σ_x). For example, for *para*-substituted π -conjugated molecules⁸

$$\sigma_n = \sigma_{n,a} - \sigma_{n,d},$$

where σ_n is the empirical Hammett constant, $\sigma_n = \log K_X - \log K_H$, where K_X and K_H are the ionisation constants for *para*-substituted and unsubstituted benzoic acids, respectively. The Hammett constants are positive for the acceptors [$\sigma_{n,a}(\text{NO}_2) = 0.778$] and negative for the donors [$\sigma_{n,d}(\text{NH}_2) = -0.66$].²⁵ It is shown^{8,26} that β_j increases linearly from $\sim 4 \times 10^{-30}$ to $40 \times 10^{-30} \text{ cm}^5 \text{ C}^{-1}$ at $h\omega = 0.65 \text{ eV}$ as σ_n increases from 0.4 to 1.5 for mono- and di-substituted stilbenes (the axis Z is directed along the dipole moment of a molecule).

IV. Typical experimental procedure

A typical SHG process includes two stages: the first one is orientational polarisation of a polymer in the external electric field, and the second one is the measurement of the intensity of the SH in the course of the polarisation or after the electric field is switched off. Two methods for the potential application to the polymeric film are used. The first one is a contact method where the potential difference is applied to the transparent electrodes with the polymeric film placed between them. $\text{In}_2\text{O}_3/\text{SnO}_2$ (ITO) or a semitransparent metal film, for example, gold are used as the transparent electrodes. The second method is the corona discharge, the charges are deposited onto the free surface of a polymer instead of the upper contact electrode. These charges result from the corona discharge (ionisation of a gas in the measurement chamber by high voltage applied to the corona electrode). This method is well developed in electrophotography.²⁷ The principal scheme of the experimental set-up for second harmonic generation with the potential application of the corona discharge method is shown in Fig. 2.²⁸ The specimen consists of a transparent ITO electrode as a substrate and a polymeric layer that generates the second harmonic. A positive or negative charge is applied to the surface of the polymeric layer by the corona discharge method. The surface potential U is registered using the ring electrode and an electrometer.

Linearly polarised laser radiation with the fundamental wavelength λ (as a rule, λ lies, in the near-IR range and is equal to 1064 nm) is applied to the sample. The intensity of the second harmonic $I(-2\omega)$ that is selected by the $\lambda/2$ interference filter (532 nm) is measured with a photomultiplier and a digital voltmeter. The effects due to the fluctuation of the incident radiation can be excluded if the intensity of the second harmonic is measured relative to the intensity of the fundamental wavelength signal taken out by the reference channel (see Fig. 2).

The intensity $I(-2\omega)$ is related to the second-order susceptibility by the expression^{1,29}

$$[I(-2\omega)] \propto [\chi_{ZZZ}^{(2)} E(\omega) E(\omega)]^2. \quad (9)$$

Figure 2. Schematic diagram of the experimental set-up for the second harmonic generation with the potential application by the corona discharge.

V. Relationship between the second harmonic and the relaxation characteristics of a polymeric matrix

A detailed analysis of studies on the second harmonic generation in polymeric systems performed before 1994 is presented in a review by Burland *et al.*⁵ It is noted that one of the main problems in the consideration of the nature of SHG in polymeric materials is the elucidation of the role of charges in the stabilisation and kinetic characteristics of the second-order susceptibility.

The coincidence of the decay of the second-harmonic intensity when the corona discharge is switched off and decay of the surface potential U in a poly(vinyl acetate) film containing 2 mass % of DO3 (Table 2) is established.²⁸ The plots $[I(-2\omega, t)]^{0.5}$ and $U(t)$ (Fig. 3) coincide over all time of measurement (22 min) after the corona electrode is switched off and correspond to a biexponential dependence. Thus, the susceptibility $\chi^{(2)}$ is completely controlled by the surface potential U . A biexponential decay of the surface potential in the polymeric films is observed for a large number of polymers³⁰ and can be associated with two processes, *viz.*, autolocalisation of the charge carriers in the polymeric dielectric

Figure 3. The kinetics of the decay of the second harmonic signal after the switch-off of the corona discharge for the sample of PVAC + 5 - mass % of DO3.

(1) equation (19) with parameters $\phi = 0.33$, $\tau_1 = 0.52$ min, $\tau_2 = 8.3$ min; (2) equation (19) with parameters $\phi = 0.35$, $\tau_1 = 2.1$ min, $\tau_2 = 28$ min; (3) keeping at 43°C for 5 min, then charging by the corona discharge for 2 min at 35°C , measurement at 35°C ; (4) keeping at 43°C for 5 min, then charging by the corona discharge for 2 min at and then 2 min at 35°C , measurement at 35°C ; (5) keeping at 43°C for 5 min, then keeping at 35°C for 4 h, charging by the corona discharge for 2 min at 35°C , measurement at 35°C .

responsible for the initial fast region (τ_1), and a charge carrier drift responsible for the decay of the potential with the time constant τ_2 .

Only in a few studies^{31–35} the kinetics of the decay of the susceptibility $\chi^{(2)}$ and a decrease in the residual electric field were measured simultaneously³⁵ to take account of the effect of trapped charges in the relaxation processes. It was assumed earlier that the contact method entirely excludes the influence of the residual electric field after the cut-off of the potential difference. However, the electric current passing through a cell with poly(isobutyl methacrylate) (PIBMA) and a chromophore DANS (1 mass %) placed between the ITO electrodes has been registered.^{32–34} It was concluded that ITO is an injecting electrode and the current is caused by the ionic impurities in the polymeric matrix. In this case, a residual charge, which can significantly influence the characteristics of the SH relaxation remains in the sample. An attempt was made to exclude the influence of captured electrons on the SH relaxation introducing an insulating SiO_2 interface between the ITO anode and the polymer.^{32–34}

The effect of traces of solvent (chloroform) on the kinetics of SH decay was observed.³³ In the authors' opinion, the solvent

Table 2. Relative contribution of the third-order nonlinearity into $\chi_{ZZZ}^{(2)}$ (see Ref. 37).

Chromophore	Name	Abbreviation	$\frac{\gamma}{\gamma + \beta\mu/5kT}$
	4-dimethylamino-4'-nitrostilbene	DANS	0.2 ± 0.03
	(N-ethyl)-N-(2-hydroxyethyl)-4-(p-nitrophenylazo)aniline, dispersion red dye 1	DR1	0.12 ± 0.02
	4-(p-nitrophenylazo)aniline, dispersion orange dye 3	DO3	0.16 ± 0.03
	4-(dimethylamino)benzylidene-malononitrile	DMN	0.06 ± 0.02

diffuses from a nonpolar polymer into a microvolume that surrounds the chromophore with a high dipole moment. This leads to the change in the dielectric constant and also to the significant decrease in viscosity in the microenvironment of the chromophore. As a consequence, this results in a decrease in the activation energy of the chromophore orientational relaxation. The content of traces of solvent is difficult to monitor. Therefore, the experimental results are often irreproducible. In this connection, one should pay attention to the dry process for the fabrication of films with oriented chromophores by spray-coating the polymer onto the electrode.³⁶

According to the formula (7c), the second harmonic contains the contribution of the third-order nonlinearity, which has to be taken into account in the analysis of the relaxation processes. The kinetics of the decay of $\chi_{ZZZ}^{(2)}$ in polymeric matrices (PMMA, poly(methyl methacrylate) (PEMA), and PIBMA) containing 2 mass % of a chromophore at 30 °C was measured after the constant electric field was switched off.³⁷ Depending on the nature of the chromophore (see Table 2), the susceptibility $\chi_{ZZZ}^{(2)}$ decreases by 6%–20% over the period 10^{-4} –0.5 s and then slowly diminishes over 10^3 – 10^4 s. Fast decrease in the susceptibility after the cut-off of the constant field E is related to the disappearance of the contribution of the third-order nonlinearity. This contribution $\gamma/(\gamma + \beta\mu/5kT)$ for different donor-acceptor molecules are also listed in Table 2. The value of this contribution depends only slightly on the nature of the polymeric matrix: in the PEMA and PIBMA containing 2 mass % of 4-tricyanovinyl-*N*-ethyl-*N*-(2-hydroxyethyl)aniline (TC1) this contribution was 4% at 30 °C.³⁸ For polyamide [–CONH–X–HNCO–(CH₂)–]_{*n*}, where the chromophore X was of the following structure,

the initial fast decay of the second-harmonic intensity $[I(-2\omega, t)/I(0)]^{0.5}$ down to 25% of the initial value was also explained³⁹ by the disappearance of the contribution of the molecular third-order susceptibility γ . Here $I(0) \equiv I(-2\omega, 0)$ is the second-harmonic intensity at the moment of the polarising field cut-off. This decay continues for ~ 20 s after the cut-off of the constant electric field. Possibly, such a delay is caused by the gradual drain of the surface charge deposited by the corona discharge.⁴⁰

The rate of the decay of the second-harmonic intensity after the real removal of the electric field is caused by the orientational relaxation of the chromophore and is determined by its structure, the character of the linkage with the polymer, and free volume of the polymer. The investigation of the kinetics of this process is an informative method of analysis of the polymer dynamics. The measurement of the SH after the switch-off of the electric field may last from ~ 0.5 s to an indefinitely long time. Different mechanisms of the relaxation of the system chromophore–polymer are found in the measurement.

As a rule, the study of the second-harmonic relaxation is based on the concept that these processes are caused by the rotational diffusion of chromophore. When the electric field is applied, they are described in the framework of the Smoluchowski model by equation^{5,31,41}

$$\frac{\partial G(\theta, t)}{\partial t} = D_{\text{rot}} \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left\{ \sin \theta \left[\frac{\partial}{\partial \theta} G(\theta, t) + \frac{G(\theta, t)}{kT} \frac{\partial}{\partial \theta} V(\theta, t) \right] \right\}, \quad (10)$$

where $G(\theta, t)$ is the distribution function of the orientations of the dipole moment of the chromophore as the projection of the solid angle θ at the moment t ; θ is the angle between the macroscopic axis Z normal to the film surface and coinciding with the direction

along the constant electric field E , and the long axis of the chromophore, $D_{\text{rot}} = \langle [\theta(t) - \theta(0)]^2 \rangle / 4\tau$ is a coefficient of the rotational diffusion of the chromophore, τ is the relaxation time, and $V(\theta, t) = -\mu E \cos \theta$ is the potential energy of the chromophore. The change in the chromophore orientation after the switch-off of the constant field at the moment $t = 0$

$$\frac{\partial G(\theta, t)}{\partial t} = D_{\text{rot}} \frac{\partial G(\theta, t)}{\partial (\sin \theta d\theta)^2} \quad (11)$$

(the second Fick law) determines kinetics of the decay of the second-order susceptibility according to the expression^{5,40–42}

$$\frac{\chi^{(2)}(-2\omega, \omega, \omega, t)}{\chi^{(2)}(-2\omega, \omega, \omega, 0)} = A \exp(-2D_{\text{rot}}t) + B \exp(-12D_{\text{rot}}t). \quad (12)$$

Here [see Eqn (7)],

$$\frac{\chi^{(2)}(-2\omega, \omega, \omega, t)}{\chi^{(2)}(-2\omega, \omega, \omega, 0)} \equiv \left(\frac{I(-2\omega, t)}{I(0)} \right)^{0.5} \equiv \frac{\langle \cos^3 \theta, t \rangle}{\langle \cos^3 \theta, 0 \rangle}.$$

The representation of the function $G(\theta, t)$ in the form of the Legendre polynomial is used in the calculation and the same D_{rot} value is assumed for all chromophores. The latter condition is more characteristic of the temperatures higher than T_g .

The kinetics of the decay of the second harmonic intensity ($\lambda/2 = 532$ nm) in the polymer with the pendent chromophoric groups has been studied by Firestone *et al.*^{40–42} Polyhydroxystyrene (PHS) with the portion of hydroxy group (x) esterified with *N*-(4-nitrophenyl)-(S)-proline [(S) = NPP] was the object of the investigations

The kinetics was measured over a wide range of temperatures near the T_g of the polymer, which depends on the degree of substitution x , and decreases from 146 °C at $x = 12\%$ to 134 °C and 96 °C at $x = 36\%$ and 90%, respectively.⁴¹

The calculations have shown^{5,40} that the relationship between pre-exponential factors in Eqn (12) depends on the poling field strength and at $E = 2.5 \times 10^5$ V cm⁻¹ (at $D_{\text{rot}} = 1.5 \times 10^{-5}$ rad² s⁻¹) the kinetics of the decay of the $\chi_{ZZZ}^{(2)}$ is mainly characterised by the stretched exponent: $A \simeq 1$, $B \simeq 1.5 \times 10^{-5}$ at 130 °C. If the poling field increases by an order of magnitude the contribution of the fast exponent increases to $B = 0.0712$. Thus, one should expect the first-order exponential orientational relaxation of the chromophores after the switch-off of the constant field. The experimentally measured decay of the SH intensity $[I(-2\omega, t)]^{0.5}$ in (S)-NPP-PHS with $x = 36\%$ at temperatures higher than the T_g for this polymer (134 °C) after the cut-off of the field $E = 1.1 \times 10^6$ V cm⁻¹ is mainly characterised by the fast exponent only at 153 °C: $B = 0.998$, $A \simeq 0.0016$, and $D_{\text{rot}} = 9.7 \times 10^{-3}$ rad² s⁻¹ [or in Eqn (12) the relaxation time $\tau_2 = (1/12)D_{\text{rot}} = 8.6$ s]. The contribution of the slow relaxation increases with the decrease in the temperature of the measurement: at 149 °C $B = 0.88$, $A \simeq 0.12$, and $D_{\text{rot}} = 8.7 \times 10^{-3}$ rad² s⁻¹ ($\tau_2 = 9.6$ s), and at 134 °C $B = 0.52$, $A \simeq 0.43$, and $D_{\text{rot}} = 2.3 \times 10^{-3}$ rad² s⁻¹ ($\tau_2 = 36.2$ s). Revealing the biexponential relaxation instead of the calculated monoexponential process suggests in the authors' opinion^{40–42} the presence of two fractions

in the structure of the polymer, *viz.*, the liquid one responsible for the fast relaxation and the glassy one responsible for the slow orientational relaxation of chromophores.

The contribution of the liquid fraction increases with the increase in temperature and prevails at $T_g + 19$ °C. It was also noted that this two-fraction consideration is possibly unnecessary as the model of rotational diffusion itself predicts the biexponential relaxation according to the relation (12).

The temperature dependence of the orientational relaxation of chromophores in the range higher than T_g does not obey the Arrhenius law and is well described by the Williams–Landel–Ferry formula

$$\lg\left(\frac{\tau(T)}{\tau(T_g)}\right) = -\frac{C_1(T - T_g)}{C_2 + (T - T_g)}, \quad (13)$$

where C_1 and C_2 are empirical coefficients, and τ is the relaxation time. The values $C_1 = 17.44$ and $C_2 = 51.6$ °C are typical of polymers. In the measurement of the kinetics of $\chi_{ZZZ}^{(2)}$ decay at different temperatures these coefficients are as follows: $C_1 = 1.94$ and $C_2 = 39.1$ °C, *i.e.*, measurement of the second harmonic gives information on the relaxation in the local chromophore micro-environment rather than the universal macroscopic relaxation.^{40, 42}

In viscous media, the individual chromophores differ in their orientational relaxation time and a distribution of the relaxation processes can be represented by the empirical Kohlrausch–Williams–Watts (KWW) function⁴²

$$\frac{\chi_{ZZZ}^{(2)}(t)}{\chi_{ZZZ}^{(2)}(0)} = \left(\frac{I(-2\omega, t)}{I(0)}\right)^{0.5} \equiv G(t) = \exp\left(-\frac{t}{\tau_{KWW}}\right)^b, \quad (14)$$

where τ_{KWW} is the mean relaxation time [the time counted from the moment of the field cut-off to the moment of a 2.7-fold decrease in the distribution function $G(t)$], parameter b characterises the width of the distribution of chromophores according to the orientational relaxation time. The values of the coefficient b vary from 0 to 1. At temperatures higher than the glass transition temperature $b \approx 1$, *i.e.*, all chromophores are characterised by the same τ_{KWW} . The decrease in b as the temperature decreases indicates a growing deviation of the relaxation time of the individual chromophore from the mean value. In a number of publications (see, for example, Ref. 13), difficulties in the transformation of the experimental results to the form of function (14) using a single value of τ_{KWW} are noted. It is suggested to use of a bimodal representation in order to avoid difficulties

$$G(t) = \varphi_1 \exp\left(-\frac{t}{\tau_{1,KWW}}\right)^{b_1} + \varphi_2 \exp\left(-\frac{t}{\tau_{2,KWW}}\right)^{b_2}. \quad (14a)$$

Here, parameters $\tau_{1,KWW}$, b_1 , and $\tau_{2,KWW}$, b_2 show the presence in the polymer of domains with the fast and slow relaxations distributed according to the energies.

The relationships of the type (14a) bear little information as they contain a large number of parameters and, naturally, allow one to describe any experimental dependence.

The process of the chromophore orientation immediately after the switch-on of the poling constant field can be represented by the modified KWW function

$$[I(-2\omega, t)]^{0.5} = 1 - \exp\left(-\frac{t}{\tau_{KWW}}\right)^b. \quad (14b)$$

It was mentioned above that the exponential dependence corresponding to $b = 1$ in Eqn (14) is found in (S)-NPP-PHS with $x = 36\%$ at $T_g + 19$ °C.⁴⁰ As temperature decreases, b gradually decreases, which indicates a deviation of the relaxation time of individual chromophores from the mean value. The empirical functions (14) and (14b) describe well the process of the depolarisation/polarisation at the temperatures smaller than

T_g . The decay of the second harmonic intensity measured after the switch-off of the poling field ($E = 1.25 \times 10^6$ V cm⁻¹, poling time 20 min) at $T_g = 134$ °C corresponds [see Eqn (14)] to the values $\tau_{KWW} = 63$ s, $b = 0.61$, and at 120 °C $\tau_{KWW} = 972$ s, $b = 0.5$. The growth of $[I(-2\omega, t)]^{0.5}$ after the switch-on of the field corresponds to the dependence (14b) with the parameters $\tau_{KWW} = 79.8$ s, $b = 1$ at T_g and $\tau_{KWW} = 3126$ s, $b = 0.41$ at 120 °C.⁴² The decrease in the coefficient b with the decrease in temperature, *i.e.*, the broadening of the distribution function of the chromophores according the orientational relaxation times and the increase in the mean duration of relaxation τ_{KWW} in both processes (polarisation and depolarisation) indicate the heterogeneous character of the distribution of the microdomain sizes at temperatures below T_g .

An Arrhenius-type temperature dependence of the orientational processes was established at temperatures below T_g .^{40, 42}

$$\lg\left(\frac{\tau}{\tau_0}\right) = \frac{E_a}{kT}, \quad (15)$$

where τ_0 is a constant, E_a is the activation energy. In the samples of (S)-NPP-PHS with $x = 36\%$ $E_a = 24.7 \pm 2.6$ kcal mol⁻¹ either at a growth or decay of $[I(-2\omega, t)]^{0.5}$, *i.e.*, upon switch-on and off of the poling field.

According to the principles developed by Turnbull and Cohen and Chalykh,^{43–45} molecular diffusion is determined by the free volume of the polymer. Migration of a molecule in amorphous media becomes possible if a microcavity the volume of which exceeds some critical value $V' \simeq V_m$ (V_m is the volume of the diffusing molecule) appears in the vicinity of the diffusing molecule as a result of the thermal redistribution of the free volume.⁴⁴ In this case, the diffusion coefficient (D) is proportional to the probability of redistribution of the free volume and is determined by the relation

$$D \propto \tau^{-1} \propto \exp\left(-\frac{cN_A V'}{V_{fr}(T)}\right), \quad (16)$$

where $c \approx 0.5–1$ is a factor of the overlap of the microcavities, $V_{fr}(T) = [V(T) - V_v]$ is the molar free volume of the polymer repeating unit, $V(T)$ is the molar volume of the polymer at given temperature, and V_v is the Van der Waals molar volume of the repeating unit.

An analysis of the decay kinetics carried out by Firestone *et al.*^{40–42} demonstrated the link between the characteristics of the second harmonic and relaxation processes in the polymer. However, the authors failed to rationalise the disagreement between theoretical order of the exponential dependence of the orientational relaxation of chromophores using diffusional model and the measured biexponential dependence of the decay of the susceptibility $\chi_{ZZZ}^{(2)}$. In the authors opinion, the theoretical consideration carried out is simplified as it does not take into account different specific effects, for example, the interaction of the chromophore dipoles with the polymeric matrix or with each other.

An analysis of the relaxation processes gives a good correspondence³⁵ between the experimental results and calculations based on a Gaussian distribution of the activation energy E_a (see Refs 32–34) or according to Eqn (15)

$$\begin{aligned} \Phi(t) &= \left(\frac{I(-2\omega, t)}{I(0)}\right)^{0.5} = \int_{-\infty}^{\infty} \Gamma(\ln \tau) \exp\left(-\frac{t}{\tau}\right) d \ln \tau = \\ &= \pi^{-1/2} \int_{-\infty}^{\infty} \exp(-u^2) \exp\left[\left(-\frac{t}{\tau_G}\right) e^{-\sigma_G u}\right] du. \end{aligned} \quad (17)$$

Here $\Gamma(\ln \tau) = (\pi \sigma_G^2)^{-1/2} \exp(-u^2)$ is the Gaussian distribution of $\ln \tau$, $u^2 = (\ln \tau - \ln \tau_G)^2 / \sigma_G^2$, σ_G is the half-width of the distribution at $\Gamma_{\max}/2.7$, and τ_G is the most probable relaxation time. Verbiest

*et al.*³⁵ have used the Eyring theory of absolute reaction rates according to which

$$\ln \tau = \ln \frac{2\pi h}{kT} - \frac{\Delta S}{R} + \frac{\Delta H}{RT},$$

where R is the gas constant, ΔS and ΔH are the entropy and enthalpy of activation, respectively. Therefore, the thermal characteristics of the processes are estimated according to the dependence

$$\ln(\tau T) = \ln \frac{2\pi h}{k} - \frac{\Delta S}{R} + \frac{\Delta H}{RT}.$$

On the basis of the fact that $E_a = \Delta H + RT$ and in majority of cases $\Delta H \gg RT$ the authors suppose that $E_a \approx \Delta H$.

The distribution function (17) and the empirical KWW function (14) are characterised by two parameters, *viz.*, τ_G , σ_G and τ_{KWW} , b , respectively. The parameters of the Gaussian distribution τ_G and σ_G were compared with the coefficients τ_{KWW} and b for the decay curves $[I(-2\omega, t)]^{0.5}$ measured at different temperatures in a polyetherimide containing chromophore lophine 1 (L1)³⁵

and also in PMMA containing dye DR1 (see Table 2). It was shown that as the temperature increases the increase in b from 0.2 to 1 corresponds to a decrease in σ_G from 10 to 0. In the range of $\sigma_G = 0-2$ the value of $\ln(\tau_{KWW}/\tau_G)$ is equal to zero and then decreases linearly down to -1.3 with an increase in σ_G to 10.

The characteristics of the orientational relaxation of chromophores in co-polymers consisting of the repeating units (P1, $x = 2$ and 6) with the following structure

and polymers including DANS, whose donor fragment is incorporated into the main chain (P2), and also containing DR1 (see Table 2) in the side chain (P3)

where $R = -C(O)-O-(CH_2)_2-R''$ ($R'' = \text{carbazolyl}$) and the chromophore $R' = -C(O)-O-(CH_2)_2-N(Et)-C_6H_4-N=N-C_6H_4-NO_2$ are the side substituents have been studied.⁴⁶ The susceptibility was measured when the poling electric field was switched on at room temperature, then the temperature was gradually increased to T_g , the sample was kept at this temperature until the constant value of $\chi^{(2)}$ was achieved, then the temperature was decreased again to 20 °C. The decrease in the temperature was accompanied, according to relation (7a) by an increase in the susceptibility to the limiting value $\chi_{\max}^{(2)}$, which could be achieved upon prolonged poling at the temperatures near the T_g . Then the poling electric field was switched off. It is established that in all polymers $\chi^{(2)}$ was increased up to 60% of $\chi_{\max}^{(2)}$ in 30 s at 20 °C. As this value exceeds a possible contribution of the third-order susceptibility (20%, see Table 2) the fast rise of $\chi^{(2)}$ was related⁴⁶ to the local motion of the chromophore in the free volume of the polymer. It was found that upon cut-off of the electric field in the samples cooled down to room temperature the value of the fast decay is less than 60%; for the P1 polymer this value is $\sim 20\%$ of

$\chi_{\max}^{(2)}$. In the authors opinion such a decrease in the contribution of the fast component of $\chi^{(2)}$ is caused by the decrease in the free volume, which resulted from the poling at T_g . The 'memory effect'[‡] in PIBMA containing DANS, *i.e.*, the increase in the duration of the decay of the second harmonic intensity τ in repeated cycles on-off of the polarising field at $T = T_g + 27$ °C [for the relationship between τ and V_{fr} , see Eqn (16)] was explained by the decrease in the free volume.³⁴ A gradual increase in τ_{KWW} after keeping a poly(arylene ether) composition doped by 10% of chromophore DANS ($T_g = 185$ °C) in a constant electric field at 45 °C (*i.e.*, at $T_g - 140$ °C) was also related to the decrease in the free volume.⁴⁷ The composition was preliminarily poled for 25 min at 190 °C (*i.e.*, at $T_g + 5$ °C). It was shown that upon keeping at 45 °C τ_{KWW} increases from 0.27 to 4.06 h after 31 h.

Polymers with $T_g = 82.7$ °C containing donor carbazole groups in the main chain substituted at positions 2 and 3 by acceptor substituents have been synthesised.⁴⁸ In contrast to the majority of polymeric systems with quasi-unidimensional chromophores, the direction of the dipole moment vector in these polymers does not coincide with the direction of the charge transfer, which results in an contribution of a nondiagonal coefficient of the second harmonic d_{ZX} is increased. The authors assume that the biexponential decay of $[I(-2\omega, t)]^{0.5}$ after the cut-off of the poling electric field measured at temperatures from 20 °C to 100 °C ($T_g + 17.3$ °C) is caused by two effects, *viz.*, the fast decay is determined by the movement of chromophore in a local free volume, and the slow decay is related to the recombination of the injected charges.⁴⁸

The values of τ_{KWW} and b in Eqn (14) obtained in the measurement of the second harmonic decay and an analysis of the electrochromic relaxation at 85–105 °C of a system consisting of PMMA and 1 mass % of nitroaminostilbene (NAS) ($T_g = 117$ °C), have been compared.^{49,50} These compositions possess electrochromic properties, *i.e.*, upon application of the poling field the optical density of the chromophore decreases reversibly. It is established⁵⁰ that the relaxation time (τ) of the NAS chromophores after the switch-off of the electric field estimated from the decay of the second harmonic intensity coincides with the time of the electrochromic relaxation. For such polymers as PMMA, poly(vinyl chloride) (PVC), and polycarbonate (PC) the time τ increases by an order of magnitude near the T_g on going from PVC to PMMA in the series $PVC < PC < PMMA$. This increase is believed to be caused by the decrease in the free volume of polymers [see relation (16)].⁵⁰ Such a conclusion provokes objections that the free volume is increased rather than decreased as on going from PVC to PMMA and makes up 18.56 and 23.17 cm³ mol⁻¹ at 20 °C, respectively (see Ref. 51). As the thermal extension coefficients for these polymers are similar $[(2.7-2.9) \times 10^4 \text{ K}^{-1}]$ (see Ref. 52), and the T_g of (PVC + NAS) is equal to 59 °C (see Ref. 49), which is almost half the T_g of (PMMA + NAS) (117 °C), the relation $V_{fr}(PVC) < V_{fr}(PMMA)$ holds and at elevated temperatures, too. It is possible that the captured charges determine the significant increase in the relaxation time on going from PVC to PMMA. It is to the accumulation of charges captured during poling that the memory effect in these compositions is related.⁵⁰

In the high-temperature corona poling, the sharp initial increase in $[I(-2\omega, t)]^{0.5}$ is followed by its gradual decay both in the polymers with the chromophores in the main chain⁵³ and in the doped polymers.³¹ Such behaviour of the polarisation curves can be caused by the decrease in the surface potential under equilibrium conditions due to the penetration of deposited charge into the bulk of the polymer and the increase in the film electric conductivity in the constant field due to the thermal increase in the crystallinity of the materials.

‡ The manifestation of this effect is that the repetition of the cycles polarisation/cut-off of the electric field results in the increase in the time of electrochromic relaxation, while optical density is not restored to the initial value.⁵⁰

The dynamics of the dipole reorientation at different temperatures in pure polymers, *viz.*, PMMA, PC, and polyimide (PI, $T_g = 207^\circ\text{C}$) not-doped with chromophores has been investigated.⁵⁴ The characteristics obtained by the method of the generation and decay of the second harmonic (532 nm) and by the method of the dielectric relaxation were compared. The values of $\chi^{(2)}$ appeared to be small, however, it was established that the decay plots of $[I(-2\omega, t)]^{0.5}$ can be described by the dependence (14). Two effects have been found. The first one lies in the fact that the decay time of the second harmonic τ_{KWW} measured in PI is increased by an order of magnitude when the same on-off cycle is repeated. The temperature dependences of the decay time for the second harmonic intensity $\tau(\text{SH})$ and the dielectric relaxation time $\tau(\text{DR})$ at the temperatures higher than T_g for all polymers are described by Eqn (13). The second effect is illustrated by the example of PVC where $\tau(\text{SH})$ is five orders of magnitude higher than $\tau(\text{DR})$ at $T_g + 23^\circ\text{C}$. This difference gradually decreases as the temperature decreases, and $\tau(\text{SH}) \approx \tau(\text{DR})$ at T_g . Both effects were explained by the influence of the captured charges on the decay time of $[I(-2\omega, t)]^{0.5}$ after the cut-off of the poling electric field. Presumably, the significant difference in the relaxation times is caused by the fact that at temperatures higher than T_g the polymeric chains are mobile and only captured charges hold the dipole in the oriented state thereby decreasing the orientational relaxation time $\tau(\text{SH})$.⁵⁴ At T_g , where the mobility of the polymeric chains is restricted, the role of the captured charges in the stabilisation of the oriented dipoles decreases.

Unfortunately, as a rule, in the studies mentioned above the decay of the potential was not measured simultaneously with the relaxation. Therefore, the suggestion of the influence of the captured charges on the characteristics of the relaxation processes are sufficiently justified, but are not proved.

VI. The influence of the captured charges on the characteristics of second harmonic generation and relaxation

The analysis of nonlinear optical characteristics of the polymeric materials presented above leads to the conclusion that a preferred orientation of the dipole chromophores is required to obtain noncentrosymmetrical structures in the optically transparent uniform polymeric films. The chromophores can be introduced in the polymeric chain or can be present as the side substituents in the macromolecule. Also, they can participate in the formation of a host-guest system as a low-molecular-weight additive to the polymeric matrix. The orientation of the chromophore groups results from the application of the poling electric field to the polymer film in the direction normal to its surface.

It is usually assumed that the contact polarisation method allows one to observe the nonlinear effects in the pure form, *i.e.*, without the influence of the residual charge after the cut-off of the poling field. However, in the electrode poling the current is passing through the film, even if an additional dielectric layer of SiO_2 is deposited between the anode and the polymer, see above. This indicates unambiguously the charge penetration into the film.³³ Even in the absence of the external potential difference, the charge up to $\sim 10^{-8} \text{ C cm}^{-2}$ is deposited on the surface of the dielectric polymeric film, when it comes in a contact with the metal owing to contact charging.^{55, 56}

It is shown³³ that the SHG characteristics are independent of the film conductivity, if the charge carrier concentration is several orders of magnitude smaller than the concentration of the chromophore. For example, for the film PIBMA + 1 mass % of DANS these concentrations are $10^{10} - 10^{15}$ and $5 \times 10^{19} \text{ cm}^{-3}$, respectively. In addition, the residual solvent (chloroform) even after careful removal is retained in the film at a concentration of five molecules per one DANS molecule, which influences significantly the kinetic characteristics of the SH decay. If nonpolar toluene is used as a solvent, the effect of the solvent traces on the

SHG characteristics is considerably less. It is assumed that the polar solvent affects significantly the local field factor, which is often estimated according to the Lorentz equation

$$f(\omega) = \frac{\varepsilon(\omega) + 2}{3}$$

or in a more accurate approximation through the Onsager equation

$$f(\omega) = \frac{(\varepsilon_\infty + 2)\varepsilon(\omega)}{\varepsilon_\infty + 2\varepsilon(\omega)}.$$

These expressions are strictly correct for a spherical symmetry and a continuum approximation for the dielectric medium surrounding the chromophore molecule. Thus, the decrease in the SH intensity is not necessarily associated with the change in the mean orientation of the chromophore molecules [see Eqn (7)]. However, the orientation can also be changed because of the change in the local electric field owing to molecular inhomogeneity.³³ All together, this differs from the concepts according to which the decrease in the SH intensity after the cut-off of the poling field (usually the experiment is carried out in such a way) is related only to the change in the mean orientation of the chromophore. The authors' conclusion³³ is made on the basis of the fact that the decrease in the SH intensity was observed experimentally when the poling field was not switched off.

The study of the decay of the SH intensity after the cut-off of the poling electric field seems to be most interesting. The characteristic time of the SH decay determines the stability of the operation of the nonlinear optical element. The features of the SH decay kinetics allow one to obtain information on the relaxation processes of polymeric chains and low-molecular-weight additives oriented by the poling electric field. It has been mentioned above that the great variety of these decay features were found in different studies: the exponential with saturation,³³ the sum of two exponents [see Eqn (12)],^{5, 40-42} the stretched exponent represented by the empirical function (14), the sum of two stretched exponents [see Eqn (14a)],^{13, 57} *etc.*

It should be noted that all effects connected to the SHG and observed upon multiple charging of the polymeric film, or upon changes in the solvent content in the sample, or after the cut-off of the poling field depend to a considerable degree, and sometimes crucially, on the value and kinetics of the surface charge relaxation. Thus, in order to obtain correct conclusions one should follow the change in the external electric field connected with the charges captured on the surface and in the bulk of the polymeric film and the SHG characteristics simultaneously. A simple relation exists between the surface potential, the external electric field $E(t)$ and the captured charge

$$E(t) = \frac{U(t)}{d},$$

$$U(t) = \frac{d\sigma(t)}{\varepsilon\varepsilon_0} + \frac{1}{\varepsilon\varepsilon_0} \int_0^d (d-x)\rho(x, t)dx, \quad (18)$$

where d is the film thickness, $\sigma(t)$ is the charge density of the film surface, ε is the dielectric constant, ε_0 is the permittivity of free space, and $\rho(x, t)$ is the charge density of the same sign in the polymer bulk at a distance x from the surface.

Simultaneous measurement of the decay kinetics of the second-order susceptibility and the surface potential of a PMMA film containing 4 mass % of DANS after charging by the corona discharge was performed by Liu *et al.*³¹ for the first time. It was established that at the temperatures of measurement higher and lower than T_g ($T_g = 88^\circ\text{C}$) the change in the relaxation of the normalised surface potential U/U_0 and normalised susceptibility χ/χ_0 are similar. The experimental results in the polymeric host-guest system studied could be explained if a

dynamic model that takes into account the Brown motion of the chromophores, the influence of the electric field, and the limitations imposed by the polymer matrix was used. The model contains four parameters, viz., D_{rot} (coefficient of the rotational diffusion); $a = \mu E/kT$; $b = v(g_1 - g_2)(E^2/kT)$, and θ_0 (the angle of the cone within which a chromophore molecule vibrates). Here, μ is the constant dipole moment of the chromophore, $v(g_1 - g_2)$ is the difference in the polarisability in the directions parallel and normal to the axis of the chromophore molecule. Small difference in the decay kinetics of U and $\chi^{(2)}$ is explained by the fact that the change in $\chi^{(2)}$ is more probably related not to the surface potential, but rather to the mean rotational moment $\langle T \rangle$ acting on the chromophore dipole in the external electric field,

$$\langle T \rangle = \int_0^\pi T(\theta) p(\theta, t) \sin \theta d\theta,$$

where $T(\theta) = \mu E \sin \theta - E^2 \cos \theta \sin \theta v(g_1 - g_2)$.

The coincidence of the decay curves for $\chi^{(2)}$ and $\langle T \rangle$ hardly should be paid great attention as the parameter $v(g_1 - g_2)$ was obtained from the experimental $\chi^{(2)}$ values rather than from independent data. In any case, in the experiments considered the decay kinetics of $\chi^{(2)}$ were determined either directly or through $\langle T \rangle$ using the decrease in the surface potential. The problems of the reason for the decrease in U and of the mechanism of this phenomenon are discussed neither in the paper cited (see Ref. 31) nor in other publications.

Practically, the main goals of the studies considered were the fabrication of the polymeric films with large values of $\chi^{(2)}$ that did not change with time and under the action of external factors. The decrease in $\chi^{(2)}$, fast or retarded, for different polymers at room temperature, indicates different thermal disordering of the chromophore orientation. Thus, it is possible to expect that the electric field results in the orientation of chromophores not only at high T_g , but at room temperature, as well. Consequently, it is possible to obtain polymeric films with nonlinear characteristics that can be manipulated by changing the external electric field in usual conditions. Using a simple system of PMMA + 2-methyl-4-nitroaniline (MNA) two components of the SHG response were registered at room temperature⁵⁸ when an alternating voltage of variable frequency was applied to the specimen comprising a film deposited on a glass substrate, and two metallic electrodes with a gap of 25 μm between them. The first component related to the orientation of the chromophore molecules is slow, and is observed up to 3×10^2 Hz. It lags in phase and decreases in the amplitude as the frequency of sinusoidal voltage increases. The second component, which seems to be caused by the third-order $\chi^{(3)}$ contribution into the SHG, is fast. This is characterised by the constant amplitude up to the maximum alternating field frequency 2×10^4 Hz and coincides with it in phase. The change in the slow component of the SH signal is determined by the rotational relaxation time of the oriented chromophores in the PMMA matrix, which is $\sim 10^{-2}$ s at room temperature.

The polymeric films of the type considered can be used for the elaboration of fast nonlinear optical devices of a new type controlled by the external electric field. In order to obtain stable SHG it is necessary to stabilise the oriented state of the chromophores because the process of the electric poling disturbs the equilibrium of the system, and after the cut-off of the corona discharge the dipole chromophores tend to disorder their orientation. This inevitably leads to the decrease in the second harmonic intensity, especially if a rapid decrease in the surface potential takes places. Several methods that allow one to minimise disordering of the chromophores are suggested.

1. The synthesis of polymers with high T_g , and consequently with small free volume at room temperature. This ensures low mobilities of the charged particles and prolonged preservation of the surface potential and nonlinear properties. Polyimides with $T_g > 200$ °C can be mentioned as an example. However, the necessity to use high temperature for the poling leads to the

evaporation of the chromophore in the host – guest systems based on such polymers. In addition, in the host – guest systems the chromophore concentration is limited as it is crystalline and plasticises the polymer at high concentrations.

2. Chemical or photochemical cross-linking of a polymer containing the corresponding cross-linking groups in the macromolecule in the poling at T_g . The mechanism of the influence of cross-linking on the charge of the SHG characteristics is the same as in the former case. However, this method leads to an increase in optical losses because of nonuniformity of cross-linking reaction in the polymer bulk.

3. The synthesis of polymers the macromolecules of which contain chromophores and the groups that favour strong intermolecular interaction and consequently high rigidity of the system. The simultaneous investigation of the SHG and the surface potential in a polymeric system of the third type has been carried out.⁵⁹ A polyurethane (PU) $[-1,3-\text{C}_6\text{H}_4(4\text{-CH}_3)-\text{NH}-\text{CO}-\text{O}-(\text{CH}_2)_2-\text{NR}-(\text{CH}_2)_2-\text{O}-\text{CO}-\text{NH}-]_n-$ was synthesised, where the side substituent R has the following structure

High chromophore group concentration (68 mass %) was the reason for high $\chi^{(2)}$ values: up to 200 pm V⁻¹ ($d_{33} = 100$ pm V⁻¹, see Table 3). The formation of hydrogen bonds between neighbouring macromolecules favours an increase in the polymer hardness and the stabilisation of noncentrosymmetrical structure. In the corona discharge, $\chi^{(2)}$ and U are changed in the following way: at room temperature after the discharge is switched on, $\chi^{(2)}$ is increased sharply; $\chi^{(2)}$ and U remain constant as the temperature increases up to 145 °C ($T_g = 121$ °C), and at this temperature fast increase in $\chi^{(2)}$ is observed. Further heating to 190 °C leads to the decrease in the $\chi^{(2)}$ and U to zero, and the film becomes electroconducting. Subsequent cooling of the film starting from 170 °C to 145 °C is accompanied by the significant increase in the $\chi^{(2)}$ and U . In the process of cooling to room temperature, $\chi^{(2)}$ and U were little changed. At room temperature, after the switch-off of the corona discharge, the decrease in the surface potential to zero and the increase in the $\chi^{(2)}$ by $\sim 20\%$ were observed. The latter is possibly related to the noncolinearity of the dipole moment vector (that follows the direction of the electric field) and the largest component of the β tensor, which after the cut-off of the field can take the position corresponding to the increased value of $\chi^{(2)}$. After such treatment, the value of $\chi^{(2)}$ remained constant for at least 33 days. Consequently, strong intermolecular interaction providing for the system rigidity causes the preservation of the chromophore group orientation in the absence of the external electric field.

The relationship between kinetic parameters of the surface potential U and susceptibility $\chi^{(2)}$ was studied in the films of poly(vinyl acetate) (PVAC) doped with the chromophore DO3.^{28,60} It was shown for this system^{61–63} that the stepwise temperature decrease from $T_g = 41.5$ °C to 35 °C results in isothermal relaxation of the specific volume over 4 h. The decay of the normalised value of the second-order susceptibility after the cut-off of the corona discharge immediately after the temperature jump, and after 4 h is illustrated in the Figure 3. As is seen, the decay of $\chi^{(2)}$ in both cases is well approximated by the biexponential function

$$\left[\frac{I(-2\omega, t)}{I(0)} \right]^{0.5} = \varphi \exp\left(-\frac{t}{\tau_1}\right) + (1 - \varphi) \exp\left(-\frac{t}{\tau_2}\right). \quad (19)$$

Complete relaxation of the specific volume leads to the significant retardation of both fast and slow components: at 35 °C, in the case of nonrelaxed film the kinetic curves of the $\chi^{(2)}$ decay are characterised by the parameters $\varphi = 0.35 \pm 0.05$,

$\tau_1 = 0.6 \pm 0.1$ min, $\tau_2 = 8 \pm 0.5$ min, while for the relaxed film $\varphi = 0.35 \pm 0.05$, $\tau_1 = 2 \pm 0.3$ min, $\tau_2 = 28 \pm 2$ min.

The measurement of the decay kinetic curves for $\chi^{(2)}$ and U at 23°C (Fig. 4) have practically have shown their virtually complete identity; $\varphi = 0.3 \pm 0.05$, $\tau_1 = 2.1 \pm 0.3$ min, and $\tau_2 = 110 \pm 5$ min. Consequently, the SHG in the PVAC + DO3 films is completely governed by the surface potential, *i.e.*, by the charges deposited on the films by the corona discharge in the range from T_g to 23°C . A direct proof of this conclusion was obtained using an effective method for the removal of the surface charge: the film was immersed for 15 s in a saturated aqueous NaCl solution, which led to the disappearance of SHG and the surface potential (see Fig. 4, points on the x axis). Preliminary experiments have shown²⁹ that other known methods of the surface potential removal, namely, keeping in a moist atmosphere, contact with the grounded metallic electrode, *etc.*, are ineffective. With a PMMA + DO3 film non-swelling in water as an example it was shown that the disappearance of the surface charge is not

connected to the swelling and plasticisation of the PVAC immersed for a short time in an aqueous solution. The SHG behaviour of this film after the removal of the surface charge is similar to that in the PVA + DO3 film (see Fig. 4).⁶⁴ For the latter system, it was sufficient to use even distilled water, *i.e.*, the charged particles are water-soluble; the cycles 'discharge in water – charging by the corona discharge' can be repeated many times without change of nonlinear optical and electrical characteristics; the charged film retains constant surface potential and $\chi^{(2)}$ for several months (time of observation) while kept in ordinary conditions. The unambiguous conclusion can be made on the basis of these results that all charge is concentrated on the film surface. In such a case, the surface potential is determined by the first term in Eqn (18).

Charging the film by the negative corona discharge results in predominant deposition of the CO_3^- ions onto the surface (see Refs 65, 66). The subsequent fate of the deposited ions depends on the characteristics of the polymeric system. First, the existence of

Figure 4. The kinetics of the decay of the second harmonic intensity and the surface potential. PVAC + 2 mass % of DO3 (1). PMMA + 5 mass % DO3 (2).

(1) second harmonic signal for PVAC + 2 mass % of DO3, keeping at 43 °C for 5 min, then charging by the corona discharge for 2 min at 23 °C; (2) surface potential for PMMA + 5 mass % DO3, charging by the corona discharge for 10 min at 23 °C, measurement at 23 °C; (3) second harmonic signal; (4) surface potential. the curve is plotted according to equation (19) with parameters $\varphi = 0.3$, $\tau_1 = 2.3$ min, $\tau_2 = 115$ min.

the electronic conductivity can not be assumed in the films. Even if we consider that the chromophores can serve as the electron-transport centres, their concentration (2 mass %–5 mass %) is definitely insufficient for the effective electron (or hole) transport through the film as the mean distance between neighbouring transport centres should not be exceeded ~ 15 Å.⁶⁷ In addition, penetration of ions into the bulk of the film should possibly be excluded. This is supported by the fact that after the polymer film treatment in the electrolyte solution the surface charges are practically completely removed (see Fig. 4).

The process of the surface potential decrease consisting of relatively fast (hundreds of seconds) and slow steps is well known. This was observed for different polymeric films without low-molecular-weight chromophores charged by the corona discharge (see Ref. 30 and references therein). For different polymers, the magnitude of the surface potential at the fast step varies from several to dozens percent relative to the initial value. It is assumed that the fast decay is connected with the drift of ions and their capture near the film surface by the polarisation and structural traps. The slow exponential decay seems to be related to the discharge of the captured charge because of the intrinsic bulk electric conductivity of the film. The rate of this decay is determined by the dielectric relaxation time (τ_M). Polymeric films always possess some ionic conductivity due to the residual solvent or ionic dissociation of the polar groups in macromolecules.^{30, 68} Thus, the decay of the surface potential is expressed by equation

$$U = U_0 \left[\varphi \exp\left(-\frac{t}{\tau}\right) + (1 - \varphi) \exp\left(-\frac{t}{\tau_M}\right) \right],$$

where $\tau = (v_t N \sigma)^{-1}$, $\tau_M = \varepsilon \varepsilon_0 / e n \mu$, v_t is the thermal velocity of ions, N is the concentration of the capture centres, σ is the charge capture cross-section, e is the electron charge, n and μ are the concentration and the mobility of the free charge carriers in the polymer bulk.

Retardation of the decay kinetics of $\chi^{(2)}$ upon physical ageing of a polymer can be explained by the decrease in the polymer free volume. The diffusion coefficient of molecules D in an amorphous phase at $T < T_g$ is linked to the free volume by Eqn (16). Taking into account the Einstein relation

$$\frac{\mu_d}{D} = \frac{e}{kT},$$

where μ_d is the mobility, we obtain that the decrease in $V_{fr}(T)$ leads to the increase in τ_M .

VII. The second harmonic electrooptical coefficient and nonlinear coefficient

The idea of using light for information transmission has become a reality after the invention in the 50–60s of coherent radiation sources in UV, visible, and IR ranges, as these allow one to increase substantially the capacity of the transmitting optical systems and to multiply the capacity of systems in the millimetre range. However, in addition to the coherent light sources it was necessary to develop transmitting media, active optical elements, materials for recording, storage and reproduction of optical information that would be cheap, technological, highly efficient, and compatible with modern microelectronic devices. Nowadays, organic polymeric materials of different chemical structure meet these requirements entirely. Polymeric nonlinear optical systems are promising for their utilisation as the light beam modulators, fibre optic switches, the laser radiation harmonic generators for enhanced capacity of recording, photorefractive media for the reversible recording of the holograms with the diffractive efficiency close to 100%, etc.^{69–71} The main parameter, which characterises an electrooptical material is the electrooptical coefficient r . For example, r is 1.43 pm V⁻¹ for AsGa, and 30 pm V⁻¹ for LiNbO₃, it increases considerably (up to 100 pm V⁻¹) for polymers.⁷⁰

On the one hand the electrooptical coefficient relates the change in the refractive index Δn of a polymer to the magnitude of the external electric field E : $\Delta n = -0.5n^3 r E$. On the other hand, the electrooptical coefficient is connected with the second-order susceptibility, which determines the intensity of the second harmonic

$$r = -\frac{2\chi^{(2)}}{n^2 \varepsilon}, \quad (20)$$

If r directly characterises the effects of modulation and switching of light fluxes and also the efficiency of the hologram recording on polymeric photorefractive materials, $\chi^{(2)}$ determines the efficiency of the laser radiation frequency transformation. Generally, the quantities r and $\chi^{(2)}$ are of equal value for the characterisation of the electrooptical properties of the material, however, in this review more numerous and detailed studies on the second harmonic generation are analysed. In addition, the relation of $\chi^{(2)}$ to the molecular motions in a polymeric matrix is direct and more obvious.

The steady-state values of the second harmonic nonlinear coefficient ($d_{33} = 0.5\chi_{zzz}^{(2)}$) measured (mainly at 20 °C) after the orientation of the chromophores in a constant electric field at the glass transition temperature for different polymeric systems are listed in Table 3. Despite different conditions corresponding to the measurement of this characteristic, some general features may be found. As is seen, the host–guest systems with small rotational diffusion times are characterised by low d_{33} values. The nonlinear coefficient in polyesters with chromophores in the pendent substituents (entries 17–19) is close to the d_{33} values in inorganic crystals and is increased markedly upon replacement of the stilbene-containing chromophores by the diazo groups. In the polymer 19 (where $-X=X-$ is $-N=N-$), the increase in the concentration of the chromophore groups first results in the increase of d_{33} , then it passes through a maximum (with one third of the repeating units containing the chromophores), and then gradually decreases. The decrease is related to the change in the polymer conformation at high chromophore content. The d_{33} values of polyimides (entry 24) with the high glass transition temperatures and, consequently, low polymeric chain mobility at room temperature exceeding remarkably those in inorganic crystals. Polyurethanes (entry 27), which acquire rigid structure after

the orientation due to the presence of intermolecular hydrogen bonds, possess the highest d_{33} values (≥ 200 pm V $^{-1}$).

Polyesters with the pendent chromophore groups that alternate with the cinnamate groups $-(CH=CH)-_n-R$ (R is alkyl), are used for the creation of a rigid polymeric matrix following UV radiation.⁹⁵ It is known that UV light induces $[2 + 2]$ -cycloaddition involving of the double bonds and results in cross-linking of the neighbouring side groups. The polymers 16b and 17 contain the epoxy groups which are cross-linked in the course of the orientation in the constant field at the temperature above 70°C. The absence of the effect of the epoxy groups (see entries 16a and 16b) is explained by the fact that the cross-linking proceeds faster than orientation, which becomes ineffective in the rigid cross-linked matrix. It should be added that in polydiacetylenes^{96,97} the stable oriented state is achieved even in the absence of the external electric field, namely, upon radiation-chemical or thermal synthesis from substituted diacetylene leading to the formation of a cross-linked three-dimensional structure. The polymer obtained in this synthesis had $d_{33} = 5.57$ pm V $^{-1}$.

All systems considered above contain chromophores with intramolecular electron transfer. Significant effects can be expected in polymeric systems with intermolecular donor-acceptor complexes. This followed from the fact that self-organised Langmuir–Blodgett films⁹⁴ consisting of centrosymmetrical molecules of 2,4-bis[4-(*N,N*-dibutylamino)-phenyl]squaraine $(C_4H_9)_2N-C_6H_4-C_4O_2-C_6H_4-N(C_4H_9)_2$ possessed high second-order susceptibility $\chi_{ef}^{(2)} = 250$ pm V $^{-1}$ ($d_{ef} = 125$, see Table 3, entry 28). The effect is due to the formation of the noncentrosymmetrical intermolecular donor-acceptor T-shape complexes, where the donor amino group of one molecule is oriented towards the central four-membered acceptor ring $-(C_4O_2-)$ of another molecule.

As regards practical application of polymeric materials with stable nonlinear second-order properties, for example, as optical switches or modulators, the absence of optical absorption at the wavelength of the second harmonic and photochemical stability of the chromophore groups and molecules with respect to the atmospheric oxygen are of significant importance.⁹⁸ The former demand can be met by the synthesis of appropriate chemical structures, and the latter is achieved by the introduction of oxygen acceptors into the working layer and the use of protective layers. In all cases, low electric conductivity of polymeric nonlinear optical systems is a must.

VIII. Conclusion

In polymeric host–guest NLO systems in ordinary conditions (room temperature or temperature up to T_g , the range of characteristic time from ~ 0.1 s to ∞) the decay kinetics of the SH intensity is determined entirely by the kinetics of the change in the surface potential. This phenomenon is explained by the fact that the characteristic times of the rotational diffusion of chromophores are shorter than the times of flight of the charged particles through the polymeric films. The reasons for the decrease in the surface potential and the features of this process are not sufficiently studied to date. In polymeric systems where chromophores are chemically linked to the polymer chain (pendent substituents) or they are the fragments of the main chain, at the temperatures below T_g the behaviour of the SH is determined by the dynamic characteristics of the polymeric matrix. For example, the formation of a polymeric network or strong intermolecular interaction due to the formation of the hydrogen bonds or the presence of the charged groups determine the SH stability with time, which is not connected with the presence of an external electric field.

Contents

I. Introduction	467
II. Methods for generation of nitrosoalkenes	467
III. Structure and physical properties of nitrosoalkenes	472
IV. Reactions of nitrosoalkenes	473

Abstract. Published data on the preparation, structure, physical and chemical properties, and reactivity of nitrosoalkenes are described systematically. The influence of the structure and stereoelectronic effects of substituents at the double bond on the stability of nitrosoalkenes is analysed. Primary attention is paid to concerted cycloaddition of nitrosoalkenes to miscellaneous multiple bonds, in particular, to the problems of regio-, stereo-, and enantioselectivity of [4 + 2]-cycloaddition of nitrosoalkenes to alkenes. The bibliography includes 183 references.

I. Introduction

The nitroso group is a powerful electron-withdrawing substituent; this has a crucial effect on the chemical properties of all conjugated systems containing this group. In particular, the nitroso group is known to promote efficiently nucleophilic substitution in benzene derivatives, and in some cases its activating influence is even more pronounced than that of the nitro group.^{1,2}

The main methods for synthesis, physical properties, structures, and reactivities of conjugated nitrosoalkenes are considered in only one review covering publications which appeared before 1983.³ However, more recently, some important aspects of the chemistry of these compounds have been further developed, most of all, owing to the efforts of the research groups headed by Reissig and Gilchrist. In the present review, we generalise and describe systematically the data published up to the end of 1997 including those concerning participation of nitrosoalkenes in concerted processes, primarily, in [4 + 2]-cycloaddition to alkenes.

The formation of nitrosoalkenes as reactive intermediates was hypothesised as early as 1898;⁴ however, it was not until 1960 that synthesis of the first stable compound of this type, trifluoronitrosoethylene, was reported.⁵ Since then, only a few stable nitrosoalkenes have been prepared; they usually contain bulky aryl, *tert*-alkyl, or halo substituents at the β -carbon atom. Nitrosoalkenes in which the β -carbon atom is included into a heterocyclic system can also be put into this group.

However, there is strong evidence indicating that many nitrosoalkenes can exist in solutions as unstable intermediates. They comprise a large number of β -alkyl- and β -aryl-substituted nitro-

soalkenes, several halo-substituted derivatives, and only few compounds containing OR or NR₂ groups at the β -position. Some of these intermediates have been identified by spectroscopy, while others have been detected on the basis of their characteristic blue colour. The lifetimes of these compounds vary a over wide range.

Finally, there exist nitrosoalkenes, which cannot be detected due to their instability. The formation of these compounds is judged based on experiments on their trapping. Thus all the known intermediates of the general formula CH₂=C(R)NO belong to this group. The properties of typical representatives of nitrosoalkenes **1** are listed below in Table 1.

This review consists of three parts. The first part is devoted to the methods for the synthesis of nitrosoalkenes, and the second one deals with their physical properties and structures. The third part describes chemical transformations of nitrosoalkenes, classified according to the type of reaction.

II. Methods for generation of nitrosoalkenes

1. 1,4-Elimination in α -substituted oximes under the action of bases

In recent years, the chemistry of nitrosoalkenes **1** (Table 1) has been developing especially successfully, mostly owing to the elaboration of a simple and reliable method for their generation from available precursors, α -substituted oximes.

This method has been used to prepare all the compounds listed in Table 1, except for trifluoronitrosoethylene **1a**. The chloride ion is the most frequently used leaving group; however, other halides are also suitable. Since nitrosoalkenes are sensitive to nucleophilic attacks, it is very important to choose appropriate conditions for their generation. The reaction should be carried out using weakly nucleophilic solvents and bases, except for those cases where they are used to trap nitrosoalkenes. Stable nitrosoalkenes have been synthesised using tertiary amines, Et₃N⁶ and 1,5-diazabi-

^b Mor = 

cyclo[4.3.0]non-5-ene (DBN).⁷ Unstable intermediates are better generated by treatment of α -halo oximes in non-nucleophilic organic solvents with insoluble inorganic bases such as Na₂CO₃^{17, 18} or Ca(OH)₂.¹⁰ These conditions ensure maintenance of a very low steady-state concentration of the highly reactive intermediates **1** and, as a consequence, suppression of the undesirable side processes involving more than one nitrosoalkene molecule, for example, polymerisation.

Denmark *et al.*^{19, 20} proposed a very interesting and useful modification of this method, namely, generation of nitrosoalkenes under 'neutral' conditions by treating *O*-trialkylsilyl derivatives of α -halo oximes with fluoride ions in weakly nucleophilic aprotic solvents. The best results were obtained with CsF and KF in MeCN;²⁰ however, AgF or Bu₄NF can also be used.

One of the synthetic modifications of the general method for the generation of the compounds **1** is rupture of the C–O bond in the isoxazoline ring of compound **2** as a result of deacetylation of the oxyimino group on treatment with a base and subsequent elimination of Br[–].²¹

Since α -halo oximes are important precursors of nitrosoalkenes, we considered it pertinent to outline here the three main methods for the synthesis of these compounds.

The first method is based on the reaction of the corresponding halo ketones with hydroxylamine. In particular, α -chloro oximes are prepared from α -chloro ketones and hydroxylammonium chloride in protic solvents.¹⁹ To synthesise α -bromo oximes, hydroxylammonium sulfate is used in order to avoid halogen exchange.²² It is undesirable to use alcohols as solvents, because they can substitute the halogen if the reaction time is long.¹⁶ According to the Denmark modification,¹⁹ *O*-trialkylsilyl derivatives of α -chloro oximes are prepared by condensation of the corresponding chloro ketones with *O*-trialkylsilylhydroxylamine in CHCl₃ in the presence of 4 Å molecular sieves.

The second method includes interaction of nitro alkenes with SnCl₂²³ or TiCl₄.⁸ It is used to prepare some α -chloro oximes or α -chlorohydroxyiminoyl chlorides, respectively.

The third method is also applicable only to the synthesis of chloro oximes. It is based on the addition of nitrosyl chloride to alkenes,^{24–29} and was first proposed more than a hundred years ago²⁶ for the synthesis of crystalline derivatives of terpenes. In the 60s, this reaction was extended to a broad range of nucleophilic and electrophilic alkenes mostly in the studies by Ogloblin *et al.*^{27–29} It is a convenient pathway to chloro oximes of the type ClCH₂C(R)=NOH [R = C(O)H, Ac, C(O)Ph, and CN]. The reactions of alkenes with NOCl yield initially β -chloro nitroso-compounds, which can subsequently dimerise to give compound **3** and/or rearrange into α -chloro oximes **4**. The latter route is possible if the carbon atom bound to the nitroso group carries a hydrogen atom (Scheme 1).^{24, 25}

The reactions with ordinary alkenes can be classified as electrophilic substitution, and the adduct is formed in conformity with the Markovnikov rule.^{24, 25} The fact that nitrosyl chloride adds unexpectedly rapidly to some α,β -unsaturated carbonyl compounds^{27–29} might be due to preliminary coordination of the nitrosonium cation (NO⁺) to the oxygen atom of the carbonyl group.

Scheme 1

If there are substituents at the C=C bond of the substrate molecule, able to stabilise efficiently the carbocationic site resulting from the attack by the NO⁺ cation, the reaction product has an ionic structure. The reactions shown in Scheme 2 are interesting examples of the generation of ionic intermediates of this type.³⁰

Scheme 2

$\text{X} = \text{Cl}$ (**a**), OSO_2OMe (**b**).

The nitrosation of the double bond in compound **5** by nitrosyl chloride or the acid-catalysed reaction of alkyl nitrate with the immonium cation **6** give compounds **7a,b**. To prepare nitrosoalkene **8**, the nitrosation product is treated with a base. During the transformations presented in Scheme 2, the sterically hindered radical site remains intact.³⁰

The type **3** dimers of β -chloro nitroso-compounds have also been used as precursors of some nitrosoalkenes.^{31–34} Thus the reaction of Bu_3N with dimers of chloro nitroso-compounds prepared from styrenes affords only orange dimers of β -nitroso styrenes **9**.³³

There are only few examples of generation of nitrosoalkenes from oximes with leaving groups other than halide ions. Thus products of the addition of nitrosyl sulfate ($\text{NO}^+\text{HSO}_4^-$) to alkenes have been used as the initial compounds for the preparation of nitrosoalkenes.³⁵ The nitrite ion can also serve as the leaving group.⁷ Yet another interesting variant of this approach is cleavage of the oxirane rings in α -epoxy ketoximes on treatment with the cuprate reagent to give compound **10**.³⁶

The acid-catalysed dehydration of sulfoxide **11** involves presumably the intermediate formation of the nitrosoalkene **10**.³⁷

However, as far as we know, the direct dehydration of α -hydroxy ketoximes has not been used as a method for generation of nitrosoalkenes.

2. Reactions of nitrogen(II) oxide with vinylic radicals

Trifluoronitrosoethylene **1a** was obtained by photolysis of trifluoroiodoethylene **12** in the presence of nitrogen(II) oxide.⁵

It has been assumed that the reaction product is formed upon recombination of trifluorovinyl radical with NO . To date, the compound **1a** is the only vinylic nitroso derivative prepared in a pure state using this type of reaction; however, in a number of other syntheses, nitrosoalkenes have been postulated as reaction intermediates.

Thus acetylene reacts with hydrogen atoms and NO to give HCN and formaldehyde resulting apparently from rearrangement and fragmentation of the intermediate nitroso ethylene **1k**.³⁸

Several more reactions of this type have been reported.^{38,39} For example, nitrosoalkene **13** was postulated as an intermediate in the reaction presented below:³⁹

3. 1,3-N,C-elimination of trialkylsilanol from silyl nitronates

The reactions of 1,4-elimination of HX from α -substituted oximes under the action of bases is the most important and the most general method for the generation of nitrosoalkenes **1**.

It is curious to note, however, that the 'alternative' possibility of 1,3-elimination of HX from compounds like **14** as a route for generation of nitrosoalkenes has not been specially considered until recently.

The possibility of this transformation was first hypothesised by Seebach *et al.*⁴⁰ They postulated 2-nitrosohept-1-ene **1p** as an intermediate in the reaction of *tert*-butyldimethylsilyl nitronate **14a** with excess organolithium reagent. The first equivalent of RLi reacts as a base facilitating the abstraction of *tert*-butyldimethylsilyl, and the second equivalent reacts with the resulting nitrosoalkene **1p** as a nucleophile, and this leads to the final reaction product, dialkyl ketoxime **15**.⁴⁰

Later, in studies by Ioffe *et al.*,^{41–44} β -functionally substituted nitrosoalkenes **1** have been considered as the most probable intermediates for trimethylsilylation of nitro compounds containing electron-withdrawing groups at the β -position (Scheme 3). In the authors' opinion, these substituents facilitate spontaneous fragmentation of the intermediate trimethylsilyl nitronates **14**. The fate of the resulting nitrosoalkenes **1** depends on their structure, in particular, on whether or not protons or electron-withdrawing groups are present at the γ -position of the initial nitro compound.⁴⁴ The final reaction products are either *O*-trimethylsilyl-derivatives of α,β -unsaturated oximes **16** [pathway (a)] or *N,N*-dialkenyl-*N*-trimethylsilyloxyamines **17** [pathway (b)]. The reaction follows pathway *a* if the molecule **1** contains two electron-withdrawing groups (R^2 , R^4) such as CN or COOMe. In the latter case [pathway (b)], silyl nitronates **14** not only serve as the source of nitrosoalkenes **1** but also react with them according to the pattern of 1,2-addition to the nitroso group.

Recently, the generation of silyl nitronates **14** and then of nitroso alkenes **1** during the formation of type **17** products was confirmed by selective trapping of these intermediates in the silylation of methyl 3-nitropropionate.⁴⁵

The above sequence of reactions confirms the possibility of generating nitrosoalkenes **1** from silyl nitronates **14**. This is

fundamentally important, since the compounds **14** are readily accessible and can prove to be convenient precursors of nitrosoalkenes, especially, of β -functionally substituted ones, which have scarcely been studied.

4. Nitrosation of C=C bonds enriched in electrons

When dithiafulvenes **18** are treated with amyl nitrite, nitroso-compounds of the type **19** are readily produced.⁴⁶

$\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$ (a); $\text{R}^1 = \text{R}^2 = \text{CO}_2\text{Me}$ (b).

The ease of nitrosation is due to the presence of the electron-donating heterocyclic fragment, which efficiently stabilises the positive charge on the endocyclic C(2) atom by means of aromatisation. The reaction is accelerated by catalytic amounts of acids and inhibited by tertiary amines; therefore, it is believed that at the first stage, the nitrosonium cation is generated. However, in the opinion of the researchers cited,⁴⁶ the electrophilicity of the NO^+ cation is insufficient to accomplish nitrosation by an electrophilic mechanism; therefore, as the most probable reaction route, they proposed a scheme involving single-electron transfer.

Selenium-⁴⁷ and tellurium-containing⁴⁸ analogues have been synthesised in a similar way.

$\text{X} = \text{Se}, \text{Te}$.

Nitration or nitrosation of trithiapentalene **20a** has given unsaturated nitroso-derivative **21a**, the first representative of 2,4-epidithio-1-nitrosobuta-1,3-dienes.⁴⁹

Scheme 3

BSA is *N,O*-bis(trimethylsilyl)acetamide;

(a) $\text{R}^1 = \text{CH}_2\text{R}^4$; R^2 , R^4 are electron-withdrawing groups;

(b) 1,2-addition of **14**.

$R^1 = \text{Ph}; R^2 = \text{Ph}$ (**a**), SMe (**b**), NMe_2 (**c**); $R^1 = R^2 = \text{SMe}$ (**d**).

$R = \text{PhCO}$ (**a**), NO_2 (**f**);

(**a**) $\text{HNO}_3 - \text{AcOH}$; (**b**) $[\text{HONO}]$; (**c**) $\text{Hg}(\text{OAc})_2$.

At $R^1 = R^2 = \text{Ph}$, the introduction of a nitroso group is accompanied by the transformation of the thiobenzoyl substituent into benzoyl (compound **21a**).⁴⁹ The formation of 2,4-epidithio-1-nitrosobuta-1,3-dienes **21b–d** from the corresponding trithiapentalenes **20b–d** occurs with retention of the thiocarbonyl fragment.^{49, 50} The CS_2Me group in the compound **21b** is removed on treatment with mercury(II) acetate.⁴⁹ The nitrosation of the corresponding 2,4-epidithiobuta-1,3-dienes yields the compounds **21a**⁴⁹ and **21f**.⁵¹

5. Other methods

Other methods are as yet of limited utility. Examples of generation of nitrosoalkenes from substrates having some specific structural features have been reported; in some cases, the arguments for the intermediate formation of nitrosoalkenes are based on the analysis of the final reaction products and, hence, they are not always convincing.

For example, 2-azidopyridine *N*-oxides **22** have been shown to undergo a number of transformations on exposure to radiation or on heating above 85°C .^{52–54} It is assumed that upon ring opening and concerted elimination of N_2 , the compounds **22** can be converted into conjugated nitroso dienes, which then cyclise. When a substituent is present at the 3-position, two types of products can be formed, namely 6*H*-1,2-oxazines **23** and cyclic nitrones, 2*H*-pyrrole *N*-oxides **24**. When $R^1 = \text{Cl}$ or Br , the compounds **23** can undergo subsequent transformations in the presence of nucleophilic solvents.⁵³

When $R^1 = \text{Me}$ or H , the oxazines **23** are kinetically controlled products, whereas the nitrones **24** are thermodynamically controlled products of cyclisation of the intermediate nitroso dienes.⁵⁴ Similar transformations have also been observed for azidopyrazine 1-oxides **25**⁵² and azidoquinoxaline

1,4-dioxides **26**.⁵⁵ In the opinion of Abramovich *et al.*,⁵⁴ in the latter case, a cyclic nitrone of type **24** is the kinetically controlled product, and 1,2-oxazine of type **23** is the thermodynamically controlled product.

The generation of nitrosoalkenes **27** is accompanied by isomerisation of the carbon skeleton of the substrate.⁵⁶

One more particular example of formation of nitrosoalkenes is retro-[2 + 4]-cycloaddition, which is facilitated by the formation of the stable aromatic structure of substituted indole.⁵⁷

$X = \text{COMe}, \text{CO}_2\text{Et}$.

Apparently, the reactions of sulfonium ylides with nitrile oxides also proceed *via* nitrosoalkenes, which then react with nucleophilic ylides according to the addition–elimination reaction pattern or addition followed by cyclisation.^{34, 58–61} An example of this type of reaction is presented below:

Indian researchers⁶² have shown that the addition of gaseous NOCl in CH_2Cl_2 at 0°C to the triple bonds in methyl alkynoates affords the corresponding β -chloro nitrosoalkenes. They found that nitrosoalkenes of type **28a** can isomerise to the corresponding chloro ketene oximes **29**. However, it should be mentioned that this isomerisation has never been observed for other nitrosoalkenes.

$R = \text{H}$ (**a**), Alk (**b**); $R^1 = (\text{CH}_2)_n\text{CO}_2\text{Me}$.

Condensation of oximes **30** with allylamine⁶³ or benzylamine⁶⁴ makes it possible to isolate moderately stable nitrosoalkenes **31** as highly coloured crystals. The structure of the compound **31a** was confirmed by X-ray diffraction analysis.⁶⁴

Ar = 4-ClC₆H₄; R = Ph (**a**), CH = CH₂ (**b**).

Methylation of 5-hydroxyiminomethyl-1,2,3-thiadiazole followed by treatment with a base affords a stable nitrosoalkene in a low yield.⁶⁵

Oxidative dimerisation of α,β -unsaturated steroid oxime **33** gives rise to nitrosoalkene **34**, which is formed apparently by a radical mechanism.⁶⁶

Deoxygenation of perchloro-2-nitrobuta-1,3-diene upon treatment with R¹P(OR)₂ results in the formation of perchloro-2-nitrosobuta-1,3-diene **1e** (see Table 1). The yield of this product is not indicated in the study cited.⁹ Gas-phase thermolysis of nitroethylene on Fe or Ni at 883 K yields nitrosoethylene **1k**, together with MeCN.⁶⁷

There exist two groups of compounds that can serve as close precursors of nitrosoalkenes, owing to their structural features. The first group comprises *N,N*-bis(lithioxy)enamines **35**, which were first described by Seebach *et al.*,⁶⁸ and the second group includes *N,N*-bis(trialkylsilyloxy)enamines of type **36**. It was shown⁶⁸ that treatment with benzoyl chloride of 1-[*N,N*-bis(lithioxy)]amino-2-phenylethylene, the product of double deprotonation of 1-nitro-2-phenylethane, gives a polymer. This was explained by assuming the generation and subsequent polymerisation of β -nitrosostyrene under the reaction conditions. However, no additional evidence supporting this hypothesis was presented.⁶⁸ Moreover, β -nitrosostyrene had been described earlier³³ as a stable crystalline dimer.

R¹ = Ph, R² = H, R³ = PhCO (**37a**); SiAlk₃ (**37b**).

N,N-Bis(trialkylsilyloxy)enamines **36** were first described⁶⁹ as products of double silylation of aliphatic nitro compounds. The thermal instability of the compounds **36** (Alk = Me) observed in some cases was explained by possible easy elimination of (Me₃Si)₂O giving nitrosoalkenes, which then polymerise. However, the attempt to trap nitrosoethylene **1k** as the corresponding adduct with cyclopentadiene during decomposition of the enamine **36** (R¹ = R² = H, Alk = Me) failed.⁶⁹

Nevertheless, compounds **37** which have become quite available by now, are of interest as initial compounds for the generation of nitrosoalkenes *via* anionic intermediates of the semiacetal type by treatment with reagents possessing nucleophilic properties with respect to the trialkylsilyl group (see Scheme 3). Previously this route for the construction of a nitroso group has been realised during ring opening in *N*-trimethylsilyloxyisoxazolidines.^{41, 71}

III. Structure and physical properties of nitrosoalkenes

As was to be expected, stable nitrosoalkenes, the properties of which are listed in Table 1, have been characterised most comprehensively by spectroscopic data.

Spectroscopic characteristics of long-lived nitrosoalkenes have been described systematically.⁸ The blue colour of these compounds is due to absorption in the visible region (λ_{max} = 675–795 nm) with low extinction coefficients (ϵ = 20–60).¹⁹ Absorption is also observed between 250 and 350 nm (in some cases, two maxima can be distinguished).

IR spectra of nitrosoalkenes contain two absorption bands in the region 1420–1660 cm⁻¹. A band in the range 1420–1480 cm⁻¹ corresponds to the stretching vibrations of the N=O bond (for 2,2-di-*tert*-butylnitrosoethylene **1c**⁷ this band occurs at 1485 cm⁻¹). The same region contains the absorption bands for the N=O bonds in other monomeric nitroso compounds.⁷² The absorption at shorter wavelengths (1500–1600 cm⁻¹) was assigned to stretching vibrations of the C=C bond.⁸

In the ¹H NMR spectra of the compounds **1b** and **1f** (see Table 1), the vinylic protons account for signals at δ 9.13 ppm⁶ and 8.68 ppm,¹⁰ respectively. In the case of the nitrosoalkene **1c**, the signal due to the proton at the carbon atom bound to the nitroso group manifests itself in a substantially higher field (δ 6.30 ppm).⁷ Thus, spectral data attest to the occurrence of appreciable π -conjugation between the C=C bond and the nitroso group.

The stability of nitrosoalkenes markedly increases in the presence of halogen atoms or bulky aryl or *tert*-alkyl groups (see Table 1), as well as upon formation of strong intramolecular hydrogen bonds (compound **31b**)⁶³ or complexes with transition metals (compound **38**).⁷³

The high stability of 2,4-epidithio-1-nitrosobuta-1,3-dienes **21**, the nitroso compound **32**, the nitroso fulvenes **19**, and their selenium- and tellurium-containing analogues is due to the fact that the β -carbon atom of the nitrosoalkenyl fragment and the electron-donating substituents attached to it are incorporated into a common 6π -electron heterocyclic system.

The structure of the nitrosobutadienes **21a,f** was unambiguously determined based on X-ray diffraction analysis. It was found that the $S\cdots O$ interatomic distance is much shorter than that expected on the basis of the van der Waals radii of the S and O atoms.^{74–76} The abnormally short distance between the sulfur and oxygen in the nitrosobutadienes **21** is explained by the ability of the formally divalent sulfur atom to be involved into additional binding, which can be accomplished either with participation of the sulfur d orbitals or due to the formation of a three-centred electron-enriched $S-S-O$ bond.⁷⁵ It is noteworthy that, according to X-ray diffraction data, the $S\cdots O$ interatomic distance formed upon coordination of the nitroso group to sulfur is markedly shorter than that arising upon coordination to a carbonyl⁷⁶ or nitro group.⁷⁴ The configuration of the $C=C$ bond in the compounds **21** is determined by the fact that sulfur coordinates preferentially to the oxygen atom of the nitroso group rather than to other groups ($C=S$, $C=O$, or NO_2).⁵¹ In terms of the valence-bond method, the $S\cdots O$ binding can be represented by the following canonical structures:

The CNDO/2-SCF-MO calculations⁷⁷ for a hypothetical structure of aldehyde **39** demonstrated the possibility of this binding. The X-ray diffraction⁷⁸ and ¹⁵N NMR spectroscopy⁷⁹ data for 1,2,3-thiadiazole **40** also imply a thiapentalene character of this structure.

Mass spectra of 2,4-epidithio-1-nitrosobuta-1,3-dienes **21b,e,f** have been studied.⁸⁰

Unstable nitrosoalkenes have scarcely been investigated by spectroscopy. The structure of the *s-trans*-rotamer of nitrosoethylene **1k** generated by pyrolysis of chloroacetaldoxime has been studied by microwave spectroscopy in the gas phase.¹³ The molecular orbitals of **1k** have been calculated by the Hückel⁵⁶ and CNDO⁸¹ methods. The optimised structures, bond orders, and electrostatic potentials for the compound **1k** and fluoronitrosoethylenes have been calculated by the *ab initio* (SCF-MO) method.⁸² It was found⁸¹ that the *s-trans*-rotamer of **1k** is somewhat more stable than the *s-cis*-rotamer.

IV. Reactions of nitrosoalkenes

Due to the presence of the $C=C-N=O$ fragment, nitrosoalkenes are highly reactive compounds; they readily undergo intramolecular rearrangements, react with nucleophiles, and enter into concerted cycloaddition reactions.

1. Unimolecular reactions

Two types of intramolecular rearrangements of nitrosoalkenes have already been mentioned here; these are cyclisation to 1,2-oxazetines followed by fragmentation (see Section II.2) and cyclisation of nitroso-dienes to 6*H*-1,2-oxazines and 2*H*-pyrrole *N*-oxides (see Section II.5). Taking into account the reaction conditions described in Ref. 30, the transformation of the nitrosoalkene **8** into the final product **42** upon treatment with acetyl chloride occurs most probably *via* an intermediate 1,2-oxazetene rather than according to the haloform decomposition pattern, as the authors cited³⁰ believe.

The intramolecular route of fragmentation of nitrosoethylene **1k** involving intermediate formation of 1,2-oxazetene was confirmed subsequently by *ab initio* (SCF-MO) calculations.⁸³

Oxazetines have also been isolated after thermal rearrangement of the nitrosoalkene **1c**⁷ and after the reaction of bromo oxime **43** with bases. In the latter case, the intermediate formation of the nitrosoalkene **1o** was assumed.³⁷

DBN is diazabicyclononane.

It has been suggested⁸ that cyclisation to 1,2-oxazetines followed by fragmentation is the main route of decomposition of many other nitrosoalkenes, which do not isomerise to unsaturated oximes without external nucleophiles. The examples of formation of PhCN and Ph₂CO upon treatment of oximes **44** and **45**, respectively, with Na₂CO₃ in CH₂Cl₂ were presented as evidence supporting this hypothesis.⁸

Yet another characteristic type of intramolecular rearrangements is [1,5]-shift of a hydrogen atom. This is the main route of transformation of internal nitrosoalkenes having allylic hydrogen atoms. This rearrangement results in the formation of the corresponding unsaturated oximes in 28%–72% yields.³¹ Thus it has been assumed³⁵ that the [1,5]-shift of hydrogen in 2-methyl-1-nitrosocyclohexene **46** gives unsaturated oxime, which has been identified³ as having the structure **47**. During the reaction, the blue colour, typical of solutions of the nitrosoalkene **46**, disappears.

When chlorinated oxime **48** is treated with Na_2CO_3 ,⁸⁴ [1,5]-shift of hydrogen results in the formation of unsaturated oxime **49**. The same compound is formed as a side product in cycloaddition reactions of the nitrosoalkene $\text{MeCH}=\text{C}(\text{Ac})\text{NO}$ ¹⁶ (see Section IV.3).

It has been found¹⁹ that the rearrangement giving unsaturated oximes can occur not only as an intramolecular transformation but also as a base-catalysed one. Thus nitrosoalkene **50** for which concerted hydrogen [1,5]-shift is impossible due to steric reasons, is much less stable than compound **51**, which contains no hydrogen atoms at C(3) (the half-life $\tau_{1/2}$ for the compound **50** in a dilute solution is 12 min, while that for the compound **51** is 900 min).¹⁹

The scheme of transformation of the isoxazolinone **2** into the corresponding α,β -unsaturated oxime (see Section II.1)²¹ and the synthesis of *O*-trimethylsilyl derivatives of the α,β -unsaturated oximes **16** (see Scheme 3)⁴⁴ have also been assumed to include stages involving the [1,5]-shift of hydrogen.

2. Reactions with nucleophiles

In the nitroso compounds **1**, the $\text{C}=\text{C}$ double bond is conjugated with the nitroso group and is thus activated. The reactivity of nitrosoalkenes obviously resembles those of other activated alkenes, for example, conjugated nitroalkenes. The presence of π -conjugation accounts for the high electrophilicity of the β -carbon atom in nitrosoalkenes; therefore, these compounds are especially prone to react with nucleophiles.

The reactions of nitrosoalkenes with nucleophiles can be conventionally divided into two groups: (1) 1,2-addition at the $\text{N}=\text{O}$ bond and (2) conjugate 1,4-addition.

Only two examples of reactions of the former type are known. These are addition of silyl nitronates to the nitroso group in β -substituted vinyl nitroso compounds [see Scheme 3, pathway (*b*)] and intramolecular condensation of substituted nitrosoalkenes **52** to the corresponding vinylimidazoles **53**.⁶³

Conjugate 1,4-nucleophilic addition is much more typical of vinyl nitroso compounds and largely determines their synthetic value.

When α -halo oximes are used as synthetic precursors of the substituted oximes **54**, two routes are, in principle, possible: (1) 1,4-elimination–addition with intermediate formation of nitrosoalkenes and (2) direct substitution of the halogen by a nucleophile by the $\text{S}_{\text{N}}2$ mechanism. Is it possible to determine which of the mechanisms is realised in each particular case? This important question has been answered⁵⁵ based on a semiquantitative study of the rates of *N*-alkylation of azoles **55a–e** by model α -bromo oximes **56a,b**. The results of this study are presented in Table 2.

$\text{R} = \text{H}$ (**56a**, **57a**), CMe_2OMe (**56b**, **57b**).

It can be seen from the data of Table 2 that imidazole **55a** and 3,5-dimethylpyrazole **55b** react with α -bromo oxime **56a** much faster than their less basic analogues. On passing to the bromo oxime **56b**, the rate of the reaction with the compounds **55a,b**

Table 2. Effect of the basicity of the azoles **55a–e** on the duration of *N*-alkylation with α -bromo oximes **56a,b**.

Substrate 55	$\text{pK}_{\text{a}}^{\text{a}}$	Duration of the reaction (h) with the oximes	
		56a	56b
a	7.10	0.2	24
b	4.12	0.5	48
c	3.32	24 ^b	—
d	2.52	72	—
e	2.27	72	—

Note. An azole (2.0 mmol) and a bromo oxime (1 mmol) in 25 ml of MeCN, 20 °C. ^aFor aqueous solutions of conjugated acids. ^bThe ratio **57e**:**57f** = 2 : 1.

markedly decreases and becomes comparable with the rates of reactions of weakly basic azoles.

Evidently, the azoles **55a,b** are sufficiently basic to react with the oxime **56a** via the 1,4-elimination–addition pattern involving intermediate formation of the corresponding nitrosoalkene, acting simultaneously as bases and as nucleophiles. Bromo oxime **56b** cannot react according to the elimination–addition scheme. In this case, the reaction occurs as direct S_N2 substitution. The conclusion about the formation of ethyl α-nitrosoacrylate **1r** during this reaction was confirmed⁸⁵ by its trapping. The product of reaction of the nitrosoalkene **1r** with 2,5-dimethylfuran **58** was obtained in 50% yield.

The reaction of the oxime **56a** with a weaker base, pyrazole **55d**, in the presence of 2,5-dimethylfuran yields only the corresponding *N*-alkylation product, cycloadduct of type **58** being totally missing. When Na₂CO₃ is added to a solution of pyrazole **55d** and bromo oxime **56a** under standard conditions, the reaction is completed over a period of 10 min giving the corresponding *N*-alkylation product in a high yield.⁸⁵ Based on these data, it was concluded that the reactions of the azoles **55c–e** with the oxime **56a** and of the compounds **55a,b** with the oxime **56b** occur as direct S_N2 substitution.

The facts presented in the study cited⁸⁵ to justify the assumption that the mechanism of *N*-alkylation changes upon a decrease in the azole basicity seem quite convincing. However, in our opinion, the reaction mechanism depends not only on the basicity of the nucleophile but also on the acidity of the preceding oxime, which varies as a function of the substituent X at the C=N bond.

There are weighty arguments that the reactions of the dimers of β-chloro nitroso compounds **3** with nucleophilic bases occur by the elimination–addition mechanism. These compounds react with MeONa faster than with piperidine; however, when both bases are present, α-piperidino oximes **59** are the major reaction products.³³

The experimental results rule out the direct substitution mechanism. It is obvious that the ratio of the reaction products is determined by the fact that at a fast reaction step, piperidine which possesses stronger nucleophilic properties, adds preferentially to the nitrosoalkene **1**.

Study of the reactions of *syn*- and *anti*-α-bromoacetophenone oximes with morpholine in an aqueous buffer solution also points to the intermediate formation of 1-nitroso-1-phenylethylene **11**. Reactions with both bromo oximes give *anti*-α-morpholino oxime **60**.¹⁵

Presumably, bromo oximes undergo fast deprotonation and then eliminate Br[−] in the rate-determining step yielding the intermediate 1-nitroso-1-phenylethylene **11**. Morpholine adds to the nitrosoalkene **11**, which occurs in the transoid conformation.

In the majority of other cases, the mechanisms of reactions of nucleophiles with α-halo oximes and with dimers of β-chloro nitroso compounds have not been studied. Alkylation of the anions derived from 1,1-dinitroalkanes⁸⁶ or tertiary phosphines^{87,88} with α-halo oximes proceeds apparently as the direct S_N2 substitution of the halogen atom. In view of the relatively low basicity of these nucleophiles, the intermediate formation of nitrosoalkenes during their alkylation seems unlikely.

Below we discuss only those examples in which either the reaction conditions strongly imply the occurrence of the elimination–addition mechanism or independent evidence for the intermediate formation of nitrosoalkenes exists.

Examples of interaction of *N*-, *O*-, and *S*-nucleophiles with nitrosoalkenes are presented in Table 3.

Table 3. Addition of *N*-, *O*-, and *S*-nucleophiles with nitrosoalkenes.

Scheme 4

The reaction follows the general Scheme 4; however, the primary adducts often undergo subsequent transformations. For example, treatment of chloroacetone oxime with aqueous ammonia affords tertiary amine **61**.⁴ Reactions of this type have also been observed for 1-haloalkyl phenyl ketoximes.⁹⁰ The dichloroacetaldehyde oxime reacts with primary amines to give imines **62** resulting from elimination of HCl from the primary adduct **63**;⁹⁶ the chloral oxime reacts in a similar way.⁹⁶ The reactions with thiocyanate ions yield 2-aminithiazole *N*-oxides **64** formed upon cyclisation of the primary adducts.^{31, 91, 98}

The interaction of nitrosoalkenes with enamines and other electron-donating alkenes will be considered in Section IV.3.b among cycloaddition reactions. In this section, we shall discuss reactions of nitrosoalkenes with carbanions and also electrophilic substitution in aromatic substrates.

Vinyl nitroso compounds are convenient reagents for alkylation of nucleophilic carbon atoms under mild conditions. Reactive carbanions or their equivalents serving as nucleophiles in these reactions are taken in a twofold (or larger) molar excess. The first mole of a nucleophilic compound reacts as a base with liberation of an intermediate nitrosoalkene, and the second mole acts as the nucleophile. A typical example of these reactions is the generation of nitrosoalkenes followed by nucleophilic addition of organometallic substrates to them, which gives rise to the compounds **10**³⁶ and **15**.⁴⁰

EtMgBr ,¹¹ PhMgBr ,⁹⁴ and $\text{EtC}\equiv\text{CLi}$ ⁹⁹ have also been used in similar reactions.

α -Bromo oximes have been used to alkylate lithium enolates prepared from substituted cyclopentanones.^{100, 101}

$\text{R} = (\text{CH}_2)_3\text{CH}=\text{CH}_2$.

The reactions of nitrosoalkenes with other stabilised carbanions are presented in Table 4. In many cases, EtONa and EtOH are used as the base and the solvent, respectively; in some cases, Na_2CO_3 in CH_2Cl_2 ⁹³ or in Bu^tOMe ¹⁷ or piperidinium acetate in THF ⁹⁶ are also employed.

The reaction products are 1 : 1 adducts; they exist in solutions as mixtures of linear tautomers and five- or six-membered cyclic species, as for example, the adduct **65** (Scheme 5).¹⁷

Scheme 5

Some of the addition products can undergo subsequent transformations. Thus the adducts obtained from the nitrosoalkene $\text{ClCH}=\text{CHNO}$ eliminate HCl under the reaction conditions giving rise to α,β -unsaturated oximes $\text{R}^1\text{R}^2\text{C}=\text{CHCH}=\text{NOH}$.⁹⁶ Some of the adducts can be converted into the corresponding 1-hydropyrroles by treatment with an acid.^{102–105, 107} An example is provided by the formation of 3-acetyl-1-hydroxy-2,5-dimethylpyrrole **66** from the adduct of chloroacetone oxime and acetylacetone.¹⁰²

Reactions of sulfonium ylides yielding isoxazolines and α,β -unsaturated oximes have been described above (Section II.5).^{34, 58–61}

It seems very attractive to use nitrosoalkenes as electrophiles in aromatic substitution reactions, because they are generated under mild conditions in the absence of acids. This reaction would permit introduction of various functional groups. However, in practice, only highly electrophilic nitrosoalkenes in combination with highly nucleophilic aromatic and heteroaromatic systems are suitable for this purpose. Thus alkylation of 1,3-dimethoxybenzene with electrophilic nitrosoalkenes is one of the few

reported examples of this type of reaction.¹⁶ The ratio of the isomers **67** and **68** formed in this process is 1 : 4.

R	H	Me	OEt
Yield of 67 + 68 (%)	41	63	11

Alkylation of 1,4-dimethoxybenzene, *N,N*-dimethylaniline, and 2-naphthol with 3-nitrosobut-3-en-2-one **1m** gives the corresponding products **69–71** in low yields; less electrophilic ethyl α -nitrosoacrylate **1r** does not alkylate 2-naphthol.

R¹, R² = H, NMe₂.

The reactions of nitrosoalkenes with heteroaromatic systems (furans, benzofurans, pyrroles, and indoles) are more general. In this review, we classify these reactions as electrophilic substitution. However, this classification is quite arbitrary (see, for example, Refs 16, 17, and 108), because for these heterocycles it is often difficult to decide between electrophilic substitution and [4 + 2]-cycloaddition reaction mechanisms.

The reactions of pyrroles with ethyl α -nitrosoacrylate **1r** involve only the 2-position.^{108, 109} The data about the formation of 3-substituted pyrroles^{3, 16} as side products have not been supported later.¹⁰⁸ Depending on the presence and the positions of substituents, pyrroles give 1 : 1 adducts of two types, **72** and **73**. This is apparently due to proton migrations in the adducts formed initially. Unfortunately, the attempt to involve ethyl α -nitrosoacrylate **1r** in the reaction with 1,2,5-trisubstituted pyrroles, which would rule out the possibility of these migrations, was unsuccessful. Ethyl α -nitrosoacrylate also did not react with less electron-donating *N*-(toluene-4-sulfonyl)pyrroles and pyrrole-2-carbaldehyde.¹⁰⁸

R = Me, Ph (**72**); R = H, Me (**73**).

Unlike pyrroles, indoles are alkylated by nitrosoalkenes; the reaction involves the 3-position and yields two types of adducts, **74** and **75**, depending on whether or not this position contains substituent.

In the case of electron-deficient nitrosoalkenes — CH₂=C(CO₂Et)NO (**1r**),^{16, 93, 110} CH₂=C(Ac)NO (**1m**),¹⁶ and CH₂=C(CF₃)NO (**1n**)¹⁷ — the corresponding adducts are formed in high yields (65%–88%) even from equimolar amounts of bromo oxime and indole.¹⁶ However, at elevated temperatures, the yields decrease, because the reaction becomes noticeably reversible.⁵⁷ When 1-nitroso-1-phenylethylene **1l** reacts with *N*-methyltetrahydrocarbazole, cyclic nitron **76** and 2 : 1 adduct **77** are formed together with the main product **74**.⁵⁷

R, R = (CH₂)₄.

Alkylation of 2-substituted indoles by the nitrosoalkene CH₂=C(CO₂Et)NO (**1r**) is the key stage in the synthesis of several tryptophan derivatives.^{111, 112} A series of studies^{113–115} have been devoted to alkylation of 3-substituted indoles with ethyl α -nitrosoacrylate aimed at the synthesis of biologically active tryptophan derivatives. In some cases, the primary adducts were found to be unstable and to rearrange readily.^{113–115}

The reactions with less aromatic substrates such as furan,^{16, 18, 93} 2-methyl-,¹¹⁶ 2,5-dimethyl-,^{16, 18, 116, 117} and benzofuran¹⁶ always afford cycloadducts **78** and **79**, which readily undergo selective cleavage on treatment with acids^{16, 118} or bases¹¹⁶ to give either products of oxazine ring opening or products of more extensive transformations.^{116, 118}

3. Cycloaddition reactions

Nitrosoalkenes can participate in cycloaddition reactions either as 2 π -electron systems (the reaction involves the nitroso group) or as 4 π -electron conjugated heterodienes (1,2-dihetero-1,3-diene systems). No examples of reactions involving only the C=C bond have been found yet. However, some researchers^{119, 120} have suggested that nitrosoalkenes enter into [4 + 2]-cycloaddition reactions with 1,3-dienes as 2 $\pi_{C=C}$ components, which are followed by fast [3,3]-sigmatropic rearrangement of the resulting adducts into the final products. For example, cycloaddition of nitrosoalkenes to cyclopentadiene to give adduct **80** can be considered within the framework of this hypotheses; however, no facts supporting it have been obtained.

R = Ar, C(O)R.

a. Nitrosoalkenes as 2 π systems in cycloaddition reactions

Cycloaddition to a nitroso group acting as a 2 π -electron system is typical of nitroso compounds of many classes.^{121–123} In the case of nitrosoalkenes, this type of reaction is limited to β,β -dihalo- and β -halo- β -alkyl-derivatives.⁸ For example, trichloronitrosoethylene **1s** reacts as heterodienophile with various cyclic and

acyclic nucleophilic dienes including butadiene,⁸ 1-methoxybutadiene,⁸ cyclopentadiene,⁸ cyclohexadiene,⁸ and benzene oxide.¹²⁴

Adducts formed from cyclic dienes are thermally unstable and readily rearrange at room temperature to epoxyaziridines, similarly to the [4 + 2]-cycloadducts of 1,3-dienes with singlet oxygen, which are converted into 1,3-diepoxydes.^{125, 126}

The structure of the adduct derived from β,β -dichloronitrosoethylene **1t** and cyclopentadiene **81** was confirmed by recording its low-temperature NMR spectrum.¹²⁷

It should be emphasised that the rearrangement to epoxyaziridines is typical only of adducts of halo-substituted nitrosoalkenes with cyclic dienes. Cycloadducts of nitrosoalkenes with acyclic dienes,⁸ as well as the products of [4 + 2]-cycloaddition of cyclic 1,3-dienes to the nitroso groups of other types of nitroso compounds,^{121, 127} do not undergo this rearrangement. This regularity has not been explained yet.

It has been shown that tetrafluoroethylene and chlorotrifluoroethylene add to the nitroso group of trifluoronitrosoethylene **1a** according to the [2 + 2]-cycloaddition pattern to give 1,2-oxazetidines.⁵

b. Nitrosoalkenes as conjugated heterodienes in the cycloaddition to C = C bonds

The [4 + 2]-cycloaddition to alkenes is perhaps the most important reaction of nitrosoalkenes, which has mainly determined the vigorous development of the chemistry of these compounds in the last decade. In this reaction, nitrosoalkenes **1** act as electron-withdrawing 4π -components (conjugated heterodienes) and give rise to 5,6-dihydro-4*H*-1,2-oxazines **82**, which are valuable intermediate compounds in the synthesis of various cyclic and linear polyfunctional compounds.

This type of addition was observed for the first time in the reaction of cyclopentadiene¹⁸ with 1-nitroso-1-phenylethylene **11**. Later, this reaction route has been extended to other alkenes and nitrosoalkenes; as a rule, the latter contain unsubstituted β -carbon atoms ($R^1 = R^2 = H$).^{8, 14, 16} although this type of cycloaddition is also possible^{8, 16, 45, 128} for some β -substituted nitrosoalkenes, for instance, $\text{MeCH}=\text{C}(\text{Ac})\text{N}=\text{O}$ (**1u**)¹⁶ and $\text{MeO}_2\text{CCH}=\text{CHN}=\text{O}$ (**1q**).⁴⁵

The reaction is highly regio- and stereoselective; in the adducts of type **80** derived from cyclopentadiene, the oxygen atom of the nitroso group is always attached to the allylic carbon atom of the cyclopentene fragment. Other linear and cyclic conjugated dienes add to nitrosoalkenes of the general type $\text{CH}_2=\text{C}(\text{R})\text{NO}$ in a similar way.^{8, 14, 18, 120, 129}

Another type of nucleophilic dienes, methoxyallenes **83**, readily react with nitrosoalkenes to give 6-methoxy-substituted cycloadducts **84** with high regioselectivity.^{130, 131} The successful synthesis of these compounds opened up new opportunities for using the oxazine ring in various transformations.^{132–136}

Unfortunately, the attempt to extend cycloaddition to allene, phenylallene, and trimethylsilyllallene was unsuccessful, indicating that the electronic requirements to allenes are stricter than those to alkenes.¹³¹

Electron-deficient alkenes, diethyl fumarate,¹⁶ *trans*-1,2-dichloroethylene,¹⁶ and maleic anhydride¹³⁷ do not form [4 + 2]-cycloaddition products with nitrosoalkenes.

Simple alkenes, oct-1-ene,^{14, 16} *cis*-cyclooctene,^{16, 138} and cyclohexene,¹⁶ react only with highly electrophilic nitrosoalkenes **1** ($R^1 = R^2 = H$), containing substituents such as Ac, CHO, or 4- $\text{NO}_2\text{C}_6\text{H}_4$ at the α -position; these reactions can give mixtures of regioisomers. Thus 1-nitroso-1-(4-nitrophenyl)ethylene **1v** reacts with oct-1-ene giving rise to a mixture of 6- and 5-*n*-hexyl-substituted 1,2-oxazines **82** in a ratio of 85:15.¹⁴ However, the reactions of nitrosoalkenes with conjugated terminal mono- and disubstituted alkenes result in the formation of only 6-mono- and 6,6-disubstituted regioisomers **82** ($R^4 = R^5 = H$; $R^6 = \text{NR}_2$, OR or Ar; $R^7 = H$, Alk, or Ar).^{14, 18, 120} The interaction with 1,2-disubstituted alkenes follows a more complex route. Thus the reaction of *trans*-1-phenylpropene with nitrosoalkenes affords both regioisomers with low regioselectivity. The introduction of an electron-donating methoxy group into the *para*-position of *trans*-1-phenylpropene markedly increases the regioselectivity of this reaction; in this case, regioisomers containing the aryl group at the 6-position are formed predominantly.¹⁴

The cycloaddition of nitrosoalkenes to 1,2-disubstituted alkenes, containing an OR or NR_2 group as one of the substituents at the C = C bond, always yields 6-alkoxy(or silyloxy-) or 6-dialkylamino(or disilylamino)-substituted 1,2-oxazines, respectively.^{117, 120, 139–144} The versatility and high regioselectivity of the cycloaddition of nitrosoalkenes to vinyl ethers or enamines have stimulated investigations of the synthetic potential of the reaction products, namely, 5,6-dihydro-4*H*-1,2-oxazines containing OR or NR_2 groups at the 6-position.^{93, 107, 117, 118, 138–140, 145–152}

It is noteworthy that allylsilanes proved to be convenient ene components for [4 + 2]-cycloaddition to nitrosoalkenes (triallylbutylstannane reacts in a similar way¹²⁰). The reaction is highly regioselective and results in the formation of 6-(1-trimethylsilylalkyl)-1,2-oxazines,^{120, 151, 152} which can be converted into valuable compounds by modification of the oxazine ring¹⁵⁵ and also proved to be convenient starting compounds for the synthesis of γ,δ -unsaturated ketones and amines.^{120, 153–155}

Using the method of competing reactions, it has been found¹⁶ that the rate of [4 + 2]-cycloaddition of alkenes to 3-nitrosobut-3-en-2-one **1m** increases with increase in the electron-donating capacity of the substituents at the C = C bond in the alkenes; in terms of the reaction rate, the alkenes studied can be arranged in the following sequence:

Reissig *et al.*¹²⁸ studied the relative reactivities of various alkenes in more detail. They used mainly trimethylsilyl ethers of enols and chose 1-nitroso-1-phenylethylene **11** as the model nitrosoalkene.¹²⁸ The following relative rate constants (*k*) were obtained for cycloaddition of various alkenes to 1-nitroso-1-phenylethylene:^{128, 156}

Alkene	<i>k</i>	Alkene	<i>k</i>
	17		0.33
	11.5		0.2
	8.5		0.19
	3.5		0.13
	2.2		0.11
	1.2		0.09
	1.0		0.09
	0.95		< 0.01
	0.6		< 0.01
		(R = Pr ⁱ , Ph, Bu ^t)	

The rate constant (*k*) values presented above indicate that the EtO group possesses higher activating ability than the Me₃SiO group. It is also noteworthy that the reactivity of 1,1-disubstituted trimethylsilyl enol ethers is much lower than that of 1,2-disubstituted derivatives. For example, the relative reactivity of *E*-(1-trimethylsilyloxy)propene is ~100 times higher than that of (2-trimethylsilyloxy)propene, and the enol silyl ethers containing Prⁱ, Ph, or Bu^t groups at the α-position do not react with the nitrosoalkene **11** at all. The absence of the reaction in the latter case is due to the steric influence of substituents and, hence, it confirms indirectly the concerted mechanism of [4 + 2]-cycloaddition of nitrosoalkene. If the reaction occurred by a stepwise mechanism, these substituents would efficiently stabilise the positive charge or the radical site in an intermediate.¹²⁸

The substantially higher reactivity of the *E*-isomers of vinyl ethers compared to that of the *Z*-isomers also deserves attention.¹²⁸ The ratios of the reaction rates for *E*- and *Z*-isomers [*k*(*E*)/*k*(*Z*)] are the following:

Compound	The <i>k</i> (<i>E</i>)/ <i>k</i> (<i>Z</i>) ratio
MeCH=CHOSiMe ₃	26
Pr ⁱ CH=CHOSiMe ₃	25
PhCH=CHOSiMe ₃	> 50
Me ₃ SiOCH=CHOSiMe ₃	> 50
MeCH=CHOEt	6

This relationship has found application in the development of an elegant method for the kinetic resolution of mixtures of the *E*- and *Z*-isomers of trimethylsilyl vinyl ethers,¹⁵⁷ based on the difference between the rates of their cycloaddition to 1-nitroso-1-phenylethylene **11** and diphenyl ketene.¹⁵⁷ 1-Nitroso-1-phenyl-

R = Me (a), Ph (b);

(a) $\text{Ph}-\text{CH}=\text{NOH}$, Na_2CO_3 , Et_2O ; (b) $\text{Ph}_2\text{C}=\text{C}=\text{O}$.

Compound	(<i>E</i>)- 85a	(<i>Z</i>)- 85a	(<i>Z</i>)- 85b
Yield (%)	66	43	99
Degree of enrichment (%)	> 98	> 99	> 99

ethylene **11** generated *in situ* reacts selectively with the *E*-isomers of the silyl ethers **85a,b**, whereas diphenyl ketene reacts with the *Z*-isomers; as a consequence, the initial mixtures of trimethylsilyl enolates become enriched in the less reactive isomers.

Although alkyl ethers of enols are generally more reactive towards nitrosoalkenes than silyl ethers,¹²⁸ the reaction of dihydrooxepines **86a,b** with the nitrosoalkene **1n** gives fused 1,2-oxazines **87a,b** as the only reaction products. This unexpected result has been explained by assuming that specific conformational features of the dihydrooxepine ring prevent the lone electron pair of the endocyclic oxygen atom from overlapping efficiently with the C(5)=C(6) double bond, and hence, the C(2)=C(3) bond becomes more reactive.¹⁵⁸

R = H (a), R = Me (b).

The high stereospecificity of cycloaddition confirms its concerted mechanism. It has been established reliably that the formation of mixtures of *cis*- and *trans*-1,2-oxazines from *cis*-alkenes, observed in some cases, is due to some amounts of *trans*-isomers present in the initial alkenes. Since the rate of cycloaddition of nitrosoalkenes to *trans*-alkenes is markedly higher, and the typical experimental procedure involves the use of a large excess of the alkene, the content of *trans*-substituted 1,2-oxazines in the reaction products can be quite noticeable.^{14, 16, 17, 128}

The nitrosoalkenes **1** with R¹ = R² = H are extremely unstable (see Table 1); therefore, their relative reactivities can hardly be estimated. Nevertheless, some qualitative conclusions have been drawn.

For example, the yields of cycloaddition products obtained from 1-nitroso-1-(4-nitrophenyl)ethylene **1v** were generally higher than those obtained from 1-nitroso-1-phenylethylene **11**. Therefore, it was concluded that the former is more reactive.¹⁴ 3-Nitrosobut-3-en-2-one **1m**, which is more reactive, forms adducts with cyclohexene and benzofuran, whereas ethyl α-nitrosoacrylate **1r** does not react with these substrates. This reflects the general tendency of the reactivity to decrease upon replacement of the acetyl group by CO₂Et.¹⁶ As noted above, sterically hindered alkenes like CH₂=C(R)OSiMe₃ (R = Prⁱ, Ph, Bu^t) do not react with 1-nitroso-1-phenylethylene **11** or ethyl α-nitrosoacrylate;^{120, 128} however, more reactive 1,1,1-trifluoro-2-nitrosopropene **1n** does form cycloadducts with these alkenes, although in low yields.¹⁷ The higher reactivity of the nitrosoalkene **1n** compared to 1-nitroso-1-phenylethylene **11** was also confirmed by MNDO calculations.¹⁷

Nitrosoethylene,¹⁸ 2-nitrosopropene,^{8, 120} and some other 1-alkylnitrosoethylenes¹²⁰ form cycloadducts in extremely low yields or do not react at all even with the most reactive dienophiles, cyclopentadiene and ethyl vinyl ether.

Recently, calculations have been carried out for some cycloaddition reactions of nitroso ketene¹⁵⁹ and nitrosoethylene.^{160, 161}

It is of interest that trichloronitrosoethylene **1s** readily reacts with various alkenes as a conjugated heterodiene,¹⁶² although as has been noted above, it behaves as a typical dienophile towards conjugated dienes.

The reactions of 1-nitroso-1-phenylethylene **11** with norbornene and norbornadiene yield mainly *exo*-adducts.¹²⁰

The diastereoselectivity of cycloaddition of alkenes to 3,4-dihydro-1-nitrosonaphthalene **88** has been studied.¹²⁸

Ratio <i>exo</i> - 89 : <i>endo</i> - 89	R ¹	R ²	R ³
> 97 : 3	H	H	OSiMe ₃
64 : 36	Me	H	OSiMe ₃
18 : 82	(CH ₂) ₃		OSiMe ₃
1 : 1	H	H	CH ₂ SiMe ₃

It was found that trimethylsilyloxyethylene affords almost exclusively the *exo*-adduct. When there are one or two alkyl substituents at the double bond, the proportion of the *endo*-adduct increases. In the case of 1-trimethylsilyloxycyclopentene, the *endo*-adduct **89** predominates among the reaction products. Evidently, in this case, the *exo*-approach in the transition state is sterically hindered. For methoxyallene, the steric obstacles to the *exo*-approach prove to be insignificant, and consequently, this alkene, like trimethylsilyloxyethylene, forms predominantly the *exo*-adduct (the *exo* : *endo* ratio is 92 : 8).¹³¹ The fact that the reaction of 1-nitroso-3,4-dihydronaphthalene **88** with allyltrimethylsilane is less diastereoselective than its reaction with trimethylsilyloxyethylene has been explained¹²⁸ by different reactive conformations of these molecules.

Intramolecular [4 + 2]-cycloaddition of the nitroso-alkene fragment to the vinyl-ether fragment in compound **90** has been studied.²⁰ An equimolar mixture of the *E*- and *Z*-isomers of **90** was converted into a mixture of *endo*- and *exo*-adducts **91** in a ratio of 3.4 : 1 (total yield 35%). Based on these data, it was concluded that the *endo*-approach is preferable.

However, in our opinion, this selectivity is actually due to the fact that the *Z*-alkene fragment is much less reactive than the *E*-fragment.

Arnold and Reissig¹⁶³ were the first to use nitrosoalkenes in enantioselective synthesis. They studied [4 + 2]-cycloaddition to optically active vinyl ethers with various optically active fragments and alkenyl residues. The highest diastereoisomeric excess (up to 90%) was observed for the reaction of 1-nitroso-1-phenylethylene **11** with isomeric bulky norbornane derivatives **92a,b**.¹⁶³

Further studies along this line have shown¹⁶⁴ that readily available diacetone glucosyl is the most versatile optically active fragment. Compounds with the general formula **93**, where R are various alkenyl groups (including the allenyl group) ensure high diastereoisomeric yields in [4 + 2]-cycloaddition to terminal nitrosoalkenes.

R = CH = CHMe (*E*, *Z*) (**a**); CH = CMe₂ (**b**); CH = C = CH₂ (**c**).

The above characteristic features of the cycloaddition of nitrosoalkenes to alkenes lead to the clear idea that this is a concerted Diels–Alder reaction with inverse electron demand.^{165–168} The concept of this reaction, first proposed by Gilchrist,^{3,14} is based on interaction of the lowest unoccupied molecular orbital (LUMO) of nitrosoalkene, acting as an electron-withdrawing conjugated heterodiene, with the highest occupied molecular orbital (HOMO) of the alkene, which serves as the electron-donating dienophile. The regioselectivity of this reaction is determined by the HOMO coefficients of the atoms in the alkene (the greatest coefficient characterises the β-C atom) and the LUMO coefficients of the atoms in the nitrosoalkene (the greatest coefficient belongs again to the β-C atom) (Fig. 1); the greater these coefficients, the higher the cycloaddition rate.

Figure 1. Reaction of nitrosoalkenes with alkenes in terms of the MO LCAO method.^{3,14}

It should be emphasised that no examples of participation of nitrosoalkenes in any Diels–Alder reactions of the standard type have been found so far. The attempts to carry out their cycloaddition to alkenes with electron-withdrawing substituents^{16,137} failed.

It would be expedient to systematise the available arguments supporting the concerted mechanism of cycloaddition of nitrosoalkenes to alkenes:

- (1) there are no indications of formation of any long-lived dipolar¹⁴ or diradical¹²⁸ intermediates;
- (2) the process is highly stereospecific;
- (3) the relative rate constants for the cycloaddition of *E*- and *Z*-isomers of alkenes are substantially different;
- (4) the rates of cycloaddition substantially decrease on passing to alkenes like CH₂ = C(R)OSiMe₃;
- (5) there are no rearrangements during cycloaddition to strained alkenes: norbornadiene,¹²⁰ norbornene,^{120,128,156} and benzvalene.^{128,156}

In a more detailed investigation of the reaction mechanism, it was noted¹²⁸ that, despite the concerted character of the reaction, the transition state can be asymmetrical; in particular, the formation of the C–O bond can lag behind the formation of the C–C bond. This assumption was confirmed by PM3 calculations. It has also been suggested¹³¹ that in special cases, this reaction can follow a two-step mechanism involving formation of 1,6-zwitterion intermediates. This occurs, for instance, when 1-nitroso-1-phenylethylene **11** adds to highly sterically strained 1-(hydroxydi-phenylmethyl)-1-methoxypropa-1,2-diene.¹³¹

The closest analogues of nitrosoalkenes in [4 + 2]-cycloaddition reactions are vinylnitrosonium cations **94**^{169–172} and conjugated nitro alkenes.^{173–177}

Apparently, the range of cycloaddition reactions of nitrosoalkenes to C = C bonds is not exhausted by the data presented above. Thus Gilchrist *et al.*^{18,93} believe that the reaction of α -halo oximes with enamines in the presence of Na₂CO₃ involves generation and subsequent [4 + 2]-cycloaddition of nitrosoalkenes to electron-rich C = C bonds.^{18,93}

However, the alkylation of enamines with α -bromo oximes^{152,153} in the absence of bases should apparently be regarded as direct S_N2 substitution of bromine, because the intermediate immonium salts can be isolated. The structures of these intermediates have been established by IR, UV, and ¹H NMR spectroscopy.¹⁵¹ It was found that on treatment with bases, the immonium salts cyclise to 6-(*N,N*-dialkylamino)-5,6-dihydro-4*H*-1,2-oxazines. This sequence of reactions is considered below in relation to the alkylation of 1-pyrrolidincyclohexene **95** with α -bromoacetophenone oxime.¹⁵¹

[4 + 2]-Cycloaddition of nitrosoalkenes can be accompanied by the formation of side products. Thus the reactions of 1-nitroso-1-(*p*-nitrophenyl)ethylene with styrene, α -methylstyrene, and α -phenylstyrene, in addition to 1,2-oxazines, affords β,γ -unsaturated oximes **96**¹⁴ (the formation of similar products has also been reported in another study¹⁵²).

R¹ = Ph; R² = H, Me, Ph; R¹ = Me, R² = Ph.

c. [3 + 2]-cycloaddition of nitrosoalkenes to alkenes

[4 + 2]-Cycloaddition of 1-nitroso-1-phenylethylene **11** and 1-nitroso-1-(4-nitrophenyl)ethylene **1v** to 2-methoxypropene giving rise to the corresponding 1,2-oxazines is accompanied by [3 + 2]-cycloaddition, which yields cyclic nitrones **97** as minor products¹⁴ (see also Section IV.2, compound **76**). It was shown in special experiments that the ratio of the [4 + 2]- to [3 + 2]-cycloadducts does not depend on the *E*- or *Z*-configuration of the α -bromo oximes, precursors of nitrosoalkenes.¹⁴

In Gilchrist's opinion,³ for concerted [3 + 2]-cycloaddition to occur, the nitrosoalkene molecule should assume a reactive conformation in which the lone electron pair of the nitroso-group nitrogen atom lies in a plane parallel to the plane of the $\pi_{C=C}$ bond, according to the 1,3-dipole type (Fig. 2).

At the same time, it was noted¹⁴ that the minor products **96** and **97** are formed in those cases where the possible dipolar intermediates are efficiently stabilised. However, in both cases, the product ratio proved to be insensitive to an increase in the polarity of the solvent.¹⁴

Figure 2. Conformation of nitrosoalkene during [3 + 2]-cycloaddition.

The [3 + 2]-cycloaddition of 1-nitroso-1-phenylethylene **11** to *o*-methylstyrene gives nitrone **98**.¹⁷⁸

X = H, NO₂.

The reaction of nitrosoalkenes considered in this Section resembles the known [3 + 2]-cycloaddition of azines to multiple bonds.¹⁷⁹

d. Nitrosoalkenes in cycloaddition to C = N, C = S, and C $\equiv$ C bonds

[4 + 2]-Cycloaddition of nitrosoalkenes is a general method for functionalisation of alkenes. However, cycloaddition to nitrosoalkenes is not restricted to the reactions with carbon-carbon double bonds. Nitrosoalkenes are able to add to C = N bonds in some cyclic 1,2-oxazines to give nitrones **99**^{119,180} (see also Section IV.2, compound **77**) and fused 1,2,5-oxadiazines **100**,¹⁸¹ their yields ranging from low to moderate. This reaction is not a general transformation of the oximine fragment.¹⁸⁰

Recently, it has been shown that nitrosoalkenes react smoothly with amidines of type **101** and **102** according to the [3 + 2]-cycloaddition fashion giving rise to the corresponding imidazoline *N*-oxides **103** and **104**.¹⁸²

This reaction is general and, in the opinion of the researchers cited,¹⁸¹ occurs *via* formation of a stabilised dipolar intermediate.

The use of the C = S bonds of thiocarbonyl compounds as a heterodienophilic 2 π -component in [4 + 2]-cycloaddition to substituted α -nitrostyrenes has been reported.¹⁸² The reaction of trichloronitrosoethylene **1s** with Ph₂C = S is an example.¹⁶²

X = H, OMe, NO₂; R¹, R² = Ar, PhS, R₃Si.

Trichloronitrosoethylene is capable of reacting with methyl propargyl ether to afford 4*H*-1,2-oxazine **105**;¹⁶² however, the attempts to involve various alkynes in cycloaddition to nitrosoalkynes of the type $\text{CH}_2=\text{C}(\text{R})\text{NO}$ were unsuccessful.^{3, 17, 120}

e. Other reactions

The known chemistry of nitrosoalkenes is virtually exhausted by the information presented here. At present, there are no reliable data concerning radical addition or ene reactions of these compounds, although these are typical reactions of other types of nitroso derivatives. It can only be added that 1-nitrosocyclohexene **1f**¹⁰ and trifluoronitrosoethylene **1a**⁵ can undergo electrophilic addition. The addition of HCl to some nitrosoalkenes has been reported.¹⁰ Trifluoronitrosoethylene **1a** is able to polymerise by a radical mechanism in solution.⁵ The reduction of the nitrosoalkene **8** with NaBH_4 gives rise to the corresponding oxime.

Several reactions have been reported for the nitrosofulvene **19b**, namely, reversible *O*-protonation, oxidation to nitrofulvene by *m*-chloroperbenzoic acid, and deoxygenation by tertiary phosphines followed by fast fragmentation of the intermediate nitrene **106**, resulting in the generation of carbene **107**.⁴⁶

MCPBA = 3-ClC₆H₄COOOH.

Nitrosoalkenes (nitrosodithiofulvenes and nitrosodiselenofulvenes) form coordination compounds with PdCl_2 .¹⁸³

IX. Conclusion	509

Abstract. Data on palladium carbonyl complexes are described systematically and subjected to a critical analysis. The methods of synthesis and data on the structures and chemical properties of mono- and poly-nuclear carbonyl-containing palladium complexes in which the formal oxidation state of the metal varies from 0 to +2 are discussed. Virtually all the publications on this question up to 1997 are examined. The bibliography includes 241 references.

I. Introduction

The interest in the chemistry of palladium carbonyl complexes is to a large extent determined by the activity of palladium and its compounds in the catalysis of reactions involving CO. Such reactions include in the first place the catalytic oxidation of CO to CO₂, the synthesis of alkyl oxalates and alkyl carbonates, reactions involving the carbonylation of alcohols, saturated hydrocarbons, and aromatic nitro-compounds, *etc.*¹ The study of the properties and reactivities of carbon-containing palladium complexes is an essential stage in the investigation of the mechanisms of the reactions occurring with participation of palladium catalysts.² The carbonyl complexes of palladium and other platinum metals are of undoubted interest from the standpoint of the theory of coordination compounds, especially the nature of the bond in complex many centre systems of clusters containing the metal in the lowest oxidation states.

The susceptibility of PdCl₂ to reduce by carbon monoxide to the metal, *i.e.*

was observed more than 100 years ago.^{3–5} Palladium carbonyl chlorides were among the first platinum metal carbonyl complexes synthesised.⁶ However, owing to their higher reactivity compared

with other platinum metal carbonyls, they remained for a long time represented by a few poorly characterised compounds. The available information about their structures and reactivities was based solely on indirect data (mainly by analogy with compounds of other platinum metals).

Data on the chemistry of palladium carbonyl complexes have been partly surveyed in a monograph⁷ in which none of the compounds of this class have been reliably characterised. A review⁸ presents the structural characteristics of two palladium carbonyl complexes — [Pd(dam)Cl]₂CO,^{9,10} where dam = bis(di-phenylarsino)methane, and Pd₄(CO)₄(OAc)₄.^{11,12} Since the end of the 1970s, the number of studies on palladium carbonyls has increased sharply.

The classification of the compounds constituting the subject of the present review is based on the formal oxidation state (FOS) of palladium. The formal oxidation state of the metal atom in a complex is defined as the average charge of the metal atoms which they possess after the removal of the ligands.^{13,14} It is assumed that in the leaving ligands (for example, such as H[–], Cl[–], O^{2–}, OH[–], NH₂[–], NR₂[–], PR₂[–], SnCl₃[–], and CH₃[–]) the electron shell of the atom linked to the metal corresponds to the shell of the nearest inert gas atom; the ligands are removed in the form of neutral molecules (CO, NO, N₂, CO₂, C₂H₂, C₂H₄, *etc.*). As regards certain π -linked organic groups (allyl C₃H₅, cyclopentadienyl C₅H₅), they are regarded as anions, like the σ -linked C₃H₅[–] and C₅H₅[–] groups.

Mainly mononuclear compounds are considered in classical coordination chemistry. The stable oxidation states 0 and +2 are attributed to palladium. However, the study of polynuclear, mainly cluster, compounds has shown that many of them have an oxidation state of +1; there are also compounds in which the formal charge per metal atom is nonintegral. Palladium carbonyl hydride complexes, for which the exact stoichiometry of the polyhydrides can be established in by no means all cases which precludes in its turn the determination of the FOS of the metal, constitute a separate group. A separate Section has been devoted to the palladium carbonyls isolated in zeolite cells, which may function as polyanions.

[†]Commemorating Professor Peter M Maitlis on the occasion of his 65th birthday.

A systematic treatment of heteronuclear, palladium-containing complexes in accordance with the above principles is in many cases difficult. The FOS of palladium can be comparatively readily inferred, provided that the structure of the heterometal-containing species forming part of the complex remains unchanged on formation of the compound.

For example, the reaction^{15, 16} of the benzonitrilepalladium(+2) complex $\text{PdCl}_2(\text{NCPh})_2$ with $\text{Na}[\text{Co}(\text{CO})_4]$ affords, after the substitution of Cl^- by $[\text{Co}(\text{CO})_4]^-$, the trinuclear cluster $\text{Pd}[\text{Co}(\text{CO})_4]_2(\text{NCPh})_2$, in which the palladium atom is believed to retain a FOS of +2. However, on interaction of this cluster with dppm [dppm = bis(diphenylphosphino)methane], which leads to $\text{PdCo}_2(\text{CO})_5(\mu\text{-dppm})_2$, not only are the benzonitrile ligands displaced but also three carbonyl groups are lost by the two anionic carbonylmetallates $[\text{Co}(\text{CO})_4]^-$. The CO-containing complexes formed ultimately have to analogues in classical coordination chemistry and this hinders the overall classification.

The present review deals with individual heteronuclear palladium-containing complexes, the assignment of which to a particular Section of the review is not open to doubt.

Since the aim of the present review is the analysis of the methods of synthesis and the characteristics of the structures and reactivities of molecular palladium complexes with carbonyl ligands, we shall deal only briefly with data on the palladium carbonyls formed on the surface of oxide carriers.

II. Activation of carbon monoxide in the coordination sphere of the transition metal and the strength of the M–CO bond

In the complexes of transition metals carbon monoxide effectively stabilises their lowest oxidation states. The carbonyl complexes of each metal from the first series of transition elements have been well characterised.¹⁷ The composition of the compounds obeys the '18 electron' rule, which predicts monomeric compounds for Group IV metals, for example, $\text{Cr}(\text{CO})_6$, $\text{Fe}(\text{CO})_5$, and $\text{Ni}(\text{CO})_4$. The metals in odd Groups form paramagnetic $[\text{V}(\text{CO})_6]$ or dimeric $[\text{Mn}_2(\text{CO})_{10}]$ or $[\text{Co}_2(\text{CO})_8]$ carbonyls. Mononuclear complexes are not very characteristic of transition metals in the second and third series. These metals afford preferentially compounds in which the number of metal atoms is from 2 or 3 to several hundreds.^{18–21} From a formal point of view, features, structure and chemical properties) common to mononuclear carbonyls and a metallic surface coated by adsorbed CO molecules are characteristic of these clusters.²²

A considerable number of communications (see, for example, Refs 23–27) have been devoted to the question of the stability of monomeric transition metal, especially palladium, carbonyls. It has been established on the basis of quantum-chemical calculations that, among the transition metal carbonyls $\text{M}(\text{CO})_6$ (M = Cr, Mo, W), $\text{M}(\text{CO})_5$ (M = Fe, Ru, Os), and $\text{M}(\text{CO})_4$ (M = Ni, Pd, Pt), the metal–carbonyl bond energy and the dissociation energy of the first carbonyl ligand are a minimum for $\text{Pd}(\text{CO})_4$. Calculations led to the conclusion that the π -back-donation from the ligand to the metal makes a much greater contribution in the stable $\text{M}(\text{CO})_m$ systems than the σ -donor bond.

Thus the results of quantum-chemical calculations have shown the palladium carbonyls should have a minimum thermal stability and a maximum kinetic lability among transition metal carbonyls. These properties of the Pd–CO bond have probably in fact been responsible for the activity of palladium and its compounds in the catalysis of processes occurring with participation of carbon monoxide. However, the same properties have apparently 'inhibited' the development of the chemistry of palladium carbonyl complexes compared with other transition metal complexes.

The catalytic activation of carbon monoxide entails a change in the molecular orbitals of this ligand due to coordination to the metal atom. Carbon monoxide is a weak σ -donor ligand, but it

Figure 1. Schematic illustration of the bonds between carbon monoxide and a metal atom.

can bind fairly strongly to the metal atom. The overall mechanism of the binding of carbon monoxide to a metal atom is presented in Fig. 1.

According to this scheme, apart from the ligand–metal interaction determined by the σ -donor properties of the ligand, the back-donation from the occupied d orbitals of the metal to the occupied antibonding π orbitals of the ligand takes place. Evidently, these two bonding modes should lead to opposite effects in the resulting transfer of electron density between the metal and the ligand.²⁸ Until recently the view that the π -acceptor properties of the ligand predominate in the formation of the metal–carbonyl bond was dominant. This was used to account for the weakening of the C–O bond in the carbonyl ligand itself, observed on coordination of CO to metals in the lowest oxidation states, and hence for the appreciable decrease in the ν_{CO} stretching vibrational frequencies in the IR spectra of the compounds.

However, on coordination of CO to metals in high oxidation states, for example on formation of $\text{Pd}(+2)$ carbonyls, the predominance of the σ -donor properties of the ligand over their π -acceptor properties was noted, which leads in its turn to an increase in ν_{CO} to values equal to and even exceeding the stretching vibrational frequencies of CO in free carbon monoxide.²⁹

III. Palladium(0) carbonyl complexes

All the Pd(0) complexes described hitherto have been described by convention in two groups — binary carbonyls (compounds containing only CO molecules as the ligands) and complexes with additional stabilising ligands (as a rule N- or P-donor ligands).

1. The binary carbonyls

The binary carbonyls are characteristic of many Group VIII metals and are readily formed even at room temperature when the metal interacts with carbon monoxide. In contrast to these metals, palladium does not form binary carbonyls on direct interaction with CO at room or elevated temperature.

The binary palladium carbonyls began to be synthesised simultaneously by two groups of investigators.^{30–34} The method involving the joint condensation of metal vapour and CO at 4.2–27 K with isolation of the carbonyl in a crystalline argon or CO matrix was employed. At 4.2–10 K and for a CO content in the gas phase ranging from 100% to 10%, $\text{Pd}(\text{CO})_4$ was obtained. On raising the temperature and on reducing the partial pressure of CO, the formation of $\text{Pd}(\text{CO})_3$, $\text{Pd}(\text{CO})_2$, and $\text{Pd}(\text{CO})$ was observed.

All the conclusions concerning the structure of the binary palladium carbonyls are based on the results of the study of their vibrational spectra. Analysis of the Raman and IR spectra of carbonyl molecules containing isotope-substituted CO fragments ($^{12}\text{C}^{16}\text{O}$, $^{13}\text{C}^{16}\text{O}$, $^{12}\text{C}^{18}\text{O}$) showed that the $\text{Pd}(\text{CO})_4$ molecule is tetrahedral like $\text{Ni}(\text{CO})_4$ (T_d symmetry).³³ The frequency of the stretching vibration active in these spectra (the T_2 band) is 2066 cm^{-1} ; the frequency of the A_1 vibration, active in the Raman spectrum, is 2122 cm^{-1} and the force constant $k_{\text{CO}} = 17.48\text{ mdyn \AA}^{-1}$ in the Cotton–Kraihanzel approximation. It is of interest that the force constant k_{CO} for the more stable $\text{Ni}(\text{CO})_4$ molecule is virtually the same ($17.23\text{ mdyn \AA}^{-1}$). The M–C stretching vibrational frequency and force constant are more sensitive to the nature of the central atom. The $\nu_{\text{M-C}} = 258\text{ cm}^{-1}$ for palladium tetracarbonyl, whereas the

corresponding band has been observed at 435 cm^{-1} for nickel tetracarbonyl.³⁴

Spectroscopic data have led to the conclusion that the $\text{Pd}(\text{CO})_3$ molecule is planar (D_{3h} symmetry), while the $\text{Pd}(\text{CO})_2$ (D_h symmetry) and $\text{Pd}(\text{CO})$ (C_v symmetry) molecules are linear. The frequencies of the IR-active vibration are respectively 2060, 2044, and 2050 cm^{-1} for these molecules, but the force constant k_{CO} varies from 17.35 to $16.96\text{ m dyn } \text{\AA}^{-1}$.³² The decrease in the force constant is correlated with the decrease in the stability of the carbonyls in the sequence $\text{Pd}(\text{CO})_4 > \text{Pd}(\text{CO})_3 > \text{Pd}(\text{CO})_2 > \text{Pd}(\text{CO})$.³³ Apparently the palladium mono-, di-, and tri-carbonyls are mononuclear, the CO groups are terminal, and there is no metal–metal interaction.^{31,33} The stretching vibrational frequency of the terminal CO group in the mononuclear complexes is in the range $2050\text{--}2066\text{ cm}^{-1}$.

The formation of binary carbonyls stable at temperatures up to 190 K has been noted in the deposition of palladium from a gas phase containing carbon monoxide onto an Al_2O_3 surface.³⁵ These carbonyl compounds have been characterised under high vacuum conditions by thermal desorption spectroscopy (TDS), diffraction of slow electrons (LEED), UV photoelectron spectroscopy (UPS), and X-ray electron spectroscopy (ESCA).

Another type of binary palladium carbonyls — the cationic complexes $[\text{Pd}(\text{CO})_4]^{2+}$ — is considered below.

2. Palladium(0) carbonyl complexes containing stabilising ligands

The binary $\text{Pd}(0)$ carbonyls are extremely unstable and decompose at a temperature above 20 K. The insertion into the coordination sphere of palladium of additional ligands having low-lying unoccupied orbitals capable of accepting the d electrons of the central atom (for example, N- and P-donor bases) made it possible to obtain relatively thermally stable $\text{Pd}(0)$ complexes.

Carbonyl-containing $\text{Pd}(0)$ complexes are synthesised mainly by three methods: by the reduction of $\text{Pd}(+2)$ complexes under a CO atmosphere; by the substitution of ligands by carbon monoxide in preformed $\text{Pd}(0)$ complexes; by the mild oxidation of coordinated ligands (for example, by the oxidation of phosphines to phosphine oxides, which leads to the ‘liberation’ of coordination sites and hence the formation of clusters with a greater nuclearity).

Only the first method or the first method combined with the third have been used to obtain $\text{Pd}(0)$ carbonyl complexes. When the first method was used, carbon monoxide served only in rare instances both as a reductant and as a stabilising ligand. As a rule, more vigorous reductants have been used in the reduction of $\text{Pd}(+2)$ to $\text{Pd}(0)$; the products of such reduction were small clusters. In order to obtain clusters with a greater nuclearity (Pd_{10} and above), ‘mild’ oxidation (*i.e.* oxidation of only some of the isotypical ligands) has been used, leading to the liberation of coordination sites and the formation of new metal–metal bonds. Mainly $\text{Pd}(+2)$ and $\text{Me}_3\text{N}^+\text{O}^-$ have been used as the oxidants in this instance.

a. Mononuclear palladium(0) complexes

The reduction of $\text{Pd}(+2)$ in the presence of carbon monoxide and additional stabilising ligands leads as a rule to di- and poly-nuclear complexes; the number of isolated and reliably characterised mononuclear $\text{Pd}(0)$ complexes is extremely small (Table 1).

The first mononuclear $\text{Pd}(0)$ complex was obtained by the reduction of palladium acetylacetonate with triethylaluminium in toluene at 223 K.³⁶

Together with mononuclear complexes, the formation of the polynuclear complexes $\text{Pd}_3(\text{CO})_3(\text{PPh}_3)_3$ **2** and $\text{Pd}_3(\text{CO})_3(\text{PPh}_3)_4$ **3** has been observed.

Table 1. Mononuclear palladium(0) complexes.

Complex	Physical methods used to characterise the substance	$\nu_{\text{CO}}/\text{cm}^{-1}$	Ref.
$\text{Pd}(\text{CO})(\text{PPh}_3)_3$	elemental analysis, IR spectroscopy	1955	36–38, 40, 41
$\text{Pd}(\text{CO})(\text{NP}_3)^a$	elemental analysis, IR spectroscopy, $^{31}\text{P}\{^1\text{H}\}$ NMR	1930	42
$\text{Pd}(\text{CO})[\text{MeC}(\text{CH}_2\text{PPh}_2)_3]$	elemental analysis, IR spectroscopy, XRD	1919	44
$\text{Ba}[\text{Pd}(\text{CN})(\text{CO})]_2$	elemental analysis, IR spectroscopy	1780, 1720	45
$[\text{RPh}_3\text{P}]^+[\text{Pd}(\text{CN})(\text{CO})]_2^-$	the same	1790	45

^a $\text{NP}_3 = \text{tris}(2\text{-diphenylphosphinoethyl})\text{amine } \text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_3$.

Complex **1** has also been obtained by the reduction of the phosphinepalladium(+ 2) chloride complex in methanol at 228 K by the reaction.³⁷

The interaction of $\text{PdCl}_2(\text{PPh}_3)_2$ and CO in a mixture of methanol with primary or secondary alkylamine also results in the formation of complexes **1** and **3**.³⁸ However, one cannot rule out the possibility that in this instance the amine itself exhibits reducing properties. When a primary or secondary amine is replaced by a tertiary amine, a methoxycarbonyl derivative of divalent palladium, $(\text{PPh}_3)_2\text{PdCl}(\text{COOMe})$, is formed.³⁸ This complex has also been synthesised by Zhir-Lebed' *et al.*³⁹

The formation of complex **1** has been noted in the carbonylation of $[(\eta^3\text{-allyl})\text{PdCl}]_2$ in the presence of PPh_3 in solution in methanol or ethanol ($P_{\text{CO}} = 4\text{ atm}$; 293 K).⁴⁰

The divalent palladium acetate complex $(\text{PPh}_3)_2\text{Pd}(\text{OAc})_2$ is not reduced by carbon monoxide in methanol under mild conditions.⁴¹ Only at 323 K and a CO pressure of 20–50 atm is $\text{Pd}(+2)$ reduced to $\text{Pd}(0)$ with formation of a mixture of complexes **1** and **3**.

In all the studies described, complex **1** was characterised solely by elemental analysis and IR spectroscopic data. The stretching vibration frequency of the carbonyl group is fairly low (1955 cm^{-1}), which precludes an unambiguous determination of the mode of coordination of this ligand (bridging or terminal carbonyl) and it is therefore impossible to estimate the reliability of the conclusion that this compound is mononuclear. However, later investigations of the complexes $\text{Pd}(\text{CO})\text{L}_3$ made it possible to regard complex **1** as mononuclear with a terminal carbonyl ligand.

Thus, when carbon monoxide is passed through a benzene solution of $\text{Pd}(\text{NP}_3)$ [$\text{NP}_3 = \text{tris}(2\text{-diphenylphosphinoethyl})\text{-amine } \text{N}(\text{CH}_2\text{CH}_2\text{PPh}_2)_3$], $\text{Pd}(\text{NP}_3)\text{CO}$ **4** was obtained.⁴² Complex **4** is stable only under a CO atmosphere. Its IR spectrum contains an intense band at 1930 cm^{-1} . The presence of a band at 2820 cm^{-1} , assigned to the stretching vibrations of the CH–N bond, showed that the nitrogen atom is not linked to the metal atom. The $^{31}\text{P}\{^1\text{H}\}$ NMR spectrum indicated the equivalence of all the phosphorus atoms. On the basis of the entire set of data obtained and comparison with the data for the analogous nickel complex characterised by X-ray diffraction,⁴³ the structure assigned to compound **4** consists of a tetrahedron in the centre of which is the palladium atom and whose vertices are occupied by the carbon atom of the carbonyl ligand and the three phosphorus atoms of tris(phosphino) amine. The complex $\text{Pd}[\text{MeC}(\text{CH}_2\text{PPh}_2)_3](\text{CO})$ **5**, obtained later and characterised by X-ray diffraction, has precisely this structure.⁴⁴

Complex **5** is formed on interaction of Pd(DBA) (DBA = dibenzylideneacetone) and the triphosphine ligand MeC(CH₂PPh₂)₃ in toluene under a CO atmosphere. It has been isolated in the form of yellow needles and characterised by IR spectroscopy ($\nu_{\text{CO}} = 1919 \text{ cm}^{-1}$) and X-ray diffraction. In the molecule of compound **5**, the palladium atom is linked to the carbon atom of the terminal CO group and the phosphorus atom of the triphosphine, forming a trigonal pyramid.

Carbon monoxide is capable of substituting CN^- in $\text{Pd}(\text{CN})_2^{2-}$, obtained by the reduction of $\text{Pd}(\text{CN})_4^{2-}$.⁴⁵ On treatment with oxygen-free dry CO in liquid ammonia (196 K), the following reaction takes place:

Complex **6** has been isolated⁴⁵ in the form of a salt with PRPh_3^+ (R = Me or Ph) and also in the form of a barium salt and has been characterised by elemental analysis and IR spectroscopy. The stretching vibrational frequencies, which are extremely low for a terminal carbonyl ligand ($\nu_{\text{CO}} = 1790 \text{ cm}^{-1}$ for the phosphonium salts and $\nu_{\text{CO}} = 1780$ and 1720 cm^{-1} for the barium salt), provide grounds for the assumption that in these compounds the CO group is a bridging structure between two or three metal atoms and the compounds themselves are at least dinuclear.

The ability of carbon monoxide to reduce Pd(+2) in aqueous solutions has been used to obtain carbonyl complexes stabilised by 1,10-phenanthroline (Phen) or α, α' -bipyridyl (Bipy).⁴⁶ When a solution of PdCl_2 containing Phen or Bipy is treated with CO containing 5% of O₂, a bright-red solution is obtained, from which the substance (L)Pd(CO)·4H₂O (L = Phen or Bipy) was isolated on treatment with acetone. Certain properties of this complex (good solubility in water, inability to dissolve in organic solvents resistance to the action of oxygen, etc.) provide grounds for the assumption that it contains ionogenic groups and that the oxidation state of palladium is greater than zero.

b. Polynuclear palladium(0) complexes

Polynuclear (cluster) Pd(0) complexes consist mainly of compounds containing carbonyl and phosphine ligands. Clusters comprising metals having a large number of valence electrons (nickel, palladium, and platinum) are capable of coordinating a smaller number of ligands than clusters of the preceding transition metals, which leads to the instability of their carbonyl derivatives.⁵⁰ The coordination of tertiary amines, which produce the same number of valence electrons as carbon monoxide but ensure, by virtue of steric factors, more effective shielding of the surface of the metal core, leads to the formation of fairly stable compounds. The methods of synthesis structures and reactivities of phosphine palladium carbonyl clusters are considered below.

The formation of the dinuclear $\text{Pd}_2(\text{dppm})_2(\text{CO})$ is described in a communication⁴⁷ devoted to the synthesis of catalysts for the hydrogenation of carbon dioxide. The complex, believed to contain a bridging carbonyl group, was obtained by the reduction of $\text{PdCl}_2(\text{dppm})_2$ with sodium tetrahydroborate in ethanol under a CO atmosphere. There are only elemental analytical and IR spectroscopic data ($\nu_{\text{CO}} = 1820 \text{ cm}^{-1}$) and the conclusions concerning its structure are therefore insufficiently reliable.

Complexes which are at least dinuclear and contain sulfide ligands in addition to the carbonyl group have been obtained.^{48,49}

The reduction of palladium acetate with carbon monoxide in an aqueous solution of trifluoroacetic acid in the presence of an

excess of dialkyl sulfides R_2S (R = Me, Et, Prⁿ, Buⁿ) afforded complexes with the overall composition $\text{Pd}(\text{R}_2\text{S})_3(\text{CO})$.⁴⁸ The band at $1828 - 1838 \text{ cm}^{-1}$ (ν_{CO}) in the IR spectra of the complexes indicates the bridging coordination of the carbonyl ligand and hence the di- or poly-nuclearity of the complexes.

Compounds with the overall composition $\{\text{Pd}_2[\text{RS}(\text{CH}_2)_m\text{SR}]_2(\text{CO})(\text{HOAc})_m\}$ have been obtained similarly from palladium acetate in the presence of sulfides having the general formula $\text{RS}(\text{CH}_2)_m\text{SR}$, where $m = 1, 2$, or 3 and R = C₃H₇, C₇H₁₅, Ph, or Ph-CH₂.⁴⁹ The IR spectra of all the complexes isolated contain an intense band in the region of 1800 cm^{-1} , which has been assigned to the stretching vibrations of the bridging carbonyl ligand. Measurements of the molecular masses of the complexes, whose solubility is low, did not allow a choice to be made between dinuclear and tetranuclear complexes.

3. The trinuclear complexes $\text{Pd}_3(\text{CO})_3\text{L}_3$ and $\text{Pd}_3(\text{CO})_3\text{L}_4$

Clusters with the composition $\text{Pd}_3(\text{CO})_3\text{L}_3$ are known only for very bulky ligands (L = PBu_3 , PBu_3^tPh). Such clusters were obtained by the interaction of coordinatively unsaturated complexes PdL_2 and carbon monoxide.⁵¹ An X-ray diffraction analysis has been carried out only for the platinum analogue $\text{Pt}_3(\text{CO})_3[\text{P}(\text{cyclo-C}_6\text{H}_{11})_3]$.⁵² It has been established that the cluster has a metal core shaped as an equilateral triangle (in which the Pt-Pt bond length is $2.665 \text{ \AA}$), to the sides of which the bridging CO groups are coordinated. All the phosphorus atoms of the terminal phosphine ligands, one of which is coordinated to each metal atom, lie in the Pt_3 plane.

The interaction of $\text{M}[\text{M}'(\text{NR}_2)_2]_3$ and CO afforded⁵³ the heteronuclear clusters $\text{M}_3[\mu\text{-M}'(\text{NR}_2)_2]_3(\text{CO})_3$ **7** (M = Pd or Pt, M' = Ge or Sn, R = SiMe₃), which were characterised by IR spectroscopy and NMR involving various nuclei. X-Ray diffraction study of the structure of complex **7** with M = Pd and M' = Sn showed that it has a planar metal core, whose base consists of the Pd_3 triangle. The bridging $\text{Sn}(\text{NR}_2)_2$ ligands are coordinated symmetrically to the sides of the triangle. The carbonyl groups are terminal ($\nu_{\text{CO}} = 2038 \text{ cm}^{-1}$), one being coordinated to each palladium atom.

Heteronuclear clusters of another type, $\text{Pd}_3\text{Sn}_2(\eta^2\text{-acac})_4(-\text{CO})_2(\text{PR}_3)_3$ **8** (R = Ph, Et), was obtained by the interaction of the clusters $\text{Pd}_4(\mu\text{-CO})_5(\text{PR}_3)_4$ and $\text{Sn}(\text{acac})_2$ in a hydrocarbon solution.^{54,55}

Compounds **8** are sensitive to moisture and are unstable in solution. In the region of the vibrational frequencies of the carbonyl groups, their IR spectra contain only bands due to the bridging CO groups in the range $1770 - 1890 \text{ cm}^{-1}$. According to X-ray diffraction data, the palladium atoms in clusters **8** (R = Ph) form an isosceles triangle, the sides of which are spanned by bridging CO groups, while the base is coordinated to two $\text{Sn}(\eta^2\text{-acac})_2$ bridging ligands. One phosphine ligand is linked to each palladium atom. In principle, the Pd_3Sn_2 metal core may be regarded as a 'propeller' with a Pd-Pd axis and triangular wings made up from a Pd atom and two Sn atoms.

The trinuclear clusters $\text{Pd}_3(\text{CO})_3\text{L}_4$ are obtained by reducing PdCl_2L_2 (L = PPh_3)³⁶ or palladium acetate with carbon monoxide in the presence of NaOAc and two equivalents of the phosphine ligand (L = PPh_3 , $\text{P}(\text{C}_6\text{H}_4\text{OMe-}p)_3$).⁵⁶ The structure of clusters of this type has been established in relation to $\text{Pd}_3(\text{CO})_3(\text{PPh}_3)_4$.⁵⁷ The molecule of the cluster consists of an isosceles triangle, to the sides of which $\mu\text{-CO}$ groups are coordi-

nated. Each metal atom in the base of the triangle is linked to one phosphorus atom, while the atom at the apex of the triangle is linked to two phosphorus atoms of the phosphine ligands. Such coordination of the phosphines leads to the nonequivalence of the carbonyl groups, which is reflected in the IR spectra: two intense bands are observed in the region of the stretching vibrations of the CO groups ($1820-1880\text{ cm}^{-1}$).

4. The tetranuclear clusters $\text{Pd}_4(\text{CO})_5\text{L}_4$ and $\text{Pd}_4(\text{CO})_6\text{L}_4$

It was noted above that the coprecipitation of Pd and CO *in vacuo* at low temperatures leads to mononuclear complexes which decompose even on a slight increase in temperature. On the other hand, if hexafluorobut-2-yne $\text{F}_3\text{CC}\equiv\text{CCF}_3$ (HFB) is added to Pd and CO, then precipitation *in vacuo* at -196°C results in the formation⁵⁸ of a volatile substance having the tentative composition $\text{Pd}(\text{CO})_2(\text{HFB})$, which is converted into the cluster $\text{Pd}_4(\text{CO})_4(\text{HFB})_3$ on slow heating. The substance has been characterised by osmometric data obtained in acetone (molecular mass), IR spectroscopy ($\nu_{\text{CO}} = 2138$ and 2122 cm^{-1}), and ^{19}F NMR spectroscopy.

$\text{Pd}(\text{OAc})_2$ is usually employed for the synthesis of tetranuclear carbonyl clusters with phosphine ligands, but the conditions used in the preparation of compounds with aliphatic and aromatic phosphines are different.

The tetranuclear cluster $\text{Pd}_4(\text{CO})_5(\text{PPh}_2\text{Me})_4$ was obtained⁵⁸ by reducing $\text{Pd}(\text{NO}_2)_2(\text{PPh}_2\text{Me})_2$ with carbon monoxide in methylene chloride. The cluster $\text{Pd}_4(\text{CO})_5(\text{PPh}_3)_4$ **9** was obtained later in a similar reaction.⁵⁹ X-Ray diffraction analysis of $\text{Pd}_4(\text{CO})_5(\text{PPh}_2\text{Me})_4$ ⁵⁸ and compound **9**⁵⁹ showed that the metal cores in both clusters have the form of a tetrahedron with one elongated edge ('open' tetrahedron or 'butterfly'). All the carbonyl groups are involved in μ -type coordination on the edges, each metal atom being linked to one phosphorus atom of the phosphorus ligand. The IR spectra of the complexes in the region of the stretching vibration of the CO groups are characterised by one intense band.

The $\text{Pd}_4(\text{CO})_5\text{L}_4$ clusters are not very stable in solution and are capable of adding additional ligands. Thus, slow crystallisation of $\text{Pd}_4(\text{CO})_5(\text{PBu}_3)_4$ under a CO atmosphere results in the addition of another CO molecule with formation of $\text{Pd}_4(\text{CO})_6(\text{PBu}_3)_4$ **10**.⁶⁰ According to X-ray diffraction data, the cluster has a tetrahedral metal core, to which bridging CO groups are coordinated along all the edges and each palladium atom is linked to one terminal phosphine ligand.

The interaction of the $\text{Pd}_4(\text{CO})_5\text{L}_4$ clusters with organomercury compounds takes place virtually without change in the metal core. Thus 8-(α -bromomercurioethyl) quinoline, both parts of the

molecule of which may assume the role of an additional ligand (substituted quinoline as a N,C-chelating ligand and mercury as a metalloligand) reacts with the $\text{Pd}_4(\text{CO})_5(\text{PEt}_3)_4$ cluster to form a heteronuclear compound.⁶¹

There is no information about the 'fate' of the quinoline component of the molecule. Formally, the two HgBr species generated as a result of the homolytic dissociation of the C–Hg bond, substitute one carbonyl group. However the coordination modes of CO and HgBr are different. According to X-ray diffraction data, the metal core is retained in cluster **11** in the form of an 'open' tetrahedron or a 'butterfly', to which external triangular faces the HgBr ligands are coordinated.

5. Pentanuclear palladium clusters

The pentanuclear carbonyl-containing platinum clusters are fairly numerous (see, for example, the review of Eremenko *et al.*⁵⁰). The methods of their synthesis include either the reductive carbonylation of platinum(+2) compounds or the interaction of platinum dicarbonyl with phosphines. Similar approaches have proved ineffective for the carbonyl-containing palladium clusters. Compounds of this group were obtained⁶² as a result of ligand substitutions in the presynthesised pentanuclear cluster $\text{Pd}_5(\mu\text{-SO}_2)_2(\mu_3\text{-SO}_2)(\text{PR}_3)_5$ **12**.⁶³

Thus, when CO was passed through a solution of compound **12** ($\text{R} = \text{Ph}$ or $\text{C}_6\text{H}_4\text{OMe-}p$) in dichloromethane, the corresponding complexes having the general formula $\text{Pd}_5(\text{SO}_2)_2(\text{CO})_2(\text{PR}_3)_5$ were obtained. They were characterised by ^{31}P NMR and mass spectrometry (fast atom bombardment method, FAB). If the initial complex contained another phosphine ligand, for example $\text{PR}_3 = \text{PMe}_2\text{Ph}$, the analogous reaction led to the complex $\text{Pd}_5(\text{SO}_2)_3(\text{CO})_2(\text{PMe}_2\text{Ph})_5$ **13**, characterised by X-ray diffraction data. The metal core of compound **13** consists of a tetrahedron, to one edge of which a fifth palladium atom ($\text{Pd}_{\text{bridge}}$) is μ -coordinated. The Pd–Pd distances are in the range from 2.73 to 2.97 Å.

The bridging SO_2 groups are coordinated to two $\text{Pd}_{\text{bridge}}-\text{Pd}$ bonds and to the edge of the tetrahedron most remote from $\text{Pd}_{\text{bridge}}$. The carbonyl ligands are coordinated on the opposite faces of the tetrahedron and their coordination may be regarded as highly distorted μ_3 -coordination.

6. Hexanuclear palladium clusters

The first cluster containing six palladium atoms with the composition $\text{Pd}_6(\mu_3\text{-CO})_4(\text{PMe}_3)_7$ **14**, was obtained by the interaction of $\text{Pd}(\text{PMe}_3)_4$ and carbon monoxide ($P_{\text{CO}} = 1$ atm) at 323 K.⁶⁴ The cluster has a distorted octahedral metal core, on whose faces four carbonyl ligands are μ_3 -coordinated. The even phosphine ligands are linked to each of the palladium atoms.

The reduction of potassium hexachloropalladate K_2PdCl_6 with sodium tetrahydroborate in the presence of dppm under a CO atmosphere in a toluene–ethanol mixture afforded the complexes $\text{Pd}_2(\mu\text{-CO})(\mu\text{-dppm})_2\text{Cl}_2$, $[\text{Pd}_3(\mu_3\text{-CO})(\mu\text{-dppm})_3\text{Cl}] \cdot \text{Cl}$, $\text{Pd}_2(\mu\text{-dppm})_3$, and $\text{Pd}_6(\mu\text{-CO})_6(\mu\text{-dppm})_3$ **15**. The IR spectrum of the last compound contains bands characteristic of the stretching vibrations of the bridging CO groups ($\nu_{\text{CO}} = 1818\text{--}1884\text{ cm}^{-1}$).

According to X-ray diffraction data,⁶⁵ the palladium atoms in cluster **15** form two almost equilateral triangles in which the length of one side is 2.658–2.714 Å. The triangles are linked by three bridging diphosphine ligands. One carbonyl group is coordinated to each side of each triangle. The coordination of the diphosphine ligands is such that they form almost planar trimeric $\text{Pd}_3(\mu\text{-CO})_3\text{P}_3$ species, which are linked by the $-\text{CH}_2-$ bridges belonging to the dppm ligand. The Pd_3 triangles are almost parallel and have rotated relative to one another by 10° . Thus the metal core of the cluster can be regarded as a slightly distorted trigonal prism, the distances between the bases of which (along the Pd–Pd edges) are 3.030, 3.010, and 2.948 Å.

7. The heptanuclear $\text{Pd}_7(\mu_3\text{-CO})_4(\mu\text{-CO})_3(\text{PMe}_3)_7$ cluster

The heptanuclear $\text{Pd}_7(\mu_3\text{-CO})_4(\mu\text{-CO})_3(\text{PMe}_3)_7$ **16** cluster has been obtained by the reduction of the complex $\text{Pd}(\eta^1, \eta^3\text{-C}_8\text{H}_{12})(\text{PMe}_3)$ with carbon monoxide and is the only example of palladium clusters with the above degree of nuclearity.⁶⁶ The IR spectrum of the complex contains absorption bands in the region characteristic of the stretching vibrations of the bridging CO group ($1685\text{--}1825\text{ cm}^{-1}$). The structure of the cluster has been established by X-ray diffraction. The metal core consists of an octahedron with one ‘capping’ palladium atom. The additional palladium atom is located asymmetrically above the face of the octahedron: one of the interatomic ‘nonbonding’ $\text{Pd}_{\text{cap}}\text{--Pd}_{\text{octahedron}}$ (3.17 Å) is appreciably longer than the other two bonds (2.73 Å). The metal–metal bond lengths in the octahedron are 2.75–2.81 Å; these are typical values for distances over which direct metal–metal interaction usually takes place.

8. The octanuclear $\text{Pd}_8(\mu_3\text{-CO})_2(\mu\text{-CO})_6(\text{PMe}_3)_7$ cluster

The syntheses of phosphinepalladium(0) carbonyl are carried out under similar conditions. The formation of clusters with different nuclearities can be accounted for by the extreme sensitivity of the process leading to the formation of the cluster metal core to the nature of the reaction medium and the source of the palladium atoms. Thus, when a solution of $\text{Pd}(\text{DBA})_2$ (DBA = dibenzylideneacetone) was treated with carbon monoxide ($P_{\text{CO}} = 1$ atm) in dry CH_2Cl_2 containing PMe_3 , $\text{Pd}_8(\text{CO})_8(\text{PMe}_3)_7$ **17** was obtained in a high yield at room temperature.

The cluster was isolated in the form of dark reddish-black plates and was characterised by IR spectroscopy ($\nu_{\text{CO}} = 1763\text{--}1878\text{ cm}^{-1}$) and X-ray diffraction data.⁶⁷ According to the X-ray diffraction data, six of the eight palladium atoms in the cluster form a regular octahedron. The remaining two palladium atoms behave as ‘caps’ on two opposite faces of the octahedron and are linked to the same apical palladium atom not joined to the terminal phosphine ligand.

9. The decanuclear clusters $\text{Pd}_{10}(\text{CO})_{12}\text{L}_6$ and $\text{Pd}_{10}(\text{CO})_{14}\text{L}_4$

a. Clusters with aliphatic phosphines

The synthesis of palladium clusters with aliphatic phosphines has been studied in greatest detail. The compounds are formed on reduction of palladium acetate by carbon monoxide in the presence of CF_3COOH . In these syntheses, the acid generates the optimum equilibrium concentration of the free phosphine, the excess of which is bound in the phosphine salt $[\text{HPAlk}_3]^+[\text{CF}_3\text{COO}]^-$.^{60,68,69} Superstoichiometric amounts of PAlk_3 and the presence of a strong acid are necessary in the syntheses of the complexes $\text{Pd}_{10}(\text{CO})_{12}(\text{PEt}_3)_6$ **18**, $\text{Pd}_{10}(\text{CO})_{12}(\text{PBu}_3)_6$ **19**, and $\text{Pd}_{10}(\text{CO})_{14}(\text{PBu}_3)_4$ **20**. On the other hand, in weakly acid and neutral media, it is necessary to reduce the concentration of PAlk_3 to give stoichiometric ratios.⁶⁸ The compounds which could be isolated at a low PAlk_3 concentration in a neutral medium proved to be noncrystalline.

Clusters **18–20** were characterised by IR spectroscopic data (the bands in the range $1810\text{--}1920\text{ cm}^{-1}$ were assigned to the stretching vibrations of the bridging CO groups) and ^{31}P NMR

spectroscopic data.^{60,68–71} The ^{31}P NMR spectra of clusters **18** and **19** are characterised by two signals with an intensity ratio of 2:1 and $\delta = -11.0$ and -3.1 ppm for cluster **18** and $\delta = -4.0$ and $+3.3$ ppm for cluster **19**. The ^{31}P NMR spectrum of cluster **20** contains one singlet at $\delta = -5.0$ ppm.^{69,70}

The spectroscopic data are consistent with the structure of the clusters determined by X-ray diffraction analysis. Thus cluster **19** is an octahedron, over all the nonadjacent faces of which ‘capping’ palladium atoms are located.⁶⁹

The palladium atoms of the metalpolyhedron can be subdivided into equatorial, apical (in the octahedron), and ‘capping’. Since the $\text{Pd}_{\text{cap}}-\text{P}_{\text{eq}}$ distance (2.694–2.722 Å) is much shorter than the $\text{Pd}_{\text{cap}}-\text{Pd}_{\text{apic}}$ distance (3.301–3.421 Å), it would be more logical to regard the ‘capping’ atoms not as atoms μ_3 -linked to the Pd_3 face of the octahedron but as bridging atoms on the $\text{Pd}_{\text{eq}}-\text{Pd}_{\text{eq}}$ edges. The Pd–Pd distances in the inner octahedron are in the range from 2.791 to 2.851 Å. Eight $\mu\text{-CO}$ groups behave as bridges on the $\text{Pd}_{\text{cap}}-\text{Pd}_{\text{eq}}$ edges and four CO groups are μ -coordinated to the four free faces of the octahedron. The coordination of these CO groups is also asymmetric, but, in contrast to the ‘capping’ metal atoms, the carbon atoms of the $\mu_3\text{-CO}$ groups are displaced towards the apical palladium atoms. The six phosphorus atoms of the tributylphosphine ligands are bound to four capping and two apical palladium atoms.

Treatment of complex **18** with the isocyanide XylNC ($\text{Xyl} = \text{C}_6\text{H}_3\text{Me}_2\text{-2,6}$) leads to the displacement of some of the coordinated CO groups and the formation of the cluster $\text{Pd}_{10}(\mu\text{-CO})_6(\mu_3\text{CO})_2(\mu\text{-CNXyl})_2(\text{PET}_3)_6$ **21**. According to X-ray diffraction data⁷² cluster **21** retains the same metal core as cluster **18**.

b. Clusters with aromatic phosphines

Aromatic phosphines [for example, PPh_3 , PMePh_2 , and P(OMe)Ph_2] are very weak bases and a very high content of hydrogen ions is required to regulate their concentration.

Attempts have been made^{69–71} to synthesise these compounds under neutral conditions with vigorous control of the concentration of the initial phosphine. The clusters $\text{Pd}_{10}(\text{CO})_{12}\text{L}_6$ [$\text{L} = \text{PPh}_3$, PMePh_2 , and P(OMe)Ph_2] were isolated in the solid state and identified by elemental analysis and IR spectroscopy.

10. The hexadecanuclear cluster $\text{Pd}_{16}(\text{CO})_{13}\text{L}_9$

The use of the traditional procedure — oxidation of CO by trimethylamine *N*-oxide⁷³ — made it possible to obtain⁷⁴ the 16-nuclear cluster $\text{Pd}_{16}(\text{CO})_{13}(\text{PET}_3)_6$ **22** by the reaction of $\text{Pd}_4(\text{CO})_5(\text{PET}_3)_4$ and $\text{Pd}_{10}(\text{CO})_{12}(\text{PET}_3)_6$. X-Ray diffraction study demonstrated the presence in this cluster of the centred icosahedron $\text{Pd}_{13}(\mu_3\text{-CO})_7(\text{PET}_3)_6$, overlaid by three bridging $\text{Pd}(\mu\text{-CO})_2\text{L}$ fragments. These fragments impart chirality to the centred icosahedral metal core of the cluster, reducing its idealised symmetry I_h to D_3 . The centrosymmetric racemic crystals of the clusters contain equal numbers of the optically active isomeric molecules.

Compound **22** is the first example of a polynuclear palladium complex with icosahedral packing of the metal atoms.

11. Tricosahedral clusters

The use of $\text{Pd}(\text{OAc})_2$ as a mild acceptor of phosphine ligands made it possible to convert decanuclear carbonyl–phosphine clusters into the compounds with a high nuclearity. Thus the interaction of $\text{Pd}_{10}(\text{CO})_{12}(\text{PET}_3)_6$ and $\text{Pd}(\text{OAc})_2$ (molar ratio 1:1) in benzene at 293 K for 24 h and subsequent addition of heptane afforded the cluster $\text{Pd}_{23}(\text{CO})_{22}(\text{PET}_3)_{10}$ **23**.⁷⁵ A slight change in the conditions of the synthesis (molar ratio $\text{Pd}:\text{Pd} = 1:1.5$; methanol–ether mixture, 303 K, 2.5 h) leads⁷⁶ to another 23-nuclear cluster having the composition $\text{Pd}_{23}(\text{CO})_{20}(\text{PET}_3)_8$ **24**. Both clusters have been characterised by X-ray diffraction data (Fig. 2a).

Figure 2. The structure of the metal cores of the $\text{Pd}_{23}(\text{CO})_{22}(\text{PET}_3)_{10}$ (a) and $\text{Pd}_{23}(\text{CO})_{20}(\text{PET}_3)_8$ (b) clusters according to X-ray diffraction data.^{75,76} The crosses designate the positions of the carbon atoms of carbonyl ligands.

The metal core of the centrosymmetric molecule of cluster **23** can be regarded as a cubooctahedron (designated by thickened lines in Fig. 2a) with one metal atom at the centre. This cubooctahedron has an idealised O_h symmetry. Six 'capping' palladium atoms are μ^4 -coordinated to each square face of the cubooctahedron while the remaining four metal atoms are symmetrically μ -coordinated to the four edges of the cubooctahedron. The metal–metal distances between the central and peripheral metal atoms (on average 2.847 Å) and between pairs of peripheral metal atoms (2.849 Å) in the cubooctahedron are virtually equal. All the other metal–metal distance in the metallopolyhedron are in the range from 2.720 to 2.920 Å.

Clusters **23** and **24** have a 22-atomic metallopolyhedron and one endopolyhedral metal atom. However, in contrast to complex **23**, containing a fragment with cubic close packing of metal atoms, the metallopolyhedron in complex **24** has a different structure. In the immediate environment of the endopolyhedral palladium atom, there are not 12, as in complex **23**, but 14 metal atoms; the average Pd–Pd distance (2.918 Å) exceeds by almost 0.17 Å the metal–metal distance in metallic palladium. The central palladium atom with metal atoms in its immediate vicinity is approximately regarded as a fragment with body-centred cubic packing (BCC), although the appreciable distortions of the idealised BCC packing observed in complex **24** are more likely to indicate that the polyhedron is not so regular in its shape. This polyhedron, made up of 15 metal atoms, is overlaid by eight 'caps' comprising palladium atoms, which are also coordinated to eight terminal phosphine ligands. The composition of the coordination sphere also includes three μ_3 -CO and seventeen μ -CO ligands.

12. The cluster $\text{Pd}_{34}(\text{CO})_{24}(\text{PET}_3)_{12}$

The 34-nuclear cluster $\text{Pd}_{34}(\mu\text{-CO})_{20}(\mu_3\text{-CO})_4(\text{PET}_3)_{12}$ **25** has been obtained as a by-product of the elimination of phosphine ligands from the decanuclear clusters $\text{Pd}_{10}(\text{CO})_{12}(\text{PET}_3)_6$ and $\text{Pd}_{10}(\text{CO})_{14}(\text{PET}_3)_4$, leading to the formation of a 38-nuclear cluster with 'irregular' packing of atoms in the quasi-spherical metal polyhedron (see below). According to X-ray diffraction data,⁷⁷ the metal polyhedron of the cluster contains four inner palladium atoms located at the apices of a distorted octahedron. Each of these atoms has a distorted icosahedral environment comprising 12 palladium atoms. This environment does not occur in the crystal lattice of the bulk metal but is encountered in the metal cores of cluster with finite dimensions. The observed metal–metal distances in the metal core of cluster **25** indicate unambiguously an icosahedral type of packing of the metal atoms (Fig. 3). Histograms of the metal–metal distances in large palladium clusters based on X-ray diffraction data have been compared with atomic radial distribution curves calculated from EXAFS data (Fig. 4).⁷⁸

Figure 3. The structure of the metal core of the cluster $\text{Pd}_{34}(\mu\text{-CO})_{20}(\mu_3\text{-CO})_4(\text{PET}_3)_{12}$ according to X-ray diffraction data (the dark lines designate the inner metal tetrahedron).⁷⁷

Figure 4. Histograms of the distribution of interatomic distances in the Pd_{34} metal core of the cluster $\text{Pd}_{34}(\mu\text{-CO})_{20}(\mu_3\text{-CO})_4(\text{PET}_3)_{12}$ with participation of only four intracluster atoms (a) with participation of all the remaining distances in the Pd_{30} metal 'shell' (b), and the theoretical distribution for the standard (idealised) icosahedral packing of the metal (c).

13. The cluster $\text{Pd}_{38}(\text{CO})_{28}(\text{PET})_{12} \cdot \text{Me}_2\text{CO}$

The cluster $\text{Pd}_{38}(\text{CO})_{28}(\text{PET})_{12} \cdot \text{Me}_2\text{CO}$ **26** was obtained, like the 23-nuclear clusters, by the reaction of the $\text{Pd}_{10}(\text{CO})_{12}(\text{PET}_3)_6$ with $\text{Pd}(\text{OAc})_2$ (molar ratio 1 : 2) in acetone in an argon atmosphere. The complex was isolated in the form of crystals sensitive to atmospheric oxygen and characterised by X-ray diffraction data (Fig. 5).⁷⁹

The cluster metal core has an incompletely regular structure with noncrystallographic symmetry close to D_2 . The flattened inner Pd_4 tetrahedron with two long (2.958 and 2.970 Å) and four short (2.539, 2.610, 2.603, and 2.514 Å) Pd–Pd bonds is surrounded by twenty metal atoms, located in four approximately parallel layers, and two metal atoms located outside these layers. All this corresponds to the 4 : 8 : 2 : 8 : 4 configuration. The 26-

Figure 5. The structure of the metal core of the cluster $\text{Pd}_{38}(\text{CO})_{28}(\text{PET})_{12}$ (the filled circles identify the inner metal atoms).⁷⁹

nuclear metal core thus obtained is linked to twelve ‘capping’ palladium atoms, while each ‘capping’ metal atom is linked to the phosphorus atom of the terminal phosphine ligand. The average Pd–Pd distance for 118 metal–metal bonds is 2.775 Å. Among the 28 carbonyl groups, four are μ_3 -coordinated, whilst the others are μ -coordinated.

Analysis of the structures of the polynuclear phosphinepalladium(0) carbonyl complexes showed that the ‘tendency’ to form a spherical metallopolyhedron, leading to the minimisation of the surface of the molecule, is characteristic for these compounds, as in the case of the platinum and nickel clusters (Table 2). The structures of clusters **24–26** provide a good illustration of the characteristic feature of the structure of the entire class of large clusters: the possibility of the rearrangement of the metallopolyhedron following a change in the ligand environment and the ‘tendency’ to achieve close packing of the metal atoms.

In order to investigate the structure and nature of the chemical bonding in the palladium(0) carbonyl clusters, an attempt has been made⁸⁰ to apply an incorporation method as the basic procedure for the ‘construction’ of large clusters by the addition of ‘caps’ to the triangular and/or rectangular faces of the metallopolyhedron. The method is based on the graph theory. Thus the structures of clusters **16**, **17**, **19**, and **20** are produced by the addition of one, two, three, and four palladium ‘caps’ respectively to the central Pd₆ octahedron. However, for the description of the Pd₂₃ and Pd₃₈ clusters, this approach requires the introduction of additional concepts and appears somewhat artificial.

The results of the determination of the metal–metal bond length in a series of phosphinepalladium(0) carbonyl complexes from X-ray diffraction and EXAFS data agree well.⁷⁸ This gives rise to the hope for a wider application of the EXAFS method in the study of the structures of cluster compounds.

14. Infrared spectra of palladium(0) carbonyl complexes

Analysis of the IR spectra (Table 2) of structurally characterised carbonylphosphine clusters^{81,82} permitted the conclusion that the characteristic differences in the region of the stretching vibrations of the carbonyl group are observed only as the coordination mode of the carbonyl ligands is varied. Thus the vibrations of the terminal CO groups are manifested in the short-wavelength region (2000–2050 cm^{−1}), those of the μ -CO groups are in the middle region ($\sim$ 1850–1950 cm^{−1}), and those of the μ_3 -groups are shown in the longest-wavelength part of the spectrum. The regions corresponding to absorption by the last two types of CO ligands overlap appreciably. Complexes of different nuclearity, containing the same type of CO ligand, have no stable distinctive features in the IR spectra.

On the other hand, the presence at one metal atom of only one terminal group and three *n*-donor atoms {for example, in the complexes Pd(CO)(PPh₃)₃, Pd(CO)(NP₃) and Pd(CO)[MeC(CH₂PPh₂)₃], see Table 1} leads to a decrease in ν_{CO} to values characteristic of the stretching vibrations of the bridging CO groups, *i.e.* the region of the stretching vibrations of the bridging and terminal carbonyl groups overlap. It is noteworthy that in all other complexes where the number of *n*-donor atoms at each metal atom is smaller (for example, two or one phosphorus atoms), the stretching vibrational frequencies of the terminal CO group lie above 2000 cm^{−1}.

IV. Palladium(+1) carbonyl complexes

The coordination compounds in which palladium is present in the formal oxidation state +1 have been frequently postulated as active intermediates in palladium-catalysed reactions.^{84–86} This applies to a considerable extent to reactions occurring with participation of carbon monoxide. Palladium(+1) intermediate

Table 2. Characteristics of the polynuclear palladium(0) complexes containing carbonyl ligands.

Compound	Coordination of CO	$\nu_{\text{CO}}/\text{cm}^{-1}$	Metal core	Pd–Pd /Å	Ref.

^a Average distance.

complexes could arise either in the reduction of Pd(+2) by carbon monoxide or in the oxidation of Pd(0), for example, during oxidative addition in a medium containing CO as the stabilising ligand. These postulates constitute the basis of the syntheses of palladium(+1) carbonyl complexes, although other products of the oxidation–reduction reactions [except Pd(+1)] have by no means been characterised in any way and discussed in all cases.

The first among palladium(+1) carbonyl complexes was the carbonyl chloride Pd(CO)Cl obtained in 1926.⁸⁷ The structure of this complex and in the first place the coordination mode of the carbonyl group remained obscure for many years. It was not until more than half a century later that X-ray diffraction studies on the structures of palladium carbonyl complexes were published. [Pd(μ -dam)Cl]₂(μ -CO)^{9,10} and Pd₄(μ -CO)₄(μ -OAc)₄^{11,12} were investigated. X-Ray diffraction data with IR spectroscopic data provided answers to a number of questions concerning the structure of palladium carbonyl chloride, its analogues, and derivatives.

1. The syntheses and structures of palladium(+1) carbonyl complexes

a. Palladium(+1) carbonyl halides and their anionic derivatives

The carbonyl chloride Pd(CO)Cl was first obtained by the reaction of solid PdCl₂ with carbon monoxide saturated with methanol vapour at 0 °C and atmospheric pressure.⁸⁷ A more convenient method of synthesis of the carbonyl halides involved the reaction of PdX₂ (X = Cl, Br) with CO at atmospheric pressure in a concentrated aqueous solution of the corresponding hydrogen halides. The formation of diamagnetic powdered Pd(CO)Cl and Pd(CO)Br deposits was observed when an aqueous solution of the corresponding palladium salt was treated with carbon monoxide or after treatment with formic acid.⁸⁸ Palladium carbonyl chloride has also been obtained by carbonylation of a suspension of PdCl₂ in the presence of acetyl chloride⁸⁹ or small amounts of H₂O^{90,91} and also by the reaction of PdCl₂ and allyl chloride with CO at both atmospheric and elevated pressures.^{91,92} The benzonitrile complex (PhCN)₂ · PdCl₂ — a convenient reagent which has proved very useful in the preparation of alkene palladium π -complexes⁹⁴ — has been employed as the starting material for the synthesis of Pd(CO)Cl.^{91,93}

The carbonyl chloride Pd(CO)Cl (ν_{CO} = 1975 cm⁻¹) has also been obtained⁹⁵ by treating the palladium(+2) carbonyl complex Pd₂(CO)₂Cl₄ with carbon monoxide (Ac₂O, 25 °C, 24 h, P_{CO} = 1 atm).

In contrast to the binary palladium(0) carbonyl compounds, which are not formed from metallic palladium at temperatures above 323 °C, the palladium(+1) carbonyl chloride can be produced from powdered palladium at a CO pressure of 170 atm and 190 °C in a phosgene-containing solution in *o*-dichlorobenzene.⁹¹ The palladium(+1) carbonyl fluoride or carbonyl iodide could not be obtained by any of the methods indicated above.

The elemental composition of palladium(+1) carbonyl chloride specimens obtained by different methods^{88–93} as a rule corresponds to the formula Pd(CO)Cl: the IR spectra of three specimens agree satisfactorily. A powdered amorphous or very fine-crystalline substance, which does not dissolve in organic solvents and is thermally stable up to 60 °C but readily decomposes on treatment with water or even atmospheric moisture, was obtained in all cases.

The reaction is strongly inhibited by H⁺ or Cl⁻ ions, as a result of which the carbonyl chloride dissolves almost without decomposition and is stable in concentrated hydrochloric acid. The properties of the thermally more stable (T_{decomp} = 120 °C) carbonyl bromide Pd(CO)Br are similar. This too is stable in concentrated aqueous HBr solution.⁸⁸ Both palladium(+1) carbonyl halides are relatively stable in air in the absence of H₂O.

Thermolysis of the carbonyl halides leads to the elimination of CO and the formation of palladium metal. Probably as a result of slight decomposition the colour of the Pd(CO)X specimens obtained by different workers varies from yellow-green to dark-violet. The stretching vibrational frequency of the CO groups in these compounds varies in the range from 1850 to 2000 cm⁻¹.^{96,97}

It was postulated in early investigations that the compounds Pd(CO)X are polymers with halide⁸⁸ or carbonyl⁹⁸ bridges. On dissolution in the corresponding hydrogen halide solution, depolymerisation takes place with formation of mono- or di-nuclear anions, for example:

The crystalline substance with the composition (NH₄)₂[Cl₂Pd(CO)]₂ has been isolated from a solution of (NH₄)₂PdCl₄ in concentrated HCl, treated with carbon monoxide for several days, while in the presence of enH₂²⁺ and [Pt(NH₃)₄]²⁺ cations the crystalline salts of the latter with the [Pd₂(CO)₂Cl₄]²⁻ anion were obtained. It was assumed that the anion contains Pd(+3) atoms linked by bridging CO groups to form a dimer.⁹⁹ Without going into the question of the electronic structure of the anion, we may note that, since the CO group is electrically neutral, the formal oxidation state of palladium is in this instance +1. One cannot rule out the possibility that a metal–metal bond is present in the dimeric anion. The diamagnetism of the cesium rubidium, and tetraalkylammonium salts of the anions [Pd₂(CO)₂Cl₄]²⁻ and [Pd₂(CO)₂Br₄]²⁻ obtained by a similar method^{88,98} agrees with this hypothesis. Treatment of the complex Pd(CO)Cl with an equimolar amount of NH₂Et₂Cl afforded the anionic complex [NH₂Et₂]₂[Pd₂(CO)₂Cl₄], characterised by elemental analysis and IR spectroscopy (ν_{CO} = 1916 cm⁻¹).⁹⁵

The structure of the anionic carbonyl halide complex [Bu₄N]₂[Pd₂(CO)₂Cl₄], synthesised by Goggin and Mink,⁹⁸ has been investigated by X-ray diffraction.¹⁰⁰ The 1966 and 1906 cm⁻¹ frequencies correspond to the stretching vibrations of the CO groups in the complex in solution in CH₂Cl₂. The palladium atoms in the anion of the complex are linked by two carbonyl bridges, each metal atom being bound to two terminal chloride ligands.

The metal–metal distance (2.697 Å) indicates the presence of the Pd–Pd single bond. Each palladium atom has a highly distorted tetrahedral environment, the PdCl₂ plane making a dihedral angle of 8–10° with the Pd₂(μ -C)₂ plane.

The planar configuration of the Pd₂(μ -C)₂ species agrees well with the IR spectrum of the solid complexes (the spectrum contains only the ν_{CO} = 1903 cm⁻¹ band due to the asymmetric vibrations). The presence in the spectrum of the solution in CH₂Cl₂ of a band at 1966 cm⁻¹ assigned to the symmetrical vibrations of the CO group, indicates the distortion of the planar configuration of the Pd₂(μ -C)₂ species in solution.

Thus the carbonyl ligand in virtually all the reliably characterised neutral and anionic palladium(+1) carbonyl halide complexes is a bridge between two metal atoms. The only exception is the complex [Pd(CO)₂(μ -Cl)]₂ **27** obtained when CO is passed (6 h, 60 °C) through a reaction mixture containing PdCl₂ and NaHCO₃ in anhydrous methanol in the presence of 2-(1,5-dimethylhex-4-enyl)-3-hydroxy-5-methyl-1,4-benzoquinone.¹⁰¹

Complex **27** has been isolated from *n*-hexane in the form of crystals stable in air. Unfortunately, the very brief relevant publication¹⁰¹ contains no comments whatsoever concerning the fairly unexpected choice of reagents and the role of sodium bicarbonate or the substituted benzoquinone. The IR spectrum of the complex contains bands characteristic of terminal CO groups (2103, 2082, 2024, and 1997 cm⁻¹). According to X-ray diffraction data, the two palladium atoms of the complex, at a distance of 3.114 Å, are joined by two chloride bridges *cis*-posed relative to the Pd...Pd axis (the dihedral angle of the Pd...Cl triangle is 124°). Each metal atom is also joined to two terminal CO groups, which builds up their environment to a distorted planar square.

b. Palladium (+1) carbonyl halides containing *n*-donor stabilising ligands

Neutral molecules containing an element E (E = N, P, As, Sb), which is capable of donating an unshared electron pair, are usually employed as additional stabilising ligands. In the chemistry of carbonyl-containing palladium(+1) compounds, nitrogen-containing ligands are relatively rare, whilst phosphorus-containing ones (mono- and di-phosphines) are very common.

The complexes [(PdXL)₂CO]_n, where X = Cl, Br, or I and L = PPh₃, PPh(*p*-MeOC₆H₄)₂, PPh₂(C₆H₄COOH), PPh₂(C₆H₄F), PPh₂(C₆H₄Cl) or PPh₂(C₆H₄Me), have been obtained by the reactions of the corresponding phosphine with a solution of H₂Pd₂(CO)₂Cl₄ in concentrated HCl.¹⁰² The IR spectra of the solid complexes contain two bands in the range 1860–1962 cm⁻¹, which have been assigned to the stretching vibrations of the bridging CO groups. On the other hand, if a solution of H₂Pd₂(CO)₂Cl₄ in concentrated HCl is acted upon initially by a solution of SnCl₂ and then triphenylphosphine in concentrated HCl, all the acido-ligands are displaced from the initial carbonyl chloride and [Pd₂(PPh₃)₂(SnCl₃)₂]CO (*ν*_{CO} = 1800–2000 cm⁻¹) is formed.¹⁰³ The complexes [(PdXL)₂CO]_n, containing stabilising ligands of the type of arsine (L = AsPh₃) or stibine (L = SbPh₃) have been obtained on partial substitution of carbonyl and acido-ligands in palladium(+1) carbonyl halides and carbonyl acetate complexes by organoelement ligands.¹⁰⁴ The complexes have been characterised by elemental analysis, ESCA, and IR spectroscopy. Judging from the *ν* = 1710–1890 cm⁻¹ region, the carbonyl group in these compounds is involved in bridging coordination.

The dinuclear complex Pd₂(CO)Cl₂L₃ (L = PEt₂Ph) **28** has been obtained⁵⁹ in a fairly high yield (49%) yield by the reaction of CO with Pd(NO₂)₂L₂ in dichloromethane (293 K, *P*_{CO} = 1 atm, 48 h) and subsequent precipitation of the compound formed on treatment with CO-saturated hexane at 273 K. In the formation of compound **28**, the source of chloride ligands could be dichloromethane itself, although the authors did not rule out also the possibility of the interaction of the initial Pd(NO₂)₂L₂ and HCl or Cl₂, present in the solvent, with formation of PdCl(NO₂)L₂. In order to confirm this hypothesis, *trans*-PdCl(NO₂)L₂ was obtained. Its treatment with CO also affords the dimer **28**.

According to X-ray diffraction data, the two palladium atoms in the molecule of compound **28** (the Pd–Pd distance is 2.652 Å) are linked asymmetrically by the coordinated semibridging carbonyl ligand (the Pd–C distances are 1.874 and 2.110 Å, while the Pd–C–Pd angle is 83.3°).¹⁰⁵ They have nonequivalent environments. The palladium atom involved in the shorter bond with the carbonyl group is also linked to the second metal atom, one chloride ligand, and one phosphine ligand. It has a highly distorted 4-coordinated environment. There are five atoms in the

environment of the second palladium atom: one Cl atom, two phosphorus atoms of the phosphine ligands, palladium, and a somewhat remote carbon atom of the carbonyl ligand.

Unfortunately the authors do not quote spectroscopic data for complex **28**.

Complexes containing the Pd₂(μ-Q)₂ moiety, where Q = diphosphine or diarsine ligands having the composition R₂E(CH₂)_nER₂ (E = P or As, *n* = 1–3), constitute a special group. As a rule, such complexes are formed by the insertion of CO in the metal–metal bond in the dinuclear palladium(+1) complexes Pd₂(μ-Q)₂X₂ (X = Cl, Br, I), which are formed in their turn in the reaction of the polymeric [Pd(CO)X]_n (or its anionic derivatives) with the bidentate ligand Q. In the interaction of [Pd(CO)X]_n and dppm, the coordinated CO group is fully displaced with formation of the complexes [Pd(dppm)X]₂.⁸⁸ In the case of dam, the reaction product depends on the nature of the halogen: if X is chlorine or bromine, [Pd(μ-dam)X]₂(μ-CO) **29** is formed, whereas in the case where it is iodine the product is [Pd(μ-dam)I]₂.^{9, 10, 105}

In complex **29** (X = Cl) palladium atoms are bound to two dam molecules and the carbonyl bridge.

The Pd–Pd distance (3.274 Å) exceeds twice the covalent radius. Nevertheless, the compound is diamagnetic, so that the spins are apparently paired via the carbonyl bridge, which in this case is fairly unusual: the Pd–C–Pd angle is 119° and not 85–89° as in the majority of transition metal carbonyl complexes.

When [Pd(μ-dppm)X]₂ (X = Cl, Br) is treated with CO in dichloromethane, [Pd(μ-dppm)X]₂(μ-CO) (*ν*_{CO} = 1704 cm⁻¹) is formed;¹⁰⁶ it liberates CO reversibly on heating in solution in dichloromethane. The complex Pd₂(μ-CO)(μ-dppm)₂Cl₂ has been obtained as a result of the addition of oxalyl chloride ClC(=O)C(=O)Cl to Pd₂(dppm)₃ in dichloromethane.¹⁰⁷

The kinetics of the reversible insertion of carbon monoxide in the Pd–Pd bond of the complex Pd₂(dppm)₂X₂ with formation of Pd₂(μ-CO)(μ-dppm)₂X₂ have been investigated spectrophoto-metrically.¹⁰⁸ It was established that the reaction obeys a first-order equation with respect to both the metal and carbon monoxide.

The reaction of the polymer [Pd(CO)Cl]_n with dmpm (dmpm = bis(dimethylphosphino)methane) in dichloromethane at 198 K leads to the formation of Pd₂Cl₂(dmpm)₂ **30**. Treatment of compound **30** with carbon monoxide results in the formation of [PdCl(μ-dmpm)]₂(μ-CO) **31** with a bridging carbonyl ligand (*ν*_{CO} = 1710 cm⁻¹). According to X-ray diffraction data, the distance between the metal atoms in the molecule of compound **31** (the Pd–Pd distance is 3.169 Å) exceeds the sum of the covalent radii of palladium and the environment of each metal atom consists of an almost planar square.^{109, 110}

In contrast to analogues containing dppm, an unusually high solubility and stability in aqueous solution were characteristic of complex **31**. On the basis of IR, Raman, and NMR spectroscopy involving different nuclei and electrical conductivity data, it has been shown that the following reactions take place readily in water:

The interaction of $[\text{Pd}(\mu\text{-dppm})\text{X}]_2$ and SnCl_2 followed by treatment of the resulting solution with carbon monoxide afforded ¹¹¹ *in situ* the complex $\text{Pd}_2(\mu\text{-dppm})_2\text{Cl}(\text{SnCl}_3)(\mu\text{-CO})$ ($\nu_{\text{CO}} = 1688 \text{ cm}^{-1}$).

The principal characteristic feature of the reaction involving the insertion of small molecules in the Pd–Pd bond is the increase in the metal–metal distance on the formation of bridges. Despite the fact that the palladium–palladium distance increases to a value greatly exceeding the sum of the covalent radii, the compounds containing palladium in the formal +1 oxidation state remain diamagnetic. The probable causes of the diamagnetism of these compounds will be discussed below.

c. The binary palladium(+1) carbonyl

The only compound in which the Pd(+1) atom is linked to carbonyl groups only is the cationic complex $[\text{Pd}_2(\mu\text{-CO})_2](\text{SO}_3\text{F})_2$.

The reductive decomposition of the divalent palladium carbonyl $\text{Pd}(\text{CO})_2(\text{SO}_3\text{F})_2$ in solution in fluorosulfonic acid HSO_3F at 298 K leads to the formation (according to IR spectroscopic data) of a mixture of complexes containing both bridging and terminal CO groups.¹¹² Slow crystallisation (for about three weeks) of the mixture from fluorosulfonic acid leads to the precipitation of needle-like crystals.

It has been suggested that the reduction of Pd(+2) to Pd(+1) includes the elimination of the $\text{SO}_3\text{F}^\cdot$ radicals and their dimerisation to $\text{S}_2\text{O}_6\text{F}_2$ with simultaneous liberation of one mole of CO in accordance with the equation

which is probably followed by the oxidation of CO to CO_2 :

The formation of $\text{S}_2\text{O}_5\text{F}_2$ in the reaction mixture has been confirmed by ^{19}F NMR (signal at $\delta = 47.5 \text{ ppm}$).

The complex $[\text{Pd}_2(\mu\text{-CO})_2](\text{SO}_3\text{F})_2$ has been characterised by elemental analysis IR spectroscopy ($\nu_{\text{CO}} = 1977 \text{ cm}^{-1}$), and X-ray diffraction data. Its molecular structure consists of cyclic, almost planar four-membered $\text{Pd}_2(\mu\text{-CO})_2$ species, in which the palladium atoms are linked together as a result of direct metal–metal interaction (the Pd–Pd distance is $2.698 \text{ \AA}$) and by two symmetrical carbonyl bridges. The individual metalocycles are joined by symmetrical bridging bidentate fluorosulfate groups, forming a planar polymer chain. Thus the coordination sphere of each palladium atom incorporates the two carbon atoms of two *cis*-disposed carbonyl groups, two oxygen atoms of two fluorosulfate groups, and a neighbouring palladium atom. If the metal–metal bonding is ignored, the geometrical environment of each palladium atom can be regarded as a slightly distorted square.

d. Other palladium(+1) complexes containing carbonyl and organic ligands

The interaction of the complex $\text{Pd}_2(\mu\text{-Cp})(\mu\text{-Br})(\text{PR}_3)_2$ and CO in toluene leads to the displacement of the bromide and cyclopentadienyl bridges to axial positions and to the formation of

$\text{Pd}_2(\mu\text{-CO})(\eta^5\text{-Cp})(\text{Br})(\text{PR}_3)_2$ **32** [$\text{R} = \text{Et}$ (**32a**), $\text{R} = \text{Pr}^i$ (**32b**)].¹¹³ The analogous initial compound containing an acetate instead of a bromide bridge reacts with CO also with formation of complex **32**.¹¹⁴ Complexes **32a,b** have been characterised by IR spectroscopy ($\nu_{\text{CO}} = 1804$ and 1828 cm^{-1} respectively) and NMR spectroscopy on different nuclei. The structure of complex **32b** has been investigated by X-ray diffraction. The metal atoms in the molecule of the complex are linked both to one another (direct metal–metal interaction, the Pd–Pd distance is $2.67 \text{ \AA}$) and with the bridging carbonyl. The phosphine ligands are *trans*-located relative to the metal–metal axis. It has been shown that the carbonyl bridge in complex **32** is readily substituted by other small molecules, for example SO_2 or CH_3NC . The dinuclear complexes $(\text{PR}_3)_2\text{Pd}_2(\mu\text{-Cp})(\mu\text{-X})$ ($\text{X} = \text{Cl}$ or CH_3COO) readily react with $\text{NaCpM}(\text{CO})_3$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$) or $\text{NaCo}(\text{CO})_4$. Such interaction affords the heteronuclear clusters $(\text{PR}_3)_2\text{Pd}_2(\mu\text{-Cp})[\mu\text{-M}(\text{CO})_3\text{Cp}]$ **33** and $(\text{PR}_3)_2\text{Pd}_2(\mu\text{-Cp})[\mu\text{-Co}(\text{CO})_4]$ **34** respectively.¹¹⁵ These complexes have been characterised by spectroscopic methods. It has been established that the cyclopentadienyl and carbonylmetallate ligands function as bridges between the two palladium atoms, while the phosphines occupy the axial position. The attempt to substitute the cyclopentadienyl ligand in complexes **33** and **34** by a second carbonylmetallate in order to obtain tetranuclear clusters was unsuccessful, but such clusters have been obtained by another method.

The interaction of *trans*- $\text{Pd}(\text{PEt}_3)_2\text{Cl}_2$ and $[\eta^5\text{-CpM}(\text{CO})_3]^-$ results in the formation^{116,117} of the tetranuclear clusters $\text{Pd}_2\text{M}_2(\eta^5\text{-Cp})_2(\mu_3\text{-CO})_2(\mu\text{-CO})_4(\text{PEt}_3)_2$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$) **35**. All three complexes have been characterised by X-ray diffraction data. The metal atoms in complex **35** ($\text{M} = \text{Mo}$) are in the same plane and form a rhombus with a short Pd–Pd diagonal. One $\mu_3\text{-CO}$ group is linked to each Pd_2Mo triangle ($\nu_{\text{CO}} = 1772 \text{ cm}^{-1}$), while a $\mu\text{-CO}$ group is linked to each Pd–Mo edge ($\nu_{\text{CO}} = 1842$ and 1801 cm^{-1}).

A similar cluster with another phosphine ligand, $\text{Pd}_2\text{Mo}_2(\eta^5\text{-Cp})_2(\mu_3\text{-CO})_2(\mu\text{-CO})_4(\text{PBzPh}_2)_2$ (the Pd–Pd and Pd–Mo distances are 2.58 and 2.86, 2.82 $\text{ \AA}$ respectively), has been synthesised.¹¹⁸

Palladium(+1) complexes with terminal carbonyl groups have been obtained¹¹⁹ in a study of the reactions of a dimeric univalent palladium complex with phosphide bridges as a result of the following transformations in solution in dimethoxyethane:

where $\text{X}^- = \text{CF}_3\text{SO}_3^-$ or BF_4^- . Complexes **36** and **37** have been characterised by NMR and IR spectroscopy ($\nu_{\text{CO}} = 2080$, 2055, and 2045 cm^{-1} for complex **37**) and also by X-ray diffraction data (the Pd–Pd distances are 2.611 and 2.682 $\text{ \AA}$ for complexes **36** and **37** respectively). The NMR spectra have shown that complex **37** exists in the form of a mixture of isomers differing in the relative

disposition of the carbonyl and phosphine ligands. Complex **37** is stable only under a carbon monoxide atmosphere; it is readily decarbonylated *in vacuo*, on passing nitrogen, on heating, or on UV-irradiation.

e. Palladium(+1) carbonyl carboxylates

All the carbonyl-containing univalent palladium complexes presented above are as a rule dimers or linear polymers. The tetranuclear carbonyl carboxylates having a planar cyclic metal core are an exception. The structure and chemical properties of compounds of this group have been thoroughly investigated.

The complexes containing simultaneously both carbonyl and carboxylate ligands are usually obtained by reduction of palladium(+2) carboxylates with carbon monoxide in a carboxylic acids or in an inert solvent containing the corresponding carboxylic acid. The second method of synthesis involved the substitution of ligands in the presynthesised palladium(+1) carbonyl carboxylates. The cluster $\text{Pd}_4(\mu\text{-CO})_4(\mu\text{-OAc})_4$ **38** was obtained^{11,12} by the first methods, *i.e.* by carbonylating ($P_{\text{CO}} = 1$ atm) palladium acetate in glacial acetic acid at 323 K.

The cluster crystallises with two molecules of acetic acid to give $\text{Pd}_4(\mu\text{-CO})_4(\mu\text{-OAc})_4 \cdot 2\text{AcOH}$ **38a**, while on drying *in vacuo* over KOH it loses an acetic acid molecule and is converted into $\text{Pd}_4(\text{CO})_4(\text{OAc})_4$ **38b**. The IR spectra of the complexes each contain intense bands corresponding to the stretching vibrations of the CO groups (1934 and 1975 cm^{-1} for **38a** and 1940 and 1975 cm^{-1} for **38b**) and bands due to the stretching vibrations of acetate groups coordinated as bidentate species. According to X-ray diffraction data, the cluster as an almost rectangular metal core with angles of 83.4° and 96.6° . The sides of the rectangle, linked by acetate bridges are longer ($2.909\text{ \AA}$), while the sides linked by carbonyl bridges are shorter ($2.663\text{ \AA}$) than the metal—metal distance in metallic palladium ($2.751\text{ \AA}$) (Fig. 6).¹²⁰

Figure 6. The structure of the cluster $\text{Pd}_4(\mu\text{-CO})_4(\mu\text{-OAc})_4$ according to X-ray diffraction data.¹²²

The mechanism of the formation of cluster **38** has been investigated by spectroscopic and kinetic methods. The data obtained led to the conclusion that the formation of complex **38** involves the transfer of an oxygen atom from the carboxylate group to the coordinated carbonyl group. This results in the formation of the coordinated acyl $[\text{CH}_3\text{CO}]$ and in the elimination of carbon dioxide.^{121–123}

It has been established that the coordinated acetate groups in complex **38** are substituted by other carboxylates in the reactions with the corresponding acids, for example:

$\text{R} = \text{CD}_3, \text{C}_2\text{H}_5, \text{C}_6\text{H}_5, \text{CF}_3, \text{CCl}_3, \text{CH}_2\text{Cl}.$

According to IR spectroscopic data, all the complexes contain bridging carbonyl and carboxylate groups. Comparative analysis of X-ray diffraction data for palladium carbonyl acetate and of

EXAFS data for all carbonyl carboxylate complexes permitted the conclusion that they all have a similar structure — a planar metal core (rectangle, square, or rhombus) to the sides of which bridging carboxylate and carbonyl ligands are coordinated.¹²⁴

Together with the existence of isomers having different metal cores, there is also a possibility of the existence of isomers with different relative dispositions of ligands: disposition of ligands in pairs (for example as in complex **38** characterised by X-ray diffraction analysis) and uniform distribution of similar ligands. The influence of substituents in carboxylated groups on the isomerism of the metal core of the carbonyl carboxylates has been examined in detail.^{125,126}

f. Derivatives of palladium(+1) carbonyl carboxylates with N- and P-donor ligands

The interaction of complex **38** with ligands such as Py, dppe, PPh_3 , Bipy, and Phen leads to a series of complexes, the composition of which depends on the initial Pd/ligand(L) ratio. The palladium complexes formed with the Pd/L = 2 ratio are unstable. With decrease in the ratio, more stable compounds appear.

The interaction of complex **38** with Py and its alkyl derivatives (with the ratio Pd/Py = 1) entails the disproportionation of Pd(+1) to Pd(0) and Pd(+2):

The interaction of complex **38** and dppe (Pd/dppe = 1) in benzene affords the complex $\text{Pd}_2(\text{dppe})_2(\text{CO})(\text{OAc})_2$.^{127,128}

40

According to IR spectroscopic data, the group CO in complex **40** is of the bridging type ($\nu_{\text{CO}} = 1790\text{ cm}^{-1}$). The fairly low stretching vibrational frequency in the compound where the metal atoms are linked also by a further two diphosphine bridges indicates an increase in the Pd–Pd distances compared with the analogous distances in complex **38**. Analysis of the stretching vibrational frequencies of the acetate group in the IR spectrum of complex **40** [$\nu_{\text{as}}(\text{COO}) = 1580\text{ cm}^{-1}$, $\nu_{\text{s}}(\text{COO}) = 1380\text{ cm}^{-1}$, $\Delta\nu = 200\text{ cm}^{-1}$] permits the conclusion that monodentate coordination of the acetate groups takes place. Apparently the structure of complex **40** is analogous to that of palladium(+1) carbonyl halide complexes with diphosphine and diarsine groups.^{9,10} The coordination sphere of each metal atom consists of two phosphorus atoms of the two diphosphine ligands, the carbon atom of the carbonyl group, and the oxygen atom of the terminal acetate group.

The analogous complex $[\text{Pd}(\text{dppm})(\text{O}_2\text{CCF}_3)]_2(\mu\text{-CO})$ has been isolated in the course of the study of the kinetics of the interaction of the dimer $[\text{Pd}(\text{dppm})(\text{O}_2\text{CCF}_3)]_2$ and carbon monoxide in dichloromethane.¹²⁹ The complex has been characterised by IR spectroscopy ($\nu_{\text{CO}} = 1720\text{ cm}^{-1}$) and NMR spectroscopy involving different nuclei and also by X-ray diffraction analysis.

The two palladium atoms in the molecule of the complex, linked by a bridging CO group, are at a distance of $2.896\text{ \AA}$. This is less than the sum of the covalent radii of palladium ($2.98\text{ \AA}$) and is appreciably shorter than the Pd–Pd distance ($\sim 2.7\text{ \AA}$) characteristic of the Pd(+1) dimers. Each palladium atom in the molecule is surrounded by the same set of atoms: the carbon atom of the carbonyl group, two phosphorus atoms of the two diphosphine ligands, and one oxygen atom of the terminal carboxylate ligand. If the Pd–Pd bond is excluded from consideration, then environment of each palladium atom consists of an almost planar square (the deviation from the plane of the square is not more than $0.02\text{ \AA}$), whereas the environment of the second metal atom is close to being tetrahedral. The authors believed that in this case the distortion of the symmetrical structure may be caused by a redistribution of electron density in the complex and that the latter can be regarded as an intermediate in the dissociation of the trifluoroacetate complex leading to $[\text{Pd}_2(\mu\text{-dppm})_2(\mu\text{-CO})(\text{O}_2\text{CCF}_3)]^+(\text{CF}_3\text{CO}_2)^-$.

The interaction of complex **38** and dppe, taken in ninefold excess in tetrahydrofuran, leads to the formation of a cationic complex in accordance with the equation

According to ^{31}P NMR data the diphosphine ligands in the complex are involved in both bridging and terminal coordination, whereas the carbonyl group serves as a bridge between the two metal atoms.

Treatment of complex **38** with PPh_3 leads to the complex $\text{Pd}_2(\text{CO})(\text{PPh}_3)(\text{OAc})_2$:

41

Complex **41** contains a bridging CO group ($\nu_{\text{CO}} = 1800 \text{ cm}^{-1}$). Depending on the conditions in the synthesis, compounds differing in the coordination of the acetate groups are formed. Thus, when the process is carried out in tetrahydrofuran a complex with acetate bridges is produced [$\nu_{\text{as}}(\text{COO}) = 1530 \text{ cm}^{-1}$, $\nu_{\text{s}}(\text{COO}) = 1400 \text{ cm}^{-1}$, $\Delta\nu = 130 \text{ cm}^{-1}$], whereas the reaction of complex **38** with PPh_3 in benzene leads to a compound with terminal OAc groups [$\nu_{\text{as}}(\text{COO}) = 1610 \text{ cm}^{-1}$, $\nu_{\text{s}}(\text{COO}) = 1350 \text{ cm}^{-1}$, $\Delta\nu = 260 \text{ cm}^{-1}$].

In the interaction of complex **38** and Bipy at an initial Bipy concentration $> 0.5 \text{ M}$ and a concentration of complex **38** of $5 \times 10^{-3} \text{ M}$ all the CO molecules are displaced:^{49, 50}

At low Bipy concentrations ($< 5 \times 10^{-3} \text{ M}$), only half of the CO's are displaced from complex **38**:

In contrast to Bipy, *o*-phenanthroline (Phen) displaces from complex **38** only half of the CO groups present even at the highest ligand concentrations. In the reaction of complex **38** with Phen, in the proportions Phen: Pd = 1:1, in acetic acid, a tetranuclear cationic complex is formed:¹³⁰

42

The complexes have been characterised by IR spectroscopy ($\nu_{\text{CO}} = 1800 \text{ cm}^{-1}$) and X-ray diffraction data.¹³⁰ In the cation **42**, the four metal atoms form a tetrahedron, to the two mutually perpendicular edges of which bridging CO groups are coordinated. The remaining metal-metal bonds are unbridged. One Phen molecule is coordinated as a chelate species to each palladium atom, while all the acetate groups are displaced to the outer sphere

On passing from complex **38** to **42**, all the metal-metal distances change significantly. The Pd-Pd distance in the $\text{Pd}(\mu\text{-CO})\text{Pd}$ fragments increases from 2.667 Å in complex **38** to 2.890 Å in complex **42**, while the unbridged Pd-Pd bond is shortened from 2.909 to 2.718 Å to compare with the $\text{Pd}(\mu\text{-OAc})\text{Pd}$ fragment in the initial carbonyl acetate.

It has been suggested that the conversion of the neutral molecule of complex **38** into the cationic cluster **42** involves the

interaction of complex **38** and Phen, which results in the displacement of the acetate groups and the formation of the dication $[\text{PhenPd}(\text{CO})_2\text{PdPhen}]^{2+}$. This is followed by the elimination of half of the coordinated CO groups and the dimerisation of coordinatively unsaturated species produced, which leads to the appearance of cluster **42**.

g. The structure of palladium(+1) complexes containing a bridging CO group

The palladium(+1) complexes containing a bridging CO group have been reliably characterised by the results of spectroscopic and structural studies (Table 3).

In the complexes where the palladium atoms are not linked to *n*-donor atoms (Nos 1–3), the metal-metal distances are close to

Table 3. Certain spectroscopic and structural data for palladium(+1) complexes containing a bridging carbonyl group.

No. Complex	<i>n</i> -Do- nor atom	Pd-Pd /Å (XRD)	ν_{CO} /cm ⁻¹	Ref.

^a According to EXAFS data. ^b For comparison, the Pd-Pd distance in $\text{Pd}_2(\mu\text{-dppm})_2\text{Br}_2$ is 2.699 Å.

that in metallic palladium, which is 2.7 Å. The stretching vibrational frequencies of the CO group in these complexes vary from 1900 to 2000 cm⁻¹. The presence of powerful electron-withdrawing groups, for example CF₃COO (complex No. 4), increases the stretching vibrational frequency of the CO group to 2000 cm⁻¹.

After the insertion of *n*-donor phosphorus atoms (axial phosphine ligands in complex Nos 5 and 6) into the coordination sphere of palladium, the Pd-Pd distance does not change, but ν_{CO} falls sharply. Only the presence of chelating phenanthroline molecules, linked to one palladium atom (No. 7), or of bridging diphosphino and diarsine ligands (complexes Nos 8–10) leads to a simultaneous increase in the Pd-Pd distance and decrease in the stretching vibration frequency of the bridging carbonyl ligand.

It is of interest that powerful electron-accepting ligands, for example trifluoroacetate groups, in the axial positions in complex No. 4 (Table 3) somewhat 'extinguish' the effect involving the donation of *n* electrons by phosphorus atoms, which is probably the reason for the shortening (compared with other complexes containing diphosphines and diarsines) of the Pd-Pd distance.

As mentioned above, all the complexes discussed are diamagnetic. On the other hand, the metal-metal distance in complexes with diphosphines and diarsines (complexes Nos 9 and 10 in Table 3) greatly exceeds the sum of the covalent radii palladium and for this reason the pairing of electrons as a result of the formation of the Pd-Pd bond is impossible. The diamagnetism of such complexes has been explained by the exchange of charges in the $\text{Pd}_2(\mu\text{-CO})$ fragment with participation of the structure

Evidently the hypothesis of the resonance of structures with different numbers of unpaired electrons ($\text{Pd}^+ \dots \text{Pd}^+$ and $\text{Pd}^{2+} \dots \text{Pd}^0$) conflicts with the main principles of the resonance theory.¹³¹ At the same time, the bond in the group made up of two palladium atoms and one carbon atom of the carbonyl group can be described approximately in terms of a localised three-centre system of molecular orbitals, similar to that which occurs in the allyl radical. The diamagnetism of the dinuclear palladium(+1) compounds under consideration implies, in terms of this approximation, that four electrons (one from each palladium atom and two from the carbonyl ligands) fill the bonding and nonbonding molecular orbitals of the system (Fig. 7).

Within the framework of this approximation, all the changes in the Pd–Pd distance and ν_{CO} frequencies should be considered from the standpoint of the variation of the electron density on the metal atoms and the variation of the levels of the atomic orbitals in view of the change in the nature of the ligand atoms coordi-

Figure 7. The three-centre system of molecular orbitals in the group comprising two palladium atoms and one carbon atom.

nated to palladium. It is easily seen that in the isomeric ylide the frequencies of the carbonyl group should be significantly reduced compared with the frequencies of the dimetallocyclopropanone. The complexes presented in Table 3 may be regarded as models of the intermediate states on the path to the isomerisation of the dimetallocyclopropanone to the corresponding dimetalloylide:

The strong electron-donating influence of the ligands linked to the palladium atom may weaken the Pd–Pd bond and increase the distance between the atoms involved. This is equivalent to the isomerisation of the cyclopropanone to an ylide with an opened ring:

2. The reactivity of palladium(+1) carbonyl complexes

The available information about the chemical properties of palladium(+1) carbonyl halides is limited to data concerning their behaviour in relation to water and under thermal decomposition conditions. The reactivity of the carbonyl carboxylate complexes and their derivatives has been investigated much more fully.

a. Ligand substitution reactions in palladium(+1) carbonyl carboxylates

Synthesis of a carbene cluster by the substitution of CO groups

When certain acido-ligands (for example, the acetate groups in complex **38**) are substituted by other carboxylates, new carbonyl carboxylate complexes are formed.

The substitution of neutral carbonyls has been observed in the interaction of complex **38** with diphenyldiazomethane.¹³² The interaction of complex **38** and Ph_2CN_2 , which is capable to generate diphenylcarbene groups *in situ*, results in the displacement of the CO groups and the formation of a new complex (Fig. 8);

Complex **43** contains bridging acetate groups. It has been established by IR spectroscopic studies that $\nu_{\text{as}}(\text{COO}) = 1560 \text{ cm}^{-1}$, $\nu_{\text{s}}(\text{COO}) = 1400 \text{ cm}^{-1}$, and $\Delta\nu = 160 \text{ cm}^{-1}$. The signals due to the protons of the phenyl and acetate groups in the ratio $\text{H}_{\text{Ph}}/\text{H}_{\text{OAc}} = 10/3$, *i.e.* there is one CPh_2 ligand per acetate group, have been observed in the ^1H NMR spectrum. According to EXAFS data, the coordination sphere of each palladium atom in cluster **43** includes two metal atoms at a distance of 2.67 Å, one metal atom at a distance of 3.65 Å, and also two light atoms in each case (in all six) at distances of 1.86, 2.03, and 3.25 Å. These values agree with the structure proposed by Stromnova *et al.*^{132, 133} (Fig. 8).

Figure 8. The structure of the cluster $\text{Pd}_4(\mu\text{-CPh}_2)_4(\mu\text{-OAc})_4$ according to EXAFS data.^{132, 133}

Oxidative substitution of carbonyl ligands

The coordinated carbon monoxide in transition metal carbonyl complexes may be oxidised by an outer-sphere oxidant, for example trimethylamine *N*-oxide:

or by other compounds containing the N–O group.^{73, 134}

In a study of the interaction of complex **38** with organic compounds containing the N–O group, such as nitrobenzene, nitrosobenzene, azoxybenzene, phenylhydroxylamine, and trimethylamine *N*-oxide, it has been established¹³⁵ that only nitrosobenzene and phenylhydroxylamine are capable of oxidising the coordinated carbon monoxide under mild conditions, like trimethylamine *N*-oxide:

The complex $\text{Pd}_2(\mu\text{-Ac})_2(\text{Ph-N-C}_6\text{H}_4\text{-NO})_2$ **44**, containing a new ligand — phenyl-*o*-nitrosophenylamide, is formed in the reaction between complex **38** and nitrosobenzene together with organic products (azoxybenzene, azobenzene, and aniline) of the transformation of the NO-containing compound.¹³⁶

This ligand is obtained by the reaction of a nitrene species (the product of the deoxygenation of nitrosobenzene when the latter is acted upon by the CO group) and a second nitrosobenzene molecule.

Reactions of complex **38** with anionic carbonylmetallates

Presumably, like the substitution of the OAc groups in complex **38** by carboxylate groups, the same groups might be substituted by more complex ones, for example the carbonylmetallates $\text{Co}(\text{CO})_4^-$, $\text{V}(\text{CO})_6^-$, and $\text{CpMo}(\text{CO})_3^-$. Such reactions would make it possible to obtain heteronuclear palladium-containing clusters. Indeed, the reaction of complex **38** with $\text{NaCpMo}(\text{CO})_3$ in tetrahydrofuran entails the formation of the octanuclear cluster $\text{Na}_2\{\text{Pd}_4[\text{CpMo}(\text{CO})_3]_4\} \cdot 2\text{THF}$.^{137, 138}

X-Ray diffraction analysis has shown that the structural unit in the crystals investigated consists of the centrosymmetric anion $\{\text{Pd}_4[\text{CpMo}(\text{CO})_3]_4\}^{2-}$, two sodium cations, and two tetrahydrofuran molecules. The palladium atoms are located at the vertices of a square (the Pd–Pd distances are 2.675–2.691 Å). Each molybdenum atom forms an almost regular triangle with the two palladium atoms (the Pd–Mo distances are 2.723–2.741 Å), and all the metal atoms lie in the same plane. The observed metal–metal distances correspond to single bonds. Three carbonyl ligands are linked to each molybdenum atom and one of the carbonyls is a μ_3 -bridge on the Pd_2Mo face, while the other two are bridges on the Pd–Mo bonds (Fig. 9).

Figure 9. The structure of the anion $\{\text{Pd}_4[\text{CpMo}(\text{CO})_3]_4\}^{2-}$ according to X-ray diffraction data.^{137, 138}

The IR spectrum of the complex contains bands at 2000, 1945, 1900, 1870, and 1830 cm^{-1} referring to the coordinated CO groups.

In the course of the formation of the octanuclear cluster, not only are the acetate ligands substituted by the $\text{CpMo}(\text{CO})_3^-$ anions, but the neutral CO molecules are also displaced. The

vacancies liberated in the coordination sphere of palladium in this process are occupied by the CO molecules coordinated to the molybdenum atom, which are converted into bridging ligands. However, it is significant that the process is not restricted to the substitution of ligands: during the reaction, the Pd(+1) atoms are reduced, apparently as a result of the one-electron oxidation of the $\text{CpMo}(\text{CO})_3^-$ anions. The overall process is described by the equation

The dimer $[\text{CpMo}(\text{CO})_3]_2$ has been found in the reaction products

If it is assumed that the molybdenum atoms incorporated in the complex retain a zero oxidation state, then the observed reaction can be regarded as the reduction of the Pd(+1) atoms to Pd(+0.5). The resulting cluster is the first example of a compound in which eight metal atoms linked by the metal–metal interaction lie in the same plane.

The interaction of the another carbonylmetallate — $[(\eta^5\text{-C}_5\text{H}_4\text{Me})\text{Mn}(\text{CN})(\text{CO})_2]^-$ (in the form of the sodium salt) — and complex **38** leads,¹³⁹ as in the preceding case, to the displacement of all the ligands and the formation of the octanuclear cluster $[(\text{OC})\text{Pd}(\mu\text{-NC})\text{Mn}(\eta^5\text{-C}_5\text{H}_4\text{Me})(\text{CO})_2]_4$ **45**. In contrast to the preceding reaction, in this case the formation of the cluster is not accompanied by any kind of oxidation-reduction reactions and, if it is assumed that the carbonylmanganate ligand retains a formal –1 charge, then the formal oxidation state of palladium in cluster **45** remains +1.

The structure of cluster **45** is unusual. It can be regarded as two mutually orthogonal bent metal chains Mn–Pd₂–Mn with short metal–metal distances. The metal chains are linked to one another by four cyanide bridges.

Furthermore, one terminal carbonyl group is linked to each palladium atom, while the coordination environment of each manganese atom is supplemented by the methylcyclopentadienyl ligand and two carbonyl groups (one terminal and the second behaving as a semibridge in relation to the nearest palladium atom).

b. Reactions of palladium carbonyl acetate with oxygen-containing nucleophiles

In the presence of alkali metal acetates in solution in glacial acetic acid, complex **38** decomposes to metallic palladium in accordance with the equation

Analysis of the kinetic data permits the conclusion that the reaction mechanism involves a repeated alternation of the following cycles: insertion of CO in the Pd–OAc bond, elimination of CO₂ with formation of an acyl fragment, liberation of Ac₂O, and the formation of the Pd–Pd bond. Overall, the process proceeds *via* the reductive condensation of the palladium clusters.^{124, 140}

Presumably the interaction of complex **38** and water described by the equation

also takes place *via* a reductive condensation mechanism.

The reaction of complex **38** with aliphatic C₁–C₃ alcohols proceeds simultaneously *via* several paths with formation of CO₂ and dialkyl carbonate — the products of the oxidation of the coordinated CO molecules, as well as carbonyl compounds arising owing to the oxidation of the corresponding alcohols. It has been observed that the reaction with ethanol results in the appearance of both dialkyl carbonates and carbonyl compounds — acetaldehyde and its acetals. In the case of isopropyl alcohol, dialkyl carbonate and carbonyl compounds are produced. The reaction of cluster **38** with methanol leads to the formation of only methyl acetate. It has been shown^{141, 142} that the reactions of complex **38** with alcohols proceed *via* several paths with formation of carbonyl [L_nM(CO)], alkoxy- (L_nMOR), alkoxycarbonyl (L_nMCOOR), and acyl [L_nMC(O)R] derivatives of palladium.

In the interaction of complex **38** with phenol,¹⁴³ reactions *via* three paths, leading to the formation of phenyl acetate, diphenyl carbonate, and phenyl salicylate (paths A, B, and C), are also observed.

c. Oxidation of the coordinated CO groups in the carbonyl carboxylate complexes

The thermal decomposition of carbonyl complexes leads as a rule to the elimination of carbon monoxide. The thermolysis of the carbonyl carboxylate clusters proceeds *via* a fundamentally different path. It has been observed that the thermolysis of the clusters in the absence of oxygen entails the inner-sphere oxidation of the neutral ligand with formation of CO₂. In the reaction, an oxygen atom is transferred from the carboxylate group to the carbonyl group, *i.e.* the acetate group functions as an oxygen donor (oxidant).^{124, 144, 145}

The oxidation-reduction process which has been put forward, in which carbon monoxide is oxidised by the oxygen of the coordinated carboxylate groups, apparently involves the insertion of CO in the metal–oxygen bond with formation of an unstable intermediate:

The decomposition of the intermediate leads to the elimination of CO₂ and the formation of reduced forms of palladium and coordinated acyl groups:

The recombination of the two acyl ligands bound to the core of the cluster affords the biacyl:

If the thermolysis of the carbonyl carboxylate clusters is carried out in benzene or toluene solution, the main product of the oxidation of the coordinated CO groups is not CO₂ but an arenecarboxylic acid:

Presumably oxidative addition of an arene molecule to the palladium core with dissociation of the H–Ar bond, followed by the insertion of CO₂ in the Pd–C_{aryl} bond, takes place simultaneously with the transfer of an oxygen atom from the carboxylate to CO:

The inner-sphere transfer of an oxygen atom from the carboxylate group to the neutral carbonyl group is a fairly general reaction. Complexes containing as ligands carboxylate groups having both powerful electron-donating substituents at the carboxylate group [the acetate CH₃COO and the pivalate (CH₃)₃COO] and powerful electron-accepting substituents (the trifluoroacetate CF₃COO and the monochloroacetate CH₂ClCOO) are capable of entering into this reaction. The CO₂ produced by the reaction is coordinated to the palladium atoms of the decomposing cluster, exhibits unusual properties, and is capable of being inserted into the C–H bonds of aromatic compounds.

Summarising the data on the synthesis, structures, and reactivities of the carbonylpalladium(+1) complexes, one should note that their number is appreciably smaller than that of the carbonylpalladium(0) complexes.

All the palladium(+1) complexes contain an even number of metal atoms (2 or 4). Since the main structural element of polymeric carbonyl halides is the species [X–Pd(μ-CO)₂Pd–X] and there is no metal–metal bond between such species, it appears legitimate to regard them as dinuclear. Complexes with a higher nuclearity have not been described for Pd(+1). All the palladium(+1) carbonyl complexes are diamagnetic and the pairing of electrons at the two metal atoms, having the *d*⁹ electronic configuration, takes place either as a result of the formation of a metal–metal bond (with a Pd–Pd distance of ~2.7 Å) or *via* the formation of a three-centre four-electron bond incorporating two palladium atoms and one carbon atom of the bridging carbonyl ligand.

In complexes containing only carbonyl and halide, carboxylate, or fluorosulfate ligands, the Pd–Pd distance is close to 2.7 Å and the stretching vibrational frequency of the μ -CO group is in the range from 1900 to 2000 cm^{-1} . Being relatively resistant to thermal decomposition, these complexes are fairly sensitive to the action of oxygen-containing nucleophiles and, when treated with, for example, water or lower aliphatic alcohols, decompose with formation of palladium metal.

The introduction of n -donor ligands into the complexes leads as a rule to an increase in the metal–metal distance in the Pd(μ -CO)Pd fragment and to a decrease in the stretching vibrational frequency of the μ -CO group. The resistance of these complexes to reductive decomposition on treatment with nucleophiles increases simultaneously and some of them, for example, $[\text{Pd}_4(\text{CO})_2\text{Phen}_4](\text{OAc})_4$ or $[\text{Pd}(\mu\text{-dmpm})\text{Cl}]_2(\mu\text{-CO})$, are readily soluble and are stable even in aqueous solutions.

In contrast to palladium(0) carbonyls, the reactivity of palladium(+1) carbonyls is not limited to ligand substitution reactions and has been investigated much more fully. In our view, the oxidation–reduction reactions of carbonyl carboxylate clusters is of greatest interest. In the first place, this is the reaction involving the intramolecular transfer of an oxygen atom from the carboxylate ligands to the coordinated carbonyl group. This reaction can serve as a model for the whole series of oxidation–reduction processes occurring with participation of CO and catalysed by palladium compounds.

V. Palladium(+2) carbonyl complexes

A considerably smaller number of palladium(+2) complexes with carbonyl ligands than palladium carbonyls containing the metal in other oxidation states have been synthesised and reliably characterised at the present time. This can probably be accounted for primarily by the striking tendency of Pd(+2) to be reduced by carbon monoxide and hence by the high lability of Pd(+2) carbonyls in proton-donating basic solvents.

1. Binary carbonyls

The first studies on the chemistry of palladium(+2) carbonyls date back as early as the past century,⁶ but sufficiently definite conclusions concerning the structure of the palladium(+2) carbonyl complexes have been reached on the basis of studies carried out in the last three–five years. In these investigations, the key compounds were characterised by X-ray diffraction. This applies primarily to the binary cationic carbonyls.

A series of cationic carbonyls have been obtained quite recently in strong protic acids (HSO_3F) or superacids ($\text{HSO}_3\text{F}\cdot\text{SbF}_5$).^{146, 147} In the solid state, the carbonyl cations were stabilised by very weakly basic anions SO_3F^- or $\text{Sb}_2\text{F}_{11}^-$. These are singly-charged linear cations $[\text{M}(\text{CO})_n]^+$ [$\text{M} = \text{Au}$ or Ag , $n = 1$ or 2 ;^{148–150} $\text{M} = \text{Hg}$, $n = 1$ (Ref. 151)] or square-planar cations $[\text{M}(\text{CO})_4]^{2+}$ [$\text{M} = \text{Pd}(\mathbf{46})$ or $\text{Pt}(\mathbf{47})$]^{152, 153}.

Complexes **46** and **47** have been obtained as a result of the reductive carbonylation of $[\text{Pd}(\text{SO}_3\text{F})_3]_2$ or $\text{Pt}(\text{SO}_3\text{F})_4$ respectively and the subsequent solvolysis of the resulting neutral complex in liquid antimony(+5) fluoride.

Treatment of the solid salt containing Pd(+2) and Pd(+4) with CO ($P_{\text{CO}} = 0.5$ atm, 25 °C) affords $\text{Pd}(\text{CO})_2(\text{SO}_3\text{F})_2$ in accordance with equation

According to IR spectroscopic data, when the reaction is carried out in the absence of solvent, complex **48** is formed exclusively as the *cis*-isomer. On the other hand, when fluorosulfonic acid HSO_3F is used as the solvent, a mixture of isomers is produced. In liquid antimony fluoride in the presence of free carbon monoxide ($P_{\text{CO}} = 0.5$ atm, 60–80 °C), complex **48** is converted into $[\text{Pd}(\text{CO})_4][\text{Sb}_2\text{F}_{11}]_2$ in accordance with the equation

Complex **47**, the platinum analogue of complex **46**, was obtained in the same manner. Complexes **46** and **47**, isolated in the form of white powders, are thermally fairly stable (they begin to decompose at 155 and 200 °C respectively), but are extremely sensitive to moisture. The stretching vibration frequencies of the CO groups in both complexes are very high (2259 cm^{-1} for complex **46** and 2261 cm^{-1} for complex **47**) and are higher by approximately 120 cm^{-1} than for free carbon monoxide. These data suggest that, as in the neutral and anionic divalent palladium carbonyl halides, in these compounds the σ -donor properties of the CO group greatly predominate over its π -acceptor properties.

Dicarbonylpalladium fluorosulfate **48** (a precursor of complex **46**) has been obtained¹⁵⁴ in the form of a thermally fairly stable yellow substance (decomposition temperature 117 °C). Complex **48** is the first example of a thermally stable compound in which two monodentate carbonyls are coordinated to one Pd(+2) atom. Two other complexes of the type $\text{Pd}(\text{CO})_2\text{R}_2$ ($\text{R} = \text{C}_6\text{F}_5$ or C_6Cl_5),¹⁵⁵ where two terminal carbonyls are coordinated to one palladium atom, are much less stable and already begin to decompose at a temperature below –30 °C. The fluorosulfate group in complex **48**, which has a pronounced electron-withdrawing capacity, probably enhances the electron-accepting properties of the metal atom. The stretching vibrational frequency of the CO group is 2218 cm^{-1} , which is the highest observed for all the known neutral carbonyl complexes of platinum metals.

Complex **48** is the first example of a structurally characterised neutral palladium carbonyl.¹⁵⁶ Crystals of the *cis*-isomer of compound **48**, suitable for X-ray diffraction, have been obtained on slow recrystallisation of the complex from its saturated solution in fluorosulfonic acid. The palladium atom in the molecule of compounds **48** is surrounded by two *cis*-disposed terminal carbonyl groups and monodentate fluorosulfate groups located at the corners of a planar square. The C–O bond is fairly short (1.106 Å), which agrees well with its high frequency ν_{CO} in the IR spectra and with the conclusion that the π -back-donation from the metal to the carbonyl group is absent or at least greatly reduced. A weak interaction of the noncoordinated oxygen atom with the carbon atom of the carbonyl groups has been noted (the C–O distance is 2.819–3.172 Å). In the absence of π -back-donation, secondary contacts, with participation of the electrophilic carbon atom of the CO group as an electron acceptor probably promote somewhat charge compensation and exert a stabilising influence on the entire molecule.

2. Neutral and anionic palladium(+2) carbonyl halides

The synthesis of the three carbonyl derivatives of palladium $\text{PdCl}_2 \cdot (\text{CO})$, $\text{PdCl}_2 \cdot (\text{CO})_2$, and $\text{PdCl}_2 \cdot (\text{CO})_3$ on interaction of solid PdCl_2 with carbon monoxide at 260 °C, described by Fink,⁶ could not be reproduced subsequently. Manchot¹⁵⁷ showed that complexes having this composition are actually formed by the platinum present as an impurity in the initial palladium salt. However, one of these complexes has been obtained from pure palladium chloride. The divalent palladium carbonyl $\text{Pd}(\text{CO})\text{Cl}_2$, which is extremely unstable when acted upon by atmospheric moisture, has been obtained¹⁵⁸ at 20 °C from solid PdCl_2 and carbon monoxide, from which water vapour had been carefully removed and which had been saturated with anhydrous methanol vapour, and also from a suspension of PdCl_2 in anhydrous methanol on treatment with dry carbon monoxide:

A similar complex $\text{Pd}(\text{CO})\text{Br}_2$ has been obtained by the interaction of PdBr_2 and carbon monoxide saturated with methanol vapour and also on treatment of a suspension of K_2PdBr_4 in dioxane containing 0.5%–2.0% of H_2O with carbon monoxide. Palladium(+2) bromide complexes are not carbonylated in anhydrous dioxane.^{96, 158} It has been suggested¹⁵⁸ that the above palladium(+2) carbonyl halides are dimeric and that the anions

$[\text{Pd}(\text{CO})\text{X}_3]^-$ are also present in a solution containing an excess of halide ions. In these anionic complexes, isolated in the form of a salt with the tetrabutylammonium cation,¹⁵⁹ the CO molecule may be bound as a monodentate ligand, like the alkene in a π -complex of the Zeise's salt type.

The complexes listed above (both neutral and anionic) were initially insufficiently fully characterised and the information available about their structure was tentative. However, later the structure of analogues of these compounds was established quite definitely.

Thus the carbonylation of PdCl_2 in thionyl chloride under fairly strong conditions ($P_{\text{CO}} = 50$ atm, 120°C) yielded¹⁶⁰ $\text{Pd}_2(\text{CO})_2\text{Cl}_4$ **49**:

The interaction of $\text{NH}_2\text{Et}_2\text{Cl}$ and compound **49** in solution in CH_2Cl_2 leads to the formation of the anionic complex $\text{NH}_2\text{Et}_2[\text{Pd}(\text{CO})\text{Cl}_3]$ **50**. Complexes **49** and **50** have been characterised by elemental analysis and IR spectroscopy ($\nu = 2167\text{ cm}^{-1}$ for complex **49** and 2141 cm^{-1} for complex **50**).

Complex **49** is stable only in a CO atmosphere, decomposing in the absence of CO. The terminal CO groups are readily substituted by tertiary phosphines, forming initially $\text{Pd}_2(\mu\text{-Cl})_2\text{Cl}_2(\text{PPh}_3)_2$ and then *trans*- $\text{PdCl}_2(\text{PPh}_3)_2$.

It has been suggested that complex **49** is a dimer with two chloride bridges; the two terminal carbonyl ligands are *trans*-disposed relative to the metal-metal axis. This is in fact the structure of the platinum analogue $\text{Pt}_2(\text{CO})_2\text{I}_4$ isolated in a crystalline form and characterised by IR spectroscopy ($\nu_{\text{CO}} = 2122\text{ cm}^{-1}$) and X-ray diffraction data.¹⁶¹ This is a dimer with a nonbonding metal-metal spacing, two bridging iodide ligands, and two *trans*-disposed terminal carbonyl groups.

The complex to which the authors attribute the composition $\text{PdCOCl}_2(\text{PPh}_2\text{-polymer})$ may have a similar structure (but with carbonyl and not halide bridges). The complex has been obtained¹⁶² by carbonylating the corresponding benzonitrile derivative 'attached' to the polymeric support *via* a phosphide bridge. The stretching vibrational bands of the CO group in the range $1944\text{--}1964\text{ cm}^{-1}$ have been found in the IR spectrum of the complex, indicating that these groups are of the bridging type.

On the basis of spectroscopic data for the anion of complex **50**, a structure has been proposed in which the metal atom has a planar environment (three chlorine atoms and one carbon atom of the terminal carbonyl ligand). It has been found that the anion of the salt $(\text{NBu}_4^+)[\text{Pd}(\text{CO})\text{Br}_3]^-$ **51** has precisely this structure. Complex **51** has been obtained by treating a solution of $(\text{NBu}_4^+)(\text{PdBr}_3)$ in tetrachloroethane with CO ($P_{\text{CO}} = 1$ atm).¹⁶³

The carbonylation of PdBr_2 ($P_{\text{CO}} > 70$ atm) leads to the formation of $\text{Pd}_2(\text{CO})_2\text{Br}_4$, which, judging from the IR spectra ($\nu_{\text{CO}} = 2145\text{ cm}^{-1}$), is constructed similarly to complex **49**. The iodide analogue of complex **49** could not be obtained. However, treatment of a solution of PdI_2 in toluene with CO in the presence of stoichiometric amounts of I^- leads to $[\text{Pd}(\text{CO})\text{I}_3]^-$. The latter has been isolated as a salt with (NBu_4^+) and has been characterised by IR spectroscopy ($\nu_{\text{CO}} = 2015\text{ cm}^{-1}$).

According to X-ray diffraction data for complexes **50** and **51**, the palladium atoms in the anions $[\text{Pd}(\text{CO})\text{Cl}_3]^-$ and $[\text{Pd}(\text{CO})\text{Br}_3]^-$ have a square-planar environment with the usual Pd-C_{CO} (1.87 Å for both anions) and C-O (1.10 and 1.11 Å respectively) distance. The stability of the palladium carbonyl halide complexes (both neutral and anionic) decrease in the sequence $\text{Cl} > \text{Br} > \text{I}$.¹⁶³

The study of the kinetics of the exchange of the carbonyls in the carbonyl halides between $[\text{M}^{(13}\text{CO})\text{X}_3]^-$ and ^{12}CO (IR and ^{13}C NMR spectroscopy) showed that the carbonyl ligands in these complexes are bound fairly strongly and that the rate of exchange of the carbonyls is lower almost by six orders of magnitude than the rate of exchange of ethene in the analogous ethene π -complexes.¹⁶⁴

The formation of complex **49** in thionyl chloride has been investigated and the thermodynamic constants of the process have been determined, which made it possible to estimate the energy of the Pd-CO bond ($\sim 24\text{ kcal mol}^{-1}$).¹⁶³ Analysis of the thermodynamic and spectroscopic data led to the conclusion^{155,165} that the contribution of metal-to-ligand the π -back-donation in the palladium carbonyls is slight and that the strength of the Pd-CO bond is determined almost exclusively by the σ -donor capacity of the carbonyl ligand.

This conclusion appears fairly justified for the neutral and anionic palladium(+2) carbonyl halides, but the question of the contribution of the σ -donor and π -acceptor interactions in organopalladium compounds with carbonyl ligands (see below) requires additional discussion.

The contribution of a particular type of bonding of the carbonyl ligands may be inferred from spectroscopic data.²⁹ As a result of the predominance of the σ -donor properties over the π -acceptor properties in the coordinated carbon monoxide molecule, the stretching vibration frequency of the CO group becomes higher than in free CO, while the chemical shift of the carbon atom in the ^{13}C NMR spectra is observed at $\delta = 120\text{--}130$ ppm, in contrast to $190\text{--}220$ ppm for the classical carbonyls.

3. Palladium(+2) carbonyl halides containing additional stabilising ligands

Palladium(+2) carbonyl halide complexes with additional stabilising ligands have been obtained in both neutral and anion forms. For example, the reaction of CO with a suspension of the $[\text{Pd}_2\text{Cl}_2(\text{PET}_3)_4]^{2+}$ fluoroborate in chloroform afforded the cationic complex $[\text{PdCl}(\text{CO})\text{PET}_3][\text{BF}_4]$, which has been characterised by elemental analysis and IR spectroscopy ($\nu_{\text{CO}} = 2140\text{ cm}^{-1}$) and which is comparatively stable under a CO atmosphere. In the absence of CO from the gas phase over the complex a carbon monoxide molecule is evolved and the initial complex is reformed.^{166,167} In this case it is reasonable to postulate that the CO groups are terminal if the palladium atom contains four ligands in the coordination sphere, as in the majority of other palladium(+2) complexes. For the complex anion $[\text{Pd}(\text{CO})(\text{SnCl}_3)\text{Cl}]^-$ isolated¹⁶⁸ as a salt with NEt_4^+ the frequency ν_{CO} is equal 2054 cm^{-1} .

The neutral complexes $\text{Pd}(\text{CO})(\text{L})\text{Cl}_2$, where L = dimethyl sulfoxide, diethyl sulfoxide, or diethyl sulfide, have been obtained^{169,170} by carbonylating $[\text{PdLCl}_2]_2$. The authors attribute a mononuclear structure to these compounds, but on the basis of IR spectroscopic data ($\nu_{\text{CO}} = 1927\text{--}1977\text{ cm}^{-1}$) one may postulate that the complexes are at least dinuclear and contain bridging CO groups.

The complex $\text{Pd}(\text{PhN}=\text{NPh})\text{Cl}_2(\text{CO})$, obtained by the reaction of CO and $\text{Pd}(\text{PhN}=\text{NPh})\text{Cl}_2(\text{PhCN})$,¹⁷¹ should also probably be at least dimeric. The stretching vibrational frequency of the CO group in the complex is 1900 cm^{-1} , which definitely indicates a bridging coordination of the ligand.

Unfortunately, none of the complexes of this type have been characterised by X-ray diffraction analysis.

4. Organopalladium compounds containing carbonyl ligands

The complexes obtained by the reaction of carbon monoxide and dimeric palladium complexes containing oxime ligands may be regarded as an example of palladium(+2) compounds containing both the carbonyl ligand and an organopalladium group with a Pd-C σ -bond.¹⁷²

R = Ph, Me, H.

Table 4. Palladium(+2) carbonyl complexes characterised by X-ray diffraction.

^a For free carbon monoxide, $\nu = 2140 \text{ cm}^{-1}$.

Complexes of type **52** have been isolated in the solid state and characterised by elemental analysis and IR spectroscopy ($\nu_{\text{CO}} = 2108\text{--}2136 \text{ cm}^{-1}$).

The dimeric complexes containing an organopalladium group with a Pd–C σ -bond proved to be convenient precursors for the synthesis of heteronuclear compounds.¹⁷³ Thus the cyclopalladated dimers with the general formula $[\text{Pd}(\text{C}-\text{N})\text{Cl}]_2[\text{C}-\text{N} = \text{dimethylbenzylamine (dmdba), 2-(dimethylamino)-toluene (dmat), or 8-methylquinoline (8-mq)}]$ react with anionic carbonylmetalates M^- ($\text{M}^- = [\text{Co}(\text{CO})_4]^-$, $[\text{Fe}(\text{CO})_3(\text{NO})]^-$, or $[\text{M}(\text{CO})_3\text{Cp}]^-$, where $\text{M} = \text{Cr, Mo, or W}$), the carbonylmetalates substituting one of the bridging chloride ligands and forming thereby the heterometallic complexes $(\text{C}-\text{N})\text{Pd}(\mu\text{-Cl})(\mu\text{-M})\text{Pd}(\text{C}-\text{N})$ **53**. The structures of complexes **53a** ($\text{C}-\text{N} = \text{dmdba}$, $\text{M}^- = [\text{Co}(\text{CO})_4]^-$) and **53b** ($\text{C}-\text{N} = \text{dmdba}$, $\text{M}^- = [\text{Mo}(\text{CO})\text{Cp}]^-$) have been investigated by X-ray diffraction analysis. In both molecules the palladium atoms are at a distance exceeding the sum of the covalent radii (3.442 Å for **53a** and 3.241 Å for **53b**). In complex **53a**, the Co atom is linked to two Pd atoms, two carbonyl groups are bridging in relation to the Pd–Co bonds, and two others are coordinated terminally to the cobalt atom. In complex **53b**, having a similar metal core, among the three carbonyl ligands two are bridges on the Pd–Mo bonds, whilst the third is μ_3 -coordinated to the Pd_2Mo metallotriangle.

Organopalladium carbonyl complexes of another type have been synthesised¹⁷⁴ by ligand substitution on treatment the complexes of the type $\text{Pd}(\text{C}_6\text{F}_5)(\text{ClO}_4)\text{L}_2$, where $\text{L} = \text{Bipy, Phen, tetraethylenediamine, or } 2\text{PR}_3$ with CO ($P = 1 \text{ atm, } 0^\circ\text{C}$, toluene, chloroform, or acetone).

The available information about structures of this type is also limited to the results of elemental analysis, the conductivity of solutions, and IR spectroscopy ($\nu_{\text{CO}} = 2132\text{--}2160 \text{ cm}^{-1}$). There are no structural data for the complexes, but the frequencies, ν_{CO} , in the IR spectra indicate unambiguously the terminal coordination of the carbonyl.

The interaction of $[\text{PPh}_3(\text{CH}_2\text{Ph})]_2\text{Pd}(\text{R})\text{Cl}(\mu\text{-Cl})_2$ and carbon monoxide ($P_{\text{CO}} = 1 \text{ atm, } 20^\circ\text{C}$, CH_2Cl_2) yielded¹⁷⁵ the complexes $[\text{PPh}_3(\text{CH}_2\text{Ph})][\text{Pd}(\text{R})\text{Cl}_2(\text{CO})]$ [$\text{R} = \text{C}_6\text{H}_3(2\text{-Me})(6\text{-NO}_2)$ (**54**) or $\text{C}_6\text{H}_2(\text{NO}_2)_3\text{-2,4,6}$ (**55**)]. These complexes are stable in the solid state, but in solution they eliminate CO, reconvert to the initial state. The IR spectra of both complexes contain characteristic bands of terminal CO groups 2100 cm^{-1} for **54** and 2115 cm^{-1} for **55**). The frequencies ν_{CO} are lower than for the cationic complex $[\text{Pd}(\text{C}_6\text{H}_5)(\text{CO})\text{L}_2]^+$ ($2132\text{--}2163 \text{ cm}^{-1}$)¹⁷⁴ or the neutral complex $[\text{Pd}(\text{C}_6\text{F}_5)_2(\text{CO})_2]$ ($2152\text{--}2186 \text{ cm}^{-1}$),¹⁵⁵ but

higher than the frequencies ν_{CO} for the palladium carbonyl complexes containing the metal in lower oxidation states (for example, for $\text{Pd}(\text{CO})_n$, where $n = 4, 3$ or 2 , $\nu_{\text{CO}} = 2060, 2044$, and 2050 cm^{-1} respectively³³). IR spectroscopic data indicate the occurrence of the 'classical' π -donation in the complexes **54** and **55**.

The structure of complex **54** has been investigated by X-ray diffraction. In the anion, the palladium atom has a planar environment consisting of two *cis*-disposed chlorine atoms, the carbon of the terminal carbonyl group (the Pd–C bond length is $1.853 \text{ \AA}$ and the Pd–C–O angle is 175.4°) and the 2-methyl-6-nitrophenyl ligand. The C–O distance, amounting to $1.145 \text{ \AA}$, has the usual value for terminal carbonyl groups.

Summarising the data presented on the structure of palladium(+2) carbonyl complexes, one should note that all the reliably characterised homonuclear complexes (Table 4) are monomers with terminal CO groups. In complexes containing halide and alkyl ligands (No. 2–No. 5, Table 4) apart from the terminal carbonyl, the strength of the Pd–C_{CO} bond is low, which is the reason for the low thermal stability of the carbonyls. The presence of the fluorosulfate group, which possesses strong electron-withdrawing properties, in the complex $\text{Pd}(\text{CO})_2(\text{SO}_3\text{F})_2$ (No. 1, Table 4) leads to an increase in the electron-accepting capacity of the palladium atom. The consequence of such increase is, on the one hand, the strengthening of the Pd–C_{CO} bond, expressed by an unusually high thermal stability of palladium complexes with a terminal carbonyl group, and, on the other hand, extremely high stretching vibrational frequencies of the CO group.

In the Pd(+2) complexes where the metal atom has the d^8 electronic configuration and a much smaller ability to donate the metal π electrons to the corresponding orbitals of the CO molecule than in the palladium(0) and palladium(+1) complexes, an enhancement of the σ -donor properties of the carbonyl has been observed. The enhancement of the σ -donor and the weakening of the π -acceptor properties of the carbonyl ligand are accompanied by an increase in the stretching vibration frequencies of the CO group (Table 4).

VI. Palladium carbonyl complexes containing the metal in fractional oxidation state

The appearance of unusual or 'intermediate', including fractional, oxidation states of transition metals is associated with the development of the chemistry of polynuclear compounds, especially the chemistry of clusters.

1. The synthesis and structure of clusters containing a metal in a fractional formal oxidation state

π -Allylbis(carbonylchloropalladium) having the composition $\pi\text{-C}_3\text{H}_5[\text{PdCl}(\text{CO})]_2$ **56**, described as early as 1964, should probably be regarded as the first palladium carbonyl in which the formal oxidation state of the metal atom proved to be nonintegral.¹⁷⁶ The authors proposed a composition for the complex where there are three singly-charged acido-ligands for two palladium atoms; the FOS of the metal in the complex is +1.5. The complex was obtained by passing carbon monoxide through a solution of a mixture of PdCl_2 and HCl in methanol in which π -allylpalladium chloride had been suspended. The IR spectrum of the resulting bright-yellow precipitate, which did not dissolve in the usual organic solvents, contained an intense band at 1940 cm^{-1} , which the authors attributed to the stretching vibrations of the terminal CO group. The absence of bands in the range $286\text{--}360\text{ cm}^{-1}$, characteristic of the vibrations of the Pd–Cl bond, led to the conclusion that the chloride ligands were involved in bridging coordination. The following structure of **56** was proposed:

However, the structure of complex **56** is somewhat more complicated. On the basis of current data concerning the structure of palladium carbonyls, one may postulate that the carbonyl groups in this compound are bridges, like the chloride ligands. The bridging coordination of the allyl ligands cannot be ruled out either.

Similar complexes with the composition $\pi\text{-C}_3\text{H}_5[\text{PdX}]_2(\text{CO})$ **57**, where $\text{X} = \text{Cl}$ or Br , have been obtained by passing carbon monoxide through a methanol solution of π -allylpalladium chloride.⁸⁹ The authors suggest that the compounds formed are tetramers, in which bridging halide and semibridging carbonyl groups alternate:

$\nu_{\text{CO}} = 1937\text{ cm}^{-1}$ (for $\text{X} = \text{Cl}$), $\nu_{\text{CO}} = 1929\text{ cm}^{-1}$ (for $\text{X} = \text{Br}$).

The presence of three singly-charged acido-ligands in the molecule containing two metal atoms makes it possible to assign a formal oxidation state of +1.5 to palladium. Unfortunately, in both cases the substances were characterised only by elemental analysis and IR spectroscopy, so that the interpretation of their structure does not appear sufficiently reliable. However, the presence in these compounds of bridging carbonyl groups is undoubtedly reliable. Furthermore, the data on the magnetic properties of complexes **56** and **57** might prove useful in the interpretation of their structure. Thus if the proposed formulae are correct, it follows that complex **56** should be paramagnetic and complex **57** diamagnetic.

The trinuclear carbonyl clusters synthesised later were more fully and reliably characterised. Thus the interaction of LiPBu_2^t and the polymeric carbonyl chloride $[\text{Pd}(\text{CO})\text{Cl}]_n$ in THF at -78°C afforded (together with other products) the cluster $\text{Pd}_3(\mu\text{-PBu}_2^t)_3(\text{CO})_2\text{Cl}$ **58**, in which the metal has a formal oxidation state of +1.33.¹⁷⁷

According to X-ray diffraction data, the palladium atoms in complex **58** form a triangle with Pd–Pd distances ranging from 2.949 to 3.000 Å which indicates a weak metal–metal interaction. All the phosphide groups are bridges along the Pd–Pd bonds, while one chloride and two carbonyl ligands are terminal. The relatively low stretching vibrational frequencies of the terminal CO groups (two bands in the IR spectrum at 2035 and 2030 cm^{-1}) compared with the ν_{CO} in the mononuclear complexes (usually above 2100 cm^{-1}) are due to the presence of phosphide species with their high electron content.

Another type of carbonyl trinuclear clusters represented by the dication $[\text{Pd}_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ **59**, was described for the first at time by Manojlovic-Muir *et al.*¹⁷⁸ and Puddephatt¹⁷⁹ and was characterised in detail by Lloyd and Puddephatt¹⁸⁰. Cluster **59** has been obtained by the reaction of $\text{Pd}(\text{OAc})_2$ and dppm with carbon monoxide ($P_{\text{CO}} = 1\text{ atm}$) in solution in aqueous acetone containing an excess of trifluoroacetic acid and was isolated as a salt with CF_3COO^- **59a**. The interaction of complex **59a** with an excess of $\text{NH}_4(\text{PF}_6)$ leads to the formation of $[\text{Pd}_3(\mu_3\text{-CO})(\mu\text{-dppm})_3](\text{PF}_6)_2$ **59b**. Complex **59** has been characterised by IR spectroscopy ($\nu_{\text{CO}} = 1820\text{ cm}^{-1}$) and X-ray diffraction. The palladium atoms in the cation form a triangle (the Pd–Pd sides are 2.576, 2.607, and 2.610 Å, to the sides of which diphosphine bridges are coordinated symmetrically, while the carbonyl group is linked to all three metal atoms (the Pd–C distance ranges from 2.09 to 2.18 Å).

In the clusters of type **59** containing only neutral ligands, there are two positive charges on three metal atoms and hence the FOS of each palladium atom is +0.67.

The interaction of halides or of the trifluoroacetate anion with the dication **59** is reversible, without change in the FOS of the metal atoms, and leads to the formation of $[\text{Pd}_3(\text{X})(\mu_3\text{-CO})(\mu\text{-dppm})_3]^+$ ($\text{X} = \text{CF}_3\text{COO}, \text{Cl}, \text{Br}, \text{I}$) **60**. It has been established that the capacity for coordination diminishes in the sequence $\text{I} > \text{Br} > \text{Cl} > \text{CF}_3\text{COO}$ and that each successive ligand can be quantitatively substituted by the preceding one.^{181, 182}

Clusters **60** have been isolated in the form of a salt with CF_3COO^- and have been characterised by X-ray diffraction analysis for $\text{X} = \text{I}$ ¹⁸⁰ and Cl .¹⁸¹ In both cases, the anionic ligand X is μ_3 -coordinated to the side of the Pd_3 triangle opposite the side to which the $\mu_3\text{-CO}$ group is coordinated.

It is noteworthy that the Pd–X distances in the $\text{Pd}_3(\mu_3\text{-X})$ groups are fairly large (the Pd–X distance is 2.741–3.161 Å for $\text{X} = \text{Cl}$ and 2.951–3.083 Å for $\text{X} = \text{I}$) and an unambiguous conclusion concerning the incorporation of X in the coordination sphere of the cluster cannot be reached on the basis of X-ray diffraction data. However, the results of studies of the molar conductance of solutions of the clusters and of their spectra in the

Table 5. Palladium complexes containing the metal in fractional oxidation states.

visible region on titration of the cluster solution with a solution of KX ($\text{X} = \text{Cl}, \text{Br}, \text{I}$) showed that the anionic ligand is incorporated into the coordination sphere of the palladium cluster and that the contribution of the covalent component to the formation of the $\text{Pd}-\text{X}$ bond greatly exceeds that of the ionic component.

The mechanism of the formation of clusters **59** and **60** has been investigated¹⁸² by ^{31}P NMR. The NMR monitoring of the reaction solution containing initially $\text{Pd}(\text{OAc})_2$, dppm , and CO in an acetone– $\text{CF}_3\text{COOH}-\text{H}_2\text{O}$ mixture made it possible to identify the formation of the complexes $\text{Pd}(\text{CF}_3\text{COO})_2(\text{dppm})$ **61**, $\text{Pd}_2(\text{CF}_3\text{COO})_2(\mu\text{-dppm})_2$ **62**, $\text{Pd}_2(\text{CF}_3\text{COO})_2(\mu\text{-CO})(\mu\text{-dppm})_2$ **63**, and $[\text{Pd}_3(\mu\text{-CF}_3\text{COO})(\mu_3\text{-CO})(\mu\text{-dppm})_3](\text{CF}_3\text{COO})$ **64**. There are grounds for the postulate that a short-lived palladium(0) complex with diphosphine is formed initially and then reacts with complex **61** to form compound **62** or **63**. The subsequent reaction of the palladium(0) complex containing bis(diphenylphosphino)methane with compound **62** or **63** leads to the appearance of $[\text{Pd}_3(\mu_3\text{-X})(\mu_3\text{-CO})(\mu\text{-dppm})_3]^+$ ($\text{X} = \text{CF}_3\text{COO}$) **60**. It can be assumed arbitrarily that the two palladium atoms in the base of the triangle, linked by a shortened $\text{Pd}-\text{Pd}$ bond (2.567 Å), have a FOS of +1. The third metal atom at the apex of the triangle than has a zero FOS. Incidentally, such treatment should be regarded as a marked simplification, which is used only for a clear representation of a more complex situation. The bridging halide ligand in the inner coordination sphere of complex **60** is readily substituted by another halide when the complex interacts with KX in acetone.

Palladium carbonyl complexes with a nonintegral FOS of the metal are few in number, are not distinguished by a structural diversity, and are represented (among reliably characterised complexes) only by clusters with a triangular metal core (Table 5). Whereas, the $\text{Pd}-\text{Pd}$ distances are fairly short (2.58–2.61 Å) in clusters **59** and **60**, where each metal atom has a FOS of +0.67, and indicate the occurrence of a direct metal–metal interaction, in cluster **58** (the FOS of the metal is +1.33) such interaction is weaker, which is reflected in the length of the metal–metal bonds (2.95–3.00 Å).

Certain heteronuclear complexes should apparently be assigned to compounds in which the metal atom has a nonintegral FOS. Thus in the octanuclear complex $\text{Na}_2[\text{Pd}_4\{\text{Cp-Mo}(\text{CO})_3\}_4]$,¹³⁸ there are two positive charges on the four palladium atoms (the palladium atoms form a square with 2.675–2.691 Å sides), *i.e.* the FOS is +0.5.

Another example is provided by the anionic cluster $[\text{Pd}_6\text{Ru}_6(\text{CO})_{24}]^{2-}$ **64** obtained¹⁸³ by the interaction of $[\text{Ru}_3\text{H}(\text{CO})_{11}]^-$ and $\text{Pd}(\text{PhCN})_2\text{Cl}_2$. The palladium atoms in the cluster form an octahedron, the ruthenium atoms serve as ‘caps’ on the faces of the octahedron, while the carbonyl ligands are involved in terminal (12 molecules) and bridging (six molecules are μ -coordinated and six are μ_3 -coordinated) coordination. If it is

assumed by analogy with the preceding cluster that the ‘capping’ ruthenium atoms represent together with the carbonyl ligands anionic carbonylmetallates, then a formal charge somewhat exceeding +1 should be attributed to the palladium atoms forming the inner octahedron, but in principle such a procedure does not appear sufficiently legitimate.

The picture becomes even more complex with increase in the number of atoms in the cluster. Thus the interaction of $\text{Pd}(\text{PPh}_3)_2\text{Cl}_2$ and $[\text{Ni}_6(\text{CO})_{12}]^-$ afforded¹⁸⁴ the anionic cluster $(\text{Pd}_{33}\text{Ni}_9(\text{CO})_4(\text{PPh}_3)_6)^{4-}$ isolated in the form of a salt with $[\text{PPh}_4]^+$ and characterised by X-ray diffraction (Fig. 10).

Figure 10. The structure of the metallopolyhedron of the heterometallic cluster anion $(\text{Pd}_{33}\text{Ni}_9(\text{CO})_4(\text{PPh}_3)_6)^{4-}$ according to X-ray diffraction data.¹⁸⁴

The metal atoms in the cluster form five triangular layers and the vertices of the upper, lowest, and middle triangles are occupied by nickel atoms. The carbonyl ligands (not shown in Fig. 10) consist of five terminal and 36 bridging groups the terminal carbonyl being linked to the three nickel atoms of the middle layer and the central palladium atoms of the upper and lowest layers.

2. The reactivity of clusters containing the metal in a fractional formal oxidation state

The reactivity of the clusters under discussion is characterised by two distinctive features: the coordinative unsaturation of the clusters (and hence their ability to coordinate additional ligands) and the ability of clusters containing metal atoms in the lowest oxidation states to enter into oxidative addition reactions.

Such features are most characteristic of the type **59** clusters $[\text{M}_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$, the reactivity of which has been characterised in fair detail.

a. Coordination of additional ligands

It has been shown that cluster **59** ($M = \text{Pd}$ or Pt) is capable of coordinating two- and four-electron donor ligands and the newly introduced ligands can be both terminal and bridging on the M_3 triangle, or on the sides of this triangle, and their coordination has an appreciable influence on the coordination of the carbonyl ligand.

Since cluster **59** and the products of its interaction with various reagents are much more stable in the case where $M = \text{Pt}$ than for $M = \text{Pd}$, the authors were as a rule able to characterise fairly reliably the platinum-containing products, the analogous properties and structures being merely attributed to the palladium complexes.

Thus it has been shown in relation to the platinum complex by NMR involving different nuclei¹⁸⁵ that complex **59** can combine with a second CO molecule with formation of two isomers; the first with terminal and μ_3 -coordinated carbonyls and the second with two μ_3 -coordinated carbonyl ligands:

Phosphines and phosphites (L) are coordinated as monodentate species in reactions with complex **59**, forming $[\text{Pt}_3(\mu_3\text{-CO})(L)(\mu\text{-dppm})_3]^{2+}$. The coordination of the carbonyl group and of the diphosphines does not then change.^{186, 187}

Treatment of cluster **59** ($M = \text{Pd}$ or Pt) with the cyanide ion in acetone solution at -78°C and subsequent heating of the solution to room temperature lead to the formation¹⁸⁸ of the adduct $[\text{M}_3(\text{CN})(\mu_3\text{-CO})(\mu\text{-dppm})_3]^+$. According to X-ray diffraction data for $M = \text{Pt}$, the cyanide ligand in such an adduct is linked to one of the platinum atoms in such a way that the $\text{Pt}-\text{C}-\text{N}$ line is virtually perpendicular to the plane of the Pt_3 triangle.

The study of the behaviour of this adduct by ^{31}P NMR in solution at -90°C showed that the central ligand migrates rapidly around the Pt_3 triangle. This migration is not accompanied by the dissociation of the carbonyl or cyanide ligand and involves in all probability an intermediate with a μ_3 -coordinated cyanide ion.

On interaction of cluster **59** ($M = \text{Pt}$) with isocyanides RNC ,¹⁸⁹ initially one isocyanide molecule is coordinated and then a second one is attached to the same metal atom. On coordination of a second isocyanide molecule, a CO molecule is displaced and the cluster $[\text{Pt}_3(\text{RNC})_2(\mu\text{-dppm})_3]^{2+}$ is formed.

If the isocyanide molecule contains a bulky group, its reaction with complex **59** proceeds in a somewhat different manner.¹⁹⁰ Thus, the interaction of complex **59** ($M = \text{Pd}$) with $\text{XyN}=\text{C}$ ($\text{Xy} = 2,6\text{-C}_6\text{H}_3\text{Me}_2$) results in the formation of $[\text{Pd}_3(\text{XyNC})(\mu\text{-dppm})_3]^{2+}$ **64**, in which the μ_3 - η^2 -isocyanide ligand is coordinated

(according to X-ray diffraction data) over the Pd_3 plane. Cluster **64**, containing 42 valence electrons, combines reversibly with a second isocyanide molecule, forming the 44-electron cluster $[\text{Pd}_3(\mu_3\text{-CNXy})_2(\mu\text{-dppm})_3]^{2+}$. The reaction of complex **59** ($M = \text{Pd}$) with 0.5 mole of $1,4\text{-C}=\text{NC}_6\text{Me}_4\text{N}=\text{C}$ also leads to the substitution of CO. The cationic cluster $\{\text{Pd}_3(\mu\text{-dppm})_3\}_2(\text{CNC}_6\text{Me}_4\text{NC})\}^{4+}$ **65** is then formed. It was isolated in the; form of a salt with PF_6^- or CF_3COO^- . X-Ray diffraction analysis showed that the diisocyanide ligands in complex **65** serve as bridges between the $\text{Pd}_3(\mu\text{-dppm})_3$ species.

By analogy with the isocyanides, the anion SnX_3^- ($X = \text{F}$ or Cl) initially forms the 1:1 adduct $[\text{Pt}_3(\mu_3\text{-CO})(\mu_3\text{-SnX}_3)(\mu\text{-dppm})_3]^+$ in the reaction with complex **59** ($M = \text{Pt}$) and then combines with a second equivalent of SnX_3^- . This leads to the displacement of CO and the formation of $[\text{Pt}_3(\mu_3\text{-SnX}_3)(\mu\text{-dppm})_3]$.^{53, 191}

It has been shown by the NMR method¹⁹² that the interaction of complex **59** and NaBH_4 entails the initial formation of the fragment $[\text{Pt}_3(\mu_3\text{-CO})(\mu_3\text{-H})(\mu\text{-dppm})_3]^+$, which affords $[\text{Pt}_3(\mu_3\text{-H})(\mu\text{-dppm})_3]^+$ after eliminating CO.

The reaction of complex **59** with halide ligands proceeds similarly to the reaction with hydrides but terminates at the first stage. Complex **59** combines with a halide ligand to form $[\text{M}_3(\mu_3\text{-CO})\text{X}(\mu\text{-dppm})_3]^+$. In the case where $M = \text{Pd}$, it has been established by X-ray diffraction study that the halide μ_3 -coordinated to the second side of the Pd_3 triangle is built into the $\text{Pd}_3(\mu_3\text{-CO})(\mu_3\text{-X})$ bipyramid.^{180, 181}

The pseudohalide SCN^- also forms 1:1 adducts, but it has been established by X-ray diffraction that in $[\text{Pt}_3(\mu_3\text{-CO})(\text{SCN})(\mu\text{-dppm})_3]^+$ the thiocyanate ion assumes the role of a terminal ligand coordinated to one metal atom.¹⁹³ Complex **59** does not react directly with diphosphine ligands (even in the presence of their large excess). Other bidentate ligands, such as R_2NCS_2^- and R_3PCS_2^- , form¹⁹⁴ the complexes $[\text{Pt}_3(\mu\text{-CO})(\mu\text{-dppm})_3(\mu\text{-S}_2\text{CNR}_2)]$ or $[\text{Pt}_3(\mu\text{-CO})(\mu\text{-dppm})_3(\mu\text{-S}_2\text{CBr}_3)]^{2+}$.

Thus complex **59** can combine with one- or two-electron ligands or a bidentate four-electron ligand with formation of 44- and 46-electron clusters. On addition of weakly coordinated halide or trifluoroacetate, the number of valence electrons of the cluster may reach 48. In the cluster, the M_3P species is planar and the $M-M$ bond lengths vary within a very narrow range. Additional ligands may bind to complex **59** via the unoccupied P_z orbitals of the metal and not the unoccupied σ^* orbitals of the metal-metal bond of the cluster. This conclusion has been confirmed by a theoretical analysis.^{195, 196} The additional ligands can interact with one, two, or three metal centres, the first case being most frequently encountered. The degree of displacement of the carbonyl group from the symmetrical μ -coordination (expressed by a change in the $M-C$ bond lengths) reflects the donor properties of the additional ligand. It increases in the sequence $\mu_3\text{-I} < \mu_3\text{-}\eta^2\text{-CF}_3\text{COO}^- < \text{SCN}^- < \text{P}(\text{OPh})_3$.

b. Oxidative addition reaction

In the cluster $[\text{M}_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ or $[\text{M}_3(\mu_3\text{-H})(\mu\text{-dppm})_3]^+$, the formal +2 charge is distributed among three metal atoms, which corresponds to a FOS of +2/3. After the removal of a further two electrons from these complexes the formal 4+ charge is distributed among three palladium atoms, which corresponds to a FOS of +4/3. In the oxidised complexes, one of the sides of the metal triangle increases to a size exceeding the sum of the covalent radii of palladium and precluding direct metal-metal interaction. In this case, one may assume that the complexes contain the $(\text{M}_2)^{2+}\text{M}^{2+}$ species, where M^{2+} is linked to the $(\text{M}_2)^{2+}$ cations only via two $\mu\text{-dppm}$ groups and the outer μ_3 -ligand introduced during the oxidation process.

The oxidative addition reactions have been examined in relation to platinum compounds.¹⁹⁷⁻¹⁹⁹ The complex $[\text{Pt}_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ reacts with H_2E or REH ($\text{E} = \text{S}$ or Se , $\text{R} = \text{Et}$ or Ph) with the elimination of the CO molecule and the formation of $[\text{Pt}_3\text{H}(\mu_3\text{-ER})(\mu\text{-dppm})_3]^{2+}$ or $[\text{Pt}_3\text{H}(\mu_3\text{-E})(\mu\text{-dppm})_3]^+$. The

palladium cluster reacts similarly, but the Pd–H bond is more labile and the complexes formed could not be isolated in a crystalline form. The reactions described above are of interest as model processes involving the poisoning of platinum or palladium catalysts by hydrogen sulfide.

The complex $[\text{M}_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ reacts with SCN^- to form $[\text{M}_3(\mu_3\text{-CO})(\text{SCN})(\mu\text{-dppm})_3]^+$ which undergoes a thermal or photochemical rearrangement¹⁹³ with dissociation of the S–C bond and the formation of $[\text{M}_3(\text{CN})(\mu_3\text{-S})(\mu\text{-dppm})_3]^+$. The mechanism of this reaction has been investigated²⁰⁰ and it has been established that the principal characteristic features of the process extend also to the interaction of complex **59** and the heterocumulenes $\text{S}=\text{C}=\text{E}$ ($\text{E} = \text{N}^-, \text{O}, \text{S}, \text{or NR}$). In all cases, the reaction proceeds with formation of the adduct $[\text{M}_3(\text{S}=\text{C}=\text{E})(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$, which is followed by the oxidative addition of the heterocumulene to the C=S bond, the elimination of CO, and the appearance of $[\text{M}_3(\mu_3\text{-S})(\text{C}=\text{E})(\text{dppm})_3]^{2+}$.

VII. Palladium carbonyl hydride complexes

The palladium complexes containing simultaneously both carbonyl and hydride ligands are of great interest primarily as possible intermediates (or models of intermediates) in catalytic reactions occurring with participation of carbon monoxide and hydrogen. This is a wide range of processes including the industrially important alkene hydroformylation, alkoxy carbonylation, *etc.* reactions. The carbonyl hydride complexes are believed to be intermediates in the key stages of the processes, but the evidence for the formation of such complexes is extremely scanty or completely absent.^{201–203} There are few reliably characterised palladium carbonyl hydride complexes.²⁰⁴

The first communication about the synthesis of a carbonyl hydride complex appeared as early as 1969.²⁰⁵ A solution of palladium chloride in 2-methoxyethanol was treated with carbon monoxide until the formation of a yellow solution. A brown diamagnetic complex was precipitated on treatment with AsPh_4Cl . The sparing solubility of this complex precluded the study of its ^1H NMR spectra. On the basis of the results of elemental analysis, conductimetric measurements (the compound behaved as a 1 : 1 electrolyte in solution in dimethylformamide), and IR spectroscopic data (the weak band at 1960 cm^{-1} was assigned to the stretching vibrations of the M–H bond, while the intense band at 1900 cm^{-1} was assigned to the stretching vibrations of the terminal CO group), the authors postulated that the compound is the carbonyl hydride $[\text{AsPh}_4][\text{Pd}(\text{CO})(\text{H})\text{Cl}_2]$. In the light of later data on palladium carbonyl and hydride complexes, taking into account the new interpretation of the IR spectra of these compounds (both bands in the IR spectra should be more correctly assigned to the stretching vibrations of bridging groups), this hypothesis appears insufficiently well founded. The complex probably has a more complicated dinuclear structure, particularly since mononuclear compounds are absent among the palladium carbonyl halides described later.

On protonation of $\text{Pd}(\text{PPh}_3)_4$ with aqueous trifluoroacetic acid at 25°C or on reduction of $(\text{PPh}_3)_2\text{Pd}(\text{CF}_3\text{COO})_2$ with hydrogen in solution in aqueous CF_3COOH at 70°C , the complex $[(\text{PPh}_3)_3\text{PdH}]^+$ is formed *in situ*, carbonylation of the complex afforded^{206–208} the carbonyl hydride $[(\text{PPh}_3)_4\text{Pd}_2(\mu\text{-H})(\mu\text{-CO})](\text{CF}_3\text{COO})$ in accordance with the equation

66

$\text{X} = \text{CF}_3\text{COO}.$

Complex **66** has not been isolated in the solid state but it has been fairly completely characterised by NMR data, which agree well with those for platinum analogues.^{209, 210}

The protonation of $\text{Pd}(\text{PPh}_3)_4$ in toluene under a CO atmosphere or of $(\text{PPh}_3)_3\text{Pd}(\text{CO})$ in toluene on treatment with the sulfonic acid $\text{H}_2\text{C}(\text{SO}_2\text{CF}_3)_2$ also leads to the formation of

complex **66** [$\text{X} = \text{HC}(\text{SO}_2\text{CF}_3)_2$], which has been isolated in the solid state and characterised by elemental analysis and IR spectroscopy ($\nu_{\text{CO}} = 1851\text{ cm}^{-1}$), while the complex in solution in CD_2Cl_2 has been characterised by NMR spectroscopy involving different nuclei.²¹¹

Complex **66** ($\text{X} = \text{BPh}_4$) has been obtained^{212, 213} in a study of the nature of the compounds responsible for the catalysis of the reduction of nitro-compounds by carbon monoxide in the $\text{Pd}(\text{OAc})_2/\text{PPh}_3/\text{CO}/\text{PhNO}_2/\text{Bu}^n\text{OH}/\text{H}_2\text{SO}_4$ system.

The only palladium carbonyl hydride the structure of which has been investigated by X-ray diffraction has been synthesised^{214, 215} by a fairly unusual method — the interaction of the organopalladium compound $\text{Pd}(\text{dipp})\text{Ph}(\text{Cl})$, where $\text{dipp} = 1,3\text{-bis}(\text{diisopropylphosphino})\text{propane}$, and methanol in the presence of an excess of triethylamine at 60°C in accordance with the equation

Experiments using CH_3OD showed that methanol is in fact the source of hydride ions in the synthesis of complex **67**. The carbonyl groups also arise as a result of the decarbonylation of methanol. The ^1H NMR spectrum of complex **67** contains a signal at $\delta = -5.17\text{ ppm}$ (quintet, $^2J_{\text{P-H}} = 41.1\text{ Hz}$); the IR spectrum contains an intense band at 1789 cm^{-1} , which does not change when the hydride is replaced by deuterium and which has been assigned to the stretching vibrations of the CO group. The relatively low stretching vibrational frequency of the carbonyl group reflects the presence of an increased electron density on the metal atom, arising as a consequence of the high donor capacity of the chelating phosphines.

According to X-ray diffraction data, the two palladium atoms in complex **67** are at a distance of $2.767\text{ \AA}$, indicating a metal–metal single bond.

The hydride ligand is localised and the Pd–H distance is $1.53\text{ \AA}$, which is within the range of distances determined for the structurally characterised palladium hydrides.^{216–218}

A complex analogous to complex **67** has also been obtained by decarbonylating methanol.²¹⁹ On heating to 80°C a solution of the acetyl complex $\text{Pd}(\text{COMe})(\text{Cl})\{(\text{S,S})\text{-bdpp}\}$, where $(\text{S,S})\text{-bdpp} = (2\text{S},4\text{S})\text{-2,4-bis}(\text{diphenylphosphino})\text{pentane}$, in a methanol–toluene- d_8 mixture in an inert gas atmosphere, an equimolar mixture of $(\text{bdpp})\text{PdCl}_2$ and $[\text{Pd}_2(\mu\text{-H})(\mu\text{-CO})(\text{bdpp})_2]^+\text{Cl}^-$ is formed.

The interconversions of the polynuclear palladium hydride and carbonyl hydride complexes have been described.^{2, 220–226} The reduction of $\text{Pd}(\text{OAc})_2$ by molecular hydrogen in glacial acetic acid in the presence of L ($\text{L} = \text{Phen}$ or Bipy) leads to the formation of X-ray-amorphous substances with the approximate composition $[\text{Pd}_4\text{L}(\text{OAc})_2\text{H}_4]_n$, where $n \sim 100$. The reaction of polynuclear hydrides with carbon monoxide leads to the carbonyl hydride clusters $[\text{Pd}_4\text{L}_3(\text{CO})_3(\text{H})_2(\text{OAc})_3]_n$ ($n = 2, 3$). The interaction of CO with a 1 : 1 solution of $\text{Pd}(\text{OAc})_2$ and Phen in acetic acid at 20°C leads to the formation of the complex $[\text{PhenPd}(\text{-CO})(\text{OAc})]_n$, which does not contain hydrides.

If the temperature of the reaction mixture is raised to 50°C , a polymeric carbonyl hydride having the general formula $[(\text{Phen})_2\text{Pd}_2(\text{CO})(\text{H})(\text{OAc})\cdot\text{AcOH}]_n$ is formed; the signal of its hydride hydrogen atoms in the ^1H NMR spectrum is $\delta = -15.5\text{ ppm}$. Finally, the interaction of $\text{Pd}(\text{OAc})_2$ and Phen

in acetic acid under a mixed H_2/CO atmosphere affords the carbonyl hydride $[(\text{Phen})_3\text{Pd}_4(\text{CO})_3\text{H}_3(\text{OAc})_2 \cdot \text{AcOH}]$.

All the carbonyl hydrides have been characterised by elemental analysis and IR, ^1H NMR, and EXAFS spectroscopy. On the basis of the data obtained from these compounds, a structure has been proposed. It is based on tetrahedral palladium fragments with chelating phenanthroline ligands and bridging CO groups, which are linked to one another by bridging hydrides.

Thus the palladium carbonyl hydride complexes described are represented either by dinuclear singly charged cations with bridging carbonyl and hydride ligands or by polynuclear compounds also containing bridging carbonyls and hydrides. In all cases, the FOS of the palladium atoms has an intermediate value between 0 and +2.

VIII. Palladium carbonyl complexes in zeolites

In the early studies devoted to the adsorption of carbon monoxide on palladium(0) deposited on oxide carriers,^{227, 228} it was established that two types of adsorption exist: weak reversible and strong irreversible adsorption. In the former case, the carbon monoxide molecules are involved in terminal coordination according to IR spectroscopic data ($\nu_{\text{CO}} = 2085 \text{ cm}^{-1}$), while in the latter bridging CO groups predominate ($\nu_{\text{CO}} = 1960 \text{ cm}^{-1}$).

The authors of later studies^{229–236} obtained additional data on the structures of palladium carbonyls in the cavities of the NaY and 5A zeolites by employing modern physical research methods (Fourier transform IR spectroscopy, atomic radial distribution methods, and EXAFS), as well as data obtained for the structurally characterised palladium(0) carbonyls. Thus comparative analysis of the IR spectra of compounds of palladium and carbon monoxide, located in the cavities of the NaY zeolites, and data on the molecular clusters of ruthenium and iridium carbonyls in zeolites led to the conclusion that the principal form of the palladium carbonyl consists of the clusters $\text{Pd}_{13}(\text{CO})_x$ containing both bridging and terminal CO groups.²³⁷ The size of the cluster is determined by the size of the zeolite cavity and is almost independent of either the initial form of palladium or of the cluster formation conditions.²³⁰

Subsequent studies by the EXAFS method confirmed the hypothesis that the Pd_{13} clusters predominate. These can have a metal core in the form of both a cubooctahedron and an icosahedron.²³¹ In the initial stage of the formation of the compound on treatment of palladium immobilised on the surface of the zeolite with carbon monoxide at room temperature, the formation of the Pd_6 cluster was observed. The subsequent migration of such clusters and species with a smaller nuclearity into the zeolite cavity leads to Pd_{13} . On raising the temperature to $\sim 200^\circ\text{C}$, there is a possibility of the growth of the metal core right up to Pd_{40} . However, all the conclusions concerning the nuclearity of clusters in the zeolite and their composition and nature are tentative.

It is believed that, under the conditions where the $\text{Pd}_{13}(\text{CO})_x$ clusters are formed on the NaY zeolites, clusters having the composition $\text{Pd}_6(\text{CO})_x$ predominate on the surface of the 5A zeolite. The presence of mainly terminal and μ_3 -bound CO groups is characteristic of $\text{Pd}_6(\text{CO})_x$.²³²

The ability of various zeolites to form palladium carbonyls with different nuclearities has been used in the preparation of catalysts altering the selectivity in various processes. Thus the hydrogenation of CO on Pd/5A leads to methanol and dimethyl ether, whereas the employment of Pt/NaY leads mainly to the formation of C_2 hydrocarbons.²³⁴

IX. Conclusion

The organic chemistry of palladium was initiated by the study of the π -complexes and alkyl derivatives of this metal.²⁰¹ The carbonyl complexes played only a modest role at this stage.

The last quarter of the century has been marked by the development of a series of processes which have found industrial applications or for which prospects for an industrial application exist. Carbon monoxide plays the role of one of the substrates in this series, whilst the active component of the catalytic system consists of palladium compounds.²³⁷

Simultaneously with this field of chemistry, the chemistry of palladium carbonyl complexes developed, its importance growing far beyond the framework determined by utilitarian needs.

The synthesis and study of palladium carbonyl complexes, regarded as a chemical rarity as late as 25 years ago, posed a series of problems before the theory of the chemical bond and of the reactivity of compounds. Modern ideas about the nature of the metal–metal and metal–organic ligand chemical bonds²³⁸ are based in many respects on the existing factual data and the chemistry and structure of platinum group metal carbonyl complexes.

The analysis of these data carried out in the present review has confirmed the existing hypothesis that the stability of polynuclear compounds diminishes with increase in the formal oxidation state of the central atom in palladium carbonyls and hence the number of reliably characterised compounds diminishes sharply on passing from Pd(0) to Pd(+2). Thus, whereas binary carbonyls and mononuclear and polynuclear compounds with various forms of the metal core and all the forms of the coordination of carbonyl ligands have been described for palladium(0), all the known palladium(+2) carbonyls are limited by mononuclear compounds with terminal carbonyl groups.

Among the fairly wide range of methods of synthesis of transition metal carbonyl complexes^{239–241} (direct carbonylation of the metal, reductive carbonylation, oxidative carbonylation, reduction of carbonyl complexes, substitution of ligands *etc.*), only some have been applied in the chemistry of palladium carbonyls, different numbers of compounds being obtained by the application of a particular method. Thus only four complexes have been synthesised by the coprecipitation of palladium metal and CO at low temperatures; the reaction involving the substitution of ligands by carbon monoxide has also been successful in only isolated instances. The method involving the insertion of CO in the metal–metal bond in dinuclear and polynuclear palladium complexes and reductive carbonylation of palladium compounds have proved much more productive. It is noteworthy that the vast majority of compounds have been obtained by the latter method and not only palladium(0) or palladium(+1) complexes but also palladium(+2) complexes.

Palladium(0) carbonyls constitute the most numerous class among palladium carbonyl complexes, polynuclear carbonyls, including also large clusters with several tens of palladium atoms in the metal core, predominating. Probably one of the most important causes of such diversity of the complexes is the stability of the Pd–CO bond determined by the combination of the σ -donor and π -acceptor properties of the CO molecule and the ability of the palladium atom (d^{10} electronic configuration) to donate the electron density from the $3d$ metal orbital to the π^* -orbital of the CO molecule.

The stability of the Pd–CO bond in palladium(+1) complexes, where the metal atom has the d^9 electronic configuration, is lower and hence the number of such complexes is much smaller than that of palladium(0) carbonyls. All the palladium(+1) complexes contain an even number of metal atoms — 2 or 4. They are diamagnetic and the pairing of electrons at the two metal atoms, having the d^9 configuration, occurs either as a result of the formation of a metal–metal bond (with a Pd–Pd distance of $\sim 2.7 \text{ \AA}$) or by the formation of a three-centre four-electron bond incorporating two palladium atoms and one carbon atom of the bridging carbonyl ligand.

The palladium(+1) complexes are fairly sensitive to the action of oxygen-containing nucleophiles and, when treated with, for example, water or lower aliphatic alcohols, they decompose with the formation of palladium metal. The insertion of π -donor

ligands into these complexes promotes an increase in their resistance to reductive decompositions.

In the palladium(+2) complexes where the metal atom has the d^8 electronic configuration and the possibility of the donation of electrons from the metal to the corresponding orbitals of the CO molecule is much smaller than for Pd(0) and Pd(+1), an enhancement of the σ -donor properties of the carbonyl is observed. All the palladium(+2) carbonyl complexes are monomeric with terminal CO groups. The strength of the Pd–CO bond is as a rule small, which leads to a low thermal stability of the complexes. The presence in the palladium(+2) carbonyl complex of groups with strong electron-withdrawing properties, for example SO_3F^- , enhances the electron-accepting properties of the palladium atom and hence leads to an increase in the thermal stability of the complexes.

There are few palladium carbonyl complexes containing the metal in fractional oxidation states. In fact, only compounds having the $\text{Pd}_3(\mu_3\text{-CO})$ core can be regarded as reliably characterised. The reactions involving the coordination of additional ligands are characteristic of these compounds and the newly introduced ligands can be both terminal or can function as μ_3 -bridges on the Pd_3 triangle. Reactions of the second type are oxidative addition reactions. As a consequence of the change in the charge on the Pd_3 triangle, the metal core is altered and the charges are redistributed, which actually leads to a species with nonequivalent metal atoms.

Palladium carbonyl hydrides are of enormous interest primarily as possible intermediates (or models of intermediates) in catalytic processes occurring with participation of carbon monoxide and hydrogen and catalysed by palladium and its compounds. The number of such complexes, which have been postulated in a large number of studies, is small. All the palladium carbonyl hydrides are represented either by dinuclear singly-charged cations with bridging carbonyl and hydride ligands or by polynuclear compounds also containing bridging carbonyl and hydride ligands. In all cases, the FOS of the palladium atoms is intermediate between 0 and +2.

Summarising the data described above concerning the characteristic features of the Pd–CO bond in the carbonyl-containing complexes, one should note that such a bond may be described by several models distinguished by different contributions of the σ - and π -interactions. The symbolism introduced by Willner and Aubke (Fig. 11) appears very clear in the simplest case where the overlap of orbitals in an individual M–CO fragment with CO groups bound as terminal species is considered.²³⁸

Figure 11. A schematic model of the formation of the bond in the M–CO fragment.

In this scheme, the σ -donor bond arising from the 5σ molecular orbital of CO is shown as an arrow directed from the carbon atom to the metal atom, while the π -acceptor bond, responsible for the donation from the nd_{xz} or nd_{xy} orbital of the metal to the π^* molecular orbitals of CO is shown by arrows directed towards CO. The thin lines indicate a weak bond, whereas thick lines demonstrate the dominant type of bond and the boundary situations. Figure 11a illustrates the dominant π -back-donation (this involves predominantly highly reduced carbonylmetallates), whilst Fig 11c illustrates the predominance of σ -bonding (cationic carbonyls). Figure 11b characterises the bonding in typical metal carbonyls, where the bonds of the types indicated in Fig. 11a and Fig. 11c may overlap depending on the

oxidation state of the metal. Apparently there are at present no physicochemical data which would make it possible to assign the type of bonding in the carbonyl fragments solely to the ' π -interaction' or the ' σ -interaction' and both types of bonding occur in any of the existing compounds.

The palladium carbonyls where the bond might be assigned to the type presented in Fig. 11b and which should have a large positive charge, for example $[\text{M}(\text{CO})_4]^{4+}$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$) and $[\text{M}(\text{CO})_4]^{3+}$ ($\text{M} = \text{Co}, \text{Rh}, \text{Ir}$)²⁴² have not so far been described and the possibility of the synthesis of such reduced carbonyl carbonylpalladates appears doubtful. In the vast majority of the palladium carbonyl complexes, the bond is of the type presented in Fig. 11b (the σ - and π -interactions are combined). Only one complex — the palladium(+2) carbonyl complex $[\text{Pd}(\text{CO})_4]^{2+}$ — may be assigned to complexes in which a bond of the Pd–CO type presented in Fig. 11c is achieved. Only in this complex is an anomalously high stretching vibrational frequency of the CO (2248 cm^{-1}) observed, exceeding the value of ν_{CO} for free carbon monoxide.

In the case of all other palladium carbonyl complexes, the energy of the Pd–CO bond and the vibrational frequencies ν_{CO} , indirectly characterising this bond, depend on a whole series of ancillary factors. Thus the vibrations of the terminal CO groups are manifested in the shortest-wavelength region ($2000\text{--}2050\text{ cm}^{-1}$), those of the μ -CO groups are in the middle region ($1850\text{--}\sim 1950\text{ cm}^{-1}$), while the vibrations of the μ_3 -groups are in the longest-wavelength region. The regions corresponding to absorption by the last two types of CO ligands overlap appreciably. Complexes of different nuclearity, containing CO ligands of the same type, do not exhibit stable distinctive features in their IR spectra.

On the other hand, the presence at one atom of only one terminal carbonyl and of three n -donor atoms [for example in $\text{Pd}(\text{CO})(\text{PPh}_3)_3$, $\text{Pd}(\text{CO})(\text{NP}_3)$, and $\text{Pd}(\text{CO})[\text{MeC}(\text{CH}_2\text{PPh}_2)_3]$ leads to a decrease in ν_{CO} to values characteristic of the stretching vibrations of the bridging CO group, *i.e.* the regions of the stretching vibrations of the bridging and terminal carbonyls overlap.

The appearance of strong electron-withdrawing groups increases ν_{CO} to values characteristic of the stretching vibrations of the terminal CO groups. For example, ν_{CO} for the complex $\text{Pd}_4(\mu\text{-CO})_4(\mu\text{-OCOCF}_3)_4$ is 2003 cm^{-1} , which is characteristic of the terminal CO groups. At any rate, bearing in mind the foregoing one should treat with caution the description of the structure of carbonyls and the estimation of the strength of the metal–ligand bond on the basis of spectroscopic data.

The reactivity of palladium carbonyl complexes is restricted to a narrow range of reactions. Thus ligand substitution, which does not lead to a serious structural rearrangement, has been described for all types of palladium carbonyl complexes. Reactions leading to a change in the metal core have been described for polynuclear complexes containing Pd(0), Pd(+1), and palladium in fractional oxidation states, and such changes can occur with decrease or increase in the nuclearity of the complex [for example, the formation of various carbonyl phosphine complexes of palladium(0)] and with retention of the nuclearity [for example, the formation of the tetrahedral complex $[\text{Pd}_4(\text{CO})_2\text{Phen}_4](\text{OAc})_4$ from the carbonyl acetate $\text{Pd}_4(\text{CO})_4(\text{OAc})_4$, which has a rectangular metal core].

The reactivity of the palladium(+1) carbonyl carboxylate complexes has been studied much more widely than for the other complexes. Among the reactions investigated the greatest interest attaches to the oxidative-reduction reactions of the tetranuclear clusters. In the first place, this is the reaction involving the intramolecular transfer of an oxygen atom from the carboxylate ligands to the coordinated carbonyl, which may serve as a model of a whole series of oxidation–reduction processes proceeding with participation of CO and catalysed by palladium compounds.

The extensive field of the chemistry of palladium comprising the synthesis, the structure, and the reactivity of heteronuclear

palladium-containing complexes with carbonyl ligands has remained outside the scope of the present review.

The authors hope that the compilation of data on the synthesis, structures, and properties of palladium carbonyl complexes presented in the review will prove useful not only to chemists occupied with different aspects of the synthesis of carbonyl complexes but also to specialists in the application of these complexes in catalysis and in the study of the details of their electronic structure.

The review has been written with the financial support by the Russian Foundation for Basic Research (Project No. 96–03–34389a) and the Government of the Russian Federation (Project No. 96–15–97577).

Open-chain poly(organophosphazenes). Synthesis and properties

S V Vinogradova, D R Tur, V A Vasnev

Contents

I. Introduction	515
II. Synthesis of polyphosphazenes	515
III. Properties of poly(organophosphazenes)	524
IV. Conclusion	530

Abstract. Various methods for the synthesis of open-chain poly(organophosphazenes) are considered. The mechanism of polymerisation of hexachlorocyclotriphosphazene and the basic principles of formation of poly(organophosphazene) macromolecules by polymeranalogous reactions of poly(dichloro-phosphazene) with various nucleophilic reagents are analysed from a new viewpoint. The potential of this synthetic method for targeted design of poly(organophosphazenes) of various structures is shown. The possibility of synthesising poly(organo-phosphazenes) by polymerisation of cyclophosphazenes is also discussed. The problem of unit non-uniformity of poly(organophosphazenes) and its influence on the properties of these polymers are considered. The properties of poly(organo-phosphazenes) are considered in detail and it is shown that these polymers possess unusual valuable properties, which provide opportunities for their successful practical application. The bibliography includes 276 references.

I. Introduction

Open-chain poly(organophosphazenes) $[-PR_2=N-]_n$ constitute a relatively new class of organoelement polymers. They occupy a peculiar place among organoelement polymers. The inorganic nature of their backbone built of alternating phosphorus and nitrogen atoms and organic framing of the phosphorus atoms determine a number of specific properties in some of these polymers, namely, flexibility combined with elasticity at low temperatures; enhanced flame resistance and low smoke formation, resistance to hydrocarbon fuels and oils, low thrombogenicity, good biocompatibility, and others.

The first representatives of phosphazenes (halophosphazenes) were obtained back in the early XIX century; however, definite progress in the synthesis of poly(organophosphazenes) was achieved only in 1965–1966.

During the last two decades, studies dealing with poly(organophosphazenes) have been vigorously pursued. High-molecular-mass poly(organophosphazenes) with side groups of various structures have been synthesised. Considerable attention is being paid to the basic principles of polymer formation and to comprehensive studies of the properties of poly(organophosphazenes).

The accumulated data certainly need to be generalised. Some aspects concerning the synthesis and properties of polyphosphazenes have been outlined in several reviews.^{1–39}

In this review, we consider the synthesis of various poly(organophosphazenes) and the structure of their macromolecules. The properties of these polymers are discussed as functions of the molecular structure. The prospects for practical application of poly(organophosphazenes) are also presented.

II. Synthesis of polyphosphazenes

The search for new valuable synthetic materials has stimulated the intense development of the chemistry of polyphosphazenes during the last three decades. Considerable attention has been paid to halo-substituted polyphosphazenes, in particular poly(dichloro-phosphazene) (PDCP), which is characterised by a broad high-elasticity region (from -30 to 300°C), low glass transition temperature (-60 to -58°C), non-flammability, etc.^{1, 32, 38, 40, 41} However, since PDCP contains chlorine, it suffers from a serious drawback, namely, instability to hydrolysis: during storage in air, it rapidly and irreversibly ages and loses its properties. However, it was found that the high reactivity of the chlorine atoms in PDCP offers wide opportunities for synthesising new polymeric materials based on it by polymeranalogous transformations. Analysis of the published data demonstrates that the two-stage synthetic scheme shown below (Scheme 1) is

R = Alk, Alk_F; X = H, Na, K, Li; R' = H, R'' = Alk, Ar;
R' = R'' = Alk.

Uspekhi Khimii 67 (6) 573–594 (1998); translated by Z P Bobkova

currently the most realistic way for preparing high-molecular-mass open-chain poly(organophosphazenes).

In the first stage, high-molecular-mass soluble PDCP **2** is obtained by polymerisation of hexachlorocyclotriphosphazene (HCCTP) **1**. The second stage is a macromolecular reaction of the soluble PDCP with various nucleophilic reagents.

1. General features of the formation of PDCP

Polymerisation of cyclic halophosphazenes with ring opening is a very complicated process. Thermal polymerisation of HCCTP in the melt gives cross-linked PDCP **3** in a high yield (Scheme 1). However, this polymer is not suitable for the synthesis of poly(organophosphazenes), because of the low degrees of conversion of the P–Cl groups in reactions with nucleophilic reagents; hence, these reactions give poly(organophosphazenes) with low hydrolytic stability.

Allcock and Kugel⁴² have shown that the cross-linked polymer **3** is not an immediate product of the polymerisation of HCCTP **1** but it is rather produced from non-cross-linked PDCP **2**. A completely soluble PDCP^{42,43} was obtained by restricting the degree of conversion of HCCTP (heating was terminated at the instant when a decrease in the fluidity of the polymerisation mixture was observed) under strictly controlled temperature conditions. The data listed in Table 1 indicate that raising the temperature accelerates the formation of an insoluble cross-linked polymer.⁴⁴

Table 1. Influence of the temperature and duration of the polymerisation of HCCTP on the yield of soluble PDCP.

Duration/ h	Yield of soluble PDCP (%)	Duration/ h	Yield of soluble PDCP (%)
250 °C		300 °C	
3	12.0	0.08	0
4	13.8	0.25	13.7
5	17.0	0.41	19.3
6	23.4	0.50	27.3
21	30.8	0.66	37.9
48	70.1	1.00	50.3
96	gel	1.17	gel

According to the data of Table 1, polymerisation at 250 °C affords the cross-linked polymer over a period of 96 h, while at 300 °C this product is formed in 1.17 h.

Numerous attempts have been made to select catalysts for the polymerisation of HCCTP that would enable conducting it under milder conditions.^{1,8,9,32,37} However, these attempts have not met with success so far. Therefore, thermal polymerisation of chlorocyclophosphazenes still remains the main method for the preparation of PDCP.

Meanwhile, this method for the synthesis of PDCP suffers from one more serious drawback: the results of polymerisation are not reproducible. The yields of soluble PDCP obtained by various researchers under seemingly identical conditions vary over wide limits (from 5% to 70%).^{2,44–47}

Various opinions about the structure of soluble PDCP have been expressed.^{1–4,32} Apparently, the polymerisation product (before gelation) is a polymer with a fairly heterogeneous structure, characterised by variable and hardly controllable unit non-uniformity.² Most likely, this accounts for the irreproducibility of the yield and the properties of both PDCP itself and poly(organophosphazenes) based on it.^{12,45,48–51} Therefore, it is important to study the mechanism of polymerisation of HCCTP and side reactions resulting in the formation of branched and cross-linked polymers, in order to find the ways of controlling these processes.

The possible mechanisms of polymerisation of HCCTP have been discussed in earlier reviews;^{2,12} however, there is still no agreement on this point.^{1,2,8,12,32,46,52–54} Here we discuss the

mechanism that appears most probable from our viewpoint. A special study aimed at elucidating the influence of the residual water on the polymerisation of HCCTP in a closed system has revealed interesting and fundamental features of this process.^{2,45} It was found that the intrinsic viscosity of the PDCP formed depends on the experimental conditions and on the amounts of water and the evolved hydrogen chloride in the system; this implies that polymerisation might be catalysed by hydrogen chloride.^{2,45,50}

It has been found⁵⁵ that hydrolysis of the P–Cl bonds in HCCTP at 250 °C occurs only when the reaction mixture contains admixed higher chlorocyclophosphazenes, for example, octachlorocyclotetraphosphazene (OCCTP). Controversial opinions have been expressed in the literature about the role of this compound in the polymerisation of HCCTP. In fact, both accelerating⁵⁶ and inhibiting⁵⁷ effects as well as the absence of any activity during the polymerisation⁵⁸ have been reported for this tetramer.

Detailed study of this point has shown that the so-called ‘non-catalytic’ polymerisation of HCCTP **1** is catalysed, in reality, by the hydrogen chloride resulting from hydrolysis of the P–Cl bonds in OCCTP by the residual water.⁵⁵ There exist the optimum quantities of the tetramer and the residual water needed for successful polymerisation of the trimer. None of the reaction mechanisms proposed previously for the polymerisation of HCCTP did imply active participation of hydrogen chloride.²

It was found that highly pure HCCTP (containing ~10^{–3} mol.% of OCCTP) neither undergoes hydrolysis nor polymerises at a noticeable rate under the conditions of formation of virtually linear poly(dichlorophosphazene) (250 °C, 50 h).^{45,49} The optimum quantity of OCCTP is ~0.1 mol.%–0.2 mol.% (Table 2), which corresponds to the amount of residual water in the polymerisation vessels. Larger amounts of the tetramer markedly retard the polymerisation of HCCTP.

The known fact that the tetramer is more readily hydrolysed

Table 2. Results of polymerisation of HCCTP in the presence of various amounts of OCCTP (250 °C, 50 h).

Amount of OCCTP mixed with HCCTP (mol.%)		Yield of PDCP (%)	Intrinsic viscosity of PDCP in toluene (25 °C)/ dl g ^{–1}
total	especially admixed		
0.003	0	< 1	—
0.004	0	< 1	—
0.048	0	42	4.10
0.078	0.075	45	5.04
0.083	0.080	74	4.25
0.103	0.100	63	4.40
0.120	0	63	5.10
0.290	0	12	0.71
0.383	0.380	< 1	—
0.563	0.560	< 1	—

than the trimer **1** was rationalised based on electronic effects.⁵⁵ Study of the electronic structure by the extended Hückel method demonstrated that the P–Cl bond in OCCTP is weaker than that in HCCTP (the Mulliken populations are 0.687 and 0.724, respectively).

The above results provided grounds for the conclusion that OCCTP plays a dual role in the polymerisation of HCCTP: it acts as the source of the catalyst (hydrogen chloride) needed for the chain growth to start and as an inhibitor of the polymer growth. Thus, the process of HCCTP polymerisation could be controlled by varying the ratio of the residual water and OCCTP in the system.⁵⁵ The mechanism of polymerisation of HCCTP in the

Scheme 2

presence of OCCTP, water, and hydrogen chloride^{2, 12, 50} is presented in Scheme 2.

The first step of the reaction is hydrolysis of the P–Cl bonds in OCCTP by the residual water, which gives gaseous hydrogen chloride and hydroxyphosphazene, the latter being converted into the tautomeric oxophosphazane form. The subsequent protonation of the oxophosphazane ring with hydrogen chloride and the nucleophilic attack by the nitrogen atom of the phosphazene ring of HCCTP results in opening of the oxophosphazane ring and onset of the growth of a polymeric chain containing a terminal amino group. The chain growth occurs through subsequent addition of HCCTP molecules to the active site. When hydrolysis of the P–Cl bonds does not occur but HCl is present,⁵⁰ the phosphazene ring is also protonated; this yields molecules with terminal imino groups (Scheme 3).

Scheme 3

This mechanism of chain initiation and growth⁴⁵ is formally consistent with the view about the ionic character of the polymerisation of HCCTP but implies a completely different chemistry of this process. The possibility of polymerisation according to two pathways is fundamentally important, because it opens up way of controlling this process.^{2, 12, 50} In fact, if the reaction starts with hydrolysis of the P–Cl bonds of the ring, this affords polymeric chains with terminal amino groups. These terminal groups can react with the P–Cl bonds of adjacent macromolecules; this accounts for side reactions. Due to these processes and also to the participation of oxophosphazane rings in the polymer chain growth, anomalous units of types **B–G** arise in the polymer, together with the predominant units of type **A**. Eventually, this leads to the formation of polydichlorophosphazene with a fairly high unit non-uniformity, to poor reproducibility of the experimental results, and to relatively low yields of the soluble polymer.

It is promising to carry out the polymerisation process under conditions permitting no hydrolysis; in this case, the reaction starts with protonation of the phosphazene ring with hydrogen chloride. This permits the preparation of PDCP with more inert terminal imino groups and, hence, with a more perfect defectless final chemical structure.

Elucidation of the mechanism of polymerisation of HCCTP made it possible to find a practical method for controlling the synthesis of PDCP; this method ensures good reproducibility of the results and the formation of a practically linear PDCP with molecular masses of about $(5-10) \times 10^6$ and with a much narrower molecular-mass distribution ($M_w/M_n < 1.4$) compared to that of the polyphosphazenes described previously ($M_w/M_n \approx 7-79$ ^{3, 33, 59-63}), its yield being more than 80%.^{2, 12, 50}

The problem was solved by preliminary removal of water from the reaction system; for this purpose, the residual water was made to react with the P–Cl groups of chlorocyclophosphazene and then the resulting phosphazene derivatives containing hydrolysed fragments, which are the main source of side reactions, were separated from the reaction mixture. Polymerisation was carried out at 250 °C in a jointless Pyrex apparatus.⁴⁹ In this case, hydrogen chloride needed to initiate the polymer chain growth is retained in the reaction system.

The study of the polymerisation process has shown that the intrinsic viscosity of PDCP decreases, whereas the Huggins constant simultaneously increases following an increase in the polymerisation time. This apparently indicates that at larger degrees of conversion, branched PDCP molecules are formed.⁵⁰

The content of branched molecules and the unit non-uniformity of the polymer depend on the experimental conditions [the extent to which the reaction tubes are filled with the monomer, quantity of the catalyst (hydrogen chloride), temperature, and reaction time].

The influence of the duration of the process in a preheated polymerisation system on the yield and intrinsic viscosity of PDCP and its fluoroalkoxy-derivatives has been studied.⁶³ A nearly quantitative degree of conversion of the trimer (97%) is attained when the polymerisation is carried out for 130 h (250 °C), the resulting PDCP being completely soluble in benzene and toluene. The high degrees of polymerisation $[(4-5) \times 10^5]$ and also the fact that the molecular-mass distribution curves of various PDCP samples at low degrees of conversion of the trimer virtually coincide, together with the narrow molecular-mass distribution of the polymer, imply that the chain growth reaction occurs much faster than competing side processes. The results obtained led the researchers⁶³ to the conclusion about a cationic mechanism of HCCTP polymerisation in the melt. The same mechanism was proposed for the polymerisation of the trimer carried out in solution in 1,2,3-trichlorobenzene in the presence of sulfamic acid, ammonium sulfamate, toluenesulfonic acid, and other catalysts.⁶⁴

The polymerisation of HCCTP in the melt at 250 °C has been studied by electron microscopy.⁶⁵ In the early stages of the reaction, large spherical particles were detected, indicating a high

rate of chain growth. It was noted that poly(dichlorophosphazene) specimens prepared by the conventional procedure (method A) differ markedly from those obtained with preliminary removal of the residual water and the phosphazene products of hydrolysis from the reaction medium (method B).^{49, 50} The formation of an organised supermolecular structure in the polymer synthesised by method A is apparently hampered by the presence of cross-links between its macromolecules. On the contrary, in the case of the material prepared by method B, supermolecular associates of the lamellar type can be clearly seen in some parts of the electron photomicrography. Thus, the structure of PDCP in the aggregated state obtained at high degrees of polymerisation depends on the synthetic procedure used.

In general, it should be noted that despite the certain progress achieved in the synthesis of PDCP suitable for subsequent polymeranalogous substitution reactions, numerous important problems still need to be solved. The search for efficient catalysts for the thermal polymerisation of HCCTP, which would permit decreasing the reaction temperature and duration and increasing the yield of soluble PDCP, appears a promising and important aspect of investigations.

2. Synthesis of poly(organophosphazenes) based on poly(dichlorophosphazene)

The commonest and most available method for the synthesis of poly(organophosphazenes) is the polymeranalogous substitution of chlorine in PDCP. It should be noted that the regularities of these reactions have not yet been adequately studied, and the majority of published data on the synthesis of poly(organophosphazenes) reduces mostly to the description of the procedures used to prepare one or another particular polymer.

An important characteristics of poly(organophosphazenes) is the possible unit non-uniformity.^{2, 3, 12, 14} The properties of these polymers are known to depend on the presence of a small number of anomalous units in their chains.

The anomalous units can arise for several reasons during the synthesis of poly(organophosphazenes) from PDCP and have different chemical structures. First of all, these are branching points, which were present in the initial polymer. The data on the influence of branching points on the properties of poly(organophosphazenes) available to date are scarce, probably, since there are no sufficiently strict characteristics for them. However, this type of unit non-uniformity can be virtually eliminated by using linear PDCP in the polymeranalogous transformations. Yet another type of anomalous units arises due to incomplete substitution of the chlorine atoms in PDCP. This affords non-uniform polymers, which contain partially substituted and non-substituted chain units, in addition to the completely substituted ones.

The presence of even small proportions of the anomalous units (< 1 mol. %) with non-substituted P–Cl groups substantially decreases thermal, hydrolytic, and thermohydrolytic stabilities of poly(fluoroalkoxy- and poly(aryloxy-phosphazenes) and also facilitates their decomposition during photolysis.^{3, 12} Hydrolysis proceeding as a side process can lead to the formation of anomalous partially hydrolysed units, which occur in the polymer chain as two tautomeric forms

These units are even less stable and promote destruction of the polymeric chains.

Due to the diversity of anomalous units arising during the synthesis of poly(organophosphazenes), it is difficult to obtain well-reproducible results. Therefore, to obtain poly(organophosphazenes) possessing valuable properties, one should conduct the polymeranalogous substitution up to very high degrees of conversion under conditions ensuring almost complete suppression of hydrolysis.

The polymeranalogous substitution of chlorine in PDCP by fluoroalkoxy groups has been studied in most detail (see early reviews^{2, 3}). Sodium,^{3, 42, 44, 46, 47, 66–76} potassium,^{75, 77, 78} and lithium^{36, 74, 75, 77, 79–81} alkoxides and also fluorinated alcohols (in the presence of triethylamine) have been used as nucleophilic agents.^{3, 48, 82}

Since some regularities of the formation of poly(fluoroalkoxyphosphazenes) have been considered in our previous review,³ we do not discuss them here. We only would like to mention that the degree of chlorine substitution and the occurrence of the extremely undesirable side reactions of hydrolysis during the polymeranalogous substitution of chlorine in PDCP by sodium trifluoroethoxide, depend appreciably on the experimental conditions.^{69, 76, 83–85} The efficiency of these reactions is largely determined by the reaction medium, temperature, and duration of substitution. The amount of water in the reaction system (even at the level 10^{–2} vol. %–10^{–3} vol. %) is also significant. Hydrolysis is suppressed most efficiently when the reaction is carried out at room temperature and lasts for no more than 3 h when poly(fluoroalkoxyphosphazene) precipitates, for example, from a toluene–tetrahydrofuran solvent mixture during the process, and when all the reactants and reaction vessels have been thoroughly dried before the process.^{5, 83} The latter problem has been successfully solved, for instance, by using molecular sieves as desiccants.^{83, 86} The molecular-mass characteristics of the resulting polymer remained unchanged during the subsequent high-temperature hydrolysis in boiling aqueous acetone, indicating that the use of molecular sieves as desiccants had ensured virtually complete suppression of hydrolysis during the synthesis of poly(fluoroalkoxyphosphazenes). In particular, poly[bis(tri-fluoroethoxy)phosphazene] (PBTFEP) with a residual chlorine content of 0.04 mass % and a molecular mass of 10⁷ was obtained in this way. The molecular-mass characteristics of the polymer did not change after boiling in 10% aqueous acetone for 10 h.⁸⁶

Hydrolytic processes play a crucial role in the synthesis of poly(fluoroalkoxyphosphazenes) regarding the possibility of producing high-molecular-mass polymers. It has been noted (Table 3) that when the degree of hydrolysis of the P–Cl groups is less than 1 × 10^{–4}%, the molecular mass of PBTFPP is practically insensitive to hydrolytic destruction. The increase in the degree of conversion to ~1 × 10^{–3}% may decrease the molecular mass by a factor of two, and when the degree of conversion is ~1 × 10^{–2}%, even by a factor of ten.¹⁴

Table 3. Influence of the degree of conversion of P–Cl groups in side hydrolysis reactions on the molecular mass of poly[bis(tetrafluoropropoxy)phosphazene] (PBTFPP) according to Ref. 14.

Number of macromolecules (%)	Number of P–C groups in a macromolecule	Degree of conversion of P–Cl groups	10 ⁶ $\bar{M}_n$	Intrinsic viscosity $[\eta]^a$ of PBTFPP in THF/dl g ^{–1}
0	0	0	13.2	6.94

Note. Duration of the synthesis — 3 h; amount of sodium alkoxide — 3 moles per mole of P–Cl groups, concentration of PDCP in toluene — 0.17 mol litre⁻¹, concentration of the alkoxide in alcohol — 2.5 mol litre⁻¹. ^aDetermined by coulometric titration. ^bQuantity of P–OH groups in the samples < 0.1 mol.%.

Whereas synthesis and properties of poly(fluoroalkoxyphosphazenes) have been considered in a large number of papers (see reviews ^{1,3}), non-fluorinated poly(alkoxyphosphazenes) (PAP) have been much less studied. However, since ordinary alcohols are more accessible than fluorinated ones, it was highly desirable to study the synthesis of this type of poly(organophosphazenes). Data on the synthesis and properties of PAP can be found in a number of publications.^{44, 87–100}

To develop methods for the synthesis of high-molecular-mass PAP, a systematic study on the condensation of high-molecular-mass PDCP with several sodium alkoxides has been undertaken.⁹⁰ Data on the influence of the conditions of synthesis of PAP on the degree of conversion of the P–Cl groups in PDCP and on the intrinsic viscosity of the resulting polymers are listed in Table 4.^{90, 91}

It was found that the extent of substitution of the chlorine atoms in PDCP by alkoxy groups is much more dependent on the temperature and duration of the reaction, on the chemical nature of the nucleophilic reagent, and on the polarity of the reaction medium than similar substitution by fluoroalkoxy groups. Thus under the conditions optimum for the synthesis of poly(fluoroalkoxyphosphazenes),³ namely, when the reaction is carried out in a THF–toluene mixture at 25 °C for 3 h, the degree of conversion of the P–Cl groups into P–OC₄H₉ groups is only ~80%. This process was found to be best conducted in a mixture of toluene with the corresponding alcohol. In particular, in a mixture of toluene and butanol, the degree of conversion of the P–Cl groups at 110 °C is as high as > 99.98% over a period of 3 h and, what is especially important, these results are well reproducible.

It should be taken into account that in the synthesis of PAP, the problem of side reactions of hydrolysis proves to be much more complicated. Unlike the acidity of fluorinated alcohols, that of ordinary alcohols ($pK_a \approx 16–18$, in water) is nearly equal to or less than the acidity of water. Therefore, the reaction of the residual water with alkoxides affords NaOH, which causes the side hydrolysis.

X = Cl, OAlk.

The efficiency of hydrolysis is determined by the amount of residual water in the reaction system and by the ratio of the main and side reaction rates. The side reactions occur to the least degree when all the reactants and equipment have been thoroughly dried

prior to the reaction and when the experimental conditions employed ensure a high rate of the main reaction.⁹⁰

The set of identified regularities made it possible to synthesise successfully high-molecular-mass PAP with a low content of defective units (P–Cl, P–OH, P=O)^{90–93} as a result of the high degree of conversion of the P–Cl groups in the initial PDCP. The conditions used to synthesise PAP are presented in Tables 4 and 5.^{90–92}

Table 5. Conditions of synthesis and characteristics of poly(alkoxyphosphazenes) $[-P(OR)_2-N-]_n$.

OR	Conditions of synthesis		$[\eta]$ / dl g ⁻¹ (THF, 25 °C)	Content /mol. %	
	$T/^\circ\text{C}$	t/h		P–Cl ^a	P–OH ^b
OCH ₃	60	6	2.93	0.04	2.0

OC ₈ H ₁₇	110	3	6.07	0.04	0.1

Note. The reaction medium was CH₃C₆H₅–ROH (0.18 mol of RONa and 72 ml of ROH; 0.02 moles of PDCP in 116 ml of toluene); the intrinsic viscosity of PDCP in toluene at 25 °C was 4.1 dl g⁻¹. ^aCalculated from the content of chlorine found by coulometric titration. ^bFound by ¹H NMR. ^cContent of water in the system was > 3 × 10⁻³ vol.%; in other cases, it was < 3 × 10⁻³ vol.%.

A significant factor influencing the rate and the degree of substitution in the alcoholysis of PDCP is the reactivity of the P–Cl groups in the polyphosphazene, which can vary during the reaction under the influence of converted groups:^{14, 101, 102} the neighbouring group at the same phosphorus atom ('close neighbour' effect) and groups at the adjacent phosphorus atoms ('far neighbour' effect). The effects of neighbouring groups determine the structure of anomalous non-substituted units in the chain. Thus it has been found that fluoroalkoxy groups exert an accelerating 'close neighbour' effect in the alcoholysis of PDCP.¹⁰² Consequently, the resulting poly(fluoroalkoxy-phosphazenes), in addition to the completely substituted units, contain the original units with two chlorine atoms attached to phosphorus (–PCl₂–N–) even at high degrees of conversion of the P–Cl groups (> 99.9%). The results of quantum-chemical calculations led to

the suggestion that the accelerating influence of the neighbouring fluoroalkoxy groups during the polymeranalogous substitution in poly(dichlorophosphazene) is mostly due to polar effects.¹⁰² Unlike fluoroalkoxy groups, ordinary alkoxy groups exert a decelerating 'close neighbour' effect; as a result, the PAP formed contain partially substituted units of the type $-\text{PCl}(\text{OAlk})=\text{N}-$. Thus, for the same degree of conversion of the P–Cl groups in PDCP, the number of anomalous units in PAP is twice that in poly(fluoroalkoxyphosphazenes). In addition, extensive substitution of chlorines in PDCP by ordinary alkoxides requires more drastic conditions including elevated temperatures.⁹⁰ Due to the high activity and equal reactivity of chlorine atoms in the initial PDCP, the 'far neighbour' effect in the alcoholysis reactions is less pronounced than the 'close neighbour' effect. Like the behaviour in alcoholysis, the hydrolytic stability of the anomalous units with non-substituted P–Cl groups and, hence, the stability and reproducibility of the properties of poly(organophosphazenes), also depend on the effect of neighbouring groups.¹⁴

The microstructures of three specimens of PBTFFP with different degrees of conversion of the P–Cl groups, prepared at molar ratios of the P–Cl groups to sodium 2,2,3,3-tetrafluoropropoxide of 1:0.25, 1:0.50, and 1:0.75, have been studied by ³¹P NMR spectroscopy.¹⁰¹ It was found that the distribution of the $-\text{PCl}_2=\text{N}-$ (A) and $-\text{P}(\text{OR})_2=\text{N}-$ (B) units along the chain can be sketched as follows:

(a) for 25% degree of conversion

...AAAAA... → ...BAAABAAA...BBAAAAA...

(b) for 50% degree of conversion

...AAAAA... → ...BBAABBA...

(c) for 75% degree of conversion

...AAAAA... → ...BBBABBA...

When the degree of conversion is 25%, the polymer consists mostly of AAA triads and B units, small proportions of BB diads and AAAAA hexads being also present. In the case of 50% conversion, alternation of AA and BB diads predominates in the chain. At 75% conversion, triads BBB are separated by the initial A units.

The presence of the initial units A in poly(fluoroalkoxyphosphazenes) even at high degrees of conversion of the P–Cl groups is in good agreement with the data¹⁰³ on the photolysis of poly[bis(trifluoroethoxy)phosphazene]. According to these data, the destruction products contain chloro(trifluoroethoxy)cyclotriphosphazene with two geminal chlorine atoms.¹⁰³

The course of the polymeranalogous substitution of chlorine in PDCP depends appreciably on the chemical nature of the substituting reagent.^{80, 81, 101–109}

Fig. 1 presents the results of interaction of PDCP with lithium 2,2,3,3-tetrafluoropropoxide, phenoxide, and *o*-allylphenoxide.¹⁰⁵ It can be seen that a 96% degree of substitution of the chlorine in PDCP by tetrafluoropropoxy groups is attained as soon as after 15 min. The replacement of chlorine by phenoxy groups under similar conditions occurs efficiently during the first 2 h up to 50% degree of conversion. After 24 h, the degree of substitution increases only to 60%, and then the reaction sharply slows down. When lithium *o*-allylphenoxide is used in this reaction, the process is decelerated as soon as after a 25–30% degree of substitution.^{105, 106} A ³¹P NMR study of the nucleophilic substitution of the chlorine atoms in PDCP by the phenoxy groups has shown that one chlorine atom at each phosphorus atom is replaced first, and the polymer formed after 24 h is mostly built of $[-\text{N}=\text{PCl}(\text{OC}_6\text{H}_5)-]$ units. The substantial decrease in the reaction rate observed with phenoxides is apparently due to the fact that the chlorine atoms, the close environment of which consists of phenoxy groups, are less reactive towards subsequent nucleophilic attacks of both the phenoxide groups and other nucleophiles. In fact, unlike the initial PDCP, poly[chloro-(phe-

Figure 1. Dependence of the degree of substitution of chlorine atoms in PDCP (THF solution, concentration 0.5 mol litre⁻¹) on the duration of its reaction with a threefold molar amount of lithium tetrafluoropropoxide (1), phenoxide (2), and *o*-allylphenoxide (3) (THF solutions, concentration 2 mol litre⁻¹) at 20 °C.

noxy)phosphazene] is relatively stable to hydrolysis.¹⁰⁵ When it is made to react with lithium tetrafluoropropoxide under the conditions outlined above (reaction time 24 h), the polymers formed contain much more chlorine (6.64%) than poly(tetrafluoropropoxyphosphazene) (chlorine content < 1.00%). This indicates that chlorine in poly[chloro(phenoxy)-phosphazene] is less reactive than that in poly[chloro(tetrafluoro-propoxy)phosphazene].¹⁰⁵

When poly(organophosphazenes) are synthesised by simultaneous addition to PDCP of a mixture of lithium tetrafluoropropoxide and lithium phenoxide, taken in a molar ratio of 1:1, a large portion of lithium phenoxide remains unreacted, and according to elemental analysis, the repeating unit of the resulting polymer can be represented as $\text{NP}(\text{OC}_6\text{H}_5)_{0.5}(\text{OCH}_2\text{CF}_2\text{CF}_2\text{H})_{1.5}\text{Cl}_{0.2}$. Thus, under the conditions of competitive nucleophilic substitution, the probability of formation of the $-\text{N}=\text{P}(\text{OCH}_2\text{CF}_2\text{CF}_2\text{H})$. $(\text{OC}_6\text{H}_5)-$ units or, especially, the $-\text{N}=\text{P}(\text{OC}_6\text{H}_5)_2-$ units dramatically decreases,^{80, 105} and thus the polymer becomes enriched in units containing the more reactive nucleophilic reagent; in this particular case, it is tetrafluoropropoxide. Based on the data of ³¹P NMR spectroscopy,⁸⁰ it can be assumed that competitive substitution yields a random heterounit polymer containing phosphorus atoms with different environments.

OR = $\text{OCH}_2\text{CF}_2\text{CF}_2\text{H}$, OAr = OC_6H_5 .

It was shown⁸⁰ that the final structure of poly(organophosphazenes) depends on the order in which nucleophilic reagents are introduced in the reaction medium. To prepare a poly(organophosphazene) with mixed phosphorus environments of a specified composition, the less reactive reagent should be introduced first in the reaction area, and the process should be carried out until the desired degree of substitution is attained. Then the more reactive component should be added (the first equation in Scheme 4).

Let us consider a particular aspect concerning the synthesis of poly(organophosphazenes) with mixed structures. Recently it has been reported¹⁰⁷ that the reaction carried out in the presence of tetra-*n*-butylammonium bromide or 15-crown-5 ether is complicated by the fact that the phenoxy groups in the $-\text{NP}(\text{OCH}_2\text{CF}_3)(\text{OC}_6\text{H}_5)-$ fragments formed can be replaced by trifluoroethoxy groups and that an excess of sodium trifluoroethoxide results in replacement of the phenoxy groups in the $-\text{NP}(\text{OCH}_2\text{CF}_3)(\text{OC}_6\text{H}_5)-$ units but not in $-\text{NP}(\text{OC}_6\text{H}_5)_2-$. This

$R_F = \text{CH}_2\text{CF}_2\text{CF}_2\text{H}, \text{CH}_2\text{CF}_3$;
 $\text{Ar} = \text{C}_6\text{H}_5, \text{C}_6\text{H}_4\text{Cl}, \text{C}_6\text{H}_4\text{CH}_2-\text{CH}=\text{CH}_2$;
 $M = \text{Na}, \text{Li}$.

exchange is markedly retarded after a certain number of phenoxy groups have been substituted. The same investigators noted that tetra-*n*-butylammonium bromide can be successfully used as an agent accelerating the synthesis of poly(organophosphazenes) with bulky side groups or in those cases where chlorine is substituted by weak nucleophiles.

Carborane-containing poly(organophosphazenes) have been synthesised using lithium derivatives of phenyl-*o*-carborane and -*m*-carborane, *m*-carboranethiol, lithium *o*-carboranylmethoxide, and lithium *o*-carboranylmethylphenoxide, as well as bis(hydroxymethyl)-*o*-carborane and its lithium derivative as the nucleophilic reagents.^{108–112} The reactions involving lithium derivatives of phenyl-*o*-carborane and -*m*-carborane yielded products, the structure of which could not be determined, since they were highly unstable.¹⁰⁸ The use of lithium *m*-carboranylmethoxide, lithium *o*-carboranylmethoxide, and lithium *o*-carboranylmethylphenoxide (see Scheme 4) resulted in the synthesis of carborane-containing polyphosphazenes in 60%–70% yields.¹⁰⁸ The highest degree of chlorine substitution attained in these reactions was only 50%, evidently, due to the steric influence of the carborane substituents.

The chlorine atoms remaining in poly(chlorophosphazenes) containing *m*-carboranylmethoxy and *o*-carboranylmethoxy groups in

the side chains are hydrolytically unstable.¹⁰⁸ During the isolation of these polymers, the chlorine atoms contained in them are partially or completely hydrolysed (Scheme 5, polymer 4). The chlorine atoms in polymer 5 are not hydrolysed under similar conditions.

When lithium *o*-carboranylmethoxide and lithium tetrafluoropropoxide are added successively to PDCP, a polymer with carboranylmethoxy and tetrafluoropropoxy groups attached to the same phosphorus atom is produced (polymer 6). The reaction of bis(hydroxymethyl)-*o*-carborane with PDCP was carried out in THF in the presence of triethylamine at 20–50 °C or by the alkoxide method at 20–22 °C.^{109, 110, 112} The results obtained indicate that the two chlorine atoms at the same phosphorus atom in PDCP can, in principle, be replaced by a carborane-containing group yielding cardo-type polymers; this is accomplished using bis(hydroxymethyl)-*o*-carborane as the nucleophilic agent.

It should be mentioned that a higher degree of substitution of the chlorine atoms in PDCP is achieved in the presence of lithium alkoxide. However, in this case, the *o*-carborane rings are partially converted into dicarbaundecaborate groups, which are unstable with respect to hydrolysis and oxidation. Therefore, triethylamine appears to be the reagent of choice for trapping the hydrogen chloride evolved during the synthesis of carborane-containing polyphosphazenes. Replacement of the remaining chlorine atoms in these polymers by tetrafluoropropoxy groups (without isolation of the product formed in the first stage) has given poly(organophosphazenes) in which the surrounding groups are represented by fluoroalkoxy groups in addition to the cardo carborane groups.¹¹⁰

Poly(dichlorophosphazene) is a highly reactive initial compound for the synthesis of insoluble polymeric catalysts containing oligoethylenefragments.^{14, 113–115} The reaction is carried out with stirring in a mixture of anhydrous THF with toluene.

$R = \text{CHF}_2\text{CF}_2\text{CH}_2$.

PDCP has also served as the starting compound in the synthesis of graft copolymers. Thus copolymer 7 was synthesised by the reaction of PDCP with a polyarylene sulfone oxide, prepared from 2,2-bis(4-hydroxyphenyl)propane and 4,4'-dichlorodiphenyl sulfone, and containing a reactive terminal hydroxy group.^{116, 117}

The results obtained attest that this macromolecular reaction is fairly complicated. However, the fact that it yields graft copolymer, the composition of which is close to the specified one and the amount of which is no less than 45% of the total amount of the initial compounds indicates that this method can be used to prepare graft copolymers based on PDCP.

Since the copolymer **7** obtained in this way proved to be hydrolytically unstable, an attempt was made to replace the remaining chlorine atoms in the phosphazene moiety (one-pot procedure) by trifluoroethoxy groups in the presence of triethylamine and lithium chloride.

It was found that the polyarylene sulfoxide fragments present in the macromolecule of the graft copolymer **7** hamper the attainment of high degrees of the additional substitution of chlorine by the trifluoroethoxy groups. The substitution product **8** in which the residual chlorine content does not exceed 3 mass % is much more resistant to hydrolysis than the copolymer **7**.

Graft polyphosphazenes of yet another type have also been reported. Free radical reaction of poly[bis(4-ethylphenoxy)phosphazene] with maleic anhydride carried out in the presence of peroxides or with heating¹¹⁸ afforded a graft copolymer, poly[bis(4-ethylphenoxy)phosphazene-*g*-succinic anhydride], containing up to 14% of grafted succinic anhydride groups.

As shown in Scheme 1, amines can also be used as reagents replacing the chlorine atoms in PDCP. This yields poly(amino-phosphazenes),^{1, 9, 10, 17, 25, 32, 42, 91, 119–126} Non-branched primary amines substitute the chlorine atoms relatively easily; however, in this case, it is difficult to obtain a soluble polymer because of the possible cross-linking of macromolecules.

A detailed study of the aminolysis of linear PDCP by secondary amines made it possible to find conditions for the formation of poly(di-*n*-alkylaminophosphazenes) possessing highly chemically uniform structures with low contents of defective units and molecular masses of more than 10^6 .^{91, 119, 120} In particular, a homologous series of these polymers, $[-N=P(NHC_nH_{2n-1})_2-]_x$, where $n = 1-7$, was successfully synthesised in this way.¹¹⁹

3. Synthesis of poly(organophosphazenes) by polymerisation of cyclophosphazenes

Preparation of poly(organophosphazenes) by polymerisation of completely substituted organocyclophosphazenes would make it

possible to avoid the undesirable side processes, which occur when these polymers are synthesised from PDCP because of the hydrolytic instability of chlorine. In addition, this method would permit preparation of poly(organophosphazenes) with a regular arrangement of substituting groups at the phosphorus atoms along the polymeric chain. However, as has been noted in a number of reviews,^{1, 3, 10, 11, 32} most of the numerous attempts to synthesise poly(organophosphazenes) by this approach were unsuccessful. The attempts to accomplish thermal polymerisation of alkyl-, aryl-, alkoxy-, and aryloxy-substituted cyclophosphazenes at 150–350 °C either failed or resulted in the formation of only low-molecular-mass polymers.^{127–131} The completely substituted fluoroalkoxycyclophosphazenes containing pentafluoropropoxy¹³² and trifluoroethoxy¹³³ groups could not be involved in thermal polymerisation at 200–300 °C, or at 200 °C under an elevated pressure.⁶⁴

Attempts have been made to carry out polymerisation of fluoroalkoxycyclophosphazenes^{64, 133, 134} in the presence of various catalysts. However, only in the presence of an equimolar amount of BCl₃, did this give a polyphosphazene with a molecular mass of 23 000–33 000; however, in this case, too, half of the fluoroalkoxy groups were replaced by chlorine.¹³⁴

Nevertheless, chlorocyclophosphazenes with various degrees of substitution of chlorine by organic groups do enter into polymerisation and copolymerisation.^{132, 133, 135} Thus a polyphosphazene with a molecular mass of 110,000 was obtained by copolymerisation of hexakis(trifluoroethoxy)cyclophosphazene and hexachlorocyclophosphazene.¹³³ A rubber-like polymer has been prepared by copolymerisation of a mixture of trichlorotrimethylcyclophosphazene and tetrachlorotetramethylcyclophosphazene.¹³⁵ Thermal bulk polymerisation of geminally substituted cyclophosphazenes C₆H₅(X)P₃N₃Cl₄ (X = Cl, Br, CH₃, C₄H₉) has been studied.¹³⁶ At 250 °C, the compound with X = Cl polymerises over a period of 20–56 h, and that with X = Br reacts over a period of 4.5–24 h. The products of polymerisation of the monomers with X = CH₃ and C₄H₉ comprise a broad range of substances including both oligomers and polymers.

Allcock and Turner¹³⁷ have considered the thermal behaviour of substituted cyclophosphazenes of complex structures. It was found that thermolysis of these compounds at temperatures above 200 °C in the absence or in the presence of hexachlorocyclophosphazene, which could initiate polymerisation, affords only low-molecular-mass poly(organophosphazenes).

Below we present a number of substituted cyclic phosphazenes, products of their polymerisation and copolymerisation with hexachlorocyclophosphazene, and also poly(organophosphazenes) based on them; the latter were prepared by polymeranalogous substitution of the residual halogen atoms in the polymerisation products by the trifluoroethoxy groups.¹³⁸ Polymerisation of chlorocyclophosphazenes was carried out at 210–250 °C, while that of fluorine-substituted cyclophosphazenes was conducted at 250–300 °C. The molecular masses of the resulting polymers amounted to $(2.8-12.0) \times 10^5$.¹³⁸

R = Bu^t (**9**), Ph (**10**), Me (**11**, **13**), Et (**12**, **14**).

R = Bu^t, Ph.R = Bu^t, Et.

Allcock and Ngo¹³⁹ have synthesised a number of new phosphazene polymers by thermal polymerisation of 1,1-bis-(trichlorophosphazo)tetrachlorocyclotriphosphazene followed by replacement of the residual chlorine atoms in the polymerisation product by various organic pendent groups. Polymerisation was carried out at 150 °C at a reduced pressure for 2 h. Thermal polymerisation of phenylpentafluorocyclotriphosphazene at 300 °C for 48–72 h was used to synthesise poly(phenyl-fluorophosphazene) $[-\text{N}=\text{PPhF}-\text{N}=\text{PF}_2-\text{N}=\text{PF}_2-]_n$.¹⁴⁰ Polymeranalogous substitution of fluorine in this compound resulted in the synthesis of poly(organophosphazenes) with Me₃SiCH₂ side groups and poly(organophosphazenes) with mixed phosphorus environments containing trifluoroethoxy groups in addition to Me₃SiCH₂ groups.

Mono- (**16**), bis- (**17**), and tris- (**18**) *o*-carboranyl-substituted cyclotriphosphazenes have been prepared in order to synthesise carborane-containing polyphosphazenes.^{110, 141, 142} This polymer is formed under milder conditions than those resulting from polymerisation of hexachlorocyclotriphosphazene and previously known carboranecyclotriphosphazenes.¹⁴³ To increase the

hydrolytic stability of this carborane-containing polymer, the remaining chlorine atoms were substituted by tetrafluoropropoxy groups.¹⁴¹

Only polymerisation of mono-substituted derivative **16** gave a polymer (yield 60%) completely soluble in THF and having a reduced viscosity of 0.52 dl g⁻¹ in this solvent.¹⁴¹ Polymerisation of this monomer was carried out in the melt at 220 °C for 2 h. The data obtained by ³¹P NMR spectroscopy suggested an irregular arrangement of phosphorus atoms carrying the carboranyl groups. Apparently, the macromolecule of this polymer contains the following fragments, which are randomly distributed along the chain:

n = 1–4, m = 1–2.

This polymer is formed under milder conditions than those resulting from polymerisation of hexachlorocyclotriphosphazene and previously known carboranecyclotriphosphazenes.¹⁴³ To increase the hydrolytic stability of this carborane-containing polymer, the remaining chlorine atoms were substituted by tetrafluoropropoxy groups.¹⁴¹

The synthesis of cyclic and polymeric phosphazenes with methyl- and phenyl-*o*-carboranyl groups has also been reported.^{144, 145} Thermal polymerisation of (methyl-*o*-carboranyl)- or (phenyl-*o*-carboranyl)-pentachlorocyclotriphosphazenes was conducted at 250 °C for 120 h. The chlorine atoms remaining in the polymer and susceptible to hydrolysis were replaced by trifluoroethoxy groups.

Let us discuss one more type of polyphosphazenes, namely, poly(thiaphosphazenes), the polymeric chains of which incorporate sulfur-containing fragments in addition to the –P=N– units. Poly(chlorothiaphosphazene) has been prepared by polymerisation of cyclic thiaphosphazene N₃P₂SCl₅.¹⁴⁶

The process was carried out in Pyrex tubes at 90 °C or at room temperature. It is of interest that polymerisation of a freshly distilled specimen requires several days at 90 °C, whereas a specimen that has been first kept overnight at room temperature polymerises over a period of 4–5 h. The yield of the polymer

after two reprecipitations was 32%. Poly(chlorothiaphosphazene) proved to be readily hydrolysable. It was involved in polymer-analogous transformations with various aryloxy-containing nucleophiles.

It should be noted that some of the chlorine atoms in polymers of this type still remain unsubstituted. Their molecular masses are $> 10^5$.

Thus, the data presented above demonstrate that despite the numerous attempts to prepare poly(organophosphazenes) directly from completely substituted organocyclophosphazenes, conditions for their successful polymerisation have not yet been found. More reassuring results have been obtained when halocyclophosphazenes, in which chlorine has been partially substituted by organic groups, were subjected to polymerisation. However, due to hydrolytic instability of the resulting polymers, subsequent replacement of the residual halogen atoms by organic groups of one or another type is required. Certainly, studies on the polymerisation of organo-substituted cyclophosphazenes require further development. Currently the two-stage procedure considered above is undoubtedly the most efficient method for the synthesis of poly(organophosphazenes).

III. Properties of poly(organophosphazenes)

1. Chemical properties

In a number of publications,^{1-3,9} it has been noted that poly(organophosphazenes) are chemically stable; however, their stability depends substantially on the structure and defectiveness of their chemical structure. Thus the presence of anomalous units in poly(organophosphazenes) markedly decreases their hydrolytic stability. Completely substituted poly(organophosphazenes) with inert alkoxy and aryloxy pendent groups are stable to atmospheric moisture and to weak acids and bases.^{1,4,9} Poly(diphenoxy)phosphazene remains unchanged after refluxing in 1 M HNO_3 or 1 M aqueous KOH for 48 h.¹⁴⁷

Data concerning the behaviour of poly(fluoroalkoxyphosphazenes) on treatment with various acids are contradictory. It has been reported that in the solid state, these polymers are resistant to concentrated sulfuric⁶⁷ and glacial acetic¹ acids at low temperatures. However, it has also been reported that strong inorganic acids or glacial acetic acid diminish their mechanical properties.¹⁴⁸ Cured poly(fluoroalkoxyphosphazenes) have been noted to be stable on treatment with boiling water^{67,148} and to remain unchanged when in contact with concentrated solutions of KOH or NaOH for many months in the cold.^{1,67,148} The hydrolytic stability of poly(fluoroalkoxyphosphazenes) at moderately elevated temperatures depends on the overall contents in the polymer of all the anomalous units with P-Cl, P-OH, and P(O)-NH groups (Table 6).^{3,66,76}

Table 6. Some characteristics of poly[bis(trifluoroethoxy)phosphazene] containing predominating units $-\text{P}(\text{OCH}_2\text{CF}_3)_2=\text{N}-$ and anomalous units $-\text{P}(\text{OCH}_2\text{CF}_3)\text{Cl}=\text{N}-$, $-\text{PCl}_2=\text{N}-$, $-\text{P}(\text{OCH}_2\text{CF}_3)(\text{OH})=\text{N}-$, $-\text{P}(\text{O})(\text{OCH}_2\text{CF}_3)-\text{NH}-$, $-\text{P}(\text{OH})\text{Cl}=\text{N}-$, and $-\text{P}(\text{O})\text{Cl}-\text{NH}-$.

^a σ_r is the tensile strength of a nonoriented film; ^b ε is relative elongation at break.

Table 6 presents some characteristics of poly[bis(trifluoroethoxy)phosphazene]. Two specimens of this polymer are considered: one of them (specimen A) contained < 0.18 mol. % of anomalous units, while the other one (specimen B), 0.2 mol. % $< x < 1.0$ mol. %. For polymer B, the intrinsic viscosity substantially decreases (from 1.64 to 0.14 dl g⁻¹) after a 20-h refluxing in aqueous acetone, while in the case of polymer A, it remains virtually the same.⁷⁹ This indicates that at a particular content of anomalous units, polyphosphazene undergoes hydrolytic destruction, which can occur, for example, as follows:

Poly[bis(trifluoroethoxy)phosphazene] containing ≥ 0.2 mol. % of residual chlorine is so hydrolytically unstable that even at room temperature, it becomes insoluble in organic solvents, apparently, due to cross-links between macromolecules arising from its chemical transformations.^{3,66,76}

Poly(organophosphazenes) can undergo various chemical transformations under appropriate conditions. Reactions of poly[bis(4-methoxyphenoxy)phosphazene] and poly[bis(benzyl-oxyphenoxy)phosphazene] with BBr_3 to give the polymer $[-\text{N}=\text{P}(\text{OC}_6\text{H}_4\text{OH})_2-]_n$ have been reported.¹⁴⁹ The pendent substituents in this polymer contain free OH groups, which enable its subsequent chemical modification.

The possibility of exchange reactions of poly[bis(trifluoroethoxy)phosphazene] with esters and hydroxyl-containing com-

pounds has been studied.¹⁵⁰ It was found that the substitution of trifluoroethoxy groups by alkoxy groups carried out in a saturated solution of polyphosphazene and dibutyl adipate containing tetrabutoxytitanium at 240 °C occurs by 10% over a period of 20 h. When polyphosphazene is made to react with *m*-cresol and undecyl alcohol at temperatures below 240 °C, the exchange hardly takes place. The replacement of trifluoroethoxy groups in polyphosphazenes by alkoxy groups occurs successfully only when the corresponding metal alkoxides are used. Thus treatment of the polyphosphazene $[=NP(OR)_2-]_n$ with $R'ONa$, where R and R' are monovalent radicals of the type $F(CF_2)_xCH_2$ or $H(CH_2)_yCH_2$ (x and y vary from 0 to 9) yielded polymers with mixed environments, $[NP(OR)(OR')-]_n$.^{107, 151–153} The reaction was carried out by mixing solutions of the initial compounds in dry THF at 25 °C followed by refluxing the mixture for 4 h.^{152, 153} The use of bifunctional alcoholates, for example, the disodium hexafluoropentane-diolate, permits curing of polyphosphazene.¹⁵¹

Poly(organophosphazenes) with mixed environment containing free hydroxyl groups in some of the pendent substituents, which can be cured by diisocyanates, dicarboxylic acid anhydrides, *etc.*, have been described.¹⁵⁴

Poly(organophosphazenes) containing 0.5 mol.% – 35 mol.% of organic radicals with NH bonds, in addition to side alkoxy, fluoroalkoxy, or aryloxy groups, can be cured at room temperature by cross-linking reagents containing epoxy, anhydride, or NCO groups.¹⁵⁵ Poly(fluoroalkoxyphosphazenes) containing a small amount (0.1% – 5%) of OC_6H_4Alk-o groups in the lateral chain can be cured in compositions with various filling agents by peroxides and sulfur on exposure to high-energy radiation giving tough compounds.¹⁵⁶ Poly(organophosphazenes) with the residues of allyl, *n*-butenyl, and isobutenyl alcohols^{157–159} and allyl hydroxybenzoate^{160–162} as the P-substituents have been synthesised. Under appropriate conditions, these polyphosphazenes can be cured or involved into copolymerisation with unsaturated monomers.¹⁶²

The attempts to cure poly(fluoroalkoxyphosphazenes) by procedures used in vulcanisation of fluorinated rubbers have not been a success.¹⁶³ However, the polymers obtained upon introduction of reactive *o*-allylphenoxy groups, $[N=P(CH_2CF_2CF_2H)_2-x(OC_6H_4CH_2CH=CH_2-x)]_n$ where $x = 0.02–1.00$, acquire the ability to undergo thermal curing in the presence of initiators as well as radiation-induced and chemically induced curing.¹⁶³ It was found that organosilicon hydrides of various structures can serve as the curing agents for these polyphosphazenes. Curing with these agents was accomplished in the presence of hydrogen hexachloroplatinate both in solution and in films at 20–65 °C for 0.25–10 h.^{163, 164} The curing process may occur according to Scheme 6.

However, the fact that polyphosphazenes are cured by organosilicon monohydrides suggests that interaction by a free radical mechanism is also possible.¹⁶³

Scheme 6

A method for the preparation of hybrid polyphosphazene copolymers has been developed. The method includes the reaction of poly(tetrafluoropropoxyphosphazenes) containing 2 mol.% and 5 mol.% of *o*-allylphenoxy groups, or poly(chlorophenoxyphosphazene) containing 2 mol.% of *o*-allylphenoxy groups with polysiloxanes.¹⁶⁵ The role of the latter component was played by a poly(dimethyl-)(or methylphenyl-)(or methylvinyl)siloxane rubber (the content of methylphenylsiloxane units was 8.0 mol.%, that of methylvinylsiloxane units was 0.3 mol.%) and also by a siloxane polymer of the composition $[OSiH\text{Et}]_m$, where $m = 10–15$. In the former case, the reaction was carried out by heating films containing 2 mol.% of benzoyl peroxide at 90 °C. After 5 h of heating, the content of the insoluble fraction amounted to ~30%–70% depending on the particular polyphosphazene used. The reaction of polyphosphazenes with siloxanes containing terminal Si–H groups was carried out in films in the presence of hydrogen hexachloroplatinate, by heating the films to 65 °C. In some cases, as soon as after 2 h, the content of insoluble fraction in the reaction products was ~90%. Judging from thermomechanical testing, polyphosphazene–siloxane hybrid systems of this type surpass poly(organophosphazenes) in elasticity and heat resistance.¹⁶⁵ Poly(aryloxyphosphazenes) are capable of self-extinguishing in air with only moderate smoke evolution.^{33, 166} The limiting oxygen index of their inflammability is 24–65. Poly(fluoroalkoxyphosphazenes) do not burn in air; the oxygen index of their inflammability is 47–65, and in some cases, it is as high as 80.^{3, 77, 167, 168}

It has been found that the probability of decomposition of polyalkoxy- and polyaryloxyphosphazenes during photolysis^{103, 169} depends on the content of unsubstituted P–Cl groups. In the absence of these groups, poly(organophosphazenes) possess high light resistance.

Data on the influence of high temperatures on poly(organophosphazenes) have been reported in numerous publications.^{1, 3, 8, 9, 11, 32, 34, 36, 44, 47, 104, 121–123, 131, 170–180} Allcock¹ has noted that heat treatment of poly(organophosphazenes) is accompanied by depolymerisation and decomposition and that the size of the pendent groups attached to phosphorus has an appreciable influence on the polymer stability with respect to depolymerisation. Thus poly(aryloxyphosphazenes) are more thermally stable than alkoxy-substituted compounds. The latter completely decompose at 550 °C, whereas aryloxy-derivatives lose only 50% of their weight when the temperature reaches 600 °C (for a heating rate of 10 deg min^{–1}).⁴⁷ The decomposition of poly(aryloxyphosphazenes) affords mostly linear and cyclic oligomers.^{104, 170} Tables 7 and 8 contain thermal characteristics of some poly(diaryloxyphosphazenes) and poly(diarylamino-phosphazenes).

Note. Thermogravimetric analysis was carried out at a heating rate of 20 deg min⁻¹.

The data presented demonstrate that the temperatures of the onset of decomposition of arylamino derivatives are lower than those for poly(aryloxyphosphazenes). According to viscosimetric measurements, destruction of many poly(organophosphazenes) starts in the temperature range 100–200 °C.^{9, 69, 104, 170, 177} Thus a decrease in the molecular masses of poly(diphenoxy- and poly(dim-chlorophenoxy-phosphazenes) can be observed even at 130–160 °C.^{170, 177} Apparently, the destruction processes in poly(organophosphazenes) are strongly influenced by the end groups in the polymer chains as indicated, for example, by the fact that the rate of destruction of poly(dibutoxyphosphazene) at 200 °C *in vacuo* increases with a decrease in the molecular mass of the polymer and with an increase in the concentration of the P=O and P–OH groups.^{9, 180}

Some studies contain results of thermogravimetric analysis and thermal stability of poly(fluoroalkoxyphosphazenes); however, these data are sometimes contradictory.^{3, 70, 171} Thus it has been reported⁷⁰ that the weight loss of poly[bis(trifluoro-ethoxy)phosphazene] starts at ~200 °C, whereas other researchers^{5, 6, 34, 171} give values of 350–360 °C. Molecular-mass characteristics of these polymers have been estimated.^{69, 172–174} It was found that the molecular mass of poly(fluoroalkoxyphosphazenes) decreases relatively rapidly at 150–200 °C, probably due to the presence of defective units in their macromolecules. An attempt has been made to elucidate more precisely the nature of the defective groups and the active sites, which initiate destruction of the polyphosphazene chain in poly[bis(trifluoro-ethoxy)phosphazene].¹⁷⁶ It was shown that thermal depolymerisation of this polymer corresponds to a depolymerisation model with two-stage initiation at which normal phosphazene units are first transformed into defective ones. The latter may be represented by oxophosphazene units like $-\text{P}(\text{O})(\text{CH}_2\text{CF}_3)-\text{NH}-$ and $-\text{P}(\text{O})(\text{CH}_2\text{CF}_3)-\text{N}(\text{Cl})-$. They induce the appearance of active sites for depolymerisation, and, hence, the polymer in question undergoes complete thermal destruction even about 200 °C. Defective oxophosphazene units can arise during the synthesis of the polymer upon hydrolysis of P–Cl bonds and subsequent tautomeric rearrangement; they also can appear upon thermal transformations of normal phosphazene groups at temperatures about 400 °C. It has been suggested¹⁷⁶ that this mechanism of depolymerisation is common to all poly(alkoxy- and aryloxyphosphazenes).

In order to elucidate the possibility of increasing the thermal stability of poly(organophosphazenes), polymers of this type containing carboranyl groups have been synthesised.^{108–111, 141} It was found that a 5% decrease in the weights of these polymers in air is observed at moderate temperatures (200–270 °C). However, the positive influence of the carboranyl groups is manifested at higher temperatures. The coke residue of these polymers in air at 500 °C amounts to 50%–80% and that in a helium atmosphere can be as high as 100% even at 900 °C, whereas the initial poly(dichlorophosphazene) and some poly(organophosphazenes) completely decompose even at 500–570 °C.¹²¹

**Figure 2.** Thermogravimetric curves for polyorganophosphazenes with mixed environments recorded in air (curves 1, 2, 3) and under helium (4); heating rate 4.5 deg min⁻¹.

Figure 2 compares thermogravimetric curves for a carborane-containing polyphosphazene (3 and 4) with those for polymers containing no carborane groups (1 and 2). It can be seen that during heating in air, the weight of carborane-containing polymers changes to a much lesser degree than that of the polyphosphazenes $[-\text{N}=\text{P}(\text{OCH}_2\text{CF}_3)(\text{OC}_6\text{H}_4\text{Cl})-]_n$ and $[-\text{N}=\text{P}(\text{OC}_6\text{H}_5)\text{Cl}-]_n$. Heating in a helium atmosphere does not result in any change in the weight of the carborane-containing polymer up to very high temperatures.

Thus, thermal stability of poly(organophosphazenes) depends on a number of factors, namely, on the chemical structure of groups linked to the phosphorus, on the presence of defective fragments in the polyphosphazene chain, on the terminal groups in the macromolecules, and on the molecular mass. The thermal stability of poly(organophosphazenes) can be changed by varying the above factors or by adding special stabilising compounds to materials based on these polymers.^{3, 8, 9, 181–185}

2. Physical properties

Physical properties of poly(organophosphazenes) are intimately connected to their chemical structure. The data of Table 9 give an idea of the influence of chemical structure of poly(organophosphazenes) on their solubility. It can be seen that some poly(organophosphazenes) are readily soluble in ordinary organic solvents, which provides opportunity for investigation of their hydrodynamic, rheological, and molecular-mass characteristics and other properties, which have been dealt with in a number of publications.^{1, 3, 9, 33, 48, 59–63, 87, 91, 121–126, 177, 186–193} Studies of the molecular-mass distribution of polyphosphazenes have led to ambiguous results. Some researchers have noted broad molecular-mass distributions.^{1, 3, 60–62, 121–126, 177} Thus polydispersity factors of about 7–79 have been reported for poly(fluoroalkoxyphosphazenes).^{3, 60–62} However, in relation to poly[bis(tetra-fluoropropoxy)phosphazene], it was shown that the synthesis carried out under controlled conditions can lead to poly(fluoro-alkoxyphosphazenes) with narrow molecular-mass distributions ($M_w/M_m = 1.03, 1.39$).⁶³ A relatively low polydispersity factor, equal to 1.09, has been reported for poly[bis(octafluoropentyl-oxy)-

Table 9. Solubility of polyorganophosphazenes $[-N=PR_2-]_n$.

phosphazene].¹³ In another study, it was noted that for poly(aryloxyphosphazenes), the polydispersity factor can be as high as 30.¹²¹ According to the results of gel-permeation chromatography, these polymers are typically characterised by bimodal molecular-mass distributions.^{9, 177, 191} The polydispersity factor of poly[bis(phenylamino)phosphazene] is 13.4.¹²⁴

For a number of poly(fluoroalkoxy- and poly(alkoxyphosphazenes), the parameters of the Mark–Kuhn–Houwink equations and dependences of the sedimentation constants in THF solutions on their molecular masses have been determined (Table 10).^{13, 91, 192}

Table 10. Parameters of the equations $[\eta] = k_\eta M^a$ and $S_0 = k_S M^{1-b}$ for polyphosphazenes $[-N=P(OR)_2-]_n$.

R	k_η	a	$10^{14} k_S$	$1-b$	Range $10^{-3} \times S_0$	Ref.
CH ₂ CF ₃	1.77×10^{-4}	0.59	35.20	0.47	45.0–122.1	13, 192
CH ₂ (CF ₂) ₂ H	6.10×10^{-6}	0.85	1.17	0.39	3.6–63.1	13, 192
CH ₂ (CF ₂) ₄ H	6.74×10^{-7}	1.00	2.95	0.33	7.1–23.7	13, 192
(CH ₂) ₂ CH ₃	2.03×10^{-4}	0.65	27.00	0.45	4.8–20.9	91
(CH ₂) ₃ CH ₃	1.17×10^{-4}	0.70	33.30	0.43	2.7–28.7	91
(CH ₂) ₅ CH ₃	9.36×10^{-6}	0.88	56.00	0.37	4.0–16.1	91

For the same polymers, conformational parameters were calculated and it was shown that the statistical Kuhn segment values increase with an increase in the length of the pendent substituent.^{91, 192} Thus the Kuhn segments for the polyphosphazenes with R = $-(CH_2)_2CH_3$, $-(CH_2)_3CH_3$, and $-(CH_2)_5CH_3$ amount to 53×10^{-8} , 72×10^{-8} , and 110×10^{-8} cm, respectively. The same values for poly[bis(fluoroalkoxy)phosphazenes] with R = $-CH_2CF_3$, $-CH_2(CF_2)_2H$, and $-CH_2(CF_2)_4H$ are equal to 44×10^{-8} , 122×10^{-8} , and 160×10^{-8} cm, respectively. These results permitted the conclusion that the equilibrium rigidity of poly(alkoxyphosphazene) macromolecules is much lower than that of poly(fluoroalkoxyphosphazene) macromolecules, provided that the lengths of the lateral groups are comparable. The replacement of the oxygen atom in the side chain of poly(dihexyloxyphosphazene) by an NH group increases the Kuhn segment by a factor of about three; thus the Kuhn segment of poly(dihexylaminophosphazene) is 350×10^{-8} cm.⁹¹

In several studies^{2, 3, 48, 62, 186, 193, 194} dealing with the concentration dependence of the reduced viscosity of solutions of poly(alkoxy- and poly(fluoroalkoxy-phosphazenes), an abnormal character of this dependence has been observed, namely, the reduced viscosity increases upon dilution, as is normally observed for dilute solutions of polyelectrolytes. Viscosity, electrical conductivity, and dielectric properties of dilute THF solutions of four poly[bis(fluoroethoxy)phosphazene] samples were studied.¹⁹³ The following unusual properties were discovered:

- (1) the reduced viscosity markedly depends on the shear rate;
- (2) the reduced viscosity increases upon a decrease in the polymer concentration in the solution;
- (3) the magnitude of the reduced viscosity of a polymer solution decreases and the pattern of its concentration dependence changes in the presence of various amounts of a salt (KI);
- (4) the magnitude of the reduced viscosity and sedimentation constants S_0 of solutions decrease on passing from a more polar solvent to a less polar one.

This type of combination of hydrodynamic properties is quite typical of linear polyelectrolytes.¹⁹⁵

The polyelectrolyte character of some poly(organophosphazenes), for example, poly[bis(trifluoroethoxy)phosphazene], is caused by anomalous units such as $-P(OCH_2CF_3)=N-$ and $-P(OH)(OCH_2CF_3)=N-$ present in the polymer chain.^{2, 186, 193, 194}

The appearance of ionised groups can be explained by intra- or intermolecular interactions between two different units, for example, by formation of quaternary nitrogen atoms with chloride anions as counter-ions.¹⁸⁶ According to the results obtained by electron microscopy for dilute solutions of polymers in polar and moderately polar solvents such as acetone and tetrahydrofuran, ionised groups in these polymers result mostly from intramolecular interactions.¹⁹⁶

Several studies^{197–200} have been devoted to the Kerr effect in solutions of poly(fluoroalkoxyphosphazenes). Thus investigation of dynamic and electrical birefringence of solutions of the polyphosphazenes $-P[OCH_2(CF_2)_2H]_2=N-$, $-P[OCH_2(CF_2)_4H]_2=N-$, and $-P(OCH_2CF_3)_2=N-$ showed that the specific Kerr constants for these polymers in ethyl acetate are 4.8×10^{-8} , 5.7×10^{-8} , and 7×10^{-8} cm⁵ g⁻¹ (300 V)⁻², respectively. It was shown that polyphosphazene molecules are oriented in an electric field owing to their permanent dipole moment, which is collinear with the vector connecting the ends of the macromolecule. This accounts for the substantial contribution of large-scale motion to the orientation of macromolecules of polyphosphazene in an electric field.

The heat resistance of poly(organophosphazenes) depends appreciably on their chemical structure. Previously, glass transition temperatures for a number of poly(fluoroalkoxyphosphazenes) have been reported; for many of these polymers, these values are fairly low.³ For example, the glass transition temperature of $\{-N=P[OCH_2(CF_2)_2OCF_3]_2-\}_n$ determined by the thermomechanical method is -99°C .⁷⁷

Tables 11–14 contain data on the glass transition and melting temperatures of a series of poly(organophosphazenes) with different substituents. These data show that poly(alkoxy- and poly(fluoroalkoxy-phosphazenes) possess the lowest glass transition temperatures. On passing to aryloxy substituents, glass transition temperatures of polyphosphazenes increase; finally, poly(diarylamino)phosphazenes possess the highest glass transition temperatures (Table 14). It can be seen from Table 13 that the glass transition temperatures of polyphosphazenes with mixed environments can be varied by changing both the chemical nature of substituents at the phosphorus atom and their ratio.

The heat resistance of polyorganophosphazenes with reactive side groups can also be changed by their chemical modification,¹⁶³ which is illustrated by Fig. 3.

Data on the physical state, in particular the phase composition, of poly(organophosphazenes) have been presented in numerous publications (see, for example, Refs 3, 19, 34, 34, 70, 77, 93, 94,

100, 121, 201–246). Studies of physical transformations of poly(-organophosphazenes) carried out by scanning calorimetry, thermoanalytical methods, nuclear magnetic resonance, and X-ray diffraction^{3, 19, 34, 70, 77, 121, 202–208} demonstrated that some of them exhibit two temperature transitions, despite the fact that they are flexible-chain polymers and contain no mesogenic groups. The lower-temperature transition T_1 corresponds to melting of the crystalline phase with retention of a certain degree of ordering, i.e. at T_1 the polymer passes into a mesomorphic state.

Note. T_{gl} were determined using a thermal analyser at a heating rate of 10 deg min⁻¹.

**Figure 3.** Thermomechanical curves for poly(tetrafluoropropoxy)(*o*-allylphenoxy)phosphazene $-N=P(OCH_2CF_2CF_2H)_{1.96}(OC_6H_4CH_2CH=CH_2)_{0.04}-$.

(1) before curing; (2) after curing with tetramethylhydrodisiloxane in a film at 65 °C for 4 h in the presence of hydrogen hexachloroplatinate. The load applied to the specimen was 0.8 kgf cm⁻², the heating rate was 1 deg min⁻¹.

The upper temperature at which it transforms into an isotropic liquid is the true melting temperature (T_{melt}). For some poly(-organophosphazenes), these two transitions are separated by an unusually broad temperature range; in some cases, it reaches 150–250 °C or even more.^{6, 34} For example, T_1 and T_{melt} for poly[bis(-trifluoroethoxy)phosphazene] are approximately ~90 °C and 240–250 °C;^{13, 34} those for poly[chloro(phenoxy)-phosphazene] are 169 °C and 356 °C.³⁴

The physical state of poly(dialkoxyphosphazenes) has been studied in a number of publications.^{92–94, 244} The influence of the length of the pendent alkoxy groups (ranging from methoxy to octyloxy) in polyphosphazenes on their glass transition temperatures, crystallisation, and the ability to form mesophases has been analysed (see Table 11). For poly(dibutoxyphosphazene), it was found that a mesophase is formed only when the total content of defective units in the polyphosphazene is < 0.1 mol.%.^{93, 94} Thus, the mesomorphic properties of poly(organophosphazenes) are crucially dependent of the chemical homogeneity of their structure. The transition of poly(butoxyphosphazene) from the mesomorphic to the isotropic state occurring at 200 °C is accompanied by a small thermal effect (1.3 J g⁻¹). It was shown for poly(dipentyloxyphosphazene) that the formation of the mesophase depends not only on the content of defective units in the polymer but also on the conditions under which the sample was prepared: when the solvent (benzene, THF, chloroform) is slowly evaporated from a polymer solution, the mesophase is formed, whereas fast evaporation or precipitation of the polymer yields an amorphous phase.⁹⁴

IR and Raman spectra of poly(dialkoxyphosphazenes) $[-N=P(OC_mH_{2m+1})_2-]_n$, where $m = 1–9$, have been studied over a wide temperature range (from -100 to 100 °C).^{247, 248} It was suggested that the backbone has a helical structure. Some temperature-induced spectral changes were attributed to conformation transitions in the side chains. When the temperature is lowered, the content of *trans*-isomers increases, whereas that of *gauche*-isomers decreases.

Various aspects concerning the physical state of poly(fluoroalkoxyphosphazenes) have been studied.^{6, 13, 34, 201, 208, 210–232, 244, 245} For the homologous series of poly(fluoroalkoxyphosphazenes) with various lengths of the pendent groups,^{231, 245} it was shown that the glass transition temperatures of the polymers increase with increase in the length of the side group, whereas the temperatures of the transition to the mesomorphic state, characterised by a hexagonal packing of the macromolecule backbones, scarcely change. The increase in the range of existence in the mesomorphic state for polymers with longer pendent groups is due to higher temperatures at which the polymer passes into the isotropic melt.

It has been noted in a review¹³ that poly(fluoroalkoxyphosphazenes) are characterised by labile structures, which depend on the conditions of preparation of the polymer and its thermal prehistory. The main reason for the formation of the mesomorphic state in these polymers is specific interaction between the backbone and the pendent groups containing a large number of electronegative fluorine atoms. Primary attention was devoted to poly[bis(trifluoroethoxy)phosphazene]. It was noted that a peculiar structure of the mesophase of this polymer accounts for its ability to flow like a liquid in the mesomorphic state. The structure of the isotropic melt of the polyphosphazene retains the main features of the mesophase structure but is distinguished by a coil conformation of macromolecules.²¹² In the 453–493 K temperature range, rheological properties and structural characteristics of the mesophase melt of the polymer substantially change, which is accompanied by a thermal effect.²¹³ It is believed that this change corresponds to a conformational transition of macromolecules into a structure intermediate between one-dimensional layered and two-dimensional pseudo-hexagonal structures. The mesophase in poly[bis(trifluoroethoxy)phosphazene] was found to be highly sensitive to external pressure; when the pressure increases (up to 400 MPa), the temperature (T_1) of the polymer transition from the crystalline state into the mesophase increases, the range of existence of the mesophase is sharply extended, and the mesophase becomes more ordered.²¹¹

Temperature transitions and the orientational order in the near-surface layers of poly[bis(trifluoroethoxy)phosphazene] films have been studied.²³⁰ The glass transition temperature of this polymer is equal to -70°C , the temperature of transition of the mesophase into a new modification is 120°C , and the temperature of isotropisation and transition of the polymer into the amorphous state is 225°C . It was found that the segment optical anisotropy of poly[bis(trifluoroethoxy)phosphazene] in the bulk is twice that in solution. This points to a strong orientational interaction of the macromolecules, resulting in the higher thermodynamic rigidity of polymer chains in the bulk than that in solution. It was noted that the structure of uniaxially oriented fibres of poly[bis(trifluoroethoxy)phosphazene] is fundamentally modified upon annealing at a temperature above the mesomorphic transition. The type of packing changes, namely, non-equilibrium α -phase passes into a thermodynamically stable γ -orthorhombic form.²¹⁶ It has been suggested that macromolecules of this polymer spontaneously straighten out in the mesomorphic state.

The phase transitions in poly(organophosphazenes) with partially fluorinated alkoxy groups $\{-\text{N}=\text{P}[\text{OCH}_2.(\text{CF}_2)_x\text{CF}_2\text{H}]_2-\}_n$, where $x = 1, 3, 5$, from the crystalline phase to the mesophase, which can be regarded as a conformationally disordered crystal, have been studied in detail by various physical methods.^{217–220, 224} The temperatures of phase transitions in these polymers decrease linearly following an increase in the length of the pendent groups. The structure of poly[bis(pentafluoropropoxy)phosphazene] has been studied over a broad temperature range.^{221, 222} It was found that the polymer macromolecules in the mesomorphic state undergo orientation during extrusion. The studies confirmed the condic-crystalline type of the mesophase with a pseudo-hexagonal packing.²²² It was established that poly[bis(heptafluorobutoxy)phosphazene] is capable of existing

in the condic-crystalline and mesomorphic states. The mesophase of this polymer possesses high orientational and positional orders in the basis plane but is conformationally disordered.

The physical structure of poly[bis(halophenoxy)phosphazenes] has been considered in a number of studies.^{208, 233, 243} It was noted that the structures of their mesophases belong to the pseudo-hexagonal type. The physical structures of these polymers are markedly influenced by the thermal prehistory of a particular specimen.²⁴³ The mesophase state can also occur in poly(organophosphazenes) with the following side groups: $4\text{-n-C}_5\text{H}_{11}\text{OOCCH}_2\text{H}_4-$, $4\text{-n-C}_4\text{H}_9\text{OOCCH}_2\text{H}_4-$, and $4\text{-n-C}_{10}\text{H}_{21}\text{OOCCH}_2\text{H}_4-$.²³⁴

Study of the structures and phase transitions of poly(dialkylaminophosphazenes) has demonstrated that linear highly chemically homogeneous polyphosphazenes of this type form thermally reversible, ordered phases.¹¹⁹ An additional driving force for the self-organisation of these polymers is the formation of hydrogen bonds between the NH groups.²⁴⁴

A number of publications contain data on gas permeability of poly(fluoroalkoxyphosphazenes).^{235–240, 246} In particular, it was noted that gas transfer through poly[bis(trifluoroethoxy)phosphazene] is characterised by high selectivity parameters and, hence, this polymer is a promising material for gas separating membranes, for example, for separation of CO_2 -containing mixtures.²³⁵ The penetrability factor of this polyphosphazene in relation to the CO_2/CH_4 pair is ~ 10 . Of particular interest is the mesophase of poly[bis(trifluoroethoxy)phosphazene], which can ensure production of membranes operating reliably at elevated temperatures.²³⁵

The physical state of poly(organophosphazenes) has a considerable influence on the properties of composite materials based on these polymers. Blends of poly[bis(trifluoroethoxy)phosphazene] with polyethylene^{13, 241, 242} and with the ABS plastic (a ternary copolymer of acrylonitrile, butadiene, and styrene) have been studied.²¹⁵ It was found that the unusual rheological properties of isotropic and mesomorphic polyphosphazenes can be used to modify the technological properties of ultra-high-molecular-mass polyethylenes. Polyphosphazenes added in small amounts sharply decrease the viscosity of polyethylene during extrusion and permit production of extrudates with good surface quality.²⁴¹ A decrease in the melt viscosity by approximately 40% was observed for mixtures of the ABS plastics with 10% of poly[bis(trifluoroethoxy)phosphazene]. The increase in the elasticity of samples, formed from these mixtures, at $225\text{--}240^\circ\text{C}$ (processing temperatures) is presumably due to the orientation effect induced by the mesomorphic character of polyphosphazene in this temperature range.

Many poly(organophosphazenes) possess good film-forming properties; naturally, this requires that these polymers should have high molecular masses and homogeneous chemical structures. In particular, it has been noted⁸³ that high tensile strengths (about 2000 kgf cm^{-2}) of poly[bis(trifluoroethoxy)phosphazene] films are realised only when the molecular mass of the polymer is about 10×10^6 . In addition, the data of Table 6 clearly demonstrate the influence of the unit non-uniformity of the polymer on the strength of polyphosphazene films. Films of poly[bis(trifluoroethoxy)phosphazene] with high molecular masses and chemically homogeneous macromolecules were found to possess long-term climatic stability under conditions of cold (Yakutsk, Russia)²⁴⁹ and tropical²⁵⁰ climates. Thus the service life of these films in the Arctic environment was found to be about 18 years, whereas for polyethylene, this period is only 2 years.

3. Medical and biological properties

The high reactivity of poly(dichlorophosphazene) provides broad opportunities for preparing diverse poly(organophosphazenes) with specific biological properties, which can be used for the development of materials meant for medical purposes. They include thromboresistant,^{14, 251, 252} self-resolvable,²⁵³ biologically inert,^{35, 36} and biologically active materials,^{254–260} medi-

cines,^{35, 254–256} *etc.* In particular, biocompatibility of eight different poly(organophosphazenes) was tested *in vivo* in rat muscles.³⁶

19–22

23–26

R = CH₂CF₃ (19), C₆H₄Me-*p* (20),
C₆H₄Buⁱ-*p* (21),
C₆H₄Buⁱ-*p* (22),
R = Ph (23), C₆H₄Me-*p* (24),
C₆H₄(CH₂)₃Me (25),
C₆H₄C₆H₄Cl-*m* (26)

It was found that the influence of these substances on a living organism is as minor as that of the widely used silicone materials. These poly(organophosphazenes) can be applied as film coatings onto parts to be implanted, or introduced into various compositions.

Especially interesting results have been obtained in a study of medical and biological characteristics of poly[bis(trifluoroethoxy)phosphazene]^{14, 251, 261–263} with a molecular mass of about 16×10^6 and the minimum unit non-uniformity (the concentration of anomalous units with non-substituted P–Cl groups was as low as 5.8×10^{-4} mole fraction).²⁵¹ Thromboresistant properties of more than 100 poly(organophosphazene) samples as films and sutureless tubes have been assayed *ex vivo* by platelet tests and the dynamics of parietal thrombogenesis in dogs.^{14, 262} The results presented in Fig. 4 indicate that in thromboresistance (the number of platelets adhered to the surface of the polymers studied upon contact with blood), poly[bis(trifluoroethoxy)phosphazene] substantially surpasses poly(tetrafluoroethylene) and polyethylene

Figure 4. Thromboresistant properties (a) and dynamics of parietal thrombogenesis (duration of the contact of the polymer with blood — 1 min) (b) of 100 samples of poly[bis(trifluoroethoxy)phosphazene] ($M = 16 \times 10^6$, proportion of anomalous units 0.06 mol.%) tested in 10 mongrels.

(1) polyethylene, (2) polyphosphazene.

Table 15. Mechanical properties of nonoriented poly[bis(trifluoroethoxy)phosphazene] films after contact with blood serum at 40 °C.

Duration of the contact (months)	$[\eta]$ / dl g ⁻¹ (acetone)	σ_{tc} / kgf cm ⁻²	σ_{tr} / kgf cm ⁻²	ε (%)	E / kgf cm ⁻²
0	4.00	190	1160	530	725
3	2.90	215	1400	580	910
6	2.70	230	1370	505	1000
8	3.02	170	840	395	1120
12	2.73	160	840	415	1600
16	2.60	140	700	390	1550
24	2.68	146	653	347	1200

Note. σ_{tc} and σ_{tr} are conventional and real tensile stresses related to the initial and ruptured cross-sections of the specimen, respectively; ε is the relative elongation at break; E is elasticity modulus.

meant for medical purposes.^{14, 251} Polyphosphazene is also superior to polyethylene as regards the dynamics of parietal thrombogenesis.

The strength characteristics of poly[bis(trifluoroethoxy)phosphazene] films (Table 15) remain at a good level even after a 2-year contact with blood serum (the results were obtained *in vitro*).²⁶¹ Toxicological assays carried out with an isolated frog heart, male genital cells of animals, and isolated erythrocytes have also demonstrated that films of this polyphosphazene are free from general toxicity; they are highly chemically stable and exert no toxic effect on organs.²⁶²

Biological assays of a polyphosphazene²⁶⁴ as monofilament threads was carried out *in vivo* for 6 months in 12 rats, 4 rabbits, and 2 dogs. Suturing polyphosphazene threads were used in surgical operations in various tissues. These sutures do not cause inflammation in tissues; they are quickly covered by a conjunctive tissue and do not adsorb the tissue liquid. In addition, they are antiseptic and non-toxic and are resolved in living tissues at a controllable rate (from 2 weeks to more than 6 months).²⁶⁴ A fluorinated alcohol, phosphate, and ammonia are the final products of destruction of polyphosphazene filaments. It was concluded that the set of medical and biological properties of polyphosphazene suturing materials permit them to be widely employed in surgery. Polyphosphazene filaments can also be employed to produce a special reinforced jersey fabric for sutureless tubes used in endoprosthetic appliances for the restorative surgery of the upper respiratory tract and for other purposes.

IV. Conclusion

Nowadays, the most widespread method for the synthesis of poly(organophosphazenes) is the polymeranalogous substitution of the chlorine atoms in poly(dichlorophosphazene) by various organic groups. This opens up way for targeted design of polymeric chains and, hence, for the preparation of polymers with diverse properties. However, this synthetic route is characterised by poor reproducibility of experimental results. Nevertheless, these difficulties can be overcome provided that the regularities of the formation of poly(dichlorophosphazene) and polymeranalogous substitution are known. In this case, the method can be used successfully to prepare high-quality poly(organophosphazene) materials with long service lives.

Poly(organophosphazenes) possess a broad range of specific properties and may be of interest for various practical purposes.^{1, 3, 8, 9, 12, 14, 24, 31, 33, 35, 36, 265–276} There are prospects for using them as materials operating at low temperatures (non-freezing elastomers, lubricants, *etc.*). Vulcanisates of poly(fluoroalkoxyphosphazene) elastomers are resistant to fuels, oils, and hydraulic fluids; they are also highly stable with respect to oxygen and ozone and can operate over a wide temperature range, from –65 to 175 °C. Regarding their resistance to repeated low-

temperature deformations, these materials surpass vulcanised materials based on fluorine-containing and fluorosilicone rubbers.²⁶⁶ They can be used to manufacture antivibration and packing gaskets, rings and sleeves, fuel pipes, and other parts for air and space engineering, petrochemical industry, and other branches of industry.^{3, 4, 14, 31, 33, 148, 168, 265, 266, 268} In regions with a cold climate, poly(fluoroalkoxyphosphazenes) can be used both by themselves and as low-temperature modifiers for other materials.²⁴⁹

Some poly(organophosphazenes) can be useful as flame-retardant articles.³³ Thus poly(aryloxyphosphazenes) are highly fire-resistant, and simultaneously they evolve only little smoke. These elastomers appear to be promising as insulating materials for closed spaces such as submarines and planes; they can be used to insulate electric cables and to produce insulating foam plastics.^{265–267}

There are data on using poly(organophosphazenes) as elastic hermetic adhesives for inert materials¹⁶⁴ and for impregnation of textiles in order to impart water- and soil-repelling properties to them.²⁷² Being used to modify other polymers, polyethylene and ABS plastics,^{13, 241, 242} polyvinylphenylsiloxane rubber,^{270, 271} polyesters, phenolic and epoxide polymers,^{10, 24} etc., poly(organophosphazenes) improve in some cases technological properties, elasticity, flame resistance, and thermal stability of these materials.

Poly(organophosphazenes) present considerable interest as polymers used for specific non-trivial purposes, for example, in polymeric catalytic systems,^{14, 113, 254} as solid electrolytes,^{273, 275} or as electrodes in chemical cells.²⁷⁴

Poly(organophosphazenes) are undoubtedly promising for medico-biological purposes, for example, as self-resolvable suture materials meant for diverse purposes in surgery, anaesthetic preparations, and medicines,^{14, 35, 36, 251–264, 276} thromboresistant materials for reliably operating artificial organs (prosthetic blood vessels, heart valves, and ventricles of heart, endoprosthetic respiratory tracts, etc.)

This work was supported by the Russian Foundation for Basic Research (Project No. 95-03-09470).

Abstract. A group of fungicidal antibiotics, β -methoxyacrylic acid derivatives (strobilurins, oudemansins, and myxothiazols), their producers, and mechanisms of action are considered. The fungicidal activity of these compounds is based on the suppression of cell respiration of fungi in the bc_1 -complex of cytochromes. They also manifest other biological activities that are not always coupled with inhibition of respiration. Studies of the structure of the natural methoxyacrylates has made it possible to create a novel class of synthetic agricultural fungicides with enhanced stability, high activity, and a broad spectrum of action. The main regularities of the structure–activity relationship and methods of synthesis of these compounds are discussed. The bibliography includes 159 references.

I. Introduction

Some antibiotics produced by various microorganisms (strobilurins, oudemansins, and myxothiazols) were found to inhibit the growth of a broad range of fungi.¹ Mucidin or strobilurin A (**1a**) was the first to be discovered in this group of compounds. Later, several other compounds of similar structure that differed from mucidin only in the number of double bonds and the presence and position of substituents, were identified. These compounds were called strobilurins or oudemansins depending on the structure of their aliphatic chains. All of them are secondary metabolites of various fungi. Myxothiazol **2** has a bacterial origin and its structure differs substantially from that of strobilurin A, although both compounds comprise analogous structural elements.

$R^1 = R^2 = H$ (**a**); $R^1 = OMe$, $R^2 = H$ (**b**), Cl (**c**);
 $R^1 = H$, $R^2 = OMe$ (**d**); $R^1 = OH$, $R^2 = H$ (**e**);
 $R^1 = Me_2C=CHCH_2O$, $R^2 = H$ (**f**);
 $R^1 = OH$, $R^2 = Me_2C=CHCH_2O$ (**g**).

The distinctive feature of this group of compounds is the presence of a fragment of β -methoxyacrylic acid (as methyl ester or amide) linked through an α - or β -carbon atom to the rest of the molecule. They possess identical mechanism of action, which consists in the inhibition of cell respiration at the region of the bc_1 complex of electron-transport cytochromes (complex III). Such an inhibition mechanism made possible wide application of these compounds as a biochemical tool for the study of oxidative phosphorylation. These compounds also served as models for creation of a basically new class of pesticides currently known as 'strobilurin analogues'.

The electron-transport chain of respiratory enzymes plays a crucial role in supplying cells of all aerobic organisms (from bacteria, fungi, and plants to higher animals) with energy. The structure of components of the respiratory chain that are intermediates in the electron transfer from NADH to oxygen, varies insignificantly on passing from species to species. However, substantial differences are observed in the resistance of enzymes of the cytochrome system of various living organisms to specific inhibitors, which is used by certain organisms in the competition struggle.^{2,3}

Natural differences in the structure of respiratory enzymes can be used in the design of agrochemical preparations for achieving their high selectivity with respect to plants and low toxicity for mammals.² Owing to the wide occurrence of redox processes involving the cytochrome system, the respiration inhibitors can be used for suppressing the vital activity of a great variety of organisms. Thus many synthetic strobilurin analogues possess not only fungicidal, but also insecticidal, acaricidal, and nematocidal activities.

Other natural compounds that incorporate a β -methoxyacrylic acid fragment as a structural element are also known. For instance, a β -methoxyacrylate fragment in dihydrokawain (5,6-dihydro-4-methoxy-6-phenylethyl-2H-pyran-2-one), which has been recently isolated from kava *Piper methysticum*⁴ and possesses fungicidal activity, includes a hydroxyranone ring. However, there is no evidence that this compound inhibits respiration.

The recently discovered derivatives of mesoxalic acid amidonitrile *O*-methyloxime (e.g., cymoxanil **3**) are structurally similar

to some strobilurin analogues. However, their fungicidal activity is associated with blocking of RNA synthesis in fungal cells.⁵

II. Natural methoxyacrylate-type inhibitors

The high fungicidal activity of the new antibiotic mucidin (**1a**) isolated from the cultural medium and mycelium of the fungus *Oudemansiella mucida* was first discovered by Musilek *et al.*^{6–8} in the mid-1960's. Two fungicidal antibiotics called strobilurins A and B were isolated from mycelium of the basidiomycete *Strobilurus tenacellus* in 1977.⁹ Structural elucidation of these compounds revealed that strobilurin A and mucidin are identical and represent methyl (2*E*,3*Z*,5*E*)-2-methoxymethylene-3-methyl-6-phenylhexa-3,5-dienoate.^{10,11} The *E,Z,E*-configuration of the double bonds of strobilurins was confirmed by chemical and spectroscopic studies¹² as well as by stereospecific synthesis.¹³ The spectral properties of a synthetic *E,E,E*-isomer of strobilurin A¹³ differed from those of the natural compound.

Later, several other secondary metabolites of various fungi were isolated and characterised. They are strobilurin A derivatives containing substituents in the benzene ring or in the aliphatic chain (compounds **1b–g**, **4–8**).

X = H (**a**), OH (**b**).

^a Trivial nomenclature is retained.

aromatic ring and their positions. The same letters are used for the same substitution pattern [cf. the structures of strobilurin B (**1c**) and oudemansin B (**9b**)]. The early name of strobilurin A, mucidin, was preserved in the biochemical literature. Strobilurin X was termed by analogy with oudemansin X,¹ because the investigators who first discovered this compound did not give it any trivial name. Two strobilurins F were identified and named almost simultaneously by independent groups of investigators; therefore, they bear additional numerical indices (in the order of publication).¹

R¹ = R² = H (**a**); R¹ = OMe, R² = Cl (**b**); R¹ = H, R² = OMe (**c**).

Myxothiazol **2** (or myxothiazol A) mentioned above produced by the myxobacteria *Myxococcus fulvus* is also a derivative of β -methoxyacrylic acid.^{14,26,27} In contrast with strobilurins and oudemansins, the β -methoxyacrylate fragment of the myxothiazol molecule is represented by an amide rather than by an ester and is substituted at the β -carbon (but not at the α -carbon) atom. Nevertheless, the mechanism of biological action of this antibiotic is close to that of the natural esters of methoxyacrylic acid.^{28,29}

For a long time, myxothiazol had no analogues among β -methoxyacrylate-type compounds. However, a great number of related compounds were discovered recently. At present, 33 myxothiazols have been isolated, and the structures of 24 of them have been given in a review.¹ Unfortunately, comprehensive information about the structure of myxothiazols is still absent in the current literature. It is known only that in myxothiazols B–I, K–O (**10a**) and Q, X, and Y (**10b**), R² = MeCO, MeCH(OH), or an (*E,E*)-nonadienyl residue containing hydroxy, carbonyl, and epoxide groups. Myxothiazol J does not exist. Myxothiazol P (**11**) has only one thiazole ring. In myxothiazols R–W (**12**), the β -methoxyacrylic fragment is absent and R is an oxygenated three-, five-, or six-carbon-atom chain.¹

Oudemansins (**9a–c**) possess similar structure. Formally, they can be regarded as the products of addition of methanol at the C(3)–C(4) double bond of strobilurins. The known strobilurins and oudemansins together with their producers are listed in Table 1.

Considering the trivial names of methoxyacrylate-type antibiotics, it should be noted that the letter symbols A, B, and C in the names of strobilurins and oudemansins refer to substituents in the

R¹ = H (a), Me (b).

Strobilurins A and B, all of oudemansins,¹ and myxothiazol A³⁰ have been synthesised. The generalised data concerning natural methoxyacrylates can be found in a comprehensive review.¹

The conformer of strobilurin A (**1a**) with a minimum energy was calculated using the molecular mechanics method and the molecular orbital theory. It was found that the phenylpentadienyl and methyl β -methoxyacrylate fragments are planar, but are arranged in perpendicular planes. However, according to these calculations, the energy barrier to rotation around the C(2)–C(3) bond is low, therefore enantiomers cannot be isolated at room temperature.³¹

The structure of oudemansin A **9a** in the crystalline state was determined by X-ray diffraction analysis.²⁴ It was found that its conformation closely resembles the conformer of strobilurin A with the minimum energy.³¹ Apparently these conformations of strobilurin and oudemansin are close to the forms of these molecules bound to cytochrome.³¹

III. Biological activity of the natural compounds

Low concentrations of strobilurins, oudemansins, and myxothiazols inhibit the growth of diverse fungi. Their mechanism of action is associated with violation in electron transport in complex III of the mitochondrial membrane, which results in the inhibition of cell respiration.^{28, 29, 32–34}

Complex III (ubiquinone–cytochrome *c* oxidoreductase or the *bc*₁-complex) is an intermediate link in the chain of respiratory enzymes of bacteria and mitochondria (plant chloroplasts contain a structurally homologous *b*₆*f*-complex). It catalyses the electron transfer from hydroquinone to cytochrome *c*. The energy of the redox reaction is thereby converted into a chemiosmotic membrane potential through the translocation of 2e[−] and 4H⁺ across the membrane.

According to the Mitchell Q-cycle concept,^{3, 35, 36} complex III has two quinone reaction centres localised on opposite sides of the membrane. One of them, the so-called Q_o-centre (also designated as Q_p or Q₂), is the site of hydroquinone oxidation by the reaction:

Two electrons are transferred by a high-potential route via the FeS protein and cytochrome *c*₁ to reduce cytochrome *c*. The other two electrons move to the opposite side of the membrane by a low-potential route formed by cytochromes *b*_H and *b*_L, to the second quinone centre, the so-called Q_i-centre (also designated as Q_n, Q_c, and Q_r) where the quinone is reduced:

The inhibitors binding to the Q_i-centre induce changes in the absorption spectrum of cytochrome *b*_H (*b*₅₆₂). Antimycin is the most specific of these inhibitors. Methoxyacrylates were among

the first to be discovered in a group of compounds that block respiration by binding to the Q_o-centre. This binding results in a shift in the absorption band of cytochrome *b*_L (*b*₅₆₆).^{29, 32, 33, 37–42}

Since all tissue respiration inhibitors of this type contain a residue of *b*-methoxyacrylic acid (MOA) as a structural fragment, which seems to be the key element for manifestation of biological activity, they were termed MOA-inhibitors.³³

The binding site of MOA-inhibitors is not identical with the quinone site, since in the presence of these compounds ubiquinone remains bound with cytochrome *b*. This may be accompanied by changes in the relative position of the ubiquinone molecule at the reaction centre due to a conformational rearrangement of the cytochrome and the resulting violation of the electron transport to the FeS protein.^{43–45} Thus the concentration of myxothiazol required for 50% inhibition of bovine heart cytochrome *b* activity is 0.58 mol per mol of cytochrome.²⁹ At high concentrations, MOA-inhibitors can displace the quinone from the site of its binding with the Rieske FeS-protein.⁴¹ Apparently, the binding of inhibitors is reversible, since they can replace one another in the Q_o-centre.³⁹

Like methoxyacrylates, other compounds can also bind with the Q_o-centre. Pyridine (which inhibits also complex I), 6-hydroxy-5-*n*-undecyl-4,7-dioxobenzothiazole,² dibromothymoquinone,^{2, 41} and the chromone antibiotics stigmatellins A and B^{2, 41, 44, 46} also possess inhibitory activity. Despite the reciprocal competition of these compounds, their binding sites in the Q_o-centre are other than those of MOA-inhibitors.^{1, 2}

The structure of the *bc*₁-complex and the Q_o-centre as well as the mechanisms of resistance to MOA-inhibitors are discussed in a number of publications.^{3, 35, 36, 47}

Strobilurins and oudemansins manifest nearly identical high activity *in vitro* against a wide array of fungi,^{9, 15, 16, 18, 19–21, 23–25, 48, 49} but are inactive against bacteria. Strobilurin F-1 (**1e**), which manifests much lower activity, is an exception.²¹ For example, the minimum inhibitory concentrations of strobilurin A (**1a**) for *Candida albicans*, *C. crusei*, *C. parapsilosis*, *C. tropicalis*, *Cryptococcus neoformans*, *Trichophyton mentagrophytes*, *Epidermophyton floccosum*, and *Microsporum canis* lie in the range 0.1–12.8 mg ml^{−1}, whereas the inhibitory concentrations for *Aspergillus* spp. and *Scopulariopsis* spp. range from 100 to 1000 mg ml^{−1} (see Ref. 48). Owing to its antimycotic activity, strobilurin A has been used in clinical and veterinary medicine under the commercial name of Mucidermin Spofa.¹

Myxothiazol A **2** is one of the most active MOA-inhibitors.³² It manifests not only fungicidal properties, but inhibits also the growth of some Gram-positive bacteria,¹ reversibly inhibits the late G₁/S phase of the cell cycle of lymphoblastic T-cells,⁵⁰ and possesses insecticidal activity.¹ In addition, myxothiazol **2** can bind to the phyloquinone site in photosystem I (*K*_d = 9.5 × 10^{−6} mol litre^{−1}). However, this inhibitor does not manifest any activity *in vivo* due to the higher affinity of phyloquinone for this site.^{51, 52} Myxothiazol **2** inhibits also complex I of mitochondria.² Other myxothiazols rank below myxothiazol A in fungicidal activity.¹

Oudemansin A (**9a**),²⁴ strobilurins A (**1a**), B (**1c**),⁹ E (**5**),^{20, 49} D (**4a**),²¹ and G (**6**)¹⁵ inhibit the growth of human tumour cells, the latter three compounds manifesting the highest activity. 9-Methoxystrobilurins (**7**, **8**)²³ and strobilurin G (**6**)¹⁵ also display cytostatic activity. Strobilurins D (**4a**)²¹ and E (**5**)^{20, 49} possess antiviral properties. Strobilurins A (**1a**) and B (**1c**) as well as oudemansin A (**9a**) inhibit chitin synthase.⁵³

Strobilurins A (**1a**), B (**1c**), C (**1f**), and X (**1d**) as well as oudemansins A (**9a**) and B (**9b**) are relatively non-toxic for mice. According to different data, the peroral lethal dose, LD₅₀, for strobilurin A is 500 mg kg^{−1} (see Ref. 8) or 825 mg kg^{−1} (see Ref. 18). Intraperitoneal LD₅₀ is 250 mg kg^{−1} (see Ref. 8); that for oudemansin A exceeds 300 mg kg^{−1} (see Ref. 31). However, myxothiazol **2** is highly toxic for all animals tested (peroral LD₅₀ for mice is 2 mg kg^{−1}).²⁷

Despite the variety of useful properties, natural MOA-inhibitors have found only limited use as medicinal drugs or biochemical tools for the study of cell respiration. They cannot be used as agricultural pesticides because they have some serious disadvantages. For example, strobilurin A, which possesses high activity against a wide variety of fungi *in vitro*, is fairly inactive in greenhouse studies. This may be due to the low photochemical stability and a relatively high volatility of this compound. Hence, it rapidly evaporates from the surface of leaves of the treated plants. The time of the photochemical loss of the first 50% of strobilurin A in thin film experiments (τ_{50}) is 1 min.³¹ Nevertheless, this group of antibiotics presents substantial interest. The relative simplicity of their structure, their ability to retain high activity irrespective of significant changes in their structure, and a basically new mechanism of their action, which entails the absence of cross-resistance in pathogens insensitive to the currently used fungicides, stimulate the synthesis of biologically active analogues of the natural substances. Although respiration inhibitors may be hazardous for homoiothermal organisms, the low toxicity of individual strobilurins and oudemansins suggests that synthetic analogues may exist which differ substantially in toxicity with respect to fungi and homoiothermal organisms.¹

IV. Synthetic strobilurin analogues and structure – activity relationships

Although the first attempts to synthesise analogues of natural MOA-inhibitors were undertaken only in the early 1980's, over 200 patents for the synthesis of these compounds, their practical applications, and composite mixtures, have been published.^{31, 54, 55}

Synthetic analogues of strobilurins have been patented as broad-spectrum agricultural and industrial fungicides, nematocides, insecticides and acaricides, plant growth regulators, antitumour and antiviral preparations. The undeniable leaders in this area are the British company ICI and the German company BASF who have succeeded in creating experimental fungicides ICI-5504 (**13**) and BAS-490F (**14**).

Two fragments can be distinguished in the molecules of natural MOA-inhibitors and their synthetic analogues, *viz.*, a toxophore or a pharmacophore, and a carrier group⁵⁶ (or a ballast group⁵⁴ or backbone⁴⁷). Thus in strobilurins, the β -methoxyacrylate fragment plays the role of a toxophore and a substituted (*E,E*)-phenylpentadienyl residue is the backbone. It is the toxophore that is responsible for the binding with the methoxyacrylate site of the enzyme, although it is inactive if it is not bound with the backbone. In turn, the backbone not only imparts lipophilicity to the compounds, which is needed for the transport of a pharmacophore into the quinone centre, but also enables matching of the shape of the inhibitor molecule and that of the Q_o -centre cavity.⁴⁷

Both factors must be taken into consideration in design of strobilurin analogues. The structure of strobilurins can be modified in two independent ways: (1) substitution of the (*E,E*)-phenylpentadienyl chain of strobilurins for various aryl, heterocyclic, and other groups; (2) substitution of the toxophore element, a β -methoxyacrylic acid fragment, for isosteric fragments

of crotonic, methoxyiminoacetic, and analogous acids. Synthetic analogues of the natural MOA-inhibitors are compounds with the general formula **15**.

X = O, S, NR³; Y = O, S; Z = CH, N; V = CR⁴, O, S, NR⁵; R¹–R⁵ = H, Alk; Q = Ar, Het, ArX–, HetX–, *etc.*

In synthetic analogues, Q usually stands for a bulky hydrophobic substituent, which mimics a labile phenylpentadienyl residue (the backbone). This largely determines the biological activity, photostability, selectivity, and systemic properties of a compound. The rest of the molecule is a toxophore. The elements V, X, Y, and Z can vary rather independently. More or less active are esters, amides, and thioamides of appropriately substituted acrylic⁵⁷ and crotonic⁵⁸ acids, β -alkoxy-,⁵⁹ β -alkylthio,⁶⁰ β -aminoacrylic acids,⁶¹ *O*-alkyloximes,^{62, 63} *S*-alkylthiooximes,⁶⁴ and alkylhydrazones of glyoxalic acids⁶⁵ and unsaturated acids of analogous structure. Toxophore groups with different structures are also known. For example, compounds **15** devoid of ester or amide groups (R¹ = H, Me, X = CH₂, Y = O, Z = N, V = O, R² = Me) are known to inhibit respiration.⁴⁷ However, these compounds rank below esters and amides of the above-mentioned acids in activity.

After the discovery of a large variety of compounds that are not derivatives of β -methoxyacrylic acid but are able to inhibit cell respiration, the term 'synthetic MOA-inhibitors' is no longer a correct definition for this group of biologically active substances. It was therefore suggested that such compounds be called 'synthetic strobilurin analogues'.⁶⁶

The pioneering studies in the field of synthesis of strobilurin analogues were aimed at increasing their photostability. The effects of structural changes on the photostability of strobilurin analogues were considered by some authors more comprehensively.^{31, 56} Greenhouse studies of oudemansin activity revealed that the presence of a β -methoxyacrylate group did not decrease the photochemical stability of these compounds.^{31, 56}

The simplest strobilurin A analogue **16** with partially hydrogenated double bonds and the oudemansin A analogue **17** did not manifest any useful activity in hothouse studies, although compound **17** shows fungicidal properties on agar cultures of fungi.³¹

One of the first synthetic analogues of natural MOA-inhibitors was the so-called MOA-stilbene **18**.^{57, 67–70} This compound possesses fungicidal and insecticidal properties and surpasses its natural prototypes in activity.¹ X-Ray analysis of a monocrystal of compound **18** showed that the planar methyl β -methoxyacrylate and stilbene fragments are nearly perpendicular to each other as is the case with the strobilurin molecule.³¹ Stilbene **18**, like strobilurin A, is a potent inhibitor of mitochondrial respiration (I_{50} for stilbene is 0.04 μ M, that for strobilurin A is 0.11 μ M³¹). This compound is photochemically more stable than its natural analogue (τ_{50} for irradiation in thin film is 3 min) and less volatile.⁵⁶ The photostability of MOA-stilbene increases considerably in the presence of photostabilisers.⁵⁶

In the series of β -alkoxy- α -arylacrylates **19**, even methyl (*E*)- β -methoxy- α -phenylacrylate **19a** (without substituents in the benzene ring) manifests a pronounced fungicidal activity (Table 2).

Table 2. Comparative activities of acrylates **19**, **20**, and **21**.⁵⁷

Com-pound	R ¹	R ²	X	Subject of study ^a

Note. The infected plants were sprayed with emulsions (the concentration of active substance was 100 ppm).

^a Designations: 4 — undamaged plants; 3 — up to 5% damage; 2 — 6%–25% damage; 1 — 26%–59% damage; 0 — 60%–100% damage in comparison with nontreated plants. ^b *P.r.* — *Puccinia recondita* (on wheat); ^c *E.g.* — *Erysiphe graminis* f. sp. *hordei* (on barley); ^d *V.i.* — *Venturia inaequalis* (on apple-tree); ^e *P.o.* — *Pyricularia oryzae* (on rice); ^f *C.a.* — *Cercospora arachidicola* (on peanut); ^g *P.v.* — *Plasmopara viticola* (on grapes); ^h spraying with an emulsion with the concentration of the active substance of 25 ppm.

On the whole, phenylacrylates **19** are more active for R¹ = R² = Me than in those cases where R¹ or R² are represented by other alkyl substituents or hydrogen atoms. *E*-Isomers are usually more active than *Z*-isomers; it is probable that the latter, being very weak inhibitors of mitochondrial respiration, acquire the fungicidal activity following isomerisation.³¹ Substituents in the nucleus can both strongly enhance the activity and decrease it. Compounds having a bulky substituent similar to the styryl fragment in the strobilurin molecule at position 2 of the phenyl ring are usually more active. The activity of naphthylacrylates strongly depends on the position of a toxophore: α -naphthylacrylate **20** (X = H) is much more active than the β -isomer **21** (see Table 2).

X = H, Ph, Hal, Alk etc.

Although substituted MOA-stilbenes manifest high fungicidal activity in hothouses, in field tests they are moderately active due to their low photostability.¹ However, owing to their availability MOA-stilbenes, together with natural compounds, have found wide use as tools in biochemical studies. Of particular interest are stilbenes **22**, which are analogues of strobilurin E and possess antiviral and antitumour properties.⁷¹

In order to increase the photostability of such compounds, it was suggested to hydrogenate the double bond between two benzene rings⁷² and to replace it by other spacer groups, such as CH₂O, SCH₂, O, S,^{57, 73–75} SO, SO₂,⁵⁷ CH₂SO, CH₂SO₂,⁷⁶ etc.^{56, 77} Methyl (*E*)-methoxyimino-[2-(2-methylphenoxy)methyl]-phenyl]acetate (**14**) (BAS-490F), an experimental fungicide produced by BASF and possessing a protective, curative, and eradicating activities is an example. Its standard doses vary from 50 to 350 g ha^{−1} (see Ref. 66).

Acrylate **23a**, a diphenyl ether derivative, is also highly efficient against a great number of fungi.^{57, 78} This compound is sufficiently resistant to light (τ_{50} for irradiation in thin film is 30 h).⁵⁶ In addition, this compound possesses systemic fungicidal activity.^{1, 54} Compound **23b**, which contains three benzene rings, is even more active,^{54, 77} but is devoid of systemic properties. Besides, a serious disadvantage of this derivative is that it caused severe damages to some cultures in field tests.⁵⁴ The reasons for phytotoxicity of such compounds have not been finally established.⁷⁹ A change in the position of a phenoxy group in the molecule results in a sharp decrease in the fungicidal activity. Thus the isomer **23c** is a weak fungicide. In heterocyclic analogues of the ester **23b**, the high level of fungicidal activity is often associated with their ability to migrate in the plant. However, the biological properties of compounds change in an unpredictable manner depending on the number and position of heteroatoms in the rings: sometimes this activity drops drastically, and the action spectrum is narrowed or the phytotoxicity is enhanced.⁵⁴ Among derivatives of the heterocyclic series, methyl (*E*)-2-[6-(2-cyano-phenoxy)pyrimidin-4-yloxy]phenyl]-3-methoxyacrylate (**13**) (ICI-A5504), turned out to be the most efficient. This compound is an experimental fungicide and exerts systemic and translaminar activities against asco-, basidio-, deuterio-, and oomycetes.^{80, 81}

R = H (**a**), 3-PhO (**b**), 4-PhO (**c**).

Note. The infected plants were sprayed with emulsions (the concentration of the active substance of 100 ppm).

^a For designations see footnote to Table 2.

In a series of compounds of the formula **24** the toxophoric group of which is attached to an aryl or a heterocyclic residue not directly, but through O and S atoms or through NR or CR₂ groups, the derivatives with *meta*-substituents in the aromatic ring display the highest activity (Table 3).

A vast array of structurally diverse synthetic analogues of strobilurin are presently known. Thus biological activities of a great number of compounds with the general formula **15** (where Q designates various substituted carbo- and hetero-cycles), such as derivatives of indole,⁸³ pyrazole,^{84–86} pyrrole^{87–89} (methoxyacrylate derivatives of pyrrole have been described in the review³⁵), triazine,⁹⁰ dibenzo[*b,e*]-1,4-dioxin,⁹¹ thiazole,^{92–94} isoxazole,⁹² pyridine,^{95–98} pyrimidine,⁹⁹ *etc.*, have been assayed. The structure–activity relationships for this group of compounds are nearly the same as those for α -phenylacrylates. Thus the activity of monocyclic compounds increases as certain substituents are introduced at the position adjacent to the toxophoric group. As in the case of α -phenylacrylates, the β -styryl fragment and the radicals having similar bulk and shape, enhance the activity.

Methyl methoxyacrylates derived from amides of aromatic and heteroaromatic acids **25** possess fungicidal properties.^{100,101} In some cases, esters **26** manifested higher activity than the corresponding derivatives of glyoxylic acid.¹⁰² Fungicidal activity was also found in compounds **27** with an unusual structure of the toxophoric group.^{103,104}

Certain oximes **28**^{105,106} and **29**^{107–119} show enhanced fungicidal activity in comparison with their analogues that do not contain an oxime fragment in their backbone. The spatial isomerism about the C=N bond may be crucial for the manifestation of activity of these compounds.¹²⁰

In the series of synthetic analogues of the natural MOA-inhibitors, the experimental fungicides ICI-A5504 (**13**) and BAS-490F (**14**) have been studied in most detail. Like the natural compounds, these analogues bind with the Q_o-centre of cytochrome *b* and actively inhibit cell respiration.^{66,80,81,121,122} Both substances have low toxicity in rats (LD₅₀ > 5000 mg kg⁻¹).

The reason for such a selectivity are the peculiarities of their biokinetic properties rather than their selective affinity for the molecular target. Thus the inhibition constants of complex III from various living organisms were determined using various methoxyacrylates and their analogues.¹²¹ The *pI*₅₀ values for MOA-stilbene (**18**), BAS-490F (**14**), and myxothiazol (**2**) are given in Table 4. The oxidase from cereals was the least sensitive to all of the inhibitors tested. The difference in the *pI*₅₀ values is less pronounced for enzymes from other species. Structural changes in compounds that enhance their activity against fungi, induced analogous changes in the activities against other species.

Table 4. *pI*₅₀ Values for inhibitors with respect to complex III of various organisms.¹²¹

Compound	Yeast	Botrytis	Fly	Rat	Corn
MOA-stilbene (18)	7.3	7.4	7.8	7.6	6.3
BAS-490F (17)	7.9	7.8	6.9	6.3	6.0
Myxothiazol (2)	8.0	7.9	8.3	7.8	6.5

Analysis of biokinetic properties of a series of compounds revealed that such properties as absorption, transport, and metabolism are more important for their selective toxicity. For example, the high activity of compound **14** against surface-located powdery mildew is due to its diffusion through the gaseous phase and the low level of its absorption by leaves in which it is rapidly metabolised. In contrast, an analogue of this preparation in which the ester group is replaced by the methylamide group is expected to be highly active against endoparasitic fungi.¹²³

A recent report deals with *N*-methyl-(*E*)-methoxyimino-(2-phenoxyphenyl)acetamide (code SSF-126)¹²⁴ (**30**), a new preparation of this series, which possesses a broad spectrum of fungicidal activities and is being tested. It is assumed that the

main area of its application is the fight against paddy rice diseases.¹²⁵

Some strobilurin analogues can also bind with the *b*₆*f*-complex of chloroplasts in the Q_o or Q_i centre. Thus compounds **18** and **23a,b** bind with the Q_i centre, whereas compounds **24b,e,g**, with the Q_o centre. No binding was observed for compounds **20** (X = Ph) and **25** (Ar = 2- or 4-ClC₆H₄).¹²⁶

V. Synthesis of strobilurin analogues

Syntheses of β-alkoxyacrylates are usually based on esters of substituted acetic acid **31**. Condensation with formates in the presence of a base gives aldehydoesters **32**.^{31, 54, 56, 81} The reaction with dimethylformamide dimethylacetal gives compounds **34**, which also yield aldehydoesters **32** following hydrolysis or alcoholysis. Alkylation of enolates (compounds **32**) results in β-alkoxyacrylates **33** (Scheme 1).

(a) HCOOR, NaH; (b) Me₂NCH(OMe)₂, Py·TsOH; (c) H₂O, H⁺; (d) MeOH, H⁺; (e) B, R²X (X = Hal, SO₃OR²); R¹, R² = Alk; Q = Ar, Het, ArX-, HetX-, etc.

β-Methoxyacrylates are often synthesised from glyoxalates **36** by the Wittig reaction^{31, 56} (Scheme 2).

Synthesis of the corresponding derivatives of acetic (**31**) or glyoxylic (**36**) acids is carried out by conventional methods.

Alkylation of nitrogen-containing heterocycles with methyl bromoacetate in the presence of bases was used, e.g., in the synthesis of pyrrole derivatives **37**.^{55, 58}

Reaction of benzyl halides and their *ortho*-substituted derivatives **38** with sodium cyanide results in phenylacetonitriles. Their subsequent hydrolysis and esterification yield esters of the corresponding phenylacetic acids.¹²⁸

X = H, Hal, OAr;

(a) NaCN, EtOH, H₂O; (b) HCl; (c) MeOH.

Esters of glyoxylic acids **40** were obtained by oxidation of alkyl mandelates **39** with sodium hypochlorite.¹²⁹

X = Alk, Ar, Het.

Alternatively, they are synthesised from isatins **41**.¹³⁰ To this end, substituted isatins are hydrolysed with a solution of NaOH on heating; the amino group is then substituted for iodine by treatment of the corresponding diazo compound with potassium iodide and copper bronze. The resulting substituted *o*-iodophenylglyoxylic acids **42** are esterified with methyl chloroformate in the presence of triethylamine. In compounds **43**, iodine can be exchanged for other substituents to give a wide range of substituted glyoxylic acids.

(a) 1. aq. NaOH; 2. NaNO₂, H₂SO₄, H₂O; 3. KI, Cu;
(b) ClCO₂Me, Et₃N, CH₂Cl₂, 10°C;
X = H, Alk, AlkO, Hal, O₂N, NC.

Synthesis of compounds of the type **31** or **36** was also carried out by other methods.^{65, 74, 131–133} Thus MOA-stilbene **18** was synthesised from *o*-bromobenzaldehyde. This was coupled with benzylmagnesium bromide. The resulting alcohol was dehydrated in the presence of an acid to give 2-bromostilbene (**44**). The Grignard reagent prepared from the latter was slowly added to an excess of dimethyl oxalate. The ester arylglyoxylic acid **45** that formed was introduced into the Wittig reaction with (methoxymethylene)triphenylphosphorane. The target product **18** contained a small admixture of the *Z,E*-isomer.⁵⁷

(a) 1. PhCH₂MgCl; 2. aq. HCl; 3. H₃PO₄, Δ;
(b) 1. Mg; 2. (CO₂Me)₂; (c) MeOCH₂P⁺Ph₃Cl⁻, NaH.

Yet another method to obtain compound **18** is the bromination of (*E*)-2-(2-methylphenyl)-β-methoxyacrylate (**46**) with *N*-bromosuccinimide. The reaction of the resulting bromomethyl derivative with trialkyl phosphite and subsequent condensation of methoxyacrylate **47** with benzaldehyde by the Wittig–Horner–Emmons reaction results in stilbene **18**.⁷⁰

(a) 1. NBS; 2. (RO)₃P; (b) NaH, PhCHO.

R = H, Alk, Hal, Ar, Het; Z = CH₂, O, S, CHOH, CO, CH₂CH₂, CH=CH.

Some *S*-methylmethoxyiminothioacetates that are sometimes more active in trials than compound **14** can be obtained by hydrolysis of methoxyiminoacetic acid esters and subsequent reaction of free acids with sodium methanethiolate¹⁵⁶ in the presence of carbonyldiimidazole.

Methyl *O*-esters and amides of methoxyiminothioacetic acids are obtained by the reaction of esters and amides of methoxyiminoacetic acids with Lawesson's reagent.^{157–159}

VI. Conclusion

The modern approach to the synthesis of pesticides that makes use of the natural compounds for identification of biological targets and for modelling new biologically active substances is well known and has often been employed, *e.g.*, for elaboration of pyrethroid insecticides, nereistoxin analogues, juvenoids, neonicotinoids, 4-hydroxycoumarine derivatives, *etc.* Strobilurin analogues also provide an illustrative example of how bioisosterism can be applied for directed enhancement of properties of natural compounds. Despite high biological and particularly fungicidal activity of methoxyacrylate-type antibiotics, their application for plant protection is impeded due to their high sensitivity to light. Nevertheless, it is on the basis of the natural methoxyacrylates that synthetic agrochemical preparations with a basically new mechanism of action have been obtained.

Analogues of the natural MOA-inhibitors have indisputable advantages over other systemic fungicides because of the lack of natural resistant microbial strains. Thus, ICI-A5504 (compound **13**) efficiently inhibits fungi that are resistant to inhibitors of C-14-demethylase, phenylamides, dicarboximides, and benzimidazoles.⁸⁰

Strobilurins and their analogues constitute a large group of compounds that are hardly inferior to triazole fungicides in structural diversity. They represent a new class of plant-protecting agents that meet all the demands that are made nowadays for pesticides. Intensive studies aimed at a search for novel biologically active pesticides are currently under way by different manufacturers. However, these studies are still in their infancy and so far only three fungicides have been produced by ICI, BASF, and Shionogi. Probably, original products will be offered very soon by Bayer and Roussel UCLAF.

Interest in this group of compounds is increasing with every passing year as can be evidenced from the number of patent applications. The place occupied by strobilurin analogues on the world pesticide market will be evident in due course.

Some peculiarities of synthesis of cysteine-containing peptides

E V Kudryavtseva, M V Sidorova, R P Evstigneeva

Contents

I. Introduction	545
II. Protective groups for the thiol function	545
III. Methods for the formation of disulfide bonds	552
IV. Conclusion	560

Abstract. Data on protective groups for the thiol function of cysteine and methods of disulfide bonds formation used in modern peptide chemistry are considered and systematised. The advantages and disadvantages of protective groups, of reagents used for cyclisation, and possible side reactions associated with them are described. The bibliography includes 119 references.

I. Introduction

Among other peptides and proteins occurring in nature, those containing cysteine constitute a separate group. Disulfide bridges formed between pairs of cysteine residues play an essential role in the stabilisation of tertiary and quaternary structures of the protein molecules by determining their rigid spatial orientation and giving them a unique shape required for the fulfilment of their biological functions. In low-molecular-mass peptides, all types of noncovalent contacts are weakened; therefore, disulfide bonds are of crucial importance for the structural stabilisation of a molecule and reproduction of its biological activity.

Many peptides are known that contain one, two, or more disulfide bridges and take part in the regulation of physiological processes occurring in the organism.^{1,2} Synthetic peptides including those with S–S bonds are widely employed in many areas of medicine and pharmacology.^{3,4} Therefore, the methods used for the formation of disulfide bridges are of great practical significance.

Modern peptide chemistry possesses a wide range of methods for synthesis, purification, and analysis, which allow one to obtain virtually any kind of peptides, their analogues, and even mini-proteins. However, the synthesis of peptides containing disulfide bonds still presents a challenge because of low yields at the stage of their closure. Very often, all efforts spent to synthesise linear precursors come to an overall negative result. Elucidation of the reason for such failures often goes beyond the scope of synthetic studies. The reviews devoted to the synthesis of peptides having

disulfide bridges are very few in number and are often limited to particular aspects of the general problem.

The present review considers modern approaches to the synthesis of cysteine-containing peptides, the groups employed for protection of the thiol function, the methods for their removal, and most popular reagents used for the closure of the disulfide bonds.

II. Protective groups for the thiol function

It is necessary that the strongly nucleophilic thiol group of cysteine be protected in the course of peptide synthesis. The protective groups for the SH function of cysteine should meet the same demands as those for the protective groups of the side-chain functions of other amino acids, *viz.*, stability in the reactions of peptide chain elongation and deblocking of α -amino groups and retention of configuration of the asymmetric centre in the course of synthesis. The protective groups for the thiol function that have been successfully used in peptide syntheses are listed in Table 1. The choice of a protective group is determined by the procedure of subsequent cyclisation. Depending on conditions of cysteine deblocking, one may obtain free thiols or disulfides. The protective groups should possess different chemical stability, which would enable the selective formation of two or more disulfide bonds if required.

In order to characterise protective groups for the thiol function of cysteine used in modern peptide chemistry, Hiskey^{5,6} has proposed to classify them according to the structure of the protected derivatives, *viz.*, sulfides, thioacetals, *S*-acylamido-methyl thiazolidine derivatives, thioesters, and disulfides.

1. Protective groups that form sulfides and related compounds

Protective groups that form this type of compounds (RSR'), are the most well-known, numerous, and popular. The benzyl group proposed by Sifferd and du Vigneaud is an example of a classical protective group that forms sulfides (see Ref. 1). Rather drastic conditions necessary for the removal of the protective benzyl group (Na in liquid ammonia or HF at 25 °C) impose certain limitations on its application. It has been observed^{1,43} that HF results in desulfurisation of the cysteine residue, which may also occur with Na/NH₃. In addition, deprotection with Na/NH₃ is sometimes accompanied by the cleavage of the peptide bonds; the bonds formed by the amino group of proline appear to be the most labile under these conditions.¹ In this connection, it was necessary to design acid-labile protective groups by introducing electron-donor substituents into the aromatic ring of benzyl alcohols. A great number of such protective groups have been synthesised. In

Table 1. The protective groups for the thiol function of cysteine employed in peptide synthesis.

Name ^a	Formula of the protective group	Conditions where the protective group is stable ^b	Conditions for removal of the protective group	Ref.
Benzyl (Bzl)	CH ₂ Ph	HF, 0 °C; Tl(III); B RSCl; H ₂ /Pd; HBr/AcOH TFA; Ag(I); RSCl; B	Na/NH ₃ (liq); HF, 25 °C, 30 min HF/MeOPh, 0 °C, 60 min; ^c Tl(III)	2, 6–8
Methylbenzyl (Meb or Mbzl)	CH ₂ C ₆ H ₄ Me- <i>p</i>			6–9
3,4-Dimethylbenzyl (Dmb)		TFA; Ag(I); B; RSCl	HF/MeOPh, 0 °C, 10 min	8
2,4,6-Trimethylbenzyl (Tmb)		TFA, 23 °C, 2 h	HF/MeOPh, 0 °C, 30 min; TFA, Δ, 1 h	10
4-Methoxybenzyl (Mob)	CH ₂ C ₆ H ₄ OMe- <i>p</i>	B; RSCl; I ₂	HF, 0 °C; Hg(II); Ag(I); Tl(III); (BrC ₆ H ₄) ₃ N; TFA : CH ₂ Cl ₂ (1 : 1), 25 °C ^c	6–8, 10–13
2,4,6-Trimethoxybenzyl (Tmob)		B; Nu	30% TFA/scavengers, ^d I ₂ ; Tl(III), HF	2, 7, 14, 15
<i>tert</i> -Butyl	Bu ^t	TFA; HF, 0 °C; B; I ₂ ; Ag(I)	HF, 20 °C; HF/scavengers, ^d 0 °C; Hg(II); NpsCl; Tl(III)	2, 12, 16
Diphenylmethyl (or benzhydryl) (Dpm)	CHPh ₂	TFA; I ₂ ; ^c Hg(II); ^c Ag(I) ^c	TFA/MeOPh, Δ; HF; Na/NH ₃ (liq); HBr/AcOH; (SCN) ₂ ; NpsCl	5, 17
Di(4-methoxyphenyl)methyl (Ddm)	CH(C ₆ H ₄ OMe- <i>p</i>) ₂	HCl/AcOH; ^c B; Tl(III)	TFA, 70 °C, 2 h; TFA/MeOPh, 10 min; TFA : PhOH (85 : 15), 25 °C, 2 h	1, 5, 8
Triphenylmethyl (Trt)	CPh ₃	B; Nu	TFA/scavengers; ^d Hg(II); Ag(I); I ₂ ; Tl(III); RSCl	1, 2, 5–8, 18
4,4',4''-Trimethoxytriphenyl- methyl (TMTr)	C(C ₆ H ₄ OMe- <i>p</i>) ₃	B; Nu	TFA (dilute); I ₂ (1–2 equiv.), 25 °C, 15–30 min	2, 7
Pyridyldiphenylmethyl	(Ph) ₂ C- 	B	Hg(II) pH 4; Zn/AcOH; electrolytic reduction	19
Dibenzosuberyl		HCl(gas) in organic solvents; TFA; B	HBr/AcOH; ^c HF	6
Fluorenylmethyl (Fm)		HF; TFA; Tl(III) or I ₂ (stable for 1 h)	NH ₃ /MeOH; Pip	5, 20
2-(2,4-Dinitrophenyl)ethyl (Dnpe)	(CH ₂) ₂ - 	HF; I ₂ ; Tl(III); TFA; TFMSA	Pip	21
β,β-Diethoxycarbonylethyl (Dce)	CH ₂ CH(COOEt) ₂	HBr/AcOH	1 M KOH, 20 °C, 5–10 min	1
Adamantyl (Ad)		TFA ⁱ	Tl(III); 1 M TFMSA/PhSMe in TFA, 0 °C	13, 22, 23
Xanthenyl, R = H (Xan), R = 2-MeO (2-Moxan), R = 3-MeO (3-Moxan)		B	dilute acids in the presence of scavengers; ^d I ₂ ; Tl(III)	24
2-Quinolylmethyl	H ₂ C- 	AH	FeCl ₃ /DMF/H ₂ O; FeCl ₂ /DMF/H ₂ O; CuCl ₂ /DMF/H ₂ O	25
Ferrocenylmethyl (Fcm)	C ₅ H ₅ FeC ₅ H ₄ CH ₂	NaOH; NaOMe; I ₂ ; N ₂ H ₄ ; Pip	TFA; (SCN) ₂ ; RSCl; Hg(II); Ag(I)	26

Table 1 (continued).

Isobutoxymethyl (<i>i</i> -Bom)	CH ₂ OBu ^t	B	TFA; HCl/AcOH; Hg(II)	5, 6, 8
<i>p</i> -Chlorophenoxymethyl	CH ₂ OC ₆ H ₄ Cl- <i>p</i>	B	TFA	5
Benzylthiomethyl (Btm)	CH ₂ SCH ₂ Ph	B	HF; Hg(AcO) ₂ /HCOOH (80%), 25 °C, 20 min	5, 6, 8
Phenylthiomethyl	CH ₂ SPh	B	HF; Hg(II)	5
Acetamidomethyl (Acm)	CH ₂ NHCOMe	HF, 0 °C; B; H ₂ /Pd	Ag(I); Hg(II); I ₂ ; Tl(III); AgBF ₄ ; RSCl	2, 5, 6, 8, 18, 28, 29
Trimethylacetamidomethyl (Tacm)	CH ₂ NHCOBu ^t	HF; TFA; 1 M TFMSA; B	Hg(AcO) ₂ ; TFA/MeOPh; I ₂ (10 equiv.) in AcOH; AgBF ₄	28–31
Phenylacetamidomethyl (Phacm)	CH ₂ NHCOCH ₂ Ph	HF; B	Hg(II); I ₂ ; Tl(III); penicilline aminohydrolase	2, 32, 33
Benzamidomethyl (Bam)	CH ₂ NHCOPh	AH, B	Ag(OTf); Hg(II)	6, 18
(2-Oxo-1-pyrrolidino)methyl (Pym)		B	Hg(II); I ₂ /MeOH	34
Acetyl (Ac)	COMe	TFA (boiling); HBr/AcOH	0.1 M NaOMe/MeOH, 25 °C, 5–10 min; N ₂ H ₄ /MeOH	1, 5, 8
Benzoyl (Bz)	COPh	TFA (boiling); HBr/AcOH	0.1 M NaOMe/MeOH, 25 °C; N ₂ H ₄ /MeOH; 0.2 M NaOH	1, 5, 8
Benzylloxycarbonyl (Z)	COOCH ₂ Ph		0.1 M NaOMe/MeOH, 25 °C; aqueous alkali; NH ₃ ; Na/NH ₃ (liq); TFA/PhOH, Δ; HBr/AcOH	1, 5, 8
<i>p</i> -Methoxybenzylloxycarbonyl (pMZ)	COCH ₂ C ₆ H ₄ OMe- <i>p</i>		TFA, 20 °C; 0.2 N HBr/AcOH; HCl/AcOH; 0.5 N NaOMe in DMF; Na/NH ₃ (liq)	1, 8
<i>tert</i> -Butoxycarbonyl (Boc)	COOBu ^t		AH (TFA)	8
<i>p</i> -Nitrophenoxycarbonyl	COOC ₆ H ₄ NO ₂ - <i>p</i>		AH(TFA); Na/NH ₃ (liq)	5
Phenylthiocarbonyl	COSPh		AH	5
Butylthiocarbonyl	COSBu		AH	5
Ethylcarbamoyl (Ec)	CONHEt	4.5 M HBr/AcOH; 1 M HCl; TFA, Δ	Na/NH ₃ ; 4 M NH ₃ ; NH ₃ (liq); MeOH (1 : 1); 1 M NaOH; NaOMe; N ₂ H ₄ /MeOH; Hg(II) (pH 7); Ag(I) (pH 7)	5, 6, 8
<i>N</i> -Methoxymethylcarbamoyl	CONHCH ₂ OMe	AH	Na/NH ₃ (liq); NaOMe/MeOH; aqueous buffers (pH 9.5), 25 °C	8
<i>N</i> -[β-(<i>N</i> -Acyl- <i>N</i> -methylamino)-ethyl]carbamoyl	CONHCH ₂ CH ₂ N(R)Me R = PhCH ₂ OCO, Bu ^t OCO		AH	6
Alkylthio (SEt, SPr ⁱ , STrt)	SR R = Et, Pr ⁱ , CPh ₃	AH; NH ₄ OH; NaOH	β-mercaptoethanol; benzenethiol (pH 7.5–9); dithiothreitol; Bu ₃ P; oxidative sulfitolysis	6, 8, 35
<i>tert</i> -Butylthio (SBu ^t)	SBu ^t	HCl/dioxane; Pip; TFA; RSCl; B	Na/NH ₃ ; RSH; Bu ₃ P; 2-pyridinesulfonyl chloride; <i>o</i> -nitrobenzenesulfonyl chloride	2, 6, 8, 17, 35–37
Methoxycarbonylthio (Scm)	SCOOMe	HF; AH	RSH; mild alkaline reagents (pH 10.6)	1, 6, 8, 35, 36
(<i>N</i> -Methyl- <i>N</i> -phenylcarb-amoyl)thio (Snm)	SCON(Me)Ph	HF	RSH (especially dithiothreitol and 2-pyridinethiol)	2

Table 1 (continued).

Name ^a	Formula of the protective group	Conditions where the protective group is stable ^b	Conditions for removal of the protective group	Ref.
3-Nitro-2-pyridylthio (Npys)		HF, 0 °C (in the absence of thiols); TFA, 25 °C; ^c HOBT/DCC	RSH or other reducing agents	2, 38–41
<i>tert</i> -Butoxycarbonylthio (SCB)	SCOOBu ^t		B and AH	36
Benzoyloxycarbonylthio (SZ)	SCOOCH ₂ Ph	TFA; weak bases	40% HBr/AcOH; strong bases	36
Sulfonates	SO ₃ Na	B	Bu ₃ P; β-mercaptoethanol, dithiothreitol	42

^a The abbreviations of protective groups cited in Ref. 8 are given; ^b the following notations are adopted: B are bases; TFA is trifluoroacetic acid; Nu are nucleophiles; NpsCl is 2-nitrobenzenesulfonyl chloride; Pip is piperidine; TFMSA is trifluoromethanesulfonic acid; AH are acids; HOBT is *N*-hydroxybenzotriazole; DCC is dicyclohexylcarbodiimide; ^c partial removal; ^d scavengers are compounds that neutralise carbocations formed upon splitting of protective groups; ^e low stability.

Table 1, they are listed in the order of the increase in their acid lability. The most acid-labile group is *S*-2,4,6-trimethoxybenzyl protection,^{5, 7, 14} which is easily removed with 30% trifluoroacetic acid (TFA) in CH₂Cl₂ in the presence of phenol, thioanisole, or water (the so-called scavengers whose purpose is to neutralise the carbocations formed upon cleavage of protective groups) as well as with 5% TFA in CH₂Cl₂ in the presence of 3% triethylsilane or tri(isopropyl)silane. Scavengers are necessary to prevent the reverse addition of the trimethoxybenzyl group to the SH group.¹⁴ The distinctive feature of methoxy- and trimethoxybenzyl protective groups is the possibility of their removal with heavy metal salts, *e.g.*, Ag(I) and Hg(II), which makes it possible to selectively deblock cysteine.^{7, 11, 15} The mechanism of this reaction is analogous to that of splitting of trityl and acetamidomethyl groups and will be considered in more detail in subsequent sections.

S-tert-Butyl protection is extremely acid-resistant. Its removal can be accomplished with HF or Hg(AcO)₂ in TFA.^{2, 12} Quantitative removal of the *tert*-butyl group can be achieved with the use of strongly electrophilic reagents, such as 2-nitrophenylsulfenyl chloride, which binds two cysteine residues through intermediate mixed disulfides² (this reaction will be considered below). However, this reagent cannot be used if the peptide chain contains tryptophan because side reactions may occur in the indole ring.¹⁶

The next type of protective groups includes di- and triarylmethyl groups. In Table 1, they are also presented in the order of the increase in their acid lability:

The ease of removal of these protective groups under mild acidic conditions makes them attractive for solid-phase peptide synthesis, which makes use of *N*⁹-9-fluorenylmethoxycarbonyl derivatives of amino acids (the Fmoc-technique).^{4, 44, 45} Cleavage of these sulfides occurs faster than that of their *tert*-butyl and benzyl analogues. This is due to the greater stability of the carbocations formed; however, their higher reactivity can result in the reverse alkylation reaction of cysteine. Thus in the case of the triphenylmethyl protection, an equilibrium between the protected and free cysteine is established in TFA in 30 min and in most cases the degree of *S*-detritylation does not exceed 60%.^{1, 8} The reaction equilibrium can be shifted to the right by addition of scavengers (especially, sulfur-containing ones) or water to the reaction mixture.^{1, 5, 16}

In terms of its reactivity, the Ddm group occupies an intermediate position between the Trt and Dpm groups⁵ and is much more acid-labile than the triphenylmethyl group. This permits selective removal of the Ddm group without affecting the Trt

group.^{1, 5, 8} On the other hand, the resistance of Ddm protection to heavy metal salts allows selective splitting of the Trt group in the presence of Ddm deprotection.

Cleavage of the Trt group can be carried out with Hg(II) or Ag(I) ions.⁵ The mechanism of cleavage of sulfides with metal ions is similar to the mechanism of the acid-catalysed reaction: the difference between these mechanisms is that in the case of metal ions the last stage is irreversible and leads to a stable carbocation, which can be formed by two routes:

In some cases, silver salts are more efficient than mercuric salts, because mercuric derivatives of peptides (mercaptides) are sometimes difficult to cleave.⁵ Metal mercaptides are usually destroyed by thio alcohols. To this end, the reaction product is treated *in situ* with a 20–50-fold excess of a reducing reagent in an appropriate buffer, such as dithiothreitol or β-mercaptoethanol.^{2, 18} The reduced product is purified by gel filtration, ion-exchange chromatography, or HPLC to remove the excess of the reducing reagents. Hg(II) ions are usually removed with hydrogen sulfide.

Owing to the stabilising effect of three electron-donor methoxy groups, the TMTr protective group produces a more stable carbocation than the Trt group, which determines its specificity. The distinctive feature of this protective group is its extremely high acid lability. Deprotection is performed with dilute solutions of TFA.⁷ The tris(methoxyphenyl)methyl carbocation formed, like the trityl carbocation, can enter into the reverse reaction, *viz.*, alkylation; therefore, the use of scavengers is obligatory in this case. Both Trt and TMTr protective groups may be split off together with simultaneous closure of the disulfide bonds with iodine or thallium trifluoroacetate (see Section III).

The *S*-pyridyldiphenylmethyl group is not so popular in peptide synthesis. Only a few examples concerning this protective group are documented.¹⁹ The *S*-dibenzosuberyl protective group is also used rather seldom. In its chemical properties and deblocking conditions, it is similar to the Ddm group.⁶ The *S*-9-fluore-

nylmethyl protective group^{5,20} is one of the few groups that is removed under basic conditions, as a rule, this is performed by treatment with piperidine in DMF. The stability of this protective group under conditions of TFA treatment and in anhydrous HF makes possible its application in solid-phase syntheses, whereas its resistance to Ti(III) and I_2 allows its selective removal in the presence of such protective groups as Acm , Trt , Meb , *etc.*, and selective formation of disulfide bonds. Yet another example of a base-labile protective group is the 2-(2,4-dinitrophenyl)ethyl group.²¹ The electron-acceptor nitro groups in *ortho*- and *para*-positions make this group similar to Fm as regards its stability in the presence of strong acids and splitting by bases by a β -elimination mechanism. The presence of nitro groups allows one to increase the solubility of Dnpe derivatives in polar solvents. Like Fm , this group is completely stable under conditions of classical and solid-phase syntheses, which employ *N*²-*tert*-butoxycarbonyl derivatives of amino acids (Boc-technique)^{4,45} as well as under conditions of splitting of a peptide from the polymer with HF or trifluoromethanesulfonic acid.

Yet another alkali-labile protective group is S - β , β -di(ethoxycarbonyl)ethyl group.¹ It is easily split off by the β -elimination reaction upon treatment with 1 M KOH .¹

The advantages of the S -adamantyl (Ad) protective group,²² although it is used rather seldom, are best manifested in comparison with Mob protection. The adamantyl protective group is more resistant to TFA: the degree of cleavage is only 10% over 2.5 h at 0 °C. It is quantitatively removed with a mixture of 1 M $\text{CF}_3\text{SO}_3\text{H}$ and PhSMe in TFA (60 min, 0 °C) or $\text{Ti}(\text{CF}_3\text{COO})_3$ in TFA.^{13,22,23}

Xanthenyl and its 2(3)-methoxy derivatives are new protective groups for the thiol function of cysteine.²⁴ These acid-labile groups are eliminated by dilute acids in the presence of appropriate scavengers. An alternative procedure for their removal is the treatment with I_2 or $\text{Ti}(\text{F}_3\text{CCOO})_3$, which allows direct synthesis of cyclic disulfides.²⁵

The use of a novel quinolin-2-ylmethyl protective group has been reported.²⁵ A new procedure for the direct conversion of its derivatives into symmetrical disulfides includes treatment with FeCl_3 , FeCl_2 , and CuCl_2 .²⁵

Two new protective groups (Fc and Fcm) containing a ferrocenylmethyl fragment also deserve special mention.²⁶ These groups are rather stable under basic conditions and in the presence of reducing reagents, such as NaBH_4 and Zn in AcOH , although the Fc group is partly eliminated under these conditions. Both protective groups are rapidly split off by electrophilic reagents, *e.g.*, thiocyanogen ($\text{SCN})_2$, methoxycarbonylsulfonyl chloride, and TFA. The Fc group can be also cleaved with formic acid. Iodine only partly destroys the Fc and Fcm protective groups. Removal of both these protective groups by acids is efficient only in the presence of scavengers (*e.g.*, benzenethiol), which capture the ferrocenylcarbenium ion formed. Fcm protection, which was used in combination with *N*²-Boc or *N*²-Fmoc protections, is of greatest importance for the peptide synthesis. In this case, *p*-toluenesulfonic acid was used for selective removal of Boc protection.²⁶

The $(\eta^5\text{-cyclohexadienyl})\text{tricarbonyl iron}$ complex $\{[(\eta^5\text{-C}_6\text{H}_7)\text{Fe}(\text{CO})_3]^+\}$ was successfully used to protect the thiol function of cysteine in the synthesis of a model peptide $\text{Ac-Cys-Gly-Ala-OEt}$.²⁷ Owing to the high affinity of this complex for the SH group of cysteine, the formation of the corresponding adduct occurs rapidly and without side reactions. Protected derivatives are bright yellow coloured, which facilitates monitoring of their purification on silica gel.²⁷

2. Protective groups that form mono- and di-thioacetals

Protective groups that form mono- ($\text{S}-\text{C}-\text{O}$) and di-thioacetals ($\text{S}-\text{C}-\text{S}$) are not numerous and seldom used for cysteine protection.

The protective groups of the thioacetal type, *viz.*, tetrahydropyranyl, isobutoxymethyl, *p*-chlorophenoxymethyl, benzylthio-

methyl, and phenylthiomethyl groups, are stable under alkaline conditions and can be removed by acids. The ease of their cleavage with acids decreases in the following order: acetals $\gg$ monothioacetals $\gg$ dithioacetals, and is determined by the same factors as for sulfides, *viz.*, the ease of protonation, the stability of the cation formed, and the possibility of irreversible reactions that shift the equilibrium towards the cleavage products.⁵ S -Monothioacetal derivatives of cysteine react with acids at the same rates as do trityl sulfides, whereas S -dithioacetal derivatives resemble $\text{Cys}(\text{Bzl})$ and $\text{Cys}(\text{Bu}^t)$ under acidolysis conditions. According to the ease of their acidolysis, the protective groups are arranged in the following order:⁸

Cleavage of mono- and di-thioacetals is more efficient with Hg(II) and Ag(I) salts.⁵ The conditions for selective cleavage have been established for virtually each protective group.⁸ The mechanism of cleavage of mono- and di-thioacetals by metal ions seems to be analogous to the mechanism of cleavage of sulfides. The formation of the $\text{M}-\text{S}$ bond weakens the $\text{C}-\text{S}$ bond. The formation of a cation is the rate-determining step of this reaction. The rate of cleavage depends of the cation stability.⁵

As with sulfides, regeneration of free thiols is achieved by treatment with a great excess of mercaptoalcohols or hydrogen sulfide. It is still uncertain whether selective cleavage of S -monothioacetals can be performed in the presence of S -dithioacetals, disulfide bonds, and other protective groups that are sensitive to heavy metal ions.⁵

Direct oxidation of monothioacetals into disulfides by halogens is inapplicable to cysteine derivatives. However, there is evidence of removal of the S -Thp group from the A-chain of synthetic insulin by its direct conversion into a symmetric disulfide using $(\text{SCN})_2$.^{5,6}

3. S -Acylamidomethyl protective groups

The acetamidomethyl protective group the introduction of which can be accompanied by the formation of thiazolidine derivatives is widely employed in the synthesis of cysteine-containing peptides owing to its high stability in acidic and alkaline media and under conditions of catalytic hydrogenolysis. It is used in combination with Boc, Fmoc, and benzyloxycarbonyl protections of the α -amino group in classical and solid-phase syntheses of peptides. However, there are a few reports on the partial loss of the Acm protective group on repeated treatment of the peptide chains with HF needed for their splitting from the polymer.³⁰ The Acm protection is stable under conditions of acid-catalysed removal of Meb , Mob , Trt , and Tmob groups. Specially selected conditions of deprotection of the thiol function of cysteine with heavy metal salts in appropriate solvents ensure selective removal of the S - Acm group in the presence of Bzl and Bu^t groups. Reaction with Hg(II) salts yields an intermediate peptide-metal compound. When Hg(II) salts are used in acidic aqueous solutions, the reaction is completed within 1–2 h.⁶ Deblocking can also take place in organic solvents, *e.g.*, in DMF .²

R is the peptide residue.

As in the case of removal of Trt protection, subsequent treatment with hydrogen sulfide or mercaptoalcohols yields free thiol groups. If Hg(II) salts are used for removal of Acm protection from the SH group of cysteine in tryptophan-containing peptides, side reactions can occur.⁴⁶ Thus treatment of a bis-Acm derivative of somatostatin with a large excess of Hg(AcO)₂ (5–20 equiv. per one Acm group) in 1%–10% acetic acid results in substitution of hydrogen in positions 2 and 7 by the HgOAc group to form mono- and bis-mercuriacetates of tryptophan.

Treatment of these derivatives with β -mercaptoethanol results in the substitution of the Hg(AcO)⁺ group by HOCH₂CH₂S to yield undesirable side products. Acetoxymercuration can be avoided by decreasing the amount of Hg(AcO)₂ to 1–2 equiv. and by using 50% acetic acid.⁴⁶

There is evidence of the possibility of S $\rightarrow$ N and S $\rightarrow$ O migrations of the Acm protective group to the side carboxamide groups of asparagine and glutamine^{2,47} and to the hydroxy groups of serine and threonine.^{2,48,49} The migration of the Acm protective group to the side chain of glutamine (S $\rightarrow$ N migration) was observed in the deprotection of the thiol function of cysteine with I₂ in MeOH. This side reaction is inhibited by an excess of glutamine as a scavenger.⁴⁷ S $\rightarrow$ O Migration was observed in the deprotection of cysteine with Tl(III) and Hg(II) salts in a peptide containing several serine and threonine residues.⁴⁸ This reaction is efficiently inhibited by three-carbon alcohols (e.g., glycerol) as scavengers.^{2,48}

The anion plays an important role in the removal of the Acm group with Ag(I) salts. The reaction occurs with silver nitrate,⁵ trifluoromethanesulfonate,¹⁸ trifluoroacetate,¹⁸ and tetrafluoroborate.²⁸ Silver acetate does not remove the Acm protection. Deprotection of cysteine with silver trifluoroacetate requires that the excess of the deblocking reagent to be twice as high as that with silver trifluoromethanesulfonate. The reaction time is also twice as long;¹⁸ therefore the use of AgOTf is preferable. Silver salts are removed by large (up to 50 equiv.) excess of β -mercaptoethanol or dithiothreitol.¹⁸ Then, the reaction mixture is purified by gel filtration. This deblocking procedure does not affect such highly sensitive amino acids as methionine, tryptophan, and tyrosine.

Direct conversion of di-Acm substituted peptides into disulfides upon treatment with iodine is an attractive method for the removal of the Acm protective group.

This method will be considered in more detail in Section III.

Recently, trimethylacetamidomethyl, phenylacetamidomethyl, and benzamidomethyl protective groups, which can be regarded as derivatives of acetamidomethyl protection, have gained wide acceptance. The properties of benzamidomethyl protection are identical with those of the Acm group.^{6,18} It is also sensitive to AgOTf. However, the removal of the Bam group takes more time than the removal of the Acm protection.¹⁸

Yoshida *et al.*^{28–31} have proposed to use the trimethylacetamidomethyl group to protect the SH function of cysteine. It was found that under conditions of post-synthetic deblocking of the side functional groups of peptides with HF or NaOH, the Tacm and Acm groups, unlike the Bam group, were sufficiently stable. The authors³⁰ attribute the ease of introduction of the protective group and high yields of protected cysteine derivatives to salient advantages of Tacm protection. It should be mentioned that the formation of a side product (thiazolidine-4-carboxylic acid) cannot be avoided in the synthesis of *S*-acetamidomethylcysteine.³⁰

The phenylacetamidomethyl protective group^{32,33} is stable and is split off under the same conditions as the Acm group. Its distinctive feature is the possibility to be cleaved by penicillin aminohydrolase.² Therefore, the Phacm group is orthogonal with respect to Acm protection. First, it is possible to remove the Phacm group enzymically and then the Acm group is removed by treatment with heavy metal salts or iodine.^{2,33}

The 2-oxopyrrolidinomethyl group is resistant to reagents of peptide synthesis in a broad range of pH (from 0.5 to 13). In its resistance to alkalis, it surpasses the Bam group.³⁴ Cleavage of the Pym protection with simultaneous formation of the disulfide bond is achieved by treatment with I₂ in MeOH.³⁴

4. Protective groups that form thioesters and related compounds

Protective groups that form thioesters (RCOSR') include acetyl, benzoyl, benzyloxycarbonyl, *p*-methoxybenzyloxycarbonyl, *tert*-butoxycarbonyl, and *p*-nitrophenoxycarbonyl groups. Dithiocarbonates (RSCOSR') are represented by derivatives with phenylthiocarbonyl and butylthiocarbonyl protective groups and *N*-(alkyl)thiocarbamates (RNHCOSR'), with *N*-ethylcarbamoyl, *N*-methoxymethylcarbamoyl, and *N*-[β -(*N*-acyl-*N*-methylamino)ethyl]carbamoyl protective groups.

A characteristic feature of thioesters (acetyl and benzoyl protections), thiocarbonates (benzyloxycarbonyl, *p*-methoxybenzyloxycarbonyl, *p*-nitrophenoxycarbonyl protections), and thiocarbamates (*N*-ethylcarbamoyl and *N*-methoxymethylcarbamoyl protections) is their sensitivity to nucleophiles and bases. Similarly to the corresponding esters and urethanes, thiocarbonates containing a benzyloxycarbonyl group and its analogues as well as Boc-protection are also cleaved in acidic media and with even greater ease.⁸ Dithiocarbonates (phenylthiocarbonyl and butylthiocarbonyl protections) and thiocarbamate (*N*-[β -(*N*-acyl-*N*-methylamino)ethyl]carbamoyl protection) are cleaved only with acids. Alkaline treatment of thioesters can induce base-catalysed disulfide exchange, which can result in the formation of polymer mixtures and peptide parallel and antiparallel dimers. The side reaction of β -elimination, which is accompanied by elimination of thiobenzoic acid from the corresponding Cys(Bz) derivatives in peptides, can also take place.⁵ The occurrence of this reaction depends on the solvent polarity; therefore one must avoid the addition of DMF to the reaction mixtures in the treatment of cysteine-containing peptides with bases, such as NaOMe.⁵ Cleavage of *S*-acyl groups can be achieved by treatment with hydrazine in methanol. Under these conditions, Ac protection is split off rapidly as the corresponding acethydrazide without β -elimination.

A peculiar side reaction was observed when the protected peptide Z-Cys(Bz)-Ser(Bz)-OMe was treated with NaOMe in MeOH.¹ The serine residue was converted into an α -aminoacrylic acid residue, and the addition of the deblocked SH group to the double bond yielded products 1 and 2:

A serious limitation to the use of Ac, Bz, Z, pMZ, Boc, nitrophenylthiocarbonyl, butylthiocarbonyl, *N*-methoxymethyl-carbamoyl, Ec-, and $[\beta$ -(*N*-acyl-*N*-methylamino)ethyl]carbamoyl acyl protective groups is their proneness to S $\rightarrow$ N acyl migration. Such migration takes place in the course of elongation of the peptide chain as soon as a free amino group appears.^{5,8} This side reaction has been observed both in the classical and solid-phase peptide syntheses.⁶ When acetyl and benzoyl protective groups were used in solid-phase synthesis for protection of the thiol function of cysteine, a nearly quantitative chain growth termination occurred due to the interaction of the deblocked SH group with the residual chloromethyl groups of the polymeric support after S $\rightarrow$ N migration.⁶ Nevertheless, Ac and Bz groups are used to protect cysteine residues in solid-phase syntheses of protected peptide fragments designed for fragment condensation. The S $\rightarrow$ N acyl migration can be suppressed if highly reactive derivatives (*e.g.*, mixed anhydrides with pivalic acid) are used for the formation of the amide bond.⁵ In this case, the rate of aminolysis significantly exceeds the rate of S $\rightarrow$ N migration. The benzyloxycarbonyl group also undergoes S $\rightarrow$ N migration, but this reaction proceeds at a much slower rate. The formation of side products can be avoided in this case if condensation is carried out with pivaloyl chloride or diphenyl phosphorochloridate.⁵

The *p*-methoxybenzyloxycarbonyl protective group is distinguished by higher stability of the cation formed on its splitting and can therefore be removed not only by alkalis, but also by acids. However, its application is limited due to the difficulty of its introduction (the yields are about 30%) and high lability with respect to acids and alkalis.⁵

The *N*-ethylcarbamoyl and *N*-methoxymethylcarbamoyl protective groups are resistant to acids and easily removed by basic reagents (as a rule, without racemisation and desulfurisation), they do not undergo S $\rightarrow$ N migration. Thus, they present substantial practical interest.^{6,8} The possibility of partial splitting of the Ec group with an excess of triethylamine during solid-phase synthesis with the use of the Boc-technique (at the stage of neutralisation of the peptidyl polymer or on repeated condensation) restricts the application of this protective group.

The use of *S*-[*N*-β-(*N*-alkoxycarbonyl-*N*-methylamino)ethyl]-carbamoyl protective group, yet another group of the ethylcarbamoyl type, has been reported.⁶ In order to deblock compound **3** in which the thiol function of cysteine is protected by this group the alkoxycarbonyl (*Z* or *Boc*) group is removed by acid treatment. The resulting *N*-β-(methylamino)ethylcarbamoyl derivative **4** is cyclised to yield 1-methyl-2-imidazolidone **5** and the target thiol-containing peptide **6**.⁶

5. Protective groups that form disulfides

Disulfide derivatives (R-S-S-R') obtained after blocking of the SH group include symmetrical and asymmetrical cysteine disulfides, *S*-sulfonates, *S*-alkyl(aryl)thio, *S*-alkoxycarbonylthio derivatives, and sulfamides. Symmetrical disulfides are very seldom used in modern peptide chemistry for synthetic purposes. Ethylthio, isopropylthio, triphenylmethylthio, *tert*-butylthio, methoxycarbonylthio, (*N*-methyl-*N*-phenylcarbamoyl)thio, and 3-nitro-2-pyridinethio protective groups that form asymmetrical disulfides are good alternatives to the protective groups described above owing to their lability with respect to aliphatic and aromatic thiols. A specific feature of some of these groups (Scm, Snm, Npys) is their ability to form intra- and intermolecular disulfide bonds as soon as cysteine is deblocked. Here, the SH groups of peptide thiols play the role of a deblocking reagent (this problem will be considered in detail in Section III).

S-Methoxycarbonylthio derivatives of cysteine are highly reactive compounds.^{6,35,36} Their reactivity with respect to thiols is greater than that of *S*-sulfonates and is comparable with that of sulfenyl thiocyanates or sulfenyl iodides, which are intermediates in the closure of disulfide bonds by the corresponding reagents (see Section III). The advantages of the Scm group are the stability of protected derivatives and the irreversibility of their reaction with thiols, unlike the reaction of sulfenyl iodides and sulfenyl thiocyanates.⁶ Owing to its stability in acidic media, the Scm group can be used in solid-phase syntheses using the Boc-technique.

Cleavage of disulfides is performed in aqueous solutions (pH 7.5–9.0) with thiols, such as β -mercaptoethanol or benzenethiol, which is a stronger nucleophile.⁸ The reaction with thiols is based on the thiol–disulfide exchange. In order to shift the equilibrium in the direction of the target product, thiol must be employed in a large excess. Deblocking can also be achieved with a small excess of dithiothreitol, where the equilibrium is shifted due to the intramolecular cyclisation of the reagent, or with 1 equiv. of tributylphosphine at pH 8.⁸ Phosphines are specific reagents for cysteine and reduce only disulfide bonds; this reaction is selective.¹⁷ Disulfides may also be cleaved by oxidative sulfitolysis. The resulting *S*-sulfonates are reduced with thiols or aqueous solutions of thio acids with gentle heating.⁸

It is known that disulfide derivatives are relatively resistant to acids. Their stability decreases in the following order: $\text{RSSBu}^t > \text{RSSPr}^i \sim \text{RSSEt}$. Thus the SBu^t group is cleaved by treatment with liquid HF for 1 h at 0 °C.^{2,6} The SPr^i and SEt groups can be split off with hydrogen chloride in AcOH .⁶ Only the SBu^t group is of practical value and has been successfully used in solid-phase synthesis using the Boc and Fmoc techniques.^{36,37} The majority of mixed disulfides (Table 1) are resistant to ammonia and alkalis, which are used to split the peptides from the polymeric supports with phenolic and phenacyl anchor groups.⁸

Alkoxy-carbonylthio (*tert*-butoxycarbonylthio and benzyloxycarbonylthio) protective groups were proposed by Nokihara and Berndt.³⁶ Unfortunately, SCB derivatives proved to be not very stable on storage. Thus the cysteine derivative ZCys(SC-B)OMe turned into its cysteine analogue within 3 months. In addition, the high lability of SCB protection with respect to alkalis restricts its application in peptide synthesis.³⁶ The benzyloxycarbonylthio protective group is stable in TFA. It is more resistant to alkalis than the methoxycarbonylthio (Scm) group and can be removed by treatment with strong alkalis, though this is preserved for 2 h at pH 10.6, which results in complete removal of the Scm protection. Therefore, the SZ group can be used both for the protection of the SH group of cysteine and for the selective formation of cystines.³⁶

The *N*-methyl-*N*-phenylcarbamoylthio protective group is resistant to acids and can therefore be used in peptide syntheses with the Boc-technique. The possibility of removal of this protective group by alkaline treatment has not been finally clarified.²

Like Scm protection, the 3-nitro-2-pyridylthio and *N*-methyl-*N*-phenylcarbamoylthio protective groups may selectively generate disulfide bonds in the presence of free SH groups. These groups are removed by thiolysis, which occurs in accordance with the Scheme:^{38, 39}

It has been found³⁹ that Npys protection is the most efficiently split off with aliphatic thiols, such as β -mercaptoethanol or mercaptoacetic acid: when the thiols are taken in a 10-fold excess over 3-nitro-2-pyridylthio derivatives, the reaction is completed within 10 min. The S–Npys bond is rather resistant to the action of aromatic thiols, 1-methylimidazole-2-thiol, and pyridine-2-thiol. In this case, selective cleavage of the O–Npys and N–Npys bonds may occur.³⁹ Albericio *et al.*⁴⁰ have shown that the Npys group is more stable under standard conditions of peptide synthesis using the Boc-technique (HF, TFA, and tertiary amines) in comparison with the methoxycarbonylthio group. The Npys protection for the thiol function of cysteine is absolutely stable in solvents and reagents used in solid-phase syntheses using the Boc-technique, *e.g.*, CH_2Cl_2 , DMF, *N,N*-dimethylacetamide, *N*-methylpyrrolidone, MeOH, trifluoroethanol, dioxane, in a mixture of 40% TFA and CH_2Cl_2 , this also withstands treatment with HF (to which 10% anisole or *p*-cresol is added) for 1 h at 0 °C. Thus, the Npys group is virtually resistant under conditions of HF cleavage by the high technique.⁴⁰ The low-high technique is inapplicable in this case, since the use of *p*-thiocresol and dimethyl sulfide results in the loss of lateral Npys groups.⁴⁰ The data on the resistance of Npys protection to *N*-hydroxybenzotriazole are contradictory.^{40, 41} Partial (12%) cleavage of the Npys group was observed in the treatment with 0.1 M solution of this reagent in DMF.⁴¹ Therefore, the method of activated *p*-nitrophenyl and pentafluorophenyl esters was employed to form the amide bond (condensation).^{4, 40, 50} Matsueda *et al.*⁴¹ have successfully used *N,N'*-dicyclohexylcarbodiimide with *N*-hydroxybenzotriazole to attach Boc-Cys(Npys)-OH in the synthesis of a series of peptides. The protective Npys group was found to be very labile under conditions of solid-phase synthesis using the Fmoc-technique, but was sufficiently stable in the photolytic cleavage of peptides from the polymer.⁴⁰

Of interest is the report on the use of base-resistant *S*-sulfonates [Boc-Cys(SO_3Na)-ONa] and [Fmoc-Cys(SO_3Na)-ONa] in peptide synthesis.⁴² Deblocking of cysteine may be achieved by treatment with tributylphosphine, β -mercaptoethanol, and dithiothreitol.⁴² Splitting of the peptide from the polymer with TFA–*p*-cresol systems leads to partial loss of sulfonates.

III. Methods for the formation of disulfide bonds

Despite the intensive progress in methodology of peptide chemistry, the formation of disulfide bonds still presents a serious problem. Its solution involves: (1) the choice of a protective group for the thiol function of cysteine and (2) the selection of a method for the formation of a disulfide bridge. These two aspects are closely interrelated, for the choice of a protective group is the principal factor that predetermines the selection of the method for the formation of the S–S bonds. This problem becomes more complicated in the case where several disulfide bonds are to be formed. The so-called ‘orthogonal’ scheme of synthesis allows selective closure of disulfide bonds between definite cysteine

residues without involvement of other protected residues or the preformed disulfide bridges. In this case, the choice of protective groups that can be selectively split off and the cyclisation procedure are of crucial importance.⁸ In any case, the cyclisation process is very complicated and its successful outcome depends on many factors, such as the correct choice of the solvent, temperature, pH of the reaction medium, concentration of reagents, type of the oxidant, and so on. The methods for cyclisation can be arbitrarily classified into three groups:²

A. Deprotection and formation of a disulfide bond starting from the corresponding SH-derivatives of peptides.

B. Deprotection with simultaneous closure of the ring.

C. Closure of the disulfide bond by thiolysis. This entails two possibilities: (1) The protective group of one of cysteine residues (X^*) enhances the electrophilicity of the sulfur atom (activation). This facilitates the cleavage of the bond between the sulfur atom and the protective group in the thiolysis. The free SH group of the other cysteine residue is the necessary thiol. In this case, $\text{X}^* = \text{X} = -\text{SCOOMe}$, $-\text{SCON}(\text{Me})\text{Ph}$, 3-nitro-2-pyridylthio, *etc.* (2) The protective groups $\text{X} = \text{CPh}_3$, CH_2NHCOMe , Bu^t , *etc.*, are split off with $(\text{SCN})_2$, 3-nitro-2-pyridinesulfonyl chloride, 4-nitrobenzenesulfonyl chloride, and other reagents to form activated asymmetrical disulfides ($\text{X}^* = \text{SCN}$, 3-nitro-2-pyridylthio, 4-nitrophenylsulfonyl) that can enter into the reactions of thiol–disulfide exchange:

1. Formation of disulfide bonds in SH-derivatives of peptides

Group A methods envisage the blocking of two cysteine residues by identical protective groups that are removed under identical conditions, purification of linear polythiols, and oxidation of SH groups with any appropriate reagent providing the formation of intra- or intermolecular disulfide bonds. Oxidation of free thiols is usually carried out in highly dilute solutions at the peptide concentration 10^{-4} – 10^{-5} M in order to avoid intermolecular coupling and side reactions.^{2, 8} Direct formation of the S–S bonds in dilute solutions strongly depends on the peptide structure, particularly on the nature of the amino acids separating two cysteine residues and the number of amino acids between them.^{51, 52} If the number of amino acids between two cysteine residues (*n*) is from 4 to 20, the intramolecular S–S bonds are predominantly formed under conditions of high dilution (10^{-3} – 10^{-4} M). At $n < 3$, the limited chain flexibility results in dimers and polymers that are formed in addition to the peptides with the intramolecular S–S bonds.⁵¹ The formation of the disulfide bond between the neighbouring cysteine residues demands very strong oxidants, such as thallium(III) trifluoroacetate.⁵³ The ability to form intrachain disulfide bonds depends also on the structural stability of the disulfide loop. Thus the oxidation of peptides is facilitated by the presence in the amino acid sequence of Pro-Gly residues involved in the formation of β -folds of proteins and peptides. Many peptides (*e.g.*, oxytocin) can be readily oxidised by atmospheric oxygen. Peptide fragments of proteins having the Pro-Pro sequence between two cysteine residues are difficult to oxidise and can form only symmetrical dimers.⁵¹

a. Oxidation with atmospheric oxygen

Atmospheric oxygen is often used to oxidise thiol groups of cysteine to yield disulfides. This reaction is usually carried out in weakly alkaline solutions at pH 7.5–8.5 with vigorous stirring or by bubbling air through the reaction mixture. The required level of pH is usually maintained by adding ammonia,^{54,55} or other reagents, such as ethyldiisopropylamine.^{55,56} In some cases, cyclisation occurs much faster when ethyldiisopropylamine is used instead of ammonia.⁵⁵ The oxidations may also be carried out in 0.1 M NH_4HCO_3 (pH 8.0)⁵⁷ or 0.1 M ammonium acetate buffer (pH 6.8–7.0).⁵¹ Passage of pure oxygen (instead of air) through a solution of a peptide in 0.1 M NH_4HCO_3 did not increase the rate of cyclisation.⁵⁷ In the case of peptides that aggregate in aqueous solutions, 0.5–8.0 M urea or 0.1–1.5 M guanidine hydrochloride are added.^{2,58,59} As a rule, the oxidation is performed at 5–25 °C. The reaction time varies from several hours to several days.^{54–57} Most probably, this reaction occurs by a free-radical mechanism. The cyclisation is usually monitored by HPLC or by a reaction for the presence of a free SH group using Ellman's reagent, 5,5'-dithiobis(2-nitrobenzoic acid).⁶⁰ The yields of cyclic disulfides in this oxidation are usually small (9%–15%).^{54–56}

There are some examples of preparation of synthetic toxins, growth factors, and enzyme inhibitors by this method. That this process is lengthy and the product yields are low are serious limitations of this method. However, its simplicity makes it an attractive procedure despite the advent of new efficient reagents.

b. Oxidation with potassium ferricyanide

Potassium ferricyanide is a popular cyclisation reagent. Laloo and Mahanti⁶¹ have studied the kinetics of cysteine oxidation with potassium ferricyanide and proposed a mechanism for this reaction. Using ESR spectroscopy they have found that this reaction occurs *via* an intermediate radical, $[-\text{SCH}_2\text{C}^+(\text{NH}_2)\text{COO}^-]$.⁶¹ Depending on the solubility of a peptide, the oxidation is carried out in aqueous or aqueous-ethanolic solutions with high dilution (pH 8–10).^{60,62} Haskell-Lecevano *et al.*⁶³ performed this oxidation in a saturated solution of NH_4OAc containing methanol and acetonitrile. The termination of the reaction is judged from the appearance of a persistent yellow colouration. Inorganic impurities are removed by ion-exchange chromatography. This method mainly yields homogeneous reaction mixtures. Oxidation of sulfhydryl groups occurs virtually quantitatively.⁵⁵ This procedure has been used to obtain oxytocin,^{2,64} vasopressin analogues,⁶² somatostatin,^{2,65} and peptides with two S–S bridges (endothelin-1,⁵⁸ a bee venom peptide of mast cell degranulation,⁶⁶ *etc.*).

c. Oxidation with dimethyl sulfoxide

Dimethyl sulfoxide (DMSO) was used to oxidise peptide thiols for the first time in 1988.⁶⁷ This compound has a number of indisputable advantages: it can be used in a wide range of pH (from 3 to 8), ensures higher reaction rates (in comparison with oxidation with atmospheric oxygen), and increases solubility of peptides.^{2,59,67–71} This reaction is catalysed by acids or primary and secondary amines. The mechanism of oxidation in an acidic medium was proposed by Otaka *et al.*⁶⁸

R = Trt, Mbzl, Dpm.

The limiting step of this reaction is the formation of the intermediate compound **9**, which rapidly yields the disulfide **10** on reaction with the free thiol **8**. The optimum pH range for the reaction with DMSO is 3–8.⁶⁹ In this case, the reaction rate does not depend on pH, because in this pH range both the protonation of DMSO and the formation of a thiolate anion may take place. At pH < 3, methionine can undergo oxidation into the corresponding sulfoxide, whereas at pH > 8 the rate of disulfide exchange increases. However, there are some exceptions. For example, the oxidation of peptides with an N-terminal cysteine should be conducted at pH 6–7. If the amino groups of cysteine are acetylated, the pH is unimportant. Tam *et al.*⁶⁹ interpret this phenomenon by the fact that the weakly positive α -amino group of cysteine facilitates the formation of the unstable intermediate adduct **9**. In more acidic media, the α -amino group is protonated and does not exert such an effect.

Oxidation with dimethyl sulfoxide is carried out at its concentration in the reaction mixture from 10% to 50%. An increase in DMSO concentration increases the reaction rate. Thus complete oxidation of a linear precursor of a human growth factor fragment with 10%–30% DMSO requires 2–3 h, whereas with 40%–50% DMSO it takes only 0.5 h. The oxidation-sensitive amino acid residues of tryptophan, tyrosine, and methionine are not modified under these conditions.^{69,71}

A 10% DMSO solution in TFA has been used for simultaneous splitting of acid-labile cysteine protective groups (Trt, Mbzl, Dpm) and the closure of disulfide bonds.^{68,70} However, in this case the oxidation lasted several hours. Over this time, the unprotected tryptophan was strongly modified and methionine was oxidised into the corresponding sulfoxide. Oxytocin, which has no tryptophan or methionine in its amino acid sequence, was obtained in 73.5% yield from a bis(methoxybenzyl)cysteine derivative by treatment with 10% DMSO in TFA in the presence of anisole (12 h, 25 °C). Human calcitonin (α -hCGRP) was obtained from a bisadamantyl derivative of cysteine under identical conditions (1 h, 17%).⁶⁸

The resistance of the oxytocin derivatives [1,6-Cys(Acm)] and [1-Cys(Acm), 6-Cys(SH)] with respect to 10% DMSO in TFA has been studied.⁷⁰ The former proved to be stable for 12 h, whereas the monosubstituted derivative [1-Cys(Acm), 6-Cys(SH)] was converted into oxytocin under identical conditions within 1 h (69%); the product was contaminated with a dimer.

Tamamura *et al.*⁵⁹ reported on the closure of the S–S bonds upon action of 10% or 50% DMSO in 1 M HCl. The thiol groups of cysteine protected with Acm of Mbzl groups had been deblocked beforehand with silver trifluoromethanesulfonate in TFA. Two chemical reactions occurred simultaneously in the DMSO–HCl system: conversion of Cys(Ag) derivatives into cysteine and oxidation of cysteine residues with DMSO. This approach was used to obtain oxytocin, urotensin II, tachiplensin I, and endothelin I in 72%, 80%, 79%, and 62% yields, respectively (as calculated per bis-Acm derivatives). No side reactions that could affect methionine, tyrosine, or tryptophan residues were observed under these conditions.⁵⁹

Oxidation by DMSO is especially efficient in cyclisation of basic peptides that are insoluble in weakly alkaline solutions, which are required for oxidation with oxygen or $\text{K}_3[\text{Fe}(\text{CN})_6]$. This problem appeared in the synthesis of basic hydrophobic growth factors that remained insoluble in weakly alkaline solutions even after addition of 8 M urea.^{69,71} The advantages of this method have been also exemplified in the synthesis of a natriuretic peptide (pBNP) and tachiplensin I having two S–S bonds.⁶⁷

However, despite the obvious merits of this method, it has certain disadvantages, which are connected with the difficulty of removal of the excess of DMSO and dimethyl sulfide formed in this reaction.

d. Oxidation with hydrogen peroxide

Hydrogen peroxide is a common component of biological systems and participates in physiological oxidation processes.⁷² Therefore, the use of this oxidant in peptide synthesis is fully justified. Oxidation of thiols with H_2O_2 may occur in two ways: *via* generation of a thiolate anion (RS^-) or a radical ($\text{RS}^\cdot$):⁷³

The oxidation performed under alkaline conditions accelerates the generation of the thiolate anion; therefore in this case the formation of the disulfide occurs at higher rate.⁷⁴

Using oxidation of *N*-acetylcysteine and glutathione as examples, it was shown that this reaction proceeds *via* several thiol and disulfide complexes with H_2O_2 .^{75, 76} The important role of H_2O present in the reaction mixture was emphasised, since it stabilises these complexes by creating a solvate shell around them.^{75, 76}

The dependence of the rates of these reactions (in a phosphate buffer, pH 7.0) on the concentration ratio, $K = [\text{RSH}]/[\text{H}_2\text{O}_2]$, has been studied. The formation of the complex **11** takes place at $K < 2.5$, while that of the free disulfide **12** at $K > 2.5$, *i.e.*, where the concentration of the residual thiol is $< 10^{-2}$ mol litre⁻¹.

A systematic study of the applicability of hydrogen peroxide for the closure of disulfide bonds has been carried out by Kudryavtseva *et al.*^{77, 78} Table 2 lists the yields obtained in the formation of disulfide bonds in peptides of various lengths and structures under the action of both iodine and hydrogen peroxide.⁷⁸ Syntheses of some biologically active peptides, such as antigenic determinants of HIV proteins (compounds **13–16**, Table 2), atrial (vasodilator) (compounds **18–20**, Table 2) and vasoconstrictor peptides, containing oxidation-sensitive tryptophan, tyrosine, and methionine residues demonstrate that the oxidation with H_2O_2 enables the preparation of the target disulfides within only 15–20 min and in high yields (60%–85%) without formation of side products.⁷⁸ The oxidation was carried out in aqueous media at pH 6.5–8.0. It was also shown that H_2O_2 can be used for the synthesis of preparative (gram-scale) amounts of antigenic determinants of HIV proteins (**13–16**) and oxytocin (**17**).⁷⁸

There are other reports concerning the use of H_2O_2 in the synthesis of oxytocin and vasopressin.^{3, 79} Hydrogen peroxide was used for cyclisation of methionine-containing peptides (pH 8–11), human natriuretic peptide (α -hNAP), and somatostatin in phosphate buffer (pH 8.5, 10 min). The reaction products were obtained in more than 90% yields and with high purity.

Apparently, the use of hydrogen peroxide in cyclisation has limitations of its own. It is known, for example, that H_2O_2 may induce more profound oxidation of disulfides to sulfones.⁷²

Table 2. Comparative yields of cyclic peptides during the closure of the S–S bridge with iodine (in ACOH or MeOH) and hydrogen peroxide.

No. of compound	Structure	Yields (%)	
		I ₂	H ₂ O ₂
13	H-LGLWGCSGKLIIC-NHEt	51	75–85 ^a
14	H-LGIWGCSGKHIC-NHEt	56	85–90 ^a
15	H-NSWGCAFRQVC-NHEt	66	80–87 ^a
16	H-WGCSGKLICTTAVPWNA-OH	25	85–90 ^a
17	H-CYIQNCPLG-NH ₂	50	70–75 ^b
18	H-SSCFGGRIDRIGAQSGLGCNSFR-OH	23	83
19	H-SSCFGGRIDRIGAQSGLGCNSFRY-OH	26	50
20	H-SLRRSSCFGGRIDRIGAQSGLGCNSFRY-OH	20	62

^a The scatter in yields on oxidation of 0.1–1.5 g of the corresponding bis-Acm derivatives of peptides; ^b the scatter in yields on oxidation of 2.0–20.0 g of bis-Acm derivatives of oxytocin.

e. Oxidation with glutathione

Yet another way to close S–S bonds is the use of buffers that simulate physiological conditions. Since *in vivo* disulfide bridges are formed under reductive conditions, and the reducing medium in cells is maintained by the glutathione system (5 mM reduced and 0.1 mM oxidised glutathione),⁸¹ buffer solutions containing reduced and oxidised glutathione at a 10:1 ratio are most often used for the formation of S–S bonds.² Other ratios of reduced and oxidised forms, *e.g.*, 1:1 (Ref. 82) or 2:1 (Ref. 83) are also employed. The reaction of peptide polythiols is conducted in dilute solutions at pH 7.3–8.7 and 0.1–0.5 M Tris–HCl buffer is used for dissolution.^{83, 84} The oxidation of thiols with glutathione occurs in two steps.⁸⁵ At first, a 'reduced' peptide having free SH groups reacts with the oxidised glutathione (GSSG) to give mixed disulfides, which undergo intramolecular thiol–disulfide exchange to form disulfide bonds in peptides and the reduced glutathione.⁸⁵

The limiting step of this reaction is the reaction of the peptide with GSSG; therefore, the reaction rate depends on the concentration of the latter. The oxidation is normally carried out for 16–72 h at 25–35 °C.^{82, 83} The reaction product is purified by affinity chromatography² or by HPLC.^{83, 84} This method was used to obtain a 48-membered neurotoxin of sea anemone (yield 22.8%),⁸⁴ the trypsin inhibitor CMTI III (yield 10%),⁸² human epidermal growth factor (h-EGF) peptides,⁸³ and ω -conotoxin.⁸⁶ All these peptides contain three disulfide bonds; their closure was performed simultaneously. This method yields predominantly natural, thermodynamically favourable structures.^{82–86} However, the procedure that employs a mixture of oxidised and reduced glutathiones is mainly limited by large molecules with a thermodynamically favourable physiologically active conformation and is hardly suitable for the synthesis of short peptides containing disulfide bonds.

f. The use of polymers

Clarc and Pai have proposed an original procedure for cyclisation of linear SH-containing peptides using an EkathioxTM polymer.⁸⁷ The resin (40–80 μ , pore diameter 100 Å) contains 0.2–0.4 mmoles of oxidising functional groups per gram. The oxidising polymer was removed by filtration after 4 h at 20 °C. The efficiency of the polymer was evaluated by the formation of oxytocin (yield 92%). The authors⁸⁷ note that the high yield and the absence of dimeric side products were due to pseudo-dilution (see Section III.4), where the reaction was performed on a solid phase.⁸⁷ The polymer EkathioxTM does not modify tryptophan, tyrosine, or methionine residues. Moreover, it allows one to conduct oxidation in both aqueous and organic media. It is difficult to evaluate the advantages of this method, because the nature of the functional groups was not specified by the authors.

An alternative approach to cyclisation using polymeric reagents was proposed by Lin Chen and Barany.⁸⁸

N-Substituted 2,3-dithiasuccinimides **21** were used as oxidants to produce intramolecular disulfide bridges in the synthesis of oxytocin and deaminoxytocin performed under different conditions.

R = CH₃, CH₂CO₂H, CH₂CO₂-(P),
(P) is the insoluble polymer.

One procedure consisted in the reaction of soluble peptides with a dithiasuccinimidoacetyl polymer, and the other, the reaction of a peptidyl polymer with a soluble derivative of 2,3-dithiasuccinimide. The rate of this reaction depends on the pH of the reaction medium. The reaction kinetics has been studied in aqueous, organic, and aqueous-organic media. The disadvantage of this method is the high reactivity of dithiasuccinimide derivatives, which irreversibly oxidise functional side groups of amino acids.⁸⁸

g. Miscellaneous reagents

Other reagents, such as 5,5'-dithiobis(2-nitrobenzoic acid) (Ellman's reagent⁸⁹) and a CCl₄-NEt₃ mixture,^{2,7} have been used to oxidise free thiol groups of cysteine residues. Although these compounds did not gain wide acceptance for oxidation in solution, they have been used for solid-phase cyclisation and therefore will be considered below.

2. Removal of protective groups with simultaneous closure of an S–S bridge

Direct conversion of S-protected peptides into the corresponding disulfides is one of the most attractive methods of disulfide bond formation. A number of reagents are now available that can be used for such conversions.

a. Iodine

Iodine is the most popular reagent used in the formation of the disulfide bonds. The reactions of cysteine with Trt, Acm, Tmob, Mob, and other protective groups with iodine have been studied in great detail. Two mechanisms have been proposed to explain the conversion of a sulfide into a disulfide.⁵ One of them implies the formation of an intermediate sulphenyl iodide **22**, and the other, of alkyl(aryl)thiosulphenyl iodide **23**.

R = Acm, Trt, Tmob, Mob.

Neither of these mechanisms has been favoured, although both routes have been confirmed by several authors.⁵ Since the intermediate sulphenyl iodides are highly reactive, the efficiency of oxidation strongly depends on the amino acid sequence of a peptide.

Several procedures for oxidation of protected peptides with iodine exist, which differ in the ratios of the reaction components, solvents, reagents used to remove the excess of iodine, etc. The oxidation is carried out in both neutral solvents (MeOH or aqueous MeOH, trifluoroethanol, dioxane, CHCl₃, DMF) and in acids (acetic, propionic, trifluoroacetic) or their mixtures with water. Depending on the type of the thiol function protection and the nature of the solvent, the reaction rates may vary considerably. Thus the rates of oxidation of Cys(Trt) in MeOH, acetic acid, and their mixtures with H₂O are from 4 to 500 times as high as that of oxidation of Cys(Acm) in the same solvents. If oxidation is carried out in chloroform, dichloromethane, and trifluoroethanol, this difference is much higher. This allows selective oxidation of Cys(Trt) in the presence of Cys(Acm). On the contrary, the rate of oxidation of Cys(Acm) in DMF and its mixtures with water is 5–10-fold higher than that of Cys(Trt).²

The excess of iodine plays an important role in this process. With equimolar amounts of the oxidant with respect to the [Cys(Acm)]₂ derivative of gramicidin S, the reaction in methanol was completed within 3 h and the yield of gramicidin S was 67%.⁹⁰ The use of 5–15-fold excess of I₂ in AcOH made it possible to obtain cyclic disulfides of various lengths and structures and in sufficiently good yields.^{66,91,92} The use of 40- and 50-fold excess of I₂ in AcOH was reported to result in low yields (10%) of the target products.^{93,94}

Using the synthesis of the cyclic disulfide **15** from the bis-S-Acm-protected fragment 593–603 of HIV-2 gp41 (**24**) as an example (Scheme 1), the effect of the excess of iodine and of the solvent on cyclisation has been studied.^{55,78,95} With 2–13-molar excess of I₂ in AcOH, the yields of the target product **15** did not exceed 39%.^{55,78,95} The highest yield (66%) was obtained when

(a) 13 moles of I₂ per 1 mole of the peptide in AcOH; (b) 5 moles of I₂ per 1 mole of the peptide in AcOH.

oxidation was performed in aqueous methanol using 2 moles of I_2 per 1 mole of the peptide.^{78, 95, 96}

The excess of iodine is removed with sodium thiosulfate, ascorbic acid, zinc dust, and by extraction with carbon tetrachloride.^{2, 55, 78, 91–95} Removal of the excess of iodine with sodium thiosulfate was accompanied by modification of the cysteine residue with the thiosulfate ion^{55, 78, 95, 96} (compounds **26** and **27**, the exact positions of the Acn and S_2O_3H groups in compound **27** were not determined) (Scheme 1).

The limitation of the use of iodine for the disulfide formation is the possibility of side reactions affecting oxidation-sensitive amino acid residues, *e.g.*, iodination of the benzene ring of tyrosine,⁸ oxidation of methionine to the corresponding sulfoxide,⁸ and scission of the indole ring of tryptophan with subsequent cleavage of the peptide chain.^{8, 55, 78, 95–97} Thus the formation of a shortened peptide **25** (Scheme 1) was a result of oxidative degradation of tryptophan by iodine.^{78, 95} Since these reactions are catalysed by acids, the cleavage of the peptide chain at the tryptophan residue can sometimes be avoided if oxidation is conducted in neutral organic solvents.^{55, 95, 96, 98}

Oxidation of tryptophan-containing peptides with iodine sometimes results in tryptophan-2-yl sulfides as a side product of the type **26**. Apparently, one of the reasons for this side reaction is the formation of highly reactive intermediate sulfenyl iodides. Tryptophan-2-yl sulfides were obtained under various conditions.^{42, 95, 98} For example, in the synthesis of somatostatin from a precursor with different protective groups at cysteine residues (Acn in position 3 and Trt in position 14), treatment with iodine in 10% aqueous trifluoroethanol resulted in the formation of a side product in 65% yield.⁹⁸

According to Sieber *et al.*,⁹⁸ this reaction occurs due to the different lability of Acn and Trt groups in trifluoroethanol.^{2, 98} When oxidation was carried out in a MeOH/DMF mixture, tryptophan-2-yl sulfide was not formed. The distance between the cysteine and tryptophan residues plays a significant role in the formation of tryptophan-2-yl sulfides. Oxidation of model tryptophan-containing peptides with iodine shows that only disulfide dimers are formed if tryptophan and cysteine are separated by one or two glycine residues. If this distance is four glycine residues, the yields of tryptophan-2-yl sulfides are 40% and 70%, respectively.⁹⁸

Alternatively, tryptophan-2-yl sulfides were formed when sodium thiosulfate was used to remove iodine in the synthesis of a fragment of the HIV-2 protein gp41 (if $Na_2S_2O_3$ is replaced by ascorbic acid, this side reaction does not take place). Blocking of the thiol function of one of cysteine residues with the thiosulfate ion (compound **26**) triggers the reaction of the thiol function of the other cysteine residue on position 2 of the indole ring of tryptophan.^{55, 78, 95}

No side reactions involving the indole ring of tryptophan took place during cyclisation with iodine when its N^{im} -formyl derivative was used.⁵⁸

Despite the obvious limitations of this method, there are many examples of its successful application in the synthesis of compounds with several disulfide bonds in particular.^{54, 58, 66}

b. Cyanogen iodide and *N*-iodosuccinimide

These compounds also serve as a source of the I^{2+} ion. The mechanism of oxidation with these reagents is identical with that of iodine. Good solubility of ICN in aqueous-organic solvent systems has been reported.⁹⁹ The utility of ICN was demonstrated in the cyclisation of several Cys(Acn) peptide derivatives in aqueous methanol. A comparison of oxidation with cyanogen iodide and iodine showed that although large excess of the oxidant (from 25- to 80-fold) is required in the former case and the duration of these reactions was 24–48 h, the yields were about twice as high as with I_2 . *N*-Iodosuccinimide was used in the synthesis of oxytocin and vasopressin on a polymer,¹⁰⁰ therefore this reagent will be considered below in more detail.

c. Thallium(III) trifluoroacetate

A new, rather efficient oxidant, $Tl(CF_3COO)_3$, was first used in 1987 for removal of certain cysteine protective groups with simultaneous formation of the disulfide bond.^{9, 101} Thallium trifluoroacetate removes many protective groups of the sulfide type (Mob, Tmob, Bu^t, Trt, Xan, Ad, Meb) and acylaminomethyl derivatives (Acn, Phacm). The oxidation occurs through the formation of a highly reactive intermediate compound **28**, *viz.*, thallium(III) thiolate. At the final step of this reaction, the protective group is split off from the thiol group of the second cysteine residue with concomitant disulfide bond closure.

The oxidation is carried out in trifluoroacetic acid (1–2 h, 0 °C) in the presence of 2 equiv. of anisole to bind the carbocations formed^{9, 101} or in DMF.^{2, 7} The use of aqueous solvents is excluded in this case, since the presence of water can bring about the formation of small quantities of cysteic acid.⁹ Thallium salts are readily soluble in ether and their removal does not present any problem.⁹

The use of $Tl(CF_3COO)_3$ gave satisfactory results in the synthesis of oxytocin, urotensin II, and human calcitonin. The yields of the products purified by gel filtration were 45%, 35%, and 11%, respectively.¹⁰¹ In the latter two cases, the decrease in the product yields can be explained by the presence of a tryptophan residue in the amino acid sequences of these peptides, which undergoes considerable modification. It was shown that only 38% of tryptophan remains intact under these conditions. The use of a Trp(Mts) derivative allows one to preserve tryptophan for 60 min on treatment with $Tl(CF_3COO)_3$ at 0 °C. Methionine is partly oxidised (by ~ 38%) to the corresponding sulfoxide with $Tl(III)$ salts.⁹

The use of this reagent is efficient in the case of difficulty oxidisable thiols, where cysteine residues are adjacent as in the peptide fragment of the acetyl choline nicotine receptor (alpha 185–196).⁵³

A comparison of efficiencies of atmospheric oxygen, potassium ferricyanide, and thallium(III) trifluoroacetate as oxidants in some syntheses revealed that $Tl(CF_3COO)_3$ gave the highest yields.^{17, 53} It has been widely employed for the closure of disulfide bonds on a polymer.^{7, 17, 102} The high toxicity of thallium salts imposes certain restrictions on their application, which will hardly go beyond the scope of laboratory experiments.

d. Sulfoxides in the presence of silyl chlorides

This cyclisation method was proposed in 1991 independently by Kiso^{103, 104} and Fujii.¹⁰⁵ In the presence of silyl chlorides in trifluoroacetic acid, aryl(alkyl) sulfoxides may split off Ac^m, Tac^m, Bam, Bu^t, Meb, and other cysteine protective groups with simultaneous closure of the S–S bridges in 10–30 min at 4 °C. The mechanism of this reaction can be presented in the following way:^{103, 104}

The closure of the disulfide bond occurs through the generation of the sulfonium cation **31** upon treatment of the protected peptide **30** with diphenyl sulfoxide and silyl chloride. Further, electrophilic attack of the second substituted sulfur atom in compound **31** results in the formation of an S–S bridge and the splitting of the protective group, which is similar to the reaction of sulfonyl iodide with S-protected cysteine in the oxidation with iodine. The nature of silyl chloride seems to play a key role in the reactivity of the intermediate compound **29**. The ability of the protective group split off to form stable structures similar to the immonium ion derived from the Ac^m group is also important. These two factors determine the rate of the reaction.¹⁰⁴

The efficiency of various silyl chlorides (SiCl₄, MeSiCl₃, Me₃SiCl), and Me₄Si in combination with sulfoxides [PhS(O)Ph, MeS(O)Me, and MeS(O)Ph] has been studied.¹⁰⁴ SiCl₄ and MeSiCl₃ were found to be the most efficient silylating reagents. There was no difference in reactivities of different sulfoxides.¹⁰⁴ The Ph₂SO–MeSiCl₃ system or SiCl₄ removes Ac^m, Mob, Meb, Bzl, and Bu^t protective groups with equal efficiency.¹⁰⁵

Tryptophan is subject to side reactions under these conditions. Chlorination of the indole ring is the predominant reaction in the treatment of tryptophan-containing peptides with silyl chloride.^{104, 106} The addition of scavengers (anisole and 3-methylindole) routinely used to prevent tryptophan modification was inefficient.¹⁰⁴ It is therefore recommended to use tryptophan in the form of a formyl derivative.^{103, 104, 106} Nevertheless, successful application of this reagent has been demonstrated in the synthesis of somatostatin (yield 60%),^{104, 106} oxytocin (yield 56%–69%),¹⁰⁴ and human natriuretic peptide (hBNP) (yield 50%).¹⁰⁴ This method was also used for regioselective formation of disulfide bonds in the synthesis of conotoxin M1 and human insulin.¹⁰⁷

3. Closure of disulfide bonds by thiolysis or thiol–disulfide exchange

Implementation of the route C requires that the two protective groups of two cysteine residues be different in stability. This enables selective removal of one of the protective groups (Y), whereas the other group (X*) activates the sulfur atom of cysteine, thus facilitating the formation of a disulfide bond. In this case, the intermediate electrophilic derivative (–S–X* in compound **7**) undergoes a nucleophilic attack by the sulfhydryl group of the second cysteine residue. This approach is used for the closure of both intra- and intermolecular S–S bonds and is particularly widely employed for the preparation of asymmetrical disulfides. Methods A and B are less efficient to this end. The reason is that simultaneous oxidation of two cysteine residues, when the formation of the S–S bonds between two different peptide chains is needed, gives predominantly dimers, whereas asymmetrical disulfides are the minor products. The peptide thiols are activated by

introducing electron acceptor substituents, which enhance the ability of sulfur for the nucleophilic substitution. Activation may be accomplished either *in situ*, or as an individual stage with the isolation and characterisation of the intermediate product, or by selection of appropriate protective groups. In the latter case, the protective groups (*e.g.*, of the disulfide type) must be sufficiently stable under conditions of elongation of the peptide chain and simultaneously ensure the formation of a disulfide bond by thiol–sulfide exchange.

a. Thiocyanogen (SCN)₂

Thiocyanogen^{2, 6} reacts both with free and protected thiols. The resulting activated peptide (X* = SCN in compound **7**) reacts with the thiol group of the same or another peptide *in situ* to form a disulfide bond. It has been established that this reagent selectively reacts with Thp and Trt derivatives of peptides in the presence of Dpm and Bzl protections.^{5, 6} The reaction of thiocyanogen with sulfides can be presented as a reaction of an electrophile with a dissociated form of a sulfide.⁵

The rate of this reaction is determined by the degree of dissociation of the corresponding protected derivative **33**, which, in turn, depends on the stability of the cation R⁺ formed upon splitting. Therefore, the cyclisation of Trt and Mob derivatives of peptides occurs rapidly and specifically even in nonpolar solvents, whereas Dpm sulfides react slowly and are converted into the corresponding disulfides in 60%–75% yields.⁵ The degree of dissociation of derivatives **33** may be enhanced by acid catalysis. Cleavage of Dpm and But sulfides requires stronger acids than that of Trt and Mob derivatives. If the reaction with thiocyanogen occurs at a slow rate (as is the case with Bzl derivatives), the formation of homodimeric side products is more probable.^{2, 5} High electrophilicity of thiocyanogen favours the occurrence of side reactions.² Thiocyanogen is decomposed by amines (including free bases of arginine and histidine), the corresponding reactions may be carried out only in acidic or neutral media.

b. Aromatic sulfonyl halides

2-Nitrobenzenesulfonyl chloride (Nps-Cl) or 2-pyridinesulfonyl chloride (PyS-Cl) activate free or protected cysteine residues. The closure of the disulfide bonds by these reagents may be illustrated by the following general scheme:²

In the case of intermolecular closure of the S–S bonds, Y is a protective group of any type, and X is hydrogen or a protective group that can be removed by aromatic sulfonyl halides, *e.g.*, Trt, Dpm, Bu^t, SBU^t, and Ac^m.

Nps-Cl and PyS-Cl are extremely reactive, they decompose in the presence of moisture. PyS has been proposed for deprotection of cysteine protected with Trt, Dpm, Ac^m, Bu^t, and SBU^t groups and subsequent preparation of asymmetrical disulfides.¹⁰⁸ Reactions with this reagent are carried out in glacial acetic acid. The reactive mixed disulfide formed reacts with a free SH group to give the target disulfide. The mixed disulfide Cys(PyS) is resistant to acids. Removal of the Boc group in the derivative Boc-Cys(PyS)-OH by treatment with acid is not accompanied by splitting of the PyS group. The activation of thiols and formation of disulfide bonds occur without removal of protective groups, such as Boc, Z, and Bzl. The PyS derivatives of peptides are formed in quantitative yields and can be isolated in a crystalline state. The mixed

disulfides Cys(PyS) and the respective peptides are unstable in alkaline solutions and rapidly decompose to yield symmetrical disulfides and di(2-pyridyl) disulfide, (PyS)₂. Free SH groups may be liberated by the action of an excess of thiols (*e.g.*, β-mercaptoethanol).¹⁰⁸

Nps-Cl was used to remove Trt, Dpm, Ddm, and Acn protections¹⁰⁹ and intermediate mixed disulfides can be isolated. Free SH-derivatives can be obtained under the action of an excess of a thiol (*e.g.*, β-mercaptoethanol or dithiothreitol). Deprotection and formation of disulfide bonds using Nps-Cl occur much more slowly than with PyS-Cl.¹⁰⁸

The use of aromatic sulfonyl halides is limited because of difficulties associated with their synthesis and isolation (these compounds are easily hydrolysed even in humid air) and due to the fact that tryptophan can undergo side reactions under the action of these compounds.

Peptides containing cysteine with free SH groups can be activated directly in solution or on a solid phase with di(2-pyridyl) disulfide, (PyS)₂. Highly specific conversion of a Cys(Snm) derivative into a Cys(PyS) derivative under the action of 2-mercaptopyridine in chloroform is an alternative procedure for obtaining stable S-arylsulfonyl derivatives.² And, finally, cysteine-containing peptides may react with Ellman's reagent in buffer solutions at pH 7.4 to give intermediate disulfides. The interaction of the latter with a free SH group of the other cysteine residue also results in the closure of S—S bridges.²

c. Disulfide derivatives

The characteristic feature of this method is that disulfides play a dual role. On the one hand, they are used for protection of the thiol functions of cysteine because they are stable under conditions of a multistep peptide synthesis. On the other hand, being strong electron acceptors, they activate the thiol groups in reactions of thiol–disulfide exchange and thiolysis and thus facilitate the closure of the S—S bonds. These groups include alkoxycarbonylthio (Scm, Sce), Snm, and Npys protections.

Asymmetrical disulfides have been synthesised from peptides containing Cys(Npys) derivatives.^{17, 110}

R¹, R², R³, R⁴ are amino acids.

Derivatives containing Npys protective groups are also used to form intramolecular disulfide bonds.² This reaction is carried out over a rather broad pH range. The reaction time varies from several hours at pH ~ 4 to 30 min at pH 8–9. However, at pH > 9, disproportionation of disulfides may occur, which shifts the reaction equilibrium towards the formation of symmetrical homodimers. The probability of disulfide exchange between asymmetrical cysteines formed and the free SH groups present decreases at low pH. The optimum pH values are 4.45–9.35. The stability of the Npys protective group in acidic media (TFA at 25 °C and HF at 0 °C in the absence of thiols) makes it possible to use these cysteine derivatives in solid-phase syntheses using Boc-technique. This protection was successfully used for the formation of S—S bridges in the synthesis of insulin, its analogues, and relaxin.¹⁷

Methoxycarbonylsulfonyl chloride (Scm-Cl), like aromatic sulfonyl halides, removes such protective groups as Trt, Acn, Bu^t, Ddm, and Dpm to form Cys(Scm) derivatives.¹¹¹

X is Trt, Acn, Bu^t, Ddm, Dpm.

Compound **34** reacts with free thiols to produce the disulfide bonds.

The latter reaction is catalysed by mild bases, such as triethylamine.¹¹¹ Sulfonylthiocarbonates are unstable in the presence of alkalis; therefore, experiments with these compounds must be carried out in neutral or acidic media. However, undesirable modification of tryptophan is possible. Conversion of Acn derivatives into Scm derivatives or the reaction of free SH groups with Cys(Scm) may also be carried out on a solid phase² with formation of both inter- and intramolecular disulfide bonds.

Ethoxycarbonylsulfonyl chloride (Sce-Cl) was proposed for the formation of intramolecular disulfide bonds. This reagent is identical in structure and mechanism of action with Scm-Cl.¹¹¹ The activated cysteine derivatives thus formed react with free thiol groups of cysteine to yield intramolecular disulfide bridges. The optimum results were obtained with ammonium-acetate buffer, pH 7.0. However, this reaction may also be carried out in weakly acidic solutions, but in this case the yields are lower. The rate of this reaction is very high: cyclisation is completed within 10 min, but the reaction conditions could not be found where the yields exceeded 20%–30%.¹¹¹ The application of Sce-Cl to tryptophan-containing peptides is problematic.¹¹¹ Nevertheless, this reagent was used in the synthesis of somatostatin, urotensin IIA,¹¹¹ and a trypsin inhibitor.⁵⁶

d. Bis(*tert*-butyl) azodicarboxylate

The closure of the disulfide bond using bis(*tert*-butyl) azodicarboxylate (Boc—N=N—Boc) occurs *via* thiolysis. Boc—N=N—Boc has not gained wide acceptance despite its successful application in the synthesis of asymmetrical disulfides.^{112, 113}

The synthesis of an activated peptide derivative was carried out in DMF with 2–3 equiv. of bis(*tert*-butyl) azodicarboxylate under argon (4–12 h, 25 °C).^{112, 113} The resulting compound is rather stable and can be isolated. The activated derivative is dissolved in an appropriate solvent, after which the second peptide containing a free sulfhydryl group is added to form a disulfide heterodimer.

BocN = NBoc is bis(*tert*-butyl) azodicarboxylate.

e. The use of cysteine sulfoxide

This method is used for the closure of both intra- and intermolecular S—S bonds. One of the cysteine residues is used in the form of a sulfoxide.¹¹⁴ The reaction occurs in a strongly acidic medium (TFA or a trifluoromethanesulfonic acid–TFA mixture). Under these conditions, the sulfoxide is protonated, and the resulting electrophilic derivative readily reacts with the nucleophilic thiol.

Y is Mbzl, Ad, Bu^t; X is Acn or Mob.

Methods of direct conversion of cysteine-protected peptides into disulfides [I_2 , $Tl(CF_3COO)_3$] have proved to be very efficient in oxidation on a solid phase. Standard conditions of this oxidation include treatment of cysteine-protected (Acn, Trt, Tmob) peptidyl polymers with 3–10 equiv. of I_2 in an appropriate solvent (TFA, AcOH, DMF, *etc.*) (1–2 h, 25 °C) or with 1.2 equiv. of $Tl(CF_3COO)_3$ (1–2 h, 0 °C). The yields of cyclic products are 60%–90%.^{89,117} Treatment of peptidyl polymers with acid-labile anchor groups [*p*-alkoxybenzyl or tris(alkoxy)-benzylamide] with solutions of I_2 or $Tl(F_3CCOO)_3$ in TFA or AcOH results in simultaneous closure of S–S bridges and splitting of the peptide from the polymeric support. This approach was used by Barlos *et al.*¹¹⁸ for cleavage of the acid-labile

2-chlorotrityl anchor group with an AcOH:trifluoro-ethanol:CH₂Cl₂ mixture (1:2:7). When this mixture was used in combination with 10 equiv. of I₂ (10–15 min, 20 °C), cyclic disulfides were obtained in ~60% yields. Protective groups of the *tert*-butyl type were not removed under these conditions.¹¹⁸

The advantage of direct conversion of Cys(Acm) and Cys(Trt) peptide derivatives into the corresponding disulfides by treatment with Tl(III) salts over iodine has been demonstrated by several authors.^{89, 102, 116} Treatment of S-Acm or S-Trt derivatives of the model peptide Ac-Cys(Acm)-Pro-D-Val-Cys(Acm)-NH₂ with Tl(CF₃COO)₃ in TFA:anisole (21:1) with subsequent cleavage from the polymer with HF gave a cyclic product in 91% yield, whereas after treatment with 10 equiv. of I₂ in aqueous AcOH the yield was 52%.^{89, 116} In the latter case the decrease in the yield is unrelated to the nature of the oxidant but rather is due to the application of the AcOH–water mixture (1:4, v/v), which prevents swelling of the polystyrene-peptidyl polymer.

Cyclisation on a solid phase was highly efficient in the synthesis of parallel dimers of oxytocin and deaminoxytocin.^{7, 119} The attempts to obtain these compounds in solution failed, because in dilute solutions it was monomeric products that were predominantly formed, whereas at high concentrations polymers were formed.¹¹⁹ Rigid fixation of peptides on a polymer has made

it possible to obtain target dimers in good yields. The synthesis of a parallel dimer of deaminoxytocin is shown in Scheme 2.

The CCl₄–NEt₃ mixture was used for the closure of the S–S bond between Tmob-blocked N-terminal residues of β-mercaptopropionic acid (βMpa) after preliminary treatment of the peptidyl polymer with dilute TFA and scavengers. This procedure gave an intermediate product **37** in more than 90% yield. A mixture of the target parallel dimeric product **38** and deaminoxytocin **39** was obtained in 3:1 ratio after closure of the second disulfide bond with Tl(CF₃COO)₃ and cleavage of the reaction product from the polymer. Whether deaminoxytocin **39** results from the oxidation of an intermolecular side reaction product with Tl(F₃CCOO)₃ or from the dimer–disulfide exchange still remains unclear.¹¹⁹ A scheme with an alternative combination of protective groups [Cys(Tmob) and βMpa(Acm)] has also been tested. At the first step of this synthesis, the disulfide bond was closed between cysteine residues. It is of note that in this case the yield of the intermediate product having only one disulfide bridge was as low as 20%.

The closure of S–S bonds with *N*-iodosuccinimide in a DMF–CH₂Cl₂ mixture (1:1) in the synthesis of the (1–29) fragment of the human growth hormone having one disulfide bond (yield 15.6%) and an 18-membered peptide apamine having two S–S bonds (yield 11%) was reported.¹⁰⁰ In this case, the closure of S–S bridges did not follow the conventional procedure, *viz.*, oxidation after the completion of the linear peptide synthesis, but was rather included into the protocol of a solid-phase synthesis on an automatic peptide synthesiser using the Boc-technique. After attachment of the appropriate pair of cysteine residues, the disulfide bond between them was closed and the elongation of the peptide chain was continued. Acm and MbzI protections were used for the blocking of the thiol functions of cysteine. The use of an analogous procedure for the synthesis of oxytocin resulted in extremely low yields of the cyclic product (~1%), although [8 Arg]vasopressin was obtained in 41% yield under identical conditions. The question about the reason for such a low yield of oxytocin is still obscure. In our opinion, the authors' attempts¹⁰⁰ to interpret this phenomenon in terms of intermolecular aggregation of Cys(Acm) derivatives of oxytocin contradicts the results obtained by Albericio *et al.*^{89, 116} according to which it is cyclisation leading to oxytocin on a polymer under various conditions that occurs in sufficiently high yields, which often exceed those obtained by cyclisation in solution.

IV. Conclusion

The methods of formation of disulfide bonds considered above usually give compounds having one or two S–S bonds. However, each of the above-described methods has limitations of its own. Most often, they are related to oxidation-sensitive amino acids: tyrosine, tryptophan, and methionine. Despite the explosive development of methods and techniques of modern peptide chemistry, no versatile cyclisation procedure exists, and each time when an S–S bond is to be formed in a new compound, special experiment is required for the selection of the most adequate protection for the thiol function of cysteine and cyclisation reagent. In this context, further development of protective groups for the thiol function, elaboration of selective methods for deblocking of SH groups and specific activation of the thiol groups, and a search for new mild reagents suitable for the formation of S–S bridges are currently central tasks. Their solution assumes special importance in the synthesis of compounds with several intra- and intermolecular S–S bonds. At present, only few syntheses of such compounds have been carried out. Synthesis of complex molecules is a challenge of the nearest future. In this respect, methods of closing S–S bonds on a solid phase hold especially great promise. Further development and improvement in these techniques might facilitate laborious and sometimes unpredictable processes of cyclisation and make them

Contents

I. Introduction	563
II. Fast stage of catastrophic oxidation of metals	564
III. Super-fast stage of catastrophic oxidation of metals	569
IV. Conclusion	570

Abstract. The review deals with the current state of the problem of catastrophic oxidation of metals ('hot corrosion') caused by formation of a liquid corrosion product in a multi-component system. The kinetics, thermodynamics, and mechanisms of the two stages of accelerated oxidation of metals, namely, fast and super-fast stages, are considered with the copper–bismuth oxide system as an example. It is shown that the fast stage is caused by the formation of a liquid-channel grain boundary structure in the corrosion product, while the super-fast stage is caused by the high rate of dissolution of the oxide layer. The results of studies of the interaction of liquid phase with two-dimensional defects (grain boundaries) in solids are generalised. A model of catastrophic oxidation of metals is proposed. The bibliography includes 104 references.

I. Introduction

The creation of high-temperature corrosion-resistant materials intended for prolonged exploitation under extremely drastic conditions is a current task of materials science. Such materials are used in nuclear and fuel-based power industries, in space technology, and in other branches of industry. In most cases, composite materials based on metals, such as metal-ceramics, sintered powder compositions of metals with oxides, nitrides, and borides, as well as amorphous alloys are employed. The practical solution of problems involved in the creation of corrosion-resistant materials depends largely on the development of theoretical concepts in the field of high-temperature oxidation of metals.

By now, it has been reliably established that the rate of high-temperature oxidation of metals leading to the formation of dense scale is controlled by diffusion processes. The rate of metal oxidation is determined by bulk diffusion of the reacting ions and electron transfer through the growing scale. These aspects are described by the Wagner model^{1,2} which makes it possible to find quantitative relationships between the rate of metal oxidation, the type and extent of oxide disordering, and the partial pressure of oxygen as a function of the type of conductivity of the scale (ionic or electronic).

However, in certain cases the rate of metal oxidation exceeds that predicted by the Wagner model by several orders of magnitude. This phenomenon referred to as catastrophic oxidation of metals (COM)^{3,4} may be caused by the following.

1. The loss of isothermicity in the oxidation zone. The rate of metal oxidation increases continuously with temperature. This occurs if the liberated heat of the exothermic reaction cannot dissipate efficiently. Hence, the temperature of the metal surface increases, and the oxidation accelerates continuously. At a sufficient rate of oxygen supply, this process can result in inflammation of the metal. Inflammation of niobium, tantalum, titanium, and some other metals has been observed under extremal conditions.^{5,6}

2. The formation of volatile oxides. For example, tungsten, molybdenum, vanadium, rhenium, and osmium form volatile oxides but no protective oxide films.^{7–10}

3. The formation of a small amount of a liquid phase in the oxidation product. This may be exemplified by oxidation of alloys the components of which form low-melting oxides; oxidation of metals in an atmosphere containing vapour of low-melting oxides; direct contact of metals and alloys with low-melting oxides. Even the appearance of a small amount of a liquid phase in the scale can lead to the COM.^{11–27}

In the latter case, two stages of COM, namely, fast and super-fast ones, can take place.^{28–30} The fast stage is caused by the formation of a liquid-channel grain-boundary structure (LGBS) in the oxidation product^{31,32} and occurs by an electrochemical mechanism. The super-fast stage is caused by the high rate of dissolution of the protective oxide layer and occurs by a fluxing mechanism.

The term 'COM' has been first introduced by Leslie and Fontana^{3,4} for an abrupt (by several orders of magnitude) increase in the rate of metal and alloy oxidation under isothermal conditions in a medium containing low-melting oxides (oxides of molybdenum, vanadium, lead, *etc.*). This phenomenon is also named 'hot corrosion'.^{33–38} Strictly speaking, this definition of COM refers only to the third case discussed above. The other cases do not fit the definition completely. In the first case, metal oxidation occurs under non-isothermal conditions (a continuous increase in temperature in the reaction zone; the theory of this process has been suggested by Zel'dovich^{5,6}) and is related mainly to the physics of burning. In the second case, the oxidising medium does not contain a foreign low-melting oxide.

In the present work, only the third case is considered in detail with the copper–bismuth oxide system as an example.

To date, some progress has been achieved in the investigation of COM. However, many key questions remain debatable or unclear. For example, the mechanism of anomalously fast mass

Received 21 March 1997

Uspekhi Khimii 67 (7) 631–640 (1998); translated by S S Veselyi

transfer in solids involving the liquid phase and the mechanism of formation of a distributed structure (LGBS) are obscure; the interaction of a liquid phase with two-dimensional defects of a solid have been studied insufficiently.

In this review, the author attempted to discuss, from common viewpoints (thermodynamic, kinetic, structural), the mechanism of the COM caused by the formation of a liquid corrosion product in a multi-component system.

II. Fast stage of catastrophic oxidation of metals

1. Oxidation kinetics, structure and composition of the reaction products

Let us consider COM with the copper–bismuth system as an example, which most fully reflects the general features characteristic of other systems. It is known^{26,27} that copper coated with a thin film of bismuth (10–100 µm) undergoes catastrophic oxidation in air at 770 °C (Fig. 1). The rate of copper oxidation does not depend on the starting state of bismuth but depends on its quantity (Fig. 2). It has been found^{28,29} that the rate of copper oxidation increases with the thickness of the coating to reach a maximum at ~100 µm thickness (Fig. 3). The process of COM is determined by a parabolic time law, which indicates that the process is diffusion-controlled.

$$\left(\frac{\Delta m}{S}\right)^2 = kt \quad (1)$$

Figure 1. Kinetics of copper oxidation (1, 2) and temperature change (3); 1, without coating; 2, coated with a 30 µm-thick bismuth film.

Figure 2. Kinetics of oxidation of copper with different coatings; (1), Bi₂O₃ + Bi₂CuO₄; (2), Bi; (3), Bi₂CuO₄; and (4), Bi₂O₃. In all cases, the amount of bismuth per unit area of copper is the same, $T = 800$ °C.

Figure 3. Kinetics of oxidation of copper coated with Bi₂O₃ films of different thickness at $T = 800$ °C. Film thickness $\times 10^5$ /m: (1), 0; (2), 3; (3), 6; (4), 9; $10^5 k / \text{kg}^2 \text{ m}^{-4} \text{ s}^{-1}$: (1), 0.012; (2), 1.6; (3), 4.9; and (4), 21.

Here Δm is the change in the mass of the specimen, S is the area of the surface that undergoes oxidation, k is the oxidation rate constant, and t is time. The k value depends on the coating thickness and exceeds the scale-formation constant on copper by a factor of over 1000. The temperature of 770 °C (threshold temperature for catastrophic oxidation of copper in the phase diagram of CuO–Bi₂O₃, see Refs 39–47) corresponds to the melting of the eutectics between Bi₂O₃ and Bi₂CuO₄. The COM process is associated with the formation of a liquid phase in the reaction products.

The scale on copper consists of two layers,^{26–29} viz., the inner dark layer and outer light layer with a distinct interface (Fig. 4). The outer layer is formed of Bi₂CuO₄ with minor amounts of Bi₂O₃, Cu₂O, and CuO. The inner layer is built of CuO with minor Bi₂CuO₄, Bi₂O₃, and Cu₂O. The concentrations of the latter two compounds increase abruptly near the copper surface. The distribution of elements across the scale is in quantitative and qualitative agreement with the phase distribution shown in Fig. 4.

The position of layers in the scale shows that copper is oxidised predominantly due to oxygen diffusion.

Figure 4. Microstructure of the scale on copper coated with a Bi₂O₃ film and oxidised in air at 800 °C; magnification is $\times 400$.

2. Interaction of liquid phase with grain boundaries of the solid

Model experiments carried out in order to reveal the specific features of penetration of Bi₂O₃ and Bi₂CuO₄ into the bulk of CuO formed upon copper oxidation show that intense penetration of Bi₂O₃ or Bi₂CuO₄ (in liquid state) along CuO grain boundaries occurs at 770 °C (Fig. 5). The width of intergranular layers depends on the quantity of compound that has penetrated and can vary from fractions of a micron to several microns. The

Figure 5. Microstructure of a CuO ceramics following thermal treatment in contact with Bi₂O₃ in air (cross-section).

penetration rate is high and reaches a few centimetres per minute (Fig. 6). The dependence of the penetration depth on time is linear. The activation energy of the process is $87 \pm 20 \text{ kJ mol}^{-1}$.

Figure 6. Dependence of the depth of penetration of the liquid phase (h) along CuO grain boundaries on time at different temperatures. $T/^{\circ}\text{C}$: (1), 860; (2), 900; (3), 950; and (4), 1050.

The linear time dependence of the depth of penetration of the liquid phase along grain boundaries and its high rate indicate that the process is not diffusion-controlled.

3. Phase formation

According to the phase diagram, only one compound, namely, Bi₂CuO₄, is formed in the CuO–Bi₂O₃ system.^{39–47} The amount of this compound decreases upon heating above 730 °C (Fig. 7).³²

Figure 7. TGA (1), DTA (2), and T (3) curves for Bi₂CuO₄ exposed to cyclic heating and cooling in air.

The weight loss is accompanied by an exothermic effect on the DTA curve (2) and increases with temperature. The original weight is restored on cooling, but a small hysteresis appears on the TGA curve (1). The weight recovery is accompanied by additional exothermic effects corresponding to the reverse polymorphic transformation of Bi₂O₃, $\delta \rightarrow \gamma \rightarrow \beta \rightarrow \alpha$.^{48–58} The weight loss is caused by partial dissociation of bismuth cuprate according to the reaction

The decomposition of polycrystalline Bi₂CuO₄ occurs both from the outer and inner surfaces (grain boundaries). A liquid phase is formed at grain boundaries (Fig. 8). The figurative point of the system in the phase diagram of Bi₂O₃–Cu₂O (Fig. 9) with composition $2\text{Bi}_2\text{O}_3 + \text{Cu}_2\text{O}$ and a temperature of 730 °C is above the liquidus line, which corresponds to the liquid state. The volume fraction of the liquid phase increases with temperature. Hence, the equilibrium at the ternary diagram of Bi–Cu–O is shifted from the Bi₂O₃–CuO cross-section to the Bi₂O₃–Cu₂O cross-section. The liquid phase forms a connected network of channels along Bi₂CuO₄ grain boundaries (see Fig. 8), thus forming an LGBS.^{31,32} This implies that the thermodynamic condition of wetting, $\sigma_{\text{gb}} > 2\sigma_{\text{sl}}$ (where σ_{gb} is the surface tension of grain boundaries and σ_{sl} is the surface tension of the crystal–melt interface) is fulfilled. The exothermic effect at the DTA curve (first cycle, see Fig. 7) is probably related to wetting of grain boundaries with the liquid.

Figure 8. Microstructure of Bi₂CuO₄, quenching from 820 °C (fractured surface).

Figure 9. Cross-section of the phase diagram of Bi₂O₃–CuO, $p_{\text{O}_2} = 10^{-2} \text{ Pa}$. Point C corresponds to 60 mol.% of Cu₂O and 40 mol.% of Bi₂O₃, $T = 816^{\circ}\text{C}$.

4. Liquid-channel grain-boundary structures

Experimental results^{26–29, 31, 32} provide a reason to believe that the liquid phase plays an important role in the COM. This phase interacts with two-dimensional defects (grain boundaries) to form an LGBS, which affects considerably the mass transfer in the solid.

In some instances, the contact of solids with liquids results in the formation of grooves where grains outcrop at the outer surface;^{59–85} these grooves are characterised by a definite dihedral angle θ (Fig. 10). The value of θ is related to the surface tensions at the grain boundary and at the crystal–melt interface by a mechanical equilibrium at the groove apex:

$$\sigma_{gb} = 2\sigma_{sl} \cos \frac{\theta}{2}. \quad (3)$$

Figure 10. Profile of a grain boundary groove of liquid-phase etching.

A theoretical description of changes in topography of grain-boundary grooves and various transfer mechanisms is given by Mullins.^{60, 61} Let us briefly consider the Mullins theory of the development of a grain-boundary groove with a thermally etched groove as an example. Let a flat grain boundary outcrop at a flat surface (Fig. 10). The problem is to determine the surface profile at time t . The dependence of the chemical potential of an atom at a curved surface on the surface curvature is described by the Gibbs–Thomson equation

$$\mu_i(L) = \mu_i(\infty) + \Omega_i \sigma L, \quad (4)$$

where $\mu_i(L)$ and $\mu_i(\infty)$ are the chemical potentials of the i -th component at a surface of curvature L and at a flat surface, respectively, Ω_i is the partial volume of the i -th component, and σ is the surface tension. Hence, the chemical potential of an atom is determined by the surface curvature at this point

$$L = y'' [1 + (y')^2]^{-3/2}. \quad (5)$$

The value

$$\Delta\mu = \mu_i(L) - \mu_i(\infty) \quad (6)$$

reaches a maximum at $x = 0$ and decreases at $x > 0$ and $x < 0$. At the same time, $\nabla\mu$ is not equal to zero, causing a flux of atoms from the region with a higher potential (groove tip and banks) to that with a smaller potential (plateau), hence the groove should deepen and widen.

The dependence of the groove dimensions on time (t) is determined by the mechanism of the atom transfer. For example, for surface diffusion the groove width (w) and depth (h) are proportional to $t^{1/4}$:

$$\begin{aligned} w &= 4.6(At)^{1/4}, \\ h &= 0.97(At)^{1/4} \cotg \frac{\theta}{2}, \\ A &= \frac{D_s \sigma \Omega^2 n_s}{kT}, \end{aligned} \quad (7)$$

where D_s is the surface diffusion coefficient, n_s is the atom surface density, k is the Boltzmann constant, and T is temperature.

For bulk diffusion

$$\begin{aligned} w &= 5(Bt)^{1/3}, \\ h &= (Bt)^{1/3} \cotg \frac{\theta}{2}, \\ B &= \frac{D\sigma\Omega^2\rho}{kT}, \end{aligned} \quad (8)$$

where D is the bulk diffusion coefficient and ρ is the bulk density.

Quite a different physical picture appears if a fast diffusion pathway, such as liquid-phase diffusion, is possible. An analysis of the role of this process requires that the cases of saturated and unsaturated solutions are distinguished. The growth of a groove in a saturated solution occurs under the action of capillary forces. This process can be described using the Mullins theory, *i.e.* by the bulk diffusion of atoms through the liquid phase. This approach has been used repeatedly (see *e.g.*, Refs 76–78) to find that the groove width and depth change proportionally to $t^{1/3}$. Calculations agree satisfactorily with experimental data,⁷⁶ which shows that the maximum growth rate of the groove in this mode is as high as $\sim 0.5 \text{ mm h}^{-1}$. This value is considerably lower than that in the case of COM, where the liquid phase interacts with the grain boundaries of a solid (see Fig. 6).

Groove growth in unsaturated solution occurs under concentration gradient. Two extreme cases are possible. First, the process can occur in a kinetic mode ($h \sim t$, $w \sim t$), where the groove growth rate is controlled by dissolution, and diffusion transfer in the liquid phase occurs fast. Second, the process can occur in a diffusion mode ($h \sim t^{1/2}$, $w \sim t^{1/2}$), where the groove growth rate is controlled by diffusion through the liquid phase, and dissolution occurs rapidly. Calculations and experimental data⁷⁵ show that the maximum groove growth rate in the diffusion mode can be as high as several millimetres per hour, which is also much slower than in the case of COM.

The possibility of attainment of high rates of the groove deepening in the kinetic mode was considered by Fradkov.⁸¹ It was shown that in narrow grooves the groove tip moves much faster than the banks, resembling the movement of scissors. The groove deepening rate (v) is related to the rate of dissolution of a flat solid surface (v_0)⁸¹

$$v = \frac{v_0}{\sin(\theta/2)}. \quad (9)$$

However, an estimate of v using this formula showed that it is physically unreal to reach rates of several centimetres per minute. Such a rate can only be obtained at $\theta \approx 0.2^\circ$. Hence the Fradkov model is not applicable, as also noted by the author. The situation changes if v_0 increases. For example, this can occur if the groove deepening rate is controlled by the kinetics of channel opening at the tip rather than by that of the banks' expansion. It has been established experimentally that in the case of COM, where a liquid phase interacts with grain boundaries of a solid, the rate of the channel opening at the tip is controlled by the chemical reaction

It was noted above that Bi_2CuO_4 is thermally unstable and undergoes partial dissociation according to reaction (2). At grain boundaries, reaction (10) occurs, which [according to Eqn (2)] does not require any diffusion-controlled supply of the reagent, Bi_2O_3 , or diffusion-controlled withdrawal of the product, Bi_2CuO_4 . The oxygen evolved at the groove tip favours convective mixing (as the width of liquid channels exceeds considerably the free path of molecules).

Thus, fast penetration of a liquid along the CuO grain boundaries occurs due to acceleration of a chemical reaction at the grain boundaries rather than in the bulk. The most significant factors that favour the development of this process are the following: the chemical potential of atoms at the grain boundaries is higher than in the bulk; a chemical reaction occurs which does not require a diffusion-controlled supply of reagents (or diffusion-controlled withdrawal of products); a liquid, thermally unstable

product is formed; reaction is accompanied by gas evolution; a local temperature gradient appears due to a local chemical reaction; and the liquid is supplied to the channel by capillary forces.

The development of liquid channels occurs in the kinetic mode (see Fig. 6), hence equation (9) is still valid. However, v_0 acquires the meaning of the chemical reaction rate on a solid flat surface. Estimates show that the kinetic mode of the liquid channel growth controlled by a chemical reaction can result in narrow deep channels with a dihedral angle at the tip $0 < \theta < \pi$ at $v \sim 1 \text{ cm min}^{-1}$ and with v_0 values $0.001\text{--}1 \text{ cm min}^{-1}$, which are characteristic of topochemical reactions.^{86,87} The activation energy of the process, 87 kJ mol^{-1} , is also typical of topochemical reactions.⁸⁶

As a result of fast liquid penetration along the CuO grain boundaries, a continuous network of intergranular liquid channels is formed, eventually resulting in the LGBS formation.

Liquid-channel grain boundary structure can also be formed in different ways, *e.g.*, by topochemical decomposition of thermally unstable Bi_2CuO_4 . In both cases, the LGBS formation manifests itself as a sharp increase in electric conductivity caused by the onset of high ionic conductivity due to the oxygen ions.^{31,32} It has been shown^{28,29} that an LGBS based on CuO (see Fig. 5) readily conducts the oxygen ions. The ionic conductivity reaches $\sim 1 \Omega^{-1} \text{ cm}^{-1}$ at 780°C . The magnitude of conductivity is characteristic of superionic conductors.^{88–92}

Judging by phase composition and structure, LGBS should be attributed to heterogeneous structures. The question about the passage of electric current through heterogeneous structures has been first raised by Maxwell.⁹³ In particular, he considered the conditions of the passage of current through a two-phase system, which is a continuous medium with randomly distributed spherical inclusions. Odelevskii⁹⁴ pointed out that heterogeneous structures can be organised in two ways. A feature of distributed matrix structures is that one of the two or several constituent phases always forms a bound matrix, however small volume the phase occupies. The phases constituting a statistically distributed structure do not form a bound matrix. Therefore, we shall treat LGBS as distributed matrix structures the matrix of which consists of liquid channels with a thickness from fractions of a micron to several microns localised at the grain boundaries.

In some cases, the ionic conductivity increases at a certain ratio of phases that form a distributed phase.^{95–100} For example, the ionic conductivity can increase due to boundary phenomena on hetero-junctions.^{98,99} This is caused by disordering of crystal lattices in boundary regions and an increase in the concentration of mobile carriers. This effect is only characteristic of ionic conductors whose conductivity originates from the Frenkel or Shottky defects. Analogous effects are also possible if segregation

of an admixture on phase boundaries produces surface transition phases of a different chemical composition with enhanced conductivity.¹⁰⁰

Unlike the distributed structures mentioned above, LGBS incorporates continuous liquid channels along the grain boundaries. These channels can serve as diffusion paths for ions, since the activation energy of diffusion in a liquid is much lower than that in a solid. Figure 11 shows the dependence of the effective diffusion coefficient (D_{ef}) in LGBS on the volume fraction of phases calculated according to Maxwell and Hart.^{93,101} The diffusion coefficient in the solid phase was assumed to be $\sim 10^{-9} \text{ cm}^2 \text{ s}^{-1}$. For example, D_{ef} is $\sim 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ if the volume fraction of the liquid phase is 10%. Such a high diffusion permeability of LGBS is due to the presence of a highly conductive liquid matrix.

Thus, the high ionic conductivity of LGBS is caused by the formation of a distributed matrix structure rather than by structural disordering as is the case in superionic conductors.

5. Mechanism of the fast stage in the catastrophic oxidation of metals

The LGBS model makes it possible to explain the high COM rates. Before discussing the mechanism of copper catastrophic oxidation, let us accept several key assumptions.

1. A liquid layer is formed on the surface of copper due to thermal dissociation (or melting) of Bi_2CuO_4 . Let us assume that reaction (2) involves at least two stages:

Each of these steps has its own equilibrium constant. Since ionic bonds predominate in all of the above oxides, it may be assumed that further dissociation into ions occurs in the melt. As an example, let us express reaction (12) in the ionic form

where α characterises the degree of CuO dissociation according to reaction (12). Reaction (13), which describes an equilibrium between ions in solution, was written assuming total dissociation of CuO. In reality, the degree of dissociation is much less than unity, therefore we shall consider the liquid layer as a dilute solution.

2. As a result of interaction of grain boundaries with the liquid phase, an LGBS is formed as a product of copper oxidation.

3. Copper is oxidised with oxygen dissolved in the liquid layer. The oxygen concentration is replenished continuously by the atmospheric oxygen.

4. The diffusion of oxygen ions through the liquid layer and liquid intergranular channels (Fig. 12) is the rate-determining step of the process.

Figure 11. Effective diffusion coefficient of LGBS calculated according to Hart (1) and Maxwell (2); D_l is the diffusion coefficient in the liquid phase ($\sim 10^{-5} \text{ cm}^2 \text{ s}^{-1}$), V_2 is the volume fraction of the solid phase.

Figure 12. Topography of penetration of the liquid phase along the grain boundaries and interphase boundaries and a LGBS fragment in the catastrophic oxidation of copper.

5. The steady state is established locally all over the scale (where the scale is understood as the oxidation product + liquid layer).

6. The scale thickness is large in comparison with distances over which the effect of the bulk charge is felt (double electrical layer).

7. The solubility of oxygen in the metal can be neglected.

Let us consider the mechanism of diffusion growth of the oxide (see Fig. 12). Let us assume the thickness of copper oxide that formed to be h at time t and its growth to occur due to the oxygen supplied to the surface through liquid intergranular channels. If the concentration of oxygen in the growing oxide is designated as c^* , the mass balance equation is represented as follows

$$c^* \frac{dh}{dt} = J, \quad (14)$$

where J is the density of oxygen ion flux

$$J = -D \frac{dc}{dx}, \quad (15)$$

where D is the diffusion coefficient of oxygen ions and c is the concentration of the oxygen ions;

$$D = \frac{RT}{4F^2 \kappa}, \quad (16)$$

where κ is the partial specific electric conductivity of oxygen ions and F is the Faraday constant.

Let us consider two variants of the COM model. In the first one, the liquid layer is a film of thickness $\Delta = 10-100 \mu\text{m}$, $\Delta \leq \Delta_{\text{cr}}$, and $\Delta \leq h$ ($\Delta_{\text{cr}} \approx 100 \mu\text{m}$ corresponds to the experimentally obtained film thickness at which the maximum rate of copper oxidation is observed).^{28,29} It is assumed in this case that the material in the film is mixed and the concentration gradient of oxygen across the film thickness is absent. The oxygen concentration in the film is determined by dissociation equilibrium. However, a concentration gradient of oxygen exists in a liquid channel. The diffusion of oxygen occurs under permanent boundary conditions (stationary problem):

$$c(x=0, t) = c_0, c(x=\Delta, t) = c_1, c(x=\Delta+h, t) = c_2. \quad (17)$$

Assuming a linear distribution of oxygen concentration in the channel, one obtains

$$\nabla c = \frac{c_1 - c_2}{h}. \quad (18)$$

The oxygen concentration c_2 is very small, so one may consider $c_2 = 0$ and (taking into account the mixing in a liquid film) $c_1 = c_0$. Thus,

$$\nabla c = \frac{c_0}{h}. \quad (19)$$

Substitution of equation (19) into (15) gives

$$J = -D \frac{c_0}{h}. \quad (20)$$

The equation of mass balance (14) for thin films, taking account of (20), takes the form

$$c^* l \frac{dh}{dt} = \delta D \frac{c_0}{h}, \quad (21)$$

(l is the mean grain size of copper oxide and δ is the width of a liquid channel in LGBS) or

$$c^* \frac{dh}{dt} = D_{\text{ef}} \frac{c_0}{h}, \quad (22)$$

where

$$D_{\text{ef}} = D \frac{\delta}{l}. \quad (23)$$

Separation of the variables in equation (22) and integration gives a parabolic law of copper oxidation

$$h^2 = kt. \quad (24)$$

Here k is the rate constant for copper oxidation

$$k = 2D_{\text{ef}} \frac{c_0}{c^*}. \quad (25)$$

The diffusion of oxygen anions along the liquid channel to the growing oxide surface is accompanied by a less intense counter-diffusion of copper cations into the film, which increases their concentration in the film. According to equation (13), this shifts the equilibrium to the left. As a result, the concentration of oxygen anions c_0 , and hence k , decrease. If this phenomenon is named 'solution poisoning', it is obvious that the thinner the film the more pronounced this effect, and *vice versa*. Therefore, the dependence of k on the film thickness (for thin films, $\leq 100 \mu\text{m}$) can be explained by solution poisoning. This effect is insignificant and can be neglected for thick films.

Estimates show that if the degree of CuO dissociation according to reaction (12) equals unity and, accordingly, the degree of Bi_2CuO_4 dissociation according to reaction (11) is 0.25 (see Ref 59), and the degree of dissociation of Bi_2O_3 and Cu_2O into ions is about the same, the concentration of the oxygen anions in the liquid film is $c_0 \approx 0.03$ (in atomic fractions). The rate constant for copper oxidation under a thin layer of Bi_2CuO_4 is calculated according to the formula

$$k_{\text{theor}} = 2D_{\text{ef}} \frac{c_0}{c^*} \rho^2, \quad (26)$$

where ρ is the CuO density. At $c^* = 0.5$, $D_{\text{ef}} \approx 10^{-10} \text{ m}^2 \text{ s}^{-1}$, and $\rho_{\text{CuO}} = 6.45 \times 10^3 \text{ kg m}^{-3}$, we have $k_{\text{theor}} \leq 5.2 \times 10^{-4} \text{ kg}^2 \text{ m}^{-4} \text{ s}^{-1}$, which is comparable to the experimental value $k_{\text{exp}} \leq 2.1 \times 10^{-4} \text{ kg}^2 \text{ m}^{-4} \text{ s}^{-1}$ (see Fig. 3).

In the second case, the liquid layer thickness exceeds the critical value, $\Delta > \Delta_{\text{cr}}$ and $\Delta > h$. In this case, the gradient of oxygen concentration exists both in the channel and in the layer:

$$\nabla c = \frac{c_0 - c_1}{\Delta}, \quad (27)$$

where $\Delta = nh$, $n > 1$, i.e.

$$\nabla c = \frac{c_0 - c_1}{nh}; \quad (28)$$

in the channel

$$\nabla c = \frac{c_1}{h}. \quad (29)$$

The expressions for the flux of oxygen ions have the form:

$$J_{(\Delta)} = -D \frac{c_0 - c_1}{nh}, \quad (30)$$

in the channel

$$J_{(h)} = -D_{\text{ef}} \frac{c_1}{h}. \quad (31)$$

In the steady state

$$J_{(\Delta)} = J_{(h)}, \quad (32)$$

hence

$$D \frac{c_0 - c_1}{nh} = D_{\text{ef}} \frac{c_1}{h}. \quad (33)$$

Substituting (23) into (33), we obtain

$$\frac{c_0 - c_1}{n} = \frac{\delta}{l} c_1, \quad (34)$$

whence

$$c_1 = \frac{c_0}{1 + \delta n/l}. \quad (35)$$

The equation of mass balance (14) for thick layers is written in the form

$$c^* \frac{dh}{dt} = D_{\text{ef}} \frac{c_0}{h(1 + \delta n/l)}. \quad (36)$$

Integration of this expression gives a parabolic law of copper oxidation

$$h^2 = kt, \quad (37)$$

where

$$k = 2D_{\text{ef}} \frac{c_0}{c^*} \frac{1}{1 + \delta n/l}. \quad (38)$$

Thus, the number n increases and k decreases as the layer thickens, which is in accord with experimental results.^{28,29} The theory is also applicable if the rate of metal oxidation is controlled by the diffusion of cations. In this case, the picture changes symmetrically, and the liquid layer is adjacent to the metal (Fig. 12).

The suggested theory of COM is primarily valid in systems where oxidation results in the LGBS formation in the reaction products. As shown above, an LGBS is formed due to topochemical destruction or upon interaction of a liquid with grain boundaries of a solid. Therefore, the fast stage of the COM is most probable in metal–oxide systems in which formation of thermally unstable mixed or low-melting oxides is possible.

III. Super-fast stage of catastrophic oxidation of metals

1. Oxidation kinetics

In a study of the oxidation of copper under a bulk Bi_2O_3 layer thicker than 5 mm, it was found^{28,29} that at the instant when Bi_2O_3 melts (point A in Fig. 13) at $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}} \geq 20$, copper plates (0.5–1 mm thick) undergo super-fast (in 5–10 s) oxidation in the medium of Bi_2O_3 , thus reducing the latter. If $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}} < 20$, only the amount of copper equal to 1/20 of the Bi_2O_3 mass is oxidised super-fast, while the rest of copper is oxidised much more slowly. The $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}}$ ratio at which super-fast oxidation of

Figure 13. Kinetics of copper oxidation under a layer of Bi_2O_3 in air, $m_{\text{Bi}_2\text{O}_3} = 2.226$ g, $m_{\text{Cu}} = 0.036$ g.

Figure 14. Dependence of the critical ratio ($m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}}$) on the oxygen partial pressure (p_{O_2}).

copper occurs depends on the partial oxygen pressure p_{O_2} : when p_{O_2} decreases, $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}}$ decreases as well. The minimum value $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}} = 3.6$ is reached at $p_{\text{O}_2} \approx 10^2$ Pa (Fig. 14).

The literature contains controversial thermodynamic data for both the free energy of Bi_2O_3 formation and the dissociation pressure. According to some sources, copper reduces Bi_2O_3 , while it does not do so according to others.^{102–104}

2. Mechanism of the super-fast stage of catastrophic oxidation of metals

The high rate of copper oxidation under a layer of Bi_2O_3 melt at $p_{\text{O}_2} = 10^{-2} - 10^2$ Pa (see Fig. 14) can be explained as follows. The initial mass ratio $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}} = 3.6$ corresponds to 60 mol.% of Cu_2O and 40 mol.% of Bi_2O_3 (taking into account that all of the copper is oxidised into Cu_2O and the initial amount of Bi_2O_3 decreases accordingly). According to the phase diagram of $\text{Bi}_2\text{O}_3 - \text{Cu}_2\text{O}$ (see Fig. 9), the composition of 60 mol.% of Cu_2O and 40 mol.% of Bi_2O_3 and the temperature 816 °C correspond to point C on the liquidus line. If $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}} > 3.6$, the figurative point of the system is to the left of point C , while at $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}} = 3.6$, these points coincide. Copper is oxidised (reducing Bi_2O_3) into Cu_2O , which in turn undergoes continuous dissolution. Hence, super-fast oxidation occurs at the metal surface (without a protective oxide layer) due to a redox reaction. Withdrawal of reaction products from the reaction zone probably occurs by convective diffusion.

At $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}} < 3.6$, a fraction of copper which is 1/3.6 of the Bi_2O_3 mass is oxidised super-fast. After that, the figurative point of the system shifts to the right of C . Copper oxide formed on the copper surface is in the solid state and does not dissolve. Subsequent dissolution of copper occurs by the diffusion mechanism.

Super-fast oxidation of the metal occurs also at higher partial oxygen pressures, so that the $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}}$ ratio increases (see Fig. 14). In this case, the mechanism of copper oxidation does not differ in principle from that described above and the increase in $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}}$ at which super-fast copper oxidation occurs is due to the fact that CuO is stable at $p_{\text{O}_2} \approx 6 \times 10^3$ Pa,¹⁰² therefore the formation of Bi_2CuO_4 is possible,^{39–42} which is in accord with experimental results.^{28,29} The decrease in the amount of copper oxidised super-fast in air in comparison with the critical mass of copper oxidised *in vacuo* is due to the formation of Bi_2CuO_4 and hence depletion in the starting Bi_2O_3 . Copper undergoes super-fast oxidation and reduces bismuth oxide to the metal, which is subsequently oxidised with atmospheric oxygen (section AB in Fig. 13). Simultaneously, Cu_2O is partially oxidised to CuO . The insignificant mass decrease in the kinetic curve of copper oxida-

tion in point *A* is due to partial dissociation of Bi_2CuO_4 according to reaction (2).

Thus, super-fast copper oxidation is caused by continuous dissolution of the protective oxide film of Cu_2O in a Bi_2O_3 melt. Oxidation occurs on a permanently bare metal surface due to a redox reaction. The critical ratio $m_{\text{Bi}_2\text{O}_3}/m_{\text{Cu}}$ at which super-fast copper oxidation occurs is determined by the position of the figurative point on the liquidus line on the Bi_2O_3 – Cu_2O binary phase diagram, or on the liquidus surface in a ternary diagram if mixed oxides are formed.

IV. Conclusion

It should be noted that COM can occur both according to the electrochemical mechanism (diffusion of ions along liquid intergranular channels) and according to the flux formation mechanism (dissolution of the protective oxide layer). The realisation of the particular mechanism depends on the mass ratio of the liquid phase (m_L) and the metal (m_M) and the Gibbs free energies of formation of the solid product (ΔG_1) and the liquid phase (ΔG_2).

1. If $|\Delta G_1| > |\Delta G_2|$ and $m_L/m_M \geq A$, where *A* is the number determined by the position of the figurative point of the system on the liquidus surface corresponding to a definite composition and temperature on the phase diagram. In this case, a redox reaction is possible, while the LGBS formation is impossible; the figurative point of the system is located above the liquidus surface or coincides with it. The metal oxidation occurs at a very high rate according to the flux formation mechanism. The metal is oxidised within seconds.

2. If $|\Delta G_1| > |\Delta G_2|$ and $m_L/m_M < A$, then both the redox reaction and the LGBS formation are possible. A fraction of the metal amounting to $1/A$ of the mass of the liquid phase is oxidised according to the flux formation mechanism. The figurative point of the system is then shifted below the liquidus surface. An LGBS is formed on the metal surface. Subsequent metal oxidation occurs more slowly according to the electrochemical mechanism.

3. If $|\Delta G_1| < |\Delta G_2|$ and $m_L/m_M \geq A$, then both the redox reaction and the LGBS formation are impossible. Both the flux formation and electrochemical mechanisms are operative, therefore, the rate of metal oxidation is much lower than that in case 1.

4. If $|\Delta G_1| < |\Delta G_2|$ and $m_L/m_M < A$, then the LGBS formation is possible but the redox reaction is impossible. The metal fraction which amounts to $1/A$ of the mass of the liquid phase is oxidised as in the preceding case. The figurative point of the system is then shifted below the liquidus surface. An LGBS is formed on the metal surface. Subsequent oxidation follows the electrochemical mechanism.

The general picture of COM can be represented as follows. The catastrophic oxidation of metals under a thin liquid layer no thicker than $\sim 100 \mu\text{m}$ occurs by the electrochemical mechanism and is caused by the LGBS formation in the corrosion product. In this case, the contribution of super-fast oxidation according to the flux formation mechanism is insignificant, as the metal fraction that undergoes super-fast oxidation is as small as 0.5%–3%. As the layer thickness increases, the contribution of super-fast oxidation becomes greater, which would change the character of oxidation and increase the rate of the process.

Thus, the following conclusions can be made on the basis of the data presented above.

1. The fast stage of COM is caused by the LGBS formation in the corrosion product. The oxidation rate depends on the diffusion of ions along the liquid intergranular channels.

2. The super-fast stage of COM is caused by the high rate of dissolution of the protective oxide film. The oxidation occurs by a redox reaction on a continuously bare metal surface.

Abstract. The mechanisms of the cryotropic gelation of poly(vinyl alcohol) solutions as well as the influence of the characteristics of the polymer and the conditions of the cryogenic treatment on the structure and physicochemical properties of the cryogels obtained are examined. Data on the characteristics of the freezing of concentrated poly(vinyl alcohol) solutions are presented. The influence of soluble additives, possessing different lyotropic properties, on the course of gelation in frozen systems is discussed. The possibility of the cryocracking of poly(vinyl alcohol) chains is considered. The bibliography includes 349 references.

I. Introduction

The cryogels based on polymer systems are macroporous heterophase gels formed as a result of the freezing, storage in the frozen state, and subsequent thawing of the initial solutions or colloiddally disperse objects (colloid solutions, pastes, coagulates, *etc.*) in which preconditions for structure formation and transition into a gel are already present or are specially created (for example, by the introduction of a cross-linking agent). An obligatory condition for the formation of heterogeneous gels is then the crystallisation (freezing) of the main bulk of the low-molecular liquid (solvent). After its thawing out, anisotropic macroporous gel-like polymeric products, called cryogels, or cryostructurates are formed.^{1–4} As in the case of the usual gels, produced in a liquid solvent, the junctions of the three-dimensional network of the cryogels can be of different nature: they can be established covalently (chemically cross-linked preparations), maintained as a result of relatively undissociated salt or coordinate-ionic bonds (ionotropic systems), stabilised by noncovalent interaction forces [thermoreversible (physical) cryogels], or they may represent a combination of these types of intermolecular contacts.^{4–9}

Although individual examples of the formation of gel-like structurates after the freezing–thawing of solutions or dispersions of polymers have been known for a fairly long time (thus sponges produced by the freezing of starch paste were manufactured in Germany in the 1940s¹⁰), this type of gelation began to be studied systematically only during the last 15 years. These investigations

led to the creation of definite ideas about the principal mechanisms of the cryotropic gelation processes, specific effects characteristic of this process alone, its common features with gelation in unfrozen systems, and also the influence of various parameters of each stage of the cryogenic treatment on the properties of the materials obtained.^{2, 4–9, 11, 12}

The cryotropic gelation of solutions of poly(vinyl alcohol) (PVA) is examined in the present review. PVA-based cryogels are of great interest — both theoretical and applied. They have found extensive application in biotechnology, medicine, food industry, *etc.* In many respects, this interest is due to the excellent mechanical, diffusional, and thermophysical properties of the PVA cryogels (cryoPVAG), the availability of the polymer itself, its nontoxicity and biocompatibility, and also the relative ease of the method of formation of the gel (the PVA solution is simply frozen for a certain period and then thawed out). By varying the characteristics of the polymer employed (molecular mass, molecular mass distribution, the content of residual *O*-acyl groups, tacticity, PVA concentration in the system) the composition of the solvent, the nature of soluble additives (if these are introduced in the initial system), and also the regime in the cryogenic treatment (temperature and duration of freezing, rate of thawing, the number of refreezing cycles, *etc.*), it is possible to regulate within wide limits the physicochemical parameters of the final gels and their macro- and micro-structures. All these aspects will be discussed in the subsequent sections of the review.

The ability of PVA to give rise to gels after the freezing–thawing of its solutions (here and henceforth we are dealing mainly with a polymer having an insignificant content of acyl residues in the lateral chains) was apparently first observed by Inoue.^{13–17} He described the preparation of gel fishing baits from a mixture of a solution of PVA with fillers and aromatising agents. In order to obtain the gel, the initial suspension, poured into an appropriate mould, was initially frozen at a temperature below -5°C for several tens of hours and then thawed out. In the scientific literature, a direct indication of such gelation appeared in the paper of Kukharchik and Baramboim,¹⁸ who noted that in the case of PVA ($M = 80\,000$) solutions with a concentration $> 3\text{ g}/100\text{ ml}$ the cryolytic cycles (freezing for 2 min at -78°C and thawing at 25°C for 15 min) resulted not only in an increase in viscosity but also in gelation. However, none of the characteristic features of such gelation of PVA and the properties of the cryogels were reported in the above investigation.¹⁸

Mention should also be made of the work of Polish investigators,^{19, 20} who observed by the light scattering method the promoting effect of the cryogenic treatment on the association of

PVA macromolecules in aqueous media, and also of the somewhat later study by Peppas.²¹

Some time later, the PVA cryogels were, as it were, 'rediscovered'. This is probably associated with the observation of the possibility of increasing the mechanical strength of cryoPVAG as a result of the repeated freezing–thawing of the cryogel already obtained^{12, 22–31} or the partial dehydration of the frozen specimen *in vacuo* (partial lyophilisation).^{32–40}

According to *Chemical Abstracts*, about 500 communications have been published on the cryotropic gelation of PVA, only a small proportion of these publications having been considered in the reviews of Nambu¹¹ (1990) and Peppas and Stauffer¹² (1991), as well as in our earlier review⁴¹ (1992). The aim of the present review is to provide a more comprehensive pattern of the state of research into the given problem and also to note the problems which are still obscure.

II. Characteristic features of the freezing of poly(vinyl alcohol) solutions

It is well known that prolonged storage of concentrated aqueous PVA solutions at room temperature gives rise to gel formation (see, for example, Refs 42–46). A similar result can be achieved faster by cooling the system (without freezing)^{20, 47} or by impairing the thermodynamic quality of the solvent as a result of the introduction of nonsolvent additives.^{48–52} In all cases low-melting (melting point $T_m < 30–40\text{ }^{\circ}\text{C}$), mechanically weak, and as a rule almost transparent (opalescent) thermoreversible hydrogels are formed. On the other hand, if concentrated aqueous PVA solutions are initially frozen and are then thawed out after being maintained in the frozen state for a time, then turbid, elastic, high-melting ($T_m > 60–80\text{ }^{\circ}\text{C}$) heterogeneous gels (cryogels) are formed under certain conditions instead of the transparent hydrogels. Evidently the behaviour of the water–PVA system subjected to cryogenic action should affect the properties of the cryogels obtained and the kinetics of their formation.

Figure 1 presents a generalised picture of the variation of the temperature of the system at all the stages of cryostructuration, *i.e.* on freezing, storage in the frozen state, and thawing. Interval $A–B$ corresponds to the cooling of the specimen from the initial temperature to the temperature of the onset of crystallisation of the solvent (supercooling to a temperature T_u is frequently observed for PVA solutions). Owing to the evolution of the latent heat of crystallisation of ice, a 'crystallisation plateau' is usually recorded along section $C–B$, but at high rates of cooling ($v_c > 40\text{ K min}^{-1}$) this plateau may not in fact be observed on the real time scale.⁵³ A further decrease in temperature occurs

between the points D and E up to the experimentally specified value (T_s).

It has been shown^{4, 54, 55} that the depression of the crystallisation temperature of the system ($T_0 - T_f$) for 5%–10% aqueous solutions of PVA did not exceed $0.3–0.8\text{ }^{\circ}\text{C}$, while the extent of supercooling is a parameter poorly reproducible with respect to temperature in view of the statistical nature of the ice nucleation processes.⁵⁶ In the main, the trend is as follows: with increase in the PVA concentration in the initial solution, the supercooling temperature (T_u) falls and ice formation proper proceeds at a higher rate. The higher the rate of crystallisation, the finer are the polycrystals of the freezing low-molecular liquid produced.⁵⁷ Thus the size of the ice crystals in the 7% PVA solution frozen at $-10\text{ }^{\circ}\text{C}$ is several times smaller, and in the 14% solution — smaller by 1–2 orders of magnitude than in frozen pure water.⁵⁸

Such microstructure of the polymer-reinforced ice affects significantly the physicochemical characteristics of the frozen specimens⁵⁹ and an appreciable strengthening of such composite ice is observed even for a 1% PVA content in the initial solution and the ultimate uniaxial compression strength of the 10% preparation frozen at $-10\text{ }^{\circ}\text{C}$ is already an order of magnitude higher than for pure ice. After a time, this parameter slowly increases, which has been shown by studies involving the use of the NMR method,⁵⁸ to be accompanied by a gradual decrease in the amount of unfrozen water.

Important information about the properties of the water–PVA system at various negative temperatures has been provided by the study of the ESR spectra of a spin probe (4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl) introduced into the initial polymer solution before freezing. It has been found^{60–63} that the correlation times of the rotational mobility of the stable nitroxyl radical, which depend directly on the viscosity of the micro-environment where reorientation movements of the probe take place, corresponds, for not unduly deeply frozen PVA solutions, to the rotations of the nitroxyl radical in a highly viscous but liquid medium. This shows that such polymer solutions, solidified by freezing (in particular aqueous PVA solutions), represent at least two-phase systems incorporating the crystalline phase of the frozen solvent and the phase comprising a heavily concentrated polymer solution — the so-called liquid microphase.^{64–66} Quantitative estimates of the volume of such liquid microphases of frozen PVA solutions have been made with the aid of a special method⁶⁰ for the analysis of ESR spectroscopic data. It has been shown that the amount of the liquid component varies from $0.86–0.88\text{ g}$ of H_2O per gramme of the polymer at $-9\text{ }^{\circ}\text{C}$ to 0.75 g of H_2O per gramme of the polymer at $-85\text{ }^{\circ}\text{C}$; the latter quantity was limiting and referred to unfrozen water. Approximately the same result ($\sim 0.8–0.9\text{ g}$ of H_2O per gramme of polymer) was obtained with the aid of NMR spectroscopy^{67, 68} and differential scanning calorimetry.⁶⁹ Taking into account the 10%–15% error of the determination by each of these methods, such agreement should be regarded as rather good.

In the region of 'high' negative temperatures (from -1 to $-7\text{ }^{\circ}\text{C}$), hysteresis phenomena are observed (Fig. 2), *i.e.* the amount of the liquid microphase and hence the concentration of the polymer dissolved in it depend greatly on the thermal pre-history of the system in the real (far from equilibrium) cooling or heating regimes. In particular, if fairly rapid heating of the frozen specimen is arrested at some intermediate temperature (in Fig. 2, this is $-4\text{ }^{\circ}\text{C}$), the system gradually relaxes to a phase state closer to equilibrium (transition 3, Fig. 2). Therefore, the slower the cooling of the frozen preparation or correspondingly the slower its heating during thawing, the greater is the extent to which the possible transformations of liquid water into ice are able to occur or, conversely, the closer to equilibrium is the amount of the liquid microphase.

Direct observations at negative temperatures of the mobility of the unfrozen part of water in the water–PVA system have been carried out^{67, 68} with the aid of ^2H NMR spectroscopy. For this purpose, the polymer was dissolved in D_2O . The NMR signals of

Figure 1. Generalised thermogram for cryotropic gel formation; T_i = initial temperature of the system, T_0 = temperature at which the pure solvent is frozen, T_f = temperature at which the system is frozen, T_u = lowest supercooling temperature, T_s = temperature at which the specimen is stored in the frozen state.

Figure 2. Dependence of the relative amount of unfrozen water on the temperature of the frozen 10% PVA solution (m_w = mass of water remaining liquid in the frozen specimen; m_{PVA} = mass of PVA dissolved in the liquid microphase);⁶⁰

(1) cooling of the specimen beyond the crystallisation plateau of pure water; (2) heating; (3) thermostatic regime at -4°C .

the heavy water deuterons in the solid and liquid states differ in width by two orders of magnitude and it is therefore possible to record the spectra referring to the D_2O molecules not incorporated in the ice structure. The ^2H NMR spectra of a 10% solution of PVA ($M=82\,000$), frozen to a temperature of -52.2°C , which is 56°C lower than the crystallisation point of the pure solvent ($T_0 = +3.8^\circ\text{C}$), contain one symmetrical signal without quadrupole splitting. The width of this signal depends on the temperature and in the temperature range indicated varies from several tens to ~ 5000 Hz. The nature of the spectra then indicates the virtually isotropic reorientation of the solvent molecule, which indicates the rapid (10^{-5} s on the NMR time scale) rotational and translational diffusion of water in the isotropic medium; *i.e.* in the unfrozen liquid microphase the water molecules are subjected to interactions which are virtually equivalent and equally probable in all directions. On the other hand, the proportion of the solvent located near the anisotropic interfaces is, firstly, small and, secondly, it apparently exchanges rapidly with the molecules from the bulk of the liquid inclusions. On further cooling of the specimen to temperatures $60\text{--}70^\circ\text{C}$ lower than its freezing point, the symmetrical Gaussian peak (with a width of ~ 5 kHz at the level of half its height) is transformed into a two-component signal, the upper component of which has been broadened by a factor of 4, while the lower component, the so-called 'pedestal', corresponds to a signal with a greatly increased spin-lattice relaxation time. It has been suggested⁶⁷ that this character of the spectrum at the temperatures indicated is caused by the slow exchange of the ^2H nuclei of the solvent and the polymer.

Thus it has been shown that moderately frozen PVA solutions are heterophase objects containing the unfrozen mobile solvent, the minimum amount of which corresponds to the ratio ~ 4 water molecules for 3 polar chain groups.

Yet another effect which can occur in principle during the freezing of polymer solutions, including aqueous PVA solutions, is cryocracking, *i.e.* the cryogenic mechanical degradation of the chains of high-molecular compounds under the influence of the dynamic stresses arising on crystallisation of the low-molecular solvent. Berlin and coworkers^{70–73} were the first to draw attention to the possibility of such mechanochemical transformations of polymers during the freezing–thawing of their solutions. Somewhat later Jellinek and Fok⁷⁴ calculated the critical rates of movement of the fronts of the crystallisation of the solvent (v_{cr}) and of the migration of the microstreams of the liquid ahead of the growing faces of the crystals, which are necessary to develop forces sufficient for the disruption of the covalent bonds of the main framework of the carbochain polymers. These calculations were performed for two types of physical action on the macromolecule: (a) impact across the chain fixed (frozen in) at both ends (which is generally speaking an extremely improbable event) and (b) the

frictional shear force of the liquid stream ahead of the crystallisation front exerted on the chain fixed at one end. Calculation yielded the following values of v_{cr} : $\sim 100\text{ m s}^{-1}$ in the first case and $\sim 0.5\text{ m s}^{-1}$ in the second. On the other hand, in practice the attainable rates for preparations with a volume of several millilitres do not exceed $0.002\text{--}0.003\text{ m s}^{-1}$.⁷⁵ For preparations with a volume of several microlitres, it is possible to achieve an increase in the rate by 1–2 orders of magnitude during their rapid freezing (for example, in liquid nitrogen), but even such increase in the rate makes it possible merely to approach the second case. Therefore one should apparently not expect a real manifestation of the mechanical degradation of PVA for shallow freezing of its solution under the conditions employed for the formation of cryoPVAG.

Thus in a study of the behaviour of PVA solutions during thawing and freezing with the aid of capillary viscometry, Kukharchik and Baramboim^{18,76} failed to observe any kind of cracking of PVA either during single or repeated freezing–thawing of dilute and semidilute solutions of the polymer ($M=80\,000$). Nevertheless, facts have been described which indicate, according to the authors,^{77–80} the occurrence of homolytic cleavage of PVA by the cryogenic influence; here it has also been suggested⁷⁷ that cracking is accompanied by the simultaneous covalent cross-linking of the polymer molecules as a result of reactions between the macroradicals formed and the neighbouring chains.

However, a thorough test of the results of the above studies^{77–80} failed to confirm the conclusions reached in them.^{81,82} In the first place, the cryoPVAG are thermoreversible gels which melt on heating (for example, on a boiling water bath). Here the viscosities of the initial solutions of PVA ($c_p = 6\%\text{--}10\%$) having different molecular masses ($69\,000\text{--}110\,000$) and solutions obtained from the corresponding cryogels after fusion of the latter hardly differ, which indicates the absence of intermolecular cross-linking. Capillary viscometry does not reveal reliably detectable changes in the intrinsic viscosities of the PVA preparations, provided that the initial polymer does not contain any impurities. Thus lines 4 and 5 in Fig. 3 illustrate the dependence of $[\eta]$ on the number of cycles in the cryogenic treatment of solutions of two different batches of the same brand of technical-grade PVA, for which both a decrease (line 5) and an increase (line 4) in $[\eta]$ were observed, whereas variation within wide limits of the freezing–thawing regimes for solutions of the same polymer purified by reprecipitation does not induce changes in the intrinsic viscosity (lines 1–3, Fig. 3). Thus the possible reactive impurities contained in industrial PVA, concentrated in the liquid microphase of the frozen preparations, may be the cause of the change in the properties of the polymer recorded after the cryogenic action.

Figure 3. Dependence of the intrinsic viscosity $[\eta]$ of PVA on the number of freezing–thawing cycles (n) for a 10% PVA solution of brand 20/1.

(1)–(3) PVA purified by reprecipitation ($M=81\,700$, $\text{DD}=98\%$); (4) and (5) unpurified PVA (two different batches of technical-grade polymer). Cryogenic treatment regimes: (1), (4), and (5) $v_c = 1.8\text{ K min}^{-1}$ (freezing at -15°C and storage at this temperature for 18 h), heating rate $v_{th} = 1.0\text{ K min}^{-1}$; (2) $v_c = 1.8\text{ K min}^{-1}$, $v_{th} = 0.3\text{ K min}^{-1}$; (3) $v_{th} = 180\text{ K min}^{-1}$ (freezing in liquid nitrogen for 30 min and storage at -15°C for 18 h), $v_{th} = 0.3\text{ K min}^{-1}$.

What precisely these impurities are is unknown, their compositions and amounts are not the same in different batches of the polymer of the same brand. On the other hand, in the case of specimens of pure PVA the changes in molecular mass and manifestations of mechanical degradation are not observed either viscometrically or with the aid of high performance GPC or any other physicochemical methods — IR, ESR, *etc.*^{81,82} One may therefore conclude, to within the sensitivity of the analytical procedures employed, that the cracking of the PVA chains on cryogenic treatment is negligible, if it does occur at all, which is in no way reflected in the cryotropic gelation of the given polymer.

III. Dependence of the properties of poly(vinyl alcohol) cryogels on the characteristics of the gel forming polymer

The structure and properties of PVA cryogels depend on many factors, including both the characteristics of the polymer itself and the conditions of the low-temperature gelation. One of the most important parameters determining the possibility, in principle, of the formation of cryoPVAG, is the presence in the polymer of residual *O*-acetyl groups.^{9,24,25,83} In the majority of cases described, the cryogels were prepared from poly(vinyl alcohols) obtained by hydrolysing poly(vinyl acetate). It was found that, for a degree of deacetylation (DD) below 90%, the cryoPVAG are not formed under any, even the most favourable, conditions. For a content of *O*Ac residues of 5%, very weak cryogels are obtained, and it is actually difficult to measure correctly their rheological characteristics. Only on the basis of concentrated aqueous solutions of PVA of highly deacetylated brands (DD > 97%) is it possible to form fairly strong cryogels. Bearing in mind that the bonds between the polymer chains in the gels formed are non-covalent, *i.e.* the intermolecular contacts in the regions of micro-crystallinity are ensured by a multiplicity of hydrogen bonds between the secondary alcohol groups of different chains,^{35,84} the steric hindrance generated by the bulky *O*Ac residues, interfering with the establishment of extended complementary contacts, should be included among the evident causes of the 'poor' gelation of the insufficiently deacetylated PVA preparations.

The macromolecules of atactic poly(vinyl alcohols) in water are known^{43,85,86} to tend to associate, whereupon the intermolecular hydrogen bonds arise mainly with participation of the OH groups of the syndiotactic (*s*) PVA blocks while the intramolecular hydrogen bonds are produced with participation of the OH groups of the isotactic (*i*) fragments.

Thus the higher the content of the *s*-diads in the polymer employed, the stronger is the manifestation of the tendency towards phase separation in its solutions^{87,88} with formation of a microgel fraction, a gel, or even a precipitate. The cryogels based

on PVA enriched in syndiotactic fragments have a higher degree of crystallinity⁸⁹ compared with specimens based on the atactic polymer of approximately the same molecular mass, which indicates the retention of the above tendency also on cryotropic gelation of this polymer. Unfortunately the cryoPVAG prepared from poly(vinyl alcohols) with an increased content of *s*-sections have been inadequately investigated, but there is no doubt of the interest in such studies, particularly since new ways of synthesising PVA with a controllable tacticity are being vigorously developed nowadays.

It is entirely evident that the molecular mass of the polymer used for the formation of cryogels must influence its properties. Thus fairly weak cryoPVAG are obtained from highly concentrated ($c_p = 20\%$) solutions of PVA with a low degree of polymerisation ($M < 30\,000\text{--}40\,000$),^{4,11,24,54,90} so that it is preferable to employ PVA brands with $M > 50\,000$ for the formation of strong cryogels.

Figure 4 presents the creep curves for equiconcentrated cryoPVAG prepared from PVA with different contents of the residual *O*Ac groups and different degrees of polymerisation. For the close molecular masses (curves 2 and 4), the additional presence in the polymer of even small amounts (1.3%) of unhydrolysed side groups affords a cryogel with a compliance greater by a factor of 3, whilst in specimens with an almost identical degree of deacetylation of PVA (curves 1, 2, and 3) less compliant (more elastic) cryoPVAG are obtained for the higher the molecular mass of the polymer.⁵⁴ These and similar results^{4,24,25,90–93} for the influence of the size of the PVA macromolecules on different characteristics of the corresponding cryogels are fully consistent with the well-known dependences of the properties of noncovalent thermoreversible gels (formed at positive temperatures) based on both PVA^{49,94–97} and other polymers.^{98–101} Since the hydrodynamic dimensions of the macromolecules increase with increase in the chain length, the degree of overlap of the coils in solution rises and the number of topological entanglements increases, *i.e.* there is an increase in the number of intermolecular contacts, as a result of which a denser physical network is produced in the gel formed. Such gels are harder and have higher melting points

Figure 4. Creep curves for cryogels formed from 10% aqueous solutions of PVA with different molecular masses and degrees of deacetylation.^{54,91} (1) $M = 69\,000$, DD = 98%; (2) $M = 90\,000$, DD = 98%; (3) $M = 110\,000$, DD = 98%; (4) $M = 95\,000$, DD = 99.3%. Cryostructure regime: $T_s = -10\,^{\circ}\text{C}$, $t_s = 24\text{ h}$, $v_{th} = 1.0\text{ K min}^{-1}$.

The properties of cryoPVAG are influenced similarly also by the variation of the PVA concentration in the initial solution — the higher the concentration, the stronger and more thermostable (other conditions being equal) are the corresponding cryogels obtained.^{4,9,11,12,22–25,35–37,40,54,55,58,83,84,89,91,102–113} It is shown in Fig. 5 that the cryogel formed on cryotreatment of a 10% PVA solution is fairly compliant and is deformed appreciably during the application of a shear load, whereas the cryogels obtained from a 14% and especially a 16% PVA solution exhibit only a slight creep under the same shear stresses.

Figure 5. Creep curves for cryogels formed from aqueous solutions of PVA ($M = 69\,000$, $DD = 98\%$) with different polymer contents: (1) 10%; (2) 14%; (3) 16%.⁹¹ Cryostructuration regime: $T_s = -10\text{ }^{\circ}\text{C}$, $t_s = 24\text{ h}$, $v_{th} = 1.0\text{ K min}^{-1}$.

When a PVA solution freezes, the pure solvent crystallises initially (Fig. 1), while the solute is concentrated in the still liquid part of the specimen. Such cryoconcentration intensifies significantly the polymer–polymer interactions which ultimately leads to the formation of stable junction of the three-dimensional cryogel network. Since these processes occur in a heterophase system, a heterogeneous gel is obtained after it has thawed out. Pores of different size and geometry are formed in it under the influence of the crystals of the frozen solvent. Thus the solvent plays the role of a porogen. According to electron microscopy data, the structures of the cryoPVAG formed from solutions with unequal polymer contents differ, although their structural feature such as pronounced heterogeneity, *i.e.* the presence of micropores and macropores, is characteristic of any PVA cryogels. The morphology of 14% and 16% cryoPVAG is illustrated in the photomicrographs in Figs 6a and 6b. Their creep curves are presented in Fig. 5 (curves 2 and 3). The high porosity of the preparations is most striking. With increase in the PVA concen-

Figure 6. Structures of cryogels formed from 14% (a) and 16% (b) aqueous solutions of PVA ($M = 69\,000$, $DD = 98\%$).^{54, 91} Cryostructuration regime: $T_s = -10\text{ }^{\circ}\text{C}$, $t_s = 24\text{ h}$, $v_{th} = 1.0\text{ K min}^{-1}$.

tration, a decrease in the size of the macropores and a thickening of the elements of the polymer phase of the heterogeneous gel are observed, which agrees well with the smaller compliance of the more concentrated specimen.

Perhaps the only characteristic of PVA the influence of which on the properties of cryoPVAG has so far been virtually investigated is the molecular mass distribution (MMD) of the gel forming polymer. Nevertheless it is quite evident that the use of PVA with a narrower MMD should promote an increase in the strength parameters of the cryogels.

IV. The influence of the conditions in the cryogenic treatment on the properties of poly(vinyl alcohol) cryogels

It was already stated above that virtually all the parameters of the regimes in the cryogenic treatment influence, albeit not to the same extent, the characteristics of the cryoPVAG and the dynamics of their formation. These questions have been investigated in fair detail.

The process temperature and the effectiveness of the heat exchange determine the possibility of the supercooling and the rate of crystallisation of the specific specimen: usually the lower the T_f (Fig. 1), the lower the probability of the supercooling, and hence the more rapid the liquid–solid phase transition for the main bulk of the low-molecular solvent. By altering the thermal conductivity conditions (for example, by employing vessels made from different materials, or by increasing the thickness of the walls of the vessel, or by employing thermal insulation), it is possible to control the dynamic freezing and thawing parameters. As a result of such experiments, it has been found^{55, 102} that the degree of supercooling and the rate of crystallisation of ice do not vary in parallel with the variation of the rate of cooling, which indicates the complexity of the dependence of the freezing regimes for concentrated aqueous PVA solutions on different process factors. Thus, for a 14% polymer solution poured into a 5 mm duralumin mould, the change in v_c from 0.09 to 17.0 K min^{-1} (*i.e.* almost by a factor of 190) entails a change in v_{cr} in the range from 0.35 to 2.5 K min^{-1} (the difference is a factor of only 7.1), while the rheological parameters of the cryogels obtained altogether change very slightly and, other conditions being equal, depend little on v_c . Therefore, in comparing the properties of the cryoPVAG specimens formed at different T_f , the influence of the dynamics of the freezing itself may be virtually disregarded. In the main, the physical characteristics and the structure of the PVA cryogels are determined by the temperature and duration of the cryogenic action,^{24, 58, 91, 106, 114} provided that the preparations are thawed out under identical conditions.^{55, 115} Thus it has been observed that, after brief (up to 24 h) storage of the specimen in the frozen state, the lower the T_f , the less compliant the corresponding cryoPVAG. With increase in the duration of the cryogenic process, the trend changes (Fig. 7). The specimens kept at $-20\text{ }^{\circ}\text{C}$ and then for 24 h at $-10\text{ }^{\circ}\text{C}$ become harder than the preparations maintained at $-30\text{ }^{\circ}\text{C}$. A characteristic feature is that the duration of the storage in the frozen state ceases to influence their strength properties fairly early (after $\sim 24\text{ h}$), whereas in the specimens stored at -10 and $-20\text{ }^{\circ}\text{C}$ the values of J_0 after cryogenic treatment for 10 days still remain unstabilised,⁹¹ which indicates the continuation at these temperatures of the changes associated, as already mentioned, with the slow decrease in the amount of the uncrystallised solvent.⁵⁸

Like their strength, the thermophysical properties of the cryoPVAG also depend on the parameters examined above; the increase in the degree of deacylation or in the molecular mass of the polymer as well as in its concentration in the initial solution promotes an increase in the melting point of these thermoreversible gels.^{11, 23–25, 35–37, 40, 54, 55, 83, 105, 106} A decrease in T_f and an increase in the duration of the storage of the specimens in the frozen state exert the same influence.^{55, 106}

Figure 7. The influence of the temperature and duration of freezing of 14% solutions of PVA ($M = 69\,000$, $DD = 98\%$) on the rheological properties of the cryogels formed.⁹¹ T_s (°C): (1) -10 ; (2) -20 ; (3) -30 .

However, the most significant factors which radically affect the properties of the PVA cryogels are the regimes of the defrosting of the specimens.^{55, 106, 109, 115, 116} A detailed study of this stage of the cryostructure formation made it possible to establish the principal features of the mechanisms of this type of gel formation. It has been observed^{4, 54, 55} that, when the thawing out is carried out at a rate greater than 10 K min^{-1} , then, regardless of the conditions under which the initial polymer solution was frozen and then exposed to temperatures between -10 and -30 °C, one obtains after such 'rapid' thawing out not a gel but a viscous and turbid colloid solution. Conversely, on slow thawing out ($v_{th} \leq 0.05\text{--}0.01\text{ K min}^{-1}$) very elastic cryogels are formed.

Figure 8a illustrates the influence of the rate of thawing of the specimens on the apparent instantaneous compliances (J_0) of the PVA cryogels, whilst Fig. 8b demonstrates the dependence of the same rheological parameter on the polymer concentration in the initial solution for two series of experiments in which the thawing out was carried out at rates of 1.0 and 0.02 K min^{-1} .

Figure 8 shows that the compliance of the cryogels diminishes as the thawing out of the corresponding preparations slows down; for $v_{th} = 1.0, 0.1$, and 0.02 K min^{-1} , $J_0 = 8.1 \times 10^{-4}, 0.6 \times 10^{-4}$, and $0.45 \times 10^{-4}\text{ Pa}^{-1}$ respectively (Fig. 8a). If the PVA solution is maintained at -20 °C for 10 days and is then thawed out at a rate of 1.0 K min^{-1} , then a cryogel with $J_0 = 1.25 \times 10^{-4}\text{ Pa}^{-1}$ is obtained, while in the case where the rate of thawing is lower by an order of magnitude ($v_{th} = 0.1\text{ K min}^{-1}$), after freezing for 1 h at

Figure 8. The influence of the rate of thawing of the specimen (a) and of the concentration of the polymer in the initial solution (b) on the rheological properties of cryogels formed from aqueous solutions of PVA ($M = 69\,000$, $DD = 98\%$).⁵⁵ (a) $c_p = 14\%$; (b) $T_s = -20$ °C, $t_s = 1\text{ h}$, $v_{th} = 1.0$ (1) and 0.02 K min^{-1} (2).

Figure 9. Thermomechanical properties of cryogels formed from 14% solutions of PVA ($M = 69\,000$, $DD = 98\%$) at $T_s = -20$ °C and $t_s = 1\text{ h}$ and thawed out at different rates v_{th} (K min^{-1}):¹⁰⁶ (1) 1.0 ; (2) 0.2 ; (3) 0.02 .

-20 °C a more rigid cryoPVAG is formed. Similarly a decrease in v_{th} makes it possible to lower the concentration of the gel forming agent without loss of the strength characteristics of the cryoPVAG (Fig. 8b).

Figure 9 presents the thermomechanical curves for specimens of cryogels thawed out at different rates. It is seen from the figure that the slowly thawed out preparations are, firstly, deformed to a smaller extent by an applied load as the temperature rises and, secondly, they melt at higher temperatures on heating, *i.e.* are more thermostable.¹⁰⁶ The presence of two inflection regions on the thermomechanical curve for the specimen which was thawed out fairly rapidly (curve 1, Fig. 9) indicates the presence in the structure of such a gel of at least two types of junctions differing in the thermal dissociation energies. Those of the first type melt at $35\text{--}45$ °C, while these of the second type melt at $60\text{--}65$ °C. Two endothermic peaks have been recorded in the same temperature ranges also with the aid of differential scanning calorimetry^{38, 116} and the first of these, corresponding to the decomposition of the low-melting nodes, is approximately at the temperatures ($20\text{--}40$ °C) at which melt the usual thermoreversible PVA hydrogels formed on ageing of concentrated polymer solutions without freezing.^{44, 117} On the other hand, the complete fusion of the cryoPVAG, caused by the thermal dissociation of the high-melting junctions (the microcrystallinity zones), occurs at a temperature higher by tens of degrees. The melting points T_m , like the other characteristics of the gel objects, are sensitive to the previous thermal history of the specimens (Table 1).⁵⁵

If the dependence of the melting point of the cryoPVAG on the polymer concentration in the system is represented in terms of the variables of the Eldridge–Ferry equation⁹⁸

$$\lg c_p = \frac{\Delta H}{2.3RT} + \text{const},$$

Table 1. The influence of the conditions in the cryotropic gel formation on the melting point of cryoPVAG.

Cryogenic treatment regimes			T_m / °C
T_f / °C	t_f / h	v_{th} / K min^{-1}	
-10	24	1.00	73.5 ± 0.3
		1.00	74.0 ± 0.2
		0.20	74.8 ± 0.2
		0.02	76.0 ± 0.2
-20	72	1.00	74.1 ± 0.2
		240	74.4 ± 0.1
		1.00	74.4 ± 0.1
		1.00	73.7 ± 0.2

Note. A 14% solution of PVA with $M = 69\,000$ and $DD = 99.0\%$ was used.

Figure 10. Relation between the melting points of cryogels and the concentration of PVA ($M = 69\,000$, $DD = 98\%$) in the initial solutions frozen at $-20\text{ }^{\circ}\text{C}$ during 24 h and thawed out at the rate of $0.02\text{ }^{\circ}\text{C min}^{-1}$ (1) and $1.0\text{ }^{\circ}\text{C min}^{-1}$ (2)⁵⁵ in terms of the variables of the Eldridge–Ferry equation.

it is possible to estimate the enthalpies of fusion of the cryogels obtained under different conditions (Fig. 10). The values of ΔH are $68 \pm 2\text{ kJ mol}^{-1}$ for preparations thawed out at a rate of $1.0\text{ }^{\circ}\text{C min}^{-1}$ and $87 \pm 2\text{ kJ mol}^{-1}$ for preparations thawed out at $v_{\text{th}} = 0.02\text{ }^{\circ}\text{C min}^{-1}$.⁵⁵ Comparison of these quantities with the available data⁴⁴ for the usual PVA hydrogels obtained on ageing of 10%–20% solutions of the polymer ($M = 60\,000$), the melting points of which are in the range $14\text{--}28\text{ }^{\circ}\text{C}$ and $\Delta H = 37\text{ kJ mol}^{-1}$, shows clearly that the energy of the thermal decomposition of the junctions of the cryogel network is at least twice as high as for the usual gel, *i.e.* the promoting effect of the freezing of the PVA solutions on the association of the macromolecules of the polymer and its crystallisation is clearly seen.

The microstructure of the PVA cryogels also depends on the dynamics of the thawing out process: the slower is the thawing out process, the lower the degree of heterogeneity of the preparations according to scanning electron microscopy data.^{4,54,55,118} According to transmission electron microscopy data,⁹¹ the primary elements of the supermolecular structure of the cryoPVAG are globular formations $0.01\text{--}0.02\text{ }\mu\text{m}$ in diameter, combined into larger globular aggregates $0.2\text{--}0.5\text{ }\mu\text{m}$ in diameter, which form in their turn bead-like strands of the three dimensional network of the macroporous cryogel. It is of interest that similar globular aggregates have been observed⁵¹ also in the structure of hydrogels obtained either on ageing of concentrated polymer solutions or after the introduction of a nonsolvent.

The following question is relevant: if the rate of freezing of the polymer solutions influences little the properties of the cryoPVAG, the temperature and the time of the cryogenic treatment exert a definite effect on the characteristics of the cryogels, and the dynamics of the thawing out process is of decisive importance for them, then what is the precise stage in the cryostructure formation process where gelation proper takes place — during freezing (where the polymer is concentrated in the liquid microphase as a result of the crystallisation of ice), during the storage of the frozen solutions at a negative temperature, or in the course of the thawing out process?

It has been shown⁵⁵ that, when the PVA solution is initially frozen at $-20\text{ }^{\circ}\text{C}$ for 1 h, is subsequently maintained at a temperature in the range from -0.5 to $-6.0\text{ }^{\circ}\text{C}$, and is then rapidly (in order to rule out the influence of the thawing out dynamics) thawed out, the dependence of the rheological characteristics of the cryogels formed by means of this scheme on the temperature at which they are stored has an extremum (Fig. 11). The least compliant (Fig. 11a), *i.e.* the most elastic, cryoPVAG is formed when the frozen system is maintained in the region of $-2.5\text{ }^{\circ}\text{C}$ (Fig. 11b): above and below this temperature, less strong cryogels are obtained. On the other hand, overall the region of the

Figure 11. Dependence of the shear compliances (a) and the moduli of shear elasticity (b) of cryogels formed from 14% solution of PVA ($M = 69\,000$, $DD = 98\%$) on the temperature at which the frozen specimens were maintained in the subzero region.^{4,55}

maximum effectiveness of such cryotropic gel formation is in the subzero temperature range — only several degrees below the crystallisation point of the solvent.

Hence the influence of the thawing out kinetics on the properties of the PVA cryogels becomes understandable: the slower and closer to equilibrium conditions is the thawing out of the specimen, the longer it resides in the region of temperatures optimum for the formation of the gel network. For example, on rapid thawing ($v_{\text{th}} = 10\text{ }^{\circ}\text{C min}^{-1}$) the system ‘passes’ through the range $-5\text{--}0\text{ }^{\circ}\text{C}$ in only 30 s, in the moderate thawing out regime ($v_{\text{th}} = 0.1\text{ }^{\circ}\text{C min}^{-1}$) the passage takes 5 min, while in the slow regime ($v_{\text{th}} = 0.02\text{--}0.01\text{ }^{\circ}\text{C min}^{-1}$) the passage takes 4–8 h. Thus a slow increase in temperature during thawing out is in a certain sense equivalent to the storing of the frozen preparations for a long time at the temperatures corresponding to the formation of the strongest cryogels, when in the PVA–water system mainly the junctions of the three dimensional network of the cryoPVAG are formed. If the concentrated aqueous solutions of the polymer during their cooling to the temperatures of the most intense gelation ($\sim -2.5\text{ }^{\circ}\text{C}$) could be guaranteed to freeze, which is frequently prevented by supercooling effects, then in this case there would apparently be no need at all for the use of lower temperatures. In fact they are required to induce the crystallisation of ice.

It has been demonstrated with the aid of NMR spectroscopy^{67,68} that when the frozen preparations are heated after the attainment of a threshold temperature range, which is $4\text{--}6\text{ K}$ below the crystallisation point of the system, a sharp increase in the amount of the mobile solvent is observed. An additional amount of the liquid component appears precisely at these temperatures still in the solid frozen specimen in addition to the firmly bound unfreezable solvent (see also Fig. 2). By virtue of the partial ‘prefusion’ of the ice, a medium is produced in which the macromolecules (or their segments) acquire a certain mobility, which ultimately leads to effective polymer–polymer interactions with formation of microcrystallites performing the function of cryogel network junction knots.

It is shown in Fig. 12 that such mobility is reflected in the ^{13}C NMR spectra of the PVA–water system, while the signals of the $\text{CH}(\text{OH})$ and CH_2 groups of PVA are detected at 66 and 44 ppm respectively. Since the polymer is dissolved in D_2O in order to record the spectra, the temperature scale on the figure is

Figure 12. ^{13}C NMR spectra of a 10% solution of PVA ($M = 81\,700$, $\text{DD} = 98\%$) in D_2O frozen at -20°C and then maintained for 2 h at the temperature of the recording of the spectrum.⁶⁷

indicated both in absolute numbers and relative ($T_f - T_0$) to the melting point of the pure solvent.

At $T_f - T_0 = -7.8^\circ\text{C}$, the resonance peaks of the carbon atoms of PVA are hardly noticeable, while at a temperature three degrees higher, at $T_f - T_0 = -4.4^\circ\text{C}$, fully resolvable, although weak, signals are already observed. On further increase in temperature, but still $2-3^\circ\text{C}$ below the temperature of the thawing out of the specimen as a whole, the 'normal' spectrum of the polymer solution in D_2O is recorded. Hence it follows that, in the temperature range $5-6^\circ\text{C}$ below the freezing point of the system, there is a conventional boundary of the retardation of rapid (on the NMR frequency scale) movements of the carbochain framework of PVA. Estimation of the correlation times of the spin-lattice relaxation of the polymer carbon atoms, which serves as a criterion of the mobility of the kinetic segments of the chain, shows that the reorientation movements of the ^{13}C nuclei of the CH_2 groups of PVA in the system frozen at subzero temperatures occur more slowly by two orders of magnitude than in the initial liquid solution. It is precisely because of the low mobility of the polymer chains that a fairly prolonged time is needed for the occurrence of the cryotropic gel formation. The passage through an extremum of the dependence of the rheological properties of the cryoPVAG on the temperature of the cryotropic structuration process in its subzero region then becomes understandable (Fig. 11). On the one hand, at temperatures above the extremum there is a significant increase in the amount of the mobile solvent, *i.e.* the specific concentration of the gel forming agent is reduced in the liquid microphase. This entails a decrease in the probability of effective intermolecular contacts, which are also acted against by the intensification of the thermal movement in the system. On the other hand, at temperatures below the extremum there is a rapid decrease in the amount of the 'additional' mobile solvent (the polymer retains only very strongly bound water), *i.e.* the liquid medium in which movements leading to the mutual approach of the interacting sections of neighbouring chains may occur vanishes. Thus, having ensured a prolonged residence of the system in the temperature range -2 to -3°C after freezing, for example during slow thawing, it is possible to prepare even from solutions with a not very high PVA concentration a cryogel which is several times less compliant than the cryogel obtained from a significantly more concentrated polymer solution but under the conditions of a brief residence of the specimen at subzero temperatures [at $v_{\text{th}} = 0.02\text{ K min}^{-1}$ for an 8% PVA solution, $J_0 = 1.55 \times 10^{-4}\text{ Pa}^{-1}$ (Fig. 8b), whereas at $v_{\text{th}} = 1.0\text{ K min}^{-1}$ for a 16% PVA solution, $J_0 = 7.9 \times 10^{-4}\text{ Pa}$ (Fig. 5) for the same freezing time $t_f = 1\text{ h}$].

As regards the influence on the properties of the cryoPVAG of cryogenic treatment parameters such as the temperature and duration of freezing (Fig. 7), they are more likely to act on the process involving the formation of a microgel fraction, which then performs the function of building blocks for the formation (in the range of subzero temperatures) of a gel throughout the volume of the specimen. At any rate, the liquid colloidal systems formed were more viscous and turbid the longer the corresponding objects existed in the frozen state.⁵⁴ The structure of the supermolecular aggregates entering into the composition of such a microgel fraction has not so far been investigated, although data of this kind would be very useful for the understanding of the nature of the processes under discussion.

Yet another example of the cryogenic treatment which makes it possible to increase the strength characteristics of cryoPVAG is repeated freezing-thawing of the PVA-water system. A large number of communications (see Refs 11, 12, 23-25, 28, 30, 40, 69, 84, 104, 105, 108, 119-134) and patents^{22, 26, 27, 29, 135-151} have been devoted to the study of this phenomenon and its employment. Repeated cryogenic treatment ('temperature saw') promotes more far reaching gel formation in these systems. Thus the cryogel obtained as a result of four freezing-thawing cycles for a solution of PVA ($M = 75\,000$ and $\text{DD} = 99.5\%$, $c_p = 15\%$, $T_f = -20^\circ\text{C}$, $t_f = 24\text{ h}$, thawing at 15°C for 7 h) has a dynamic Young's modulus an order of magnitude greater³⁰ than that of the specimen obtained as a result of a single cycle. According to X-ray diffraction data,^{28, 84} such successive freezing-thawing increases the content of the crystallites and their dimensions in the cryoPVAG. The repeated 'passage' of the system through the region of temperatures corresponding to the most intense gelation both during thawing and freezing (starting from the second cycle for what are no longer solutions but cryogels) leads to the formation of new additional intermolecular contacts and to an increase in the extent of those existing beforehand. In particular, this is manifested by the appearance of numerous compacted regions in the structure of the cryoPVAG observed⁸⁴ even under the light microscope. Admittedly the authors⁶⁹ do not regard this as the main cause of the increase in the strength of the cryogels, attributing the main role to the intensification of the interactions (hydrogen bonding) between water molecules and the OH groups of the PVA chains with increase in the number of refreezing cycles. However, this conclusion appears controversial. It is more likely that the converse is true: as a result of the crystallisation of PVA, water is displaced from the microcrystallinity zones. It is apparently not permissible to disregard also the compaction of the supermolecular strands of the cryogel network by the purely mechanical mutual approach due to the action of the faces of the ice crystals growing in it. This results in an increase in the strength parameters of the cryoPVAG and an increase in their thermal stability (T_m increases).^{40, 105}

Yet another regime in the cryogenic treatment, influencing the characteristics of the PVA cryogels, is the partial sublimation of ice from the frozen specimens. As already mentioned in the Introduction, this method³¹⁻³⁹ makes it possible to increase the mechanical strength of the cryoPVAG, primarily as a result of the increase in the strength of the surface layers of the preparations,³⁷ because the sublimation of water vapour takes place initially from the peripheral open sections of the frozen block and the crystallised solvent sublimates from increasingly deeper regions only as evacuation proceeds. It has been shown³⁵⁻³⁷ that an increase in the duration of such lyophilisation leads to a lowering of the compliance of cryogels in relation to compression, to a decrease in the tangent of the mechanical losses angle following the application of a variable-sign load, and to an increase in the tensile strength of the specimens. According to patent data^{31-34, 38, 39, 152-162} the degree of hydration of the frozen PVA solutions subjected to such vacuum treatment can reach $> 90\%$, *i.e.* almost all the nonsolvate water may be removed. On subsequent immersion of the xerogel in an aqueous

medium, it swells slowly, after which the osmotic characteristics of the preparations remain unchanged for a long time.³⁷

Thus cryogenic action on the PVA–water system makes it possible to vary within wide limits the properties of the noncovalent cryogels of this polymer and to modify their macroporous structure. Here the dominant factor, determining the effectiveness of the cryotropic gelation of PVA, is the time during which the frozen preparation resides at ‘high’ negative temperatures.

V. Dependence of the properties of poly(vinyl alcohol) cryogels on the nature and composition of the initial solvent

The previous sections dealt with the influence of the characteristics of the PVA and the freezing–thawing regimes on the cryotropic gel formation and the parameters of the cryogels obtained. Only aqueous solutions of the polymer without appreciable amounts of other components were then considered as the initial objects. However, there is no doubt that the nature of the solvent employed and the presence of various additives should exert a definite effect on the freezing processes of the initial PVA solutions, the volume and composition of the liquid microphases, and the range of optimum temperatures of gel formation (if this occurs), on the one hand, and the properties and texture of the materials produced, on the other.

For example, 10%–16% solutions of PVA ($M = 69\,000$, DD = 99.0%) in DMSO ($T_0 = 18.4\text{ }^\circ\text{C}$) at room temperature remain liquid for a long time, whilst the freezing–thawing of such solutions leads, as for the aqueous solutions, to the formation of cryogels.⁹ However, the morphologies of the cryoPVAG obtained from aqueous and dimethyl sulfoxide solutions differ significantly.^{107, 163} In particular a layer of an aqueous cryoPVAG 0.6 mm thick ($M = 74\,800$ and DD = 99.5%, $c_p = 20\%$, $T_f = -20\text{ }^\circ\text{C}$, $t_f = 10\text{ h}$, thawing for 10 h at $5\text{ }^\circ\text{C}$) transmits about 40% of light at a wavelength of 570 nm, while the same layer of cryoPVAG formed from a solution in DMSO in which the organic solvent has been replaced by water transmits 76% of light, *i.e.* is more transparent.¹⁶³ Incidentally, the formation of PVA cryogels from solutions in DMSO itself disproves the hypothesis of Nagura *et al.*,⁶⁹ mentioned above, that water molecules are involved in the structure of the tight contacts between the polymer chains on formation of crystallites. The characteristic features of the cryotropic gel formation in the PVA–DMSO system are virtually the same as in the PVA–water system, although the dimensions of the molecules and the physicochemical properties of DMSO and H_2O differ significantly. In the cryogel formed from DMSO, it is possible to replace fully the DMSO by water on prolonged washing. This could hardly be done if DMSO molecules play the role of stable bridges (*via* hydrogen bonds) between the polymer chains.

The cryoprotecting properties of DMSO are well known.^{164, 165} The addition of 40%–80% of DMSO to aqueous systems very greatly reduces the freezing points of the latter. If PVA solutions are prepared in water–DMSO mixtures, they gelate on cooling long before the attainment of the freezing point,^{89, 95, 96, 166, 169} affording transparent thermoreversible gels, which after washing out the DMSO can be used for the preparation of soft contact lenses.¹⁶⁶ However, if the DMSO content in the initial system is either below 30 vol.% or above 90 vol.%, the corresponding PVA solutions freeze at $-40\text{ }^\circ\text{C}$ ¹⁰⁷ and after their thawing out macroporous cryogels are obtained (here it is important to employ rapid freezing to ensure that there is sufficient time for the crystallisation of the system before the onset of gelation).

The effects caused by the competition between the rates of freezing and formation of the ‘usual’ gels have been clearly demonstrated in studies of the cryotropic gelation processes in water–polyol–PVA systems.^{170–172} When polyols such as glycerol, ethylene glycol, and oligo(ethylene glycol) (OEG) are intro-

duced into aqueous PVA solutions, they lower the critical polymer gelation concentration and increase the temperature of the sol–gel transition as a consequence of the impairment of the thermodynamic quality of the solvent.^{48–52} However, the gelation process itself in the presence of a not unduly high content of such polyols is fairly slow and, in order to obtain the cryogels, it is therefore necessary to ‘accelerate it’ kinetically with the aid of rapid freezing. It has been found that the rate of freezing affects the compliance of the cryoPVAG prepared from aqueous solutions of the polymer to which oligomeric ethylene glycols have been added: the slower the freezing of the specimen, the weaker, other conditions being equal, the cryogel obtained.¹⁷² The main cause of the decrease in the strength of such specimens is that on slow cooling the gelation of the system begins before its freezing, as a consequence of which ice crystallises in the bulk of the gel formed, disturbing its structure. On the other hand, on rapid freezing the usual gel has insufficient time to arise and for this reason the mechanisms of the cryotropic gelation occurring in a medium significantly more concentrated in terms of the polymer than the initial solution ‘work’ subsequently in the frozen heterophase system.

The nature of the influence of the addition of ethylene glycol (EG) and its oligomers on the rheological and thermophysical properties of the corresponding cryoPVAG is illustrated in Fig. 13. An increase in the content of EG in the initial polymer solution leads to less hard and readily fusible cryogels (glycerol and propylene glycol act similarly), but, starting with triethylene glycol, an increase in the concentration of the cosolvent promotes the strengthening of the preparations and the growth of their thermal stability (incidentally, the addition of sucrose has the same effect on the properties of cryoPVAG¹⁷³). Diethylene glycol occupies an intermediate position: for a content of the additive up to $\sim 5\%$, weak cryogels are obtained, the cryogel being strengthened with increase in the concentration of diethylene glycol. It has been supposed that the strengthening effect of the OEG is caused by the liquid–liquid phase separation in the

Figure 13. Rheological (a) and thermophysical (b) characteristics of cryogels formed at $-20\text{ }^\circ\text{C}$ ($t_s = 24\text{ h}$, $v_{th} = 0.2\text{ K min}^{-1}$) from 10% solutions of PVA ($M = 81\,700$, DD = 98%) in the presence of added polyols of the ethylene glycol series: (1) ethylene glycol; (2) diethylene glycol; (3) triethylene glycol; (4) PEG-400; (5) PEG-1000.¹⁷²

Figure 14. Rheological properties of cryogels formed at $-20\text{ }^{\circ}\text{C}$ ($t_s = 24\text{ h}$, $v_{th} = 0.2\text{ K min}^{-1}$) from 14% solutions of PVA ($M = 69\,000$, $DD = 98\%$) in the presence of low-molecular electrolytes MX at different concentrations¹⁷⁷ (1) NaSCN; (2) NaBr; (3) LiCl; (4) NaCl; (5) KCl; (6) NaOAc; (7) CsCl; (8) NaF.

unfrozen inclusions, whereas in the crystallisation of ice the system falls (on the phase diagram) into the region of thermodynamic incompatibility (liquid two-phase water–PVA–OEG systems are well known¹⁷⁴) owing to the increase in the concentration of PVA and of the low-molecular polyol. As a result of this the gel forming agent is additionally concentrated in its ‘own’ (*i.e.* PVA-enriched) liquid microphase. On the other hand, an increase in the concentration of the polymer usually leads to the strengthening of the cryogel and to an increase in its melting point, which has been observed experimentally.

The influence of electrolytes on the cryotropic gelation of the polymer has been investigated.^{54, 175–177} It was found that, in terms of the nature of their effect on the properties of the cryoPVAG formed from water–salt (MX)–PVA systems (Fig. 14), cations and anions can be arranged in a sequence corresponding to the positions of the corresponding ions in Hofmeister’s lyotropic series, *i.e.* chaotropic ions (Li^+ , Br^- , SCN^- , *etc.*), which destabilise hydrogen bonding, prevent to some extent the formation of strong cryoPVAG, whilst antichaotropic ions (Cs^+ , F^- , OAc^- , *etc.*) promote the strengthening of the cryogels. Neutral electrolytes of the type of NaCl, which have a weak influence on hydrogen bonds, exhibit a small strengthening effect with increase in concentration as a consequence of phenomena involving the salting-out of the polymer.

Thus the composition of the solvent, *i.e.* its cryoscopic properties, the affinity for PVA, the effect of the medium components on hydrogen bonding, and also the salting-out and salting-in effects influence the cryotropic gelation of the polymer and hence the parameters of the cryogels obtained.

VI. Conclusion

By virtue of their high porosity and at the same time effective mechanical strength as well as stability in any biological media, the materials based on cryoPVAG have found extensive applications in various branches of biotechnology. Poly(vinyl alcohol) cryogels proved to be excellent carriers for the immobilisation of biological macromolecules^{159, 178–187} and cells^{4, 41, 188–265} and not only of microorganisms, which can stand quite well the cryogenic treatment, but also of certain animal cells.^{266–268} Since the cryoPVAG are stable up to temperatures of $70\text{--}80\text{ }^{\circ}\text{C}$, the corresponding carriers have been used for the immobilisation of both mesophilic cells and thermophilic microorganisms,^{210, 232, 237, 242, 245, 251} which functioned for more than a year at $60\text{--}65\text{ }^{\circ}\text{C}$ without loss of activity.^{242, 251} This is a record-breaking feature for biocatalytic systems entrapped in thermoreversible gel matrices. It has also been proposed that polyol cryoprotectors can be introduced for the simultaneous protection

of cultures sensitive to freezing and in order to increase the strength characteristics of the gel carrier.^{170, 172, 252}

Solid nutritional media have been developed on the basis of PVA cryogels for the culturing of microbial²⁶⁹ and plant cells, in particular the ginseng biomass.²⁷⁰ The use of such media makes it possible to replace the valuable nutrient gel former agar-agar by a synthetic polymer produced on a large scale. CryoPVAG coatings have found applications in the food industry for frozen fish and meat.^{271–275} Chromatographic materials have been created from microgranulated cryoPVAG ($0.2\text{--}0.3\text{ mm}$),²⁷⁶ while artificial bait for sporting and amateur fishing has been made from larger ($2\text{--}3\text{ mm}$) coloured granules or gel in the form of small fish-like objects.^{13–17, 277} An interesting aspect of the employment of mixed cryogels (PVA + polyelectrolyte-type polymer) is the creation of mechanochemical actuators elements simulating the work of muscle (the studies in this field are being particularly vigorously prosecuted in Japan^{127, 132, 278–292}). There have been scientific publications and a multiplicity of patents describing a wide variety of versions of polymer systems, employed in medicine, based on cryoPVAG (Refs 28, 29, 31–34, 90, 92, 93, 110, 120, 129, 131, 135, 137–143, 146–149, 154–161, 266, 268, 293–310) containing both PVA and its mixtures with other high-molecular-mass compounds and constituting composites with disperse fillers—inorganic (of the type of titanium dioxide) or organic (for example collagen fibres,^{303, 310}) *etc.* These gels have been used successfully as substitutes for the cartilage tissue,¹¹ as prostheses for surgery within the mouth,^{11, 28, 29, 34, 148} as materials for ophthalmology¹³⁹ and dentistry,¹⁴⁷ as protective coatings for wounds and burns,^{31, 135, 154} as cooling dressing, and cold helmets which do not secrete water for the prevention of hair loss in cancer chemotherapy,^{31, 137, 138, 155–158, 293} and as special purpose catheters.¹⁴¹

The application of cryoPVAG as the gel medium for the tuning and calibration of NMR tomographs^{120, 140, 143} and as systems for the controlled release of medicinal substances has been described.^{12, 110, 129, 131, 142, 149, 161, 294, 297, 298, 302, 307, 309} Materials for cosmetics,^{311, 312} *etc.* are being developed. Macroporous PVA membranes formed by cryogenic structure formation procedures may apparently find application.^{123, 124, 153} The cryostructure formation process in PVA solutions has been proposed also for the preparation of artificial ice and snow^{59, 313} and for the fixation of soils which have thawed out.³¹⁴

There is no doubt that the successful application of the above materials in medicine and other branches of science and technology^{145, 315–333} must be based on the fundamental knowledge of the mechanisms of the cryotropic gelation of PVA and of the influence of the polymer characteristics and also of the freezing–thawing parameters on the properties and structures of the cryogels formed under these conditions. All these factors promote their further comprehensive investigation. Studies on cryoPVAG are concerned with the mechanisms of gel formation,^{334–336} the macroscopic properties of cryoPVAG and materials based on them,^{337–343} and the structures of gels formed under different conditions,^{344–347} on the one hand, and fine effects associated with the different states of the solvent molecules in such heterophase polymer systems,^{348, 349} on the other. This is in fact the reason why attention has been concentrated in the review on these problems. The interested reader may become acquainted in detail with the practical applications of cryoPVAG in the literature quoted.

Abstract. The main types of heterogeneous catalysts used for hydrogenation, the methods for their preparation, and the structure and chemistry of their surfaces are considered, as well as the catalytic activity and the mechanism of action in the hydrogenation of unsaturated and aromatic compounds, of CO, and of carbonyl compounds and in the hydrotreating of fuels. Chief attention is paid to supported Ni catalysts, to the methods for their preparation and physicochemical studies, and to the development of novel catalytic systems through modification. A novel type of catalyst for hydrogenation, *viz.* metal carbides, is described. Some aspects of the mechanochemical treatment of hydrogenation catalysts, including *in situ* methods, are discussed. Sulfide catalysts for hydrotreating are also discussed in detail. The bibliography includes 340 references.

I. Introduction

Catalytic hydrogenation includes a large group of addition reactions of hydrogen at unsaturated bonds $C=C$, $C=O$, $C\equiv N$, $C\equiv C$ *etc.*, as well as hydrogenolysis (cleavage and reduction) of $C-C$, $C-O$, $C-S$, and other bonds.

In addition to heterogeneous catalysts applied in large-scale processes, homogeneous metal-complex and hydride catalysts are also used (mostly, in fine organic synthesis). Enantioselective hydrogenation catalysts, basically metal-complex compounds of Ni, Co and other metals with optically active ligands, are also being increasingly used.

In 1991, of 1040 catalysts for oil processing produced by world industries the number of hydrogenation catalysts was 380.¹ However, modern technologies require more effective and less expensive hydrogenation catalysts. They can be designed only by development of novel scientific approaches to the preparation of

supported catalysts and by the use of new physicochemical techniques.

Supported nickel catalysts of hydrogenation are the most widely used ones; they are followed by catalysts based on noble metals. Binary Ni–Mo, Ni–W, Co–Mo and Co–W catalysts are extensively employed in the processes of hydrotreating and hydrodesulfurisation. Metal carbides appear to be new promising catalysts.

This paper reviews certain problems related to the preparation, composition, and mechanism of action of heterogeneous catalysts of hydrogenation of unsaturated compounds (including aromatics), hydrogenation of CO and carbonyl compounds, as well as to the processes of hydrotreating. Primary attention is given to supported Ni catalysts, which have found increasing use in recent years not only in large-scale processes but also in fine organic synthesis. Catalysts based on noble metals (Pt, Pd, Ru, Rh, Ir), supported sulfide catalysts of hydrotreating and some novel hydrogenation catalysts, such as metal carbides, which have been extensively studied in recent years, are also the subjects of discussion. Some examples are given of the use of mechanochemistry techniques for preparing catalysts allowing the synthesis of environmentally safe motor fuels.²

At present, the most widespread are the following hydrogenation catalysts:

Process	Catalyst
Hydrogenation of alkenes	supported Ni, Cu, Pt, Pd, Ru, and Rh
Hydrogenation of alkynes	supported Ni, Pd, Ni–Pd, Co–Pd, and Cu–Pd
Hydrogenation of aromatic hydrocarbons	supported Ni, Pd, Rh, Pt, and Co–Mo, Raney Ni
Hydrotreating of motor fuels	Ni, Ni–Mo, and Co–Mo on Al_2O_3 and kieselguhr
Hydrogenation of carbonyl compounds	skeletal and supported Ni and Co, supported Pd, Rh, and Pt, and Cu–Cr–O, Cu on kieselguhr
Hydrotreating (hydrodesulfurisation)	Ni–Mo, Ni–W, Co–Mo, Co–W, and Ru on Al_2O_3 and carbon, Mo and W carbides
Hydrogenation of nitriles	supported Ni, Pd, and Pt
Hydrogenation of CO and CO_2 (methanation)	supported Ni, Cu, Co, Fe, Pt, and Rh, Pt mesh, Mo and W carbides

Received 25 August 1997

Uspekhi Khimii 67 (7) 656–687 (1998); translated by V D Gorokhov

This review is confined to heterogeneous hydrogenation catalysts and leaves out consideration of numerous homogeneous systems, as well as Raney catalysts (Ni, Co, Cu, and others) and co-precipitated catalysts.

II. General characterisation of hydrogenation catalysts

1. Conventional hydrogenation processes and catalysts

The first industrial hydrogenation process used a nickel catalyst discovered by Sabatier in 1897.^{3,4} Other well known hydrogenation catalysts were proposed later: Group VI–VIII metals, including platinum group metals, both on supports and as components of complex oxide systems, as well as Raney metal catalysts.

The results of Ipat'ev's studies of catalytic hydrogenation reactions under pressure dating back to the beginning of this century have served as the basis for the development of processes that are widely used in modern industries. Many specific hydrorefining catalysts have been developed that were obtained by impregnation or co-precipitation (Al–Co–Mo, Ni–Mo, sulfide Ni–W–S catalysts, *etc.*) and proved to be resistant to catalytic poisons present in crude oil (S-, N-, and O-containing compounds).⁵

Production of catalysts for the synthesis of organic compounds is rather limited. Relatively large-scale industrial processes of this type are hydrogenation of fats, 2-ethylhexenal, acetylene (for its removal from ethylene), hydrogenation of benzene to cyclohexane required for the manufacture of caprolactam, and some others. Hydrogenation catalysts are increasingly used for the production of drugs and physiologically active compounds. Important properties of this category of catalysts are high selectivity, extended lifetime, and the fact that they meet environmental requirements. Such characteristics are basically displayed by supported metal (Ni, Pt, Pd, and Ru) catalysts, and co-precipitated Cu–Cr and Ni–Cr catalysts.

Hydrogenation of benzene to cyclohexane may be used as an example illustrating the trends for the use of particular catalysts depending on the strictness of requirements for the final product purity.^{4,6} Cyclohexane of high purity (99.88% and above) is used for the manufacture of caprolactam and fibres based on it, and for nylon-6. In the USA alone the cyclohexane output in 1992 was $1.363 \times 10^6 \text{ m}^3$ (Ref. 7).

Since the beginning of this century benzene has been traditionally hydrogenated on nickel (Raney Ni, impregnation catalysts) and on supported platinum group metals. In early industrial processes carried out under high pressure and at high temperature, the main reaction was accompanied by side reactions: cracking with production of n-hexane, isomerisation of cyclohexane to methylcyclopentane, isomerisation and cracking with the formation of lower hydrocarbons.⁴

A two-stage scheme gives the best results in the production of high-purity cyclohexane: in the first stage, a supported Ni catalyst is used (30%–45% Ni/Al₂O₃), while in the second stage, a supported Pt catalyst (0.2%–1.0% Pt/Al₂O₃) is used. Here, the purity of cyclohexane is 99.57%–99.88%.⁸

An important contribution to the development of hydrogenation catalysts has been made by D V Sokol'skii and his associates.^{9,10}

In our country, much attention was given to co-precipitated Ni–Cr catalysts enabling the production of high-purity cyclohexane in a few stages in tubular reactors provided the technological requirements are strictly observed. Such catalysts were prepared by precipitation of Ni and Cr nitrates with a sodium carbonate solution at room temperature. This was followed by filtration, washing of the precipitate to remove nitrate ions, drying, calcination, pelleting, and activation in a flow of hydrogen.¹¹ The contents of Ni and Cr₂O₃ were 48 mass %–63 mass % and 37 mass %–52 mass %, respectively. The disadvantages of

this and other techniques for preparing Ni–Cr catalysts are their multistage character, cumbersome filtration equipment, large volumes of waste water from the washing stage, *etc.*

In this connection, a sewage-free method was proposed for producing Ni–Cr catalysts¹¹ that included the stage of mixing Ni(NO₃)₂ and (NH₄)₂Cr₂O₇ solutions with subsequent drying and calcination of the resulting mixture by spraying it over a heated inert packing in the fluidised bed reactor system at 310–340 °C, pelleting, and reduction.

A multistage synthesis of Ni–Cr and co-precipitated Al–Co–Mo, Al–Ni–W and Ni–W catalysts used in oil refining^{5,12} is complicated, and the technology of catalyst preparation is also complex. Besides, these catalysts are insufficiently active and require large quantities of active additives. Even at a high Ni percentage in Ni–Cr catalysts the active surface does not exceed 25–30 m² g^{−1}, while their thermostability is preserved only up to 250–280 °C,^{9,11} which imposes definite restrictions on technological processes.

The method of impregnation of supports possessing specific structures and properties yields more active Al–Ni–Mo and Al–Co–Mo catalysts.

2. Modern trends in the development and application of new hydrogenation catalysts

In the 1980s, studies were undertaken aimed at developing supported Ni hydrogenation catalysts the activity of which and other parameters were not inferior to those of skeletal catalysts. Such properties are displayed, for example, by Euro-Ni-1 catalyst (25% Ni/SiO₂) developed by a large group of investigators headed by Coenen.^{13–15} This catalyst has been prepared by homogeneous precipitation in which part of the nickel forms hydrosilicate on the support. The specific surface of the active metal reaches 113–182 m² g^{−1} (Ref. 15). Homogeneous precipitation of Ni was carried out in the presence of urea on a water-suspended microspherical silica gel, which was prepared by direct flame pyrolysis of SiCl₄.¹⁴ In the presence of SiO₂, the pH of an aqueous solution of Ni(NO₃)₂·6H₂O does not exceed 5.3–5.5, whereas in its absence the pH reaches 5.8 during precipitation of nickel hydroxide and remains constant.

The existence of a strong interaction between Ni and SiO₂ in the preparation of the catalyst is evident from the difficulty of reduction of Ni species, especially in comparison with the non-supported Ni(OH)₂. Complete reduction of the Euro-Ni-1 catalyst requires temperatures above 400 °C, up to 600 °C.¹⁴

In the deposition of Ni on SiO₂, the development of the surface may take place due to the formation of intermediate nickel hydrosilicate.¹⁴ However, this depends on the conditions, Ni: SiO₂ ratio, and the reactivity of SiO₂. Along with Euro-Ni-1, in recent years novel technologies allowed preparation of Ni/SiO₂ catalysts with a lower metal content (10 mass %–15 mass %) for the hydrogenation of acetone.¹⁶ In these catalysts, the specific surface of Ni does not exceed 10–30 m² g^{−1}.

Other attempts aimed at increasing the specific surface of Ni on supports with a concomitant decrease in its content down to 4%–10% have also been undertaken.^{17,18} To this end, use was made of both the impregnation technique and organometallic complexes, modifying the surface of SiO₂ and Al₂O₃ supports, in organic solvents. According to the available data,^{18–20} the active surface of Ni may reach 124 and 197 m² g^{−1} at its content of 4.8% and 10%, respectively.

In the 1980s, great interest arose in Russia in the so-called 'sorptional' catalysts.^{19–21} The method of their preparation consisting of binding of organometallic complexes to the surface of the support, is rather complex and expensive. Nonetheless, this technique may be successfully used for the preparation of Pd catalysts with a unique mechanical strength, which is achieved by proper selection of supports, while the size and structure of metal particles may be controlled.^{21,22}

In recent years, public concern about environmental problems has become especially acute in many countries. For example, the

US 'Clean Air Act', of 1992 rigorously limits the content of carcinogenic aromatic compounds, sulfur and other noxious compounds in motor fuels (both hydrocarbon- and alcohol-based).^{23–32} New requirements stimulated the rapid development of refining of various fuels thus making the role of hydrogenation catalysts very important.

To meet all normative requirements under the conditions of a total ban on the use of tetraethyllead in gasoline, it is necessary to restructure the entire oil refinery sector; specifically, to replace reforming by other processes of high-octane gasoline production.^{2, 24, 25, 28} The size of the required investment amounts to hundreds of billion dollars.³⁰ There are doubts whether this task may be coped with at all.⁵

Nowadays, along with studies aimed at replacing reforming by alkylation, skeletal isomerisation, and synthesis of oxygenates allowing an increase in the octane number of gasoline, hydrogenation of aromatic and unsaturated hydrocarbons is extensively studied (to remove their excess from petroleum fractions), and the appropriate catalysts of hydrotreating of motor fuels are being developed and improved.

The content of aromatic hydrocarbons in gasoline and diesel fuel fractions can vary within broad limits. Fractions from direct petroleum refining contain from 20 vol.% to 40 vol.% of aromatic compounds, while diesel fractions after cracking range from 40 vol.% to 70 vol.%.

Hydrotreating of directly distilled gasoline involves mainly co-precipitated Al–Co–Mo catalysts capable of removing sulfur. These catalysts ensure only partial hydrogenation of aromatic compounds^{5, 12, 31} and are insufficiently active in general for the hydrogenation of aromatic and unsaturated compounds. In some cases, Ni–W–Al or Ni–Mo–Al catalysts are more suitable for this purpose.

In major modern catalytic upgrading technologies, the directly distilled gasoline is supplemented with products of secondary processing of heavier fractions, which are even more enriched in aromatic hydrocarbons and alkenes (gasoline of catalytic cracking, hydrocracking, reforming, pyrolytic gasoline). Therefore, catalytic hydrodearomatisation and hydrogenation of unsaturated hydrocarbons, which are also used for alkylation, have become highly important for the production of high-quality and ecologically clean reformulated gasoline, jet and diesel fuels. In the preparation of jet fuels by hydrodearomatisation of kerosene, the co-precipitated Ni–W sulfidised catalysts proved to be the best of the known Co–Mo, Ni–Mo, and Ni–W systems.^{5, 12} In such catalysts, the content of tungsten reaches 20 mass %–30 mass %; hence, they are rather expensive and their practical application is limited.

In recent time, much attention has been given to new types of supported Co–Mo, Ni–Mo, and Ni–W catalysts, as well as to the catalysts based on noble metals.^{5, 12, 31–40}

Sulfur-resistant catalysts are widely used in both single- and two-stage processes for hydrogenation of aromatics.^{31, 38–40} It was found³¹ that the Ni–W/Al₂O₃ catalyst is poisoned by sulfur more intensely than Ni–Mo/Al₂O₃. Therefore, two-stage hydrotreating involves the Ni–Mo catalyst in the first stage (mainly, hydrogenation of sulfur compounds), whereas in the second ('final' hydrogenation) stage low-percentage Ni–W catalyst *e.g.*, (6%Ni + 20%WO₃)/Al₂O₃ is used.³⁹

Since the late 1980s a number of companies dealing with hydrotreating of motor fuels have been developing new Ni–W catalysts on supports.^{31–35, 39} A common shortcoming of all proposed catalysts is the rather high content of WO₃; furthermore, effective hydrotreating on these catalysts requires high pressures (up to 10 MPa) and temperatures (up to 360 °C).^{35, 39}

Thus, at present the most attractive and inexpensive catalysts for the hydrogenation of unsaturated compounds (including aromatics) are supported Ni-containing catalysts modified with W or Mo oxides.

The nickel-based catalysts are also successfully used in other processes, *e.g.*, for the hydrogenation of CO into methane and

other hydrocarbons.^{41–43} Most catalysts of CO methanation are also prepared on supports (Al₂O₃, Cr₂O₃, kieselguhr, Mg-containing spinels). In addition to nickel, the role of active component may be played by Co, Pt, and Pd; however, the resulting systems are less active than the modified Ni-containing catalysts. Investigation of CO methanation has become topical due to attempts to adapt this process for the large-scale production of clean gaseous fuels through gasification of low-grade coals,⁴⁴ as well as for the realisation of chemical-energetic transfer and the use of heat from nuclear power stations and other industrial fields.⁴⁵ Effective methanation of CO has been found to require⁴⁶ thermally and mechanically stable Ni catalysts possessing the largest possible specific surface. These requirements can be met using appropriate supports supplemented with structure modifiers and promoters.

Until the 1980s, the long-term operation of a catalyst was believed to be associated with a sufficiently high content of an active metal (up to 35 mass %). For this reason, preference was given to co-precipitated rather than to impregnated catalysts.⁴⁶ However, the results of recent studies disprove this belief. At present, there is a trend for the use of modified low-percentage Ni catalysts (0.8 mass %–8.0 mass % Ni) on supports both for the hydrogenation of unsaturated and aromatic compounds^{34, 39} and for the methanation of CO.^{47–49}

3. Catalysts for the hydrotreating of motor fuels

According to the estimates of experts,⁵⁰ the oil reserves will substantially decrease and their quality will worsen by the year 2000. As pointed out above, further use for motor transport of fuels with excess levels of aromatic compounds and alkenes may result in air pollution hazardous to humans.^{23, 25}

Upgrading technologies for motor fuels (gasoline, diesel, and kerosene distillates) involve a number of catalytic processes that ensure the transformation of directly distilled crude oil or products of petroleum processing into high-quality fuels meeting rigorous norms for the levels of toxic admixtures, primarily reactive aromatics and alkenes. The actual content of aromatic hydrocarbons in the diesel fractions of petroleum is considerably higher than the mentioned norms and reaches 80%–95%. In the 1980s, they were mostly removed by extraction, while nowadays preference is given to catalytic methods of dearomatisation.^{5, 12, 31, 32, 35–37} This improves both the environmental and operational parameters of diesel fuels. Thus, the decrease in the content of aromatic compounds from 46.5% to 30% increases the cetane index of diesel fuel to the allowed level (from 31–34 to 40–46).⁵¹

Many reports^{31, 37, 40, 50} describe new catalytic processes for dearomatisation of different types of diesel fuel. The Arosat and Synsat processes developed by the Lummus Co. make it possible to reduce more than 50% of aromatic components of raw materials by the combined application of two catalysts designed by the Criterion Co. in a stationary layer under a relatively low pressure.³² The resulting diesel fuel meets the European standards (content of aromatics, 20%–25%; cetane index, 40–45).

The catalysts of the Criterion Co. offer four ways for the decrease in the content of aromatic compounds in diesel fuel.³²

1. Single-stage hydrogenation under high pressure (103 atm) and a moderate flow rate (1.0 h^{–1}). When supported catalysts (Ni, Ni–W, or Ni–Mo on Al₂O₃) are used, the level of aromatic compounds in raw materials can be > 50%.

2. Hydrocracking under high pressure (100–140 atm) at a moderate flow rate with the use of Ni-containing catalysts on different supports (Al₂O₃, aluminosilicates, zeolites). This one- or two-stage process is most popular.

3. Two-stage hydrogenation under pressure ranging from medium to high (83–105 atm.) with the use of supported noble metal catalysts in the second stage. The pressure is determined by the conditions of the first stage aimed at maximum removal of heteroatom-containing components by drastic hydrotreating on Al₂O₃-supported catalysts (Co–Mo, Ni–W, and other).

4. Single-stage hydrogenation under low pressure and small flow rate (the Synsat process). In this process, the above-mentioned combination of Ni-containing catalysts on supports is used. The catalysts are placed in the reactor in such a way that the products obtained in the first catalytic layer improve their characteristics upon passage through the second layer. Under a pressure of 43 atm and a flow rate of 0.5 h^{-1} the degree of saturation of aromatic hydrocarbons present in the diesel fraction reaches 40%–50%. When it is necessary to reduce the level of aromatics below 10% (for preparing a high-quality jet fuel), it is sufficient merely to increase the pressure. Realisation of the Synsat process requires relatively modest expense.

Modern catalytic processes for hydrotreating diesel fuels are more efficient, flexible and economical than the extraction used earlier for the increase in cetane index. The efficiency and simplicity of hydrodearomatisation are provided by the use of catalysts that in most cases refer to supported nickel contacts.

Nishijima *et al.*⁵² reported a two-stage process of hydrotreating of middle and heavy distillates with using new catalysts. Heteroatom-containing compounds are removed in both stages. In the first stage, hydrogenation takes place, whereas in the second stage the remaining aromatic component undergoes hydrocracking.

Fundamental physicochemical studies allowed the development of two types of industrial catalysts on supports for single- and two-stage hydrotreating. The composition of the catalysts obtained, predominantly Ni-containing ones, is presented in Table 1. Catalysts were modified in order to make them suitable for hydrogenation or hydrocracking. Changes in the character of hydrogenation were brought about by the use of specific supports. As regards their hydrogenation activity in the presence of sulfur-containing compounds, the Al_2O_3 -supported catalysts form the following series: Ni–W > Ni–Mo > Co–Mo.

Table 1. Catalysts for the two-stage hydrotreating of diesel fuels.⁵²

Active component	Support	Content of active components (mass %)				Process
		CoO	NiO	MoO ₃	WO ₃	
Co–Mo	$\gamma\text{-Al}_2\text{O}_3$	0–6	–	10–30	–	hydrogenation
	USY ^a – Al_2O_3	0–5	–	10–25	–	hydrocracking
Ni–Mo	$\gamma\text{-Al}_2\text{O}_3$	–	0–6	10–30	–	hydrogenation
	$\text{SiO}_2\text{--Al}_2\text{O}_3$	–	0–3	0–15	–	hydrocracking
	$\text{TiO}_2\text{--Al}_2\text{O}_3$	–	0–3	0–15	–	"
	USY ^a – Al_2O_3	–	0–5	10–25	–	"
	ZSM-5– Al_2O_3	–	0–3	0–15	–	"
	Mordenite– Al_2O_3	–	0–3	0–15	–	"
Ni–W	$\gamma\text{-Al}_2\text{O}_3$	–	0–6	–	16–48	hydrogenation
	USY ^a – Al_2O_3	–	0–5	–	16–40	hydrocracking

^a USY is an ultrastable zeolite of Y type.

Physicochemical studies pointed to a different behaviour of Ni–W and Ni–Mo catalysts on Al_2O_3 . They possess higher hydrogenation activity at a smaller and larger degree of sulfidation of tungsten and molybdenum, respectively. Consequently, the choice of a Ni-containing catalyst for a single-stage hydrotreating depends on the content of sulfur in the raw material.

Similar results were obtained earlier³¹ in the studies of Ni–W and Ni–Mo catalysts for hydrodearomatisation of diesel fuel fractions containing up to 70% of aromatic compounds. The ratios of the rate constants for hydrogenation on Ni–Mo and Ni–W catalysts were 100:90 (1.7% sulfur) and 100:225 (0.14% sulfur).

The trend for maximum decrease in the content of sulfur in motor fuels of all types (down to 0.01%–0.05%) will favour wider use in the near future of two-stage hydrotreating in which the first

stage provides for profound hydropurification of fuel from sulfur, while in the second stage aromatic compounds undergo hydrogenation on efficient Ni–W catalysts. At present, platinum catalysts (0.6%Pt/ Al_2O_3) are used in such processes at a residual sulfur concentration of 1.5 ppm.^{31,40} In the pressure range of 4.5–6.0 MPa, at temperatures 320–400 °C, and at flow rates of 0.75–1.0 h^{-1} , the degree of hydrogenation of the aromatic component is 60%–70%.

The Haldor Topsøe Co. has also developed single- and two-stage hydrotreating refinement processes⁴⁰ for producing high-quality diesel fuels (the so-called City Diesel) with the levels of aromatic compounds below 10 mass % and sulfur below 5 ppm. In the two-stage process, the first stage is based on the use of common sulfidised Co–Mo, Ni–Mo, and Ni–W catalysts, while the second stage relies on the Pt- and Pd-zeolite catalysts. The latter are more resistant to sulfur than the bimetallic catalysts Pt–Re/ Al_2O_3 , Pt–Sn/ Al_2O_3 , Pd/LaY, and others. The catalyst designed for the final hydrogenation preserves its activity at levels of sulfur up to 1000 ppm and nitrogen up to 50 ppm. After the first stage, the diesel oil contains 10 ppm of sulfur, less than 1 ppm of nitrogen and 18 vol.% of aromatic compounds, and the cetane index is 52. After the second stage, the nitrogen content remains at the same level, the sulfur content drops below 1 ppm, the level of aromatics decreases down to 4 vol.%, and the cetane index is 55.5. It is seen that the most significant removal of aromatic compounds is achieved in the second stage.

According to earlier estimates,^{36,50} by the year 2000 the predominant type of fuel produced will be low-sulfur fuel (sulfur content 0.05 mass % instead of 0.1 mass %–0.3 mass %) with a reduced content of aromatics. To achieve this, it was recommended:

(1) to restrict the content of high-boiling components in the diesel fuel since sulfur is most difficult to remove from fractions with b.p. > 315 °C;

(2) to conduct hydrotreating refinement at relatively low temperature, reduced flow rate, and high hydrogen pressure;

(3) to remove aromatic compounds on supported Ni–Mo or Ni–W catalysts.

These predictions are somewhat at variance with the critical need for additional resources of diesel and jet fuels.⁵³

The proportion of the diesel fuel and gasoline consumed is known to shift in favour of the former.⁵⁴ The need for the jet fuel also increases, while its production by direct distillation and hydrotreating refinement of crude oil fractions cannot meet the demand.^{55,56} For this reason, in some countries specialists propose to raise the limiting boiling point of diesel fuels to 360–370 °C⁵⁵ and to include in the diesel fuel some gasoline fractions, as well as secondary products of petroleum refining (gas oils from hydrocracking, fracturing, coking, *etc.*) that will unavoidably lead to a poorer quality of the final products. In gasoils from the secondary oil refining, the content of aromatic compounds reaches 46%–87%, while the cetane index does not exceed 25–39. Hydrogenation of such feed stocks improves their quality but makes them as expensive as synthetic liquid fuels. Hydrogenation of coal is equally expensive, while the products of its liquefaction contain up to 54% of aromatics.⁵⁴

The ways of expanding the production of high-quality diesel and jet fuels have been discussed.⁵³ It was pointed out that, in addition to the above methods, the processes of motor fuel production from alkenes (the MOGD[†] process of Mobil Co.) and from synthesis gas formed upon coal gasification (the Sasol process), are promising as well as the processes based on natural gas conversion (SMDS[‡] of Shell Co. and the Moss gas process) and gasification of any hydrocarbon raw material.^{57–66}

Selective oligomerisation of light alkenes to heavy isoalkenes over zeolite-based catalysts (ZSM-5, ZSM-12, H-offretites and

[†] Mobil Olefins to Gasoline and Distillates.

[‡] Shell middle distillate synthesis.

other) (the MOGD process) allows preparation of gasoline or middle distillates with upgraded characteristics after the hydrogenation stage in which noble metals on supports are commonly used as catalysts.^{57,58} After hydrogenation, the cetane index increases from 33 to 52, while the levels of aromatic compounds and sulfur become 2%–4% and 0.002%, respectively. These parameters are much better than those of diesel fuel from petroleum or coal (hydrogenation), while they remain inferior to the parameters of fuels from the synthesis-gas produced by the Fischer–Tropsch synthesis. For instance, low-temperature hydrogenation of CO on a Ru catalyst can yield diesel fuel that is predominantly composed of n-paraffins (72.4%) and is free of aromatics and sulfur. After the hydrostabilisation stage (removal of alkenes), the cetane index of the product is 90 and it may be used as a high-cetane component of the diesel fuel.⁶⁶

As regards its characteristics, the jet fuel produced by the MOGD process differs favourably from the existing commercial fuels of petroleum origin. It contains as little as 4% of aromatic compounds (instead of 25%), 1% of alkenes (instead of 5%), and less than 0.002% of sulfur (instead of 0.3%–0.4%), while the proportion of paraffins and isoparaffins is 96%. However, the aircraft engines are continuously upgraded with more and more rigorous requirements for the fuel.

Catalytic hydroprocessing of raw oil is a method widely used for producing high-quality aircraft fuels with low sulfur content, increased thermal and oxidation stabilities, and upgraded environmental characteristics.^{67,68} Earlier, hydrotreating of directly distilled fractions was mostly carried out¹² on Co–Mo–Al catalysts at 350–400 °C, 30–50 atm, and a raw material flow rate of 2–5 h^{–1}. The process of single-stage hydrorefinement of kerosene fractions reduced the level of sulfur, while the decrease in the level of aromatic compounds and alkenes was insignificant. The need for the hydrotreating of gasoils of secondary origin with a high content of aromatic compounds and alkenes, using the technology based on Co–Mo–Al catalysts that is popularly used in Russia, has necessitated an increase in the pressure in the system to 140 atm. To reduce the pressure down to 35–80 atm, the products of secondary refining were mixed with directly distilled fractions so that the percentage of aromatic compounds was 34%–36%.⁵⁶ However, even under a pressure of 83–85 atm, hydrotreating on the Co–Mo–Al catalyst was not sufficiently effective. The resulting product contained 18%–19% of aromatic compounds, which is considerably higher than the level admissible for jet fuels.

Two-stage processes in which hydrodesulfurisation (*e.g.*, on a Co–Mo–Al catalyst) and hydrodearomatisation (*e.g.*, on supported Ni–Mo or Ni–W catalysts) are conducted separately (see above) are efficient. In Western technologies, in the second stage the sulfur-free raw materials are hydropurified from aromatic hydrocarbons and alkenes on Pt- or Pd-containing catalysts since the exhaustive hydrogenation on Ni catalysts with oxide additives of the MoO₃ or WO₃ type requires elevated pressures.⁴⁰

Studies of benzene hydrogenation and thiophene hydrogenolysis on Ni–W–Al catalysts have shown⁶⁹ that both processes take place in the same active centres that are poisoned with hydrogen sulfide. The rate of benzene hydrogenation may be increased 30–70-fold under non-steady-state conditions and after pretreatment of the catalyst with hydrogen. The results obtained made it possible to develop a process of dearomatisation of petroleum fractions in a non-steady-state regime.

The production of environmentally clean gasoline is much more problematic. The products of catalytic reforming yielding a high-octane gasoline contain large quantities of aromatic hydrocarbons and alkenes. For this reason, reforming should be replaced by other processes. Even under the conditions of catalytic cracking, current technologies yield on average 29.7% of aromatic compounds (which is 20%–25% higher than the required level) and more than 5 mass % of alkenes (up to 30%).

In order to produce high-octane gasoline, attempts are made to use processes of skeletal isomerisation, alkylation, synthesis

and addition of oxygenates. Hydrodearomatisation and hydrogenation of alkenes as gasoline components attracted less attention, though these processes will in the near future be among the leading methods in the technologies of oil refining targeted at the production of environmentally clean motor fuels.^{23,24,29,70} In these processes a special role is played by supported Ni-containing catalysts. The possibility of their upgrading and the relatively low production cost (by an order of magnitude lower than that of Pt- or Pd-containing hydrogenation catalysts) make them rather attractive subjects for further studies.

4. CO Hydrogenation catalysts

Like hydrorefining, catalytic hydrogenation of CO and CO₂ is highly interesting from the environmental viewpoint and may be used for large-scale production. Carbon mono- and di-oxides are contained in the exhaust gases from power stations and different chemical industries. The simplest reaction of CO hydrogenation (methanation)

allows an energetically advantageous production of a valuable fuel, *viz.* methane, that is used further in gas turbines. In connection with the depletion of natural gas resources studies are being undertaken as to the possibility of the environmentally clean coal gasification with subsequent CO methanation.^{44,71–73} In the first decade of the 21st century, important facilities for coal gasification and methanation are expected to be put into operation.^{72–74} This requires the development of new technologies and active catalysts.

This review leaves out other reactions of CO hydrogenation that yield various products (paraffins, alkenes, alcohols,⁷⁵ aldehydes, *etc.*) depending on the catalysts applied and the conditions of the process.

Catalytic methanation finds applications in chemo-energetic cycles where atomic (nuclear reactors) or solar energy is used.^{74,76} The thermochemical cycle includes the exothermic reaction of methanation (1) and endothermic reactions of conversion of the methane produced

which are conducted in reactors with heat withdrawal or supply, respectively. These reactions require active and highly selective catalysts. Specifically, only the catalysts inhibiting side reactions in which CO can be consumed are suitable for methanation:

Common and widespread Ni catalysts for reactions (1)–(3) are rapidly deactivated, and it was proposed to replace them by noble metals on supports.⁷⁴ The major difficulties are associated with carbonisation in reactions (1)–(3), particularly, in the methanation at low H₂:CO ratios. On noble metals, the carbonisation is considerably less pronounced, especially in an excess of water vapour due to the reaction

Reaction (6) is best accelerated by Ru catalysts, while Rh is more suitable for methanation.⁷⁴

Thermodynamic calculations show that it is advantageous to obtain methane in reaction (1) at temperatures not exceeding 550–600 °C. The yield of CH₄ is increased at higher pressure and H₂:CO ratio. At low H₂:CO ratios and temperatures up to 600 °C, the common Ni and Ru catalysts may be replaced by an expensive rhodium catalyst (0.5% Rh/Al₂O₃).⁷⁴

The activity of metals on supports in the methanation reaction strongly depends on the mode of the catalyst preparation and

§ See also V N Parmon *Catal. Today* **35** 153 (1997).

conditions of its pretreatment and reduction. In this respect, Ni and Co catalysts have been studied in most detail. In the methanation reactions, supported catalysts containing Ni on metal oxides (MgO, Cr₂O₃, ThO₂, ZrO₂, MoO₃, SiO₂, Al₂O₃), promoted by Cu (0.1%–0.3%), promoted by alkali metals, and Ni sulfide on Al₂O₃ are the most efficient.⁷⁵

The specific activity of Group VIII metals on Al₂O₃ supports decreases in the following series: Ru > Ni > Co > Rh > Pd > Ir. It is noteworthy that the Ni catalyst with a well developed surface is highly active and rather selective in the methanation reaction. In some cases, depending on the mode of preparation, the nature of the support, and other factors, the Ru catalyst proves to be more efficient.⁷⁵

A Ni catalyst with a highly developed surface is applied for the selective CO methanation in the presence of CO₂.⁷⁷ On a number of catalysts, viz., 0.5%Ru/α-Al₂O₃, Raney nickel of ICI (30%Ni–18%Al–52%Al₂O₃), 58%Ni/kieselguhr (Harshaw), 47%Ni/Al₂O₃ (CCI), and 32%Ni/Al₂O₃ (Girdeer, G-65), selective hydrogenation of CO in a mixture 0.3%CO + 80%H₂ + 19.7%CO₂ can be carried out at atmospheric pressure and at 125–300 °C.⁷⁷ In all cases, the maximum conversion occurs in the temperature range 200–250 °C.

Some catalytic systems including Ni, Fe, Rh and Ru are more active and selective in the reaction of CO₂ methanation than in reaction (1).^{78,79} For example, the rate of CO₂ methanation on a Ni/MgO catalyst is higher than that of CO methanation, especially after the catalyst has been reduced at 600 °C.⁷⁷ Examples of higher activity and selectivity of different metal catalysts in the hydrogenation of CO₂ are reviewed.⁸⁰

Inui and Takeguchi⁸¹ described a Ru-containing supported Ni catalyst of methanation with a low content of components (3%Ni, 2.5% La₂O₃, and 0.7%Ru). The catalyst has a meso-macro-bimodal porous structure with finely dispersed components and displays a very high activity in the reaction of CO₂ methanation. The role of Ru in this catalyst is explained by its involvement in the hydrogen spillover to the active Ni centres.

Numerous studies and reviews are devoted to the problems of the catalyst formation and the mechanism of CO hydrogenation.^{75,82–86} Krylov *et al.*⁸⁵ consider in detail the results of studies into the formation mechanism of the active centres of Fe catalysts for the Fischer–Tropsch synthesis and of Ni catalysts of methanation and their effect on the catalytic activity and selectivity.

Much attention is given to the investigation of the formation of active centres in finely dispersed metal particles obtained by decomposition of carbonyl clusters on oxide supports. The carbonyl clusters interact with the hydroxyl groups of the support forming bridging bonds with the metal (M) atoms in a lower oxidation state:

Active and selective contacts can be obtained by deposition of carbonyl complexes [*e.g.*, Co₂(CO)₈] and a number of complexes with organic ligands on γ-Al₂O₃. In this case, the hydroxyl cover of the support is of critical importance.⁸⁵ Some complexes are oxidised to form Co²⁺ particles which aggregate into clusters on the surface. Heating under an inert gas atmosphere favours formation of a cluster containing 3 or 4 Co atoms. Further heating to 220 °C leads to dimerisation of the complex with subsequent formation of metal particles. To increase the activity of a catalyst in the CO hydrogenation, it is necessary to have large Co⁰ clusters. As to selectivity, it is increased when oxidised Co species that are produced on the hydroxylated Al₂O₃ surface upon deposition of low-nuclear complexes are present on the surface. Carbonaceous ligands present in the cluster inhibit the process of hydrogen spillover and impede the complete hydrogenation of CO to CH₄. The use of carbonyl clusters containing two different metals allows the preparation of catalysts with new properties. For example, hydrogenation catalysts prepared from Co–Fe carbonyl clusters manifest the activity of cobalt and the selectivity of iron.

High-resolution electron microscopy and X-ray phase analysis *in situ* were used to study the mechanism underlying the formation of Ni catalysts of methanation.^{85,87} In contrast to hydrogenation on Fe or Co, the hydrogenation of CO on Ni yields only methane. After the dissociation of CO on the Ni surface, the consecutive transformations C → CH → CH₂ → CH₃ take place. Active carbon exists on the surface in a rather narrow temperature range: it is not formed below 200 °C since there is no CO dissociation, while above 450 °C it is rapidly transformed into inactive graphite. The methanation rate at the Ni (100) face is higher the larger the carbon concentration on the surface, and the yield of higher hydrocarbons is larger the higher the CO concentration.⁸⁴

Two nickel specimens were shown to behave differently^{85,87} under the conditions of CO methanation. Nickel oxide obtained by a plasmochemical technique forms cubic crystals with the most developed face (100). Under the reaction conditions this face is the site of epitaxial growth of cubic Ni crystals, while the polycrystalline carbide Ni₃C is formed only in later stages. NiO prepared by decomposition of NiCO₃ is composed of lamellar crystals with the developed face (111) on which nickel carbide builds up epitaxially, whereas the phase of metallic nickel appears only after heating to 283 °C and decomposition of carbide. No direct correlation between the methanation rate and the carbide content was established. The reaction occurs most likely at the Ni/NiO interface (possibly, on NiO defects).

The nature of the support influences the catalytic properties of Co and Ni in hydrogenation of CO to methane and its homologues.⁸⁶ Thus, the activity and selectivity of supported metal catalysts depend on the nature and acid-base properties of the support. The specific catalytic activity of supported Co catalysts decreases in the following series of supports: SiO₂ > TiO₂ > ZrO₂ > BeO > Cr₂O₃ > Al₂O₃ > MgO > WO₃, while that of supported Ni catalysts decreases in the order: ZrO₂ > TiO₂ > BeO > MgO > Al₂O₃ > SiO₂ > Cr₂O₃ > WO₃.

The heat of adsorption of carbon monoxide (*q*_{CO}) and, consequently, catalytic activity and selectivity strongly depend on the mean size of metal particles. According to quantum-chemical calculations,⁸⁸ the M–CO bond is weakened on transition from small clusters to large crystallites. Co/SiO₂ (mean particle size *d* = 32 nm) and Ni/WO₃ catalysts (*d* = 97 nm) are the most active in the reaction of CO hydrogenation. Co/WO₃ and Ni/WO₃ catalysts (*d* = 60 and 120 nm, respectively) manifest noticeable activities only at *T* > 300 °C.⁸⁹ The only reaction product is methane. These data indicate that the optimum sizes of Co and Ni particles are different. Prokhorenko *et al.*⁸⁶ explain this by the difference in their *q*_{CO} values. The heat of CO adsorption on Co must be lower than that on Ni, and this was confirmed experimentally. In order to have similar *q*_{CO} values for both metals, the nickel particles should be larger than those of cobalt. At small *q*_{CO} values, the filling of the Co and Ni surfaces is insignificant and the selectivity is low. With the increase in *q*_{CO}, the extent of filling increases as well as the probability of non-linear stages of reactions of CO leading to the formation of higher hydrocarbons.

However, the heat of CO adsorption is not the only factor affecting the selectivity.⁸⁶ For example, Co/ZrO₂ and Co/SiO₂ have virtually the same degree of dispersion (*d* = 97 and 103 nm, respectively), though their selectivities differ by 34%. Transformations of an intermediate compound are supposed to involve the support and to occur at the metal/support interface. The increase in the acidic character of the support on transition from ZrO₂ to WO₃ results in an increase in the selectivity of methane formation to 100%.

5. Catalysts for hydrogenation of carbonyl compounds

Catalysts for the hydrogenation of carbonyl compounds (aldehydes, ketones, and carboxylic acids) present in alcohols as admixtures are of commercial interest. In particular, this reaction is used for hydrotreating of alcohol-based motor fuels. Hydro-

genation of aldehydes and ketones is also of an independent significance since it allows the preparation of alcohols free of by-products. For example, 2-ethylhexanol is produced from 2-ethylhexanal on an industrial scale.^{90,91}

The first industrial hydrogenation of aldehydes on copper catalysts dates back to the 1920s. However, after the appearance of Raney nickel (1925) most processes of hydrogenation of aldehydes were modified to use catalysts of this type. The industrial importance of techniques for the alcohol production from aldehydes increased after the discovery of oxosynthesis in 1938.⁹⁰

In parallel, a strong impetus was given by the production of plastics [specifically, poly(vinyl chloride)], where respective alcohols are used as plasticisers. Lower alcohols are used as solvents, while higher alcohols are used in the production of detergents. In 1992, the world production of alcohols was (millions of tons): n-butanol, 1.7; isobutanol, 0.4; 2-ethylhexanol, 2.4; higher alcohols, 0.2.⁹⁰

Despite the very high activity of Ni-containing catalysts, they prove sometimes to be unsuitable for the hydrogenation of aldehydes, especially when high selectivity of the process is required. Thus, the preparation of n-butanol from crotonaldehyde proceeds more selectively on copper catalysts. In addition, Ni unlike Cu, often catalyses splitting of CO from saturated aldehydes:

When a Ni catalyst is sufficiently active, subsequent hydrogenation of alkenes occurs with the predominant formation of alkanes.

Modified Ni catalysts on supports are free of these shortcomings. Their activity may be reduced using such supports as SiO₂ subjected to high-temperature treatment, or employing a special impregnation technique of Na⁺-containing SiO₂, and calcinating the specimens additionally at 600–700 °C.¹⁶ To this end, TiO₂ may also be used as a support.⁹⁰ The high activity of Ni and Ni–Cu catalysts allows their use in liquid-phase reactions, which facilitates the removal of heat released during the reaction.

In addition to Cu and Ni, supported Co and noble metals (Pt, Pd, Ru, and Rh) are also applied for the hydrogenation of carbonyl compounds. Of all noble metals only palladium is a component of catalysts for the selective hydrogenation of α,β -unsaturated aldehydes to saturated ones. Furthermore, along with nickel, palladium ensures complete hydrogenation of unsaturated aldehydes, *e.g.*, 2-ethylhexenal.⁹¹

III. Nickel hydrogenation catalysts

1. Methods for preparation

Industrial production of nickel catalysts relies basically on precipitation of components from aqueous solutions and suspensions and on impregnation of specially prepared supports with aqueous solutions of active metal compounds. The activity of hydrogenation catalysts prepared by the impregnation of supports is usually higher than that of catalysts produced by co-precipitation.^{9, 12, 22}

In the late 1980s, the relevant literature (especially the Russian) opposed the impregnation and ‘sorptional’ catalysts.^{17–20} In our opinion, the technology for the preparation of the latter does not differ substantially from impregnation. It consists of the deposition of an active component on a support from different solutions (including non-aqueous ones) using organometallic compounds. In this case, optimally distributed active centres are formed on the support surface, and their characteristics are best suited for hydrogenation.

Generally, the procedure for the preparation of Ni catalysts includes the stages of impregnation, drying, dehydration, activation (calcination), reduction, and passivation.

The preparation of precipitated and impregnated Ni catalysts involves the following processes.⁹²

1. Impregnation of supports (Al₂O₃, SiO₂, carbon, zeolite) with a salt solution, *e.g.*, nickel nitrate. Then the catalyst is dried and calcined at high temperature (400–500 °C) in air.

2. Mixing of precipitated active hydroxide Ni(OH)₂ with a hydrogel of the support. The mixing lasts for 20–30 h, followed by extrusion, drying, and calcination.

3. Deposition of one precipitate onto another. For instance, nickel hydroxide is precipitated with ammonia from a nickel nitrate solution in the presence of a suspension of hydrated alumina. The precipitate is filtered off, thoroughly washed, dried, and calcined at 500 °C for 2 h in air.

4. Co-precipitation. For example, a boiling solution of sodium silicate is slowly added to a nickel nitrate solution. The precipitate is filtered and washed. Also, ammonia may be added to a mixed solution of nickel and aluminium nitrates at 70 °C. Then the precipitate is filtered off, washed, dried, and calcined.

5. Hydrothermal treatment of mixed precipitates. A mixed paste of Ni(OH)₂ and SiO₂ is heated with water vapour in an autoclave for 25 h at 250 °C and 50 atm; the precipitate is filtered off, dried, and calcined.

6. Superhomogeneous co-precipitation. Three salt solutions, *e.g.*, Ni(NO₃)₂, NaNO₃, and Na₂Si₂O₅, are mixed to form a supersaturated solution. Under intense stirring, a homogeneous precipitate is formed which is separated, washed, dried, and calcined.

Prior to their use in reactions, the catalysts are reduced with hydrogen (sometimes with the reaction mixture) at 400–500 °C. The catalysts prepared by impregnation are the easiest to reduce, while those obtained by co-precipitation and hydrothermal treatment undergo reduction with more difficulty. In the supported catalysts the specific surface of the active nickel is usually 100–120 m² g^{−1}, whereas in the precipitated catalysts it varies from 20 to 70 m² g^{−1} (*cf.* Ref. 93). Depending on the treatment and reaction conditions, the metal particles on supports have sizes from 2 to 10 nm.^{94,95}

In recent years, efficient catalysts on supports have been prepared using the so-called CVD (chemical vapour deposition) technique. This consists of fixation of a metal in a layer of finely dispersed particles with the aid of vapour-phase adsorption of intermediate compounds, *e.g.*, metal acetylacetonates, which are subject to subsequent decomposition on the supports.⁹⁶ In this case, the surface is the first formation site for catalytic precursors, ensuring high metal dispersion upon their subsequent decomposition. The Amoco Co. proposed the use of CVD method for binding the silanol groups in zeolite matrices to prepare metal oxide catalysts of the Fe/Mo/support type. German scientists prepared catalysts for hydrogenation and a number of other processes in which Pt, Cr₂O₃, and V₂O₅ are fixed on SiO₂ or Al₂O₃.⁹⁶

Active film structures of the metal–oxide type on supports, the analogues of metal-ceramic films, in which metal particles are regularly distributed over the surface, were also designed.^{97,98} Fixation of metal on supports is ensured by co-precipitation of salts of an active metal (Pd, Pt, *etc.*) and salts of higher carboxylic acids (resinates, stearates, abietates, and others) from organic solvents. Similar structures can also be prepared using aqueous solutions of inorganic salts and compounds of noble metals in the presence of water-soluble polymers, colloidal oxide solutions, *etc.* The common feature of all these techniques is the formation of a film on the surface of a support.

The preparation by this method of highly selective catalysts for the hydrogenation of acetylene that are suitable for large-scale hydropurification of ethane–ethylene fractions from acetylene admixtures has been patented,⁹⁹ as well as of catalysts of oxidation, isomerisation, and dehydrogenation.^{100–104} The preparation of film catalysts is based on a specific combination of several conventional techniques.^{97–100} This leads not only to regular distribution of active components in the surface layer of the support and high dispersity of metal particles, but also to the thermal stability of the catalysts.

Nonetheless, impregnation from aqueous solutions still remains an industrially preferable way of preparing the hydrogenation catalysts on supports. This takes advantage of the recent developments in the field of formation of the catalyst active phase. For example, it was established that if conditions favouring retention of a metal in the ionic form in supports (Ni/Al₂O₃, Ni/SiO₂) are met, this favours the preparation of active and stable Ni hydrogenation catalysts.^{15, 104} In particular, two-stage deposition of nickel should be applied: the first stage consists of the incorporation of difficultly reducible Ni²⁺ ions into the support as a result of ion exchange, and the second stage includes physical sorption of a readily reducible salt. The Ni²⁺ ion appears to be the centre of crystallisation and stabilisation of Ni crystallites. Heating of a Ni/TiO₂ system often leads to a decrease in the active surface of nickel due to coating of the crystallites with metal oxide.^{101, 102} This may be regarded as a manifestation of a strong metal–support interaction (SMSI) effect. The SMSI effect is enhanced in the presence of hydrogen which affects the activity and selectivity of catalysts.

2. Influence of the preparation procedure on the structure, physicochemical properties, and activity of catalysts

Principal factors that affect the catalytic and physicochemical properties of impregnated low-percentage Ni/Al₂O₃ catalysts have been studied systematically.^{47, 49, 103–111} The conditions for the realisation of major stages in the preparation of these catalysts were shown to be related to their structure, activity, selectivity, and the degree of nickel reduction and dispersion. For example, the active surface of nickel and the proportion of the reduced metal are increased by the increase in the H₂ flow rate during reduction. Passivation of the reduced Ni/Al₂O₃ catalyst at room temperature in a flow of nitrogen containing 1% of air prevents ageing and bulk oxidation of nickel, which may result from its contact with the atmosphere.

The first stage in the preparation of impregnated nickel catalysts is highly important. When a support is impregnated with an aqueous solution of a salt (or salts) precursors appear on the support surface and in its bulk, and their formation is influenced by the electrolyte concentration, pH of the medium, and ionic strength of the solution.^{105, 112–114} The first stage is supposed to generate several forms of isomorphically substituted nickel in the support lattice. At low pH, aluminium oxide is solubilised, which favours isomorphic substitution in the final forms.

The effect of pH on the concentration of nickel precipitated from a Ni(NO₃)₂ solution onto Al₂O₃ is illustrated by the data presented in Table 2.

The concentration of electrolyte, ionic strength, and pH of impregnation solution influence not only the content of Ni in the catalyst, but also the amount of active nickel precursors and hence the physicochemical properties and the hydrogenation activity of the catalysts formed.^{103, 105}

Table 2. Dependence of the Ni content in a catalyst on pH of the impregnation solution of Ni(NO₃)₂.¹⁰³

The procedure for the preparation of Ni/Al₂O₃ catalysts affects their structure, activity, and selectivity, *e.g.*, in the hydrogenation of CO.^{47, 49, 103–108} Temperature-programmed desorption (TPD) of H₂ and its interaction with CO allowed us to obtain data on the accessibility of surface Ni centres to H₂ and CO at various conditions of preparation of low-percentage catalysts. Surprisingly, the variation of Ni content from 0.8 mass % to 8.3 mass % proved to have little effect on the adsorption of H₂ and the active nickel surface calculated from the results obtained (Table 3). However, the metal dispersity varies noticeably depending on the concentration of nickel precipitated and precipitation conditions, *i.e.*, it decreases at higher concentrations.

At the same time, the analysis of temperature-programmed CO desorption spectra points to the existence of two types of adsorptional and reactive centres. The specimen with 0.8% of Ni is an exception, since its spectrum has a single peak at 260 °C. In all other cases, low-temperature (at 150–200 °C) and high-temperature peaks were observed. The increase in Ni content to 2.3% increases the portion of CO desorbed in the low-temperature range. In the case of specimens containing 2.3%–7.3% of Ni, the contribution of both peaks is nearly the same. According to Kester and Falconer,⁴⁸ the two CO peaks correspond to two types of active centres of different composition on the surface of the Ni catalyst. The low-temperature peak is supposed^{48, 105} to correspond to NiO, while the high-temperature peak corresponds to NiAl₂O₄. Stronger metal–support bonding is predominant in catalysts with low Ni content.¹⁰⁵ Low pH values facilitate isomorphic substitution of Ni in the octahedral lattice of Al₂O₃, which favours the predominant existence of this metal in the NiAl₂O₄ form. Only this structure was revealed in the 0.8% Ni/Al₂O₃ specimen.

The results reported by Huang and Schwarz¹⁰³ are at variance with those obtained by Tsai *et al.*¹¹² who have found that the increase in Ni content results in an increase in its specific surface calculated from the CO adsorption from 3.9 to 15.8 m² g^{−1}. The increase in Ni concentration from 0.8% to 2.1% is accompanied by a decrease in the degree of Ni dispersity, also calculated from the CO adsorption, from 70% to 31%, which then remained nearly constant (27%–35%).

The catalytic activity and selectivity of the Ni/Al₂O₃ specimens described above in the reaction of CO hydrogenation are closely related to their composition and conditions of preparation. This allows the prediction of their catalytic properties.¹⁰⁴ The limiting stage of the methanation is determined by the type of active centres prevalent on the surface. According to Huang and Schwarz,⁴⁷ the process of CO methanation includes the following stages:

- 1) CO_{ads} ⇌ CO_{gas},
- 2) CO_{ads} → C_{ads} + O_{ads},
- 3) C_{ads} + O_{ads} → CO_{gas},
- 4) CO_{ads} + O_{ads} → CO_{2 ads},

Investigation of the surface interaction of CO and H₂ on Ni/Al₂O₃ catalysts with variable Ni content by X-ray photoelectron spectroscopy (XPES), thermoprogrammed reaction (TPR)¹¹³ and other methods confirmed that in the case of prevalence of NiAl₂O₄ centres on the surface (catalysts with low Ni content) the methanation rate is determined by the rate of CO dissociation [stage (2)]. On catalysts with high Ni content, in which nickel is in the form of particles, the methanation rate is determined by that of hydrogenation of the CH_x fragments [stage (8)].⁴⁷ If the reaction of methanation is regarded as being structure-sensitive, then the changes in its mechanism are well explained by the lower degree of Ni dispersity and the increase in its content from 0.8 mass % to 8.0 mass %.

XPES and TPR¹¹³ studies have shown that NiAl₂O₄ centres predominate on an Ni/Al₂O₃ catalyst with 0.8% Ni, while Ni + NiAl₂O₄ centres predominate on a catalyst with 6.5% Ni.

Contrary to the CO methanation, the hydrogenation of aromatic hydrocarbons cannot occur on active centres of the NiAl₂O₃ type in which Ni is structurally bound. This requires that the active centres were formed by finely dispersed Ni particles on a support. Kester *et al.*¹¹⁵ consider the hydrogenation of aromatics as structure-insensitive reactions. There are fundamental difficulties that prevent the preparation of long-lived Ni catalysts on γ-Al₂O₃ with the Ni content below 5% for the hydrogenation of aromatic compounds. The point is that local overheating taking place during the exothermic reactions of hydrogenation induce the formation of inactive surface spinel and hence the absorption of the active component.^{48, 116–118} This explains why the industrial Ni catalysts of hydrogenation usually contain considerable quantities of metal (up to 65%) and include oxide promoter additives (Table 4) diminishing the SMSI effect.

Table 4. Industrial nickel catalysts for hydrogenation.

Composition of the catalyst			Specific surface /m ² g ⁻¹	Pore volume /cm ³ g ⁻¹
Ni (mass %)	additive	support

68	–	special support	125	0.35
46	–	"		
14	WO ₃	Al ₂ O ₃	140	0.38
Catalyst of BASF Co. (Germany)				
4–10	WO ₃	active clay	–	–

Nickel catalysts on other types of supports (*e.g.*, SiO₂) modified by Ti, Zr, and Ce oxides also manifest low activity in the hydrogenation of benzene provided the SMSI effect is realised.^{116, 119} They are one order of magnitude less active than a catalyst analogous in composition [7%Ni/SiO₂–TiO₂(ZrO₂)], prepared by precipitation of Ni(OH)₂, which is free from the SMSI effect.

The technique of homogeneous precipitation was used to prepare a highly efficient Ni catalyst (Euro-Ni-1) containing 25 mass % of Ni.^{13–15} In this case, the major part of nickel is in the form of hydrosilicate. Therefore, it was necessary to activate the catalyst at elevated temperatures in a flow of hydrogen (Table 5).

The maximum degree of reduction of nickel (96%) is achieved at 630–650 °C, though in this case its specific surface is somewhat

Table 5. Effect of temperature on the extent of Euro-Ni-1 catalyst reduction and the specific surface of nickel.¹⁵

Temperature of reduction /°C	Extent of reduction (%)	S _{Ni} /m ² (g Ni) ⁻¹ (see ^a)	S _{Ni0} /m ² (g Ni ⁰) ⁻¹ (see ^b)
430–450	85	181	213
500	90	181	201
630–650	96	113	118

^a Total specific surface of nickel. ^b Specific surface of totally reduced nickel.

decreased, possibly because of sintering. Nonetheless, it exceeds nearly eightfold the surface of Ni in a precipitated Ni–Cr catalyst containing 50 mass %–60 mass % of Ni. The main part of the active component is bound by the support (SiO₂), which results in the formation of new surface phases. This means that this method cannot yield industrial low-percentage, highly active nickel hydrogenation catalysts on the SiO₂ support.

Romero *et al.*¹²⁰ showed that the specific surface of unmodified Ni/SiO₂ and Ni/Al₂O₃ catalysts and their capacity to absorb H₂ during thermal treatment or under hydrogenation conditions decrease very rapidly on heating to 650–750 °C. Thus, after treatment at 650–750 °C, the overall specific surface of an Ni/SiO₂ catalyst diminishes from 199 to 159 m² g⁻¹, and the absorption of H₂ becomes more than twice as low.

Transmission electron microscopy data showed that the size of Ni particles increases from 2.9 to 6.8 nm. After an analogous thermal treatment, the Ni particles in the Ni/Al₂O₃ catalyst are enlarged from 2.7 to 9.3 nm, though in this case the overall specific surface and H₂ absorption do not change as strongly as upon the thermal treatment of Ni/SiO₂. In both cases the degradation of porous structures takes place. Thermal treatment of Ni/SiO₂ and Ni/Al₂O₃ decreases the specific surface of Ni by 70% and 25%, respectively.

Thermal inactivation of supported Ni catalysts can be caused by the growth of Ni crystallites, degradation of a support, metal–support interaction, or by combinations of these factors.

3. Effect of the nature of supports on the catalytic properties and specific surface of catalysts

The chemical nature of supports and their structure influence the activity and selectivity of hydrogenation catalysts.^{116–119}

Pavlenko *et al.*¹¹⁷ investigated the adsorption and catalytic properties of Ni catalysts deposited on ZrO₂, MgO, TiO₂, and SiO₂ in the reaction of CO hydrogenation (Table 6).

Table 6. Kinetic and thermodynamic parameters of CO hydrogenation on supported nickel catalysts.¹¹⁷

	6	498	3.4	52	76
	6	498	8.1	52	76

The heat of adsorption q_{CO} increases as the dispersity of Ni increases. This is in agreement with the results of quantum-chemical calculations⁸⁸ according to which the metal–CO bond becomes weaker on transition from the primary clusters to large crystals reaching a constant strength at a mean size of Ni particles 10–20 nm. The specific catalytic activity of specimens at 220 °C decreases in the following order of supports: $\text{ZrO}_2 > \text{TiO}_2 > \text{MgO} > \text{SiO}_2$, *i.e.* there is no direct correlation with the size of crystallites. The selectivity of formation of higher hydrocarbons depends on the nature of the support and varies in the same order, while that of methane formation varies in the opposite direction.

Thus, the nature of the support affects mainly the size of the crystallites and the heat of CO adsorption q_{CO} , which in turn influence the reaction parameters. There are other factors, too. Thus, according to Huang and Schwarz,^{49, 107} with the same metal dispersity, the selectivity of CO hydrogenation depends on the acid-base properties of supports. This dependence can be determined, for example, by the intermediate interaction of the surface complexes CH_xOH bound through an oxygen atom to acidic Lewis centres (L) at the metal–support interface

According to this scheme, the selectivity of formation of higher hydrocarbons should depend on the strength of CO molecule bonding (q_{CO}) and the energy of acid–base interaction.

The influence of the nature and acidity of supports on the properties of Ni-containing catalysts and the metal state in them is clearly manifested in the formation of industrially important bifunctional catalysts containing from 0.5 mass % to 2.0 mass % of Ni.^{120–123} Depending on the differential acidity of supports, *i.e.*, on the ratio of the Brønsted (B) to Lewis (L) centres, catalysts are formed with different activity and selectivity in reactions of hydroisomerisation, aromatisation, and hydrogenolysis. The acidic properties of zeolite supports influence the dispersity of nickel, the extent of its reduction and the magnitude of the SMSI effect, which in turn affects the activity and selectivity of catalysts.

Hoang *et al.*¹²¹ investigated the state of nickel in the Ni-containing catalysts by IR spectroscopy of adsorbed CO and NH_3 , thermoprogrammed reduction, chemisorption of H_2 and O_2 , and thermoprogrammed desorption of NH_3 . When zeolite is impregnated with a nickel salt solution at pH 1.8, ion exchange of B-centres in the channels of zeolite occurs. The nickel fixed in these centres is difficult to reduce; it remains mainly in the NiO form and hence cannot be determined by IR spectroscopy of adsorbed CO. Impregnation of zeolite with a nickel salt solution at pH 4.8 results in the formation of metallic Ni localised mostly outside the channels. In these two cases, the Ni-zeolite catalysts manifest different activity and selectivity in reactions of aromatisation, dehydrocyclisation, and hydrogenolysis of n-hexane.

The acidity of the support and concentration of B- and L-centres also influence the state of Ni in a reduced catalyst (Table 7). In absence of L-centres on the surface (specimen I), NiO particles are formed that interact strongly with the support, the extent of their reduction being a minimum. The presence of even a small number of L-centres (specimen II) leads to the formation of reduced particles Ni^0 , which are less dispersed than those in specimen III with the maximum quantity of L-centres. The specimen III contains highly dispersed Ni particles. In all cases, part of the Ni interacts with the B-centres to form presumably $\text{Ni}(\text{OH})^+$ ions, which are not reduced to Ni^0 .¹²¹

Similar results were reported by Romero *et al.*¹²⁰ who used physicochemical methods to study the metal incorporation into zeolite. The use of a number of additives, *e.g.*, nickel acetylacetonate, and impregnation of zeolite with a Ni salt solution

Table 7. Effect of the acidity of the support on the state of nickel in a Ni/HZSM-5 catalyst after reduction.¹²¹

Specimen	[Ni] (mass %)	Concentration of acidic centres		Extent of reduction of Ni (%)	Ni dispersity (%)	S_{Ni} , /m ² · g ^{−1}
		B ^a	L ^b			
I	0.5	1.8	0	3	—	—
II	0.5	1.6	0.09	75	6.2	0.15

produces catalysts possessing different acidity, which influences the metal state, activity and selectivity of contacts in the process of hydrocracking of n-paraffins.

Analogous conclusions about the effect of the character of distribution of acidic centres over the support with regard to the strength of these centres on the metal state, activity, and selectivity were drawn from a number of studies dealing with the preparation of Pt, Pd, and Ni catalysts on zeolite supports.^{124–127} These catalysts are applied for dearomatisation in installations for hydrotreating of diesel fuels.⁴⁰ According to Hoang *et al.*,¹²¹ the acidic function of the support controls the formation of the active surface of nickel. Impregnation Ni catalysts are less active than those obtained by ion exchange, since the extent of Ni dispersity is lower in the former case.

The use of a set of physicochemical methods (IR spectroscopy of adsorbed CO, ferromagnetic resonance, chemisorption of O_2 and H_2 , thermoprogrammed desorption of NH_3) made it possible to reveal the effect of strong interaction of Ni with zeolite supports of the Y type characterised by the different extent of Na^+ exchange for NH_4^+ ions and hence by different total acidity.¹²⁷

With the increase in the extent of ion exchange, the total acidity increases with simultaneous appearance of a trend for a larger size of Ni particles and a smaller number of d-electrons per nickel atom.

The results obtained allowed one to make a conclusion on the formation of nickel clusters on the surface of zeolite supports and a substantial role of electronic factors in this process. By controlling the formation of clusters, including SMSI regulation, one may prepare highly efficient Ni catalysts with different active centres enabling the occurrence of specific reactions involving H_2 .

Studies of the effect of the surface nature, porous structure and support crystallinity on the formation and properties of Ni catalysts are of considerable interest.⁴⁹

Table 8 presents the main characteristics of Al_2O_3 specimens of different origin (Degussa, Engelhardt, and Kaiser products) used to prepare impregnation catalysts of composition 6%Ni/ Al_2O_3 .

The preparation of catalysts involves several stages. In the first stage, the support is brought into contact with an electrolyte, which results in adsorption of precursors, most frequently by ionic adsorption. There are two ways of cation adsorption on the support surface. If the support is protonated, *i.e.*, it contains no heterometallic ions, the ion adsorption may be realised by treating the support with a solution containing metal ions at a sufficiently high pH. Then the surface H^+ ions are exchanged for metal ions, *e.g.*, Ni^{2+} , following the scheme

An increase in pH shifts the equilibrium to the right, and the concentration of metal ions may prove to be insufficient for precipitation of the metal in the form of hydroxide.

In the first stage, upon contact with a $\text{Ni}(\text{NO}_3)_2$ solution at pH 5 the support is partially dissolved and interacts with the electrolyte, whose pH is thus changed, and a portion of Al^{3+} ions

Table 8. Effect of the type of support on pH of the impregnation solution and Ni adsorption from solution.⁴⁹

Type of support	S_{sp} /m ² g ⁻¹	X-Ray crystallinity /rel. units	pH at zero charge	Pore volume (from N ₂) /cm ³ g ⁻¹	Al ³⁺ concentration /ppm ^a	Solubility /rel. units (see ^b)	Ni adsorption

Kaiser	200	1.0	9.3	0.5	2.87	35.08	1.14 · 10 ⁻²	35.0

^a Concentration of Al³⁺ in the electrolyte formed upon Al₂O₃ solubilisation and ion exchange with Ni²⁺. ^b Solubility of Al₂O₃ in an Ni(NO₃)₂ solution at pH 5.0.

pass into solution. Here, ion exchange can take place with participation of both the OH groups and the surface cations. The hydroxy groups are donors of protons, while the hydrolysed cations are donors of hydroxyls. The departing Al³⁺ cations are substituted by hydrogen as a result of hydrolysis. Subsequently, the Al³⁺ ions are readsorbed. A mixed adsorption leads to the formation of nickel aluminate on the surface.

As is seen in Table 8, the crystallinity (ordering) of the structure of Al₂O₃ and its solubility in the electrolyte change in opposite directions: solubilisation of a support with a deformed lattice occurs more easily. Transition of Ni²⁺ ions from solution to support may be explained by ion exchange with a neutral or negatively charged surface of Al₂O₃ and incorporation of Ni²⁺ into the deformed lattice of Al₂O₃. The ion exchange requires a definite pH at which Al₂O₃ is dissolved in the electrolyte. The larger the number of Al³⁺ ions passing into solution, the more deformed the support lattice, which facilitates incorporation of Ni²⁺ into the support. The most soluble Al₂O₃ of Kaiser Co. adsorbs the largest quantity of Ni²⁺, whereas the Al₂O₃ of Degussa Co. has the lowest solubility and adsorbs the smallest quantity of Ni²⁺. The order of Ni²⁺ adsorbability on various supports is the reverse to the order of their crystallinity.

The efficiency of a catalyst is substantially dependent not only on the quantity of adsorbed Ni²⁺, but also on the size of its active surface and the structure of the latter. The catalysts of the Kaiser and Engelhardt companies have similar pore sizes. However, according to Ghen *et al.*,⁴⁹ the adsorption of Ni²⁺ from aqueous solutions and treatment with HNO₃ do not affect the structure of the support of Kaiser Co., but modify the structure of Al₂O₃ of Engelhardt Co.

Thermoprogrammed reduction (TPRd) of catalysts with hydrogen reveals differences between the porous (Engelhardt and Kaiser) and non-porous (Degussa) specimens. The TPRd spectrum of the Ni catalyst on the Degussa support has no high-temperature peak, whereas the catalysts on the porous supports are characterised by two peaks (at 141–149 and 223–230 °C), though their ratio for the two above-mentioned specimens is not the same. It may be suggested that the catalyst on the Degussa support possesses only the exchangeable surface Ni and centres of the NiO type. The presence of two peaks in the spectrum of TPRd on this catalyst is indicative of the presence on the surface of reduced nickel (Ni⁰) and nickel aluminate, *i.e.* a surface compound carrying incorporated Ni. Al₂O₃ of Kaiser Co. has very little surface Ni and much incorporated Ni in comparison with Al₂O₃ of Engelhardt Co. The quantity of surface (exchangeable) nickel decreases in the order Degussa > Engelhardt > Kaiser, which correlates with the data on crystallinity, solubility, and adsorption.

The porous structure of the support was shown¹²⁸ to influence the extent of metal reduction. On the Al₂O₃ support with a smaller pore size, the mean size of metal particles and the quantity of H₂ sorbed in the low-temperature range are larger.

The readily reducible nickel oxides are believed¹²⁹ to be localised in small pores, while the oxides that are difficult to reduce occupy large pores. The oxides of the first type are close in their structure to the bulk-distributed NiO and interact very weakly with the support. The reduction-resistant oxides may

occur as small crystallites and as surface compounds. The next section is concerned with the effect of the porous structure of supports on physicochemical and catalytic properties of modified nickel catalysts studied by one of the authors of this review.

There are two peaks in the TPR spectra of CO for all reduced samples. It is supposed that the low-temperature peak corresponds to the CO adsorbed on Ni,⁴⁹ whereas the high-temperature peak is associated with the CO spillover on Al₂O₃ or with its adsorption on a surface nickel compound. In the spectrum of the catalyst on the porous support of Kaiser Co. with an abnormally small specific surface of nickel ($S_{Ni} = 2.17$ m² g⁻¹), the low-temperature peak is smaller than that in the spectrum of the catalyst on the support of Engelhardt Co. (14.89 m² g⁻¹). The low-temperature peak is larger (14.22 m² g⁻¹) in the case of the sample on the non-porous support of Degussa Co.

Thus, by selecting the type and porosity of a support, one can control the formation of precursors of active Ni centres, the extent of metal reduction, and hence the activity and selectivity of a catalyst in specific hydrogenation reactions, and regulate thermostability and physicochemical and catalytic properties of impregnation catalysts.

4. Effect of modifiers and promoters on the properties of catalysts

The mode of support preparation and its nature substantially influence the activity, selectivity and physicochemical properties of supported catalysts; however, the strongest effect is achieved by the use of promoters and modifiers.

According to Roginskii,¹³⁰ modification, unlike promotion, is 'a more complicated phenomenon associated with more profound and complex changes in the catalytic properties and specific action of additives' the introduction of which induces 'not merely changes in the absolute magnitude of activity, but also a profound modification of the surface quality'. This can result in a change in the reaction route, *i.e.*, not only in the catalyst activity, but also in its selectivity. This concerns, for example, the modified Ni catalysts of hydrogenation, if the additives, as shown below, 'can react with the surface layer of the solid'.

The application of modern physicochemical methods allows a scientifically sound selection of modifiers and promoters for preparing efficient hydrogenation catalysts for any purpose.

At present, Ni-containing catalysts of hydrogenation are prepared mostly on supports, such as Al₂O₃, SiO₂, aluminosilicates, zeolites, *etc.*, which are modified by oxides.^{5, 12, 20, 116, 131} Modifiers, which are for the most part inorganic additives (SiO₂, zeolites, Mg, Zr, and Ti oxides, boric and phosphoric acids), are introduced into supports by precipitation or impregnation techniques. This results in the enhanced thermostability and mechanical strength of the support. The activity and selectivity of the catalyst change insignificantly when the additives introduced do not affect the extent of nickel dispersity, the degree of its reduction and the magnitude of SMSI.

The fact that thermal treatment influences, as has been shown above, the dispersity and structure of supported Ni catalysts makes topical the enhancement of thermostability by modification. For example, addition of 3%–10% of BaO to γ -Al₂O₃ inhibits sintering and improves thermostability of the support.¹²

Addition of phosphoric acid to aluminium hydroxide favours an increase in the total porosity and the proportion of micropores. Other modifiers are also used.

Stabilisation of the existing Ni-containing centres, and creation of newer ones, often requires that considerable quantities of modifying oxide additives (up to 20 mass %–40 mass %) be incorporated into the catalyst.^{12, 132} Thus, the addition of 5% of B₂O₃ to the NiO–Al₂O₃ system leads solely to a lower concentration of Ni³⁺ ions that are not reduced to the metallic state. Addition of 10% of B₂O₃ precludes the formation of Ni³⁺ ions and stabilises Ni²⁺ ions (a sample with 3%Ni/Al₂O₃), though even in this case a large portion of nickel remains in the form of surface oxide associates, whose reduction to the metallic state is problematic.

An analogous situation is observed in the modification of γ -Al₂O₃ with oxides, such as WO₃ and Cr₂O₃, and zeolites. With hydrogenolysis of thiophene as an example Surin *et al.*¹³³ described the promoting effect of zeolite on the hydrotreating catalyst, Ni–Mo/Al₂O₃. Studies involving a set of techniques (DTA, TG, EPR, FMR) showed that zeolite forms thermostable compounds with molybdenum and interacts with γ -Al₂O₃. Introduction of zeolite in the Ni–Mo catalyst favours more uniform distribution of acidic centres, which exerts a substantial effect on the formation of an active hydrogenation phase: a more dispersed phase is formed upon reduction of nickel molybdates.

In recent years there has been a much greater use of nickel catalysts modified by surface hydrides formed in the process of catalyst preparation^{13–15, 134} and of the above-mentioned sorptional catalysts. The latter catalysts are highly dispersed, thermostable, and very active in hydrogenation processes, although the method of their preparation is not well-suited to industrial conditions because it includes decomposition on supports of organometallic compounds of elements belonging to Groups IV–VII (Mo, W, Re, and Sn) or Group VIII.^{18–22, 110, 116, 134} The most probable reason for the enhanced thermostability is the interaction of the active component with low-valent ions to form metal–metal bonds between cations of these modifiers and the metal of organometallic compound:¹³⁵

where $\text{M}(\pi\text{-C}_4\text{H}_7)_2$ is the organometallic compound; M^0 is the metal; E^{x+} is the modifying element of Group IV–VII.

Certain procedures developed for preparing sorptional catalysts, including nickel-containing ones, make it possible to reach a degree of dispersion close to the atomic state.^{18–22} Slinkin *et al.*¹¹⁶ described a process for preparing nickel catalysts based on ternary oxide systems Ni–SiO₂(MO₂) synthesised by the alkoxide technology. Catalysts prepared by precipitation from alcoholic or aqueous solutions and promoted with Ti, Zr, and Ce oxides were used for comparison. The extent of nickel dispersion in these catalysts and others obtained from the ternary systems using organometallic compounds proved to be much the same. However, due to the absence of a SMSI effect, the activity of the precipitated catalysts 7%Ni/SiO₂–10%TiO₂(ZrO₂) in the hydrogenation of benzene proved to be one order of magnitude higher than that of the systems synthesised by chemical mixing, where the SMSI effect takes place. In their capacity to stabilise high-dispersity crystals of nickel, the modifiers form the following series:¹¹⁶ CeO₂ > ZrO₂ > TiO₂.

A highly dispersed Ni catalyst for benzene hydrogenation was prepared by modifying the support surface with an organolithium compound from methanolic solution:¹⁸

In accordance with this scheme the so-called grafted Ni/SiO₂ catalysts with 0.8 mass%–4.6 mass% of metal were prepared. Physicochemical and catalytic studies of such catalysts showed that they possess a number of advantages compared to the impregnation systems of similar composition. The degree of reduction of the grafted catalysts at 250–400 °C does not reach 100%, and the size of Ni particles in them ranges from 4.8 to 8.5 nm, while it is 12.5 nm in the impregnation catalysts with 100% reduction. The maximum activity of grafted catalysts in the reaction of benzene hydrogenation is observed at 350–360 °C, which is 12–15 times larger than that of impregnation systems.¹⁸

The drawbacks of the method of support modification with organometallic compounds include a narrow set of compounds possessing satisfactory solubility even in organic solvents, complexity of their synthesis, high explosive tendency and fire hazard of the process, and the need for special pretreatment of supports.¹³

However, this method makes it possible to modify the support surface at the atomic level and to form active metal centres with a predetermined environment.

In our opinion, a method for preparing low-percentage Ni catalysts of hydrogenation by impregnation with mixed inorganic complex salts from aqueous solutions is more promising.^{136–145} In all cases, the role of modifier or active phase is played by heteropolycompounds (HPC) with anions of the general formula $[\text{H}_w\text{A}_x\text{B}_y\text{O}_z]^{n-}$, where A = Ni or Co; B = Mo, W, or V. Their decomposition yields supported Co–Mo, Ni–W, and Ni–Mo catalysts;¹⁴⁶ they may also be used as modifiers of Ni-containing catalysts.^{136–145}

Heteropolycompounds with anions $[\text{NiM}_6\text{O}_{24}\text{H}_6]^{4-}$ (M = Mo or W) were synthesised to prepare hydrogenation catalysts of this type aimed at modelling the known Co–Mo, Co–W and Ni–W catalysts of hydrotreating.¹⁴⁶ Their decomposition on the surface yielded the active phase. Previously, this type of salt and acid were mostly applied as catalysts of oxidation, hydration–dehydration and some other processes.^{147–151}

Supported Ni–Mo and Ni–W catalysts prepared by impregnation of their support with heteropolycompounds were tested in reactions of hydrodesulfurisation and hydrogenation.^{146, 152} They were found to be less active than the industrial Ni–Mo and Ni–W catalysts. This is rationalised by the lower content of Ni which cannot be increased because in this case HPC are used as an ordinary active phase.

In the 1980s, one of the authors of this review designed nickel catalysts of a fundamentally new type on different supports (activated carbon, Al₂O₃, and SiO₂) in which HPC of different composition (HPC₁, HPC₂, HPC₃, *etc.*) play the role of modifiers.^{136–143} They were tested in a broad spectrum of reactions (hydrogenation of alkenes, aromatic compounds, aldehydes, ketones, and CO; hydrogenation of coal; hydrodemethylation of toluene; hydrocracking of petrol fractions; dehydrogenation of cycloalkanes). It was shown that they possess high and controllable activity and selectivity. Common distinctive features of these catalysts are low metal content (2%–6% Ni), modifying salts on the surface of a support and a well-developed surface of metallic nickel with high dispersity. These catalysts exhibit high thermostability, and the procedures for their preparation match technological demands.

Table 9 presents values of the specific surface of nickel (S_{Ni}), its dispersity (d_{Ni}), and the degree of reduction (α) in modified catalysts of the new type on γ -Al₂O₃ with different HPC modifiers and, for comparison, in some industrial Ni catalysts of hydrogenation.

The extent of reduction of modified samples reaches high values, despite the fact that the reduction conditions are considerably milder (400 °C, 6 h) than, for example, those for the Euro-Ni-1 catalyst.¹⁵ In some cases, the α value for modified catalysts with low Ni content (*e.g.*, 2%Ni–HPC₁) reaches 100%. As noted above, this index is not reached for non-modified Ni/Al₂O₃ catalysts, since in these a fraction of the Ni is incorporated into the lattice forming a spinel.

Table 9. Specific surface of nickel, its dispersity, and the extent of reduction in HPC-modified and some industrial catalysts.

Catalyst	[Ni] (%)	S_{Ni} /m ² (g cat- alyst) ⁻¹	d_{Ni}^a /Å	α (%)
Ni–HPC ₁ /Al ₂ O ₃	4	220	26	70
Ni–HPC ₂ /Al ₂ O ₃	4	334	17	87
Ni–HPC ₃ /Al ₂ O ₃	4	56	100	87
Ni–Cr	48–63	25–27		
Euro-Ni-1 ^b	25–52	181	48–56	85–96
Ni/Al ₂ O ₃ (Exxon)	8–10	197	34	

^a Found from H₂ adsorption. ^b Reduction for 10–26 h at 630 °C.

The HPC-modified catalysts with 2%–4% of nickel manifest enhanced activity in the hydrogenation of mono- and bi-cyclic aromatic hydrocarbons, and their selectivity reaches 100%. Hydrogenation of toluene on HPC-modified Ni catalysts with 2%–4% of Ni occurs considerably more easily than on industrial Ni–Cr catalysts with 50% of Ni (Fig. 1).¹³⁸

**Figure 1.** The extent of toluene hydrogenation vs. time on an industrial Ni–Cr catalyst (1) and modified Ni–HPC₂/Al₂O₃ catalysts with 2 mass %, 3 mass %, and 4 mass % of Ni [(2)–(4), respectively].

The catalyst Ni–HPC₁/Al₂O₃ with 2% of Ni is more active at 3 MPa and 220 °C than its analogue with 4% of Ni, and complete hydrogenation of benzene on this catalyst occurs within a contact time less than 0.1 h.¹⁴⁰

These results confirm direct participation of HPC in the formation of active centres of hydrogenation. This follows in particular from the data on the formation of HPC oxometallates, and the formation of W-containing hydrogen bronze upon reduction of highly dispersed particles in the Pt/WO₃ system.^{141, 150, 152}

Preparation of modified Ni–HPC catalysts on carbon supports is accompanied by the formation of an active phase in which Ni particles are distributed uniformly. Figure 2 presents microphotographs of modified and non-modified catalysts on a carbon support with a specific surface of 600 m² g⁻¹. In the absence of HPC the Ni particles are nonuniformly distributed, and their size exceeds that of particles in the modified catalyst.¹³⁸ In the catalyst 4%Ni–HPC/C reduced at 300–420 °C, the size of particles can be as small as 5–7 Å, and in the catalyst on γ -Al₂O₃ they can be even smaller. To achieve optimum dispersity of Ni (5–7 Å) and maximum reduction, it is necessary to have specific HPC concentration and a Ni : HPC ratio on each support. Complete reduction of Ni is possible at a low metal content (2%–4%). In this case, nickel virtually does not interact with γ -Al₂O₃ since it is distributed on the modifier surface. Catalysts Ni/ γ -Al₂O₃ containing less

**Figure 2.** Microphotographs of reduced (at 400 °C) catalysts containing 4% of Ni on carbon supports in the absence of modifier (a) and the presence of HPC₁ (b).

than 5% of metal are virtually inactive in hydrogenation of benzene because of the difficulty in reducing NiO that is in contact with Al₂O₃.

Modification of the Ni/Al₂O₃ catalyst containing 4% of Ni with heteropolycompounds shifts the range of CO hydrogenation towards higher temperatures (250–400 °C) and substantially diminishes the CO₂ concentration in the products on total CO conversion.¹³⁹ The transition of centres of type A (Ni/NiO) to centres of type B (Ni²⁺/NiO) ensures selective hydrogenation, which occurs at a lower temperature. In the absence of a modifier, the centres of the B type are possibly not formed at all.

The assumption of the different structure of Ni centres on modified and non-modified catalysts was confirmed by the analysis of electronic spectra of diffuse reflection. It was shown that Ni catalysts modified by HPC have two types of Ni²⁺ ions with different crystalline fields, while Ni³⁺ ions are absent. Spectral parameters do not correspond to the compound NiAl₂O₄, which shows that the modifier is involved in the distribution of nickel and that the direct interaction between Ni and Al₂O₃ is absent.

The B₂O₃ modifier added in quantities considerably larger (up to 10 mass %–20 mass %) than HPC influences the thermostability of catalysts since it destroys the Ni–O–Ni clusters, inhibits the formation of spinel with Al₂O₃, and stabilises the Ni²⁺ ions on the surface.¹³² Addition of B₂O₃ to the Ni/Al₂O₃ system strongly decreases the concentration of Ni³⁺ ions, which form the oxide associates Ni–O–Ni and alters the acid-base properties of a catalyst.

Heteropolycompounds serve not only as chemical modifiers, they also influence the microporous structure of catalysts.

Figure 3. Changes in the porous support structure after formation of the active phase of Ni catalyst in the presence of HPC: (1) γ - Al_2O_3 support after thermal treatment; (2) Ni-HPC₁/ Al_2O_3 catalyst.

Figure 3 shows changes in the porous structure of γ - Al_2O_3 after introduction of HPC in the preparation of a Ni hydrogenation catalyst. The presence of micropores 20–30 Å in diameter influences rather favourably the activity of catalysts for the hydrogenation of aromatic hydrocarbons. The micropores are the sites where readily reducible nickel oxides are formed, after activation with hydrogen the oxides are transformed into highly dispersed metal particles, which ensure rapid hydrogenation of benzene. By modifying the porous support structure with HPC, one can prepare active and selective catalysts for the hydrogenation of aromatic and carbonyl compounds or CO methanation.

Table 10 presents some characteristics of HPC-modified catalysts with the same content of nickel and supports used for their preparation by impregnation. The supports were γ - Al_2O_3 with a predominant pore size of 9–12 nm (Al_2O_3 -1) or Al_2O_3 of the X type (X_1 , X_2 , X_3) with a pore size of 1–3 nm. Figure 4 shows the dependence of changes in the volume of pores (V) as a function of their radius (r) for the supports of the X type and Al_2O_3 -1.

The data presented in Table 10 show that the catalysts based on supports with similar total porosity (specimens 1, 4 and 8) and volume of micropores (specimens 1 and 4) exhibit different activities. The catalyst No. 9 prepared on the support with the largest volume of micropores is the most active in hydrogenation of benzene but is little active in the hydrogenation of acetone. On the contrary, specimens 2 and 3 prepared on Al_2O_3 -1 are not very active in the hydrogenation of benzene and highly active in the hydrogenation of acetone. The modified Ni catalysts with a well-

Figure 4. Distribution of the volume of pores in the supports γ - Al_2O_3 of the X type (a) and Al_2O_3 -1 (b).

developed microstructure (the predominant pore size 1–3 nm) were shown to have active centres of benzene hydrogenation and those with large pores (9–12 nm) — to contain active centres of acetone hydrogenation.

Dehydration of modified samples under conditions of thermoprogrammed heating in the temperature range 50–700 °C yields water as the sole product. Modification with HPC substantially alters the properties of the initial surface of Al_2O_3 . Specifically, hydrophilicity of the catalysts prepared was found to be higher than that of initial Al_2O_3 over all the measurement range. After deposition of Ni on modified Al_2O_3 , the liberation of adsorbed water in the thermolysis takes place in the temperature intervals 50–100 °C, 200–300 °C, ~400 °C, 500–600 °C, and even near 700 °C. The most actively modified Ni catalysts possess an increased capacity for H_2O (12% and more). They are characterised by the presence of water removable only in the high-temperature range.¹⁵³

IV. Catalysts based on noble metals

The Ni-containing catalysts are less expensive than those based on noble metals (Pt, Pd, Ru, Rh, Ir, and Os). However, for a number of industrial hydrogenation processes preference is given to the latter because of their high catalytic activity allowing operations at lower temperature and pressure. The lifetime of these catalysts often extends to several years. Pd, Pt, Ru, and Rh catalysts and

Table 10. Effect of the porous structure of supports on the activity of Ni catalysts in the hydrogenation of benzene and acetone.

Entry	Catalyst or support	$S_{\text{sp}}/\text{m}^2 \text{ g}^{-1}$	Total porosity $/\text{cm}^3 \text{ g}^{-1}$	Microporosity $/\text{cm}^3 \text{ g}^{-1}$	Rate constant of benzene hydrogenation $/\text{h}^{-1} \text{ cm}^{-3}$	Degree of acetone conversion (%)
1	Al_2O_3 -1	170	0.59	0.10	—	—
2	Ni-HPC ₂ / Al_2O_3 -1	—	—	—	0.40	80
3	Ni-HPC ₅ / Al_2O_3 -1	—	—	—	0.12	60
4	X_1	193	0.42	0.11	—	—
5	Ni-HPC ₂ / X_1	—	—	—	0.86	—
6	X_2	214	0.45	0.14	—	—
7	Ni-HPC ₂ / X_2	—	—	—	1.16	20
8	X_3	201	0.51	0.20	—	—
9	Ni-HPC ₂ / X_3	—	—	—	1.44	12

bimetallic systems are of special interest. The use of special supports makes it possible to bring the content of noble metals down to 0.01%–0.005% and thus make catalysts less expensive, while preserving their qualities.^{154–157}

Modern physicochemical methods allow the investigation into the mechanism of action of these catalysts, optimisation of their composition, and development of methods for controlling the metal dispersity on the support surface. Some catalysts based on noble metals are resistant to poisoning with S- and N-containing compounds.^{158, 159}

1. Hydrogenation of CO

A number of studies (see, e.g., Refs 160–163) showed that supported Pt, Pd, Ir, Ru, and Rh catalysts allow one to bring about the methanation of CO under atmospheric pressure. Hydrogenation of CO under elevated pressure in the presence of Pt/Al₂O₃, Pd/Al₂O₃, and especially Ru/Al₂O₃ and Rh/Al₂O₃ (in contrast to Ni-containing catalysts) leads to the formation of alcohols and other oxygenated compounds^{164–166}

The Fischer–Tropsch synthesis may be also carried out on Ru/Al₂O₃ and Ru catalysts on specially selected supports to produce higher (C₅–C₂₀) hydrocarbons (with selectivity up to 81%) as well as methane, C₁–C₅ alcohols, and C₂₁–C₄₀ hydrocarbons.^{167–170}

Industrial processes (Sasol-II, SMDS, and Gulf Badger) on Ru-containing catalysts allow selective formation of a diesel fraction of synthetic liquid fuel or higher paraffins the cracking of which affords high-quality diesel and rocket fuels.^{167, 170}

During the period 1987–1990, the catalytic activity of platinum group metals on supports in the reaction of CO hydrogenation, its mechanism and kinetics were systematically studied.^{117, 118, 163} The dispersities (mean size of metal particles, d_{mean}) of the catalysts studied, their activities (k), and selectivities are presented in Table 11.

Table 11. Certain characteristics of different metal catalysts for the CO methanation ($p_{\text{CO}} = 20$ kPa, $p_{\text{H}_2} = 50$ kPa, $T = 275$ °C).

Catalyst	d_{mean} /nm	$10^7 k$ /mol m ⁻² s ⁻¹	Selectivity of methane formation (%)
Ru/Al ₂ O ₃	4.4	6.7	87
Rh/Al ₂ O ₃	2.5	5.5	94
Ni/Al ₂ O ₃	2.4	4.7	96
Pt/Al ₂ O ₃	3.9	0.4	99
Ir/Al ₂ O ₃	6.8	0.2	100
Pd/Al ₂ O ₃	5.0	0.1	100

As seen in Table 11, the specific catalytic activity decreases and the selectivity increases in the series Ru → Rh → Ni → Pt → Ir → Pd. The catalytic activity decreases as q_{CO} increases.¹⁶³ The q_{CO} values determined from kinetic data increase in the following series: Ru < Rh < Ni < Pt < Ir < Pd.^{161, 171} On the whole, the specific catalytic activity of platinum group metals and nickel is lower the larger the size of the metal particles (*cf.* Table 11).

The effect of the phase structure of the support (Al₂O₃) was studied for Rh catalysts.¹⁷² Rhodium was deposited on δ-, θ-, and α-Al₂O₃ with specific surfaces from 5 to 90 m² g⁻¹. In these catalysts, rhodium was found to be present in three forms:

encapsulated, strongly interacting, and non-interacting with the support. The maximum extent of dispersity (11%) was reached on α-Al₂O₃ at low Rh content (< 1 μmol m⁻²). At higher Rh content (> 1 μmol m⁻²), the extent of dispersity was below 3%. The activity of a catalyst is enhanced if α-Al₂O₃ is used as a support, if Al₂O₃ is treated with water vapour prior to Rh deposition, and if the content of deposited rhodium is low.

2. Hydrogenation of carbonyl compounds

The similarity of the processes underlying hydrogenation of CO and carbonyl compounds on platinum group metals was reported in different studies.^{161, 167–171} The character of the dependence of specific catalytic activity on the heat of adsorption of the reactant proved to be nearly the same in both cases. The same holds for the influence of dispersity: the heat of adsorption of reactants increases with a decrease in the size of crystals leading to a lower catalytic activity. The mechanisms underlying the hydrogenation of CO and acetone were supposed to be similar (the Langmuir–Hinshelwood mechanism):

(Z, Z_a, and Z_H are the catalyst active centres).

The limiting stages are the addition of the first hydrogen atom to an adsorbed CO molecule or to the >CO group of acetone, respectively, with the formation of a ‘semi-hydrogenated’ reactant form.

However, certain differences also exist: in the CO hydrogenation, the most active catalyst is Ru, while the hydrogenation of carbonyl compounds is best catalysed by Pt. Some investigators believe^{167–171} that the reason for this difference consists in the stronger binding of C and O atoms ($q_{>\text{CO}}$) in a complex of the type

compared to the carbonyl compound binding (q_{CO}) in the complex

and thus $q_{>\text{CO}, \text{opt}} < q_{\text{CO}, \text{opt}}$. According to approximate estimates, $q_{>\text{CO}, \text{opt}} \simeq 20$ kJ mol⁻¹ and $q_{\text{CO}, \text{opt}} \simeq 100$ kJ mol⁻¹. These differences are reflected in the series of catalytic activity and selectivity. Table 12 presents data on the dispersity of metals of the platinum group and nickel deposited on Al₂O₃ and their specific activities in the acetone hydrogenation. The specific activities of catalysts with similar metal dispersion decreases in the order: Pt > Ir > Rh > Ni > Ru > Pd. The position of individual metals in this series depends on both their chemical nature and the dispersity. Hydrogenation of the carbonyl group of a ketone is a structure-sensitive reaction. This means that the probability of multipoint adsorption of complex molecules and the rate of their hydrogenation depend on the size, shape, and arrangement of microcrystals on the support. Possibly, the adjacent sites of the support surface take part in the substrate activation due to hydrogen spillover.¹⁶⁵

Table 12. Specific activity of some catalysts in the acetone hydrogenation reaction and the deposited metal dispersity.

Catalyst	d_{mean} /nm	$10^7 k$ /mol m ⁻² s ⁻¹	q_{CO} /kJ mol ⁻¹
Pt/Al ₂ O ₃	3.9	44	12
Ir/Al ₂ O ₃	6.8	11.7	20
Rh/Al ₂ O ₃	2.5	7.7	15
Ni/Al ₂ O ₃	2.4	7.5	85–25
Ru/Al ₂ O ₃	4.4	700	30
Pd/Al ₂ O ₃	5.0	0	–

3. Hydrogenation of unsaturated hydrocarbons

In some cases, noble metals rather than nickel are preferred as catalysts for the hydrotreating of motor fuels (dearomatisation, hydrogenation of alkenes).^{29, 40} Catalysts based on noble metals are more active and more resistant to poisoning by sulfur compounds. Platinum and palladium deposited on Al₂O₃ are easily deactivated at a sulfur concentration below 1 ppm;¹⁷³ however, their resistance to sulfur poisoning increases on acidic supports, such as zeolites.^{158, 159} For instance, 98% of the products of dodecane hydrocracking are alkanes on Pd/LaY under H₂S pressure of 63 kPa, *i.e.* when all palladium would be expected to pass to PdS; the catalyst activity and selectivity remain virtually unaltered.¹⁵⁹ Such an unusual behaviour of this noble metal is explained by the SMSI effect or changes in the electronic state of palladium upon its interaction with the acidic centres of zeolite.¹⁵⁸

Platinum catalysts are prepared by ion exchange or impregnation of the support with a solution of Pt(NH₃)₄Cl₂; its cation binds to an acidic centre of zeolite $\equiv \text{Al}-\text{O}^-$. The next important stage consists of the formation of centres $2(\equiv \text{Al}-\text{O}^-)\text{Pt}^{2+}$ upon calcination in air. On subsequent reduction with hydrogen, platinum becomes involved in clusters of the type $m(\equiv \text{Al}-\text{O}-\text{H}) \cdots \text{Pt}_n$. The clusters are in close contact with strong acidic centres, which makes possible the transfer of electrons from this noble metal and leads to the formation of electron-deficient metal particles (Pt^{δ+}), which are responsible for the specific properties of this catalyst.¹⁷⁴

In most cases, hydrogenation is conducted on supported palladium catalysts. Table 13 presents the data from studies of the hydrogenation reactions of CO, aldehydes, and unsaturated hydrocarbons on Pd/TiO₂ catalysts prepared by different methods and differing in the size of particles and the active surface of the metal.¹⁷⁶

The data in Table 13 indicate that the rates of CO hydrogenation and low-temperature hydrogenation of propionaldehyde to propanol increase with the Pd dispersity. However, in the hydrogenation of the C=C double bonds in ethylene, butadiene, and acrolein the reverse order of activity is observed, being particularly noticeable in the hydrogenation of the conjugated bonds of butadiene.

The relationship between the catalytic properties of supported palladium and its dispersity is widely discussed in the literature.^{174–184} In some reports, this phenomenon is explained by changes in the electronic state of Pd resulting from the SMSI

effect,^{175, 179} while in others, by the participation of both the catalyst and the support in the reaction.¹⁸⁰ Table 13 shows three Pd catalysts on the same support (TiO₂), which possess different activities and selectivities. Therefore, according to Barbier *et al.*,¹⁷³ the reason for the differences should be sought in the properties of the particles of palladium itself: in variations of their size, shape, electronic structure, and the nature of their interaction with the molecules subject to hydrogenation. For example, in the adsorption of CO an electron is transferred from Pd to CO, while in the adsorption of ethylene it is transferred in the opposite direction. This results in inverse dependences of the catalytic activity of Pd/TiO₂ on the degree of metal dispersity in different hydrogenation reactions.

Highly dispersed palladium is more active in the hydrogenation of electron-acceptor compounds, whereas the low dispersed palladium is more active in the hydrogenation of electron-donor compounds. As was shown above (see Table 11), Pd/Al₂O₃ is the least active catalyst of CO methanation. The metal in bulk is also weakly active in this reaction.¹⁸¹ Consequently, in Pd/TiO₂, palladium forms clusters or small particles which are endowed with special properties different from those of bulk Pd or Pd on Al₂O₃. Of all the catalysts listed in Table 13, the strongest Pd–support interaction may be expected for the first specimen, which is characterised by a well-developed active surface and small particle size. In this case, an effect of the SMSI type is possible.

4. Bimetallic and modified catalysts

Considerable interest arose in bimetallic catalysts on supports in connection with the development of sulfur-resistant hydrogenation catalysts based on noble metals. For example, combination of Pt and Pd deposited on zeolite is known^{183, 184} to enhance sulfur tolerance, the optimum Pt : Pd ratio being equal to 1. The support used was zeolite of the Y type with a high Si/Al ratio (Shell), and mordenites, borosilicates, and Y- and β-zeolites (Amoco).

The Haldor Topsøe company has developed two types of catalysts for the two-stage hydrotreating of petroleum fractions: Ni–Mo/Al₂O₃ for the first stage and TK908 containing a supported noble metal for the second stage.¹⁸⁵ The latter was in operation for 5600 h and the extent of its deactivation was less than 1% after 1000 h, despite the fact that the content of sulfur in raw materials reached 1000 ppm and that of nitrogen reached 50 ppm.

Ru–Pd catalysts prepared by impregnation of a support with salts of both metals are highly active. These catalysts were used to study the hydrogenation of benzene.¹⁸⁶

Bastiaux *et al.*¹⁸⁷ described in detail a new approach to the preparation of highly selective bimetallic catalysts for the hydrogenation of alkynes and dienes in the hydrotreating of pyrolysis gases and petroleum fractions. Industrial Pd catalysts were substantially upgraded by promoting them with a second metal. The choice of the second metal promoter was made on the basis of modern theories of homogeneous catalysis and of current concepts of changes in ligand mobility in organometallic compounds.¹⁸⁸ Alkanes, alkenes, and alkadienes localised on the surface of Pd catalysts may be regarded as ligands which form strong bonds with palladium in the absence of promoters, thus

Table 13. Mean activity (catalyst turnover) of different Pd/TiO₂ catalysts in the hydrogenation of CO, aldehydes, and alkenes.¹⁷⁶

Catalyst characteristics				Mean catalyst activity in hydrogenation					
[Pd] (%)	S_{sp} m ² g ⁻¹	d /nm	H : Pd	CO (methana- tion)	CO in CH ₃ OH (230 °C)	C=O bond in propion- aldehyde (80 °C)	C ₂ H ₄ (80 °C)	C=C bond in acrolein (80 °C)	C ₄ H ₆ (80 °C)
5.5	207	4.5–6.5	0.32–0.67	7.3×10^{-4}	4.3×10^{-4}	0.16	380	0.09	150
5.2	9	186	0.17	2.8×10^{-4}	4.0×10^{-5}	4.5×10^{-3}	500	–	680
4.4	9	295	0.067	5.5×10^{-4}	0	4.5×10^{-3}	580	0.4	1.05×10^3

decreasing the catalyst's activity. The strength of the alkyl–metal bond may be reduced by the addition of an electron-donor compound or a metal promoter which favours higher selectivity of acetylene hydrogenation.¹⁸⁷ New procedures for the preparation of highly selective bimetallic hydrogenation catalysts with controlled dispersities were developed using recent progress in the field of inorganic synthesis and synthesis of organometallic compounds.^{189,190} Higher yield of the target product and higher stability of catalysts are achieved by modification of the electronic properties of palladium by the second metal. This approach was employed to prepare the industrial catalyst LT-279 for the selective hydrogenation of acetylene in an ethane–ethylene fraction.¹⁸⁷

As noted above, the selectivity of acetylene hydrogenation may be considerably increased by preparing Pd catalysts on supports in the form of active film structures of the cermet type.⁹⁹ In this case, the electronic properties of palladium are modified in a different way, namely, due to the formation of a surface catalyst layer with incorporated modifying oxide additives (Al₂O₃). To this end, a simple technique may be used, such as impregnation, which is inapplicable for the production of bimetallic catalysts. The latter are synthesised by making recourse to a more complex technology using, *e.g.*, organometallic compounds or vapour condensation of two metals on a support.¹⁸⁷

Film-type Pd catalysts modified with Al₂O₃ in their surface layer contain 0.1%–0.3% of Pd. They are thermostable and may be subjected to oxidative regeneration. Metal particles are formed in them on the surface of γ -Al₂O₃ supplemented with a thermostable alumina oxide in the ratio Pd : Al₂O₃ = 1 : 1. Alteration of Pd properties leads to higher catalytic activity in the reaction of acetylene hydrogenation, which allows one to conduct it at low temperature (30 °C), low H₂ : C₂H₂ ratio (2 : 1), and high flow rates (up to 10 000 h^{–1}), with a substantial increase in the selectivity of C₂H₂ hydrogenation, *i.e.*, the same effects as with bimetallic catalysts. Modification of film-type palladium catalysts is brought about by adding very small quantities of oxide (Pd : Al₂O₃ = 1 : 1), and the procedure for their preparation is much simpler than that of bimetallic catalysts.

As for the selectivity of acetylene hydrogenation, the Al₂O₃-modified Pd (0.1%Pd) is more than twice as effective as its industrial analogue MA-15 (0.5%Pd).⁹⁹ On a bimetallic LT-279 catalyst, transformation of acetylene increases by no more than 10%–20% compared to that on a common Pd hydrotreating catalyst.¹⁸⁷

Selective hydrogenation of unsaturated hydrocarbons can be performed on new highly dispersed Pt/MoO₃ and Pt/WO₃ catalysts in which the metal particles interact on the surface with the modified support.¹⁵² The ultradispersed MoO₃ and WO₃ particles obtained in a plasma reactor are reduced in a stream of hydrogen at 300 °C. Subsequent interaction with Pt or Pd leads to hydrogen bronzes, which serve as hydrogen reservoirs for hydrogenation.^{191,192} The hydrogen bronzes are formed upon deposition of 0.2% Pt on MoO₃ or 0.1% Pt on WO₃ owing to spillover of H₂ from the metal centres to the support under the hydrogenation conditions. This results in changes in the specific surface and the size of particles that form the centres active in the hydrogenation of alkenes. The molybdenum and tungsten bronzes themselves (without hydrogen) can also catalyse ethylene hydrogenation.¹⁹³

V. The mechanism of hydrogenation on metal catalysts

The mechanism of catalytic hydrogenation, in particular the sequential formation of different surface compounds, has been reviewed recently.¹⁹⁴ Hydrogenation is assumed to involve atomic hydrogen formed upon dissociation of H₂ on metals, such as Ni, Pt, Pd, and others. This assumption is confirmed by an intense isotope exchange

and formation of monodeuterioethane C₂H₃D upon deuteration of ethylene. On oxides, in particular on ZnO, deuterioethane C₂H₄D₂ is formed from ethylene, which indicates the participation of molecular hydrogen in this reaction. However, other data¹⁹⁵ point to the possibility of participation of both atomic and molecular hydrogen in the hydrogenation on metals.

Numerous forms of adsorbed alkenes were detected on the surface of metals that were found to compete for the active centres. Strongly bound forms of the type CH₃–CH=M, CH₃–C≡M, *etc.* are hydrogenated at high temperatures, whereas at low temperatures only weakly bound forms of the π -type and π -allyl complexes undergo hydrogenation.

The hydrogenation rate may be varied by regulating the strength of alkene adsorption. For example, modification with alkylsilanes increases the activity of ZnO 20- and 150-times in the hydrogenation of butadiene and pentadiene, respectively.¹⁹⁵ This is explained by a steric effect: bulky alkylsilanes prevent strong adsorption of dienes, but do not hinder hydrogen adsorption.

It is suggested that the centres of hydrogen activation involved in hydrogenation are localised on the metal surface. Therefore, the larger the surface of a metal the higher should be its catalytic activity. If the size of metal crystallites has no effect on the specific activity of a catalyst, the catalysed reaction is called structure-insensitive. The hydrogenation of the C=C bond in alkenes is an example of such reactions. On the contrary, the hydrogenation rates of an aromatic ring, the C=O and C≡C bonds, and conjugated compounds of the butadiene type depend on the metal dispersity and hence such hydrogenations are regarded as structure-sensitive reactions.

Investigation of hydrogenation of cinnamaldehyde on Ru/Al₂O₃ showed a decrease in the specific rate constant for the C=C bond hydrogenation with an increase in the metal dispersity.¹⁹⁶ This indicates that this reaction requires a planar adsorption of substrate, *e.g.*, in the form of a π -complex. At the same time, the rate constant for the C=O bond hydrogenation increased with increase in the metal dispersity. Evidently, this reaction requires point-type adsorption (Ru···O=C<). The adsorption coefficient of the C=O bond of cinnamaldehyde is independent of dispersion, while the adsorption coefficient of the C=C bond decreases with an increase in the metal dispersity.

Apparently, intermediate semi-hydrogenated forms can manifest properties of free radicals (C₂H₅· from C₂H₄, C₃H₇· from C₃H₆, *etc.*).¹⁹⁷

Small palladium particles with a size < 2.5 nm (Pd/MgO, Pd/Al₂O₃, Pd/SiO₂, Pd films and Pt black) are less active than larger particles,^{95,198–200} and they become totally inactive when their size is < 1 nm. This is explained by the fact that very small particles cannot dissolve hydrogen. Sintering of particles leads to enhancement of the catalyst's activity and selectivity in the hydrogenation of unsaturated compounds.

The hydrogen necessary for the hydrogenation can be accumulated not only on the surface but also in the bulk of the metal. The properties of the surface- and bulk-absorbed hydrogen differ considerably. For example, in the hydrogenation of CO and CO₂ on Pd/Al₂O₃, Pd black, and Pd foil the bulk hydrogen favours formation of oxygenated compounds, CH₃OH and CH₃CHO, while the surface hydrogen favours formation of CH₄ and other hydrocarbons.²⁰¹

Other phases of a complex catalyst can also absorb hydrogen and deliver it rapidly to the compound subject to hydrogenation. Hydrogenation reactions often require the activation of both hydrogen and the compound to be hydrogenated. The latter process can be brought about on another phase. The unsaturated compound can also be localised on the metal, although covering of the surface of the metal prevents adsorption of H₂ and hampers the delivery of hydrogen in quantities necessary for hydrogenation. Hydrogenation can occur as a result of alternating interactions of different components of a catalyst with hydrogen and the compound to be hydrogenated and hydrogen spillover from

one component to another. The latest data on hydrogen spillover have been reviewed recently.²⁰²

Hydrogen exchange between the metal phase and the support occurs with participation of acidic centres of the support. This was proved by experiments on the poisoning of Pt/Al₂O₃ catalysts with ammonia under the conditions of butadiene hydrogenation.²⁰³ The results are interpreted by the authors as a redox process

The increase in the catalyst crystalline lattice parameter in the course of hydrogenation may be regarded as an indirect evidence of hydrogen dissolution. The use of neutron diffraction revealed the intercalation of hydrogen into the ZnO phase in CO hydrogenation on a Cu–ZnO catalyst.²⁰⁴ Such an intercalation leads to the formation of a solid solution of Cu in ZnO in which half of the copper ions are replaced by protons. Carbon monoxide is adsorbed on copper, while hydrogen, though also being activated on copper, is involved in the hydrogenation from the subsurface ZnO layer.

Neutron diffraction also revealed the dissolution of hydrogen in the CuCrO₂ catalyst.²⁰⁵ The defects □_{Cu2+} stabilise the dissolved hydrogen. The catalyst has in its bulk two types of hydrogen: atomic hydrogen H in the lattice interpoint space and hydrogen in the form of the OH groups resulting from Cu²⁺ exchange for H⁺.

The intercalation of hydrogen into the lattice of CeM_xO catalyst (M = Cu and Ni; 0 < x < 5) was proved by X-ray, XPES, EPR, and DTG methods.²⁰⁵ The intercalation of H atoms and reduction of Ce⁴⁺ to Ce³⁺ results in the extension of the CeO₂ lattice:

In the above consideration of Ni supported catalysts, we repeatedly mentioned the existence of two types of active centres on the surface: metallic (Ni) and oxidised (Ni²⁺) centres. Different centres are already formed in the preparation of a catalyst, *e.g.*, upon incorporation of NiO into the lattice of γ-Al₂O₃. Non-modified catalysts with a Ni content of 3.2%–4.4% were studied by the method of TPR of carbon monoxide.²⁰⁶ The degree of Ni reduction at 500 °C did not exceed 25%. Two types of CO adsorption were observed, which followed from the two peaks of methane formed upon hydrogenation. The methanation proceeds according to the following scheme:

(values of *E* are given in kJ mol^{−1}).

The conversion of CO (B) into CO (A) at temperatures below 250 °C proceeds very slowly, but upon completion of this transition, CO (A) is rapidly hydrogenated at 142–247 °C. Thus, the rate of methanation on low-percentage Ni/Al₂O₃ catalysts is determined by the rate of B → A conversion, *i.e.* of Ni atoms interacting with NiO, into the Ni centres on the metal surface. Hydrogenation of CO (B) requires a considerably higher activation energy than that of CO (A).

The presence of centres with Ni in different oxidation states is also characteristic of HPC-modified Ni catalysts on supports. We consider here a possible hydrogenation mechanism on such catalysts.

The hydroxylic cover formed on an HPC-modified surface differs substantially from that of the initial support and a binary

Ni catalyst. It is homogeneous and depends on the type and concentration of the modifier and metal concentration.

Heteropolycompounds (HPC) are directly involved in the formation of metal-containing active centres. Judging from electron microscopy (see Fig. 2), at the optimum HPC concentration the active phase is regularly distributed thus creating seeds of Ni microcrystal formation and stabilising the metal formed upon reduction. Nickel particles are distributed in the defect layer of the modifier where Ni²⁺ can also be present. They have no direct contact with the support and are exceptionally thermostable: the specific surface of the metal is not changed up to 600 °C. Hydrogen is adsorbed on the Ni surface and diffuses to the modifier (M) surface following the spillover mechanism with the possible participation of the hydroxy groups of the modifier, as shown below (the arrows indicate the direction of spillover):

An unsaturated organic compound seems to be adsorbed on the modifier phase. Thus, the functions of the two catalyst's phases *viz.*, Ni and HPC, are different. Presumably, Ni²⁺ ions formed from the metal are incorporated into the HPC structure. The initial activation of hydrogen takes place on the Ni particles:

Then a reversible reaction occurs.

This results in the formation of very small Ni particles, which in some cases cannot be detected even by electron microscopy. HPC can interact with the organic compound with transfer of the accumulated hydrogen

Probably, the active hydrogenation centres of unsaturated compounds and aromatics differ from those of CO and carbonyl compounds.

VI. Carbide catalysts

Boudart and Levy²⁰⁷ were among the first investigators to study the catalytic properties of carbides. They showed that Mo₂C possessed an unusually high catalytic activity close to that of platinum in reactions of hydrogenation and isomerisation. Nearly the same activity was found in tungsten carbide. These compounds are formed upon reactions of Mo or W salts or oxides with hydrocarbons. For example, a powder of tungsten carbide with a specific surface of 3.5 m² g^{−1} can be obtained in the reaction of WCl₅ vapour with butane at 1.3 kPa and 1340 °C.²⁰⁸ On the surface of tungsten carbide there is polymeric carbon, which decreases its hydrogenation activity. Adsorption of oxygen facilitates adsorption of H₂ by inducing the formation of islets of tungsten bronze, H_xWO₃, on the surface which is possibly a hydrogen reservoir. Under the conditions of catalysis the WO₃ oxide is not reduced. Thus, the catalytic activity is apparently manifested not by the carbide itself, but rather by a biphasic structure.

The interaction of MoO₃ with a CH₄ + H₂ mixture at 630 °C produces a powder of Mo₂C of hexagonal structure with a specific surface ranging from 50 to 100 m² g^{−1}.²⁰⁹ This also has a polymeric carbon on its surface which is removed under the hydrogenation conditions. A metastable carbide α-Mo₂C_{1-x} (x = 0–0.5) with a specific surface of 200 m² g^{−1} and particle size of 3 nm was prepared in the TPR mode by the reaction of MoO₃ with ammonia and methane.²¹⁰ First, the reaction Mo₃ + NH₃ yields nitride Mo₂N, which is then transformed into

The coke results from realisation of the so-called carbide cycle.^{212, 213} For example, the interaction of Fe with C_4H_6 involves the following transformations:

Electron microscopy studies^{87,216} showed that the general morphology of particles remained unaltered under the reaction conditions. The particles are overgrown with amorphous carbon; however, the latter does not seem to block the active centres. The size of the Fe_3O_4 and $\kappa\text{-Fe}_5\text{C}_2$ particles is ~ 60 nm and ~ 25 nm, respectively. The most interesting finding is evidence of intercalation of the carbide formed in the Fe_3O_4 lattice. In addition to electron microscopy, the electronographic analysis of selected

Thus, it is systems in which the oxide-carbide phases can be formed under the reaction conditions that are the active hydrogenation catalysts. Most recent studies have shown that the formation of oxycarbide structures favours the reactions with the participation of unsaturated compounds on tungsten and molybdenum carbides.

Many recent studies^{223–226} were devoted to the studies of hydrogenolysis of 2-methylpentane, n-hexane, and methylcyclopentene on tungsten carbide WC. This catalyst was synthesised by heating WO₃ in a mixture of 20% CH₄ + 80% H₂ in the TPR mode. In the process of reduction, intermediate species, *viz.*, W₂₀O₅₈, W₁₈O₄₉, and WO₂, were produced and a carbon layer was formed. After heating in this mixture at 800 °C for 10 h, the carbon layer disappeared to give way to WC with specific surface 12 m² g^{−1} possessing a biporous structure (the pores 2 nm and 6 nm in diameter predominate). On WC, which is similar in its catalytic properties to Ru, Ir and Ni, cracking and, to a much lesser extent, isomerisation take place in the presence of hydrogen.

According to Leclercq *et al.*,²²⁷ it is advantageous to prepare the tungsten carbide in two stages: first, carbidisation of metallic W or WO₃ with a mixture of 20% H₂ + 80% CH₄ at 650 °C produces W₂C and a small amount of free C

and then WC is formed at 800 °C in the reaction

In the presence of O₂ at 100–300 °C a complex mixture containing oxycarbide phases, WC, W₂C, WO₂, and metallic tungsten is formed.²²⁸ The properties of the catalyst are strongly changed, and it becomes similar to a bifunctional platinum catalyst and selectively accelerates skeletal isomerisation.

The development of procedures for preparing carbides with large specific surface (up to 200 m² g^{−1}) should be regarded as an important achievement.^{229–233} The hexagonal phase of Mo₂C is formed upon interaction of activated carbon with MoO₃ vapour. The unconsumed carbon is burned in the bulk of the carbide and can enhance the mechanical strength of the catalyst grains. According to the XPES data, the surface is covered by carbide alone, though the contact with oxygen leads to the formation of an oxide film. The oxide oxygen cannot be removed from the Mo₂C surface by heating in hydrogen at 850 °C without partial decarbidisation. To avoid this, the catalyst is treated with a mixture of H₂ plus a hydrocarbon. Alternatively Mo₂C or WC is impregnated with small quantities of Group VIII metal salts which accelerate decarbidisation.

However, oxygen is not always a poison for carbide catalysts. A discovery was made owing to the accidental aspiration of air into a catalytic installation:^{229–233} in the presence of hydrogen, the oxidised Mo₂C catalyses isomerisation of n-hexane into methylpentanes and dimethylbutanes without formation of aromatic compounds. This makes it possible to reform hydrocarbons into high-octane and non-carcinogenic fuel. The most efficient catalyst was obtained by treating the carbide with air for 14 h at 350 °C. This resulted in the formation of an oxycarbide layer on the catalyst surface. According to the results of XPES, the major part of the molybdenum exists in the Mo(VI) state on the surface of this catalyst (in contrast to Mo₂C). X-Ray studies showed that its structure corresponds to that of MoO₃, but the oxygen vacancies □_O on the surface are filled with carbon atoms that block the formation of MoO₂.¹⁹⁵

Such an oxycarbide possesses not only good selectivity, but also high activity and resistance to coking. It is 25 times as active as the Pt/Al₂O₃ catalyst but, unlike the latter, is little poisoned with the coke and retains its catalytic activity for a long time. The addition of methylcyclopentane to n-heptane results in slow deactivation of the catalyst due to blocking of active centres by the alkenes formed, which are readily hydrogenated. Moderate heating of the catalyst in an oxygen atmosphere is sufficient for its regeneration.²³³

High catalytic activity in the hydrogenation of isopropylbenzene is exhibited by molybdenum oxynitride. In this reaction its activity is increased due to carbidisation:²³⁴ MoN_{0.7}O_{0.7} is transformed into MoC_{0.27}N_{0.14}O_{0.76}.

VII. Mechanochemical treatment of hydrogenation catalysts

In most cases, mechanochemical treatment of solids leads to their fragmentation and the appearance of various defects. Many investigators have used mechanochemical techniques for the treatment of catalysts, since the catalytic activity usually (though not always) increases with the surface area and the number of defects. It is important that the changes obtained are preserved under catalysis conditions.

Moroz *et al.*²³⁵ studied the formation of defects in the mechanochemical treatment of a typical ZnO catalyst in a planetary centrifuge mill using stainless steel balls 0.5 cm in diameter. Electron microscopy and X-ray data showed that short mechanochemical impacts ($\tau < 180$ s) produce insignificant changes in the structure and size of the particles. At $180 \text{ s} < \tau < 600 \text{ s}$, one observes cracking of crystalline blocks, their mutual displacement, and rotation, relaxation of microdistortions in the direction (001) and their growth in other directions. At $600 \text{ s} < \tau < 1200 \text{ s}$ the crystals begin to undergo disintegration into primary crystalline blocks 5–10 nm in size with the formation of secondary aggregates of globular shape 1000 nm in size along with relaxation of microdistortions arising as a result of crystal breakdown. Thus, the general picture is not reduced to a mere increase in the catalyst surface and defectiveness of its lattice.

Streletskii *et al.*²³⁶ investigated the mechanism of changes induced by mechanical treatment of complex oxides with the perovskite structure. Powders of BaTiO₃ and SrTiO₃ were subjected to mechanical treatment in an eccentric mill with calorimetric measurement of the absorbed energy dose.²³⁷ The increase in the absorbed energy dose led to an increase in the specific surface from 7–8 to 25 m² g^{−1}, a decrease in the coherent scattering range (CSR) from 150 to 20 nm, and to the appearance of microdistortions and point defects (paramagnetic centres with a concentration up to 10¹⁸ g^{−1}). Each particle of the powder was shown to consist of several CSR blocks, the overall area of CSR being $\sim 60 \text{ m}^2 \text{ g}^{-1}$. Only a small fraction of the mechanochemical energy is spent in generating the defects preserved after the completion of mechanical treatment. The temperature of sintering of particles after mechanical treatment decreases by 300 °C. When such a treatment is performed in water, the CSR size corresponds to the particle size, while microdistortions are insignificant.

The mechanism underlying the mechanochemical transformations depends on the chemical and electronic properties of solids.²³⁸ In covalent dielectrics, *e.g.* in SiO₂, the defects after mechanical treatment are better preserved than in semiconducting metals. The application of mechanochemical techniques in the synthesis of catalysts can result not only in the formation of defects and an increased surface, but also in various chemical effects. In such a way one can prepare, for example, FeAl or FeW alloys, which cannot be formed in the usual processes because of the low mobility of the atoms, and even amorphous alloys. Recourse to mechanochemical treatment is often made in the synthesis of complex oxide systems from oxide mixtures, where the conventional thermal synthesis requires very high temperatures, which are difficult to achieve. Mechanochemical decomposition of salts and hydroxides may be used to prepare oxides with the preservation of the disordered state of their atomic structures.

There are some studies^{85,215} of the effect of mechanochemical treatment on the properties of catalysts in CO hydrogenation. We have already mentioned the formation of the two-phase oxide–carbide system in the catalyst based on α -Fe₂O₃ under the conditions of CO hydrogenation. A catalyst prepared from α -Fe₂O₃ after its treatment at high pressure with shearing on the Bridgman anvil was also studied. Such a mechanochemical treatment is known to form a great number of defects. The impact of the reaction medium on the ‘defective’ specimen is manifested

earlier than on the 'defect-free' one. In the first stage, the defective $\alpha\text{-Fe}_2\text{O}_3$ is rapidly transformed into magnetite, however its catalytic activity is lower than that of the defect-free specimen. Electron microscopy of the defective specimen reveals individual oxide and carbide particles and a small number of intercalated particles. The particle size in this specimen is smaller than that in the defect-free specimen, but the extension of the carbide-oxide interface, which determines the catalytic activity, is also smaller.

The CO hydrogenation reaction was also used for an investigation of the activity of amorphous, highly dispersed Fe-Ni-O alloys prepared by friction between two rapidly rotating discs made of iron and nickel. By modifying the friction conditions, it was possible to prepare an alloy of $\text{Fe}_{20}\text{Ni}_{20}\text{O}_{60}$ composition on the surface of which clusters are formed with a predominantly ionic type of Fe-O bonds, and an $\text{Fe}_{30}\text{Ni}_{40}\text{O}_{30}$ alloy in which, according to XPES and Auger spectroscopy, clusters with covalent-type of Fe-O bonds are prevalent. The former alloy is catalytically active in the CO hydrogenation to CH_4 and $\text{C}_2\text{-C}_4$ hydrocarbons, while the latter proved to be inactive. Under catalysis conditions a non-stoichiometric oxide $\text{Fe}_3\text{O}_{4-x}$, carbide FeC_y and metallic nickel are formed on the former alloy. The surface of the latter alloy is covered by a nonreactive oxide FeO_x , while in its bulk the spinel NiFe_2O_4 and a solid solution of iron in nickel are formed.

The formation of active centres of CO hydrogenation is crucially influenced by the type of chemical bonding. Iron carbide and oxide phases exist on the surface of active catalysts, while metallic iron does not take part in the active centre formation. In a binary alloy catalyst, iron is mostly in the oxidised state, while nickel is predominantly in the metallic state. The activation of H_2 seems to take place on Ni, whereas the CO activation occurs on Fe^{n+} .

The Fischer-Tropsch synthesis was brought about directly in a mechanochemical reactor by grinding the metal mixtures.²³⁹ Grinding allows formation of amorphous alloys $\text{Ni}_{40}\text{Zr}_{60}$, $\text{Ni}_{60}\text{Zr}_{40}$, $\text{Pd}_{30}\text{Zr}_{70}$, $\text{M}_{30}\text{Ti}_{70}$ ($\text{M} = \text{Fe}, \text{Co}, \text{Cu}$), $\text{M}_{30}\text{Ti}_{70}$ ($\text{M} = \text{Ni}, \text{Pd}$), which catalyse the CO hydrogenation. The alloy $\text{Ni}_{30}\text{Ti}_{70}$ manifests 100% selectivity. Detailed studies of structural changes in Ni-Zr alloys in the course of CO hydrogenation showed that prolonged grinding results in the formation of ZrO , ZrO_2 , Ni, and possibly ZrH_2 and ZrC phases. Zirconium oxides are formed due to CO dissociation on the segregated nickel. Hydrogenation of CO was also studied under the conditions of mechanochemical treatment of Ti, V and Zr hydrides. In contrast with the reaction on amorphous titanium and zirconium alloys, the formation of hydrocarbons on the above-mentioned hydrides proceeds without any induction period. The CO conversion reaches a stationary level and begins to decrease, when the hydrogen content in the metal becomes insufficient for the maintenance of the reaction stoichiometry.

Analogous work was done by Morozova *et al.*^{240, 241} Powders of an amorphous alloy ZrNi_{1-x} were treated in a vibrational mechanochemical reactor consisting of a cylindrical steel chamber filled with steel balls 6–7 mm in diameter.²⁴² The amorphous alloy was prepared in the same reactor by mechanochemical fusion of Ni and Zr. Experiments were carried out in the static and flow modes; in the first case, the products were analysed by mass spectrometry, while in the second case, by gas chromatography.

Under conditions of mechanochemical treatment, sorption of hydrogen rapidly increased with the dose of absorbed energy and reached a maximum. The quantity of sorbed hydrogen was approximately proportional to the zirconium content in the alloy. X-Ray phase analysis indicated that the reaction of hydrogen with zirconium and ZrNi yields ZrH_2 and $\alpha\text{-ZrNiH}_2$, respectively. After the termination of mechanochemical treatment, sorption of H_2 continued at a decreasing rate until a stoichiometric hydride was formed.

Under these conditions, chemisorption of CO increased proportionally to the absorbed energy and Zr content. It follows a dissociative mechanism and is accompanied by oxidation of Zr

In addition, reversible sorption of CO occurs, which corresponds to the nickel content. At large doses of absorbed energy, zirconium oxycarbides are decomposed

After saturation of the alloy with hydrogen, *i.e.*, after formation of ZrH_2 and ZrNiH_2 , methane, some ethane and hydrogen are formed under the conditions of mechanochemical treatment in a CO flow:

After termination of mechanochemical treatment, the formation of methane continues at a decreasing rate. Such treatment may be conducted in the flow of a CO + H_2 mixture. In this case, the rate of methane formation is 5–10 times lower than that in the stepwise process (in the hydrogenation of CO with dissolved hydrogen) under the same conditions.

In the mechanochemical treatment of a NiZr alloy, graphite also undergoes hydrogenation with formation of methane (and ethane at a high dose)

Thus, in the process of mechanochemical treatment the dissolved hydrogen acquires mobility indispensable for the realisation of reactions both on the surface and in the bulk of a powder. Interestingly, nickel, which is a typical hydrogenation catalyst, is a ballast in this case, while hydrogen is activated with participation of zirconium. In addition to the inertial process of CO hydrogenation, an inertia-free mechanochemical process leading to the formation of short-lived intermediate compounds takes place on the surface.

VIII. Sulfide catalysts for hydrotreating

1. Preparation of oxide precursors

In the first sections of this review mention was made of the use of Ni-Mo, Ni-W, Co-Mo and Co-W oxide catalysts for the hydrogenation of unsaturated compounds, especially for hydrotreating. However, industrial processes rely most widely on the application of sulfide hydrotreating catalysts prepared from oxide precursors.

The major components of sulfide catalysts for hydrotreating (hydrodesulfurisation, hydrodenitration, hydrodemetalation, hydrogenation of oxygenated and aromatic compounds in petroleum) are as a rule Co (or Ni) and Mo (or W). Nickel is cheaper than cobalt and ensures a higher hydrogenation rate but it favours rehydrogenation, which results in an increased hydrogen uptake and a lower octane number of the products. Tungsten is similar to molybdenum in its catalytic properties, but it is more expensive.

High activity is displayed by ruthenium, but this metal is very costly. The $\text{NiRu}/\text{Al}_2\text{O}_3$ catalyst is 30 times more active than $\text{RuS}/\text{Al}_2\text{O}_3$ in hydrogenation processes.²⁴³

A great number of studies (see, *e.g.*, reviews^{5, 244, 245}) are devoted to the preparation of hydrotreating catalysts, their formation under conditions of catalysis and the mechanisms underlying the relevant reactions. The common practice is to use catalysts deposited on $\gamma\text{-Al}_2\text{O}_3$ or carbon. Catalysts on $\eta\text{-Al}_2\text{O}_3$ are more active than those on $\gamma\text{-Al}_2\text{O}_3$, which is explained by the stronger bonding of MoO_3 with $\eta\text{-Al}_2\text{O}_3$ and easier subsequent sulfidisation.²⁴⁶

Ammonium molybdate $(\text{NH}_4)_2\text{MoO}_4$ is a precursor of MoO_3 . In acidic media, polymolybdates are formed

At high levels of ammonium molybdate, further condensation takes place

At $\text{pH} > 7$, polymolybdates dissociate to recover MoO_4^{2-} . These acid-base processes involve the surface of Al_2O_3 , which is amphoteric in its chemical nature

In order to form polymolybdates in the preparation of catalysts by the impregnation procedure, it is necessary that the pH be kept below the isoelectric point of a given support (3–6 for Al_2O_3 and below 2 for SiO_2). After impregnation, the catalyst is dried at 250–300 °C and calcined in air at 500–550 °C; the dispersity of MoO_3 changes insignificantly. The use of various physical methods (Raman and IR spectroscopy, EXAFS, and others) showed that at typical MoO_3 concentrations (10%–12%) the initial molybdates form Al–O–Mo bonds with Al_2O_3 and represent two-monolayer-thick islets containing seven molybdenum atoms.²⁴⁴

Supports may be impregnated with HPC solutions, *e.g.*, with nickel or cobalt heteropolymolybdates.²⁴⁷ In this case, however, because of the strong interaction of HPC with the OH groups of Al_2O_3 the precursor does not penetrate into the pores, and a ‘crusty’, rather than regular distribution, of the active component over the support takes place. Thioheteroanions are also used for the preparation of such catalysts.²⁴⁸

Another method for the preparation of the Mo–Al–O catalysts is the mechanical mixing of MoO_3 and Al_2O_3 at 400–500 °C in the presence of water. The system thus formed possesses virtually the same catalytic properties as an $\text{MoO}_3/\text{Al}_2\text{O}_3$ contact obtained by impregnation.²⁴⁴

A very large specific surface (174–184 m² g^{−1}) is characteristic of a catalyst prepared by precipitation of MoO_3 on SiO_2 in a solution of nitric acid with a mixture of urea and thioacetamide and with subsequent drying at 120 °C and sulfidisation at 400 °C.²⁴⁹

The second component (‘promoter’) is introduced by impregnating the support with cobalt or nickel nitrates; the sequence of impregnation steps may be different. It is assumed²⁴⁴ that impregnation of the support first with molybdenum and then with cobalt salts favours higher activity. There is an opposite viewpoint however, according to which it is more advantageous to impregnate the support first with cobalt salts or to bring about simultaneous impregnation with Co- and Mo-containing compounds. When Co^{2+} or Ni^{2+} are introduced by ion exchange, it is recommended to do it at low pH after deposition of molybdenum.

A two-stage method for the preparation of a catalyst includes impregnation of $\gamma\text{-Al}_2\text{O}_3$ in the fluidised bed with $(\text{NH}_4)_2\text{Mo}_7\text{O}_{24}$ solution at constant pH = 7, calcination in air at 500 °C, then impregnation with nickel or cobalt nitrates until the pores are filled, and further calcination at 500 °C.²⁵⁰

Active hydrogenation catalysts are prepared using thiosalts, *e.g.*, by impregnating a support with a mixture of $(\text{NH}_4)_2\text{MoS}_4$ and $\text{Ni}(\text{NO}_3)_2$ or $\text{Co}(\text{NO}_3)_2$ and subsequent heating in a mixture of H_2S and H_2 at 400 °C.²⁵¹

Unsupported Co–Mo–S catalysts are obtained by treating MoO_3 and Co_3O_4 powders with a hot solution of $(\text{NH}_4)_2\text{S}$ or by mixing solutions of $\text{Co}(\text{NO}_3)_2$ and $(\text{NH}_4)_2\text{Mo}_7\text{O}_{24}$ followed by addition of $(\text{NH}_4)_2\text{S}$, drying and calcination. In the latter case, the catalyst contains larger quantity of labile sulfur and is characterised by a higher dispersity of the Co_9S_8 phase and activity, though it is deactivated more rapidly.^{252, 253}

Lewis *et al.*²⁵⁴ assume that the catalyst activity depends on the acidity of the support. This is rationalised by the presence of surface OH groups capable of interaction with molybdenum and cobalt salts.

Catalysts are calcined at 400–600 °C, at which temperature the salts are completely decomposed but undesired solid-phase reactions have not yet occurred. According to results obtained by different physical methods,²⁴⁴ an amorphous MoO_3 phase and anions of the $(\text{Mo}_7\text{O}_{24})^{6-}$ type appear on the surface of Al_2O_3 after calcination of Mo–Al catalysts.

Calcination of mixed catalysts leads to the formation of polymolybdates, MoO_3 , CoMoO_4 or NiMoO_4 , Co_3O_4 , or NiO , $\text{Al}_2(\text{MoO}_4)_3$, $\text{Ni}(\text{Al}_x\text{MoO}_{4+1.5x})$ ($x = 0.1–1.0$) and Co or Ni aluminates.^{244, 255–258} At low calcination temperatures, the cobalt is mostly in the octahedral coordination. It is with the content of this Co form that the catalyst activity after its sulfidisation correlates. At higher temperatures, intercalation into the Al_2O_3 lattice results in the formation of tetrahedral cobalt, which undergoes sulfidisation with more difficulty. Therefore, calcination at temperatures above 600 °C is not reasonable.

Upon calcination, the nickel acquires octahedral coordination and interacts more strongly than cobalt with the Al_2O_3 lattice. Chukin *et al.*²⁵⁹ believe that the formation of nickel or cobalt molybdates or polymolybdates, which can be removed by extraction with water, is beneficial for the subsequent sulfidisation or formation of a mixed NiMo or CoMo phase. The introduction of NiMoO_4 prepared beforehand into the Ni–Mo–Al matrix makes it possible to enhance the catalyst activity.

The content of the active component depends on the specific surface of the support. Usually, from 8 mass % to 15 mass % of molybdenum can be deposited on Al_2O_3 , which corresponds to a specific Al_2O_3 surface of $\sim 250 \text{ m}^2 \text{ g}^{-1}$. The Co : Mo ratio varies from 0.1 to 1.0. The ratio of molybdenum to cobalt or molybdenum to nickel depends on the sequence of impregnation steps and is equal to 2 in the best catalysts.

Active catalysts may be produced by decomposition of cobalt and molybdenum carbonyls on supports.^{260, 261}

The maximum effect of promotion of $\text{CoMo}/\gamma\text{-Al}_2\text{O}_3$ catalyst with WO_3 is attained at $\text{W} : (\text{W} + \text{Mo}) = 0.25$. Impregnation of the support first with a tungsten salt solution and then with a cobalt salt solution yields more active catalysts than those resulting from the reverse impregnation order. According to the results of EPR and XPS studies, tungsten favours the alteration of the molybdenum coordination from octahedral to tetrahedral and facilitates its reduction.²⁶²

2. Sulfidisation of oxides

Sulfidisation of $\text{Mo}/\text{Al}_2\text{O}_3$ catalysts at low temperatures leads to the substitution of the oxygen atoms by sulfur

and formation of the bridging bonds $\text{Al}-\text{O}-\text{Mo}-\text{SH}$ or $\text{Al}-\text{O}-\text{Mo} \begin{smallmatrix} \text{S} \\ \diagup \diagdown \end{smallmatrix}$ (Ref. 263).

Each of the species thus formed contains seven Mo atoms. Prolonged sulfidisation at 300 °C leads to the reduction of Mo^{6+} to Mo^{4+} and formation, as follows from electron microscopy data,^{244 264, 265} of planar hexagonal MoS_2 particles below 3 nm in size that are retained on the surface by the Mo–O–Al bonds and mostly situated normally to the Al_2O_3 surface. Sulfur-containing Co–Ni heteropolymolybdates are formed in the incomplete sulfidisation.²⁶⁶

At the optimum sulfidisation temperature (400 °C), the Mo–O–Al bonds are cleaved, and the distribution of the MoS_2 particles occurs parallel to the support surface; they are enlarged, the ratio of the basal to lateral planes of particles remaining constant. However, there is no oriented growth (epitaxy) of the MoS_2 particles on Al_2O_3 ; they are linked to each other by physical forces. The smaller the mean sizes of MoS_2 and WS_2 particles the more active the catalyst in the hydrodesulfurisation processes.²⁵⁷ Higher catalyst activity appears to be reached with the incomplete sulfidisation of MoO_3 .²⁶⁷ Complete transformation of the oxygen-containing surface phase into MoS_2 occurs only at 970 °C,

though at such a high temperature the MoS₂ phase is sintered.^{268, 269}

Apparently the nature of the support does not strongly affect the final form of molybdenum and tungsten oxides and sulfides. In most cases, Mo/C proves to be more active than Mo/Al₂O₃.²⁷⁰ Isolated molybdenum ions or highly dispersed MoO₃ particles were detected on a molybdenum catalyst deposited on activated carbon. These species are sulfidised more rapidly on carbon than on Al₂O₃: at 400 °C the sulfidisation is already completed. After the sulfidisation, MoS₂ forms plates on Al₂O₃ and three-dimensional particles on carbon. This is explained by a stronger interaction of its oxide precursor with the Al₂O₃ surface than with carbon. The catalytic activity of MoS₂ is higher on carbon than on alumina.^{271, 272}

Pratt *et al.*²⁷³ observed a somewhat different orientation of MoS₂ particles on supports: plates were found on Al₂O₃ and SiO₂ oriented normally to their surface, while on TiO₂ and ZrO₂, particles were coplanar. The latter displayed higher catalytic activity.

Treatment of a MoO₃–SiO₂ system with a H₂S + H₂ mixture at room temperature leads to the formation of MoO_xS_y. At 150 °C MoS₃ particles appear, while at 250–270 °C the MoS₂ phase is formed.²⁷⁴ Electron microscopy data showed that in a Co–Mo–S/Al₂O₃ system, MoS₂ particles are formed, and their size is increased from 1 to 1.5 nm at the sulfidisation temperature.²⁷⁵ These particles are linked to form chains. At high cobalt content, the Co₉S₈ phase is formed.²⁷⁶ In Ni–Mo–S and Ni–W–S catalysts, the phase NiS was also observed along with mixed phases.²⁷⁷

According to NMR and EXAFS data, the major active phase of a molybdenum sulfide catalyst consists of MoS₂ plates with Mo coordination number 4 or 5 and with the Co atoms at their edges.²⁴⁴ The formation of a continuous MoS₂ phase, *e.g.*, after long operation of the catalyst, leads to its deactivation. Analogous phases formed on SiO₂ or carbon are less strongly bound to these supports than to Al₂O₃.

To model sulfide hydrotreating catalysts, several layers of sulfur were applied onto the Mo(110) plane with subsequent spraying of Zn or Co.²⁷² Zinc and cobalt were found to accelerate the sulfidisation of molybdenum. The hydrodesulfurisation activity of catalysts was observed to correlate with the ease of molybdenum sulfidisation. The Mo atoms become coordinatively unsaturated in the presence of zinc or cobalt.

3. The role of different phases in sulfide catalysts

To elucidate the role of different phases in the active surface formation, the following models of sulfide catalysts may be considered.⁵

1. A structural model of a Co–Mo/Al₂O₃ catalyst implies the formation of a molybdenum monolayer on the surface of alumina.²⁷⁸ According to this model, molybdenum is bound to the Al₂O₃ surface through the OH groups, whereas Co²⁺ ions replace Al³⁺ ions in the surface layer. Due to its large size, the S^{2–} ion replaces two O^{2–} ions.

2. In the initial version of the intercalation model the cobalt (nickel) ions were supposed to intercalate between the layers of the MoS₂ (WS₂) structure.²⁷⁹ Later, it was found that intercalation inside the lattice is impossible, and the model has been modified. Now it is assumed that Co ions are intercalated near the sulfide surface:

The promoter atoms interact with MoS₂.²⁸⁰

3. According to the model of contact synergism,^{257, 281} hydrogen is activated on the Co₉S₈ or NiS phases, while the compound subject to hydrogenation is activated, on the MoS₂ phase. Hydrogen spillover takes place between these phases. A later modification of the model assumes hydrogen spillover between the CoS₂ and CoMoS phases.²⁸²

In recent times, the prevalent view is that the sulfide phases Co₉S₈ and NiS apparently play no special role in the hydrotreating processes.^{5, 283–296} The application of different physical methods (EXAFS, NMR, XPD, and others) revealed a kind of a ‘Co–Mo–S phase’ in which the Co atoms are localised on lateral facets or edges of MoS₂ microplates. According to EXAFS data, the coordination number of Co is 4 or 5. The catalyst MoS₂/Al₂O₃ undergoes no deactivation after its sulfidisation. It is the distribution of Co atoms at the edges of the MoS₂ particles that determines the optimum ratio between Co and Mo. At high Co contents all its atoms cannot be placed at the edges of the MoS₂ particles.

Mössbauer spectroscopy showed²⁴⁵ that the sulfidisation of CoMo/Al₂O₃ and CoMo/C leads to the formation of the same particles as in the Co/Al₂O₃ and Co/C systems, respectively. This casts doubts on the concept of the ‘Co–Mo–S phase’ and makes one suspect that the MoS₂ phase is merely a diluent. However, it is believed that the systems CoMoS/C and CoMoS/Al₂O₃ differ. The Co/C catalyst is only three times less active than CoMoS/C, whereas Co/Al₂O₃ and CoMoS/Al₂O₃ exhibit much larger differences.

According to Chianelli *et al.*,²⁴⁵ in the Co–Mo–S system the Co atoms are situated at the edges of the MoS₂ crystallites. The Co₉S₈ phase is also present; however, its function is reduced not to hydrogen spillover, but rather to the role of an additional support for the Co–Mo–S phase.

By analogy with the ‘Co–Mo–S phase’, the ‘Ni–Mo–S phase’ is also supposed to exist.^{255, 256} The nickel-modified sulfide (MoS₂) adsorbs three times as much hydrogen as the pure MoS₂.²⁹⁷ The excess phase Ni₃S₂ can be removed from the Ni–Mo catalyst by dissolution, and this does not affect its catalytic activity.²⁹⁸

Ekman *et al.*²⁹⁹ synthesised catalysts based on the so-called Chevrel phases (M₃Mo₆Z₈, where Z = S, Se or Te and M is a transition metal). In these phases, the transition metal cations may be localised not at the edges but inside the sulfide phase. Such systems differ from the usual mixed sulfide catalysts.

The results of ⁵⁹Co NMR suggested^{287, 300} that the high activity of a Co–Mo–S system is associated with the presence of Co atoms with perturbed tetrahedral environments. In this system, octahedral cobalt is also present but the catalytic activity correlates only with the concentration of the tetrahedral cobalt. The active centre is assumed to have the following structure:

Electron exchange stabilises the structure Co_{tetr}–S–Co_{oct}–S–Mo–S.

The appearance of the NiWO₄ phase in the Ni–W–Al catalysts upon calcination of an NiO + WO₃ mixture decreases the efficiency of subsequent reduction and sulfidisation. This results in the formation of an unordered WS₂ phase and of Ni²⁺ and Ni³⁺ ions rather than an NiS phase.^{301, 302} The higher activity of an Ni–W/C catalyst than that of Ni–W/Al₂O₃ is supposed³⁰³

to be due to the fact that the active nickel in the former is linked to six sulfur atoms. The major advantage of the use of carbon as the support apparently lies in the fact that, in contrast to Al_2O_3 , it has no acidic properties and does not undergo coking.³⁰⁴

The role of cobalt (nickel) in a mixed catalyst may be dual. Presumably, cobalt (or nickel) favours the reduction of MoO_3 ³⁰⁵ or WO_3 .³⁰⁶ According to the opposite viewpoint,³⁰⁷ Ni^{3+} incorporated into the MoO_3 layer decreases its susceptibility to reduction. It is also believed^{268, 285, 299, 308, 309} that cobalt stabilises the dispersed MoS_2 microparticles preventing them from sintering. Some investigators^{283, 286, 300, 301} presume that Co does not increase the MoS_2 dispersity, but participates instead in the hydrogen activation. There are also reports^{310–312} that cobalt accelerates the sulfidation of MoO_3 and suppresses deactivation of catalysts after sulfidation.^{287, 313}

In the $\text{CoMoS}/\text{Al}_2\text{O}_3$ system, sulfur is hydrogenated at a lower temperature than in the $\text{CoS}/\text{Al}_2\text{O}_3$ or $\text{MoS}_2/\text{Al}_2\text{O}_3$ systems. The ease of sulfur hydrogenation correlates with the catalytic activity.³¹⁴ A higher rate of sulfur hydrogenation within MoS_2 was also observed when Co, Ni or Fe were deposited on a MoS_2 plate.³¹⁵

The presence of Ni in a Ni–Mo hydrodesulfurisation catalyst promotes the reduction of MoO_3 to MoO_2 and partly to Mo .³⁰⁸ Thus, nickel can act as a catalyst for MoO_3 reduction. Cobalt also accelerates the reduction of Mo(VI) to Mo(IV) and even to Mo(III) .^{316, 317} In this case, some vacancies appear in the sulfide layer.

4. The hydrodesulfurisation mechanism

The most popular hydrodesulfurisation mechanism includes the formation of anion vacancies in the sulfide layer and their subsequent filling with sulfur from a sulfur-containing compound, e.g., thiophene.^{244, 278, 318, 319} The thiophene molecules are adsorbed normal to the surface. The vacancies may either be initially present in the MoS_2 phase, most probably at the edges of the microplates, or be formed in the course of sulfide reduction with hydrogen

Low-valent forms of molybdenum were in fact revealed by IR spectroscopy and EPR. The use of these techniques also provided evidence of S–H group formation under catalysis conditions, while XPS revealed low-valent sulfur in the form of S^- or $(\text{S}-\text{S})^{2-}$.^{316, 320, 321} The disulfide groups, possibly localised at the MoS_2 edges, may take part in the hydrogen activation.

Hydrogen forms in sulfide catalysts were studied by IR spectroscopy and neutron diffraction.³²² No bands corresponding to vibrations of the Co–H and Mo–H bonds were found after the adsorption of H_2 in the systems $\text{CoMo}_{1.3}\text{S}_{1.6}$, MoS_2 and Co_9S_8 , but S–H vibrations bands were observed. This led to the conclusion that in the course of H_2 adsorption processes of the type

do not occur, giving way to the reaction

or

The Co (Ni) atoms may be directly involved in the formation of active centres or neighbours with the vacancy at the peripheral molybdenum atom. The number of cobalt atoms in the catalyst was observed to correlate with the number of peripheral molybdenum atoms. According to EXAFS,^{323, 324} the vacancies are formed near the cobalt atoms. This was confirmed in particular by experiments on the adsorption of selenophene (a thiophene

analogue).³²⁵ The vacancies available in the $\text{Co}_x\text{Mo}_{1-x}\text{S}_{2\pm\delta}$ phase are involved in the following reactions:

According to the results of TPR,³²⁶ sulfur is more weakly bound in the Co–Mo–S system than in Co_9S_8 or MoS_2 : the H_2S peak is observed at a lower temperature. However, an investigation of the isotope exchange of labelled hydrogen sulfide H_2^{35}S with the $\text{NiS}/\text{Al}_2\text{O}_3$, $\text{MoS}_2/\text{Al}_2\text{O}_3$, and $\text{NiMoS}/\text{Al}_2\text{O}_3$ catalysts unexpectedly showed that the exchange rate on $\text{NiMoS}/\text{Al}_2\text{O}_3$ was lower than on $\text{MoS}_2/\text{Al}_2\text{O}_3$, which in turn was lower than on $\text{NiS}/\text{Al}_2\text{O}_3$.³²⁷ This surprising finding was explained by the participation of sulfur atoms bound to both molybdenum and nickel in the reaction. The results reported by Topsøe *et al.*³²⁶ may also be explained by the associative mechanism of this reaction without participation of vacancies.

Experiments with ^{35}S showed that the loss of sulfur from the catalyst as a result of its interaction with hydrogen can be compensated for at the expense of thiophene sulfur.³¹⁸ The quantity of mobile sulfur and the catalytic activity increase in the presence of promoters (Co, Ni).

According to Markel *et al.*,^{328, 329} dihydrothiophene is formed as an intermediate in the reaction of thiophene hydrodesulfurisation

The idea of an associative mechanism underlying the hydrogenolysis of thiophene without participation of the sulfide layer vacancies was also put forward by Startsev,³²³ who assumed that thiophene is adsorbed on the Co(Ni)–Mo–S catalyst in the coordination sphere of cobalt, while dissociative adsorption of H_2 takes place at the terminal sulfur atoms flanking the electroneutral macromolecule MoS_2 . This viewpoint stands in need of more conclusive evidence.

Different opinions exist as to the nature of the active centres in the hydrogenation of various organic compounds. According to the most popular concepts, the role of the active centres in the hydrodesulfurisation is played by the molybdenum or cobalt atoms on the lateral facets of MoS_2 .⁵ The activity of hydrodesulfurisation catalysts was found to be proportional to the number of centres on the lateral facets of MoS_2 determined by the EXAFS method *in situ*.³²⁶ There is a relationship between the activity of catalysts and the concentration of Mo^{5+} in them (according to EPR data).³³⁰ The activity of WS_2 in the hydrogenation of benzene correlates with the concentration of $\square_{\text{s}}$ vacancies on the lateral sulfide facets measured by EPR.²⁷⁵

The mechanism of thiophene hydrodesulfurisation on the Co–Mo/ Al_2O_3 catalyst was investigated using the TPD and TPR techniques and D–H isotope exchange.^{331–335} The TPR and TPD spectra of thiophene, dihydrothiophene, and butane-thiol were found to be very similar on $\text{Mo}/\text{Al}_2\text{O}_3$ and Co–Mo/ Al_2O_3 , but somewhat shifted towards lower concentrations on the Co-containing catalyst. At the same time, the shape of the spectra on Co/ Al_2O_3 was completely different and most of the products formed in the first two systems under TPR conditions were not

produced in the latter case, whereas hydrogen was desorbed at a lower temperature. These results confirm the traditional viewpoint, according to which thiophene is adsorbed on the anionic vacancies of MoS₂, while hydrogen is activated on cobalt. We cannot say whether the Co and Mo centres are situated in different phases or in different crystallographic positions of the same phase, though they do not appear to be spatially separated. In any event, no results have been reported to disprove this viewpoint.

Desorption of thiophene at low temperatures characteristic of all catalysts is most likely to occur from the weakly bound π -adsorbed state. The high-temperature desorption of thiophene characteristic of Mo/Al₂O₃ and Co/Al₂O₃ catalysts seems to be related to the dehydrogenated forms. In such cases, strong retention of molecules by the surface is ensured by both the bonding of the sulfur atom and the σ -bonds (possibly several) of carbon atoms in the ring. When there is a surface hydrogen shortage the limiting stage of the thiophene desorption may be the interaction of such surface complexes with the hydrogen atoms.

To bring about desulfurisation, it is necessary to activate the adsorbed molecule of the S-containing compound. This first requires the formation of sufficiently strong bonding of the sulfur atom with the surface and, second, surrounding of the reacting sulfur-containing molecule with hydrogen atoms situated in the immediate proximity. Under TPR conditions, such a complex may be formed with the participation of migrating hydrogen according to the mechanism of reverse spillover from the support.

The coincidence of kinetic parameters for the formation of C₄ hydrocarbons from thiophene and tetrahydrothiophene indicates that the hydrodesulfurisation of these compounds on Mo and Co–Mo catalysts proceeds *via* the same intermediates, probably dihydrothiophenes.

Markedly easier desulfurisation of thiols than of thiophene and tetrahydrothiophene may suggest that the cleavage of the second C–S bond in the surface intermediates is not the limiting stage of the entire hydrodesulfurisation process.

In contrast with the desulfurisation of tetrahydrothiophene and thiophene, butadiene is absent from the products of butanethiol desulfuration, which indicates that the surface butanethiolate cannot be an intermediate compound in the hydrodesulfurisation of thiophene and tetrahydrothiophene, at least under low hydrogen pressure in the gaseous phase.

Rozanov *et al.*³³⁴ proposed the following generalised scheme for the desulfurisation mechanism:

According to this scheme, thiophene and tetrahydrothiophene can be interconverted *via* dihydrothiophene as the intermediate compound. Depending on the hydrogen pressure and the reaction temperature, equilibrium may be shifted towards thiophene or tetrahydrothiophene. Butene may be formed from the intermediate dihydrothiophene as a result of two-stage hydrogenolysis of α -C with concomitant cleavage of the C–S bond, while butadiene may result from β -elimination in the first stage and α -hydrogenolysis in the second stage. Presumably, hydrogenation–dehydrogenation reactions occur on one type of centres, while hydrodesulfurisation occurs on another type of centre. The limiting stage of the whole process is the cleavage of the C–S bond.

This conclusion was drawn from studies on the hydrodesulfurisation of thiophene on Rh₂S₃, Co/C, and Mo/C catalysts.³³⁶ It can be mentioned that the limiting stage of the reaction on Co–Mo/C is hydrogenation, which determines the low selectivity of formation of hydrogenation products in this case.

Some investigators believe that hydrodesulfurisation and hydrogenation take place on the same active centres,³³⁷ while others think that these centres are different.³³⁸ Hydrogenation of propylene requires molybdenum(IV), and hydrogenolysis of propane occurs on the more reduced Mo forms, up to its metallic state. On different supports, one may observe different orientations of MoS₂ and Co–Mo–S particles.³³⁹ When these particles are deposited on Al₂O₃, their activity in the hydrogenation is higher and that in the hydrocracking is lower than in their deposition on Al₂O₃·SiO₂, MgO·SiO₂ or MgO. The molybdenum- and cobalt-containing phases have no synergistic effect in the hydrodesulfurisation of thiophene, but they do manifest this effect in the hydrogenation of butenes and butadiene.³¹⁸ In contrast to Co–Mo–S, the Ni–W–S system accelerates hydrogenation of biphenyl more strongly than hydrodesulfurisation of dibenzothiophene.³⁴⁰ According to Topsøe *et al.*,⁵ the stronger deactivating effect of H₂S on Co–Mo–S catalysts in the hydrogenation of aromatic compounds than in the hydrogenation of alkenes is indicative of the difference between the active centres in these reactions.

In conclusion, it is noteworthy that the reactions of hydrogenation and hydrodesulfurisation on Co(Ni)–Mo(W) catalysts are the best studied catalytic processes, judging from the number of publications devoted to them. Nonetheless, the mechanism of these reactions has not been totally elucidated and remains the subject of numerous discussions. This also holds for the preparation of hydrotreating catalysts. Studies in which the reaction mechanism was investigated by physical methods *in situ* are virtually absent. Without an adequate understanding of the mechanism of the process, it is impossible to develop scientific grounds for the preparation of catalysts. To this end it is necessary to elucidate what component of the catalysts activates hydrogen and what component activates an organic compound, and how to distribute these components most effectively on supports.

IX. Conclusion

The aim of this review was to consider hydrogenation catalysts, including modified supported Ni catalysts, carbides, sulfides, and others that have been most actively studied in recent years.

Investigation into the mechanism of action of hydrogenation catalysts by physicochemical methods made it possible to reveal some of their common features. It was found that hydrogen and compounds subject to hydrogenation are, as a rule, activated on different active centres: the former, on metallic (or reduced) centres, the latter, on oxidised centres which are often formed by ions of the basal metal intercalated into supports or modifiers. Hydrogen transport between centres may be brought about by the spillover mechanism. Therefore, the role of support or modifier is often played by systems capable of accumulating hydrogen. The secondary structure of the support and catalyst (specific surface, dispersity, porosity) has a significant effect on the supply of hydrogen to the compound under hydrogenation, as well as on the thermostability and selectivity of catalytic systems.

Co-precipitated metal–oxide catalysts, complex oxides, skeletal catalysts, and hydrides of intermetallides, which are also actively studied nowadays, remained almost totally outside the scope of this review.

V. Prospects for the application of reactive oligonucleotides for directed <i>in vivo</i> modification of biopolymers	630

Abstract. Data on the synthesis of reactive derivatives of nucleic acid analogues and their application for the study of structure and functions of biopolymers are generalised. The main types of such analogues including photoactivated reagents containing azido-aryl, halogeno, and thiol groups, psoralen and its derivatives, platinum-based reagents, and nucleic acid analogues containing substituted pyrophosphate or acyl phosphate internucleotide groups are presented. The mechanisms of interaction of these compounds with proteins and nucleic acids are considered. The prospects for the *in vivo* application of reactive nucleic acids in various systems are discussed. The bibliography includes 76 references.

I. Introduction

Synthetic fragments of nucleic acids containing modified units are widely employed in solving practical problems of molecular biology, biotechnology, and medicine. Derivatives of nucleic acids containing reactive groups are of special interest. These compounds can form covalent bonds with the reactive groups of biopolymers and are promising tools for the study of the topography of active centres of proteins, their functional features, and molecular mechanisms of DNA–protein recognition. The interest in these compounds has been considerably increased in recent years owing to the development of sense biotechnology. The main attention is concentrated on the search for new active groups and elaboration of methods for their directed introduction into nucleic acids.

This review describes the main types of reactive analogues of nucleic acids, *viz.*, photoactivated reagents, platinum-based reagents, and new promising analogues of nucleic acids containing substituted pyrophosphate or acyl phosphate internucleotide groups. The use of reactive nucleic acids in the analysis of proteins and nucleic acids and prospects for their further application in various systems *in vivo* are surveyed. A large class of alkylating reagents first proposed by Grineva and Knorre in the late 60's is

beyond the scope of this review because this material has been considered rather comprehensively in recent reviews (see, *e.g.*, Refs 1, 2). For the same reason, reagents with redox mechanisms of action^{1,2} have been omitted from consideration.

II. Photoactivated nucleic acid analogues

In recent years, reactive nucleic acids containing photoactivated groups have gained wide acceptance as helpful tools for directed modification of proteins and nucleic acids and for the investigation of the structure and functions of these biopolymers. Normally, groups that are activated upon irradiation with light of wavelength > 300 nm are employed. This excludes the possibility of other photochemical transformations of the biopolymers themselves.

Among photoactivated compounds, nucleic acid analogues carrying azidoaryl, halogeno, or mercapto groups and various psoralen derivatives are the most popular.

1. Nucleic acid derivatives containing the azido group

Reactive azido derivatives of oligonucleotides include synthetic oligonucleotides that are modified at the sugar-phosphate backbone or at heterocyclic bases by reagents containing the azido group. Irradiation converts them into reactive intermediates (nitrenes), which can further react with reactive groups of proteins and nucleic acids.

a. Introduction of azidoaryl groups into nucleic acids

Azidoaryl groups are introduced into synthetic oligonucleotides either in the course of their synthesis with the use of modified nucleotide components³ or by postsynthetic modification of oligonucleotides by various aryl azide derivatives. The most popular reagents contain *p*-azidophenyl, 2-nitro-5-azidophenyl, and azidoperfluorophenyl groups,^{4,5} or azidoproflavin.⁶

Synthesis of azido derivatives of oligonucleotides makes use of the reactive groups inherent or incorporated into the oligonucleotides. The latter kind of groups involves aliphatic amino and thiol groups. Thus, an oligodeoxyribonucleotide azidoperfluorophenyl derivative **1** was obtained by acylation of the terminal amino group that had been introduced into the oligonucleotide using *p*-azidotetrafluorobenzoic acid *N*-hydroxysuccinimide ester **2**.⁵

I E Kanevskii, S A Kuznetsova Department of Chemistry, M V Lomonosov Moscow State University, Leninskie Gory, 119899 Moscow, Russian Federation. Fax (7-095) 939 31 81. Tel. (7-095) 939 31 53

Received 9 September 1997

Uspekhi Khimii 67 (7) 688–704 (1998); translated by R L Birnova

R is the oligodeoxyribonucleotide residue, $n = 2$ or 6 .

The azido derivative of *E. coli* tRNA^{Phe} **3** was obtained by acylation of the amino group of the phenylalanine residue that had been introduced into tRNA with *N*-(*p*-azidobenzoyl)glycine *N*-hydroxysuccinimide ester.⁷

A similar approach was used to introduce the azido group at the exocyclic amino group of cytidine. *p*-Azidobenzoic acid *N*-hydroxysuccinimide ester was used as the acylating reagent. This reaction gave the pentanucleotide azido derivative **4**.⁸

R — TAG

Various azido derivatives of the oligonucleotide d(UCCAATT) **5** were obtained by acylation of the amino group attached through a spacer to C(5) of the terminal deoxyuridine residue with *p*-azidotetrafluoro-, 5-azido-2-nitro-, or *p*-azidobenzoic acids *N*-hydroxysuccinimide esters.^{4,9}

R = d(CCACTT); X = CH₂, CH₂OCH₂CH₂, CH₂NHCOCH₂CH₂;

5-[3-(*p*-Azidobenzoyl)aminoprop-1-enyl]deoxyuridine 5'-triphosphate (**6**) was used to incorporate the azido group into the tRNA^{Tyr} SUP4 gene. This compound was obtained by the reaction of 5-(3-aminoprop-1-enyl)deoxyuridine 5'-triphosphate with *p*-azidobenzoic acid *N*-hydroxysuccinimide ester (DMF, pH 8.5, 20 °C, 3 h in the dark).¹⁰ This was followed by incorporation of compound **6** into DNA using DNA polymerase T4. The DNA thus modified was used for probing DNA–protein contacts

in a specific transcription complex comprising the modified DNA, RNA polymerase III, and several transcription factors.

Recently, a novel azido-containing reagent 4-[2-(*p*-azidobenzoyl)aminoethyl]deoxycytidine 5'-triphosphate (**7**) has been proposed for this purpose.¹¹ This compound was also obtained using azidobenzoic acid *N*-hydroxysuccinimide ester.

(a) H₂N(CH₂)₂NH₂, NaHSO₃; (b) , pH 8.5, 3 h, 20 °C.

The first step of this synthesis included the hydrogen sulfite-catalysed transamination of the amino group of deoxycytidine 5'-triphosphate with ethylenediamine and isolation of the reaction product by column chromatography. The reaction of 4-(2-aminoethyl)deoxycytidine 5'-triphosphate with a 10-fold excess of *p*-azidobenzoic acid *N*-hydroxysuccinimide ester was conducted at reduced illumination. The target product **7** was also isolated by column chromatography and analysed by TLC. Compound **7** was introduced into a specific region of the tRNA^{Tyr} SUP4 gene. The modified DNA was used for the probing of DNA–protein contacts in the transcription complex.

The reaction of 5-fluoro-2,4-dinitrophenylazide with the amino group of the ethylenediamine spacer attached at the terminal phosphate group of oligoribonucleotides gave photoactivated analogues of mRNA **8**, which represent oligoribonucleotide derivatives of various lengths having an arylazido group at the 5'-end of the oligoribonucleotide fragment.¹²

pN = pA, $n = 5$; pN = pU, $n = 4, 7$, and 8 .

The reagents **8** were used for affinity modification of the 5'-region of the mRNA-binding centre of the *E. coli* ribosome.

To study the localisation of the protein environment of DNA in chromatin, Kobets *et al.*¹³ have used a photoactivated derivative of hexadecathymidylate **9**, in which the *p*-azidoaniline residue was linked to the 5'-terminal phosphate group through a 1,4-butanediamine spacer.

Compound **9** was obtained by phosphorylation of 4-(*p*-azidoanilino)butylamine with the oligonucleotide *N*-methylimidazolid. Earlier, Godovikova *et al.*¹⁴ have studied the ability of amino acid residues to undergo modification by oligonucleotide derivatives in which the *p*-azidoaniline fragment was linked to the terminal phosphate group of the oligonucleotide directly rather than through a spacer. It was found that these reagents yield *p*-benzoquinonimide derivatives on irradiation and subsequent reaction with amino acids results in splitting of the reagent from the oligonucleotide. On the contrary, modification of proteins with reagents of the type **9** occurs specifically to give covalently bound nucleic acid–protein complexes.¹³

In addition to arylation and aroylation of aliphatic amino groups, alkylation or acylation of a thiol group that had been introduced into oligonucleotides is also employed for the preparation of azido derivatives of oligonucleotides using the corresponding halide derivatives of aryl azides. Thus acylation of the 5'-terminal thiophosphate of oligothymidylate with *p*-azidobenzoyl bromide gives the *p*-azidobenzoyl derivative **10**.¹⁵

R is the oligothymidylate residue.

Analogously, the reaction of 3-azido-6-(3-bromopropylamino)acridine⁶ or *p*-azidobenzoyl bromide¹⁶ with the terminal thiophosphate group of oligothymidylate yielded azidoproflavin (**11**) or *p*-azidobenzoyl (**12**) derivatives of oligonucleotides, respectively.

R is the oligodeoxyribonucleotide residue.

p-Azidophenacyl bromide¹⁷ was also used for modification of the oligonucleotide **13** containing an internucleotide thiophosphate group that had been introduced in the oligonucleotide synthesis.¹⁷

R and R' are fragments of the oligonucleotide sequence.

The azido group can be incorporated through a thiol group into a heterocyclic base as well. Thus 5-[(4-azidophenacyl)thio]cytidine 5'-triphosphate (**15**) has been synthesized according to Scheme 1.¹⁸ All the reactions were carried out in the dark or under reduced illumination.

(a) MeOBr, 4 °C, 12–24 h; (b) Na₂S₂, 4 °C, 5 h; 20 °C, 48 h; (c) NaBH₄, H₂O, 0 °C, 3 h; (d) BrCH₂COC₆H₄N₃-*p*, DMSO, 4 °C, 12 h.

Treatment of cytidine 5'-triphosphate **16** with methyl hypobromite gave a bromomethoxy derivative **17**. The reaction product of compound **17** with sodium disulfide was isolated by extraction and column chromatography. The yield of 5,5'-dithio-bis(cytidine 5'-triphosphate) **18** was 10%. Such a low yield was attributed to the negative charge of both reacting molecules.¹⁸ An alternative route to the disulfide from a nucleoside was also attempted.¹⁸ In this case, the yield of the reaction products was much higher. Then, the 2'- and 3'-OH groups of ribose were protected and the 5'-OH group of the disulfide derivative was phosphorylated. The final stage of this synthesis was more complicated and labourious due to a greater number of purification steps and more complex isolation procedure of intermediate compounds, which resulted in nearly the same yield of 5,5'-dithio-bis(cytidine 5'-triphosphate) **18**. 5-Mercaptocytidine 5'-triphosphate **19** was obtained from compound **18** by reduction with sodium borohydride. The reaction mixture was treated with *p*-azidophenacyl bromide in DMSO. The target product **15** was isolated by extraction and column chromatography (80% yield). The azido derivative of the nucleoside triphosphate **15** was introduced into various positions of RNA in the course of polymerase synthesis.

Thus, the methods available allow one to incorporate the azidoaryl groups both into heterocyclic bases of nucleic acids and the sugar-phosphate backbone. They involve acylation of aliphatic amino groups of nucleic acids with *N*-hydroxysuccinimide esters of azidobenzoic acid and its derivatives or alkylation (acylation) of a thiol group that had been introduced into nucleic acids using the corresponding azidoaryl halides. As a rule, these reactions occur with high efficiency (the product yield is 80%–99%). However, whereas the former route makes use of the exocyclic amino groups of heterocyclic bases of nucleic acids for the incorporation of the azido groups, in the case of azidoaryl halides an additional step is required, *viz.*, the incorporation of a thiol group into nucleic acids. This may complicate the procedure and reduce the yields of the target products.

b. Cross-coupling of nucleic acid derivatives containing the azido groups with biopolymers

On irradiation with light (photolysis), compounds containing azidoaryl groups generate highly reactive short-lived radicals, *viz.*, nitrenes. In the singlet state, the lifetime of nitrenes depends on the nature of substituents in the aromatic nucleus and varies from nano- to microseconds.¹⁹ This state of nitrene radicals is very unstable: they either undergo intramolecular rearrangements to yield various reactive intermediates or react with neighbouring reactive groups. In the latter case, intermolecular covalent bonds may be formed. Using azidophenyl derivatives as examples, it has been shown that introduction of fluorine atoms or nitro groups into the benzene ring decreases the probability of intramolecular

rearrangements and simultaneously increases the probability of nitrene involvement in intermolecular reactions.²⁰

For the first time, azido derivatives of oligonucleotides have been used for the study of the formation of cross-coupled DNA duplexes **20** from a 27-membered matrix oligonucleotide and a complementary octa(α -thymidylate) carrying an azidoproflavin residue linked with the 5'-thiolphosphate group of the α -anomer through a spacer arm.⁶

20

UV irradiation of oligonucleotides constituting the system **20** ($\lambda > 300$ nm) in 0.1 M NaCl resulted in cross-linking. The photoaddition product was treated with an alkali, which resulted in selective cleavage at modification sites. The residues T⁹ and T¹⁸ (1 : 3) of the DNA template were found to be the main sites of this cleavage. This ratio was rationalised by postulating parallel and antiparallel orientations of the oligonucleotide probe during the formation of a complementary complex or the existence of a triplex structure. Further experiments showed that the second hypothesis was more probable, since octa(α -thymidylate) in 0.1 M NaCl can form ternary complexes with the template.

Photomodification of the pentadecanucleotide **21** and the hexadecanucleotide **22** with the oligonucleotide derivatives **23–28** carrying the azido group at various positions of the nucleotide probe has been carried out by Levina *et al.*²¹

The oligonucleotide derivatives employed contained the azido group attached through a spacer to the 3' (5')-terminal phosphates (reagents **23**, **25**, and **26**) or to the C(5) atom of a terminal deoxyuridine (reagent **24**) or deoxyuridine inside the chain (reagents **27** and **28**).²¹ The reagents complementary to the adjacent sites of the target were also used in pairs: tandems of reagents **23** + **25** and **23** + **26**. UV irradiation at $\lambda = 303\text{--}365$ nm yielded products of covalent addition of one or two (in the case of tandems) reagents to the target. The efficiency of photoaddition of reagents **23** and **26** containing the azido group (at the 5'- or 3'-ends, respectively) to the pentadecanucleotide was approximately the same, and the yields of the photoaddition products were 70%. However, the use of a tandem of these reagents increases the efficiency of photomodification up to 80%. The modification predominantly affects the G⁹ residue of the oligonucleotide **21**, which is not involved in the formation of the complementary complex. The adduct yield decreases to 55% and 51%, respectively, when reagents **27** and **28** containing the uridine azido derivative inside the chain are used. The decrease in the photoreaction efficiency is apparently due to the involvement of the modified base in a complementary reaction. This is confirmed by the fact that the efficiency of photoaddition in the

case of reagent **24** having an azidonucleotide at its 5'-end reaches 69% and modification affects predominantly the G⁷ residue of the oligonucleotide **22**, whereas the G⁸ residue is modified in a lesser degree.

Highly reactive nitrenes generated from the azido derivatives of oligonucleotides upon photolysis can instantaneously react with the neighbouring reactive groups as well as with amino acid residues of a DNA–protein complex.

Investigation of the structure of the transcription factor TFIIC of RNA polymerase III was carried out using a genomic DNA sequence of yeast tRNA^{Tyr} SUP4 containing one or several azido derivatives of deoxyuridine **6**.¹⁰ A complex of modified DNA with the protein was irradiated with UV light ($\lambda = 254$ nm) for 5 min. Analysis of photoaddition products allowed one to identify four subunits of TFIIC and to establish their position relative to SUP4 in the DNA–protein complex. This study was extended by using a genomic DNA sequence SUP4 containing azido derivatives of cytidine **7**.¹¹ In contrast with the previous example, a non-purified protein fraction was used for modification. Analysis of photoaddition products revealed a protein with molecular mass of 40 kDa, which could not be detected when purified TFIIC has been used. It was assumed that this protein is a component of the transcription complex.

Affinity modification of the 5'-region of the mRNA-binding centre of the *E. coli* ribosome was studied using *N*-[2-(2,4-dinitro-5-azidophenyl)aminoethyl]-5'-phosphoramidites of oligouridylates **8**.¹² It was found that compounds **8** ($N = \text{U}$, $n = 4, 7$, and **8**) stimulate binding of code-specific aminoacyl-tRNA with the ribosome. Upon UV irradiation of the ribosome–reagent **8**–tRNA ternary complex ($\lambda > 350$ nm), covalent binding of the reagent **8** with the ribosome occurred. Up to 10% of the reagent **8** in the ternary complex was cross-linked with the ribosomal proteins of the 30S and 50S subunits. It was found that in the 30S subunit modification affected proteins S3, S4, S9, S11, S12, S14, S17, S19, and S20. In the 50S subunit, it was proteins L2, L13, L16, L27, L32, and L33 that were modified. The array of the modified proteins strongly depended on the length of the oligonucleotide fragment of the reagent and on the binding of the tRNA molecule to the site A of the ribosome.

By virtue of their ability to form stable covalent bonds with the reactive groups of proteins, azido derivatives of oligonucleotides are successfully employed for identifying amino acid residues in the active centres of DNA-recognising proteins. Thus identification of the amino acid residues of the restriction endonuclease *TaqI* that reacts with the recognition site was made using the photoreagent **13** containing the azido group just at the *TaqI* cleavage site.¹⁷ The complementary complex 'oligonucleotide probe **13**–template DNA' was UV-irradiated ($\lambda = 306$ nm, 5 min) following 5-min incubation with *TaqI*. The efficiency of formation of the covalently bound DNA–protein complex was 15%–20%. An analysis of photoaddition products allowed one to identify the amino acid residue involved in the formation of a covalent bond with the oligonucleotide probe as Tyr161.

Modified fragments of RNA containing 5-(4-azidophenyl)thiocytidine residues at the 3'-end or in the middle of the chain were used for photoaffinity modification of T7 and *E. coli* RNA polymerases.¹⁸ The complexes of modified RNA with T7 and *E. coli* RNA polymerases were UV-irradiated ($\lambda = 302$ nm) for 2–4 min at 20 °C. An analysis of photoaddition products revealed RNA-binding domains in the corresponding RNA polymerases.

In recent years, azido derivatives of oligonucleotides have been employed for modification of the proteins of chromatin. Thus reagent **9** was used to study structural rearrangements in chromatin during the cell cycle.¹³ To this end, the spectra of proteins modified in the nuclei isolated from *HeLa* cells in two different phases of the cell cycle, *viz.*, the S-phase and in the region

of transition from the G₁ to the S-phase (G₁/S), were compared. Modification of proteins in the nuclei isolated in the S-phase of the cell cycle gave five nuclear proteins with molecular masses 160, 87, 72, 59, and 46 kDa and was specific. The spectrum of the modified proteins changed on going from the S-phase to the G₁/S interface. In particular, the 160 kDa protein was not modified. The results obtained by other authors¹³ confirm the idea that photoactivated oligonucleotides are promising for studies of the structure and functions of chromatin.

Wide application of azido derivatives of nucleic acids in the studies of nucleic acid–nucleic acid and nucleic acid–protein interactions is indicated by the existence of reproducible protocols for the synthesis and their high reactivity. However, in some cases the high reactivity of nitrenes photogenerated from the azido derivatives may decrease the specificity of the reactions and thus imposes certain limitations on the application of azidoaryl derivatives of nucleic acids in structure–function studies of biopolymers.

2. Derivatives of nucleic acids containing halogen or mercapto groups

In recent years, photoactivated oligonucleotide derivatives with bromo, iodo, or mercapto groups have been widely employed for the study of nucleic acid–protein or nucleic acid–nucleic acid interactions. The interest in these compounds is due to their ability to generate free-radical intermediates that can form covalent bonds with electron-donor groups of proteins and nucleic acids on irradiation with long-wave UV light. Reactions according to radical mechanisms are also possible, but only in the case where the reacting groups are at a distance of several angström.²² This circumstance makes possible the use of oligonucleotide halogeno and thiol derivatives for identifying direct nucleic acid–nucleic acid or nucleic acid–protein contacts.

a. Synthesis of halogeno and mercapto derivatives of oligonucleotides

Oligonucleotide derivatives carrying halogeno or mercapto groups are usually obtained by chemical or enzymic syntheses using modified nucleotide components, such as 4-mercapto or 5-bromo(iodo) uridine or cytidine. DNA derivatives containing halogeno or mercapto groups are obtained by solid-phase phosphoramidite synthesis with bromo-, iodo-, or mercapto-deoxyribonucleoside phosphoramidites as monomeric units. Thus, 5-bromo-2'-deoxyuridine (5-BrdU) derivatives of DNA that included a recognition site for the transcription factor NF-κB were obtained by Liu *et al.*²³ The modified uridine was introduced into various positions of DNA by solid-phase synthesis with 5-BrdU phosphoramidites.

The 5-iodo-2'-deoxyuridine derivative of the deoxyribonucleotide GCTCACCAGAA–IdU–GC **29** was synthesised in a similar way²⁴ from compound **30** obtained in quantitative yield according to the following scheme:

(a) DMTTrCl = (*p*-MeOC₆H₄)₂C(Ph)Cl, Py; (b) (Pr₂N)₂P(OMe), Pr₂N⁺Et, CH₂Cl₂, 20 °C, 10 min.

It should be noted that the high sensitivity of aromatic iodides to nucleophilic substitution prevents deprotection of internucleotide phosphates and heterocyclic bases by conventional treatment with NH₄OH at 55 °C. Removal of protective groups leading to the oligomer **29** could be carried out by treatment with NH₄OH for 48 h at room temperature. Under these conditions, no nucleophilic substitution of iodine in the aromatic nucleus occurred, while phosphate groups and heterocyclic bases were completely deprotected.

Halogeno or mercapto derivatives of oligoribonucleotides are also obtained using modified nucleoside triphosphates as substrates for T7 RNA polymerase in the polymerase-catalysed synthesis of RNA. Thus a 19-membered oligoribonucleotide **31** containing 5-bromouridine (5-BrU) at position (–5) was used to identify amino acid residues in the site of binding of the bacteriophage R17 membrane protein with genomic RNA.²⁵ The synthesis of compound **31** was carried out using 5-bromouridine 5'-triphosphate by a T7 RNA polymerase-catalysed synthesis on a synthetic DNA template.

The same approach was used to obtain oligoribonucleotides with a nucleotide sequence analogous to that of compound **31** but with U or C 5-iodo derivatives at position (–5).²⁶

A method for the synthesis of 4-(2-cyanoethyl)thiouridine **32** phosphoramidite has been proposed (Scheme 2).²⁷ This compound was further used in the chemical synthesis of modified RNA. The 2'-OH group of ribose was protected by a 1-(2-fluorophenyl)-4-methoxypiperidin-4-yl group. The mercapto group of uridine was protected as a 2-cyanoethyl derivative.

The reaction of 2'-O-[1-(2-fluorophenyl)-4-methoxypiperidin-4-yl]-5'-O-dimethoxytrityluridine with methoxyacetic anhydride in dry pyridine gave the derivative **33** in quantitative yield. To obtain the uridine derivative **35** with a cyanoethyl group at position 4, compound **33** was treated with 2,4,6-triisopropylbenzenesulfonyl chloride, after which the sulfonate **34** was introduced into reaction with 3-mercaptopropionitrile. The resulting compound was treated with ammonia in methanol to deprotect the 3'-hydroxy group of ribose. Phosphitylation of the 3'-OH group of the protected ribonucleoside **35** was carried out with 2-cyanoethyl bis(diisopropylphosphoramidite). After purification, compound **32** was obtained in 44% yield and further used in a solid-phase phosphoramidite synthesis to obtain photoactivated derivatives

of RNA containing 4-mercaptouridine in different positions of the recognition sites of the HIV Rev protein and the bacteriophage MS2 membrane protein.

b. The use of oligonucleotide halogeno and mercapto derivatives for cross-linking to proteins and nucleic acids

As has been mentioned above, UV irradiation of bromo(iodo) or mercapto derivatives of oligonucleotides generates reactive intermediates, which interact with reactive groups of proteins and nucleic acids. Using an oligonucleotide derivative containing 5-BrU as an example, it was shown that the mechanism of photoactivated reaction of halogeno derivatives with the protein amino groups depends on the wavelength.²⁸ Upon UV irradiation with $\lambda = 308$ nm, the 5-BrU molecule passes from the low-energy singlet state to the reactive triplet state n,π^* responsible for the binding of BrU–DNA with the associated protein, presumably through the initial electron transfer. The intermolecular covalent binding of BrU with amino acid residues, such as cysteine, glutathione, or tryptophan, is accompanied by elimination of HBr.

R is the oligonucleotide residue.

Upon UV irradiation with $\lambda = 254$ nm, the 5-BrU molecule passes into a high-energy singlet state π,π^* , which results in the cleavage of the C–Br bond to yield free radicals $\text{U}^\bullet$ and a Br atom. The highly reactive radical $\text{U}^\bullet$ either reacts with the reactive groups of the nearest environment (in particular, with the formation of a covalent bond with the amino groups of a protein) or passes into the triplet state, $^3\pi,\pi^*$.²⁹

Synthetic analogues of the promoter region of DNA containing several 5-BrdU residues were used to study covalently bound complexes of a series of transcription factors of the albumin gene (HNF1, APF, vAPF, α 1TEB, HPI) with the promoter regions of this gene.³⁰ Yet another aim of this study was to identify the polypeptide chains involved in the formation of a vAPF–APF complex and the nucleotide residues involved in the interaction with the protein. Complexes of DNA derivatives with the proteins were irradiated at $\lambda = 321$ nm. An analysis of cross-linking products revealed that the DNA–protein contact sites were distributed asymmetrically on a pseudopalindromic recognition site: the nucleotides crucial for the recognition were located in the middle of the pseudopalindromic sequence but the recognition site had other contacts of the protein with several nucleotides.

In order to investigate the formation of cross-linked complexes of a membrane protein with an operator of bacteriophage R17 transcription (R17 RNA) and to identify the amino acid residue responsible for the formation of the cross-linkage, Willis *et al.*²⁵ proposed to use a synthetic analogue of R17 RNA containing a 5-BrU residue at position (–5) (compound **30**). Its complex with the membrane protein was irradiated at $\lambda = 308$ nm for 5 min after which the protein concentration was increased and the complex was irradiated for an additional 5 min. The efficiency of formation of the cross-linked complex was 22%. The amino acid residue involved in this process was identified as Tyr85. It was found that cross-linking did not occur if Tyr85 was substituted by Ser.²⁵ These results are in good agreement with the above-described mechanism of the photoinduced reaction of oligonucleotides containing 5-BrU with the amino acid residues of the protein according to which 5-BrU derivatives cross-link only with aromatic amino acids upon irradiation at $\lambda = 308$ nm.²⁹

Earlier, it was found³¹ that oligonucleotides containing 5-IU residues are more efficient reagents for cross-linking to proteins than those containing 5-BrU. The efficiency of covalent photoaddition of iodine-containing reagents is usually 3 to 5 times higher than that of their bromo analogues. Therefore, the 5-BrU residue at position (–5) of compound **30** was substituted by the 5-IC residue.²⁶ Five additional 5-IC residues were introduced into various positions of RNA **36** in order to demonstrate the specificity of formation of the cross-linked complex.

Figure 1. Model mRNA containing 4-mercaptouridine residues: A — mRNA 8'; B — mRNA 9'; C — mRNA 10'. The encoding sequences are bold-faced, and modified bases are underlined.

A complex of the membrane protein with compound **36** was irradiated with UV light ($\lambda = 325$ nm) for 2 h. The efficiency of cross-linking was 75%–95%. It is noteworthy that the formation of the cross-linked complex was accompanied by partial cleavage of the RNA chain. When an analogous RNA devoid of the 5-IC residue at position (–5) (compound **37**) was used, the cross-linked RNA–protein complex was not formed.

On irradiation at $\lambda > 300$ nm, oligonucleotides containing 4-mercaptouridine reacted by a free radical mechanism and cross-linked through reactive groups with proteins and nucleic acids.³² In the case of nucleic acids, the cross-linking was the most efficient between the adjacent uridine or adenine residues. This makes it possible to use mercapto derivatives of oligonucleotides for the studies of both nucleic acid–protein and nucleic acid–nucleic acid contacts. Thus a series of model mRNAs containing 4-mercaptouridine residues in various positions were synthesised to study cross-linking between mRNA and 18S RNA within a complex with the 80S ribosome (Fig. 1).³³ The synthetic mRNAs contained encoding sequences for glycine and/or tryptophan (GGG and ACC, respectively).

The mRNA–80S ribosome complex was irradiated with UV light ($\lambda = 320$ –365 nm) in the presence and in the absence of tRNA^{Gly} and/or tRNA^{Thr}. The efficiency of formation of a cross-linked mRNA–18S RNA complex depended on the presence of tRNA only for the mRNA 9' derivative and was 20% in the presence of tRNA and 40% in its absence. The efficiency of cross-linking was 8% and 14% for mRNA 8' and mRNA 10 derivatives, respectively. It was shown that a covalent bond is formed with U630 and U1111/A1112 of the 80S ribosome 18S rRNA.

Synthetic nucleic acid analogues having reactive thiol groups are widely employed in the studies of the structure and function of ribosomes. Thus a series of model RNAs have been synthesised to study the sites of binding of 5S RNA with the 50S subunit of the ribosome³⁴ in which 18% of uridine residues were statistically substituted by 4-mercaptouridine residues. The 5S RNA–ribosome 50S subunit complex was irradiated at $\lambda = 300$ nm for 10 min. The yield of the product of cross-linking of 5S RNA to the 23S ribosomal RNA was more than 75%. The structures of the products formed were not established, although it was shown that U89 of 5S RNA and U2477 of 23S RNA of 50S ribosomal subunits were cross-linked.

Thus, the indisputable advantage of halogeno and mercapto derivatives of nucleic acids is their high reactivity and the ability to operate at a zero distance, which makes possible the probing of direct nucleic acid–protein contacts. At the same time, the high reactivity of these intermediates may be the cause of nonspecific modification of proteins and other cell components and their partial destruction.²⁶ Moreover, the need for additional activation with light of definite wavelengths restricts the application of halogeno and mercapto derivatives of nucleic acids *in vivo*.

3. Psoralen derivatives of nucleic acids

Nucleic acids that contain psoralen residues or its derivatives belong to the most efficient, selective photoreagents that are widely employed for affinity modification and structural analysis of nucleic acids.

a. Introduction of psoralen into oligonucleotides

Psoralens (7*H*-furo[3,2-*g*][1]benzopyran-7-ones)[†] are aromatic compounds with three linearly fused rings of α -pyrone, benzene, and furan. They contain two photoactivated double bonds, C(3) = C(4) in the pyrone ring and C(4') = C(5') in the furan ring.

Irradiation with long-wave UV light ($\lambda = 300$ –365 nm) can result in cycloaddition of both these bonds to the C(5) = C(6) bond of thymidine or uridine to form a cyclobutane ring. Thus psoralen derivatives **38a** and **38b** of a dodecanucleotide containing only one thymidine residue were obtained.^{35,36}

R = d(GAAGC); R' = d(ACGAGC).

Photochemical addition of psoralen gives reactive derivatives only if the C(4') = C(5') bond of the furan ring is involved in the reaction with the thymidine residue. In the case of thymidine cycloaddition to the C(3) = C(4) bond of the pyrone ring, the psoralen derivative formed is incapable of further photochemical

[†] Hereinafter the names used in the original publications are given.

addition.³⁷ Therefore, the introduction of psoralen into terminal phosphate groups of oligonucleotides has now become an especially widespread procedure, for it allows modifications that involve the reactive centres of the psoralen molecule. Thus a psoralen derivative of a 16-membered oligonucleotide **39** has been synthesised by alkylation of its 5'-terminal thiophosphate group with 5-(ω -iodohexyloxy)psoralen.³⁸

R = TTTTCTTTTCCCCCT.

4'-Aminoalkylamino-4,5',8-trimethylpsoralen **40** was attached to the 5'-phosphate group of a methylphosphonate analogue of the oligonucleotide using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (CDI) as the activating reagent.³⁹

X = NH-CH₂; NH-(CH₂)_n-NHCH₂, n = 2, 4;

R is a methylphosphonate analogue of the oligodeoxyribonucleotide;

EDC is EtN=C=N(CH₂)₂CH₂NMe₂.

The reaction was performed in a lutidine hydrochloride buffer (pH 7.5) for 14 h at 20 °C. The yield of compound **41** was 85%.

The attachment of psoralen to the 5'-end of an oligonucleotide can also be carried out in the solid-phase oligonucleotide synthesis. Thus a 4,5',8-trimethylpsoralen residue **42** was incorporated into the oligonucleotide by phosphoramidite synthesis using psoralen β -cyanoethyl-*N,N*-diisopropylphosphoramidite **45** at the final stage.⁴⁰

(a) 1. tetrazole; 2. I₂; 3. NH₃, 55 °C, 6 h;

R = d(TAGCCGCTATCGGTAGT).

The first step of this synthesis consisted in chloromethylation of 4,5',8-trimethylpsoralen **42** with chloromethyl methyl ether. Then, a linker group was introduced into the resulting compound **43**. Phosphitylation of 4'-(2-hydroxyethoxymethyl)-4,5',8-trimethylpsoralen **44** with β -cyanoethyl-*N,N*-diisopropylamidophosphochloridite was carried out in the presence of ethyl-diisopropylamine for 30 min at 20 °C. The oligonucleotide psoralen derivative **46** was obtained on an automated DNA synthesiser using a standard phosphoramidite protocol. The psoralen phosphoramidite **45** was attached to the 5'-end of the oligonucleotide at the last stage of this synthesis. Oxidation and deprotection with concentrated ammonia gave 5'-psoralen derivative **46** in 99% yield.

A similar strategy has been used to obtain derivatives of oligonucleotides **47** and **48**.⁴¹

Compound **48** with a disulfide bond, was synthesised using a mercaptoalkyl phosphoramidite that was introduced into an automated oligonucleotide synthesis prior to the attachment of the psoralen derivative.

Thus, psoralen derivatives of nucleic acids can be obtained both by photochemical cycloaddition of psoralen to the heterocyclic bases of nucleic acids and by chemical attachment of psoralen derivatives to terminal phosphate groups of nucleic acids. The latter approach has become more popular because the ability of psoralen for subsequent photochemical addition is fully preserved in this case. Moreover, photochemical modification of heterocyclic bases of nucleic acids with psoralen makes the *N*-glycosidic bond more labile and can sometimes result in the destruction of the polynucleotide chain.

b. Cross-linking of psoralen-containing oligonucleotides to biopolymers

Psoralen-containing oligonucleotides are mostly used for directed modification of nucleic acids. A detailed study of their cross-linking to complementary sites of nucleic acids has been carried out by Shi.³⁵ To this end, the dodecanucleotide GAAGCT*AC-GAGC derivatives containing a psoralen residue fused to thymidine both by its pyrone and furan rings (compounds **38a** and **38b**,

respectively) were used. Modified oligonucleotides **38a** and **38b** were hybridised with a complementary template and irradiated with monochromatic light of various wavelengths. It was shown that irradiation of the nucleic acid–oligonucleotide **38a** complex with light in a broad range of wavelengths resulted in the predominant splitting of the 4'-hydroxymethyl-4,5',8-trimethylpsoralen residue. In this case, the efficiency of cross-linking between complementary oligonucleotides was extremely low. With irradiation of the complementary nucleic acid–oligonucleotide **38b** complex at $\lambda < 313$ nm, both splitting of the psoralen residue and simultaneous formation of a covalent oligonucleotide–nucleic acid bond occur. Irradiation of the latter complex with $\lambda > 313$ nm results in highly efficient formation of a cross-linked complex, and psoralen is not split off. These results are in good agreement with other data on the stability of the psoralen monoadduct with thymidine. It was shown that thymidine fused with psoralen at the furan ring **38b** was more resistant to irradiation at $\lambda < 313$ nm than the compound of the type **38a** with the pyrone ring fusion. Introduction of a psoralen derivative of thymidine into an oligonucleotide only slightly increases the monoadduct resistance to photocleavage.⁴²

Psoralen-containing oligonucleotides have been used in studies of DNA transcription with the RNA polymerase of *E. coli*.³⁶ 4'-Hydroxymethyl-4,5',8-trimethylpsoralen was introduced into one of the chains of a 140-membered DNA duplex containing a promoter of *E. coli* RNA polymerase. Upon irradiation at $\lambda = 320$ –380 nm, psoralen fused with a particular thymidine residue in one of the duplex chains reacted with the closely situated thymidine residue of the complementary chain. The yield of the cross-linked DNA duplex was 80%. It was shown that transcription of this duplex was blocked at a distance of one nucleotide from the site of cross-linking.

Methylphosphonate analogues of oligonucleotides having psoralen derivatives at their 5'-ends and linked to the phosphate group of the oligonucleotide through various spacer groups were used for attachment to two 35-membered deoxyribonucleotides.³⁹

X = NHCH₂, NH(CH₂)_nNHCH₂, n = 2, 4;

Ps is the 4,5',8-trimethylpsoralen residue. The fragments of oligonucleotides containing internucleotide methylphosphonate groups are underlined.

The cross-linked complex was obtained by irradiation of the duplexes **49** and **50** with light of $\lambda = 365$ nm at 4 °C for 20 min. The yield of the photoaddition products strongly depended on the length of the spacer arm and reached maximum values (75% and 80% for systems **49** and **50**, respectively) at n = 4. Studies of the temperature dependence of the photoaddition reaction revealed that the efficiency of cross-linkage of DNA duplexes was determined by the stability of the complementary complex formed. Irradiation of photoaddition products at $\lambda = 254$ nm led to the cleavage of the cross-linked DNA duplexes and recovery of the original compounds. It was thus concluded that cross-linking of modified oligonucleotides is a result of formation of a cyclobutane ring between the C(5)–C(6) bond of thymine and the C(3)–C(4) bond of the pyrone ring of psoralen. The adduct with the furan ring of psoralen is not formed due to steric hindrances.

Psoralen attached to the terminal phosphate group of an oligonucleotide through C(5) retains its capacity to form a bisadduct. Therefore, this type of psoralen-containing oligonucleotides within a triplex can form a ternary cross-linked oligonucleotide complex. The structure of the triplex is stabilised by intercalation of psoralen residues into a double helix of DNA.

Thus psoralen-containing, 16-membered homopyrimidine oligonucleotide **39** was used for cross-linking to a double-helical region of DNA of the human immunodeficiency provirus **51**³⁸ (the site where the formation of a triplex structure takes place is bold-faced).

The sequence **51** contains a recognition site for the restriction endonuclease *DraI* (TTTAAA) overlapping with two or three nucleotides in the formation of a triplex with the oligonucleotide **39**. Plasmids pLTR and pBT1 containing one or two copies of sequence **51**, respectively, were incubated with the oligonucleotide **39** and irradiated with UV light ($\lambda > 310$ nm). The photomodified plasmids were used as substrates for the restriction enzyme *DraI*. It was found that photomodification with the psoralen derivative **39** selectively inhibited the enzymic splitting at the site overlapping with the triplex structure.

The ability of psoralen-containing oligonucleotides to form cross-linked triplex complexes has been used for site-specific insertion of mutations into animal cells in order to investigate their repair mechanism.⁴¹ To this end, the frequency and spectrum of mutations induced by various psoralen-containing oligonucleotides in several cell lines with various repair disturbances, viz., *xeroderma pigmentosum* variant (XPV) and *xeroderma pigmentosum* group A (XPA), were compared with the corresponding parameters of normal and *Fanconi anemia* (FA) cells. In these studies, compounds **47** and **48** were used, which form triplexes with the 167–176 region of the *supF* gene. It is noteworthy that the psoralen residue of compound **48** is linked with the oligonucleotide through a disulfide bond, which can be cleaved by dithiothreitol; this allows one to study mutagenesis in the absence of the site-directed oligonucleotide part of the probe. The triplex structure of compound **47** (or **48**) with the *supF* gene in the vector pSP189 was irradiated with long-wave UV or visible light. UV irradiation gave a cross-linked triplex in 65% yield, while upon irradiation with visible light the yield did not exceed 1%. The cross-linkage was formed between T166 and T167 residues. The DNA vector thus modified was transformed into the appropriate cultures of human cells. Analysis of mutagenesis in the line XPV revealed an unusually high frequency of mutations (more than 30%) with a unique spectrum that differed from those of XPA, FA, and normal cells. These data led Raha *et al.*⁴¹ to conclude that this approach is useful both for the description of repair defects in XPV cells and other genetic analyses of human cells.

The reactive oligonucleotide **46**, modified at the 5'-end with 4'-hydroxyethoxymethyl-4,5',8-trimethylpsoralen, was used to obtain a cross-linked DNA duplex within the complementary complex **52**. This DNA duplex was obtained in 75% yield upon UV irradiation of the complex **52** at $\lambda = 350$ nm at 20 °C.⁴⁰

X is 4'-hydroxyethoxymethyl-4,5',8-trimethylpsoralen.

The glycosidic bond of the nucleotide involved in cross-linking of psoralen-containing oligonucleotides to nucleic acids becomes more labile. This property has been exploited in site-specific cleavage of DNA.³⁵ The cleavage site was mostly determined by the length of the spacer arm between the psoralen residue and the oligonucleotide end.

Thus, owing to their ability for selective cycloaddition to thymidine or uridine residues, psoralen-containing nucleic acids are widely employed for the study of structure and function of nucleic acids. The possibility of formation of bisadducts makes them helpful tools for the study of mechanisms of formation of triplex structures.

ion-exchange chromatography. However, when *cis*-aquahydroxydiammineplatinum (*cis*[(NH₃)₂Pt(OH)(H₂O)]NO₃) is used, modification affects all of the G, C, and A residues of the oligonucleotide. In this case, the covalent bond can also be formed between the nucleotides of the same chain. Reagents with one platinum residue can be prepared from oligothymidylates containing only one G, C, or A residue. Thus treatment of oligothymidylate having a single cytidine residue with a 10-fold excess of *cis*-aquahydroxydiammineplatinum nitrate⁵¹ gave compound **62**. The degree of conversion of the original oligonucleotide was 97%–99%:

R = d(TT), R' = TTTTTT.

The reaction was conducted in an aqueous medium (pH 7.0) for 24 h at 30 °C; the degree of conversion of the original compound and the homogeneity of the final product were estimated by microcolumn chromatography. Compound **62** was used for modification of DNA polymerase α of human placenta.

Thus, modern methods allow one to incorporate platinum both into heterocyclic bases and into a predetermined position of the sugar-phosphate backbone of nucleic acids. In the latter case, the synthesis of platinum-containing derivatives must be preceded by introduction of mercapto groups into the sugar-phosphate backbone.

2. Cross-linking of Pt-containing oligonucleotides with biopolymers

Bifunctional Pt-containing compounds are often used to obtain cross-linked nucleic acid–nucleic acid or nucleic acid–protein complexes.^{52,53} The synthesis of platinum-containing oligonucleotides makes it possible to increase considerably the efficiency and selectivity of modification of biopolymers by these reagents.

Cross-linking of Pt-containing oligonucleotides with biopolymers can be carried out in two ways: (1) by direct reaction of Pt-containing oligonucleotides with complementary sites of nucleic acids or DNA-recognising proteins and (2) by treatment of a preformed complex of a biopolymer with an oligonucleotide probe containing nucleophilic SH or NH₂ groups at predetermined positions with bifunctional Pt reagents. Thus treatment of a complementary complex **63** formed by a 322-membered DNA target and a 16-membered oligonucleotide probe carrying a cysteamine residue at its 5'-end with K₂PtCl₄ resulted in cross-linking. The efficiency of cross-linking varied from 10% to 50% depending on K₂PtCl₄ concentration.⁴⁶

X = HSCH₂CH₂NH

The reaction involved the attachment of Pt coordinated with three chloride ions to the 5'-SH group of the oligonucleotide probe and subsequent modification of the DNA target.

A similar approach was used by Chu and Orgel⁵⁴ who carried out affinity modification of the transcription factors CREB and JUN using platinum-containing oligonucleotides. To this end, six internucleotide thiophosphate groups have been introduced into each CRE and TRE recognition site for the transcription factors CREB and JUN in covalently closed DNA duplexes. The complexes of oligonucleotide probes with the corresponding proteins were treated either with K₂PtCl₄ or with *trans*- or *cis*-diamminedichloroplatinum(II). The efficiency of cross-linking between oligonucleotides and proteins with K₂PtCl₄ or *trans*-**53** was from 30%

to 50% depending on the reagent concentration. Treatment of a DNA–protein complex with *cis*-**53** did not result in cross-linking. The use of analogous probes devoid of internucleotide thiophosphate groups resulted in several-fold lower efficiency of cross-linking. Presumably, this method⁵⁴ can be employed for the isolation of DNA-recognising proteins.

A Pt-containing nonanucleotide **61** (R = TCCGCCTTT) was used for modification of a complementary hexanucleotide GGCGGA within a two-helical complex **64**.⁴⁸ The yield of the cross-linked complex was 80%.

Unlike psoralen derivatives, treatment of guanine residues of template oligonucleotides with platinum-containing reagents favours stabilisation of the glycosidic bond. An analysis of products of partial scission of the template at purine bases allows one to identify particular guanine residues that have been modified. It was found that one of the two 5-terminal guanine residues of the template was involved in cross-linking.⁴⁸

A detailed study of cross-linking of oligonucleotides modified with the reagent **55** at the 5'-terminal or at internucleotide thiophosphate groups to complementary fragments of DNA was carried out by Gruff and Orgel.⁴⁷ The reaction was studied both within DNA duplexes and within ternary complexes using oligonucleotides **56–59** and **65–68**.

Using duplexes **65–56** as an example, it was shown that cross-linking was the most efficient (64% yield) when the reagent **55** (*n* = 6) was used. This reagent was chosen for subsequent experiments. The reaction was carried out for 60 min at 37 °C in the presence of NaClO₄. Modification affected residues G19 and G20 of the oligonucleotide **65** (marked bold). Under the same conditions, the efficiency of cross-linking in duplexes **58–68** and **59–68** was much lower (46% and 41%, respectively), which was attributed to the formation of intrachain cross-links in oligonucleotides **58** and **59** containing purine bases.⁴⁷ In the case of the oligonucleotide **57**, the nucleotide composition of which is identical with that of the oligonucleotide **58** but which contains a platinum reagent inside the chain (because the thiophosphate group is present in the middle of the sugar-phosphate backbone), the efficiency of cross-linking decreased to 37%. This low efficiency may be due to the involvement of the modified base in complementary interaction. A ternary complex was formed by oligonucleotides **66** and **67** and an analogue of a Pt-containing oligonucleotide **56** in which all cytidine residues had been substituted by 5-methylcytidine (oligonucleotide **69**). Such a substitution significantly stabilised the triplex structure. The reaction carried out at 25 °C for 60 min resulted in cross-linking of the oligonucleotide **69** with the chain **66** enriched with purine nucleotides and with 53%–68% efficiency. It was shown that the efficiency of this reaction strongly depended on the stability of the triplex structure. Thus a rise in temperature up to 37 °C sharply decreased the yield of cross-linked products. Replacement of the oligonucleotide probe **69** by **56** also decreased the yield down to several per cent.

The active centre of the transcription factor HNF-1 was probed⁶¹ using a series of DNA duplexes containing an *O*-methyl-substituted pyrophosphate group in various positions (1–16) of the HNF-1 recognition site. These studies were carried out both with a gene-engineered protein, which represented a DNA-binding domain of HNF-1, and with proteins isolated from nuclear extracts of rat liver. Modified substrates were incubated with the protein or a nuclear extract at 4 °C or 20 °C for 10 min or 12 h. This reaction yielded cross-linked complexes both for the DNA-binding domain of HNF-1 and the HNF-1 of the nuclear extract. Cross-linking occurred only if a DNA duplex contained a reactive group in position 10. The efficiency of cross-linking was

40% of the non-covalent binding. It has been shown for the first time that cross-linking of a modified substrate with HNF-1 isolated from a nuclear extract occurred in a specific manner and was not accompanied by modification of other components of the nuclear extract. This finding holds much promise for the application of oligonucleotides with substituted pyrophosphate groups in various *in vivo* systems and for creation on their basis of new generations of therapeutic agents.

Compounds with a substituted pyrophosphate group were also used for establishing the contact site for the transcription factor NF- κ B and DNA.⁵⁸

RNA duplexes containing substituted pyrophosphate groups can also be used as reactive derivatives for affinity modification of biopolymers. The interaction of RNA duplexes TAR **75** with the Tat-protein and the Tat-peptide (37–72) of HIV-1 has been studied.⁶³ The RNA–protein complex was incubated for 18–24 h at 10 °C. Cross-linking with the Tat-peptide (37–72) was especially efficient when an RNA duplex containing a modified group in position 38–39 was used. The product yield was 50%. Analysis of the complex revealed that Lys51 of the main region of the Tat-peptide is involved in the formation of a covalent bond.

A first report concerning the successful application of a DNA duplex containing an acyl phosphate group for affinity modification of the p50 subunit of NF- κ B has been published recently.⁶⁴ The DNA duplex **76** containing a reactive acyl phosphate group in position 6 of the κ B region was used for cross-linking with the protein. The efficiency of cross-linking was 10%. Acyl phosphates are acylating reagents.⁵⁷ The group formed as a result of their interaction with nucleophilic amino acids of a protein is carboxamide, which unlike the phosphoramidate is relatively stable in acidic media. The application of nucleic acid analogues with an acyl phosphate group for affinity modification of DNA-recognising proteins may significantly facilitate both the isolation of protein–nucleic acid complexes and subsequent identification of amino acids that react with the reactive group.

Thus, reactive nucleic acids containing substituted pyrophosphate or acyl phosphate groups are successfully employed for the study of nucleic acid–protein interactions. It should be noted, however, that introduction of these groups into the sugar-phosphate backbone of nucleic acids increases the length of the internucleotide bond, which, in turn, may decrease the efficiency of its binding with the protein.⁶¹ This problem can be overcome through the use of nucleic acid duplexes containing reactive groups at other positions of the protein binding site.⁶¹

V. Prospects for the application of reactive oligonucleotides for directed *in vivo* modification of biopolymers

One of the most interesting applications of reactive oligonucleotides is the design on their basis of antiviral and antitumour drugs the effects of which are due to inhibition of gene expression in viral or oncogenic cells. The ability of reactive oligonucleotides to covalently bind to proteins of nucleic acid metabolism may suppress their activity and thus control the expression of the genetic material. It was found⁶⁷ that human tRNA₃^{Lys} containing 4-mercaptouridine residues efficiently interacts with HIV reverse transcriptase to form a cross-linked complex. This interaction results in the block of a region in reverse transcriptase that is responsible for the initiation of reverse transcription of HIV.

Of particular interest is the application of reactive oligonucleotide derivatives in various *in vivo* systems. The first studies in this area revealed a number of limitations related to weak penetrability of these reagents through the cellular membrane and their enhanced sensitivity with respect to cellular exonucleases. Besides, nonspecific modification of functional components of various cell structures by these reagents also presents some problem.⁶⁸ The permeability problem can be circumvented through the use of hydrophobic oligonucleotide derivatives (see

Ref. 69). Several approaches are now used to stabilise DNA fragments in the cell, such as construction of covalently closed dumbbell-like DNA duplexes,⁷⁰ cyclic DNAs,⁷¹ and DNA duplexes with covalently linked chains.⁷²

A serious limitation for the *in vivo* application of a vast number of reactive oligonucleotides is that an additional treatment (UV irradiation, heating, chemical reagents) are required for their activation. Therefore, the most promising reagents for *in vivo* application are apparently platinum derivatives and reactive nucleic acids containing substituted pyrophosphate or acyl phosphate groups. These compounds do not require additional activation; the mechanisms of their interaction with nucleic acid-recognising proteins have been studied in sufficiently great detail. Besides, they have already been used in nuclear cell extracts.^{54, 61} It should be noted, however, that modification of proteins with platinum derivatives of oligonucleotides in nuclear extracts is not always specific.⁵⁴ Besides, this procedure is inefficient unless mercapto derivatives of nucleic acids are used. At the same time, it has been shown⁶¹ that modification of the transcription factor HNF-1 in nuclear extracts of rat liver is highly specific and efficient. This circumstance gives every reason to believe that such compounds are promising for *in vivo* applications. In order to increase their resistance to cell exonucleases, it may be necessary to change their structure, *e.g.*, to design on their basis covalently closed DNA duplexes, or to synthesise DNA duplexes with covalently linked chains. The methods of their synthesis have already been developed^{61, 73–75} and the first encouraging results of the application of structures with substituted pyrophosphate groups for affinity modification of the proteins of nucleic acid metabolism have been obtained.⁷⁶

This study was accomplished within the framework of the programme 'Leading Scientific Schools' (Grant 96–15–97707).

The authors are grateful to the Doctor of Chemistry V K Potapov (Shemyakin and Ovchinnikov Institute of Bioorganic Chemistry) for assistance in writing the review and for valuable discussion.

IV. Chemical properties of 1,2,4-triazine- <i>N</i> -oxides	639
V. Conclusion	646

Abstract. This review deals with the synthesis and properties of 1,2,4-triazine *N*-oxides and their annelated derivatives. Methods for the incorporation of the *N*-oxide group in the 1,2,4-triazine ring by direct oxidation and cyclisation involving nitro, nitroso, and isonitroso groups are discussed. Reactions of 1,2,4-triazine *N*-oxides with electrophiles, nucleophiles, and dienophiles are considered. The effect of the *N*-oxide group on the chemical shifts in the ^1H , ^{13}C , and ^{14}N NMR spectra and the specific features of decomposition of 1,2,4-triazine *N*-oxides under electron impact are analysed. The bibliography includes 107 references.

I. Introduction

The present review discusses methods for the synthesis of 1,2,4-triazine *N*-oxides and reactions of these compounds. 1,2,4-Triazine is a heterocycle incorporated in many natural and synthetic compounds that possess biological activity and many practically useful properties.

The presence of the *N*-oxide group in the azine ring makes it sensitive both to nucleophilic and electrophilic attack and expands substantially the synthetic prospects for modifying nitrogen-containing heterocycles.¹ This is the reason for the ever increasing interest of investigators in heterocyclic *N*-oxides. A series of reviews on the chemistry of pyridine *N*-oxides,² pyrimidine *N*-oxides,³ and quinoxaline *N*-oxides⁴ have been published in the 90s. A monograph⁵ and several reviews^{6–9} on 1,2,4-triazines include special chapters on the chemistry of triazine *N*-oxides. However, data on the methods for the synthesis, reactivity, and properties of these compounds have not been systematised to date. The goal of this review is to bridge this gap.

II. Methods for the synthesis of 1,2,4-triazine *N*-oxides

Two main approaches are used to synthesise azines containing the *N*-oxide fragment. First, oxidation of nitrogen atoms of the ring with organic peracids or hydrogen peroxide in acidic media and, second, closing the azine ring with the participation of nitro,

nitroso, or isonitroso groups to give an *N*-oxide group.¹ Both of these methods are used for the synthesis of 1,2,4-triazine *N*-oxides.

1. Synthesis of 1,2,4-triazine 1- and 2-oxides by oxidation of 1,2,4-triazines

N-Oxides are formed rather readily in reactions of 1,2,4-triazines with organic peracids or hydrogen peroxide in the presence of carboxylic acids. In this case, only two of the three possible isomers are formed, namely, 1- and 2-oxides. The ratio of these isomers depends on the type of substituents in the starting 1,2,4-triazine.

For example, oxidation of 3-amino-1,2,4-triazines **1** gives mainly 2-oxides **2**. 3-Alkoxy-1,2,4-triazines **1** react with organic peracids to give solely 1,2,4-triazine 1-oxides **3**.^{11–14}

Oxidation of 3,5-diaryl-1,2,4-triazines **4** with *m*-chloroperbenzoic acid gives 1,2,4-triazine 1-oxides **5** in 75%–98% yields.¹⁵

$\text{R}^1 = \text{H}, 2\text{-Me}, 3\text{-Me}, 4\text{-Me}, 2\text{-Cl}, 3\text{-Cl}, 4\text{-Cl}, 3\text{-CF}_3$;

$\text{R}^2 = \text{H}, 4\text{-Br}, 2\text{-F}, 3\text{-F}, 4\text{-F}, 4\text{-Cl}, 4\text{-CF}_3$.

5,6-Diamino-3-methylsulfonyl-1,2,4-triazine 1-oxides **7** were prepared under the same conditions from 5,6-diamino-3-methylthio-1,2,4-triazines **6** in 60%–80% yields.¹⁶

$\text{R} = \text{H}, \text{CH}_2\text{Ph}$.

Oxidation of 1,2,4-triazines containing the camphor (compound **8**) or methylcyclopentane fragments (compound **9**)¹⁷ with *m*-chloroperbenzoic acid affords solely triazine 1-oxides **10** and **11**.

The reaction pathway also depends on the temperature. The reaction of 3-phenyl-1,2,4-benzotriazine **12** with peracetic acid affords 3-phenyl-1,2,4-benzotriazine 1-oxide **13** at 50 °C and 2-oxide **14** at 20 °C.¹⁸ Only the 1-oxide **16a** was obtained in 28% yield in the oxidation of 1,2,4-benzotriazine **15a**. Oxidation of 3-methyl-1,2,4-benzotriazine **15b** under the same conditions gives a mixture of 3-methyl-1,2,4-benzotriazine 1-oxide **16b** and 2-oxide **17b** in 25% and 10% yields, respectively.

$\text{R} = \text{H}$ (**a**), Me (**b**).

2. Synthesis of 1,2,4-triazine 1-oxides by cyclisation involving a nitro group

Aromatic and heteroaromatic nitro-compounds containing a guanidine fragment at the *ortho*-position relative to the nitro group readily undergo cyclisation in alkaline or acidic media to give benzo- or hetero-annulated 1,2,4-triazine 1-oxides. For example, 3-amino-1,2,4-benzotriazine 1-oxide **18** was obtained in 1913 by treatment of 2-nitrophenylguanidine **19** with an alkali.¹⁹ Subsequently, this approach was used to synthesise a number of 3-amino-1,2,4-benzotriazine 1-oxides of the type **18**.^{20–27} It is noteworthy that compound **19** can be obtained either by the reaction of guanidine with 2-nitrochlorobenzene **20** or by treatment of compound **20** with sodium cyanamide and dimethylamine (in the latter case, compounds **19** and **20** with $\text{R}^1 = \text{R}^2 = \text{Me}$ are formed).

$\text{X} = \text{H}, \text{Me}, \text{Cl}, \text{Br}, \text{NO}_2, \text{OMe}, \text{CN}$.

In a similar way, 3-amino-1,2,4-triazino[6,5-*c*]quinoline 4-oxides **22** were synthesised in 62%–95% yields by the reaction of 4-chloro-3-nitroquinoline **21** with guanidine followed by cyclisation of substituted guanidines formed in an alkaline medium.²⁸

$\text{R}^1 = \text{H}, \text{Me}; \text{R}^2 = \text{H}, \text{Me}, \text{Et}, \text{Bu}^n, n\text{-C}_{10}\text{H}_{21}, \text{Bn}, (\text{CH}_2)_2\text{NEt}_2$.

The reaction of 4-methoxy-3-nitropyridines **23a,b** with guanidine under similar conditions affords 3-aminopyrido[3,4-*e*]-1,2,4-triazine 1-oxides **24a,b**.²⁹

Cyclisation of *N*-(2-nitrophenyl)-*N'*-benzoylthiourea and its derivatives (compounds **25**) in an alkaline medium affords the corresponding 1,2,4-benzotriazine-3(2*H*)-thione 1-oxides **26**.³⁰

R = H (77%), 5-Cl (72%), 7-Cl (80%), 6-SH (40%), 7-Me (72%), 7-OMe (75%).

The reaction of *o*-nitroaniline and its 4-substituted derivatives (compounds **27**) with cyanamide gives 3-amino-1,2,4-benzotriazine 1-oxides **28**.²²

X = H, Me, OMe, Br, Cl, OPh, CN, NO₂.

3. Preparation of 1,2,4-triazine 4-oxides by cyclisation involving a nitroso or isonitroso group

Unlike 1- and 2-oxides, 1,2,4-triazine 4-oxides **29** are not formed upon direct oxidation of the corresponding 1,2,4-triazines.

Therefore, the only possibility to prepare 1,2,4-triazines with the *N*-oxide group at position 4 is to synthesise the triazine cycle from compounds with nitroso or isonitroso groups. The synthesis can be carried out in several ways.

The reaction of hydroxyamidrazone **30** with dimethylglyoxal **31** in methanol affords 5,6-dimethyl-3-phenyl-1,2,4-triazine 4-oxide **32**.³¹

The condensation of amidrazone **33** with phenylglyoxal monooxime **34** occurs through the formation of hydrazone **35**. The elimination of an ammonia molecule from compound **35** gives 3-methyl-6-phenyl-1,2,4-triazine 4-oxide **36** in a good yield.³¹

If aminoguanidine or *S*-methylisothiosemicarbazide **37** are used instead of amidrazone, 3-amino-1,2,4-triazine 4-oxides are formed. 3-Amino-5-methyl-6-phenyl-1,2,4-triazine 4-oxide **38** was synthesised in this way.^{32,33}

5,6-Diphenyl-1,2,4-triazine 4-oxide **39** was obtained by the reaction of diphenylglyoxal mono-2-ethoxymethylenhydrazone **40** with hydroxylamine.³¹ Obviously, formation of the intermediate **41** followed by its cyclisation to 1,2,4-triazine 4-oxide **39** occurs in this case.

A more promising method for the synthesis of 1,2,4-triazine 4-oxides is the cyclisation of α -hydrazonooximes **42** with ortho-carboxylates or iminoesters. Rather a wide range of 1,2,4-triazine 4-oxides **29** was synthesized using this method.^{31,34-38}

A new, rather simple method for the synthesis of 1,2,4-triazine 4-oxides **49** was suggested recently. It involves the condensation of isonitrosoacetophenone hydrazone **50** with aldehydes followed by oxidation of the condensation product with lead tetraacetate. This is a simple way to obtain 1,2,4-triazine 4-oxides with almost any aliphatic, aromatic, and heteroaromatic substituents at position 3 of the triazine cycle.⁴³

R = Me, Et, Prⁱ, C₇H₁₅, Ph, 4-NO₂C₆H₄, 4-BrC₆H₄,

To prepare fervenulin 4-oxides **47** or toxoflavine 4-oxides **51**, it is convenient to use the reaction of 1,3-dimethyl-2,4-dioxypyrimidin-6-yl hydrazone **52** or *N*-(3-methyl-2,4-dioxypyrimidin-6-yl) *N*-methylhydrazone **53** with potassium nitrate in acetic acid.^{44–48} Sometimes, diethylazo diformate is used instead of potassium nitrate.⁴⁹ In this case, cyclisation occurs simultaneously with the formation of the NO group. Compounds **52** and **53** were synthesised from the corresponding hydrazines **54** and **55** and aldehydes.

3-Anilinofervenulin 4-oxides **47** (R = ArNH) were obtained by the reaction of 6-hydrazino-1,3-dimethyluracil **54** with triethyl orthoformate followed by substitution of the ethoxy group in the resulting hydrazide **56** with an aniline residue and further cyclisation of compound **57** under nitrosation conditions.⁴⁶

R = ArNH = PhNH (51%), 4-ClC₆H₄NH (63%), 4-BrC₆H₄NH (49%), 4-MeOC₆H₄NH (47%), 4-MeC₆H₄NH (56%).

2-Nitrosophenols **58** react with aminoguanidine nitrate in the presence of nitric acid. This method gave 3-amino-1,2,4-benzotriazine 4-oxides **59**.⁵⁰

$R^1 = \text{Cl, Br, Me; } R^2 = \text{H, Me.}$

Reaction of 3-hydrazino-3-methylbutan-2-one oxime **60** with aldehydes and ketones affords 3- R^1 -3- R^2 -1,3,4,6-tetrahydro-5,6,6-trimethyl-1,2,4-triazine 4-oxides **61**.⁵¹

$R^1 = \text{H, Me; } R^2 = \text{H, Me, Pr}^i.$

Condensation of 1-morpholino-6-oximinocyclohexene **62** with hydrazine hydrate and ketones gives 2,3,5,6,7,8-hexahydro-1,2,4-benzotriazine 4-oxides **63**. In the absence of a carbonyl compound, this reaction leads to spiro compound **64**.⁵²

$R^1, R^2 = \text{Me, CH}_2\text{Ph; } R^1 - R^2 = (\text{CH}_2)_5, (\text{CH}_2)_6.$

4. Other methods for the synthesis of 1,2,4-triazine 4-oxides

There is a method for the synthesis of 1,2,4-triazine 4-oxides that is fundamentally different from those discussed above.⁵³ The reaction of nitrones **65** with an excess of hydrazine afforded 4-hydroxy-2,3,4,5-tetrahydro-1,2,4-triazines **66**. Subsequent oxida-

tion with Pb(IV) oxide resulted in the corresponding triazine 4-oxides **29**.

R^1	R^2	R^3	Yield of 29 (%)
Ph	Me	Et	57
Ph	Me	Ph	70
Me	Me	Ph	52
Ph	H	Ph	51

3-Methyl-1,2,4-benzotriazine 4-oxide **67** was obtained by the reaction of benzofurazan oxide **68** with diethylamine.^{54, 55}

III. Physicochemical characteristics of 1,2,4-triazine *N*-oxides

The incorporation of an *N*-oxide fragment in the 1,2,4-triazine molecule changes substantially the ¹H, ¹³C, and ¹⁵N NMR spectra.

In ¹H NMR spectra of 1,2,4-triazine 1-oxides, the signals of the protons at positions 3 and 6 are observed at 9.00 and 8.04 ppm, *i.e.*, they are shifted upfield by 0.6–0.7 and 1.1–1.2 ppm, respectively, in comparison with those in the 1,2,4-triazines, but the signal of the H(5) proton (8.57 ppm) remains almost unchanged.^{10, 14, 56}

A comparison of the ¹H NMR spectra of 1,2,4-triazine 4-oxides with those of the corresponding 1,2,4-triazines shows that the signals of the H(3) and H(6) protons have an almost similar upfield shift ($\Delta\delta = -0.8$ ppm), and their chemical shifts are 8.82 and 8.42 ppm, respectively. The signal of the H(5) proton is also shifted upfield by 0.3 ppm ($\delta = 8.00$ ppm) (Table 1).¹⁰

Table 1 Chemical shifts of cyclic protons in the ¹H NMR spectra of 1,2,4-triazines and their *N*-oxides in CDCl₃.

3-(<i>N,N</i> -Dimethylamino)-1,2,4-triazine 1-oxide		7.76	7.86		−0.38	−0.65	10
3-Morpholino-1,2,4-triazine		8.14	8.54				57
3-Morpholino-1,2,4-triazine 2-oxide		7.81	8.54		−0.33	−0.52	10
6-Methyl-1,2,4-triazine	9.55	8.55					31
6-Methyl-1,2,4-triazine 4-oxide	9.28	8.22		−0.27	−0.33		31
6-Phenyl-1,2,4-triazine	9.52	8.91					31
6-Phenyl-1,2,4-triazine 4-oxide	9.31	8.60		−0.21	−0.31		31

^a In [²H₆]DMSO.

The incorporation of an *N*-oxide group at position 4 of the triazine system shifts the signals of the H(3) and H(5) protons upfield by 0.1–0.3 ppm (the 9.28–9.47 and 8.55–8.90 ppm regions). It should be noted that, unlike the case of 1,2,4-triazines, these signals in 1,2,4-triazine 4-oxides appear as doublets ($J = 1.8$ Hz) (see Table 1).³¹

The ¹³C NMR spectra are also changed upon the introduction of the *N*-oxide fragment. In 1,2,4-triazine 4-oxides, the signals of the carbon atoms in the *ortho*- and *para*-positions with respect to the N–O fragment are shifted upfield by 18–20 ppm for 1-oxides, 9–18 ppm for 2-oxides, and 10–15 ppm for 4-oxides in comparison with those of the corresponding 1,2,4-triazines,^{39, 58–62} but the signal of the carbon atom in the *meta*-position is almost not shifted (Table 2).^{10, 39}

Thus, comparison of the ¹³C NMR spectra of 1,2,4-triazines and their oxides allows one to determine easily the position of the *N*-oxide group.

¹⁵N NMR spectroscopic data also allow the determination of the position of the *N*-oxide group. On going from 1,2,4-triazines to their 1-oxides, the maximum upfield shift is observed for the nitrogen atom in position 1 [$\Delta\delta = -(83-87)$ ppm]. The signals of the N(2) and N(4) atoms are shifted upfield to a much smaller extent [$\Delta\delta = -(39-46)$ ppm and $\Delta\delta = -(22-24)$ ppm, respectively]. For 1,2,4-triazine 2-oxides, the situation is somewhat different. The signals of the N(1) and N(2) atoms are shifted upfield by almost the same value [$\Delta\delta = -(70-75)$ ppm], but the signal of the nitrogen atom in position 4 is almost not shifted [$\Delta\delta = -(13-23)$ ppm] (Table 3).^{63–65}

The IR spectra of 1,2,4-triazine *N*-oxides,⁵³ as well as those of *N*-oxides of other azines,¹ contain a characteristic band of stretching vibration of the N–O group in the region near 1250 cm^{–1}.

The absorption maximum in the UV spectrum of 3,4-diphenyl-1,2,4-triazine 4-oxide is around 286 nm ($\log \varepsilon = 4.57$).⁵³

^a In CDCl₃.

A molecular ion peak (often with the maximum intensity) and intense $[M - 16]^+$ and $[M - 17]^+$ peaks typical of this class of compounds are observed in the mass spectra of 1,2,4-triazine 1- and 2-oxides. The fragmentation of 1,2,4-triazine 1- and 2-oxides is similar, which prevents an unambiguous determination of the position of the *N*-oxide group.^{62, 66, 67} However, a somewhat different picture is observed in the case of 1,2,4-triazine 4-oxides. The characteristic feature of their mass spectra is the existence of an intense molecular ion peak and a very weak $[M - 16]^+$ peak.³¹

The X-ray diffraction data for 3,6-diphenyl-5-(indol-3-yl)-1,2,4-triazine 4-oxide⁶² showed that the 1,2,4-triazine 4-oxide fragment and the substituents are non-coplanar, the slopes of the corresponding planes being within 30–50°.

IV. Chemical properties of 1,2,4-triazine-*N*-oxides

1. Tautomerism

The amino–imino tautomerism is typical of 3-amino-1,2,4-triazine 4-oxides **2a**. This is the reason for the formation of 2-oxides in the oxidation of 3-amino-1,2,4-triazines **1**.¹⁰

3-Azido-1,2,4-benzotriazine 1-oxides **69** exist only in the form of azides, both in the crystal state and in solution. This is also true for 3-azido-1,2,4-triazine 1-oxides **70**, which have not been found in the tetrazole form in any aggregation state.^{68–70}

Ring–chain tautomerism is observed for the series of 1,2,3,6-tetrahydro-1,2,4-triazine 4-oxides **61**.⁵¹ These compounds exist solely as hydrazones **61b** both in solution and in the crystal form. In aprotic non-polar solvents (*e.g.*, CCl₄), the fraction of the cyclic form **61a** is as high as 45%, depending on the nature of the substituents R¹ and R².

Ring–chain transformations are also observed for 3,4-dihydro-4-hydroxy-1,2,4-triazines **71**. For example, compounds **71** in DMSO-*d*₆ exist both in a cyclic form **71a** and in an open form **71b**. It was found that aliphatic substituents at position 3 of 3,4-dihydro-1,2,4-triazine **71** shift the equilibrium towards the cyclic form **71a**, while aromatic and heteroaromatic substituents, towards the open form **71b** (Table 4). An increase in temperature increases the fraction of hydrazone **71b**. Analysis of high-resolution mass spectra of these compounds made it possible to find out that the cyclic form **71a** prevails (70%–90%) in the gas phase.⁷¹

Table 4. Ratio of the cyclic (**71a**) to the open (**71b**) forms of 3,4-dihydro-4-hydroxy-6-phenyl-1,2,4-triazine **71** in [2H₆]DMSO and in gas phase.⁷¹

R ¹	R ²	R ³	Isomer ratio (%)

2-Phenyl-1,2,4-benzotriazin-3(2*H*)-one 1-oxide **72**, which exists in the cyclic form **72a** when in the crystal, undergoes ring opening in solution to give 2-isocyanatoazoxybenzene **72b**.⁷²

2. Deoxygenation

Elimination of oxygen (deoxygenation) occurs in 1,2,4-triazine *N*-oxides, as well as in other azine *N*-oxides, upon treatment with reducing agents.

The reaction of 1,2,4-triazine *N*-oxides **29** with triethylphosphine or PCl₃ resulted in the corresponding 1,2,4-triazines **1** (in 65%–95% yield), which were impossible to synthesise by other methods.^{31, 35} If POCl₃ is used in this reaction, deoxygenation is accompanied by chlorination of 1,2,4-triazine. For example, 5-chloro-6-phenyl-1,2,4-triazine **73** was obtained in 37% yield from 6-phenyl-1,2,4-triazine 4-oxide.⁷³

Sodium dithionite can be used for the reduction of 1,2,4-triazine 4-oxides. This method has been used in the synthesis of fervenulins **74** from fervenulin 4-oxides **47**⁴¹ and 3-bromo-1,2,4-benzotriazines **76** from 3-bromo-1,2,4-benzotriazine 4-oxides **75**.⁶⁹ Boiling of fervenulin 4-oxide **47** in DMF results in its thermal deoxygenation to form fervenulin **74**.⁴⁰

(a): Na₂S₂O₄ (55%–90%); (b): DMF, 150 °C (60%).

The reaction of 3-morpholino-1,2,4-benzotriazine 4-oxide **77** with zinc in hydrochloric acid afforded 3-morpholino-1,2,4-benzotriazine **78**.⁷⁴

UV irradiation of 3-aminopyrido[4,3-*e*]-1,2,4-triazine 1-oxides **24a,b** or 1,2,4-triazine 4-oxides **29** is also accompanied by the loss of the *N*-oxide group^{75,76} and gives the corresponding 3-aminopyrido[4,3-*e*]-1,2,4-triazines **79a,b** or 1,2,4-triazines **1**.

X = H (**a**), Cl (**b**).

The reaction of 2,3-dihydro-6-phenyl-1,2,4-triazine 4-oxide **80** with acetic anhydride leads to deoxygenation and aromatisation of the former to give 6-phenyl-1,2,4-triazine **81**.⁷⁷

3. Reaction with electrophilic agents

a. Alkylation

The reaction of 3-amino-1,2,4-triazine 1-oxide **82** with methyl iodide in the presence of sodium bicarbonate results in methylation of the amino group to give 3-methylamino-1,2,4-triazine 1-oxide **83**. In neutral media, the N(3) atom of the cycle in 1,2,4-triazine 1-oxide **82** undergoes methylation resulting in 3-imino-2-methyl-1,2,4-triazine 1-oxide **84**. It is interesting that 1-oxide **83** undergoes rearrangement to 1-oxide **84** in methanol in the presence of methyl iodide.

3-Methoxy-1,2,4-triazine 1-oxide **85** undergoes the same rearrangement under the same conditions and transforms into 2-methoxy-1,2,4-triazin-3-one **86**.⁷⁸

An abnormal nucleoside, 4-(β-D-ribofuranosyl)-1,2,4-triazin-3(4*H*)-one 1-oxide **87**, was obtained in 38% yield by the reaction of 2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl bromide with 3-methoxy-1,2,4-triazine 1-oxide **88** followed by the removal of the benzoyl protective groups with sodium methoxide.¹¹

The reaction of the sodium salt of pyrido[2,3-*e*]-1,2,4-triazine-3(4*H*)-one 1-oxide **89** (X = N) or 1,2,4-benzotriazine-3(4*H*)-one 1-oxides **89** (X = CH) with acetobromoglucose allows one to obtain the tetraacetyl derivatives of β-D-glucopyranosides **90**, the deacetylation of which affords nucleosides **91**.⁷⁹

R = Me; X = CH.

The reaction of compounds **89** (X = CH; R = H, Me) with 2-chloromethoxyethyl acetate results in *N*-alkylation products **92a,b**. Their subsequent hydrolysis affords 4-(2-hydroxyethoxymethyl)-1,2,4-benzotriazin-3(4*H*)-one 1-oxides **93a,b**.⁷⁹

R = H (a), Me (b).

3-Amino-1,2,4-benzotriazine 1-oxide **94** undergoes the Chichibabin reaction with bromoacetaldehyde to give imidazo[2,1-*c*]-1,2,4-benzotriazine 1-oxide **95**.⁸⁰

Reactions of 3-hydrazino-1,2,4-triazine 1-oxide **96** or 3-hydrazinopyrido[2,3-*c*]-1,2,4-triazine 1-oxide **97** with diethoxymethyl acetate or triethyl orthoformate followed by cyclisation afford the corresponding pyrazolo[3,4-*c*]-1,2,4-triazine 6-oxides **98** and **99**.^{81–83}

b. Electrophilic substitution of hydrogen

Halogenation of 3-*R*-1,2,4-triazine 1- and 2-oxides has been described.^{67,84} The reaction of 3-methoxy and 3-amino(alkylamino)-1,2,4-triazine 1-oxides **100** with chlorine or bromine in CCl_4 in the presence of triethylamine results in the corresponding 6-chloro- or 6-bromo-1,2,4-triazine 1-oxides **101**.

X = Cl, Br; R = OMe, NH_2 , NHMe , NMe_2 .

Halogenation of 3-methoxy- and 3-methyl(dimethyl)amino-1,2,4-triazine 2-oxides **102** occurs in a similar way to give 6-halo-derivatives **103**.

X = Cl, Br; R = OMe, NHMe , NMe_2 .

c. Other reactions

1-(Dimethylamino)-1-ethoxyethylene acts as an electrophilic agent in the reactions with 1,2,4-triazine 4-oxides **104** and **105** containing a methyl group at position 5 and/or 6. The addition of an olefin to the methyl group followed by elimination of ethanol results in the corresponding (2-dimethylamino)-1-propenyl-1,2,4-triazine 4-oxides **106** and **107**.⁸⁵

The reactivity of the hydrogen atoms of the methyl group in 1,2,4-triazine 4-oxide **36** allows one to make this compound react with nitrobenzaldehydes. This reaction gave 3-[2-(*R*-nitrophenyl)-vinyl]-6-phenyl-1,2,4-triazine 4-oxides **108**.⁷⁶

R = 2- NO_2 (27%), 3- NO_2 (47%), 4- NO_2 (48%).

The reaction of 3-hydrazino-1,2,4-triazine 1-oxides **109** with nitrous acid affords 3-azido-1,2,4-triazine 1-oxides **110**.^{68,84}

R = H (80%), Me (82%), Ph (85%).

4. Reactions with nucleophilic agents

a. Nucleophilic substitution of readily leaving groups

Substitution of nucleofugal groups is a widespread method for the modification of 1,2,4-triazine *N*-oxides. The reaction of 3-methoxy-5-phenyl-1,2,4-triazine 1-oxide **111** with ammonia afforded 3-amino-5-phenyl-1,2,4-triazine 1-oxide **112**. The reaction of 3-methoxy-1,2,4-triazine 1-oxide **87** with hydrazine results in 3-hydrazino-1,2,4-triazine 1-oxide **113**.¹⁴

7-Methyl-1,2,4-benzotriazin-3(4*H*)-one 1-oxide **114** can be obtained in a good yield by replacement of the diazo group by OH in 3-diazo-7-methyl-1,2,4-benzotriazine 1-oxide **115**, which is formed upon the reaction of the corresponding amino derivative **116** with nitrous acid.⁷⁹

Similarly, diazotisation of 3-amino-1,2,4-triazine 2-oxides **117** or 1-oxides **118** results in the replacement of the diazo group by a halogen on treatment with hydrochloric or hydrobromic acids and affords the corresponding 2-oxides **119**¹⁰ or 1-oxides **120**.⁶⁹

X = Cl: R = H (34%), Me (32%), Ph (26%); X = Br, R = H (47%).

R¹, R² = H, Me.

In turn, the halogen atom can be replaced by a different functional group. 3-Methoxy-1,2,4-triazine 2-oxide **85** (R = H) was obtained by the reaction of 3-bromo-1,2,4-triazine 2-oxide **119** with sodium methoxide. When secondary amines are used as nucleophiles, 3-amino-derivatives of 1,2,4-triazine 2-oxides **121a–e** are formed. 3-Hydrazino-1,2,4-triazine 2-oxide

R¹ = H, Me; X = Br.

Compound	R ¹	NR ₂ ²	Yield (%)	Ref.
85	H		10	10
121a	H		95	10
121b	Me		90	10
121c	H		93	10
121d	H		95	10
121e	H	NMe ₂	93	10
122	H		69	10
123	H		27	10
124	H		86	68

122 was synthesised by the replacement of bromine in 2-oxide **119** by hydrazine. The subsequent oxidation of compound **122** with Mn(IV) oxide afforded 1,2,4-triazine 2-oxide **123**,¹⁰ but the reaction of compound **119** with sodium azide gave 3-azido-1,2,4-triazine 2-oxide **124**.⁶⁸

Reactions of 3-chloro- or 3-methylthio-1,2,4-benzotriazine 1-oxides **125a,b** with amines result in 3-amino-derivatives of 1,2,4-benzotriazine 1-oxides **126**.^{24, 74, 86, 87} Replacement of the halogen in 3-chloro-1,2,4-benzotriazine 1-oxide **125a** upon the reaction with methyl 2-(4-hydroxyphenoxy)propionate proceeds in a similar way. For example, compound **127** was synthesised by this method.^{88, 89}

X = Cl (a), SMe (b).

Replacement of chlorine in the 3-chloro-derivative **125a** on treatment with sodium cyanide in methanol affords 3-methoxy-1,2,4-benzotriazine 1-oxide **128**.⁹⁰

b. Nucleophilic substitution of hydrogen

The mechanism of the nucleophilic substitution of hydrogen (S_NH) in 1,2,4-triazine *N*-oxides has been studied in most detail using 1,2,4-triazine 4-oxides **29** as an example. This mechanism is common to all 1,2,4-triazine 4-oxides. The reactions of nucleophilic substitution of hydrogen in 4-oxides **29** occur according to the 'addition–elimination' scheme; the process can stop at the step of addition to form adducts **129**. Due to the low probability of the elimination of such a particle as a hydride ion,⁹¹ aromatisation of these adducts can follow several paths.

Oxidative aromatisation leads to products of the S_NH-reaction of the type **130** [Scheme 1, pathway (a)]. Auto-aromatisation of the σ^H-adducts in two directions is also possible. For example,

Scheme 1

1,2-elimination of HX is possible in nucleophiles carrying a vicarious nucleofugal group X. In this case, a hydrogen atom is eliminated from the substrate and the X group is eliminated from the reactive fragment of the σ^H -adduct **131** [Scheme 1, pathway (b)]. Makosza⁹² named such reactions vicarious nucleophilic substitution.

Another variant of auto-aromatisation is the elimination of the HOE molecule from the σ^H -adduct **129** which is formed from the cationic derivatives of 1,2,4-triazine *N*-oxides [Scheme 1, pathway (c)]. In this case, S_NH-substitution is accompanied by the loss of an oxygen atom. It should be noted that both the hydrogen atom and the vicarious OE group are eliminated from the substrate fragment of the intermediate. Conceptually, mediated (vicarious) nucleophilic substitution of hydrogen atom is observed in this case. Sometimes, the σ^H -adducts exist in a non-cyclic form. The ring opens readily after the addition of a nucleophile to the 1,2,4-triazine 4-oxide. This process is reversible and the equilibrium is shifted towards the open form **132** [Scheme 1, pathway (d)]. In this way, the σ^H -adduct is eliminated from the reaction; however, it exists in quasi-steady-state concentrations and can be easily oxidised to the corresponding 1,2,4-triazine 4-oxide.

Oxidative aromatisation [see Scheme 1, path (a)] is achieved by the amination of 6-phenyl-1,2,4-triazine 4-oxide **133** with liquid ammonia in the presence of potassium permanganate as the oxidising agent. The reaction affords 5-amino-6-phenyl-1,2,4-triazine 4-oxide **134**.⁹³

The reaction of 6-aryl-1,2,4-triazine 4-oxides **135** with phenol, 2,6-dimethylphenol, resorcinol and phenetol in the presence of trifluoroacetic acid results in stable σ^H -adducts, 6-aryl-2,4-dihydro-4-hydroxy-5-Nu-1,2,4-triazines **136** (Nu = 2-hydroxy-, 2-ethoxy-, 4-ethoxy- or 2,4-dihydroxyphenyl). The reaction of resorcinol (R² = R⁴ = OH, R³ = R⁵ = H) with a twofold excess of triazine *N*-oxide **135** (R¹ = H, Ar = Ph) affords 4,6-bis(4-hydroxy-6-phenyl-1,2,4-triazin-5-yl)resorcinol **137**.⁹⁴

The formation of σ^H -adducts in S_NH-reactions of azine *N*-oxides was confirmed directly for the first time by the isolation and identification of compounds **136**. Before that, it was only postulated in the discussions of the mechanism of such reactions.

Dihydro-1,2,4-triazines **136** are rather stable compounds. Boiling in butanol, DMF, or trifluoroacetic acid does not result in their thermal dehydration [see Scheme 1, pathway (c)]. At the same time, their oxidative aromatisation [pathway (b)] occurs readily and in high yields. For example, compounds **136** react with potassium permanganate in acetone to form 6-aryl-5-(4-hydroxyphenyl)-1,2,4-triazine 4-oxides **138**.⁹⁴

Ar = Ph, *p*-ClC₆H₄; R¹ = H, Me; R², R³, R⁴, R⁵ = H, OH, OEt.

3-R¹-6-phenyl-1,2,4-triazine 4-oxides **49** react with indole or its 1- or 2-methyl derivatives in a similar way. When the reaction is carried out in the presence of trifluoroacetic acid, stable 4-hydroxy-5-(indol-3-yl)-6-phenyl-4,5-dihydro-1,2,4-triazines are formed.⁶² They were isolated both as trifluoroacetates **139** and as free bases **140**. Oxidative aromatisation of the σ^H -adducts obtained with potassium permanganate in acetone affords 3-R¹-5-(indol-3-yl)-6-phenyl-1,2,4-triazine 4-oxides **141**.⁶²

The reaction of 3-methoxy-1,2,4-triazine 1-oxide **87** with chloromethyl phenyl sulfone gives an intermediate adduct, whose further aromatisation [see Scheme 1, path (b)] leads to 3-methoxy-5-(phenylsulfonyl)-1,2,4-triazine 1-oxide **142** in 70% yield.⁹⁵

Another variant of auto-aromatisation occurs in the reaction of 3-amino-1,2,4-triazine 2-oxides **143** with alcohols in the presence of HCl or acetyl chloride. Elimination of water or acetic acid from the adduct **144** results in 3-amino-6-alkoxy-1,2,4-triazines **145a–e**.⁸⁴

It should be noted that 1,2,4-triazine 1-oxides do not react with alcohols under these conditions.⁸⁴

6-Chloro(bromo)-3-amino-1,2,4-triazines **146a–f** were obtained on passing gaseous hydrogen chloride or hydrogen bromide through a solution of 3-amino-1,2,4-triazine 2-oxide **143**.⁶⁷

Compound	R^1	$R^2\text{O}$	X	Yield (%)	Ref.
145a	NH ₂	OMe		71	84
145b	NH ₂	OEt		64	84
145c	NHMe	OMe		50	84
145d	NMe ₂	OMe		51	84
145e	NH ₂	OPr ⁱ		65	84
146a	NHMe		Cl	85	68
146b	NMe ₂		Cl	64	67
146c			Cl	80	67
146d			Cl	50	67
146e	NHMe		Br	25	67
146f	NMe ₂		Br	41	67

Acyl salts of 1,2,4-triazine 4-oxides **147** synthesised by the reaction of benzoyl chloride with the corresponding 1,2,4-triazine 4-oxides **148** react with water according to pathway (c) (Scheme 1). It is evident that after addition of the nucleophile at position 5 of the triazine ring, auto-aromatisation of the adduct occurs with elimination of benzoic acid and formation of 1,2,4-triazin-5-ones **149**.⁷⁶

The reaction of 1,2,4-triazine 4-oxides **49** with acetone cyanohydrin in the presence of triethylamine affords 5-cyano-1,2,4-triazines **150**.⁹⁶

If potassium cyanide in alcohols (ethanol, propanol, isopropanol) is used as a cyanating agent, 5-alkoxy-1,2,4-triazines **151** are formed in 80%–90% yields. Their formation can be explained by replacement of the cyano group by an alkoxy. In fact, 5-cyano-1,2,4-triazines **152** slowly react with ethanol at room temperature to give 3- R^1 -6-phenyl-5-ethoxy-1,2,4-triazines **151**.⁹⁶

The reaction of 1,2,4-triazine 4-oxide **153** with indole or 2-methylindole in boiling butanol in the presence of trifluoroacetic acid is accompanied by auto-aromatisation of the products of addition of the nucleophile to the 1,2,4-triazine 4-oxide and results in 5-(indol-3-yl)- and 5-(2-methylindol-3-yl)-3,6-diphenyl-1,2,4-triazines **154**.⁹⁷

The reaction of 6-aryl-1,2,4-triazine 4-oxides **155** with dialkylamines or cycloalkylamines occurs by pathway (d) (Scheme 1).⁹⁸ The adducts **155a**, which are in equilibrium with the open-chain form, *N,N*-disubstituted 3-aryl-1,4,5-triaza-1,3,5-hexatrien-1-ols **155b**, are formed in the first step. In this case, the equilibrium is shifted towards the compounds **155b**. In spite of the low concentration of the form **155a**, oxidation of the compounds **155** with potassium permanganate in solution affords 3-amino-6-aryl-1,2,4-triazine 4-oxides **156**. It is noteworthy that it is possible to withdraw the cyclic tautomer from the reaction zone, which allows one to obtain the products of hydrogen substitution at position 3 of the triazine system when the position 5 is free. Such a substitution has been carried out for the first time. Note that all the experimental data obtained until now have indicated that position 5 is the most reactive in 1,2,4-triazines and their oxides.^{5–8}

c. Reaction of 1,2,4-triazine *N*-oxides with nucleophiles accompanied by destruction of the ring

In addition to the formation of nucleophilic substitution products, the reaction of 1,2,4-triazine *N*-oxides with nucleophiles results in the opening, narrowing, or fragmentation of the 1,2,4-triazine ring. For example, the reaction of 3-methyl-1,2,4-benzotriazine 1-oxide **16b** with phenylmagnesium bromide affords 2-phenylazoacetanilide **157**.⁹⁹

The reaction of fervenulin 1-oxides **158** with secondary amines results in narrowing of the triazine ring and formation of 2-amino-5,7-dimethylimidazo[4,5-*e*]pyrimidine-4,6(5*H*,7*H*)-diones **159**. The reaction of the same *N*-oxide with ammonia affords 1,3-dimethyl-5-imino-6-isonitrosouracil **160**.¹⁰⁰

1,2,4-Triazine 4-oxides undergo hydrolysis both in acidic and basic media. For example, in the presence of 2 M KOH, opening of the triazine ring in 1,2,4-triazine 4-oxides **29** occurs with the formation of *N'*-(2-hydroxyiminoethylidene)hydrazides of carboxylic acids **161**. Hydrolysis of the 4-oxides **29** in acid media

results in narrowing of the 1,2,4-triazine ring to 1,2,3-triazole, in particular, in the formation of the compound **162**.⁷⁶

The reaction of fervenulin 4-oxide **47a** with hydrogen chloride in ethanolic solution leads to the opening of the triazine ring and the formation of 1,3-dimethyl-5-nitroso-6-hydrazouracil **48**. In fact, this reaction is reverse to that for the synthesis of the fervenulin 4-oxide.^{40, 101}

Reactions of the fervenulin 4-oxide **47a** with CH-active compounds are also accompanied by the destruction of the triazine ring.

$\text{X}, \text{Y} = \text{CO}_2\text{Et}, \text{COMe}; \text{X} = \text{NO}_2, \text{Y} = \text{CO}_2\text{Et}.$

In this case, 1,3-dimethyl-5-nitroso-6-(*N'*-ethen-1-ylhydrazino)uracils **163** are formed.¹⁰² Fervenulin 4-oxide **47a** reacts with amines or indoles in a similar way. The nucleophilic attack is accompanied by opening of the 1,2,4-triazine ring and formation of 6-aminomethylenehydrazino-1,3-dimethyl-5-nitrosouracil **164**¹⁰³ or 1,3-dimethyl-5-nitroso-6-[*N'*-(indol-3-yl)methylidenehydrazino]uracil **165**.^{104, 105}

The reaction of 3,6-diphenyl-1,2,4-triazine 4-oxide **153** with benzoylacetone under basic catalysis conditions (DMSO, NEt_3) affords 1,2,4-triazine **166** in 9% yield and bis(1,2,4-triazin-5-ylmethane) **167**.⁹⁷ According to literature data,⁹⁷ the 1,3-dimethyluracil derivative **168** with two reactive centres reacts with the *N*-oxide **153** at the uracil fragment only to form compound **169**.

5. Reactions with dienophiles

The direction of the reaction of 1,2,4-triazine *N*-oxides with dienophiles differs substantially from that for 1,2,4-triazines. 1,2,4-Triazine 4-oxides **147** act as 1,3-dienes only in the reaction with *N,N*-diethyl-*N*-(1-propynyl)amine giving 2-*R*²-5-methyl-4-(dimethylamino)pyrimidines **170**. The reaction of these 1,2,4-triazine 4-oxides with 1-(dimethylamino)-1-ethoxyethylene occurs as 1,3-dipolar cycloaddition to produce the corresponding 5-methyl-1,2,4-triazines **171**.⁸⁵

The reaction of the fervenulin 4-oxide **47a**, which is not substituted at position 3, with dimethyl acetylenedicarboxylate in various solvents affords compounds **172–174**.

If methyl propionate is used as the reagent, 6-formyl-7-(methoxycarbonyl)-1,3-dimethylpyrrolo[3,2-*d*]pyrimidine-2,4(1*H*,3*H*)-dione **175** is formed.

A similar reaction of 3-substituted fervenulin 4-oxides **47** (*R* = Me, Et, Ph) with alkyl acetylenedicarboxylates gives compounds **176**.

A — MeO₂CC≡CCO₂Me; B — MeO₂CC≡CH.

The reaction of fervenulin 4-oxides **47** with ethyl phenylpropionate also follows the pathway described above to give, depending on the presence of a substituent at position 3, 6-benzoyl- or 6-*R*-5-benzoyl-7-(ethoxycarbonyl)-1,3-dimethylpyrrolo[3,2-*d*]pyrimidine-2,4(1*H*,3*H*)-diones **177** and **178**, respectively.^{106, 107}

V. Conclusion

A variety of methods for the synthesis and subsequent transformations of 1,2,4-triazine *N*-oxides makes these compounds very promising for the preparation of new 1,2,4-triazines with or without the *N*-oxide group. Methods of direct functionalisation of unsubstituted triazines (S_NH-processes) and their transformations under the action of nucleophilic agents and dienophiles resulting in azapyrines are of undisputable interest for the synthesis of new biologically active compounds.

Complexes of natural carbohydrates with metal cations

Yu E Alekseev, A D Garnovskii, Yu A Zhdanov

Contents

I. Introduction	649
II. Complexes of mono-, oligo-, and poly-saccharides and their derivatives	649
III. Complexes of cyclodextrins	656
IV. Complexes of nitrogen-containing natural carbohydrates	657
V. Complexes of natural acids of the carbohydrate origin	659
VI. The significance and applications of metal coordination to carbohydrates	660
VII. Conclusion	663

Abstract. Data on the interaction of natural carbohydrates (mono-, oligo-, and poly-saccharides, amino sugars, and natural organic acids of carbohydrate origin) with metal cations are surveyed and described systematically. The structural diversity of carbohydrate metal complexes, caused by some specific features of carbohydrates as ligands, is demonstrated. The influence of complex formation on the chemical properties of carbohydrates is discussed. It is shown that the formation of metal complexes plays an important role in the configurational and conformational analysis of carbohydrates. The practical significance of the coordination interaction in the series of carbohydrate ligands is demonstrated. The bibliography includes 571 references.

I. Introduction

Metal complexes of natural carbohydrates have been attracting interest for many years because these compounds participate in vitally important processes; they are used for configurational and conformational analysis, determination, and separation of sugars. According to our estimates, at least 1000 studies discussing various aspects of complex formation between metal ions and natural carbohydrates (mono-, oligo-, and polysaccharides, amino sugars, their polymers, carbohydrate carboxylic acids, natural organic acids of the carbohydrate origin, and cyclic and acyclic polyols) have been published.² However, even the most comprehensive monographs dealing with the chemistry of coordination compounds¹ or carbohydrates² do not consider carbohydrates to be ligands. Several reviews published to date^{3–16} cover only some aspects of this topic.

The purpose of this review is to survey as fully as possible the published data on the known complexes of natural carbohydrates

with metal cations; therefore it includes both recent studies and the most important of early studies. The formation of complexes by nucleosides and nucleotides is beyond the scope of the review, because the carbohydrate fragments of these molecules normally do not participate in the coordination of metals. Moreover, this aspect has been the subject of numerous reviews and monographs (see, for example, Refs 17, 18). The few known examples in which the carbohydrate fragments of nucleotides and nucleosides are involved in the formation of complexes with metals are presented in Section IV.

Data on the formation of metal complexes in the series of natural carbohydrates are mainly discussed in relation to reliably established structures. The information is classified according to the type of carbohydrates. Within each type, metal cations are arranged in accordance with their electronic configuration (*s*-, *p*-, *d*-, and *f*-metals) and their position in the Mendeleev Periodic Table.

II. Complexes of mono-, oligo-, and poly-saccharides and their derivatives

1. Ionic complexes with *s*-metal cations

The first review⁶ on the complexation of carbohydrates with *s*-metal compounds was published in 1966, and now it is only of historical interest. X-Ray diffraction data for metal complexes of this type can be found in a number of reviews (see, for example, Refs 19–23) including a review devoted to saccharose.²⁴ The data on the structures of solid ionic metal complexes obtained up to the middle of 1978 are surveyed most fully in the review by Poonia and Bajai.¹¹

A systematic study of the structures of complexes of monosaccharides with *s*-metal cations in aqueous solutions carried out by Angyal^{7,8,12} has demonstrated that complexes of 1:1 composition predominate. In the case of cyclic forms of ligands, the most stable complexes are those with the axial–equatorial–axial orientation of three consecutively located hydroxyl groups in the ligand (complex **1a**, the first Angyal rule) or those with the energetically unfavourable triaxial orientation of these groups (complex **1b**, the second Angyal rule). Acyclic derivatives obey the first Angyal rule (complex **2**), while furanoses obey the second rule (complex **3** with a quasixial orientation of the hydroxyl groups). These rules were derived using ¹H NMR spectroscopy, *i.e.* they were first formulated for relatively con-

centrated solutions. Their validity for dilute solutions was confirmed later by calorimetry.²⁵

X = O, CHO; $z = 1, 2$.

Complex formation can shift the position of a tautomeric or conformational equilibrium for a ligand in an aqueous solution.^{7,8,12} The stability constants of the complexes are relatively low (0.1–6.0).^{7,8,12,16,26–30} The ability of *s*-metals to form complexes with disaccharides is less pronounced than that for monosaccharides.^{31,32} Evidently, this is due to the higher conformation rigidity of the former. The stability constants of *s*-metal complexes of monosaccharide carboxylic acids are only an order of magnitude larger.^{33–35} Thus, this complexation is very weak although fairly stereospecific. In solvents that are less polar than water (methanol, acetone, dioxane), these complexes are more stable because there are no water molecules to compete with the ligands for coordination to metal cations.³⁶

The formation of these ionic metal complexes is usually regarded^{7,11} as consecutive substitution of water molecules in the hydration shell of a metal ion by hydroxyl groups of the ligand, the optimum number of these groups (three) being determined by the Angyal rules. During the formation of solid complexes, this process is continued with participation of other ligand molecules, but does not go to completion. The data for a number of solid complexes of sugars with *s*-metal salts obtained by X-ray diffraction analysis^{10,15,37–45} and by IR spectroscopy^{46–53} permit the following general conclusions.

1. Carbohydrates act most often as bidentate ligands coordinated through vicinal diol fragments, which can be different in identical ligands. In some cases, the formation of a complex ends with incorporation of a monodentate ligand.^{38,54} Complexes of acyclic aldonic acids can contain only monodentate ligands.^{55,56}

2. Since there are only three known examples^{57–59} of tridentate coordination of cyclic ligands conforming to the first Angyal rule, one can conclude that this rule is not necessary for solid ionic metal complexes of sugars. At the same time, sugars containing no vicinal hydroxyl groups characterised by an axial–equatorial–axial arrangement (α -D-glucopyranose **4a**) do not form complexes of this type.¹¹

3. As a rule, these complexes are crystal hydrates in which all water molecules are coordinated to metal ions.

4. The complexes normally contain two or three ligands, although in some cases they contain only one ligand.^{60,61} In the case of acyclic carbohydrate derivatives, the number of ligands increases to four^{62,63} or even to six.^{55,56} The number of ligands in less studied disaccharide complexes is two^{44,64–67} or one.⁶⁸

5. After complexation, the coordination number of the metal remains approximately the same as that in the first coordination sphere of the initial hydration shell of the metal cation; most frequently it is equal to eight (square antiprism), six (octahedron), seven (pentagonal bipyramid), or nine (three-cap trigonal prism).¹³ The coordination polyhedra formed by calcium(II) ions are especially diverse.³⁹

6. In the majority of complexes of carbohydrate carboxylic acids, a metal ion is coordinated to an oxygen atom of the carboxyl group and to the hydroxyl group in the α -position (α -type coordination⁶⁹). Only in complexes with these ligands, can the ring oxygen atom be involved in coordination.⁷⁰

7. Conformational changes in the ligand following the complex formation are typical of neutral carbohydrates and normally reduce to the change in the conformation of the coordinated primary hydroxyl group⁴⁴ or in the dihedral angle between the coordinated vicinal hydroxyl groups.¹¹ In anionic ligands, coordination

mostly involves the carboxyl group; this substantially decreases electrostatic interactions between the hydroxyl groups responsible for the conformational changes.^{11,64}

8. The cation and the anion of the metal salt are coordinated separately and, thus, they are relatively far removed from each other. There is only one known example⁴⁵ of formation of a complex in which a salt occurs as a contact ion pair.

9. The majority of the complexes studied are calcium compounds, while the smallest number is represented by magnesium compounds. The particular affinity for calcium is apparently a fundamental property of carbohydrates.^{11,39}

As regards polysaccharides, complexes of neutral polysaccharides with *s*-metal cations have been relatively little studied to date. Judging by X-ray diffraction data, the K^+ and Br^- ions in the complex of potassium bromide with amylose (a polymer of α -1,4-linked α -D-glucopyranose **4a**) are coordinated alternately in the cavity of the helix-like polymer chain.⁷¹ It has been noted⁷² that cellulose (a polymer of β -1,4-linked β -D-glucopyranose **4b**) only weakly binds Ca^{2+} ions. It was established unambiguously⁷³ that reaction of cellulose with alkali metal hydroxides gives inclusion compounds containing metal ions between the planes of the cellulose crystal lattice rather than the corresponding alkoxides.⁷⁴ The formation of alkoxides was denied even for monosaccharides⁷⁵ and disaccharides;^{75,76} in these cases, the formation of adducts of the type $RO^+H(M)OH^-$ stabilised by hydrogen bonds between the neighbouring hydroxyl groups was postulated.

A more detailed study⁷⁷ has been devoted to the formation of complexes of *s*-metal cations with a number of anionic polysaccharides, first of all, with pectate **5** (α -1,4-linked poly- α -D-galactopyranosurionate), alginate **6** (a polymer consisting of α -1,4-linked disaccharides formed by the α -L-gulopyranosuronic and β -D-mannopyranosuronic acid residues), and with carrageenans (polysaccharides containing 3-substituted residues of β -D-galactose and 4-substituted residues of α -D-galactose or 3,6-anhydro- α -D-galactose sulfated at different OH groups). Studies on this type of compounds have been stimulated by the fact that they form stable gels in the presence of *s*-metal salts.⁷⁷

4a: $R^1 = H, R^2 = OH$;

4b: $R^1 = OH, R^2 = H$

Study of the complex formation with metals in these polyelectrolytes is complicated by the presence of two types of binding: territorial (non-specific) binding involving hydrated counter-ions, and site (specific) binding involving non-hydrated counter-ions.⁷⁸ The latter type of binding corresponds apparently to the formation of a complex with a metal cation on the polyanion surface. At a definite concentration of counter-ions, a stereoregular anionic polysaccharide, for example, carrageenan, acquires a helical conformation.^{77,79} In the case of gel formation, *s*-metal cations are coordinated between the chains; this yields domains consisting of double or even triple helices.⁷⁹ Some researchers suggest that only single helices participate in intermolecular complex formation.⁸⁰ However, it is generally believed that cross-linking of two adjacent chains according to the 'egg box' pattern (Fig. 1a) is the primary process.

Figure 1. Formation of the intermolecular complex of a polysaccharide with calcium ions.

This model was proposed to interpret the gel formation by poly-L-gulonate in the presence of Ca^{2+} ions.^{81,82} Later it was confirmed for systems comprising Ca^{2+} and polygalacturonate **5**^{83,84} or Na^+ and alginate **6**.⁸⁵ Intramolecular complexation occurs upon the formation of a hydrophilic cavity between monomeric units of neighbouring chains (Fig. 1b).^{86,87} The formation of these cavities can account for the more efficient binding of Ca^{2+} cations by poly-L-gulonate **5**^{87,88} and also for the preferred binding of K^+ and Rb^+ cations by carrageenans.^{89,90}

2. Complexes with *p*-metal cations

Borate complexes of carbohydrates are the most studied compounds in this series. They constituted the subject of early classical studies of Böeseken³ carried out by measuring the electrical conductivity of solutions. Later, the results of this study were supplemented by the data of ^1H (Ref. 91), ^{13}C (Ref. 92), and ^{11}B (Refs 93–95) NMR spectroscopy. This resulted in the detection of neutral complexes **7** (which predominate in acidic media),^{92,94} anionic monomeric complexes with five- (**8**)⁹⁴ and six-membered (**9**)^{94,95} rings, and anionic dimeric complexes **10**⁹⁴ of boric acid with polyhydroxyl compounds.

All these products are complexes formed by vicinal hydroxyl groups; nevertheless, complexes of the type **1b** are the most stable in conformity with the second Angyal rule.^{91,92,95,96} High stability constants (10^3 – 10^6 litre mol^{-1})^{97–99} imply a covalent character of these complexes; however, they have not been isolated in the crystalline state. Calorimetric,¹⁰⁰ titrimetric,¹⁰¹ and polarimetric¹⁰² studies have not provided evidence for the existence of the complexes of type **10**. However, they were detected in ^{11}B NMR studies.^{94,95}

Borate complexes of acyclic polyols of type **11a** can be additionally stabilised owing to the formation of intramolecular hydrogen bonds. This accounts¹⁰³ for the higher stability of these complexes compared to the complexes formed by cyclic forms of sugars.

In aqueous solutions in the presence of borate ions, aldonic and aldaric acids² tend to form complexes with Ca^{2+} ions of the

composition CaBL_2 (L is the ligand). This synergism, which is relatively uncommon in the coordination chemistry of carbohydrates, has been explained¹⁰⁴ by assuming that the preliminary binding of borate ions makes carboxyl groups approach each other, which facilitates the formation of complexes **11b**.

The complexation of sugars with other Group IIIA cations has not received much study. Neutral non-hydrolysable complexes of Ga^{III} with monosaccharide carboxylic acids such as D-glucaric acid (LH_6 , **12**) of variable composition have been synthesised.¹⁰⁵ Complexes of In^{III} with D-glucaric acid **12** of the type $[\text{InLH}_{-2}]^+$, $[\text{InLH}_{-3}]^0$, and $[\text{InLH}_{-4}]^-$ were detected (the negative numerals in the subscripts denote the number of substituted hydrogen atoms).¹⁰⁶ The results of a study of complexation of the acid **12** with Al^{III} and Ga^{III} ions carried out by electrophoresis have been interpreted¹⁰⁷ in terms of an equilibrium between monomer **13a** and dimer **13b**, only carboxyl groups of the ligands being involved in the coordination.

$\text{M} = \text{Al}, \text{Ga}$.

The complex formation of sugars with Group IVA cations is also little studied. It has been noted^{108,109} that germanic acid forms complexes of the composition $[\text{Ge}(\text{LH}_{-2})_2\text{OH}]^-$ and $[\text{Ge}(\text{LH}_{-3})_2]^{2-}$ with acyclic polyols and with α, β -D-glucopyranose **4a, b** and also 1 : 1 complexes with pentoses.⁹⁸ Note that in the latter case, the first Angyal rule holds. One publication¹¹⁰ describes the formation of 1 : 1 complexes of aldoses and ketoses with hexahydrostannate at high pH values.

The complexation of sugars with Pb^{II} has been studied somewhat more comprehensively. It has been shown¹¹¹ that pentoses and their glycosides form complexes of the composition PbL and PbL_2 . However, other researchers¹¹² claim that only the former type of complexes exists.

D-Xylaric acid reacts with Pb^{II} in an acidic medium to give the complex PbLH_{-2} as a result of deprotonation of the carboxyl groups.¹¹³ In alkaline media, this complex is hydrolysed giving a hydroxo complex.¹¹³ D-Gluconic acid **14a** in an acidic medium binds Pb^{II} only as a monodentate ligand by the carboxyl group; this gives the complexes $[\text{PbLH}_{-1}]^+$ and $[\text{Pb}(\text{LH}_{-1})_2]$.¹¹⁴ In an alkaline medium, $[\text{Pb}(\text{OH})_3]^-$ reacts with D-gluconic acid **14a** to afford complexes **15–17**.¹¹⁵ In solid lead D-gluconate, the metal coordinates two monodentate gluconate residues through the carboxyl groups and two bidentate gluconate residues through the carboxyl group and the hydroxyl group at C(2) (α -type coordination⁶⁹).¹¹⁶ Thus, the Pb^{2+} cation is surrounded by six oxygen atoms. Evidently, aldaric acids bind Pb^{II} more strongly than aldonic acids.¹¹⁷

It has been noted^{118,119} that Pb^{II} complexes with oligomeric fragments of the pectate **5** are covalent compounds. In all probability, they contain two carboxyl groups per one Pb^{2+} cation; apparently, this accounts for the high selectivity of formation of Pb^{II} complexes with pectin.¹²⁰ The formation of Pb^{II} complexes with pectin can also occur with incorporation between polymer chains.¹²¹

The complexation of sugars with Group VA elements is little studied. The formation of complexes of monosaccharides and polyols with As^{III} and As^{V} of the composition $[\text{As}^{\text{V}}(\text{LH}_{-2})_3]^-$, $[\text{As}^{\text{III}}(\text{LH}_{-2})(\text{OH})_2]^-$, and $[\text{HAs}^{\text{III}}(\text{LH}_{-2})(\text{OH})_2]$ has been reported.^{109,122} Recently the Bi^{III} complex with L-tartaric acid **18** has been studied by X-ray diffraction analysis.¹²³ The composition of this complex was found to be $\text{Bi}[\text{O}_2\text{C}(\text{CHOH})_2\text{CO}_2][\text{O}_2\text{C}(\text{CHOH})_2\text{CO}_2\text{H}] \cdot 3\text{H}_2\text{O}$. In this complex, two dicarboxylate ligands are coordinated by the carboxyl and α -hydroxyl groups (α -type coordination⁶⁹) and one monocarboxylate ligand is coordinated by the two oxygen atoms of the carboxylate ion. The coordination number of Bi^{III} is equal to nine due to the additional coordination of three water molecules.

Complexes of monosaccharides with telluric acid (Te^{VI}) provide an example of complexes obtained for Group VIA elements. For these compounds, structure **19** was proposed.^{124,125} It was found¹²⁶ that in addition to the 1:1 complex, saccharose forms the complex $\text{L}(\text{TeO}_4)_4$.

Complex formation with Group VIIA elements has been studied only for iodine. Apparently, this is due to the fact that periodate oxidation is an important process in the chemistry of carbohydrates.² It was suggested² that this process starts with the formation of an unstable complex of the IO_4^- anion with a vicinal diol group; the structure of this complex is similar to that of the tellurate complex **19**, because the sizes of the corresponding ions are close. However, monosaccharides conforming to the first Angyal rule should form¹²⁷ stable complexes with periodate, for example, a complex of type **20**.

Later, both the fact of formation of the intermediate complexes and the observance of the first Angyal rule have been confirmed by NMR spectroscopy¹²⁷ and paper electrophoresis.¹²⁸

3. Complexes with *d*- and *f*-metal cations

This field of coordination chemistry of carbohydrates has been studied in the greatest detail, although quite irregularly. The vast majority of the data refer to complexes of carbohydrates with Cu, Fe, Co, Ni, Mo, and W.

Among complexes with Group IB metal cations, those with Cu^{2+} have received most study. The dissolution of freshly prepared copper hydroxide in ammonia-containing or alkaline aqueous solutions of polyhydroxyl compounds, including carbohydrates, which has long been used in analytical chemistry, was interpreted¹²⁹ as the formation of five-membered diolate complexes **21**. The stability constants of these complexes for $\text{L} = \text{NH}_3$ are of the order of 10^2 – 10^4 litre mol^{-1} . In

this case, complexes of the 1:1 composition are always formed.^{129–131} The assumption^{132–134} that cuprammonium complexes of vicinal diols are formed as structure **22** (which apparently involves hydrogen bonds) is hardly consistent with both the stability of these complexes and the maintenance of fixed dihedral angles between the coordinated oxygen atoms.⁶

$\text{L} = \text{NH}_3, \text{H}_2\text{O}, \text{OH}^-$.

The structure **22** also does not agree with the observed induction of optical activity in the central atom (the appearance of optical activity in its electronic transitions);¹³⁵ in fact, in the complex **22**, this would be less likely than in the complexes **21**, because in the former case, the chiral centres (inducers) are further removed from the central atom.

Mannitol was found to form the complex $[\text{Cu}(\text{LH}_{-2})]$ when the ligand is present in a large excess¹³⁶ or Cu_2L when the reactants are present in equimolar amounts.¹³⁶ The latter complex is apparently anionic. This was confirmed¹³⁷ by isolation of a series of analogous anionic copper complexes of carbohydrates. An isomer of mannitol, sorbitol, forms the complex $[\text{Cu}_3(\text{LH}_{-6})]$ in strongly alkaline media¹³⁸ and a polymeric complex in less alkaline media. An NMR study with the use of a shift reagent has confirmed¹³⁹ that Cu^{II} is mostly coordinated to vicinal diol groups of the ligand, although the first Angyal rule can also be observed.¹⁴⁰ In neutral and acidic media, polyols do not coordinate Cu^{II} ions.¹⁴¹ This would require¹³⁰ deprotonation of at least one hydroxyl group. Structure **23** similar to **21** was ascribed¹⁴² to complexes containing ethylenediamine in place of ammonia.

The complexation of Cu^{II} with carbohydrate carboxylic acids has also been studied fairly comprehensively, although, as in the previous cases, these complexes have not been isolated in the solid state. D-Galacturonic acid forms¹⁴³ the complexes $[\text{CuL}_2]^{2+}$, $[\text{CuL}_2\text{H}_{-1}]^+$, $[\text{Cu}(\text{LH}_{-1})_2]$, and $[\text{CuL}_2\text{H}_{-4}]^{2-}$, whereas D-glucuronic acid forms only the second type of complex.¹⁴³ In this case, coordination involves the ring oxygen atom,¹⁴⁴ as has also been observed for *s*-metal cations (Section II.1). D-Gluconic acid **14a** or its dimethylglycine ester (**14b**, pangamic acid, vitamin B₁₅) form mixed-ligand copper complexes in the presence of glycine;¹⁴⁵ the structure of these complexes is unknown.

Glucaric acids form complexes with Cu^{II} according to the α -type of coordination (Section II.1). The tartaric acids **18** give hydroxo complexes **24**^{146,147} containing a water, ammonia, or amine molecule as a ligand. In the case of D-glucaric acid **12**, formation of the complexes $[\text{Cu}(\text{LH}_{-3})]^-$ (at pH 3.65) and $[\text{Cu}(\text{LH}_{-2})_2]^{2-}$ (at pH 5–9, coordination only through the carboxyl groups) and formation of the polymer $[\text{Cu}(\text{LH}_{-3})_n]^{n-}$ (coordination through the carboxyl group of one ligand and the α -type coordination in another ligand) have been reported.¹⁴⁸

$\text{L} = \text{H}_2\text{O}, \text{NH}_3, \text{RNH}_2$.

Binuclear copper complexes of sugars are less frequently encountered. For example, D-gluconic acid **14a** can form ^{7,149} complexes of type **25a** or **25b**. In addition, one of the bridging hydroxyl groups in the complex **25b** can be deprotonated. At a favourable arrangement of four vicinal hydroxyl groups (which occurs, for example, in mucoinositol), sugars in cyclic and acyclic forms can react with Cu^{II} at pH 5 yielding binuclear complexes of type **26** in which the hydroxyl groups of the tetradentate ligand occupy bridging positions.¹⁵⁰

Considerable attention has been devoted to the study of complexation of Cu^{II} with polysaccharides. Thus dissolution of cellulose in a cuprammonium solution is an important technological process, which has been studied most vigorously.¹⁵¹ The formation of chelates of the type **21** with coordination through the hydroxyl groups at the C(2) and C(3) atoms of β-D-glucopyranose **4b** is considered to be the most likely. Polymers having a similar structure, dextrans, are also capable of binding Cu^{II} cations in alkaline media.^{152,153} This process might be accompanied by untwisting of the helical chains of the ligand.¹⁵² The formation of complexes of the type **23** is apparently responsible for the adsorption of the complex [Cu(en)₂]²⁺ (where en is ethylenediamine) on cellulose fibres.¹⁵⁴

Study of complexation of Cu^{II} with anionic polysaccharides has shown ¹⁵⁵ that D-galacturate itself binds Cu^{II} more strongly than its polymer, polygalacturonate **5**. The affinity for Cu^{II} decreases in the following sequence: pectate (polygalacturonate) **5** > alginate **6** > polymannuronate. A similar situation was observed for Ca^{II} ions.¹⁵⁶ The complex formation is a cooperative process.^{156,157} The ligand unit in the copper complexes of pectic acids has ¹⁵⁸ an octahedral configuration, the Cu^{II} cation being coordinated to four oxygen atoms in the symmetry plane.

The formation of Cu^{II} complexes with anionic polysaccharides changes substantially the conformation of the polymer chains of the ligands. As in the case of Ca^{II}, the complex formation is a cooperative process.^{156,157} As this takes place, a sulfated polysaccharide, ι-carraginan, passes into a helical conformation.¹⁵⁹

The formation of complexes of carbohydrates with Ag^I has been studied only for the silver nitrate–D-glucurono-δ-lactone¹⁶⁰ and silver nitrate–D-glucurono-γ-lactone¹⁶¹ systems. It was concluded that in both cases, this affords two types of complexes: ‘lactone’ complex **27** and ‘carboxyl’ complex **28**.

Among complexes with cations of Group IIB *d*-metals, compounds of Zn^{II} and Cd^{II} have been studied most thoroughly. β-D-Fructopyranose **29** and L-arabinopyranose **30** react with these

cations, as with Hg^{II} cations, to give solid complexes of the composition [MLX₂·4H₂O], where X = Cl, Br. In the complex of fructose, the coordination involves two ligand molecules; one of them binds the central ion through the O(2) and O(3) atoms and the other one binds this ion through O(4) and O(5).¹⁶² In the case of L-arabinopyranose **30**, the two ligands are also coordinated through different sites: the O(3) and O(4) atoms of one molecule and the O(1) and O(5) atoms of the other molecule.¹⁶³

In the Zn^{II} and Cd^{II} complexes with both ligands (**29** and **30**), the metal ion coordinates additionally two water molecules, and thus its coordination number is equal to six. For the Hg^{II} cation, there is no coordination with water (the coordination number is four). The counter-ion of the initial salt is bound to the metal cation by electrostatic forces.

Sugars and their *O*-glycosides react with cadoxen (a solution of cadmium hydroxide in ethylenediamine) to give complexes incorporating two deprotonated equatorial hydroxyl groups of the pyranose ring. Presumably, they have the structure **31**.¹⁶⁴

This structure is additionally stabilised by hydrogen bonds. However, as in the copper complexes **22**, in this case, too, it is difficult to explain the observed induction of optical activity in the electronic transitions of Cd^{II}.¹⁶⁵

D-Gluconic acid **14a** and Cd^{II} form complexes with a Cd : L ratio of 1 : 2 (pH 5.8), 2 : 3, and 2 : 1 (pH 13–14).¹⁶⁶ D-Gluconic acid forms two types of solid complexes with Zn^{II}, Cd^{II}, and Hg^{II}: complexes produced *via* coordination through the carboxyl group and the ring oxygen atom of the first ligand molecule and the carboxyl group and the O(4) atom of the second molecule and those (**32**) in which coordination involves only the carboxyl groups.¹⁶⁷ In the *O*-methylglycoside of D-glucuronic acid, Zn^{II} is bound to the carboxyl group and to the ring oxygen atom.¹⁶ It has been noted ¹⁴⁸ that D-glucaric acid **12** forms a complex with Cd^{II}, but its structure has not been described.

© is a cellulose fragment.

Complex formation of *O*-methylglucosides in aqueous solutions of zinc chloride has been reported.¹⁶⁸ Presumably, the metal ion is coordinated to the O(2) and O(3) atoms. The complex formation accounts ¹⁶⁸ for swelling of cellulose in these solutions.¹⁵¹ Cellulose is known ¹⁵¹ to dissolve in cadoxen. Apparently, this yields polymeric complexes like **31**. The reaction of rhodanine with cellulose in the presence of a cadmium salt gives rise to complex **33** with different ligands.¹⁶⁹ Substituted rhodanines afford similar complexes.¹⁷⁰

It was found that cadmium(II)¹⁷¹ and zinc(II)¹⁷² ions are bound to pectate **5** through the carboxyl groups, although the α-type coordination also cannot be ruled out. A similar situation is observed in the case of oligosaccharide fragments of pectic acids.¹⁷²

Complexes of carbohydrates with Group IIIB *d*-metals are represented by Y^{III} complexes of tartaric acid, the composition of which varies from 1 : 1 to 1 : 5 depending on the pH,¹⁷³ and by Y^{III} complexes of D-gluconic acid **14a**, the composition of which is 1 : 1 and the charge varies depending on the pH.^{174, 175} Complexes of La^{III} with tartaric, D-glucaric **12**, and D-galactaric acids have been obtained, their composition (1 : 1 or 1 : 2) being also dependent on the pH value.¹⁷⁶ No data on the structures of these complexes have been reported.

Several complexes formed by Group IVB elements are known. These are Ti^{IV} complexes¹⁷⁷ with tartaric (**18**) and D-gluconic (**14a**) acids and with mannitol (their composition is 1 : 1 or 1 : 2 depending on the pH), the Zr^{IV} complex with trihydroxyglutaric acid [Zr(OH)₃(LH₋₂)]²⁻,¹⁷⁸ and Zr^{IV} and Hf^{IV} complexes with tartaric, trihydroxyglutaric, and D-galactaric acids, which have similar structures.¹⁷⁹

The known complexes of Group VB *d*-metals are mostly formed by vanadium. For example, metavanadate in aqueous solutions reacts with aldoses to give complexes incorporating the [VO₃L]⁻ and [(VO₃)₂L]²⁻ anions.¹⁸⁰ In the latter case, complex formation is observed only for D-glucitol (sorbitol) and maltose (which is a disaccharide). L-Tartaric acid **18**, its D-enantiomer, and the corresponding racemate form binuclear complexes with the vanadyl ion VO²⁺; the composition of the complexes is [(VO)₂L₂H_{-n}]⁽ⁿ⁻⁴⁾⁻ (*n* = 5, 6, or 8 depending on the pH).¹⁸¹ Mesotartaric acid forms a trinuclear complex, [(VO)₃L₃H₋₈]²⁻. For polynuclear complexes of acyclic polyols and aldonic acids in aqueous solutions, several types of structures containing tetradentate ligands have been proposed (structures **34–36**).^{181, 182}

Cyclic sugars and vanadate ions form mononuclear cyclic esters of 1 : 1 composition.¹⁸³ In the most stable complexes characterised by the *cis-cis* arrangement of three vicinal hydroxyl groups (for example, in the complex of β-D-mannopyranose), the ligand is coordinated in a tridentate manner, while in the other cases, in a bidentate manner. Polygalacturonates **5** are coordinated to V^{IV}O ions through the carboxyl groups.¹⁸⁴ At pH 3–7, Nb^V ions and D-gluconic acid form the complexes [Nb(OH)_n(LH₋₂)]⁽⁴⁻ⁿ⁾⁻, while at pH 7–9, the complexes [Nb(OH)_m(LH₋₂)]^{(3-m)-} are produced.¹⁸⁵

The complexation of sugars with cations of Group VIB *d*-metals has been studied fairly intensively. Primary attention has been devoted to complexes of molybdenum and tungsten. Chromium(III) cations do not form stable complexes with sugars in aqueous solutions,¹⁸⁶ whereas in dry methanol, aldoses form complexes with CrCl₃·Py (Py is pyridine); the composition of these complexes is 1 : 3 (aldose : CrCl₃·Py).¹⁸⁶ Conversely, D-glucaric acid **12** (and, perhaps, all the aldaric acids) and Cr^{III} in aqueous solutions form an equilibrium system, similar to the **13a** ⇌ **13b** system.¹⁰⁷ It has also been reported¹⁸⁷ that a stable complex of Cr^V of an unknown structure is formed during oxidation of D-galacturonic acid with Cr^{VI} cations.

The complex formation of sugars and Mo^{VI} and W^{VI} oxo cations has been studied most comprehensively. Since the structures of carbohydrate complexes formed by these metals are similar,^{188–190} they will be discussed together. In most cases, binuclear complexes ML₂ with bidentate (complex **37**) and tridentate (complex **38**) types of ligand coordination are produced in aqueous solutions. The structure of **37** was unambiguously established only for the molybdenum complex of D-glucuronic acid *O*-methylglycoside. According to X-ray diffraction analysis,¹⁵ this complex is characterised by the α-type coordination. For carbohydrates existing in acyclic forms (alditols, aldonic acids), this type of coordination is accomplished in one tetradentate ligand in which the neighbouring hydroxyl groups occupy *cis*-positions.^{191–194} The complexes like **38** are formed in conformity with the first Angyal rule^{193, 194} even if the initial chair-like conformation of the pyranose ligand is distorted.^{195, 196}

M = Mo, W.

Since, due to their conformational mobility, acyclic forms of sugars are more prone to form complexes, it has been assumed and, to some extent, confirmed¹⁹⁷ that the hydrate of the aldehyde form **39** participates in the complex formation. It has been reported¹⁹⁸ that D-lyxose, D-mannose, and L-rhamnose are coordinated as tetradentate ligands only in the cyclic pyranose form, although D-lyxose in the furanose form can be also coordinated in this way (see structures **40** and **41**). However, other researchers¹⁹⁹ claim that these ligands are coordinated in a tridentate fashion. Upon the interaction of W^{VI} ions with an acyclic polyol (sorbitol), in addition to the tetradentate coordination (1 : 1 complexes as two regioisomers), a complex of the type **37** in which the ligand is coordinated bidentately has been detected.²⁰⁰ The carbohydrate complexes of W^{VI} are three orders of magnitude more stable than complexes of Mo^{VI}. This is due¹⁹⁸ to the fact that W^{VI} forms polyoxo anions more readily than Mo^{VI}.

Attempts to determine the structure of the carbohydrate complexes of Mo^{VI} and W^{VI} by X-ray diffraction analysis are not always successful. Thus, according to X-ray diffraction data,²⁰¹ the crystalline compound isolated upon the interaction of D-xylofuranose with ammonium molybdate proved unexpectedly to be a complex of D-lyxose **40**. The transformation of D-xylose into D-lyxose, which is the C(2) epimer of the initial ligand, was explained by the Lobry de Bruyn–Alberda van Ekenstein rearrangement occurring during the synthesis of the complex (Section VI.2). It was shown that the new ligand is coordinated in the furanose form **41**. Later, using X-ray diffraction analysis, a similar structure has been found for the molybdenum complex of an acyclic tetraol (erythritol).²⁰² Based on ¹³C and ⁹⁵Mo NMR spectra, it was shown that in solutions, molybdenum complexes of other acyclic polyols (mannitol, *etc.*) have similar structures.²⁰³ After these publications, there are grounds for believing that the other Mo^{VI} and W^{VI} oxo complexes discussed above also have binuclear structures of the type **40**.

n = 1–4.

Among complexes of carbohydrates with Group VIIB *d*-metals, complexes of manganese in various (including low) oxidation states have been studied in most detail, because the low oxidation states of manganese, which are generally unstable,

can be stabilised by acyclic polyhydroxyl ligands in aqueous solutions.²⁰⁴ The greater the number of hydroxyl groups in the ligand, the more pronounced this stabilisation, because, according to the principle of hard and soft acids and bases,²⁰⁵ the Mn cations are more firmly bound to hydroxyl groups than to carboxyl groups.²⁰⁴ Judging by the results of electron–nuclear relaxation measurements, carbohydrates in the pyranose form coordinate only weakly Mn^{II} ions by the O(3), O(4), and O(6) atoms²⁰⁶ (see the structures **4a,b**). It should be noted that acyclic polyols also weakly coordinate Mn^{II}, but they form stable complexes with Mn^{III} and Mn^{IV} ions.²⁰⁴ However, it was stated²⁰⁷ that the complexes of sorbitol with Mn^{II} ions are also stable. The composition of complexes of acyclic polyols with Mn^{III} was found^{204,207} to be 1:2 or 1:3. In aqueous solutions, D-gluconic acid **14a** forms complexes [Mn^{II}(LH_{−2})₂]^{2−}, [Mn^{III}(LH_{−2})₂OH]^{2−}, and [Mn^{IV}(LH_{−2})₃OH]^{3−} (from data on electrochemical oxidation with variation of the electrode potential).²⁰⁸ The former complex is able to dimerise with successive deprotonation yielding a series of binuclear compounds. The complex of D-gluconic acid of the composition [Mn^{IV}(LH_{−2})₃OH]^{3−} is the first example of a stable carbohydrate derivative of Mn^{IV}. In the solid Mn^{II} gluconate, which is the only carbohydrate complex of manganese studied by X-ray diffraction analysis,²⁰⁹ the central ion was found to have an octahedral environment formed by two ligands and containing the carboxyl and hydroxyl oxygen atoms. These ligands exist in two conformations: a zigzag-like (similar to that of alkanes) and a bent conformation. The same conformation of the carbohydrate ligand was found in an aqueous solution of Mn^{II} gluconate.²¹⁰ Tartaric acid **18** forms a neutral Mn^{II} tartrate,²¹¹ which is deprotonated upon an increase in the pH, and in alkaline solution, it is oxidised by atmospheric oxygen to give hydroxytartrate complexes of Mn^{III}.²¹² Manganese(II) does not form complexes with D-glucaric acid **12**.¹⁴⁸ It has also been noted that Mn^{II} is bound by dextrans¹⁵³ and by polygalacturonate **5**.¹⁸⁴

Rhenium(VII) as perrhenate forms complexes with alditols (acyclic polyols), aldonic acids of the type **14a**, and their lactones. The complexation involves two hydroxyl groups having the *R*- and *S*-configuration, respectively.²¹³ It is believed that perrhenates form no complexes with these ligands.²¹³ However these data are disproved in another publication.²¹⁴

Among Group VIII elements, metals of the iron subgroup are represented most widely in the coordination chemistry of carbohydrates. Thus sugars and other polyhydroxyl compounds form stable complexes with Fe^{III} ions.²¹⁵ D-Glucopyranose **4a,b**²¹⁶ and D-fructopyranose **29**^{216–218} are the best complexones. Structural studies on the Fe^{III} complex of D-fructopyranose **29** confirm the polymeric polynuclear structure **42**.²¹⁶ In an aqueous solution, the polymer **42** occurs in equilibrium with monomeric and dimeric complexes.

The complexation of Fe^{III} with tartaric acid **18** in an alkaline medium leads to the complex [Fe(LH_{−3})₃]^{6−} with coordination through both carboxyl groups and a hydroxyl group.²¹⁹ Apparently, a complex of the type **24** is formed. A ternary complex of the composition 1:1:1 was isolated from the Fe^{III}–sodium tartrate–saccharose system.²²⁰ This accounts for the dissolution of cellulose in iron–tartrate solutions.¹⁵¹ The following heteronuclear iron–vanadium tartrate complexes were prepared:²²¹ [FeVO(LH_{−2})₂]⁺, [FeVO(LH_{−3})(LH_{−4})]^{2−}, and [FeVO(LH_{−4})₂OH]^{4−}.

D-Gluconic acid **14a** forms^{7,222} chelates with Fe^{III} with bi- and tridentate coordination through only hydroxyl groups. Later,²²³ similar structures have been proposed for Fe^{III} complexes with trihydroxyglutaric acid. However, in this case, coordination can involve either one²²³ or two¹⁴⁸ carboxyl groups. The complexes of this type are fairly stable ($K_s = 10^4$ – 10^5 litre mol^{−1}).^{224,225} Preparation of polymeric Fe^{III} complexes of the type **42** with sorbitol or D-glucuronic acid has been reported.²²⁶

Cobalt(II) and nickel(II) cations form 1:1 coordination compounds with mannitol.¹³⁶ Ammonia complexes of Co^{III} react with D-ribose and L-sorbose to give chelates [Co(NH₃)₄L₂]³⁺ chiroptical properties of which point to a structure like **43**.²²⁷ In addition to these chelates, Co^{II} ions form a binuclear complex [Co₂(N-H₃)₃(OH)₂(H₂O)₂L]³⁺ with D-arabinose.²²⁸

In the series of carbohydrate carboxylic acids, complex formation of Co^{II} and Ni^{II} with D-gluconic acid **14a** has been studied most extensively. It has been noted⁴ that this is not accompanied by substantial changes in the ligand conformation and that Ni^{II} chelates are more stable than Co^{II} chelates.²²⁹ It was found that in an acidic medium, unstable complexes [M(LH_{−1})]⁺ are formed.^{230–232} Polynuclear complexes [Co₂(OH)₃(LH_{−1})·H₂O and [Co₃(OH)₂(LH_{−2})₂·2H₂O] were detected in the pH range of 7.5–9.5.²³¹ The latter is a polymer of structure **44**. The complexes [Ni₂(OH)₃(LH_{−1})] and [Ni₂(OH)₄(LH_{−1})][−], which might have a similar structure, have been obtained.²³⁰ Tetraamminecobalt(II) reacts with D-gluconic (**14a**) and D-glucuronic acids to give the complexes [Co(NH₃)₄L]²⁺ (*n* = 4, 5) in which the ligands behave as monodentate ones.²³³ Study of solid nickel gluconates [Ni(LH_{−1})₂·2H₂O and [Ni₂(OH)₂(LH_{−2})₂·2H₂O] by spectroscopic and magnetic methods has shown that the chelate units in both complexes have a distorted octahedral configuration.²³⁴ The second complex has a polymeric structure with hydroxyl bridges, apparently, similar to the structure **44**.

The diastereomeric Λ- and Δ-complexes [Co(LH_{−1})(en)₂]⁺ have been obtained by the reaction of racemic [Co(CO)₃(en)₂]²⁺ with aldonates and separated.¹³ Aldaric acids form¹⁴⁸ chelates of the type [M(LH_{−3})][−], the structure of which is apparently **24**, and a binary complex {[Ni(bipy)₃]₂(LH_{−2})} (bipy is bipyridine).²³⁵

Data on the complexation of Co^{II} and Ni^{II} with polysaccharides are scarce. Thus it is known that these cations are bound by dextrans¹⁵³ and polygalacturonate **5**¹⁸⁴ and that cellulose dissolves in solutions of the complexes [Co(en)₃(OH)₂], [Ni(N-H₃)₆(OH)₂], and [Ni(en)₃(OH)₂] yielding complexes of an unknown structure¹⁵¹ (supposedly of the type **31**).

Complexation of carbohydrates with cations of platinum group metals has been studied mostly in connection with their therapeutic effect (Section VI.1). When cisplatin **45** was made to react with D-mannitol, two complexes with identical structures (**46**) but with different colours and different chiroptical properties were isolated.²³⁶ The reasons for this result are unknown.

The reactions of acyclic polyols with the 1,3-bis(diphenylphosphino)propane platinum complex result in the formation of stable diolate chelate-type complexes **47**, which are additionally stabilised by intramolecular hydrogen bonds.²³⁷ The complexes have been structurally characterised. The reaction is regioselective and occurs most efficiently with vicinal diol groups. Peculiar anionic complexes, so called osmarines, are formed upon the reaction of osmium salt **48** with aldoses.^{238, 239}

Ald is the aldose residue.

These complexes are polymers the backbone of which consists of linked (possibly, *via* oxygen) Os atoms with 'grafted' monosaccharide residues. The molecular masses of these compounds are between 10^3 and 10^6 dalton. Some of the aldose fragments are oxidised to aldonic acids during complex formation; therefore, the complexes can be described by the general formula $K_m Os_n Y_x Z_y (H_2O)_z$, where Y is aldose, Z is aldionate (the therapeutic properties of these polymers are described in Section VI.5).

D-Gluconic acid **14a** forms two extremely stable complexes of the composition 1 : 1 with Pt^{II} cations; these products result from slow hydrolysis of the initial polymers of the composition 6 : 1.⁷ The Ru^{III} cation also forms a stable complex compound with D-gluconic acid in an alkaline medium.²⁴⁰ Similar stable complexes of D-gluconic acid have been obtained for Os^{III} , Os^{IV} , and Os^{VI} ions.²⁴¹ Mixed-ligand chelates $[PtL(1,3\text{-diamine})]$ have been obtained with D-gluconate and D-glucuronate in the presence of 1,3-diamines.²⁴²

Among the complexes formed from *f*-metals with sugars, those of lanthanides have been studied most thoroughly. The use of water-soluble lanthanide salts as shift reagents in NMR spectroscopy has demonstrated that the first Angyal rule holds for both cyclic²⁴³ and acyclic²⁴⁴ carbohydrate forms, while the second Angyal rule is obeyed for furanoses,²⁴⁵ *i.e.* there is a similarity between the behaviours of lanthanides and *s*-metals.

The complexation of lanthanide cations with carbohydrate carboxylic acids has been studied fairly comprehensively. The chiroptical properties of the complexes of lanthanides with tartaric acid **18** are discussed in a review.²⁴⁶ The α -type bidentate coordination and tridentate coordination through both hydroxyl groups and the carboxyl group have been assumed for the complexes resulting from the reaction of glyceric acid with Co^{III} .²⁴⁷ D-Galacturonic acid coordinates Eu^{III} ions through the oxygen atom of the carboxyl group, the hydroxyl group at the C(4) atom, and the ring oxygen atom (1 : 1 complex),²⁴⁸ while the *O*-methylglycoside of this acid binds Eu^{III} only by the carboxyl group and the ring oxygen atom {the $[Eu(LH_{-1})_3]$ complex}.²⁴⁹

D-Gluconic acid **14a** forms the most stable chelates with Ce^{III} ions.⁴ Structures with the α -type coordination and with tridentate coordination involving the carboxyl group have been proposed for 1 : 1 complexes of lanthanides.^{250, 251} The stability constants of these complexes at low²⁵² and high^{253, 254} pH values have been determined. An increase in the gluconate concentration leads to the formation of complexes $[M(LH_{-1})_n]^{(3-n)+}$, where $n = 2-4$.²⁵⁵

As regards actinides, only data on the complex formation of U^{VI} (as the uranyl cation, UO_2^{2+}) have been reported. This cation coordinates aldopyranoses and cyclic polyols at pH > 10 without observance of the first Angyal rule. Apparently, this is due to its large size.¹⁹⁹ D-Gluconic acid forms complexes **49** and **50** with these ions.²⁵⁹ Similar complexes are produced in the case of tartaric acid **18** and trihydroxylglutaric acid.²⁵⁷

III. Complexes of cyclodextrins

Cyclodextrins (CD) are cyclic oligosaccharides consisting of six (α -CD), seven (β -CD), or eight (γ -CD) residues of α -D-glucopyranose **4a**. They are capable of incorporating various organic molecules into inner hydrophobic cavities.²⁵⁸⁻²⁶²

Less is known of the ability of cyclodextrins to form complexes with metal ions. Thus β -CD complexes alkali metal salts, although this mostly occurs due to binding of the anion.²⁶³ Complexes of α -CD with iodine of the type $(\alpha\text{-CD})_2 \cdot LiI_3 \cdot I_2 \cdot 8H_2O$ (a model of the blue iodine complex with amylose) and with cadmium ions have been described.²⁶⁴ In the β -CD complex with KOH, the K^+ ion is bound by six coordinate bonds with the hydroxyl groups of the glucopyranose residues thus forming a distorted trigonal prism.²⁶⁵ The lutetium ion can also be bound to β -CD.²⁶⁶ Metal complexes of coronands (crown ethers)^{267, 268} or their acyclic analogues, podands,²⁶⁸ can be incorporated into the cavities of cyclodextrins.

Some complex compounds of cyclodextrins with *d*-metal cations are also known. α -Cyclodextrin forms binuclear complexes **51** with Cu^{II} ; complexes of β -CD are formed similarly but contain deprotonated oxygen bridges.²⁶⁹⁻²⁷¹

Other *d*-metals are also prone to form polynuclear complexes with β -CD. For example, the complexes $[M_2(OH)_2(\beta\text{-CD}) \cdot 2H_2O]$ ($M = Mn^{III}, Cr^{III}$), $Na_2[M_2(OH)_2(\beta\text{-CD}) \cdot 2H_2O]$ ($M = Co^{II}, Ni^{II}, Cu^{II}$), and $[M_4(OH)_4(\beta\text{-CD}) \cdot 2H_2O]$ ($M = Fe^{III}$) have been described.^{272, 273}

However, the primary attention is paid to the inclusion of *d*-metal complexes into cyclodextrin cavities (second-sphere coordination).^{274, 275} Thus α -, β -, and γ -CD form host-guest complexes (inclusion compounds) **52a**, **52b**, and **52c**, respectively, with ferrocene.²⁷⁶⁻²⁷⁸

The 'guest' molecules in these complexes can rotate freely only at elevated temperatures.²⁷⁹ The axial incorporation of ferrocene in the complex **52b** was confirmed in a study of complexation of cyclodextrins with a model ferrocene derivative that can be arranged in the cavity only equatorially, as in the complex **52c**.²⁸⁰ Since the cavity of α -CD is small, it can incorporate only

monosubstituted ferrocenes, whereas the other cyclodextrins form complexes with disubstituted ferrocenes as well.^{277, 278} In this type of cyclodextrin complex, a chiral 'host' molecule induces optical activity in a 'guest' molecule. This facilitates investigation of these compounds.^{281, 282} The complex $[(\eta^5\text{-C}_5\text{H}_5)\text{FeC}_6\text{H}_6\text{PF}_6 \cdot 2\alpha\text{-CD}]$ ^{283, 284} of the type **52a** and its analogues containing naphthalene, indan, tetralin, or thiophene instead of benzene²⁸⁴ have been prepared. Complexes of η^6 -arenetricarbonylchromium with β - and γ -CD of the composition 1 : 1 are known.²⁸⁵

Incorporation of organometallic π -complexes such as $[(\eta^3\text{-allyl})\text{Pd}]$,²⁸⁶ $[(\text{cod})\text{RhCl}_2]$ (cod is cyclooctadiene),²⁸⁷ $[(\text{cod})\text{PtX}_2]$ (X = Cl, Br, I),²⁸⁷ $[(\text{cod})\text{Rh}(\text{NH}_3)_2]$,^{288–290} and ordinary platinum complexes such as **45**^{290–293} into cyclodextrins has been studied.

Bulky metal complexes such as macrocyclic Ni^{II} complex **53**²⁹⁴ or the Fe^{III} complex with protoporphyrin IX (hemin)²⁹⁵ can also occupy the hydrophobic cavities of cyclodextrins.

**53**

Rotaxane complexes of type **54** have been synthesised.^{296–299} Since the CD molecule is chiral, the synthesis involves asymmetric induction and yields predominantly stereoisomers with the (Δ, Δ)-configuration of the chelate units.^{298, 299}

$n = 8, 10, 12, 14$.

IV. Complexes of nitrogen-containing natural carbohydrates

In the metal complexes of ribonucleosides **55a**, metal ions are normally coordinated to endocyclic nitrogen atoms in a base of the pyridine type (B).^{300–303} In the case of ribonucleotides **55b**, additional coordination to the phosphate group is possible; this gives cyclic complexes of the type **56**,¹⁸ in conformity with the principle of hard and soft acids and bases.²⁰⁵

X = H (a), PO_3H_2 (b); B is a heterocyclic base.

However, within the scope of this review we are interested in the exceptions to this rule, namely, complexes resulting from coordination of carbohydrate fragments. Thus in disodium uridine 3'-phosphate, the Na^+ cation is coordinated not only to the phosphate but also to the oxygen atoms at C(2') and C(5').³⁰⁴ Likewise, the ribose residue is one of the sites of coordination of the Li^+ ion to the nucleosides **55a**.³⁰⁵ In the sodium inosine phosphate, the Na^+ cation is coordinated to the hydroxyl groups at the C(2') and C(3') atoms of the ribose residue.³⁰⁶ The interaction of borate ions with pyrimidine nucleosides involves coordination at the vicinal diol group at C(2') and C(3') and results in a complex of the type **8**.³⁰⁷ Vanadate ions are coordinated in a similar way.^{183, 308} The same hydroxyl groups and Cu^{II} ions give binuclear complexes Cu_2L_2 of the type **51**.^{309, 310} It has

been suggested that Cu^{II} acetate forms three-dimensional binuclear complexes like **57**;³¹¹ however, other results^{312, 313} attest to the formation of ordinary coordination units of the type **21**. The uranyl complex of adenosine has the binuclear bridged structure **58**.^{314, 315} Desoxyribonucleosides and -nucleotides do not contain a vicinal diol group; therefore, their carbohydrate fragments do not participate in coordination.

**57****58**

Among natural aminosaccharides, D-glucosamine (2-amino-2-deoxy-D-glucopyranose, **59a**) has received most attention. Metal complexes of D-glucosamine have been studied by electronic spectroscopy, potentiometric titration, calorimetry, and EPR spectroscopy. No X-ray diffraction data for these complexes are available.

The complex formation of D-glucosamine **59a** with Cu^{II} has received the most study.^{141, 316–324} This interaction involves coordination not only to the amino group but also to the hydroxyl groups at the C(1) and C(3) atoms adjacent to the amino group.^{316, 321} In the complexes CuL and CuL_2 ,^{317, 320} the hydroxyl groups of the ligands can be either free³²¹ or deprotonated.³²³ Other researchers¹⁴¹ deny participation of free hydroxyl groups in the coordination and assume that deprotonation is typical first of all of the hydroxyl group at C(1), because it is the most acidic.³²⁵ In the case of the Cu^{II} complex of N-acetylglucosamine **59b**, the N-acetyl group is not coordinated to the Cu^{II} ion but stabilises the complex $[\text{Cu}(\text{LH}_{-1})_2(\text{OH})_2]^{2-}$.¹⁴¹

**59a,b**

The complexation of D-glucosamine **59a** with Ni^{II} ,^{141, 319–322} Co^{II} ,^{316, 319–324, 326, 327} and Fe^{III} ^{317–320} ions has been studied fairly comprehensively. For complexes of the composition ML , the following stability series was obtained: $\text{Cu}^{\text{II}} > \text{Pb}^{\text{II}} > \text{Zn}^{\text{II}} > \text{Ni}^{\text{II}} \equiv \text{Co}^{\text{II}}, \text{Cd}^{\text{II}}, \text{Mn}^{\text{II}} \gg \text{Ca}^{\text{II}}, \text{Mg}^{\text{II}}$,³²¹ and for complexes ML_2 , $\text{Fe}^{\text{III}} > \text{Cu}^{\text{II}} > \text{Co}^{\text{II}}$.³¹⁹

The formation of complexes of D-glucosamine **59a** of the composition ML_2 with the above cations is a multi-stage process,^{319, 323} which includes coordination of the cation to the amino group of the first ligand, to the amino group of the second ligand, coordination to the neighbouring hydroxyl groups followed by their stepwise deprotonation, and finally coordination to a hydroxide ion in a strongly alkaline medium.^{323, 326} However, other investigators^{141, 321} deny the possibility of coordination to a hydroxide ion. Solid hygroscopic complexes of D-glucosamine of the composition ML_2 with Ca^{II} , Ba^{II} , and Sr^{II} have been obtained.³²⁴

The cationic complexes $[\text{FeL}(\text{OH})_2]^+$ and $[\text{FeL}(\text{OH})]^{2+}$ are formed from Fe^{III} and D-glucosamine **59a** in a physiological salt solution.³²⁶ The crystalline complexes $[\text{NiL}_2]\text{X}$ (X = 2Cl^- , SO_4^{2-}) have been obtained.³²⁷ Synthesis of *cis*-dichlorobis(D-glucosamine)platinum(II) has been reported.³²⁸

The interaction of D-glucosamine **59a** with tris(ethylenediamine)cobalt has led to contradictory results. First, it was reported³²⁹ that this gives an outer-sphere complex with a structure of the type **31**. Subsequently, it was shown³³⁰ that this affords four isomers with a $\Delta : \Lambda$ ratio of 7 : 3, which differ in the

anomeric configuration of the ligand and configuration of the chelate unit (complexes like **43** with an amino group instead of a hydroxyl group). Finally, recently³³¹ it was shown that the composition of the product mixture is even more complicated; eight(!) isomers were isolated from the mixture and characterised by X-ray diffraction analysis. In all of these compounds, the ligand had been converted preliminarily into a substituted *N*-glucoside, and after that, the reaction gave complexes of the type **43** [with an amino group instead of the hydroxyl group at the C(1) atom of the sugar]. The ligand in this complex was either transformed into the aldehyde form of the type **39** or into the furanose (keto) form as a result of the Amadori rearrangement,² or remained in the native pyranose form.

In order to model the chemical behaviour of natural polysaccharides containing residues of D-glucosamine **59a**, which might be able to form multi-ligand complexes, a ternary complex consisting of Cu^{II}, D-glucosamine, and prometone [2-methoxy-4,6-bis(isopropylamino)-*s*-triazine, PR] of the composition [CuPR(LH₂)₂] was synthesised.³³²

The complex formation of other natural 2-amino sugars has been much less studied. It has only been reported that Cu^{II} forms complexes with D-mannosamine,³³³ D-galactosamine, and D-talosamine.³³⁴ The latter complex is the most stable among copper complexes of natural 2-amino sugars. This was explained³³⁴ by the formation of a very strong hydrogen bond between the hydroxyl group at C(4) and the amino group at C(2), owing to their diaxial orientation.

An important constituent of natural glycolipids and glycoproteins is *N*-acetylneuraminic acid. The β -anomer of this acid **60a** forms^{335–337} a fairly stable complex with Ca^{II} of the composition 1 : 1 ($K_s = 121 \text{ litre mol}^{-1}$).³³⁵ The calcium complex with *N*-glycolylneuraminic acid **60b** is even more stable ($K_s = 193 \text{ litre mol}^{-1}$).³³⁶

R¹ = CO₂H, R² = OH; R³ = Me (**a**), CH₂OH (**b**);
R¹ = OH, R² = CO₂H, R³ = Me (**c**).

The complex formation of Ca^{II} with the ligand **60a** has been reported³³⁵ to involve the ring oxygen atom and the hydroxyl groups at the C(7), C(8), and C(9) atoms; however, according to another publication,³³⁷ coordination occurs through the ring oxygen atom and the hydroxyl groups at C(2) and C(8). The natural α -anomer of the *N*-acetylneuraminic acid **60c** weakly binds Ca^{II},³³⁷ binding of metal cations by the ligand **60c** becomes markedly stronger when Ca^{II} is replaced by Gd^{III} or Mn^{II},³³⁸ which coordinate **60c** in the region of the glycerol 'tail' and the carboxyl group. Natural gangliosides (oligosaccharides containing the acid **60c** and long hydrocarbon chains attached to them²) coordinate metal cations by the glycerol fragment of the natural α -anomer **60c**. In this case, Ca^{II} ions are bound much more strongly than Mg^{II}.³³⁹ However, since the *O*-methylglycoside of the α -anomer **60c** scarcely binds Ca^{II}, the coordination involves neighbouring monosaccharide fragments, in addition to the *N*-acetylneuraminic fragment.³⁴⁰ A similar enhancement of complexation is also observed³⁴¹ in the binding of Gd^{III} by glycoporphin A — a transmembrane glycoprotein with a high content of α -*N*-acetylneuraminic acid **60c**. In aqueous solutions, *N*-acetylneuraminic acids **60a,c** do not coordinate Na⁺ and K⁺ cations.³⁴²

Glycosaminoglycans are polymers containing 2-amino sugars and occurring in connective tissues (mucopolysaccharides²); therefore, study of their complexation presents considerable interest from biochemical and medical viewpoints. A typical representative of mucopolysaccharides is an anticoagulant hepa-

rin.^{343–345} The repeating disaccharide unit of this compound **61** consists (from left to right) of an L-iduronic acid residue sulfated at the hydroxyl group at C(2) and a D-glucosamine residue sulfated at the amino group and at the hydroxyl group at C(6'). On dissolution in water, sodium heparinate dissociates only by 34%.³⁴⁵ This corresponds to the normal behaviour of polyelectrolytes in which *s*-metal cations are bound non-specifically (territorial binding, Section II.1). In other words, they merely 'condense' on the negative charges in the polymeric chain,^{346, 347} according to the Manning theory.⁷⁸ However, in another study,³⁴⁸ specific binding of Na⁺ by two carboxyl groups of the neighbouring L-iduronic acid residues was suggested, based on the results obtained by ²³Na NMR spectroscopy. However, later the same results were explained³⁴⁹ in terms of the concept of condensation of counter-ions. On the other hand, in the case of Ca^{II}, ionic coordination with participation of the sulfo group of the L-iduronate and the sulfo group at the C(6') atom of the D-glucosamine residue³⁵¹ has been suggested.³⁵⁰ In the presence of excess Ca^{II}, neighbouring chains of the polymer are linked according to the 'egg box' pattern (Section II.1).³⁴⁵ The complexation hypothesis is supported by the series of the efficiency of binding of *s*-metals with heparin^{343, 352} (Na⁺ < K⁺ < Mg²⁺ < Sr²⁺ < Ba²⁺ < Ca²⁺), since, according to the condensation theory,⁷⁸ the most efficient binding would be observed for the Mg²⁺ cation characterised by the maximum charge density. The data of circular dichroism spectroscopy,³⁵³ which confirm this series, indicate simultaneously that there is no specificity in the binding of Ca^{II}. This contradiction might be explained by the fact that heparin is capable of both non-specific (condensation) and specific (complexation) binding of *s*-metal cations. This was discovered³⁵⁴ for electrostatic binding of heparin with Zn^{II}. It has been noted³⁵⁵ that this ability is peculiar only to heparin; however, according to another publication, heparin just possesses the highest affinity for Zn^{II} compared to other glycosaminoglycans.³⁵⁶

The interaction of heparin with Cu^{II} cations occurs as chelation involving the amidosulfate group.^{357, 358} At higher pH, the complex formation is enhanced. This was explained^{357–359} by straightening (despiralisation) of heparin molecules resulting in liberation of new coordination sites. It was suggested³⁵⁷ that Cu^{II} is coordinated inside the cavity of a helix, as in the case of Cu^{II} complexes with cyclodextrins (see Section III, the compound **51**). Among glycosaminoglycans, heparin possesses the highest affinity for [Co(NH₃)₆]³⁺ cations, apparently due to the high negative charge density in its macromolecule.³⁶⁰

Studies on the complexation of other glycosaminoglycans have also been concerned with hyaluronic acid (its dimeric unit **62** consists of the residues of D-glucuronic acid and *N*-acetylglucosamine **59b**) and chondroitinsulfates.³⁶¹ The latter compounds are built of dimeric units comprising a D-glucuronic acid residue and a residue of *N*-acetyl-D-galactosamine sulfated at the 4-position (chondroitin-4-sulfate, **63a**) or at the 6-position (chondroitin-6-sulfate, **63b**).

X = SO₃[−], Y = H (**a**); X = H, Y = SO₃[−] (**b**).

The presence of doubly charged *s*-metal cations ensures^{362,363} a helical conformation of hyaluronic acid **62**. In accordance with polarographic data, Cu^{II} forms complexes of the type CuL, CuL₂, and CuL_{*n*} (L is deprotonated hyaluronic acid).³⁶⁴ In the former case (an inner-chain complex), Cu^{II} is chelated by the carboxyl group and by the bridging oxygen atom,³⁶⁵ while at high pH values, the deprotonated *N*-acetyl group also participates in the coordination.³⁶⁶

Chondroitin-6-sulfate **63b** binds Na⁺ and Ca²⁺ ions non-specifically.³⁶⁷ In terms of the strength of their binding to chondroitin-4-sulfate, *s*-metal cations can be arranged in the same sequence³⁶¹ as in the case of heparin (see above). In the case of chondroitin-6-sulfate, there is no difference between the strengths of binding of doubly charged *s*-metal cations.³⁶¹ For a mixture of chondroitinsulfates **62a,b**, it has been shown³⁶⁸ that the efficiency of binding increases in the sequence Cu^{II} < Yb^{III} < La^{III}. In addition, chondroitin-4-sulfate **63a** binds Yb^{III} cations by the carboxyl group and the sulfo group of one chain and by two carboxyl groups of a parallel chain.³⁶⁹

V. Complexes of natural acids of the carbohydrate origin

In this Section, we describe a number of complexones such as ascorbic (**64**), shikimic (**65**), kojic (**66**), and phytic (phytin, myo-inositol hexaphosphate, **67**) acids. These particular subjects were chosen due to their biosynthetic origin from carbohydrates.^{2,370,371}

Numerous studies and a comprehensive review⁹ covering publications up to 1977 have been devoted to metal complexes with ascorbic acid (vitamin C) **64**. Being a dibasic acid [owing to the protic activity of the hydroxyl groups at C(2) and C(3)], ascorbic acid **64** can be converted into two anions, (LH₋₁)⁻ and (LH₋₂)²⁻. It forms complexes [M_xL_{*y*}]^z, [M_x(LH₋₁)_{*y*}]^z, [M_x(LH₋₂)_{*y*}]^z, and [M_x(LH₋₂)_{*y*}OH]^z virtually with all metal cations including oxo cations.⁹ Salts of ascorbic acid **64** [M_x(LH₋₁)^z] are formed upon coordination of a metal cation by the deprotonated hydroxyl group at C(3) (the strongest acidic site). The subsequent coordination involves the hydroxyl group at C(2) (either free or deprotonated) and the lactone carbonyl group at C(1). The vicinal hydroxyl groups in the 'tail' at the C(5) and C(6) atoms do not participate in the coordination in solutions,^{372,373} although in the condensed phase, this coordination is possible.^{374–377} Thus in solid Ti^{IV} ascorbate, the metal ion is additionally bound not only to the hydroxyl groups at C(5) and C(6) but also to the lactone carbonyl group. In solid ascorbates of divalent *s*-metals, a cation is coordinated to three anions, and only Mg^{II} binds two anions.³⁷⁹ In aqueous solutions, cations of univalent *s*-metals are bound by an ionic bond, except for Li⁺, which is bound by a covalent bond.³⁸⁰

In the case of In^{III} and Ga^{III}, polynuclear complexes predominate in acidic media,³⁸¹ while lanthanides form³⁸¹ complexes [M(LH₋₁)₂]⁺. The following stability series has been elucidated³⁸² for the complexes of divalent metals: Be > Pb > Mn > Fe > Co > Ni. These metals form complexes of the composition 1 : 1, and only Be^{II} forms stable 1 : 2 complexes.³⁸²

Complex formation of V^{IV}^{9,380,383} and V^V,³⁸⁴ which is accompanied by oxidation of the ligand yielding dehydroascorbic

acid, has been studied in detail. Upon the reaction with V^{IV}, dehydroascorbic acid undergoes the lactone ring opening being thus converted into diketogulonic acid. Chelate **68** is formed apparently from the enol form of this acid and the vanadyl ion.^{372,373,385–388}

Complex formation of ascorbic acid with *d*- and *f*-metal cations has been studied.⁹ This ligand forms solid three-dimensional polymeric complexes with Zn^{II}, Co^{II}, and Hg^{II}.³⁸⁹ In solutions, monodentate [through the O(3) atom] or bidentate [through the O(2) and O(3) atoms] coordination is possible.³⁸⁹ The complexes of the acid **64** with Co^{II} in solutions have been studied in most detail.⁹ A study of spin–lattice relaxation in the ¹³C NMR spectra has confirmed³⁹⁰ the predominant chelation of Co^{II}, Fe^{II}, and Mn^{II} by the O(2) and O(3) atoms, while the lactone and ring oxygen atoms and the hydroxyl groups at C(5) and C(6) are weaker coordination sites.

The reaction of the acid **64** with [Co(NH₃)₄]²⁺ gives two complexes: a monodentate complex [with coordination through O(3)] and a bidentate one (with coordination to the lactone and ring oxygen atoms).³⁹¹ A stable ternary complex **69** formed by ascorbic acid and bis(2,2'-bipyridyl)copper(II) has been described.³⁹² Binuclear complexes of Cu^{II} **70** are readily reduced by ascorbic acid **64** if the sizes of the reactants are fitted in the intermediate complex **70**.³⁹³

An unusual organometallic complex of platinum with ascorbic acid (**71**) containing a C–Pt σ-bond has been synthesised within the framework of studies dealing with the development of new anticancer preparations.³⁹⁴ Complexes of the acid **64** with dicyclopentadienyltitanium [η-C₅H₅)₂TiL₂] and with dialkyltin [R₂SnL·H₂O] (R = Me, Et) have also been obtained.³⁹⁵ In the latter complex, the ligand L can be coordinated both in monodentate [by O(3)] and bidentate [by O(2) and O(3)] fashions.

Shikimic acid **65** forms³⁹⁶ a (1,2-diaminocyclohexane)platinum complex similar to the compound **71** prepared from ascorbic acid [the metal is coordinated to the carboxyl oxygen atom and to the alkene carbon atom C(2)].

Kojic acid **66a** containing an oxo-enol fragment forms numerous complexes with various cations^{371,397} including *s*-metal ions.^{13,371} The compounds of kojic acid with metal ions can be built³⁷¹ either as complex salts with coordination to the oxygen atom at C(6) or as chelates with an additional coordination to the oxo group. Synthetic 5-phenacylkojic acid **66b** also acts as a complexone.^{11,398–400} In its complexes, a metal ion is linked to

the carbonyl fragment of the phenacyl group, to the carbonyl group at C(4), and to the oxygen atom at C(6).

The formation of metal complexes with phytin has been intensely studied due to the dietary significance of this compound (Section VI.1). The thermodynamics of phytin complexation with Ca^{II} ,⁴⁰¹ Zn^{II} ,⁴⁰² Cu^{II} ,⁴⁰³ Mn^{II} ,⁴⁰⁴ Co^{II} , Ni^{II} ,⁴⁰⁵ Fe^{III} , and Cr^{III} ⁴⁰⁶ have been studied by calorimetry. Complex formation of incompletely substituted ester, myo-inositol 1,2,6-triphosphate, with alkali⁴⁰⁷ and transition⁴⁰⁸ metal cations has been investigated. For none of the complexes obtained, has the structure been determined.

VI. The significance and applications of metal coordination to carbohydrates

1. The influence of complex formation on the chemical properties of carbohydrates

The catalytic role of metal cations in a key transformation of carbohydrates, namely, in the Lobry de Bruyn–Alberda van Ekenstein rearrangement^{2,409} [epimerisation of aldoses at the C(2) atom and their conversion into ketoses], has been explained by assuming the intermediate formation of complex **72**.⁴⁰⁹ In a discussion of the dehydration of carbohydrates, the special case of alkaline dehydration of D-mannose was interpreted using the suggestion⁴¹⁰ of formation of an enediol complex of type **73**. The formation of similar enediol metal complexes has been assumed⁴¹¹ to rationalise the mechanism of oxidation of monosaccharides by hydrogen peroxide. These complexes have been identified by electronic and NMR spectroscopy.⁴¹² The enediol complex **74** has been isolated and characterised.⁴¹³

Thus, the hypothesis of the formation of enediol forms of carbohydrates stable as metal complexes, put forward^{2,370} to account for the above transformations, can be considered to be experimentally proven. However, in view of the most recent results, participation of these species in epimerisation seems doubtful (see below).

Angyal *et al.*^{6,414–417} have shown that *O*-glycosylation according to Fischer (treatment of sugars with a methanolic solution of HCl)² carried out in the presence of calcium or strontium salts results in increased yields of *O*-methylfuranosides. This discovery made this type of compound readily accessible. Acyclic forms, aldose dimethyl acetals, can also be formed under these conditions.⁴¹⁸

The promotory effects of Ca^{2+} and Ba^{2+} ions on the alkaline oxidation of aldoses by 2-anthraquinonesulfate to aldonic acids of the type **14a** has been explained⁴¹⁹ by the fact that the stability of the intermediate aldoses-2-uloses **75** increases when these metal ions are coordinated to the hydroxyl group at the C(3) atom and to the oxo group. The angle between the two coordinate bonds must be $0–30^\circ$; otherwise, the influence of these cations is not manifested.

$\text{R} = \text{H}, \text{CH}_2\text{OH}.$

Complexation with boric and phenylboronic acid has been used⁴²⁰ to perform selective acetonation of monosaccharides; a similar approach used in the series of nucleosides and nucleotides is employed for their selective methylation at the base.⁴²¹ The use of a complexing polymer, polystyrylboronate, made it possible to prepare partially acetylated derivatives of *O*-methylglycosides, valuable from the synthetic viewpoint.⁴²² The addition of a borate during the aldol condensation of 2-acetamido-2-deoxy-D-glucose **59b** with oxaloacetate giving *N*-acetylneuraminic acid (a mixture of anomers **60a,b**) increases the yield of the product. Apparently, complexation suppresses side reactions.⁴²³ The presence of a borate shifts the aldose $\rightleftharpoons$ ketose equilibrium (the Lobry de Bruyn–Alberda van Ekenstein rearrangement^{2,409}) towards the latter.^{424,425} Cations of *d*-metals also catalyse this rearrangement.⁴²⁶ It was shown^{427,428} that the main event in the catalytic action of sodium aluminate on the isomerisation of D-glucose to D-fructose is stabilisation of the intermediate enediol *via* coordination giving a structure like **73**. The presence of an anion exchanger in the paramolybdate form also facilitates this transformation by suppressing side reactions.⁴²⁹

Complex formation has been successfully used to protect particular functional groups during selective *N*-acylation of aminoglycoside and aminocyclitol antibiotics in the presence of heavy metal salts.^{430–432} The direction of acetylation can be changed simply by changing the metal cation used.⁴³⁰

The numerous reactions of oxidation of aldoses in the presence of metal salts often yield initially intermediate metal complexes the stability of which varies over wide limits. Complex formation can occur in a transition state, or it can give highly unstable complexes.^{433,434} The intermediates can decompose either in a single-electron process giving free radicals, which act as the reactive species,^{435–438} or by a two-electron transfer mechanism giving reaction products.^{439–441}

In a number of studies,^{442–458} a preparative method has been developed, based on the ability of molybdate ions MoO_4^{2-} to catalyse epimerisation of aldoses and ketoses and their derivatives in relation to the carbon atom nearest to the carbonyl group. The most prominent example of this epimerisation,²⁰² the transformation of D-xylofuranose into D-lyxose, was discussed in Section II.3. When molybdate is replaced by tungstate, the complexation is not accompanied by epimerisation,⁴⁵⁹ because the carbohydrate complexes of tungstate are much more stable than the molybdate complexes¹⁹⁸ (see Section II.3). However, in the presence of a borate, D-arabinose incorporated in the tungstate complex readily epimerises to D-ribose, since the borate complex of the latter is more stable.⁴⁶⁰

Previously, the mechanism of epimerisation has been interpreted by assuming^{13,442} the intermediate formation of planar complex **76**, deprotonated at the C(2) atom, in which the metal is coordinated to the O(1) and O(3) atoms of the cyclic form of the substrate. The subsequent diastereofacial protonation of the complex **76** was assumed to give both the complex of the substrate and that of the product. However, later, using NMR spectroscopy of aldoses enriched in the ^{13}C and ^2H isotopes at the C(1) atom, it was shown⁴⁶¹ that in reality, this epimerisation includes a rearrangement of the substrate carbon skeleton. The C(1) and C(2) atoms exchange their positions in the hypothetical binuclear transition complex **77** containing the initial aldose in the acyclic aldehyde form. A similar complexation has been proposed⁴⁶² to explain epimerisation of D-glucose to D-mannose catalysed by $\text{Mo}_7\text{O}_{24}^{3-}$ ions.

It has been suggested^{13,463,464} that in the presence of Ni^{II} and N,N,N',N' -tetramethylethylenediamine, aldoses are wholly epimerised at the C(2) atom with a similar rearrangement of the carbon skeleton *via* transition complex **78** with the aldehyde form of the substrate. An analogous reaction occurs when Ca^{II} is used instead of Ni^{II} .⁴⁶⁵ Finally, it has been found⁴⁶⁶ that a rearrangement of the carbon skeleton of carbohydrates accompanied by epimerisation occurs even in such a simple system as methanol–calcium hydroxide. It is obvious that in view of these findings, the generally accepted mechanisms of the Lobry de Bruyn–Alberda van Ekenstein rearrangement⁴⁰⁹ should be revised. In the methanol– Ni^{II} – N,N' -diethylethylenediamine system, D-fructose **29** undergoes a more extensive rearrangement of the carbon skeleton resulting in a branched aldose, 2-C-hydroxymethyl-D-ribose.⁴⁶⁷ It is noteworthy that the side formation of ketoses in these processes is not accompanied by a rearrangement of the carbon skeleton of the initial aldoses.⁴⁶⁶ Apparently, ketoses are formed *via* the generally accepted mechanism of the Lobry de Bruyn–Alberda van Ekenstein rearrangement.^{2,409} The discovery of the change of the carbohydrate carbon skeleton upon the formation of metal complexes is undoubtedly an outstanding achievement in the coordination chemistry of carbohydrates.

Solv is solvent.

2. Reactions involving metal complexes of carbohydrates

Cyclodextrins react with RhCl_3 to give colloidal dispersions of rhodium, which efficiently catalyse hydrogenation of alkenes carried out at 30 °C under atmospheric pressure of hydrogen.⁴⁶⁸ Complexes of Cu^{II} with β -CD and its polyphosphate initiate vinylic polymerisation.⁴⁶⁹ Sugars are often used as donors of hydrogen in the catalytic hydrogenation of carbonyl compounds with hydrogen transfer.⁴⁷⁰ The mechanism proposed for this process⁴⁷⁰ assumes participation of metal complexes of carbohydrates formed intermediately. One example of the use of cyclodextrin as phase transfer catalyst, owing to its ability to coordinate s -metal cations, was reported.⁴⁷¹

The chirality of carbohydrates is employed in enantioselective catalysis. Well known^{472–475} catalysts for hydrogenation are L-tartaric acid **18** or its D-enantiomer adsorbed on the metal surface; in this case, chelation leading to the formation of a chiral environment on the metal surface is assumed. The optical yields in these reactions reach 55%–63%.^{476–478} This is a significant achievement, because these catalysts can be used repeatedly. Similar reactions catalysed by palladium supported on cellulose⁴⁷⁹ resulted in optical yields of only 0.10%–0.15%. Apparently, in the latter case, no metal binding on the surface of a chiral support is involved. The optical yields in the reduction of the complexes of ferrocenyl ketones with β -CD of the type **52b** vary from 5%⁴⁸⁰ to 32%–80%.^{481,482}

3. Modelling of enzymes by metal complexes of carbohydrates

This field of application of carbohydrate metal complexes is still limited to cyclodextrins. Thus alkaline hydrolysis of *p*-nitrophenyl acetate is suppressed almost entirely by the addition of the binuclear complex of Cu^{II} with α -CD **51**.⁴⁸³ When the corresponding complex with β -CD is used, the retardation of the reaction is less pronounced. This is due to the formation of a stable inclusion compound from the former complex and the substrate; this permits regarding this complex as an adequate model of a metal enzyme.⁴⁸³ A structurally related binuclear complex of Mn^{II} with

β -CD has been proposed⁴⁸⁴ as a model of a photosynthesis enzyme, which catalyses water oxidation to oxygen. It has been shown^{485,486} that complex formation of d -metals with cyclodextrins is a general way of stabilising hydroxo complexes of d -metals for the modelling of terminal enzyme systems for photosynthesis.

One aspect of enzyme activity, namely, the decrease in the number of degrees of freedom of the substrate upon its complexation with the enzyme, has been modelled by alkaline hydrolysis of esters of ferrocenecarboxylic acids.^{487–490} The molecular design was accomplished in such a way that the catalytic centre (a hydroxyl group of cyclodextrin) was located in the optimum vicinity of the reaction centre of the substrate when the latter had entered the cyclodextrin cavity.^{487–490}

4. Analytical methods based on the formation of metal complexes with carbohydrates

An important application of complex formation with metals is the solution of analytical and structural problems in the series of carbohydrates.

A large set of qualitative and quantitative electro(iono)-phoretic and chromatographic methods for the separation of sugar mixtures based on the complexation with metals have been developed. Early^{491,492} and more recent⁴⁹³ reviews survey the data on paper electrophoresis of sugar mixtures in aqueous solutions in the presence of various salts such as borates, germanates, stannates, arsenites, molybdates, and tungstates. It is significant that these modifications of the method supplement one another. Other efficient procedures are paper electrophoresis in the presence of Cu^{II} periodate, tellurate,⁴⁹⁴ acetate, and basic acetate^{150,495} and capillary electrophoretic separation of enantiomeric monosaccharides in the borate–dextrin (cyclodextrin) system, *i.e.* under conditions of double complexation.⁴⁹⁶ Electrodialysis through a polymeric membrane with grafted boric acid residues has been proposed as a method for separation of multicomponent product mixtures obtained upon the formose reaction.⁴⁹⁷

A broad range of methods consisting in paper and column chromatography of carbohydrates based on complex formation with metals have been surveyed in a review.⁴⁹³ The main column chromatography technique is ion exchange chromatography using Li^+ , K^+ , Ca^{2+} , and Ba^{2+} forms of cation exchangers and cellulose or silica gel impregnated with a borate. Column chromatography of aqueous solutions of sugars on alumina is also accompanied by complex formation.⁴⁹⁸ Closely related approaches are chromatography on anion exchangers in the aluminate form⁴⁹⁹ and chromatography on paper (cellulose) containing carboxylate groups grafted as La^{3+} , Ca^{2+} , and Ba^{2+} salts.⁵⁰⁰ Yet another efficient method is thin layer chromatography of sugars and their derivatives using the Ca^{2+} and La^{3+} forms of cation exchangers.⁵⁰¹ Racemic mixtures of ferrocene derivatives are readily separated on polyamide when an aqueous solution of β -CD is used as the eluent.⁵⁰²

Complex formation with metals has long been used for the determination of sugars. The most widely used procedures are the quantitative Bertrand method⁵⁰³ based on oxidation of copper complexes of aldoses to give Cu^{I} oxide and the related qualitative Fehling² and quantitative Somogyi⁵⁰⁴ methods. There are grounds for believing that oxidation occurs in enediol Cu^{II} complexes.⁵⁰⁵ Determination of sugars based on their oxidation by the Cu^{II} periodate complex⁵⁰⁶ or Ce^{IV} sulfate⁵⁰⁷ has also been described.

The formation of complexes of carbohydrates with metals proved to be useful for electrochemical, mainly polarographic, determination of metals. In the presence of acyclic or cyclic polyols, the half-wave potential of the metal cation being analysed substantially shifts, which enables its determination in the presence of other metal cations.^{508–510} The volumetric determination of Pt^{II} in an alkaline solution of D-mannitol in the presence of

cations of other platinum metals is another example of this approach.⁵¹¹

It is difficult to overestimate the role of complex formation in the configurational and conformational analysis of carbohydrates.^{512, 513} Thus, determination of the stability constants of the borate complexes of pyranoses permitted Angyal to propose a method for the calculation of the conformation energies of these ligands,^{512, 513} while the change of the specific rotation of aldoses following their complexation with borate made it possible to determine their anomeric configuration.^{2, 3}

Several methods of the conformational analysis of carbohydrates are based on the correlation between the complexing and rotational (chiroptical) properties of ligands [optical rotatory dispersion (ORD) and circular dichroism (CD) spectroscopy^{514–518}]. Thus CD spectroscopy of molybdate complexes has revealed⁴⁶⁹ a correlation between the orientation of the hydroxyl groups at the C(2) and C(3) atoms in the pyranose form (see the structures **4a,b**) and the signs of the Cotton effects in the CD spectrum of a colourless solution of the molybdate complex. Chiroptical methods are applied most often to solutions of coloured metal complexes containing Cotton-genic (manifested in the visible ORD and CD spectra) groups. This line of research was initiated by the classical studies of Reeves⁴ dealing with the rotational properties of copper complexes of *O*-methylglycopyranosides. As a result of these studies, a clear correlation between the sign of rotation of model compounds with a fixed arrangement of the hydroxyl groups and the sign of the dihedral angle between them was elucidated. Later, these results were confirmed by chiroptical methods^{135, 519–522} (ORD and CD spectroscopy). Similar correlations have been found for Ni^{II} complexes of carbohydrates,^{227, 228, 523, 524} Other Cotton-genic derivatives such as Mo^{II} acetate⁵²⁵ and other *d*-metal acetates,⁵²⁶ which form chiral complexes with vicinal diol groups of sugars, proved to be more convenient compounds from the viewpoint of methodology.

Complex formation of sugars with lanthanide cations used as shift reagents has also found a wide utility in the conformational analysis of carbohydrates by NMR spectroscopy.^{243–245, 527–537} Boric acid⁵³⁸ and Cu^{II} cations^{139, 539} have also been used as shift reagents.

The complex formation of sugars with metals has been employed^{540–542} for improvement of the mass spectrometry methods for their identification. The complexation of anthrylboronic acid with sugars is accompanied by quenching of its fluorescence; therefore, it has been used⁵⁴³ for the development of fluorescence chemical sensors for sugars.

5. The significance for biology and medicine

Previously the views on the biological functions of carbohydrates reduced to their food (glucose, fructose, starch) and structural (cellulose, chitin) properties. However, during the last decades, carbohydrates have been found to play a crucial role in a number of vitally important processes such as mutual recognition of molecules and cells (cell adhesion, agglutination, reception),⁵⁴⁴ tissue calcification as the initial stage of the formation of vertebrate bones and shells of molluscs and bird eggs.⁵⁴⁵ These discoveries substantially raised the biological status of carbohydrates. Since all the processes listed above are Ca²⁺-dependent, this has also stimulated studies dealing with the complex formation of carbohydrates with *s*-metal cations (Section II.1). The studies performed have demonstrated that carbohydrates are weak complexones for these cations and that complex formation with *s*-metals cannot play an important role in the above biological processes. For example, *N*-acetylneuraminic acid **60c**, which is an indispensable component of biologically significant oligo- and polysaccharides, forms Mg^{II} and Ca^{II} complexes in aqueous solutions the stability constants of which are 1.5 and 1.9 litre mol^{−1}, respectively.³⁴² Since in a living organism, carbohydrates are almost necessarily linked to proteins (glycoproteins and

proteoglycans²), a number of studies^{546–548} have been devoted to the complex formation of a model cation (Gd³⁺) with synthetic glycopeptides. It was found that coordination occurs both in the carbohydrate and peptide fragments, the latter being preferred. In general, there are no grounds to believe that complexation of carbohydrates themselves plays a significant role in biological processes. The examples given below confirm this point.

When sugars are specifically bound by protein compounds, lectins,^{549–552} in the presence of metal cations, the protein–sugar interaction is accomplished only by hydrogen bonds.⁵⁵² Apparently, metal cations ensure the appropriate conformation of the protein needed for sugar reception.⁵⁴⁹ At a certain stage of cell recognition, interaction of carbohydrate-containing proteins is due to the Ca²⁺ cation, but it is unknown to what particular fragment this ion is coordinated. By analogy with lectins, it can be assumed that in this case, too, the metal ion is coordinated to the protein fragment.^{553, 554} The complex formation of Ca²⁺ with sulfated polysaccharides is considered to play a certain role in its deposition in tissues.⁵⁴⁵

Metal complex formation with natural carboxylic acids of carbohydrate origin (see Section V) is important for medicine. Thus ascorbic acid decreases the level of mutations in workers in contact with heavy metals.⁵⁵⁵ Phytic acid is present in substantial amounts in vegetable oils, and its ability to form an insoluble complex with Ca²⁺ decreases the removal of calcium with urine.⁵⁵⁶ Binding with heavy metal cations can even inactivate metal-dependent enzymes, for example, α -amylase⁵⁵⁷ and carboxypeptidase A.⁵⁵⁸

The platinum complexes **46**²³⁶ and [PtL(1,3-diamine)]²⁴² (L is D-gluconate or D-glucuronate) exhibited a considerable antitumour activity. This activity was also found for the platinum complex **71**.³⁹⁴ Polymeric osmium carbohydrate complexes, osmarines,^{238, 239} (Section II.3) are used as antiarthritis preparations owing to their capability of binding superoxide ions, which are responsible for this disease.²³⁹ Copper(II) complexes with cyclodextrin of the type **51** can be used⁵⁵⁹ for treating the mildew blight of grapes, because these compounds are not toxic in wine. Water-soluble iron complexes of glucose and fructose **42** are used to treat anemia.⁵⁶⁰ Phytin **67** prevents foodstuffs from going bad under the action of atmospheric oxygen, because it binds Fe³⁺ and Cu²⁺ cations, which can act as efficient catalysts for undesirable oxidation processes.⁵⁶¹

The complex formation of metals with polysaccharides has also found use in medicine. Pectins (polymers of the type **5** with partly esterified carboxyl groups) isolated from fruits or vegetables efficiently bind toxic metal cations and thus they can be used for detoxification of an organism.⁵⁶² It has been proposed⁵⁶³ to use iron complexes of chondroitinsulfates **63a,b** for curing iron deficiency anemia. Metal complexes of dextran and inulin can be used as paramagnetic contrasting reagents⁵⁶⁴ in medical NMR spectroscopy. Treatment of cellulose with heavy metal salts and subsequent interaction with antibiotics imparts antibacterial properties to textiles.⁵⁶⁵

In nature, complex formation of metals with polysaccharides can be undesirable. Thus the formation of gels on the surface of plant roots may have negative consequences for plants, since their main components, acidic polysaccharides, bind metal cations, which come directly from soil particles and are needed for nutrition.⁵⁶⁶

s-Metal cations⁵⁶⁷ and *d*-metal cations⁵⁶⁸ are used to strengthen agaroid jellies. *d*-Metal hydroxides treated with sugars are employed for enzyme immobilisation.⁵⁶⁹ The natural polymer of *N*-acetyl-D-glucosamine — chitin — has been proposed⁵⁷⁰ as a reagent for extraction of heavy metals from waste water; the ferrite–alginate system is employed for the preparation of ferromagnetic particles used as a contrasting reagent⁵⁷¹ in NMR spectroscopy for medical purposes.

VII. Conclusion

The modern coordination chemistry of carbohydrates resembles an enormous picture painted with rough strokes in which only some sections are drawn thoroughly. This is due to the extreme complexity of the investigation subjects, caused by the specific character of carbohydrates as complexones. Carbohydrates can exist in both cyclic and acyclic forms; they can act as polydentate ligands and form regioisomeric complexes. In addition, chirality of carbohydrates results in the formation of unequal amounts of diastereoisomers in relation to the chelate unit. This diversity of compounds can be found in a single reaction mixture. Therefore, the overwhelming majority of conclusions concerning the structures of carbohydrate metal complexes have been drawn relying on more or less likely suggestions, except for those few cases where researchers were able to obtain a crystalline compound and study its structure by X-ray diffraction analysis. However, with the advent of NMR techniques using metal cations as shift reagents, it became possible to determine fairly reliably the structures of a number of metal complexes of carbohydrates in solution. It would hardly be an overstatement to say that nowadays the coordination chemistry of carbohydrates experiences a new stage of its development.
