Abstract. Methods of synthesis, physicochemical and structural characteristics, and reactivity of 1,8-bis(dialkylamino)naphthalenes and some of their close analogues pertaining to the class of so-called ‘proton sponges’ are considered. The bibliography includes 154 references.

I. Introduction

In 1968, Alder *et al.*¹ reported on a discovery of unusual changes in the variations of basicity in the series of *N*-methylated 1,8-diaminonaphthalenes (Table 1). It has been found that the pK_a values for the unsubstituted diamine **1** and its mono-, di-, and trimethyl derivatives **2–5** fall in the range typical of ordinary aryl amines, while that for 1,8-bis(dimethylamino)naphthalene **6** increases abruptly by nearly six orders. As a result, the basicity of compound **6** exceeds greatly that of both the known aromatic amines and practically all alkylamines. Further studies revealed that this feature is characteristic not only of aqueous solutions of the amine **6**, but also of solutions in non-aqueous solvents (*e.g.* acetonitrile²) and the gas phase.³

	Compound	R ¹	R ²	R ³	R ⁴
1		H	H	H	H
2		Me	H	H	H
3		Me	H	Me	H
4		Me	Me	H	H
5		Me	Me	Me	H
6		Me	Me	Me	Me

It is believed that the abnormally high basicity of the compound **6** is caused by three main factors: (1) destabilisation of the base due to strong repulsion of unshared electron pairs of nitrogen atoms, (2) formation of a strong intramolecular hydrogen bond (IHB) in the protonated form, the cation (**6-H⁺**), and (3) steric strain relief in the molecule upon the transition from a non-planar base to a planar cation.

Another peculiar feature of the compound **6** is the slowness of proton addition–detachment due to the shielding of internitrogen space by four methyl groups. Thus, the high thermodynamic basicity of 1,8-bis(dimethylamino)naphthalene is associated with its rather low kinetic basicity. This circumstance made it possible to establish a similarity in the behaviour of the diamine **6** and genuine sponges, which slowly absorb water and retain it very strongly so that water is difficult to squeeze out. For this particular reason, the compound **6** has been named ‘proton sponge’,⁴ which is generally accepted now and is further extended to all other compounds possessing this type of properties. At present, we can speak about the concept of ‘proton sponges’, which is based on the following principles: (1) the proper structural organisation of their molecule which provides rigid fixation of two nitrogen atoms at a sufficiently close distance from each other; (2) the existence in the molecule of a base of a destabilising repulsion effect of unshared electron pairs of the nitrogen atoms; (3) the occurrence of a strong IHB in the cation, which relieves steric and electronic strains characteristic of a base, and (4) the presence of a hydrophobic environment at the nitrogen atoms, most often in the form of alkyl groups, which actually accounts for the ‘sponge’ effect.

Received 7 April 1997

Uspekhi Khimii **67** (1) 3–27 (1998); translated by R L Birnova

On the basis of this concept, the synthesis of a series of non-naphthalene proton sponges has been carried out since the mid-1980's. Thus, the research group headed by Staab *et al.* synthesised and analysed sponges of the fluorene **7**,⁵ heterofluorene **8**,⁶ and phenanthrene **9**⁷ series and their analogues **10**,^{8,9} and **11**¹⁰ with an sp^2 -hybridised nitrogen heteroatom. The vinamidine sponges **12**, **13** possessing even stronger basicity than compounds **6–11** were synthesised by Schwesinger *et al.*¹¹

Until now, the main attention in the studies on 'proton sponges' has been given to their structural and physicochemical characteristics and bases and cations were considered from somewhat different points of view. Thus the following aspects have been studied for cations: (1) geometry of the intramolecular hydrogen bond (the distance between the amine nitrogen atoms, the N—H...N angle and, particularly, the position of the proton responsible for the IHB symmetry, (2) the ¹H NMR spectra (primarily, the chemical shift of the NH-proton and the constants of its spin-spin coupling with the NMe₂ groups), (3) kinetic NH-acidity (deprotonation rate).

Bases were analysed as regards: (1) their molecular geometry (the distance between the nitrogen atoms, distortion from the planar structure of the rings, conformational phenomena), (2) basicity, (3) the nature of interactions of unshared electron pairs of the nitrogen atoms with one another and with the π -system of the ring, and (4) reactivity.

Several reviews survey exclusively structural and physicochemical aspects of the 'proton sponges'.^{12–15} At the same time, a vast range of interesting information has been accumulated concerning methods of their synthesis and, especially, their reactivity. This review has been written with the aim of generalising the data on the methods of synthesis, reactivity, and physicochemical characteristics of 'proton sponges' of the naphthalene series. The literature cited herein includes the works published before 1997.

II. The types of naphthalene 'proton sponges'

The types of naphthalene 'proton sponges' known to date are represented by the structures **14–30**.

These include 1,8-bis(dialkylamino)naphthalenes **14** (the substituents R¹–R⁴ can be identical or different), their analogues **15–18** in which the amine nitrogen atoms are incorporated into five- or six-membered rings, compounds **19–24** with bridgehead heteroatoms, compounds **25–27** with the nitrogen atoms incorporated in the fused rings, and the so-called double 'proton sponge' **28**. The properties of 'proton sponges' have also been found in iminophosphoranes **29** and 1,8-bis(dimethylamino-methyl)naphthalene **30**.

III. Synthesis of 1,8-bis(dialkylamino)-naphthalenes and their analogues

1. 1,8-Bis(dialkylamino)naphthalenes

There are two general approaches to the synthesis of these compounds which successfully complement each other. The first of them is based on the alkylation of 1,8-diaminonaphthalene or its partially alkylated derivatives. In the second, 1,1,3-trialkyl-2,3-dihydroperimidinium salts serve as the starting compounds.

a. Syntheses based on 1,8-diaminonaphthalenes

The first representative of naphthalene 'proton sponges' described in the literature was 1,8-bis(diethylamino)naphthalene **31**, which was obtained by heating the diamine **1** with an excess of ethyl bromide at 135 °C in the presence of alkali¹⁶ (see also Ref. 17). Later, 1,8-bis(dimethylamino)naphthalene **6** was synthesised by treating the diamine **1** with dimethyl sulfate (the yield was not specified).¹⁸ Initially, this compound was characterised as an oil,

although it is now known as a crystalline substance with m.p. 47–48 °C.¹

Two convenient procedures have been elaborated for exhaustive alkylation of the diamine **1**. Both of them entail the use of strong bases (sodium or potassium hydrides in anhydrous tetrahydrofuran¹⁹ or potassium hydroxide in dimethyl sulfoxide) for the ionisation of N–H-bonds.²⁰

Obviously, under these conditions it is the N-anions of the original diamine and intermediate substitution products that undergo alkylation. The ionisation is favoured by the very high (in comparison with ordinary arylamines) NH-acidity of the diamine **1** (pK_a = 24.5, DMSO, 25 °C), which is ascribed to the stabilisation of the N-anion **32** through IHB.²¹ The yields of 'proton sponges' vary from high to satisfactory. Thus in the alkylation of the compound **6** in the presence of KH–THF or KOH–DMSO systems, the yields exceed 90%. To obtain good yields of the compound **31**, it is recommended to use hexametapal as a solvent instead of DMSO.²⁰ However, the alkylation of 1,8-diamino-2,7-dimethoxynaphthalene **33** gives compounds **34** and **35** in low yields (40% and 21%, respectively).²² The yields of the 'proton sponges' **37**, **38** obtained by the alkylation of the diamine **36** are even lower.²³ The yield of the 'double sponge' **28** obtained by methylation of 4,5-diamino-1,8-bis(dimethylamino)naphthalene with dimethyl sulfate in an NaH–THF system was 31%.²⁴

Depending on the length of the methylene chain, alkylation of the diamine **1** with α,ω -dihalogenoalkanes gives various types of 'proton sponges' (Table 2). If the halogens are separated by 4 or 5 atoms, compounds **15**–**18** are formed in which the amine nitrogen atoms are incorporated into five- or six-membered rings. With a closer arrangement of the halogen atoms, bridged sponges **22**–**24** are formed. Interestingly, the alkylation with 1,3-dibromopropane gives, along with compound **23**, a low yield of the pentacyclic compound **27**. Apparently, its precursor is naphtho[1,8-*b,c*]-1,5-diazacyclooctane (also isolated in low yield),

Table 2. 'Proton sponges' obtained by treatment of 1,8-diaminonaphthalene with α,ω -dihalogenoalkanes and their analogues.²²

'Proton sponge'	α,ω -Dihalide	Reaction conditions	Yield (%)
15	Br(CH ₂) ₄ Br	Na ₂ CO ₃ , reflux	60
16	α,α' -Dibromo- <i>o</i> -xylene	Na ₂ CO ₃ –DMF, reflux	5
17	Br(CH ₂) ₅ Br	Na ₂ CO ₃ , reflux	60
18a	O(CH ₂ CH ₂ Cl) ₂	Na ₂ CO ₃ , 150 °C	10
22	BrCH ₂ CH ₂ Br	Na ₂ CO ₃ –DMF, reflux	42
24	Br(CH ₂) ₃ Br	Na ₂ CO ₃ –acetone, reflux	34
23	Br(CH ₂) ₃ Br	DMF, diglyme	1–5
27	Br(CH ₂) ₃ Br	or sulfolane, 150–200 °C	1–2

which undergoes first *N*-, and then intramolecular *C*-alkylation with 1,3-dibromopropane.

In some cases, 1,8-bis(methylamino)naphthalene and its derivatives served as the starting compounds in the synthesis of 'proton sponges' by alkylation. Thus heating of 1,8-bis(methylamino)-4,5-dinitronaphthalene **39** with methyl iodide in DMF in the presence of potassium carbonate gave the compound **40** (yield 32%).²⁴

Alder *et al.*²² have synthesised a series of 'proton sponges' **19**–**21** by treating 1,8-bis(methylamino)naphthalene **3** with α,ω -dihalogenoalkanes (Table 3).

Table 3. 'Proton sponges' obtained by treatment of 1,8-bis(methylamino)-naphthalene with α,ω -dihalogenoalkanes and their analogues.²²

'Proton sponge'	α,ω -Dihalide	Reaction conditions	Yield (%)
19b	Br(CH ₂) ₂ Br	NaH–THF	80
19b	Br(CH ₂) ₂ Br	NaHCO ₃ –DMF	25
19c	Br(CH ₂) ₃ Br	NaHCO ₃ –MeO(C ₂ H ₄ O) ₂ Me, 190 °C	43
19c	Br(CH ₂) ₃ Br	NaH–THF	1
19d^a	Br(CH ₂) ₄ Br	NaHCO ₃ –MeO(C ₂ H ₄ O) ₂ Me, reflux, 46 h	58
19e	Br(CH ₂) ₅ Br	Na ₂ CO ₃ –MeO(C ₂ H ₄ O) ₂ Me	25
20	O(CH ₂ CH ₂ Cl) ₂	Na ₂ CO ₃ –MeO(C ₂ H ₄ O) ₂ Me, reflux	77
21	α,α' -Dibromo- <i>o</i> -xylene	Na ₂ CO ₃ –DMF, reflux	13

^a The compound was isolated and purified as a salt with the BF₄[–] anion.

The alkylation of *N,N,N'*-trialkyl-substituted 1,8-diaminonaphthalenes proceeds very smoothly. The reaction is usually performed by heating the latter compounds with an excess of alkyl halide in an appropriate solvent or without any solvent. The proton sponge salt formed is converted into the base by treatment with an aqueous alkali.^{25, 26}

b. Syntheses based on 1,1,3-trialkyl-2,3-dihydroperimidinium salts

Far from all of the naphthalene 'proton sponges' can be obtained by alkylation of *peri*-diamines or by functionalisation of the unsubstituted compound **6**. Therefore, the author of this review with his coworkers have developed an alternative and practically versatile procedure for the synthesis of 1,8-bis(dialkylamino)-naphthalenes from 1,1,3-trialkyl-2,3-dihydroperimidinium salts. First, quaternisation of readily available 1,3-dialkyl-2,3-dihydroperimidines **41** gives the salts **42**, which are subjected to reductive scission with lithium aluminium hydride, resulting in the corresponding 'proton sponge' (in the ring-opening, the μ -methylene group is converted into the methyl group, *i.e.*, in this case R⁴ = Me). However, sometimes this reaction does not proceed smoothly, *e.g.*, if the molecule of a salt contains halogens or other easily reducible groups. Better results are achieved when the salts **42** are treated with an aqueous alkali, which gives high yields of the corresponding *N,N,N'*-trialkyl-substituted 1,8-diaminonaphthalene **43**. Its alkylation and subsequent treatment of the quaternary salt with alkali give the target 'proton sponge'. This approach was used, in particular, in the synthesis of 1,8-bis(dialkylamino)-

naphthalenes **6**, **31**, and **44–47** with all possible combinations of the methyl and ethyl groups.²⁵

Compound	R ¹	R ²	R ³	R ⁴
44	Me	Me	Me	Et
45	Me	Me	Et	Et
46	Me	Et	Me	Et
47	Et	Et	Et	Me

In a similar way, the acenaphthene ‘sponges’ **48**, **49**,²⁵ 4-halogeno- and 4,5-dihalogeno-1,8-bis(dimethylamino)naphthalenes **50–53**,^{27,28} and partially hydrogenated derivatives of 10-dimethylaminobenzo[*h*]quinoline **25** and quinolino[7,8:7',8']-quinoline **26** were synthesised.²⁹

48, 49
48: R = Me;
49: R = Et.

50–53
50: R¹ = Cl, R² = H;
51: R¹ = Br, R² = H;
52: R¹ = R² = Cl;
53: R¹ = R² = Br.

It should be noted that quaternisation of 6-halogeno-1,3-dimethyl-2,3-dihydroperimidines **54a,b** gives a mixture of isomeric salts **55a,b** and **56a,b** in comparable amounts. Separation of this mixture is not required, since methylation of the isomeric *N,N,N'*-trialkyl-substituted 1,8-diaminonaphthalenes formed upon alkaline treatment give the same final product.^{27,28}

R = Br (**a**), Cl (**b**), NO₂ (**c**).

In some cases, however, alkylation of non-symmetrical dihydroperimidines occurs regioselectively. Thus if the nitrogen atoms have different substituents (*e.g.*, Me and Et), quaternisation affects only the nitrogen atom carrying the smallest group.²⁵ Analogously, but owing to electronic (rather than steric) factors, methylation of 1,3-dimethyl-6-nitro-2,3-dihydroperimidine **54c** gives exclusively the salt **55c**.³⁰

The latter manifests an abnormal behaviour upon alkaline treatment. The main product of this reaction is the naphthol **57** formed in 65% yield. Dihydroperimidine **54c** was formed in a small amount (5%), whereas nitronaphthylenediamine **58** was present in only trace amounts.

2. Analogues of ‘proton sponges’ with *N*-aryl groups

Two compounds of this type have been described thus far, *viz.*, 1,8-bis(diphenylamino)- and 1,8-bis(methylphenylamino)-naphthalene,³¹ which do not resemble classical ‘proton sponges’ in properties and molecular geometry. Fairly accessible 1,8-bis(phenylamino)naphthalene **59** served as the starting compound for their synthesis. Its sequential arylation (with dehydrobenzene generated from *o*-bromofluorobenzene and then with iodobenzene according to Ullman) has led, *via* the triphenyl-substituted compound **60**, to 1,8-bis(diphenylamino)naphthalene **61**. An attempted exhaustive Ullman arylation of the diamine **1** was unsuccessful. To synthesise 1,8-bis(methylphenylamino)-naphthalene **62**, the diamine **59** was converted into the dilithium salt, which was further subjected to methylation.

3. Iminophosphorane ‘sponges’

In addition to iminophosphorane **29**, its analogues **63** and **64** were synthesised.^{32,33} The general method for the synthesis of these compounds involves the reaction of a bromine–triphenylphosphine (diphenylmethylphosphine) complex with the corresponding amine in the presence of triethylamine. The yields are high, as a rule.

4. 1,8-Bis(dimethylaminomethyl)naphthalene

Compound **30** was obtained in 90% yield by reduction of 1,8-bis(dimethylcarbamoyl)naphthalene with lithium aluminium hydride.³⁴ In some features (see below), this can also be referred to as a ‘proton sponge’.

IV. Physicochemical properties of naphthalene 'proton sponges'

1. Basicity

Unquestionably, high basicity is the main distinctive property of all the 'proton sponges'. The analysis of factors influencing this parameter sheds more light on both structural peculiarities of these compounds and their reactivity. We have already mentioned the three main reasons for the high basicity of 'sponges', namely, destabilisation of the base as a result of repulsion of unshared electron pairs of the proximal nitrogen atoms, steric strain relief upon the transition to the cation, and the formation of a strong IHB in the cation. The greatest importance is given to the latter factor, therefore the stability and geometry of IHB in cations of the 'proton sponges' have become objects of intense studies using ^1H NMR, IR spectroscopy, X-ray analysis, and other methods (see below).¹³

The contribution of IHB to the general increase in the basicity of a 'proton sponge' can be roughly estimated from the $\text{p}K_{\text{a}}$ value of 2,2'-bis(dimethylamino)diphenyl **65**. This value is equal to 7.9, *i.e.*, the basicity of this compound is nearly three orders of magnitude higher than that of *N,N*-dimethylaniline.³⁵ Since the benzene rings in the compound **65** are turned at an angle of 135° relative to one another, this is free from both noticeable repulsion of unshared electron pairs of the nitrogen atoms and steric strain due to this repulsion. Thus this difference in basicity can be ascribed, with a fair degree of confidence, to the stabilising effect of the IBH in the cation **65-H**⁺. Apparently, the energy contribution of the IBH in case of the 'proton sponge' is even higher, since the cation **6-H**⁺ contains a six-membered ring, which is more stable than the seven-membered ring in the cation **65-H**⁺.

Of special note is the fact that the second ionisation constant of the 'proton sponge' measured in water ($\text{p}K_{\text{a}}^2 = -9.0$)³⁶ is much lower than the first one ($\text{p}K_{\text{a}}^1 = 12.1$). It is not surprising that in contrast to 1,8-diaminonaphthalene, which gives a stable crystalline dihydrochloride, the corresponding salts of the 'proton sponge' cannot be obtained. The reason is that the rupture of the IBH needed for the second *N*-protonation is energetically unfavourable even under the action of strong acids. Cations of other 1,8-bis(dialkylamino)naphthalenes behave in a similar way. At the same time, under the action of HClO_4 or $\text{CF}_3\text{SO}_3\text{H}$, the *N*-methylated cation of the 'proton sponge' **66** devoid of the IHB forms the dication **67**, which is partly isomerised into the *C*-protonated forms **68** and **69**.^{37, 38}

For the same reason, the chelated cations **19d-H**⁺ and **19e-H**⁺ do not undergo second *N*-protonation under analogous conditions, whereas the non-chelated cations **22-H**⁺ and **23-H**⁺ do form the *N*(1),*N*(8)-dication.³⁷

Tables 4 and 5 present the values of the basicity constants, $\text{p}K_{\text{a}}$, of the naphthalene 'proton sponges' both without additional substituents in the naphthalene nucleus (**6**, **31**, **44–47**), and with substituents at *ortho*- (**25**, **26**, **70–73**) and *para*- (**48–53**, **74–86**) positions, as well as for one 2,4-disubstituted **87** and polynuclear compounds **88–93**. Only a few of the $\text{p}K_{\text{a}}$ values have been measured in water or in mixtures of water with other solvents. Most of the data were obtained for acetonitrile; in some cases the measurements were performed in DMSO. The $\text{p}K_{\text{a}}$ values of the compound **6** in acetonitrile (18.2), water (12.1, 12.3), and DMSO (7.5) indicate that the basicity of the 'sponge' drops by more than ten orders of magnitude as the proton-acceptor properties of a solvent increase.

Table 4. Basicity constants, $\text{p}K_{\text{a}}$, of naphthalene 'proton sponges' and some of their analogues in aqueous solvents.

Compound	Solvent ^a	$\text{p}K_{\text{a}}$	Ref.
6	H_2O	12.3; 12.1	1, 17

Measurements of the gas-phase basicity (that is the proton affinity) of the 'proton sponge' and other 1,8-diaminonaphthalenes have been carried out.³ The corresponding values are given in Table 6 in comparison with analogous values for methylated derivatives of aniline and ammonia. The abrupt jump in basicity in both the gas phase and water is observed only for the transition from 1-dimethylamino-8-methylaminonaphthalene **5** to 1,8-bis-(dimethylamino)naphthalene **6**. This indicates that the abnormally high basicity of the 'proton sponge' in vapour and in water is due to the same factors. It is interesting to note that in the gas phase, all 1,8-diaminonaphthalenes are protonated at the nitrogen atom, whereas 1-aminonaphthalene and 1,3-diaminobenzene are protonated in the ring. It is believed that the stability of 1,8-diaminonaphthalene *N*-cations in the vapour is accounted for by the stabilising effect of the IHB.

Table 6. Effect of *N*-methylation on the gas-phase proton affinity (PA) and changes in free energy (ΔG_0^1) of protonation of the succeeding base in comparison with the preceding base in the gas phase and in water.^{3, 47}

The dependence of gas-phase basicities of amines (including 1,8-diaminonaphthalenes) and core-bond energies of the σ -back-bone has been studied.⁴⁷ It is linear for the bases the geometry of which is not changed significantly upon protonation. However, such a correlation was not found for compounds **3**, **5**, and **6**. It was suggested that for these compounds the degree of deviation from linearity can serve as a measure of steric strain relief upon the transition from the base to the cation. For the 'proton sponge' **6**, this value was estimated to be 62.8 kJ mol⁻¹, and for the amines **3** and **5**, 37.7 and 33.5 kJ mol⁻¹, respectively.

Let us now consider the effect of structural changes at the nitrogen atoms and in the ring on the basicity of 'sponges'. Successive substitution of the *N*-methyl groups by ethyl groups slightly increases the basicity, as a result of which the pK_a value of the 'tetraethyl sponge' **31** is 0.8–1.2 units higher than that of its tetramethyl analogue **6** (*cf.* Tables 4 and 5). More substantial changes in basicity are observed in those cases where the amine nitrogen atoms are incorporated into the rings. Thus, the basicity of 1,8-dipyrrolidino- and 1,8-dimorpholinonaphthalenes **15** and **18** is lower by 2.5 and 4.5 orders of magnitude, respectively, than that of the 'proton sponge' **6** (Table 4). The same tendency, although less pronounced, is manifested in compounds **25** and **26** (Table 5) the nitrogen atoms of which are incorporated into fused ring systems. It may be assumed that their structure is not optimum for the formation of a sufficiently strong IHB in the cation, *e.g.*, because the axes of unshared electron pairs of the nitrogen atoms can hardly be coplanar with the ring. This phenomenon was also noted for some non-naphthalene 'proton sponges'. Thus the basicity of benzo[1,2-*h*:4,3-*h'*]diquinoline **11** with a helicene structure is 2.5 orders of magnitude less¹⁰ than that of the planar quino[7,8-*h*]quinoline **10** (Ref. 8) ($pK_a = 10.3$ and 12.8, respectively).

As can be inferred from Table 4, of a set of diamines **19**, only compounds **19c–e** can be regarded as 'proton sponges'. The basicity of the first two representatives of this series lies at a level characteristic of ordinary arylamines. It is understandable that the methylene and ethylene bridges in the molecules **19a,b** provide rigid fixation of the nitrogen atoms in the configuration where unshared electron pairs largely acquire *p*-character without any noticeable reciprocal repulsion; in addition, the IHB cannot be formed in their cations. Apparently, for this reason the bridged diamines **22–24**, which form the non-chelated cations **22-H⁺** and **23-H⁺**, are not 'proton sponges'.

The effect of substituents in the nucleus on the basicity of 'proton sponges' is roughly as expected (Tables 4 and 5) for 2,7-dialkoxy derivatives **34**, **35**, **37**, and **38** the basicity of which is four orders of magnitude higher than that of the non-substituted 'sponges' (Table 4), and their salts are not significantly deprotonated by strong aqueous alkalis. Formerly, these compounds were considered to be the strongest of the known neutral bases. It is believed that the molecules of compounds **34**, **35**, **37**, and **38** manifest the so-called 'supporting effect' [Buttress effect. Ed.], in which *ortho*-substituents favour closer approach of unshared electron pairs of both dialkylamino groups to each other, enhancing electrostatic repulsion and, presumably, steric strain in the base. The 'supporting effect' was also observed in 2,7-dichloro- and 2,7-dibromo-1,8-bis(dimethylamino)naphthalenes **72** and **73**.^{44,48}

The attempts to separate the first and second ionisation constants for the binaphthyl **90** and binaphthylmethane **91** 'sponges' were unsuccessful.⁴⁴ Apparently, both their basic centers have little influence on each other.

The basicity of compounds **29**, **63**, and **64** could not be determined experimentally due to their poor solubility, slow rates of protonation, and hydrolysis of the iminophosphorane group. However, using complex extrapolations, the pK_a value for compound **29** in water was estimated to be equal to 15.6, which markedly exceeds the basicity of the classical 'proton sponges'.⁴⁹

The basicity of 1,8-bis(dimethylaminomethyl)naphthalene **30** ($pK_a^1 = 18.3$, $pK_a^2 = 11.4$ in acetonitrile) is at a level typical of the 'naphthalene sponges'.⁵⁰ However, the fact that this compound binds two protons instead of one (as is the case with the classical 'proton sponges') testifies to the insufficiently strong IHB in the monocation; the latter finding was confirmed by ¹H NMR spectroscopic data.

2. The mechanism and rates of deprotonation of cations

As has already been mentioned, the high basicity of 'proton sponges' is combined with low rates of their protonation–deprotonation. The deprotonation rate constants for several 'sponges' are given in Table 7, which also contains data for the 1-dimethylamino-8-methoxynaphthalene cation **94-H⁺** and 8-dimethylaminonaphthol **95** for comparison.

Whereas the deprotonation rate for ordinary ammonium salts is limited by diffusion ($k \approx 3 \times 10^{10}$ litre mol^{−1} s^{−1}),⁵¹ in the case of 'sponge' cations this process is much slower. Thus for the cation **6-H⁺** $k = 1.9 \times 10^5$ litre mol^{−1} s^{−1}, and for its tetraethyl analogue **31-H⁺** k is even one order of magnitude lower. Deprotonation of their 2,7-dimethoxy derivatives, **34-H⁺** and **35-H⁺**, is especially slow, and in the latter case the reaction can even be followed spectrophotometrically. It is noteworthy that because of the high basicity of compounds **34** and **35**, the deprotonation of their cations is observed only in alkaline solutions of DMSO.

Table 7. Rate constants for the reaction of deprotonation of some 'proton sponge' cations.

Note For more detailed information see Refs 23 and 40.

^a Ratio of components is given in brackets (*v/v*). ^b HPO₄^{2−} was used as the base instead of OH[−].

It is reasoned that the low rates of cation deprotonation are mainly caused by the necessity of cleavage of a very strong IHB. Presumably, a certain role is played by steric factors: in the cation, the proton resides in a sort of hydrophobic 'pocket', therefore, access to a base must be hindered (especially in the case of tetraethyl 'sponges'). Compounds **94-H⁺** and **95** are also deprotonated very slowly, but still faster than the 'sponge' cations. It may be inferred from these data (Table 7) that the strength of the IHB decreases in the following order: **6-H⁺** > **95** > **94-H⁺**.

Vivid debates in the current literature concern the mechanism of deprotonation of chelated species of 'proton sponge' cations.¹⁴ Virtually all the data indicate that this process occurs in two steps: first, the IHB is cleaved under the influence of a base, and then deprotonation of the unchelated cation takes place. Apparently, the limiting step in this process is its first stage, therefore, the equilibrium concentration of the unchelated cation at each moment of time is low. However, we have recently observed for the first time in our laboratory all the three particles (both cations and the deprotonated base) in equilibrium, with 4-nitro-1,8-bis(dimethylamino)naphthalene **84** as an example.⁵⁵ It was found that the ¹H NMR spectrum of the cation **84-H⁺** in [D₆]-DMSO contained peaks not only of the chelated cation **84-H⁺-a**, but also those of the free base **84** and of a third species the characteristics of which corresponded to those of the non-chelated cation **84-H⁺-b**. At an initial concentration of the dissolved perchlorate **84-H⁺** of 5×10^{-2} mol litre^{−1}, the ratio **84-H⁺-a** : **84-H⁺-b** : **84** is 68 : 19 : 13, *i.e.*, under these conditions the chelated cation is predominant. If the concentration of the

original salt decreases by one order, this ratio changes drastically (26:5:69) and the deprotonated base becomes the predominant form. The cation **84-H⁺-a** does not undergo any noticeable changes in acetonitrile. Similarly, the cation of the 'proton sponge' **6-H⁺** is the only species that is present in [2H₆]-DMSO.

Apparently, there are three reasons for the abnormal behaviour of the cation **84-H⁺**: (1) considerable asymmetry of the IHB [according to X-ray and ¹H NMR data, the proton resides predominantly at the N(8) atom], (2) decreased (four orders of magnitude in comparison with compound **6**) basicity of the nitro-derivative **84**, and (3) the optimum moderate basicity of dimethyl sulfoxide sufficient to induce partial scission of the IHB and subsequent deprotonation, but at the same time insufficient for the complete shift of the equilibrium between the non-chelated cation and the base to the right.

3. Molecular and crystalline structure

a. Bases

The most important peculiarity of 'proton sponge' bases is a considerable distortion of the planar structure of their molecules due to the trend of the dialkylamino groups to maximally separate from one another. According to X-ray data, for compound **6**,⁵⁶ (1) the angle C(1)–C(9)–C(8) increases to 125.8°; (2) the distance C(1)–C(8) increases to 2.56 Å against 2.45 Å in naphthalene; (3) the distance N···N is rather large (2.79 Å) (*cf.* 2.72–2.74 Å in 1,8-diaminonaphthalene).⁵⁷ The mean plane of the naphthalene system is formed by C(2), C(3), C(9), C(10), C(6), and C(7) atoms, whereas the C(1)–C(9)–C(10)–C(4) and C(8)–C(9)–C(10)–C(5) fragments are symmetrically twisted relative to the central bond C(9)–C(10); the torsion angles are equal to 8.9° and 10.5°, respectively. Thus the two benzene rings begin to resemble two chairs put against each other so that the back of one chair is next to the legs of the other chair, and *vice versa*. As a consequence, the C(1) and C(8) atoms and, correspondingly, the nitrogen atoms deviate (the latter, by 0.4 Å) in opposite directions from the mean plane of the fused system (Fig. 1*a*). The orientation of the methyl groups is also different (Fig. 1*b*) as if one pair is directed inward towards the cyclic system, while the other is directed outward, the latter lying nearly in the mean plane of the ring. Obviously, the axes of the unshared electron pairs at the nitrogen atoms are also oriented in opposite directions to form an angle of about 40° with the axes of the aromatic *p*-electrons. The latter circumstance deserves special notice, since with such angles the conjugation of the dimethylamino groups with the π -system of the ring is still considerable.

Figure 1. Structure of the 'proton sponge' molecule **6**: view from the top (*a*) and along the mean plane of the ring (*b*) (the empty and full circles belong to the atoms located on different sides of the mean plane).

Table 8. The distance between the nitrogen atoms, $r(\text{N}\cdots\text{N})$, in some 1,8-diaminonaphthalenes.

Compound	$r(\text{N}\cdots\text{N})/\text{\AA}$	Ref.	Compound	$r(\text{N}\cdots\text{N})/\text{\AA}$	Ref.
1	2.72; 2.74 ^a	57	28	2.75	24
6	2.79	56	34	2.76	60
17	2.89	58	84	2.86	55
18a	2.86	58	81	3.03	61
23	2.89	59	96	2.95	61
61	2.86	31			

^a For two independent molecules.

An analogous pattern with some modification is also observed for other 'proton sponges' (Table 8). Thus in the 4-nitro-derivative **84**, as well as in 4,5-**81** and 2,5-dialdehydes **96**, the distance between the nitrogen atoms of the dimethylamino groups shows a tendency to increase, presumably, as a result of conjugation of the latter with π -acceptor substituents. This must be accompanied by flattening of bonds at the amine nitrogen atoms (due to the greater contribution of the structures of the type **84a** and **84b**), so that NMe₂ groups require larger space. Accordingly, the C(1)–N(1) and C(8)–N(2) bonds in compounds **84** (1.37–1.38 Å) and **81**, **96** (1.36 Å) become somewhat shorter than those in the 'proton sponge' **6** itself (1.40 Å).

In compounds with electron-donor groups **28** and **35**, the lengths of C(1)–N(1) and C(8)–N(2) bonds are the same as in compound **6** (1.40 Å). The N···N distance remains virtually unchanged, although the distortions in the naphthalene ring structure become more pronounced. As expected, the N···N distance increases in the 'proton sponges' **61**, **17**, **18a**, and **23** having bulkier or less flexible substituents at the amine nitrogen atoms.

A characteristic feature of the molecular structure of 1,8-bis(dimethylaminomethyl)naphthalene **30** is the practically planar geometry of the naphthalene ring.⁶²

b. Cations

A great number of X-ray studies have been carried out with the salts of the 'proton sponge' **6-H⁺** with various anions (Table 9). All these studies have demonstrated that the transition to the cation brings about drastic changes in the molecular structure. Owing to the formation of the hydrogen bridge, the dialkylamino groups rotate in such a way that the dihedral angle between them and the naphthalene system plane tends to reach 90°. This results in steric strain relief, flattening of the naphthalene fragment, and considerable approach of the nitrogen atoms. The N···N distance varies within the range of 2.55 to 2.65 Å, being, on the average, 2.58 Å. In the majority of salts, the naphthalene ring is virtually flat and both N atoms lie in the same plane. For some salts ($\text{X}^- = \text{C}_6\text{Cl}_5\text{O}^-$, BF_4^- , SCN^-), the twisting (by no more than 4–5°) of the planes of C(1)–C(9)–C(10)–C(4) and C(8)–C(9)–C(10)–C(5) around the central bond C(9)–C(10) still takes place. As a result, the molecule acquires a propeller shape, and the nitrogen atoms diverge in different directions from the mean plane (up to 0.25 Å). However, these deformations are much less than those observed in the 'proton sponge' base. The C(1)–N(1) and C(8)–N(2) distances in the cation **6-H⁺** increase up to 1.45 Å, which testifies to the lack of conjugation between the

dimethylamino groups and the aromatic π -system. This conclusion is confirmed by a variety of other data.

In contrast to 1,8-bis(dialkylamino)naphthalene cations, the naphthalene ring in cations of the iminophosphorane ‘sponges’ **29**, **63**, and **64**, is strongly distorted, but the distance between the nitrogen atoms is smaller (2.52–2.60 Å).^{32, 33}

The main attention in the studies of ‘proton sponge’ cations has been paid to the symmetry and geometric characteristics of the hydrogen bridge. This problem was comprehensively discussed in a number of reviews,^{13, 86} therefore we shall confine ourselves to a mere statement of the central issues. Theoretically, four types of potential energy curves for the $\text{N}\cdots\text{H}-\text{N}$ system are possible (Fig. 2).

The profile *a* having one minimum corresponds to a completely symmetrical bridge, whereas the profile *b*, which has a low activation barrier, reflects the rapid tautomeric equilibrium between two equivalent asymmetric structures. It is the question as to which of these two profiles is realised in the cation of the ‘proton sponge’ 6-H^+ that has been discussed in most detail.

Theoretical calculations of an $[\text{H}_3\text{N}\cdots\text{H}\cdots\text{NH}_3]^+$ system have shown that when the distance between the nitrogen atoms is 2.75 Å, the potential curve has two minima with a barrier of 10.9 kJ mol⁻¹; with a decrease in the distance down to 2.50 Å, the barrier disappears.¹³ In terms of the data listed in Table 9, these results may indicate that the energy profile for the cation 6-H^+ corresponds to type *b* with a low barrier of transition between the structures $6\text{-H}^+ \text{-a}$ and $6\text{-H}^+ \text{-b}$.

**Figure 2.** Types of potential energy curves for the IHB in ‘proton sponge’ cations; for *a–d*, see text.

Indeed, in some cases it was shown that the proton NH lies in the plane of symmetry of the cation **6-H⁺** not only at room temperature, but even at low temperatures; the length of the N–H bond is averaged (~ 1.3 Å). In those salts (which constitute the majority), where the hydrogen bridge is asymmetrical, the N–H bond is much longer than the standard value (~ 0.9 Å). In the case of the salt **6-H⁺** with the dianion of the chloranilic acid, a decrease in the temperature from 300 to 150 K results in the shortening of this bond from 1.14 to 1.07 Å. This is indirect evidence that the elongation of the N–H bond is due to the disordered position of the NH-proton oscillating between the nitrogen atoms and the plane of symmetry. Obviously, the anion influences the mode of these oscillations and, correspondingly, the geometry of the hydrogen bridge both through the electric field induced by it and due to the changes in the crystal lattice. The formation of a weak bifurcated hydrogen bond involving the anion and the NH-proton was recorded both for the **6-H⁺** salt with hydrosquarate and squarate anions. Thus at present the majority of researchers tend to accept that the cation **6-H⁺** exists in a position of fast tautomerism

An asymmetrical hydrogen bridge was observed in crystals of the ‘double sponge’ dication **28-(2H⁺)** as well as in cations of the bisiminophosphorane **29** and the compound **30**. It is probable that the energy curve profile of the type *c* corresponds to these bridges. As expected, in cations of unsymmetrical bases, e.g., **84-H⁺** or **63-H⁺**, the proton practically completely resides on the more

basic of the two N atoms: on N(8) and the imine nitrogen, respectively (type *d* curve, Fig. 2) (Table 10).

It should be mentioned in conclusion that in cations of all the ‘proton sponges’ the hydrogen bridge is non-linear and the N–H $\cdots$ N angle lies within the range of 150–160° with only few exceptions. The neutronographic method, which is considered to be more precise for establishing the molecular structure than X-ray structural analysis (as was shown with the **6-H⁺** salt with the dichloromaleic acid anion), gives basically the same results.^{85,87}

4. NMR spectra

¹H, ¹³C, and ¹⁵N NMR spectra of the ‘proton sponges’ and their cations were investigated both for solutions and solid state. NMR spectroscopy was used to establish structural characteristics, π -electron distribution, and the ease of proton exchange between the cations and bases.

a. Bases

As expected, the signals for all the aromatic protons in the ¹H NMR spectrum of compound **6** (Table 11) are at higher field than those for naphthalene (δ 7.46 and 7.81 ppm for α - and β -protons, respectively). The greatest shielding is of the protons at positions 2 and 7, then H3(6) and H4(5), the difference in the chemical shifts between *meta*- and *para*-protons being very small.

- 94:** R¹ = OMe, R² = NMe₂;
97: R¹ = R² = OMe;
98: R¹ = NMe₂, R² = H;
99: R¹ = OMe, R² = H.

94, 97–99

If one assumes that the degree of proton shielding is proportional to the +*M*-effect of the substituents, the following conclusion can be made: the electron donor capacity of the NMe₂ groups in the molecule of compound **6** is somewhat lower than that of the *peri*-substituents in 1-dimethylamino-8-methoxy- **94** and 1,8-di-methoxynaphthalenes **97** (Table 12). Even in 1-methoxynaphthalene **99**, the donor effect of the substituent seems to be higher than in 1-dimethylaminonaphthalene **98**. This conclusion is confirmed by analysis of ¹³C NMR spectra (Table 13). Since in benzene derivatives the shielding effects of NMe₂ and MeO groups are opposite and correspond to the Hammett σ -constants, it is reasonable to conclude that the decreased electron donor capacity of the NMe₂ groups in 1-dimethylamino- and 1,8-bis-(dimethylamino)naphthalenes is a

^a Spectrum for solid compound.

result of their considerable non-coplanarity with the nucleus caused by *peri*-interactions. It is noteworthy in this respect that the chemical shift of the *N*-methyl groups (δ 2.8 ppm) in the ‘proton sponge’ is lower than that of 1-dimethylaminonaphthalene (δ 3.0 ppm), which testifies to an increased contribution of the *s*-component in the *n*-orbital of the amine nitrogen.

Evidence for the effects of substituents in the nucleus on the parameters of the ^1H NMR spectra can be inferred from Table 14. As can be seen, *ortho*- (Cl, Br) and *−M*-substituents at position 4 (CHO, COCF₃, NO₂) cause a down-field shift of the *N*-methyl signals (by $\sim$ 0.2 ppm). In addition, *−M*-substituents produce a strong deshielding effect on H(5) [to a lesser degree, on H(3)]. This is accompanied by reduction of the spin-spin coupling constant $J_{\text{H}(5)-\text{H}(7)}$ and marked increase in the spin-spin coupling constant $J_{\text{H}(2)-\text{H}(3)}$ (presumably, due to an increased contribution of structures of the type **84a,b**).

Recent measurements of MAS ^1H NMR and ^{13}C NMR spectra of a solid sample of the ‘proton sponge’ **6** gave quite unexpected results:⁹⁶ they revealed strong asymmetry of its molecule. It was found that all four methyl groups, like all ten ring carbon atoms, resonate as separate peaks, *i.e.*, they are non-equivalent (Table 13). This has been interpreted in terms of electrostatic interactions between the neighbouring molecules in the crystal lattice and has led to partial revision of the previously established⁵⁶ results of X-ray studies of the ‘proton sponge’.

^1H NMR spectra have been used to study the ease of the proton exchange between the bases of the ‘proton sponge’ **6** and its tetraethyl analogue **34**, on the one hand, and the corresponding cations, on the other.⁹⁷ The ^1H , ^{13}C , and ^{15}N NMR spectra of compound **30** have also been recorded.^{34, 98}

b. Cations

On going from the base **6** to the cation **6-H⁺**, the signals for all the protons are shifted down-field: H[2(7)], by +1.1 ppm, H[3(6)], by +0.4 ppm, H[4(5)], by +0.7 ppm, and CH₃, by +0.3 ppm. Although it would be logical to expect that the signals of *ortho*-protons were at the lowest field, it is not always the case (Table 11). For example, in a solution of the perchlorate **6-H⁺** in [²H₆]-DMSO, the signals of *ortho*- and *para*-protons overlap; however, in CD₃CN and CD₃NO₂, the doublet of doublets of H[4(5)] are at lower field. The signals of the both types of protons can be distinguished by larger values of the *ortho*-constants, $J_{H(3)-H(4)}$ and $J_{H(5)-H(6)}$ in comparison with $J_{H(2)-H(3)}$ and $J_{H(6)-H(7)}$. The nature of the anion in 'proton sponge' salts has practically no effect on their NMR spectra (Table 11).

Yet, the main peculiarity of the ¹H NMR spectra of 'proton sponge' cations is the unusually high chemical shift of the NH-proton (δ 18–20 ppm), which is indicative of strong chelation. For the cations of symmetrical 'proton sponges' including **6-H⁺**, the NH signal in high-resolution spectra has thirteen lines due to spin-spin coupling with the protons of the methyl groups. The signal of the latter is split into a doublet with an intensity of 12 proton units with a spin-spin coupling constant of about 2.5 Hz. Thus the NMR method has permitted recording of a symmetrical IHB for these cations at room temperature, which probably reflects rapid (on the NMR time scale) deviations of the NH-proton relative to the plane of symmetry. The same is observed in the spectra of the symmetrical iminophosphorane 'sponges' **29** and **64**.^{32, 49} Although, as has been shown earlier, the hydrogen bridge has an asymmetrical shape in crystals of their cations, according to NMR data both tautomeric forms are in fast

equilibrium and the NH-proton is shared equally by both nitrogen atoms.

In non-symmetrically substituted cations, the dimethylamino groups are non-equivalent, they are observed as two doublets with different spin-spin coupling constants (Table 15). It has been suggested to use the relationship between the coupling constants for estimating the degree of IHB asymmetry in a particular cation.⁹³ The most asymmetrical is the hydrogen bridge in the cations of 2-halogeno-1,8-bis(dimethylamino)naphthalene **70-H⁺** and **71-H⁺**; in [²H₆]-DMSO, the NH-proton belongs to the N(8) atom by more than 80%. The asymmetry of IHB in the cations of 4-amino- **76-H⁺** and 4-methylamino derivatives **78-H⁺** is very strong [in these cases, the NH-proton is closer to the N(1) atom] and it is somewhat less in the cations having *M*-substituents at position 4: **80-H⁺**, **82-H⁺** – **84-H⁺**, and **100-H⁺**. The least asymmetrical is the IHB in the cations of 4-vinyl- **74-H⁺**, 4-acetamido- **77-H⁺**, and 4-halogeno-derivatives **50-H⁺** and **51-H⁺**. It was established that the transition from [²H₆]-DMSO to a less proton-accepting solvent, acetonitrile, favours the symmetrisation of the hydrogen bridge, which is especially pronounced in the cations of 2-halogeno- and 4-amino-1,8-bis(dimethylamino)-naphthalenes.

^a Indices of proton localisation at each of the dimethylamino groups (PL) were calculated by the formula:

$$PL = [J_{NH-1(8)-NMe_2} / (J_{NH-1-NMe_2} + J_{NH-8-NMe_2})] \cdot 100\%.$$

For a series of compounds of the same type, there is no apparent correlation between the stability of the IHB and the chemical shift of the NH-proton. It is therefore sufficient to compare the cation **6-H**⁺ and its 4-nitro-derivative **84-H**⁺. Although in the latter case, the signal of the NH-proton is shifted down-field by 0.4 ppm relative to the analogous signal in the spectrum of the cation **6-H**⁺, its hydrogen bridge is partly cleaved by DMSO and other dipolar solvents (see section IV. 2), whereas in the cation **6-H**⁺, no signs of its cleavage were observed. Apparently, the stability of the IHB is largely determined by the basicity of the corresponding 'proton sponge', while the δ_{NH} value depends on the distance between the nitrogen atoms and the degree of NH-proton expulsion from the plane of the ring as a result of which it experiences the effect of the diamagnetic component of the magnetic field of the naphthalene π -system. The unusually high chemical shift of the NH-proton ($\delta \sim 20.0$ ppm) in the spectra of cations of 2,7-dihalogeno-derivatives of the 'proton sponge' is indirect evidence in favour of this explanation. It is unlikely that in these compounds the NH-proton lies in the plane of the ring. More probably, the nitrogen atoms become closer to each other pushed by the halogens, so that this proton is out of the plane and undergoes strong deshielding in the cation **11-H**⁺ (δ_{NH} 24.0 ppm).¹⁰ On the whole, the factors influencing the magnitude of the chemical shift of the NH-proton in 'proton sponge' cations have been studied insufficiently. For example, it is still unclear why the signals of the NH-protons in the cations **25-H**⁺ (δ 16.56 ppm), **26-H**⁺ (δ 14.90 ppm),²⁹ **29-H**⁺, **64-H**⁺ ($\delta \sim 16.5$ ppm),^{32,49} and **30-H**⁺ ($\delta \sim 15.8$ ppm)³⁴ are at much higher fields than those in the cations of 1,8-bis(dialkylamino)naphthalenes.

¹³C and ¹⁵N NMR spectra of salts of **6-H**⁺ (with tetrazolide,⁹⁹ 1-methyltetrazole-5-thiolate, and hydrogen squarate¹⁰⁰ anions) were recorded for solutions in MeCN and in the solid state. As expected, the signals of C(2) and C(4) nuclei are more sensitive to salt formation: they shift 4–5 ppm down-field. However, the largest changes in the chemical shifts (by 6 ppm for solutions in MeCN and by 10 ppm in solid state) are observed in the ¹⁵N NMR spectra upon transition from the base to the cation. It is ¹⁵N NMR spectroscopy that is recognised as being the most appropriate for the study of the structure of cations in solution and in the crystalline state. Recent ¹H and ¹³C NMR spectral data of solid samples of **6-H**⁺ with thiocyanate and tetrafluoroborate revealed two types of *N*-methyl groups, presumably located close to the plane of the ring and remote from it. At the same time, unlike the base, the naphthalene ring of the cation **6-H**⁺ itself did not reveal any signs of asymmetry.⁹⁶

¹³C (Ref. 49) and ³¹P MAS (Ref. 101) NMR spectra of cations of the iminophosphorane 'proton sponges' **29**, **63**, and **64**, and ¹³C and ¹⁵N NMR spectra of the salts **30-H**⁺ have been analysed.⁹⁸

c. NMR spectra and molecular dynamics

The majority of the naphthalene 'proton sponges' are sterically strained, therefore, many of them exist in different conformations due to hindered rotation of dialkylamino groups around the C_{Ar}–N bonds, distorted ring shape, inversion of nitrogen, *etc.* The corresponding transitions can most effectively be followed by NMR spectroscopy. Sometimes, dynamic processes manifest themselves even at room temperature as a widening (sometimes, rather prominent) of peaks of the *N*-alkyl groups and aromatic protons.

Although the solution ¹H and ¹³C NMR spectra of the 'proton sponge' **6** demonstrate the equivalence of all the four *N*-methyl groups at room temperature, this was shown to result from rapid reversible transitions that average the respective conformations on the NMR time-scale.²⁶ It was found that the singlet of the methyl groups in the ¹H NMR spectrum of compound **6** in CF₂Cl₂ splits into a doublet upon cooling down to –120 °C. The free energy of activation ($\Delta G^\ddagger$) for the conformational transition was estimated as 31.4 ± 0.8 kJ mol^{–1}. It

was assumed that the interconversion of the methyl groups is of a 'narcissistic' type and occurs *via* a planar transition state with C_{2v} symmetry (Scheme 1).

Scheme 1

In the case of sterically more hindered 1-benzylmethylamino-8-dimethylaminonaphthalene, the conversion of the NMe₂ group singlet into the doublet occurs at –38 °C; simultaneously, the methylene group singlet splits into a quartet. In this case, the $\Delta G^\ddagger$ value is equal to 57.3 ± 1.7 kJ mol^{–1}.²⁶ Similar dynamic processes were observed in the ¹H NMR spectra of compounds **62**,³¹ **53**,²⁷ and **90**.¹⁰²

5. Nuclear quadrupole resonance spectra

Contrary to the original interpretation of the ¹⁴NQR spectrum, with cross-relaxation, of the base **6**,¹⁰³ recent measurements revealed the presence in this spectrum of four (rather than two) resonance peaks from two nitrogen atoms.¹⁰⁴ This finding unambiguously testifies to their non-equivalence and thus correlates with NMR data on the asymmetry of the 'proton sponge' molecule in crystals.

6. Electron spectroscopy for chemical analysis

According to Hasselbach *et al.*,¹⁰⁵ neither NMR nor X-ray diffraction analysis can give an unequivocal answer to the question about the IHB symmetry in the 'proton sponge' cation. This can be done only with the help of 'faster' methods, such as electron spectroscopy for chemical analysis (ESCA). Here, the ionisation of core electrons takes about 10^{–16} s, therefore the non-equivalent atoms can be distinguished even at fast equilibrium. The ESCA spectrum recorded for the salt **6-H**⁺ BF₄[–] in the N1s energy region revealed two maxima of identical height, which points to the non-equivalence of nitrogen atoms in the cation **6-H**⁺. However, the splitting of the two peaks was relatively low. This points to the fact that the hydrogen bridge in the cation **6-H**⁺ is nevertheless nearly symmetrical. ESCA studies of a number of other 'proton sponge' salts have also been carried out.^{106, 107}

7. Electronic absorption spectra, colour, and solvatochromism

Perhaps the most valuable information about the electron interaction of dialkylamino groups and the naphthalene π -system in 'proton sponges' can be derived from UV spectra. The longwave absorption band in the UV spectra of 1,8-diaminonaphthalene and its *N*-alkyl derivatives including compound **6** lies in the region 340–350 nm (Table 16). As in the case of other aryl amines, it is ascribed to the transfer of electron density from the *n*-orbital of the nitrogen atoms to the π -antibonding orbital of the naphthalene system (*p*– π^* transition). The intensity of this band strongly depends on steric factors influencing the rotation of the amino group around the C_{Ar}–N bond. We used this circumstance² to determine the value of the dihedral angle (φ) between the plane passing through the C_{Ar}–N bond perpendicularly to the aromatic system and the plane passing through the same bond and the symmetry axis of the unshared electron pair of the nitrogen atom. The angle φ was determined from the known ratio, $\varepsilon/\varepsilon_0 = \cos^2\varphi$, where ε is the extinction coefficient at the absorption maximum for the amine under study, and ε_0 is the same for a planar model, in which $\varphi = 0$, *i.e.*, the conjugation is a maximum. 1,3-Dimethyl-2,3-dihydroperimidine **19a** was used as a model for which the longwave absorption band did have the maximum intensity. The experimental values of φ are listed in Table 16. For the 'proton

Table 16. The position of longwave absorption bands ($\lambda_{\max}$, ε) and magnitudes of dihedral angles (φ) in UV spectra of 1,8-diaminonaphthalenes.²

Compound	$\lambda_{\max}$ /nm	$10^{-3} \varepsilon$ /litre mol ⁻¹ cm ⁻¹	φ /deg
1	337	10.40	42
2	339	8.96	46
3	351	6.07	55
4	341	8.72	90; 14
5	351	9.50	81; 0
6	341	12.40	35
19a	344	18.60	0

sponge' **6**, $\varphi = 35^\circ$, which agrees well with the X-ray data ($\varphi = 40^\circ$)⁵⁶ and other estimates.¹ The not very high value of the angle φ points to the possibility of significant conjugation of the dimethylamino groups with the naphthalene system in the base **6**, which is confirmed by all its physicochemical properties and reactivity.

The π -donor effect of the dimethylamino groups is especially prominent in the derivatives of the 'proton sponge' containing $-M$ -substituents at position 4. In contrast to the colourless compound **6**, these compounds give different colours from yellow to violet depending on the electron-acceptor properties of the substituent (Table 17). As expected, the longwave absorption band, which is determined by direct polar conjugation, is very sensitive to the solvent polarity. Thus in the case of the 4-nitro-derivative **84**, the $\lambda_{\max}$ in hexane, benzene, methanol, and DMSO is 411, 444, 463, and 484 nm.⁵⁵ Such a solvatochromism may be due to the different solvation of the excited state, which can be represented by bipolar structures of the type **84a,b**. Evidently, the more polar the solvent, the stronger the solvation, the smaller the electron transfer energy, and the deeper the colour.

Table 17. Position of the longwave absorption band in UV spectra and colour of some 'proton sponge' derivatives (in methanol).

Compound	$\lambda_{\max}$ /nm	lg ε	Colour	Ref.
74	353	3.62	Pale yellow	109
75	516	4.02	Dark violet	110
80	407	3.84	Yellow	61
81	449	3.52	Brown	61
82	389	3.68	Yellow	110
83	431	3.68	Red	110
84	463	4.02	Dark red	55
89	521	4.00	Claret	110
96	403	3.67	Yellow	61
101	405	3.57	"	110
102	413	3.82	"	110

Since chelation of the NH-proton takes the dimethylamino groups completely out of conjugation with the ring, the absorption spectra of 'proton sponge' cations closely resemble the spectra of appropriate naphthalenes devoid of dimethylamino groups. Thus, the $\lambda_{\max}$ of the longwave absorption band for the cations **6-H**⁺ and **84-H**⁺ are equal to 288 nm (lg $\varepsilon = 3.85$)¹⁰⁸ and 334 nm (lg $\varepsilon = 3.50$)⁵⁵ (in 0.1 M HCl), whereas the corresponding values for naphthalene and 1-nitronaphthalene are 297 nm (lg $\varepsilon = 2.82$) and 342 nm (lg $\varepsilon = 3.59$).

An interesting variety of solvatochromism was observed for the cation **84-H**⁺.⁵⁵ When the colourless perchlorate is dissolved in DMSO, DMF, or pyridine, the solution immediately turns deep red or red-orange (for DMF); in the majority of other solvents, colourless, yellowish, or pink solutions are formed. The reason for solvatochromism is the decreased basicity of 1,8-bis(dimethylamino)-4-nitronaphthalene **84** and IHB asymmetry in its cation,

so that the solvents with high proton-acceptor capacity disrupt the IHB, thereby releasing the dimethylamino groups for the conjugation. Practical applications of solvatochromism of the perchlorate **84-H**⁺ are proposed.⁵⁵

8. Infrared spectra

The most important in the IR spectrum of the base **6** are the bands at 2780, 2830, 2870, and 1580 cm⁻¹ (Refs 86, 111). The first three of them, known as Bolman bands, are associated with stretching vibrations of the C—H bonds of the methyl groups *trans*-oriented with respect to the unshared electron pairs of the nitrogen atoms. The band at 1580 cm⁻¹ is associated with stretching vibrations of the ring. Its high intensity is the consequence of the asymmetry of the naphthalene system. Indeed, the intensity of this band sharply decreases upon protonation, and the band slightly shifts towards high frequencies. The Bolman bands also practically disappear upon transition to the cation or, in the case of partial protonation, decrease in intensity. These changes can be used for the quantitative estimation of the degree of protonation of the base **6** by different acids including phenols. However, the most interesting feature is the appearance of stretching vibration bands of the hydrogen bridge $\nu_s(\text{NHN})$ in the IR spectra of **6-H**⁺ salts. The dependence of the position of this band on pressure,¹¹² counterion structure,¹¹³ deuteration [the isotope ratio, $\nu(\text{NHN})/\nu(\text{NDN})$ was determined],¹¹⁴ and the change in the aggregate state¹¹⁵ was studied. In solution (the measurements were performed in acetonitrile, dichloromethane, and dichloroethane), the band manifests itself as a very broad 'continuum' at the background level extending from 3000 to about 300 cm⁻¹. In the crystalline state, the type of absorption changes drastically; the band shifts towards 800–250 cm⁻¹ and acquires fine structure. This phenomenon is typical of very stable hydrogen bridges having a short N...N distance (~ 2.55 – 2.65 Å). It is assumed that the band structure can be explained in detail only by taking into account the superposition of δ - and γ -deformation oscillation, their overtones, and internal oscillations causing modulation of the hydrogen bridge geometry.¹¹¹ These data are consistent with the abnormally high isotope ratio, which in some cases reaches 1.8–2.05 (in the case of weak IHBs, it is less than 1.45).¹¹⁴ There is a tendency to broadening of the $\nu_s(\text{NHN})$ band, and its shift towards higher frequencies with an increase in the proton-acceptor capacity of the anion.^{113, 114} Thus, in the case of the anions Ph₄B⁻ and F⁻, the centre of the band is at 463 and 583 cm⁻¹, respectively. The effect of the anion was explained by its bifurcation interaction with the NH-proton of the cation. It should be recalled, however, that X-ray studies of numerous salts of the 'proton sponge' allowed one to reveal reliably the bifurcation effect only in two cases (Section IV. 3. b).

On the basis of the IR spectral data of proton sponge salts, most authors concluded that the potential energy curve for the hydrogen bridge corresponded either to a potential with two minima and a very low barrier, or to a potential with one minimum and a flat bottom (Fig. 2a, b).

Because of the nearly planar structure of the naphthalene system in compound **30**, its IR spectrum differs substantially from that of the 'proton sponge' **6**.⁶²

9. Mass spectra

Mass spectra of sterically hindered bis(dimethylamino)arenes including various types of 'proton sponges' were studied in most detail.^{116, 117} In all cases, the fragmentation of the molecular ion which is the most intense, as a rule, is determined by the proximity of dimethylamino groups (the so-called 'proximity effect') and at early stages involves practically only these groups. The fragmentation processes include isomerisation and elimination of the MeNH₂, Me₂NH, and H⁺ fragments giving rise to stable heterocyclic ions.

Four main pathways of fragmentation of the molecular ion of the base **6** under electron impact are shown in Scheme 2.¹¹⁶ The first pathway (a) is a stepwise counterflow intramolecular transfer

of H^+ and Me^+ species from one nitrogen atom to another resulting in the ions $6\text{a}^{+\bullet}$, $6\text{b}^{+\bullet}$, and $6\text{c}^{+\bullet}$, respectively.

Scheme 2

The latter eliminates MeNH_2 , which accounts for the presence in the spectrum of an intense peak with m/z 183; this peak was assigned to the 1,2-dimethyl-1,2-dihydrobenzo[*c,d*]indolium ion. Its subsequent aromatisation gives the 1-methylbenzo[*c,d*]indolium ion (m/z 168). The peak of this ion is second in intensity after the peak of $\text{M}^{+\bullet}$ and in some 'proton sponge' derivatives it is the most abundant. The second pathway of fragmentation (*b*), which also gives the 1-methylbenzo[*c,d*]indolium ion, consists in the elimination of Me_2NH from the $6\text{a}^{+\bullet}$ ion. The third (*c*) and the fourth (*d*) pathways represent direct fragmentation of the molecular ion $6^{+\bullet}$ consisting in the loss of Me_2N^+ or Me^+ species. In the latter case, methyl derivatives of the benzo[*c,d*]indazolium ion with m/z 199 and 184 are formed.

The above fragmentation features are observed in the mass spectra of other derivatives of the 'proton sponge' and, which is the most interesting, in the spectrum of 1,8-bis(diphenyl-amino)-naphthalene **61**.¹¹⁷

10. Dipole moments

Dipole moments in benzene were measured for three compounds of the given series: the 'proton sponge' **6**, its 4-formyl- **80**, and 4,5-diformyl derivatives **81**.⁶¹ The dipole moment of compound **6** ($\mu = 1.19$ D) is precisely equal to that of 1-dimethylaminonaphthalene. This is lower than the expected value, since the π -conjugation of both dimethylamino groups with the ring would result in the summation of the vectors of the corresponding dipole moments. Apparently, due to the high non-coplanarity of the molecule **6**, both vectors are directed at a considerable angle to each other. In contrast, the dipole moments of the aldehyde **80** ($\mu = 5.44$ D) and the dialdehyde **81** ($\mu = 9.21$ D) appeared to be unexpectedly high. This suggests that the conjugation of the aldehyde and the NMe_2 groups in them is very efficient. The additional moment of the π -interaction, μ^π , in compounds **80** and **81** is equal to ~ 1.4 and 2.3 D, which is higher than in 4-dimethylaminonaphthalene-1-carbaldehyde ($\mu^\pi = 0.35$ D) and even in *p*-dimethylaminobenzaldehyde ($\mu^\pi \approx 1$ D). These data are in good agreement with the X-ray data for compound **81**. The high dipole moment makes this compound closer to ionic substances; it is therefore not incidental that in contrast to many

other derivatives of the 'proton sponge', the dialdehyde **81** is rather soluble in water and has a high melting point ($162\text{--}164^\circ\text{C}$).

11. Donor-acceptor properties

a. Gas-phase ionisation potentials

The gas-phase ionisation potentials, IP_1 , of the 'proton sponge' **6** and its partially *N*-methylated precursors **1–5** measured by electron impact were strikingly similar, from 7.38 to 7.47 eV (see Table 18).² This could indicate that the first electron is ejected from the π -orbital of compounds **1–6**. Indeed, if these values characterised the ejection of an *n*-electron, then, taking into account significant differences in the basicity of these compounds, the ionisation potential of the 'proton sponge' would be much lower in comparison with that of the diamines **1–5**. However, Maier,¹¹⁸ who used photoelectron spectroscopy to measure the ionisation potentials of compounds **1** and **6**, came to a somewhat different conclusion. The IP_1 value for the diamine **1** (7.10 eV) was also assigned to the π -ionisation potential, while for the 'proton sponge' **6** ($\text{IP}_1 = 7.05$ eV) it was ascribed to electron ejection from the *n*-orbital. This conclusion was made on the basis of calculations using perturbation theory, which revealed that the highest occupied π -MO for compound **6** correlated better with the second ionisation potential, $\text{IP}_2 = 7.47$ eV. It is hardly probable that this argument is self-explanatory. It will be recalled once again that according to UV spectroscopy data, the conjugation of the nitrogen atoms with the naphthalene ring and, correspondingly, the π -donor capacity of compound **6** is at least no less than that of 1,8-diaminonaphthalene.

b. Anodic oxidation potentials. Radical cations

Electrochemical oxidation of the 'proton sponge' **6** on a platinum disc electrode in MeCN gives two reversible one-electron waves with $E_{\text{ox}}^{1/2} = 0.36$ and 1.02 V.¹¹⁹ Presumably, the radical cation $6^{+\bullet}$ is formed at the first step, and the dication **103**, at the second; the structure with a σ -bond between the nitrogen atoms was ascribed to the latter. The radical cation $6^{+\bullet}$ was also generated by oxidation of compound **6** with PbO_2 . Its EPR spectrum represents an unresolved singlet with a width ΔH of 23 G ($g = 2.0043$). On the basis of these data, it was concluded that the conjugation of the dimethylamino groups with the naphthalene ring in compound **6** is significant and according to its electron-donor properties it occupies a position between *N,N*-dimethylaniline ($E_{\text{ox}}^{1/2} = 0.68$ V) and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine ($E_{\text{ox}}^{1/2} = 0.015$ V).

The oxidation of compound **23** occurs in an analogous way, but more easily.¹²⁰ Its radical cation can be conserved unchanged in acetonitrile over a period of many months. The UV spectrum of this radical cation ($\lambda_{\text{max}} = 480$ nm, $\lg \epsilon = 3.1$) is very similar to that of compound **23** itself, which has led to a conclusion that the naphthalene fragment of the molecule does not take part in the oxidation. In contrast to compounds **6** and **23**, the 'double proton sponge' **28** is oxidised in one two-electron wave with $E_{\text{ox}}^{1/2} = -0.50$ V (relative to $\text{Fc}/\text{Fc}^+ = 0.0$ V, Fc is ferrocene).²⁴ Apparently, the driving force of this process is the formation of the resonance-stabilised dication **104**, which was isolated in the form of black crystals and thoroughly characterised.^{24, 121} The radical cation $28^{+\bullet}$ giving the EPR spectrum with hyperfine structure can be obtained by chemical oxidation of compound **28**.²⁴

c. The formation of π -complexes

All 1,8-diaminonaphthalenes, including the 'proton sponge' **6** can easily form molecular complexes (MC) in which they act as donors. An attempt has been made to use the complexes with 1,3,5-trinitrobenzene (1 : 1, the complex formation constants K_c lie in the range 2.0–3.4 litre mol⁻¹) for estimating their electron-donor capacity.² Presumably, stronger donors would produce MC with an absorption maximum of the charge transfer band shifted to longer wavelengths. However, measurements revealed (Table 18) the lack of correlation between the basicity of 1,8-diaminonaphthalenes and the ease of formation of MC by these compounds. Moreover, the most basic compound (the 'proton sponge' itself) gives a MC having the lowest value of $\lambda_{\max}$ (500 nm). It was therefore concluded that compounds **1–6** behave as π -donors in the formation of MC, whereas the differences in the ease of formation and stability of MC are determined predominantly by steric factors and inductive effects of the methyl groups.

Table 18. Ionisation potentials, IP₁, and electrochemical oxidation potentials ($E_{\text{ox}}^{1/2}$) of 1,8-diaminonaphthalenes and the long-wave absorption maximum (UV spectra) of their molecular complexes with 1,3,5-trinitrobenzene.

d. The formation of H-complexes

In some cases, IR and NMR methods were used to investigate the interaction of compound **6** with phenols,^{113, 122–124} carboxylic acids,¹²³ and SH-acids.¹²⁵ An unexpected finding was that phenol ($\text{p}K_a = 9.99$) hardly protonated the 'proton sponge', although its basicity exceeded that of the phenolate anion by more than two orders of magnitude. Distinct protonation is observed only with phenols having $\text{p}K_a < 8.4$. This reaction gives two types of salts having the composition of 1 : 1 and 1 : 2, the latter being much more stable. This is rationalised by formation of homoconjugated anions, $\text{ArOH} \cdots \text{OAr}$. Evidence for their stability can be derived from the fact that the salt of the base **6** with pentachlorophenol (1 : 1) disproportionates in acetonitrile to give a 1 : 2 salt and a non-protonated 'proton sponge':¹¹³

e. Electron acceptor properties. Radical anions

There is only one study concerned with the ability of 'proton sponges' to undergo one-electron reduction.¹²⁶ It has been shown that treatment of compound **6** with sodium in 1,2-dimethoxyethane gives a stable radical anion; its EPR spectrum was recorded at -20°C . The hyperfine splitting constants (HFS) for the unpaired electron with cyclic protons are: $a_{\text{H}(4),\text{H}(5)} = 4.46$, $a_{\text{H}(3),\text{H}(6)} = 1.77$, and $a_{\text{H}(2),\text{H}(7)} = 1.39$ Gs, *i.e.*, they are somewhat smaller than the corresponding values for the naphthalene radical anion. At the same time, the HFS constants with the protons of the methyl groups and ¹⁴N nuclei are very small. This was interpreted as a result of non-coplanarity of the dimethylamino groups and the naphthalene ring. The magnitude of the dihedral angle between the axes of unshared electron pairs of the nitrogen and the $2p_\pi$ -orbitals of cyclic C-atoms in the radical anion **6^{•-}** was estimated to be $60-70^\circ$.

12. Quantum-mechanical calculations

Using the *ab initio* method with optimisation of geometry, the optimum structures of the 'proton sponge' **6** and its protonated form **6-H⁺** were calculated.¹²⁷ The following main conclusions were made: (1) in the gas phase, the molecule of compound **6** has C_2 symmetry and the fragment $\text{N}(\text{C}_{10}\text{H}_6)\text{N}$ is essentially non-planar; (2) the degree of non-planarity in the isolated molecule of the base is lower than in the crystals; (3) increased orders of the $\text{N}-\text{C}_{\text{Ar}}$ bonds attest to a significant conjugation of the nitrogen atoms with the π -system of the ring; (4) in protonation, the molecule becomes practically planar and its symmetry approximates the C_{2v} type; (5) the hydrogen bridge in the isolated cation **6-H⁺** is symmetrical; its optimum parameters are as follows: $r[\text{N}(1)-\text{H}] = 1.05 \text{ \AA}$, $r[\text{N}(2) \cdots \text{H}] = 1.64 \text{ \AA}$, the angle $\text{N}(1)-\text{H}-\text{N}(2) = 156.8^\circ$.

Semi-empirical simulations of the optimum structures of the base **6** and the cation **6-H⁺** were made^{13, 84} using the AM1 and PM3 methods; the enthalpies of protonation for compounds **1**, **3**, **5**, and **6** and some hypothetical aza-derivatives of the 'proton sponge' were also estimated.¹²⁸

V. Reactivity of naphthalene 'proton sponges'

Naphthalene 'proton sponges' are typical electron-rich compounds. In addition to high basicity, they are characterised by significant π -donor capacity and the presence of a negative π -charge on the cyclic carbon atoms. It is not surprising that electrophilic substitution and oxidative conversions are the most typical reactions for these compounds. A few examples of nucleophilic substitution are reported, only for compounds with electron-acceptor groups in the ring. It is probable that some reactions of the 'proton sponge', *e.g.*, chlorination with *N*-chlorobenzotriazole (CBT) or bromination with *N*-bromosuccinimide (NBS) occur through a radical mechanism, as can be judged from their unusual orientation. However, convincing evidence for this mechanism is absent, and the corresponding transformations are discussed in Section V. 2 dealing with reactions with electrophiles.

1. Oxidation

As has been mentioned above, electrochemical or chemical oxidation of 'proton sponges' results first in the formation of radical cations and then of dication. Thus treatment of the 'double sponge' **28** with an excess of iodine at -10°C gave black needles of the salt **104** (with the I_3^- anion), which could be studied by the X-ray method.¹²¹ It is noteworthy that increase in temperature to 25°C or heating of the salt **104** results in its isomerisation, presumably *via* the immonium cation **105**, into the dication **106**.¹²¹ The 'proton sponge' undergoes similar conversions under the action of certain complexes of Rh^{3+} , Ru^{3+} , and Ru^{2+} , which result in the formation of the 1,1,3-trimethyl-2,3-dihydroperimidinium cation **42** ($\text{R}^1 - \text{R}^3 = \text{Me}$).¹²⁹

Oxidation of compound **6** with thallium triacetate or lead tetraacetate in dichloromethane at low temperature¹⁰² or, which is better, with iodine in boiling acetonitrile¹³⁰ gives the 1,1'-binaphthyl 'sponge' **90** in moderate yields. The latter is also formed as a by-product (yield 10%) in the nitration of compound **6**.¹³⁰ Apparently, in all these cases it is the intermediate radical cation **6**^{•+} that undergoes dimerisation.

2. Electrophilic substitution reactions

'Proton sponges' manifest unusually high activity in reactions of electrophilic substitution. To avoid resinification and to ensure desired regioselectivity, the syntheses are usually carried out at low temperatures (< 0 °C). In some cases (the Friedel–Crafts acylation), the substrate should be passivated by being converted into a salt. It should be noted that such catalysts as AlCl₃ or BF₃ do not give *n*-complexes with 'proton sponges'. As a rule, the first substituent enters only at positions 4 and 5 (for exceptions see Section V.2.b). The second and subsequent substituents can occupy both the *para*- and *ortho*-positions. The specific orientation is determined by the nature of the substituent already present and, consequently, by the p*K*_a of the substrate and the degree of symmetry of the IHB in the corresponding cation. There is good reason to believe that some reactions of naphthalene 'proton sponges' with electrophiles occur through a radical cation mechanism, where the radical cation generated first undergoes further nucleophilic attack by the anion present in the reaction mixture (see Section V.2.b).

a. Nitration

Nitration of the 'proton sponges' **6** and **31** in acetic acid gives directly the 2,4,5,7-tetranitro-derivative of the type **107** irrespective of the amount of nitric acid.⁴⁶ This was explained by the fact that due to the decrease in basicity of each subsequent substitution product and the increase in the concentration of the corresponding free base the rate of each successive nitration increases. Mononitration, which gives the 4-nitro-derivatives **84** and **85** in 50%–70% yields, can be carried out only in concentrated sulfuric acid with one equivalent of HNO₃^{46,55} (as mentioned above, the binaphthyl 'sponge' **90** is also formed as a by-product). Obviously, in strongly acidic media, compounds **84** and **85** are present exclusively in the form of cations, and the reaction does not proceed further. However, an attempt at subsequent nitration of compound **84** gave only the tetranitro-derivative **107**. In the case of the ethyl analogue **85**, dinitration could be accomplished with one equivalent of HNO₃ to give the 2,4- and 4,5-dinitro-derivatives **108** and **109** in yields 32% and 28%, respectively.⁴⁶ The nitration of compound **6** can be controlled to a greater extent when nitrogen dioxide is used as a nitrating agent.¹³⁰

R = Me (**6**, **84**), Et (**31**, **85**).

Nitration of 4-bromo-1,8-bis(dimethylamino)naphthalene **51** with one equivalent of HNO₃ in concentrated H₂SO₄ gave 4-bromo-5-nitro- and 4-bromo-2-nitro-derivatives (yields 27% and 15%, respectively).²⁷

b. Halogenation

On treatment of the 'proton sponge' **6** with one equivalent of bromine in acetic acid or CCl₄, a crimson-coloured complex of an unknown structure precipitates, and gradually resinifies. Treatment of the complex with concentrated H₂SO₄ converts it into 4-bromo-1,8-bis(dimethylamino)naphthalene **51** in good yield. Subsequent bromination could be achieved only with NBS.²⁷ First, with 1 equiv. of NBS, a mixture of 2,4- and 2,5-dibromo-derivatives **110** and **111** is formed in a 54:46 ratio. Further bromination of this mixture (1 equiv. of NBS) gives 2,4,7-tribromo-1,8-bis(dimethylamino)naphthalene **112** as the only product. An attempt to convert it into a tetrabromo-derivative was unsuccessful. Thus unlike nitration, acylation, and formylation (see below), *peri*-dibromination in naphthalene 'proton sponges' does not take place, presumably due to larger steric hindrances exerted by bromine atoms.

It is noteworthy that bromination of the 'proton sponge' **6** with NBS (1 equiv.) in chloroform occurs in quite a different way.⁹³ In this case, 2-bromo-**71** and 2,7-dibromo-derivatives **73** are formed in 36% and 52% yields, respectively. *ortho*-Substitution occurs nearly quantitatively in the chlorination of compound **6** with *N*-chlorobenzotriazole (CBT) to give 2-chloro-**70** and 2,7-dichloro-derivatives **72**.²⁸ Probably, these reactions proceed with the participation of the 'sponge' base (rather than the cation) in which the π -electron density at positions 2 and 7 is greater than at positions 4 and 5. At the same time, one should not rule out the radical mechanism of substitution.

Hal = Cl (70, 72), Br (71, 73).

Recently, in our laboratory we have established that treatment of compound **6** with sodium nitrite in hydrochloric acid gives 4-chloro-1,8-bis(dimethylamino)naphthalene **50** in a nearly quantitative yield. If hydrobromic acid is used instead of hydrochloric acid, the yield of the 4-bromo-derivative **51** is much lower (~20%).¹³⁰ The formation of these somewhat unusual products is a convincing proof of the radical-cation mechanism of halogenation. Obviously, at the first stage the 'proton sponge' is oxidised with nitrous acid to the radical cation, which is subjected to nucleophilic attack by the halide anion at position 4, where the highest positive charge is accumulated.

c. Formylation and acylation

Formylation of the 'proton sponges' **6**¹³¹ and **31**¹³² under conditions of the Vilsmeier reaction in a deficiency of POCl₃ (0.5 equiv.) gives the corresponding 4-formyl-derivative **80** and **113** in moderate yields. When an equimolar amount of POCl₃ is used, compound **6** gives the 4,5-dialdehyde **81** and small amounts of the 2,5-dialdehyde **96** along with the monoaldehyde **80**.¹³¹

R = Me (**80**), Et (**113**).

1,8-Bis(dimethylamino)naphthalene **6** does not undergo the Vilsmeier-Haack acylation or acylation with carboxylic acids in polyphosphoric acid (as takes place in the series of perimidones, 2,3-dihydroperimidines, and perimidines).¹³³ At the same time, under conditions of the Friedel-Crafts reaction in the presence of AlCl₃ or AlBr₃, acyl chlorides acylate the 'sponge' base even at -90 °C.¹¹⁰ The reaction is not very smooth, therefore it is more convenient to perform it with the salt 6-H⁺. The yields of the ketones **82** and **101** are virtually quantitative.

The reaction of the base **6** with trifluoroacetic anhydride does not require a catalyst and proceeds at -30 °C. This results in the formation of the 4-trifluoroacetyl derivative **83** in moderate yield.

Treatment of the base **6** with an excess of benzoyl chloride gave the 4,5-benzoyl derivative **102** (yield 7%). Under the same conditions, the reaction with excess acetyl chloride gives phenalene-9-one **89** (yield 27%), presumably as a result of intramolecular aldol condensation of the intermediate, the 4,5-diacetyl derivative. The progenitor of this phenalene series (**114**) was synthesised (yield 15%) by intramolecular acylation of ethyl acrylate **115** upon heating in polyphosphoric acid (PPA).¹¹⁰

d. Hydroxymethylation

'Proton sponges' undergo hydroxymethylation with paraformaldehyde in polyphosphoric acid at 45 °C to give the alcohols **116a,b**.^{132, 134} At higher temperatures, compound **6** is converted into naphthopyran **88** in good yield, apparently as a result of dehydration of the intermediate 4,5-bishydroxymethyl derivative **117**. The alcohols **116** were also obtained by reduction of the aldehydes **80** and **113** with LiAlH₄.¹³²

e. Miscellaneous reactions

The 'proton sponge' **6** reacts with alkanesulfonyl chlorides to give the 4-alkylsulfonyl derivatives **118** and **119**.¹³⁵ It was established that the active species, which directly interacts with compound **6**, is the corresponding chlorosulfine generated *in situ*. Compounds

119 can be also obtained by the reaction of the 'proton sponge' **6** with alkanesulfinyl chlorides.

R = H, Me, PhCH₂.

R = H, Me, CF₃, F, Cl.

Compound **6** behaves as a strong CH-nucleophile with respect to 4,6-dinitro-derivatives of benzofuroxan and benzofurazan to give the corresponding adducts **120**.¹³⁶

X = N, N→O.

The 'proton sponge' easily adds to perfluorocycloalkanes with exocyclic double bonds. This reaction involves both *peri*-positions and the phenylene derivatives are formed **121,122**.¹³⁷

3. Reactions involving dialkylamino groups

The following four types of these reactions are known: (1) quaternisation, (2) dealkylation, (3) substitution of the dialkylamino groups, and (4) oxidative conversions. The latter have already been described in Section V. 1. Here, only the first three types will be considered. Practically all these reactions have been performed with compound **6**.

Only one example of quaternisation of the 'proton sponge' is known. Contrary to the original report,¹ it was established that its treatment with methyl fluorosulfate gives the non-crystalline salt **68** (as the SO₃F⁻ anion), which is converted into the crystalline

tetrafluoroborate **67** under the action of NaBF₄.³⁷ An attempt to synthesise the borate complex **123** by treating the cation **6-H**⁺ with pyridine-borane was unsuccessful.¹³⁸ At the same time, complexes of this type are easily formed with tetramethyl-*o*-phenylenediamine and 2,2'-bipyridyl. This circumstance can be regarded as additional proof of the extremely low nucleophilicity of the 'proton sponge'.

Heating of 'proton sponge' salts containing mild nucleophiles, such as thiocyanate,²⁶ phenylmercaptide, and phenylselenide¹³⁹ leads to demethylation and the formation of 1-dimethylamino-8-methylaminonaphthalene **5**. This reaction proceeds especially smoothly with selenophenol; the yield of the amine **5** is close to quantitative. It is of note that if the 'sponge' **6** is heated with thiophenol and selenophenol, the formation of the cation **6-H**⁺ proceeds at a very low rate (> 1 h).

Nu⁻ = SCN⁻, PhS⁻, PhSe⁻.

Demethylation of 'proton sponge' bases occurs only if the ring contains strong electron-acceptor groups and if the reaction is carried out in a superbasic medium.³⁰ Thus, treatment of the 'nitro sponge' **84** with a solution of KOH in DMSO (40 °C, 24 h) gave the trimethyl-substituted compound **58** (yield 40%). The two other reaction products were naphthol **57** (yield 7%) and, which is especially unexpected, lactam **124** (yield 11%).

The formation of naphthol **57** seems to be a result of nucleophilic substitution of the dimethylamino group in the more activated position 1. Some complex reactions also entail hydrolytic substitution of the dimethylamino group by the carbonyl group (see Section V. 5). The mechanism of formation of the lactam **124** is not known with certainty. Presumably, this reaction begins with the generation of an equilibrium amount of the carbanion **125** in which intramolecular nucleophilic substitution of the 8-NMe₂ group takes place. The 1-methyl-6-nitro-1,2-dihydrobenzo[*c,d*]indole **126** formed undergoes further autooxidation, which is also characteristic of other compounds of this kind.

It is known that the 8-NMe₂ group can be substituted by hydrogen in the catalytic hydrogenation of the 'nitro sponge' **84** (see Section V. 4).

4. Reactions of functional groups

The greatest number of 'proton sponge' derivatives (azomethines, hydrazones, oxime, nitrile, *etc.*) were synthesised from the 4-aldehyde **80**.¹²⁹ The latter was also converted by the Wittig reaction into 4-vinyl-1,8-bis(dimethylamino)naphthalene **74**¹⁰⁹ and compound **115**.¹³¹ A number of other 4-vinyl derivatives (**75**, **127**, **128**) were synthesised by condensation of the aldehyde **91** with the corresponding CH-acids. The conditions for polymerisation of the vinyl 'sponge' were investigated.¹⁰⁹ It was found that heating of compound **127** with boron trifluoride etherate results in the reduction of the exocyclic C=C bond and the concomitant formation of the naphthylmethyl derivative of diethyl malonate **129** instead of the expected intramolecular cyclisation into the corresponding phenalenone.¹³¹ It was assumed that the ethyl groups of the etherate play the role of a hydride donor, and the reaction can be realised due to polarisation of the C=C bond, which is enhanced by the donor effect of the dimethylamino groups.

Upon boiling in water, the dialdehyde **81** undergoes the intramolecular Cannizzaro reaction to give the naphtho[1,8-*c,d*]pyranone derivative **130** in 36% yield.¹³¹ The unusual feature of this reaction is that it does not require any alkali. Apparently, the alkalinity of the medium sufficient for the formation of the anion **131** is created by the 'proton sponge' itself. It should be noted that unlike the naphthalene-1,8-dicarbaldehyde, which exists under ordinary conditions only in the form of a cyclic hydrate, the dialdehyde **81** is stable. This may be ascribed to the stabilising effect of the dimethylamino groups, which, when entering into conjugation, reduce the partial positive charge on the carbonyl carbon atoms and thus hamper the hydration. However, the formation of the hydrate **132** which is needed for the Cannizzaro reaction, does take place upon boiling of the dialdehyde **81** in water.

Catalytic hydrogenation of the 'sponge' **84** gave the amine **76**,⁴⁵ which is extremely unstable and oxidisable in air. 4,5-Diamino-1,8-bis(dimethylamino)naphthalene was obtained by hydrogenation of the dinitro-derivative **40**.²⁴ Subsequent hydrogenation of compound **76** is accompanied by elimination of the 8-NMe₂ group and the formation of 1-dimethylamino-4-aminonaphthalene **133**. The amine **76** gives azomethine with *p*-nitro-

benzaldehyde and the *N*-acetyl derivative **77**; the latter was methylated to give quite stable 4-methylamino- **78** and 4-dimethylamino-derivatives **79** of the 'proton sponge'.⁴⁵ The latter can be regarded as a kind of a 'sesqui-sponge'.

5. Transformations of naphthylmethyl carbocations derived from the 'proton sponge'

It has recently been established in our laboratory that treatment of the alcohol **116a** with concentrated hydrochloric or phosphoric acid gave unexpectedly the spiro compound **93** containing two fragments of the 'proton sponge' in a nearly quantitative yield.^{134, 140}

R = Me (**116a**, **93**), Et (**116b**, **136**).

There are reasons to assume that the key intermediate in this synthesis is the naphthylmethyl carbocation **134a** (structure **A**) in which strong resonance stabilisation involving both dimethylamino groups provides the fixation of the diene system containing the *exo*- and *endo*-cyclic bonds CH₂=C and C(4a)=C(5) (structures **B** and **C**). In the subsequent [4π + 2π]-cycloaddition, one molecule of the carbocation behaves as a diene, whereas the second one plays the role of a dienophile; this reaction occurs in a 'head-to-head' mechanism as shown in the scheme. An analogous spiro compound (**136**) is obtained from the alcohol **116b**; however, this reaction is much slower and the yield is lower (~22%).¹³² This may evidently be due to insufficient stabilisation of the carbocation **134b** due to the more pronounced non-coplanarity of the ring and the diethylamino groups.

The cycloaddition reaction observed when the alcohol **116a** was heated in benzene in the presence of solid acidic adsorbents (Al₂O₃, SiO₂, or TiO₂) occurs in a different direction.^{132, 141} In this

case, the main reaction product is the isomeric spiro compound **92** of the 'head-to-tail' type (yield 23%). This reaction also gives dinaphthylmethane **91** (10%), the aldehyde **80** (19%), and the 4-dimethylaminomethyl derivative of the 'proton sponge' **137** (22%) (all the yields are given for Al_2O_3 ; for other supports they vary somewhat).

Most probably, all these compounds are the products of transformation of the carbocation **134a**. Thus the formation of the aldehyde **80** can be explained by the well-established ability of carbenium ions to oxidise alcohols to aldehydes through elimination of the hydride ion. The formation of the dinaphthylmethane derivative **91** seems to be due to the *ipso*-substitution of the CH_2OH group in the original alcohol **116a** by the carbocation **134a**. An attack by the carbocation at the second possible direction of the free *peri*-position 5 in the molecule of compound **116a** should lead to the formation of the alcohol **138**, which further generates the carbocation **139**. Subsequent intramolecular *ipso*-attack by the carbenium centre on the other residue of the 'proton sponge' at position 4 gives ultimately the spiro product **92** via the immonium salt **140**. The dimethylamine liberated in the hydrolysis of the immonium group reacts with the carbocation **134a** to give compound **137**.

The different direction of cycloaddition reactions in protic media and in the presence of Lewis catalysts is explained in the following way. In a strongly acidic protic medium favouring the formation of the non-symmetrical spiro compounds **93** and **136**, the original alcohol appears to be fully protonated due to the high basicity of the 'proton sponge'. It is therefore hardly likely that it will easily interact with the carbocation **134a**. As a result, the $[4\pi + 2\pi]$ -cycloaddition remains the only possible reaction of the carbocation, especially when its concentration is high enough. At the same time, on the surface of an adsorbent the carbocation **134a** is formed in a low concentration. Being surrounded by an excess of the original alcohol, it will primarily react with the latter to give the symmetrical spiro compound **92**, or with another strong nucleophile. Thus for naphthyl carbocations derived from 'proton sponges' there exist two different cycloaddition reactions, which follow different mechanisms and give spiro compounds of two different types.

The most surprising feature in the formation of the spiro compounds **93** and **136** is that contrary to electrostatic laws, the positively charged carbon atoms from two methylene groups combine. Quantum mechanical calculations^{140, 142, 143} suggest that this process is favoured by the symmetry of their boundary orbitals. This process may not be synchronous and occurs *via* the formation of a biradical intermediate.

The secondary alcohols **141**–**143** behave differently in the presence of acids. Whereas the two former do not change even on prolonged heating in concentrated HCl or $\text{CF}_3\text{CO}_2\text{H}$, their phenyl analogue forms the spiro compound **144** in 87% yield.¹⁴⁰ At first, this compound was erroneously identified as **93**; however, subsequent X-ray analyses confirmed the validity of the symmetrical structure.¹⁴⁴ At present, it still remains obscure whether compound **144** is formed by a mechanism of two-step electrophilic substitution, as is the case with the spiro adduct **92**, or as a result of a $[4\pi + 2\pi]$ -cycloaddition of two molecules of the cation **147** and its abnormal direction is due to steric factors.

The behaviour of the alcohols **141**–**143** with respect to Al_2O_3 is also different. When boiled in benzene in the presence of Al_2O_3 , compound **141** underwent dehydration, presumably, by a mechanism of *E1*-elimination *via* the carbocation **145**. This reaction gives the 4-vinyl derivative **74** in good yield. The alcohols **142** and **143** do not change under these conditions.¹⁰⁹ The inertness of the alcohol **142** in both protic media and in the presence of Al_2O_3 might be due to stabilisation of the cation **146** by the electron-acceptor group CF_3 , so that it is not formed at a steady-state concentration that is sufficient for this reaction.

$\text{R} = \text{Me}$ (**141**, **145**); CF_3 (**142**, **146**), Ph (**143**, **147**).

Apparently, the specific reactivity of naphthalene 'proton sponges', which is ultimately due to the potent +*M*-effect of two dimethylamino groups, is manifested in cycloaddition reactions to a far greater degree than in any other conversion. Indeed, although these reactions have been later discovered in alcohols derived from 1,8-dimethoxy-, 1-dimethylamino-8-methoxy-,¹⁴⁵ and even 1-dimethylaminonaphthalene,⁹² they proceeded with considerable difficulty and gave spiro compounds in low yields and of only one specific type.

VI. Applications of the 'proton sponges' in organic syntheses

There are numerous indications of the use of 'proton sponge' in organic syntheses, mostly as a strong but low-nucleophilic base. Its application is useful in those cases where it is necessary to ionise the acidic X–H bond or to bind an acid liberated in the course of the reaction without any effect on other base-sensitive groups. A typical example is the cyclisation of the imidazoles **148** in 2-dimethylsila-3*H*-imidazo[2,1-*b*]thiazoles **149**, which occurs in the presence of the 'proton sponge' **6** and in more than 80% yield. Substitution of compound **6** by ordinary bases (OH[−], MeO[−], etc.) leads to the cleavage of the S–Si bond.¹⁴⁶

R = H, Ph.

In reactions of chiral compounds requiring the use of a base, the 'proton sponge' hardly causes any racemisation and favours the retention of high optical purity.^{147–149} An example is the conversion of optically active alcohols into ethers under the action of triethyloxonium tetrafluoroborate:¹⁴⁷

Quite unexpected was the use of the 'proton sponge' as a debrominating agent in the conversion of *vic*-dibromides into alkenes.¹⁵⁰ Thus, heating of compound **6** with dibromoacenaphthene in dimethoxyethane gives acenaphthylene in a nearly quantitative yield. Dibromides of coumarin, isocoumarin, chalcone, etc., enter into this reaction. However, the fate of the 'proton sponge' in this conversion could not be followed.

Other applications of the 'proton sponge' in organic syntheses are documented in several publications.^{151–154}

VII. Conclusion

The discovery of the high basicity of 1,8-bis(dialkylamino)-naphthalenes has given a strong impetus to the search for other, still stronger neutral organic bases. Developments in this field have led to the appearance of an interesting branch of organic chemistry, namely, the chemistry of 'proton sponges'. Although naphthalene 'proton sponges' are no longer record holders among neutral bases, their potential in the design of novel compounds possessing unusual physicochemical properties has by no means been exhausted. Of substantial interest are *inter alia* combined (e.g., proton-hydride) 'sponges', the synthesis and study of their hydroxy derivatives, and the development of organometallic chemistry based on them. Finally, it may be expected that the naphthalene 'proton sponges' will be effective building blocks in the construction of supramolecular structures manifesting specific receptor properties.

This review has been written with the financial support of the Russian Foundation for Basic Research (Project No. 96-03-32153a).

IV. Quantum-chemical calculations of the physicochemical parameters of fluoroalkenes	30
V. Conclusion	32

Abstract. The results of simulations of the reactions and reactivity of fluoroalkenes by semiempirical and non-empirical methods of quantum chemistry are summarised. In addition to the isolated molecule approximation, methods based on the calculations of potential energy surfaces of reactions and transition states are used. The shortcomings of such calculations are analysed. The nature of chemical bonds in fluoroalkenes and the applicability of quantum chemistry methods for the calculation of their physicochemical and energy characteristics (with ionisation potentials and dipole moments as examples) are discussed. The bibliography includes 106 references.

I. Introduction

Investigation into the reaction mechanisms of fluoroalkenes is not only of theoretical significance but it is of great practical importance as well. For instance, polymerisation and copolymerisation of these compounds lead to the formation of heat-resistant fluoroplastics, the properties of which depend, in particular, on the sequence of monomers in the copolymer. Fluoroorganic compounds (including those obtained in reactions of fluoroalkenes) are widely used as lubricants, dyes, medicines, *etc.* The kinetics and mechanisms of the reactions depend on the conditions (temperature, pressure, solvent), structures and physicochemical properties of reagents, and structures of transition states. The methods of quantum chemistry can be applied to the estimation of the influence of structural and electronic factors on the course of a reaction.

As a rule, quantum chemistry calculations of potential energy surfaces for reactions and transition states give useful information, which allows a qualitative description of the reaction mechanism. However, these calculations are time-consuming and can be performed only for relatively simple systems. Furthermore, due to the approximations implied in the computational methods, the results of the calculations do not always agree with the experimental data. General principles for the construction of

potential energy surfaces for reactions using quantum chemistry methods were described in detail elsewhere.^{1–3} For reactions of fluoroalkenes with the simplest radicals, these calculations were performed for the first time in the early 1980's (see below). Therefore, calculations within the isolated molecule approximation are still a current topic in the theory of reactivity of alkenes since they allow one to determine the most probable site of the bond to be cleaved, or to trace changes in reactivity along certain series of molecules, in terms of different reactivity indices.

Simulation of reaction mechanisms and reactivities is closely connected with the problem of the description of chemical bonding and with physicochemical parameters of molecules. However, in quantum-chemical calculations of such characteristics as ionisation potentials, electron affinity, dipole moments, *etc.*, problems as to their accuracy arise. These questions will be also discussed below.

Three chapters of our earlier monograph⁴ were devoted to the quantum chemistry of fluorine-containing molecules (including fluoroalkenes). However, a number of new studies using modern computational methods have appeared, and these studies should also be summarised. Many results of these studies are based on those of earlier investigations discussed in the monograph⁴, and thus we have to cite this reference often.

II. Isolated molecule approximation

The problem of the strength of the double bond in ethylene and fluoroethylenes is still far from being completely solved. According to the experimental data on bond lengths, frequencies of valence vibrations, and calculated force constants for the C=C bond, the energy of this bond should increase along the series⁴

The strength of the π -component of the C=C bond changes presumably in the same order (though, this conclusion was derived in earlier studies based on the primitive Hückel method).

According to the results of non-empirical calculations,⁵ some deviations for non-symmetrical fluoroethylenes were observed. In the case of symmetrical molecules, the energy of the double bond increases along the series:

For non-symmetrical fluoroalkenes energy of the C=C bond changes as follows:

Received 6 March 1997

Uspekhi Khimii 67 (1) 28–38 (1998); translated by Ya V Zubavichus

However, these conclusions⁵ (as well as the results of other non-empirical and semiempirical calculations that use the optimised geometry) should be used with certain precautions (see below).

The maximum force required for the cleavage of the double bond in fluoroethylenes was taken as a criterion of its strength.⁵ Non-empirical calculations within the Hartree–Fock approximation with the 5-31G basis set (modified program HONDO) were used.

The thermochemical estimation of the energy of the π -bond is based on the heats of different reactions that occur with the cleavage of this bond (chlorination, bromination, hydrobromination, polymerisation, cyclisation, *etc.*). In all cases, the heat of the corresponding reaction of tetrafluoroethylene exceeds that of ethylene by 10–16 kcal mol⁻¹.^{4,6} However, further calculations of the energy of the C=C bond were performed assuming equality of the energies of the C–F bonds in CF₄ and C₂F₄, and of the C–H bonds in CH₄ and C₂H₄, which is in our opinion a very rough approximation. In one of our previous studies we attempted to explain the differences observed for the heats of reactions of ethylene and tetrafluoroethylene.⁴ Quite rough estimates using the Hückel method lead to agreement between the changes in the π -bond energies for a series of fluoroethylenes and the known data on bond lengths and frequencies of stretching vibrations [series (1)]. However, this result was also obtained within rather rough approximations.

An attempt to explain the thermochemical differences in energies of the double bonds in C₂H₄ and C₂F₄ was undertaken⁶ based on non-empirical calculations in the 6-31G* basis set with the use of the unrestricted Hartree–Fock (UHF) wavefunctions and Møller–Plesset second order perturbation theory (MP2). The energy required for the cleavage of the π -bond in ethylene and tetrafluoroethylene as a result of rotation of the molecule to a biradical transition state in the process of *cis*–*trans*-isomerisation was calculated. Thermochemical estimates of the bond energy were confirmed, and weakening of this bond in C₂F₄ compared to C₂H₄ was explained by a ‘planarisation’ of two CF₂ groups (since the carbon atoms in these groups in the biradical transition state are ‘pyramidised’ to a great extent).

An approach to estimating the energy of the π -bond as the difference between the energies of a triplet *twist*-biradical and a planar alkene⁶ does not take into account changes in the energy of C=C, C–F, and C–H σ -bonds in the rotation. Therefore, we suppose that the data on bond lengths and frequencies of stretching vibrations of the double bond in alkenes [series (1)] describe more adequately the order of changes in the energy of the C=C π -bond in fluoroalkenes (since, in general, substitution hardly affects the length of the σ -bond).

The rates of different reactions of fluoroalkenes that occur with cleavage of the C=C π -bond increase along the series (1). This refers to the reactions with nucleophilic reagents^{4,7} and to some radical reactions. Tetrafluoroethylene reacts with alcohols even at room temperature, whereas an analogous reaction for ethylene is impossible,^{8–10} which is explained only by kinetic rather than thermodynamic factors. For instance, at 25 °C the equilibrium for the reaction of ethylene is almost totally shifted towards etherification.¹¹

The reactions with nucleophilic reagents should proceed more easily the lower the energy of the lowest unoccupied molecular orbital (LUMO), *i.e.* the higher the affinity of the molecule for the electron. According to results of CNDO and INDO calculations,¹² the LUMO of fluoroethylenes is an antibonding π -orbital of ethylene perturbed by fluorine atoms. The values of E^n for ethylene and tetrafluoroethylene are 5.36 eV and 3.72 eV (CNDO) and 5.91 eV and 4.20 eV (INDO), respectively. These

values clearly explain why tetrafluoroethylene reacts much more easily with nucleophiles than ethylene.[†]

Of course, the values given are relative, but they agree qualitatively with the results of calculations by different modifications of non-empirical methods that use basis sets with only *s*- and *p*-orbitals. However, an introduction of *d*-orbitals into the basis leads to opposite results, which are in agreement with rather scarce and approximate experimental data (see below). A decrease in the calculated values of E^n along the series F₂C=CF₂ > F₂C=CFCF₃ > F₂C=C(CF₃)₂ is also in agreement with the experimentally observed increase in the reactivity of the above-mentioned molecules in reactions with nucleophiles.¹³

Populations on carbon atoms and overlapping populations of the C=C π -bond on lower occupied π -orbitals formed by conjugation of lone pairs on the fluorine atom with the π -bonding orbital of ethylene are negligibly small compared to the population of the highest occupied π -orbital formed primarily by the π -orbital of ethylene (see Ref. 4 in which the results of the *ab initio* calculations are given).

In reactions with alcohols, thiols, and amines, tetrafluoroethylene gives only addition products.^{7,13} Together with addition products (2), perfluoropropylene also gives products of vinylic (3) and allylic (4) substitution.

In the case of perfluoroisobutylene, only reactions (2) and (3) occurred.^{6,13,14} Vinylic substitutions

could be accomplished in the case of chlorotrifluoroethylene⁴ and perfluoro-*tert*-butylethylene.¹⁵ In the latter, only the fluorine atom *trans* to the (CF₃)₃ group undergoes substitution in reactions with carbonylmetallates. However, in the case of (CF₃)₃CCF=CFX (X=Cl or Br), in the reaction with carbonylmetallates, the substitution products are not formed.¹⁵ Other examples of analogous reactions with fluoroalkenes are given elsewhere.^{4,14–17}

Products of vinylic substitution, together with addition products, are also formed in reactions of 1,2-dibromo-1,2-difluoroethylene, tribromofluoroethylene, and bromotrifluoroethylene with alkoxides.^{18,19} In the case of F₂C=CFBr, the main site of attack by a nucleophile is the carbon atom of the CF₂ group (the yield of the addition products and the products of substitution of a fluorine atom in the CF₂ group by OR is 80%–94%). Oligomers or polymers and trifluoroethylene are also formed as by-products (less than 0.5%).

The above-mentioned features of reactions of perfluoropropylene and trifluorochloroethylene were interpreted in terms of the results of quantum-chemical calculations by the CNDO method.^{20–22} Allylic substitution in the case of perfluoropropylene occurs because, according to the results of the calculation, the carbon atom of the trifluoromethyl group carries the maximum positive charge. However, due to great steric hindrances, reaction (2) appears to be preferable (attack at the CF₂ group, which also carries a relatively large positive charge). In the case of perfluoroisobutylene, the reaction (4) is impossible due to steric hindrance. The same holds for the reaction of perfluoropropylene with bulky thiol molecules, which follow only pathways (2) and (3).¹³

[†] It should be noted that many features of reactions with fluoroethylenes and of changes in their reactivity have already been rationalised in the first quantum-chemical studies using the primitive Hückel method (for more details, see Ref. 4).

Vinylic substitution (3) can be explained by a substantial increase in the polarity of the C–F bond of the CF₂ group on going from tetrafluoroethylene to perfluoroisobutylene and chlorotrifluoroethylene.²⁰ Despite the fact that the negative charge on the fluorine atom is almost constant for all the four molecules considered, the positive charge on the carbon atom of the CF₂ group in perfluoropropylene, perfluoroisobutylene, and trifluoro-chloroethylene is substantially higher than in tetrafluoroethylene (Table 1).

In the case of phosphorus fluorides for which substitution of the fluorine atoms is typical, the P–F bond is even more polar according to calculations by the CNDO method.^{4,22,24} Vinylic substitution in fluoroethylenes for which experimental data are lacking, has been analysed based on the bond polarity criterion.²²

According to the polarity criterion for the C–F bond, the probability of vinylic substitution is low in monofluoroethylene and both (*cis* and *trans*) 1,2-difluoroethylenes: the difference between the charges on the carbon and fluorine atoms Δq (calculated by the CNDO method) is substantially smaller than in tetrafluoroethylene. However, these reactions are highly probable for 1,1-difluoroethylene and trifluoroethylene: the difference in charges on the carbon and fluorine atoms for these molecules is more than 0.55 (as for perfluoropropylene, perfluoroisobutylene, and chlorotrifluoroethylene), which is larger than the corresponding value for tetrafluoroethylene (0.48, Table 1).

Similar results were obtained in *ab initio* calculations, which are summarised in Table 1, *viz.* atomic charges and Δq values calculated from the data on populations of the corresponding atomic orbitals.²³ Values of Δq for 1,1-di- and tri-fluoroethylenes are also substantially larger than for other members of the series.

Similar results were obtained by the INDO method.²²

Charge distributions in non-symmetrical fluoroethylenes indicate^{4,12} that the addition of hydrogen halides to these molecules should obey the Markownikoff rule, which is in agreement with the experimental data.^{7,13} The results of the corresponding semi-empirical (CNDO, INDO) and non-empirical calculations⁴ also support this conclusion (see also charges of the carbon atoms given in Ref. 5). In reactions with alcohols and thiols, the RO[–](RS[–]) group also adds to the carbon atom, which according to calculations¹² has a relatively high positive charge. A similar conclusion was derived^{4,12,20} from calculations of 1,1-dichloro-2,2-difluoroethylene, chlorotrifluoroethylene, perfluoropropylene, and perfluoroisobutylene which is confirmed by the experimental data. The orientation of borane addition to monofluoroethylene according to calculations by the MNDO method,²⁵ is also in accordance with the experimental data (see also charges of fluoroalkenes calculated by the CNDO method²⁶).

Generally, in vinylic substitution in non-symmetrical haloethylenes, nucleophilic attack can occur at both carbon atoms of

the double bond (see, for example, Ref. 15). The probability of such attack should increase with a decrease in the charge difference between the two carbon atoms. If a molecule contains a CFX group (X = Cl, Br), substitution of both F and X is possible.¹⁵ This is observed, for example, in the reaction of β -chloro- α,β -difluorostyrene with phenyllithium and KFe(CO)₂Cp.¹⁵ The difference in charges on the carbon atoms of the double bond is small (0.171, calculated by the AM1 method).²⁷ Despite the fact that the charge of the carbon atom on the PhFC group is greater than that of the CFCl group, a nucleophile attacks only the =CFCl fragment (presumably, due to steric hindrances because of the presence of the benzene ring in PhFC=). A competitive substitution of both fluorine and chlorine atoms occurs.

Unfortunately, the charges on the F and Cl atoms were not given in Ref. 27, and thus it is impossible to estimate the probabilities of the two reactions in terms of polarity of the C–X bond. Presumably, the substitution of the F atom is more probable. This assumption is in agreement with the results of calculations for other molecules (chlorotrifluoroethylene, in particular²⁰) and with the above-mentioned data on reactions of tribromofluoroethylene.¹⁹ In addition, we believe that KFe(CO)₂Cp or Re(CO)₅, in general, cannot be considered as classical nucleophiles. In the course of the reaction, intermediate complexes can be formed through dative bonds between the Fe (Re) atom and the π -orbital of alkene as well as by donor–acceptor bonds between CO and the vinyl group.

A detailed study of electrochemically activated reactions of nucleophilic substitution of polyfluorinated vinyl halides was performed,^{27,28} and quantum-chemical calculations for the nine alkenes considered, four fluorinated butadienes, and fluorinated acetylenes were accomplished.²⁷ The semiempirical AM1 method with full geometry optimisation was used. Energies of frontier π -orbitals of the molecules studied and charges on the vinylic carbon atoms were determined. Other parameters (in particular, charges on halogen atoms, interatomic distances, bond angles) were not given in Ref. 27. However, certain problems in the interpretation of the results of quantum-chemical calculations that use optimised geometry may arise (see below). The electron acts as the simplest nucleophile. In the case of the formation of rather stable radical-anions upon interaction of a haloalkene with an electron [for instance, (RFC=CFX)^{•–}], the nucleophilic substitution is a ‘multi-step’ process.²⁷ If no radical-anions are formed, the nucleophilic substitution is a ‘one-step’ process.

Changes in frontier π -orbitals of ethylene upon substitution of halogens for hydrogen were thoroughly analysed.²⁷ Energetic, spatial, and kinetic factors were considered.

The energy of the π -orbitals of the double C=C bond perturbed by halogen atoms depends both on conjugation of a lone *p*-electron pair of the halogen with the electrons of the π -bond

Table 1. Charges on the carbon (q_C) and the fluorine (q_F) atoms in fluoroalkenes calculated by the CNDO²² (I) and *ab initio*²³ (II) methods and the difference between the charges of C and F (Δq).

Note. The fluorine atoms for which values of q_F are given are underlined. Values of q_F are given for the fluorine atom in the *cis*- (no parentheses) and *trans*- (in parentheses) positions to the fluorine atom of the CFX group. In calculations on chlorotrifluoroethylene, vacant 3*d*-orbitals of the Cl atom were included into the basis set.

Other examples of similar studies are given elsewhere.⁴ A problem arises in the choice of the molecular geometry. In non-empirical and semiempirical calculations, the energy minimisation procedure is often applied, and further calculations of quantum-chemical characteristics are performed for the structure, which corresponds to the global energy minimum. However, noticeable deviations between the calculated and experimental geometrical parameters for the gas phase are often observed. For example, for fluoroethylenes, the difference between the experimental and calculated bond lengths does not exceed 0.03 Å, which can hardly affect substantially the calculated physicochemical parameters. Only for calculations by the MNDO method do the calculated bond lengths deviate strongly from the experimental ones. How-

ever, the difference between the calculated and experimental bond angles in some cases reaches 4° , which inevitably introduces errors in the values of some physicochemical parameters and quantum-chemical indices (dipole moments, ionisation potentials, *etc.*).⁴ For instance, changes in ionisation potentials for the series of fluoroethylenes obtained by the LCAO SCF *ab initio* calculations in the DZ basis not only disagree with the experimental data, but do not reflect any regularity in contrast to the results of semi-empirical calculations (EHT, CNDO, INDO), which use the experimental molecular geometry (see Refs 4 and 12).[‡]

The same problem was discussed in another study.³² It was shown that in the case of full geometry optimisation by the MNDO and *ab initio* methods, not only the calculated bond angles, but also the C=C and C–F bond lengths differ considerably from the experimental values.

Recently,³³ enthalpies of formation, moments of inertia, vibration frequencies, and geometrical parameters for more than 100 fluorinated hydrocarbons and radicals containing one or two carbon atoms were calculated using the non-empirical BAC-MP4 method (fourth order Møller–Plesset perturbation theory corrected for additivity of bonds). It was found that the bond angles coincide with the experimental data within 1° on average. However, as can be seen from the tables given in Ref. 33, this is not quite true for fluoroethylenes, especially for non-symmetrical ones. In some cases, as well as in the studies mentioned above, deviations from the experimental data reach 4° , for example,

Angle	Value of angle /deg.		Angle	Value of angle /deg.	
	calcu- lation ³³	experi- ment ⁴		calcu- lation ³³	experi- ment ⁴
CCF	122.4	120.98	CCF ¹	125.4	125.43
CCH ¹	125.7	127.70	CCF ³	120.6	118.81
CCH ³	119.8	121.41	CCH	123.4	127.20
CCH ²	121.5	123.93			

The problems discussed in Ref. 33 lie somewhat beyond the objectives of the present review (though the authors point to the need for kinetic studies). In the above-mentioned study, neither data on the energy of molecular orbitals, nor populations of atomic orbitals and atomic charges were given, and the mechanisms of the reaction with participation of the compounds studied were not considered.

III. Potential energy surfaces of reactions and structure of transition states

First studies devoted to calculations of potential energy surfaces of reactions with the participation of fluoroethylenes appeared in 1980.^{34,35} The unrestricted Hartree–Fock method with split valence basis set 4-31G was used. In particular, a mechanism of reaction of monofluoroethylene with atomic hydrogen was discussed.³⁴ Potential energy surfaces of the following reactions were studied by non-empirical MO LCAO methods:

as was of a similar reaction of ethylene.³⁵ The main contribution to the potential barrier (E) of reaction (6) equal to $5.6 \text{ kcal mol}^{-1}$ arises from deformation of the H_2CCHF segment in the transition state ($4.5 \text{ kcal mol}^{-1}$); the rest ($1.1 \text{ kcal mol}^{-1}$) is due to interactions of the $\text{FHC}=\text{CH}_2$ fragment with H. The potential barrier of reaction (6) exceeds by $3.3 \text{ kcal mol}^{-1}$ that of the reaction

The lifetime of $\text{H}_2\text{CCH}_2\text{F}^\bullet$ is relatively great (10^{-9} s). If the process has adiabatic character, the energy E converts to the translation energy of the reaction products³⁵ (see also Ref. 4).

The studies^{34,35} were based on general principles of analysis of potential energy surfaces for radical reactions developed by Nagase, Morokuma, and Kern.^{34,36,37}

Reactions of atomic hydrogen with 1,1-difluoroethylene and monofluoroacetylene were studied in detail.³⁸ An *ab initio* method within the unrestricted Hartree–Fock theory (modified version of Gaussian 70) was used. It was demonstrated that in both cases the preferential site for a nucleophilic attack is the carbon atom not bonded with the fluorine atom. The potential barrier to the reaction of 1,1-difluoroethylene ($4.1 \text{ kcal mol}^{-1}$)³⁸ is higher than that of ethylene ($2.2 \text{ kcal mol}^{-1}$).³⁴

Potential energy surfaces, structures of transition states for reactions of fluoroethylenes with alkyl radicals and heteroradicals as well as the regioselectivity of alkyl radicals in reactions with non-symmetrical fluoroethylenes were discussed in a number of papers^{39–44} (see also Ref. 4). The extended Hückel method (EHT) was used.^{39,40} The conclusions derived in Refs 39 and 40 are not always correct from our viewpoint. For instance, attempts to analyse the mechanisms of the reactions studied of ethylene and fluoroethylenes⁴⁰ with $\text{CH}_3^\bullet$ and $\text{CF}_3^\bullet$ using different correlations between the experimental activation energy and the calculated quantum-chemical indices do not meet any criteria of mathematical statistics.[§]

A more thorough analysis of the mechanisms of radical reactions was performed using the concept of ‘phility’ of free radicals in reactions of addition to alkenes.^{41–44} This concept is based on a hypothesis⁴⁵ of a parallelism between the direction of the charge transfer and localisation of the bonds formed and cleaved and on an assumption⁴⁶ that the potential barrier to a reaction depends on the charge transfer stage and that the strongest charge transfer in a transition state corresponds to the most preferable reaction pathway. A hypothesis⁴⁷ stating that the interaction of centres with the maximum electron density on frontier orbitals of the reagents (the HOMO of the alkene and the orbital with the unpaired electron of the radical for the stage of charge transfer from alkene to radical; and the LUMO of the alkene and the same orbital of the radical for the stage of charge transfer from the radical to the alkene) is the most preferable, is also implied.

Depending on the substrate, a radical can act as a nucleophile and an electrophile, and can exhibit ambiphilic properties (in the case that the charge transferred from the orbital of the radical occupied by one electron to the lowest unoccupied π -orbital of the alkene is close to the charge transferred in the opposite direction from the highest occupied π -orbital of the alkene to the radical orbital). In general, certain radicals and an alkene can act as nucleophiles and electrophiles (donors and acceptors) simultaneously donating and accepting electrons. The ‘phility’ is determined by the predominating process.

The ‘phility’ concept,⁴¹ first, allows one to determine the most reactive centre of a non-symmetrical alkene molecule; second, to predict changes in the reactivity of a given radical with different alkenes or a given alkene with different radicals; and third, to estimate the preferred direction of charge transfer in the system (from the alkene to the radical or, conversely, from the radical to the alkene).

To determine the reaction rate constants, the stabilisation energy method,¹ the concept of a ‘quasi- π -electron system’ of the

‡ Unfortunately, there are no published data on the orbital populations and all atomic charges of fluoroalkenes calculated *ab initio* with a more complete basis set.

§ Plots of dependences of $(E - E_0)_{\text{exp}}$ on the theoretical value $(E - E_0)_{\text{theor}}$, the sum of contributions of charge transfer, and contributions of exchange repulsion were discussed⁴⁰ (E and E_0 are activation energies of fluoroethylene and ethylene, respectively). However, only four or five experimental points (equal to the number of molecules studied) were used in data processing, and strong deviations from the theoretical line were observed. No statistical criteria, except for the correlation coefficient, for the dependences obtained were given⁴⁰ (for details, see Ref. 4).

transition state (*i.e.* the electron system that comprises π -systems of the initial molecules),⁴⁸ and a one-electron method of perturbation theory within the frontier orbitals approximation have been used.^{42,43}

Reactions of ethylene and fluoroethylene with six alkyl and halogenoalkyl radicals ($\text{CH}_3^\bullet$, $\text{CH}_2\text{F}^\bullet$, $\text{CHF}_2^\bullet$, $\text{CF}_3^\bullet$, $\text{C}_2\text{F}_5^\bullet$, and $\text{CCl}_3^\bullet$) and four heteroradicals [$\text{PH}_2^\bullet$, $\text{P}(\text{CH}_3)_2^\bullet$, $\text{SH}^\bullet$, $\text{S}(\text{CH}_3)_2^\bullet$] were discussed.^{42,43} An analogous approach was also used for the qualitative prediction of the direction of radical substitution reactions in an aromatic ring⁴⁹ and for a investigation of the reactions of fluoroethylene copolymerisation.⁵⁰

The results obtained^{41–44,49,50} reflect adequately the experimental data on reaction mechanisms and reactivities of the molecules studied. Generalisation of these results has led to the development of a model of intermolecular ambivalence in organic reactions.⁵¹

After publication of the monograph,⁴ several studies devoted to quantum-chemical calculations of potential energy surfaces for reactions of fluoroalkenes appeared. Hydrogen migration in the monofluoroethylene molecule was studied⁵² *ab initio* on a Hartree–Fock atomic orbital basis using perturbation theory. It was shown that a local minimum on the energy surface does not correspond to the singlet state of the rearrangement product.

The problems of accounting for the correlation effects that arise when determining the geometry of transition states are the same as in calculations of the ground state structures of molecules. The authors of a study⁵³ of addition reactions of $\text{H}^\bullet$, $\text{OH}^\bullet$, $\text{NH}_2^\bullet$, and $\text{CH}_3^\bullet$ radicals to mono- and 1,1-di-fluoroethylenes using non-empirical calculations (up to MP4/6-31G**) came to a conclusion on the necessity of accounting for the electron correlation when determining the structures of transition states for reactions of fluoroalkenes with electrophilic radicals. The importance of accounting for the electron correlations in quantum-chemical calculations of reactions of fluoroethylenes with radicals was also discussed in other studies.^{52,54,55} In all these studies, different modifications of the *ab initio* method were used [Hartree–Fock atomic orbitals MP2–MP4/DZ + P; 6-31G**, 6-311G**, 6-311 + G(2d,p); 6-311 + G(3df,2p), *etc.*].

The relative reactivity of the above-mentioned radicals in reactions with monofluoroethylene and difluoroethylene obtained from calculations⁵³ is in agreement with the experimental data. However, the regioselectivity of $\text{OH}^\bullet$ and $\text{NH}_2^\bullet$ radicals is very 'sensitive' to the level of theoretical calculations, and an increase in this level up to MP4/6-31G** may lead to a contradiction with the experimental data (an attack at the carbon atom of the FHC and F_2C groups according to calculations rather than of the H_2C group according to experiment).⁵³

Non-empirical calculations of potential energy surfaces of addition reactions of $\text{H}^\bullet$, $\text{CH}_3^\bullet$, $\text{CH}_2\text{OH}^\bullet$, $\text{CH}_2\text{CN}^\bullet$, and *tert*- $\text{C}_4\text{H}_9^\bullet$ radicals to alkenes $\text{H}_2\text{C}=\text{CHX}$ ($\text{X} = \text{H}$, CH_3 , NH_2 , OH , F , SiH_3 , Cl , CN , CHO , NO_2) were performed.^{54,55} A correlation between the potential barrier and the reaction enthalpy was established ($R^2 = 0.973$). However, besides the correlation coefficient, no other statistical criteria were used for the dependence obtained, which does not allow one to judge its correctness. Problems of the statistical significance of correlation equations were analysed in detail elsewhere.^{56–59}

The methyl radical does not manifest nucleophilic properties in reactions with the alkenes studied ($\text{X} = \text{F}$, H , OH , CH_3 , SiH_3 , and NH_2) and acts as an electron acceptor (*i.e.* the charge is transferred from the alkene to $\text{CH}_3^\bullet$).⁵⁴ In the case where $\text{X} = \text{Cl}$, according to the results of calculations, charge transfer does not occur at all; for $\text{X} = \text{CHO}$, NO_2 , and CN , methyl acts as an electron donor (*i.e.* exhibits nucleophilic properties: the charge is transferred from $\text{CH}_3^\bullet$ to the alkene).

Electron-acceptor groups increase the reactivity of alkenes due to an increase in the exothermicity of the reaction rather than the polar character of the transition state.⁵⁴

The stability of fluorine-containing cations including $\text{H}_2\text{C}=\text{CHFCH}_3^+$ and $\text{H}_2\text{C}=\text{CHCHF}^+$ was studied by the *ab initio* SCF method in the 6-31G basis set (Gaussian 82 programme).⁶⁰ An analysis of singlet and triplet transition structures in the process of trifluoroethylene formation in the photolysis of 2,2,2-trifluorodiazoethane was performed⁶¹ using the *ab initio* method at the QCISD(T)-FC/6-311(2s,2p)/MP2-FC/6-31G** theory level.

The results of non-empirical calculations for $\text{C}_3\text{H}_2\text{F}^+$, C_3HF_2^+ , and C_3F_3^+ ions are given elsewhere⁶² (SCF, Hartree–Fock, 6-311G).

Potential energy surfaces for molecules of X_2F_4 type ($\text{X} = \text{C}$, Si , Ge , Sn , and Pb) were studied in detail using *ab initio* methods (RHF and UHF, DZ and DZd basis sets).⁶³ In particular, it was established that the planar structure of C_2F_4 corresponds to the energy minimum. Similar energy minima were found for ground states of Si_2F_4 , Ge_2F_4 , Sn_2F_4 , and for a singlet excited state of Pb_2F_4 . It was shown that a biradical triplet particle $\text{F}_2\text{X}^\bullet-\text{X}^\bullet\text{F}_2$ has higher energy than the singlet particle in the ground state.

IV. Quantum-chemical calculations of the physicochemical parameters of fluoroalkenes

Different aspects of the quantum chemistry of fluoroalkenes, such as the nature of the chemical bonds therein, relative stability of geometrical isomers, and calculations of physicochemical parameters, have been discussed in detail previously.⁴ Problems arising from the interpretation of the results of calculations and from calculations of certain parameters (ionisation potentials, dipole moments, different energy characteristics, magnetic shielding constants of ^{19}F and ^{13}C nuclei, and so on) have been also analysed. Most of these parameters affect the character and quantitative characteristics of reactions of fluoroalkenes and thus they are closely connected with the objectives of the current review. The results of quantum-chemical calculations of physicochemical parameters of fluoroalkenes obtained in the 1990's have been analysed in another review.⁶⁴ Here, we will discuss in brief only the problems that concern the reactivity and mechanisms of reactions of compounds of this class.

Difficulties arising from the calculations of geometrical parameters of molecules have already been mentioned. Non-empirical calculations of neutral molecules and dications of type $\text{C}_2\text{X}_2\text{Y}_2^{2+}$ were performed⁶⁵ in the 3-21G*(d) basis set using the Gaussian 88 programme. In particular, it was shown that dication $\text{C}_2\text{F}_4^{2+}$ has a planar configuration in the ground state in contrast to the *twist*-structure of $\text{C}_2\text{H}_2^{2+}$. Serious problems also arise in the calculation of the ionisation potentials and dipole moments of molecules.

1. First ionisation potentials; electron affinity

The first ionisation potential I , which corresponds to detachment of an electron from the HOMO, is the most interesting for chemists: the value of I to some extent correlates with the reactivity of a molecule in reactions with electrophilic reagents. Linear correlations between the logarithms of rate constants of certain reactions and I values are often found for narrow subsets of closely related compounds.

In order to estimate I , the difference between the energies of the ion formed and the initial molecule $\Delta E'$ has to be calculated.

According to Koopmans theorem,⁶⁶ if wavefunctions are not changed after detachment of an electron from certain MO, the corresponding ionisation potential is equal to the energy of this orbital E_i . This implies that the difference between the correlation energies of the ion and molecule ΔE_c is equal to the reorganisation energy ΔE_r taken with the opposite sign,⁶⁷ since

$$I + E_i = \Delta E_c + \Delta E_r,$$

where ΔE_r is the difference between the energy of the HOMO calculated in the optimum modification of the Hartree–Fock method and the ionisation potential.⁶⁸

Usually, ionisation potentials I calculated according to Koopmans theorem using different semiempirical and non-empirical methods of the self-consistent field (SCF) approach exceed the experimental values.

At the same time, the use of $\Delta E'$ may lead to errors due to the difference in the correlation energies of the ion formed and the initial molecule. This often results in lower values of the ionisation potentials I compared to the experimental ones. The results obtained according to Koopmans theorem may be corrected (for example, by changing the calculated values of I by 8%), however, such corrections give satisfactory results only for ionisation from the two lowest MOs.

As an alternative, averaged values of ionisation potentials obtained by the two above-mentioned methods can be used for a comparison of calculated and experimental results.²³ But this artificial approach does not lead to good results in all cases.⁴

According to the Frank–Condon principle, the internuclear distance should be kept constant as an electron is detached. But there is no reason to state that the ion formed in this case will be in its ground state. It is more probable that the interatomic distances of the ground state of the initial molecule correspond to an excited vibrational state of the ion. In this case, the so-called vertical ionisation potential I_v , which can be determined, for instance, by the electron impact method, includes energy from the excitation of the molecule in addition to the adiabatic ionisation potential (I_a). Discrepancies between the values of I_v determined in different studies are sometimes equal to 0.15–0.40 eV.^{4,64} At the same time, the accuracy of the experimental determination of the adiabatic ionisation potentials is very high (± 0.01 – 0.02 eV).⁴

Adiabatic ionisation potentials, which correspond to the difference in the energy of ground states of the ion and molecule,

can be measured with high precision using spectral and photo-ionisation methods.

Obviously, calculation of the adiabatic ionisation potentials requires that the difference in energies of the ion and molecule, calculated for optimised geometries corresponding to the energy minima of both particles, should be determined. Ionisation potentials calculated according to Koopmans theorem should correspond to the experimentally determined vertical ionisation potential. However, the change in, for example, energies of HOMOs calculated by the Hückel method as well as by EHT, CNDO, INDO methods^{12,69–74} for a series of haloethylenes corresponds to a change in the first adiabatic potentials and at the same time does not reflect changes in the vertical potentials. Therefore, in many studies the first ionisation potentials I_a of haloethylenes calculated using the corresponding parametrisation are taken to be equal to the energy of the HOMO.

Surprisingly, the best results were obtained using the Hückel method. Presumably, it is a relatively simple procedure to adjust the parameters required for the calculations using experimental data for a small subset of molecules that accounts for this fact.

Of course, it is possible to try to adjust the corresponding parameters for calculations of ionisation potentials of haloethylenes within semiempirical SCF quantum-chemical methods. However, such a procedure and subsequent calculations are much more time-consuming than the corresponding calculations by the Hückel method. Thus, merely from a pragmatic viewpoint, the results^{71–73} are still timely, and a similar approach can be successfully applied for other classes of compounds.

Attempts at calculations of ionisation potentials of fluoroethylenes using various semiempirical and non-empirical versions of the SCF method did not, in general, lead to positive results. The most complete study of ionisation potentials of molecules of the

Table 2. Calculated and experimental values of the first adiabatic ionisation potentials of haloethylenes (eV).

^a In Ref. 79, the results of calculations on fluoroalkenes by the Hückel method with different complicating corrections were also given. ^b Experimental data were obtained after publication of the corresponding results of calculations.^{72, 73}

class considered was performed by the *ab initio* MO LCAO method in the DZ basis set,²³ these values were calculated both according to Koopmans theorem and as a difference in total energies of the ion formed and the initial neutral molecule. However, even the direction of change of the calculated ionisation potentials did not correspond to the change in experimental adiabatic and vertical ionisation potentials (see Refs 4, 23, 64 and results of Refs 32, 75–78). Possible reasons for this fact have already been mentioned.

Table 2 shows adiabatic ionisation potentials of haloethylenes calculated by the Hückel method. Differences between the calculated and experimental values do not exceed a few hundredths of an electron-volt. This suggests that the calculated ionisation potentials of 28 haloethylenes (Table 3) for which there are no experimental data are also reliable. After publication of the studies^{72–74}, adiabatic ionisation potentials of some mixed haloethylenes were measured; for them, good agreement between the calculated and experimental data was also observed (Table 2).

Table 2 shows that experimental ionisation potentials of *cis*- and *trans*-1,2-haloethylenes are virtually identical, and this fact justifies the application of the computational methods that do not take into consideration geometrical differences between the isomers.

It should be noted that according to mass spectrometric data,^{84,86} the first ionisation potential of fluoroethylenes can be interpreted as the energy of a π -electron of the C=C bond (taken with the opposite sign). This conclusion can also be derived from the calculations on these molecules by the CNDO, INDO, MNDO, and *ab initio* methods (see Refs 4 and 64): the orbital formed by a π -bonding orbital of ethylene perturbed by fluorine atoms has the highest energy of all the π -orbitals.

The great scatter of experimental data on electron affinity (*A*) does not allow one to derive unambiguous conclusions on changes in *A* for fluoroethylenes. For example, in a reference book,⁸³ the value $A > -2.15$ eV is indicated for ethylene, while for fluoroethylenes the data are absent. In more recent studies,^{54,87} the values of *A* for C₂H₄ and CH₂=CHF are -1.74 eV and -1.91 eV, respectively, *i.e.* ethylene manifests a higher electron affinity than monofluoroethylene. However, a non-empirical calculation⁵⁴ (MP2, 6-31G**/HF/6-31G* basis) gives other results: -1.86 eV and -1.62 eV. The same result was obtained in Ref. 88: calculations by the CNDO and *X_α* methods as well as non-empirical calculations using the Hartree–Fock functions in 6-31G and 6-31G* basis sets lead to a more stable lowest vacant orbital in fluoroethylenes compared to that in ethylene. Only the inclusion of *d*-functions into the 6-31G* basis set gives agreement with the above experimental results.

Table 3. Calculated⁷³ first adiabatic ionisation potentials (*I_a*/eV) for haloethylenes (experimental data for the given molecules are absent).

Molecule	<i>I_a</i>	Molecule	<i>I_a</i>
Br ₂ C=CH ₂	9.81	ClBrC=CHBr	9.34
Br ₂ C=CBr ₂	9.09	FBrC=CHBr	9.42
FBrC=CH ₂	9.88	Cl ₂ C=CClF	9.45
ClBrC=CH ₂	9.84	Cl ₂ C=CClBr	9.26
FHC=CHBr	9.80	Br ₂ C=CBrF	9.26
ClHC=CHBr	9.54	Br ₂ C=CClBr	9.15
ClBrC=CHF	9.74	F ₂ C=CBr ₂	9.61
FBrC=CHCl	9.52	Cl ₂ C=CBr ₂	9.21
FCIC=CHBr	9.50	FCIC=CClF	9.57
F ₂ C=CHBr	9.73	FBrC=CBrF	9.39
Cl ₂ C=CHF	9.79	ClBrC=CBrCl	9.20
Cl ₂ C=CHBr	9.39	F ₂ C=CClBr	9.64
Br ₂ C=CHF	9.70	Cl ₂ C=CBrF	9.36
Br ₂ C=CHCl	9.41	Br ₂ C=CClF	9.36
FBrC=CHF	9.79	FCIC=CBrF	9.48
FCIC=CHCl	9.61	FCIC=CClBr	9.40
ClBrC=CHCl	9.45	FBrC=CClBr	9.30

Probable experimental errors have also to be taken into account. However, due to the lack of experimental data, this question is open to discussion.

2. Dipole moments of molecules

The polarity of a molecule can substantially affect its reactivity and reaction mechanisms. Problems arising in quantum-chemical calculations of dipole moments have been considered in a number

Table 4. Calculated and experimental values of dipole moments of fluoroalkenes.

F ₂ C=CClF	CNDO ²¹	0.33	0.38 ⁹⁸

^a MM is the molecular mechanics method. ^b Results of calculations with different basis sets for experimental (gas phase),¹⁰⁰ standard¹⁰⁴, and optimised (in parentheses) molecular geometry; fixed standard parameters are as follows:¹⁰⁴ bond lengths C–C, C–F, and C–H are equal to 1.34, 1.33, and 1.08 Å, respectively, all angles are equal to 120°.

of studies.^{4, 56} The calculated and experimental values of dipole moments of fluoroethylenes are summarised in Table 4. In the study,⁹⁴ which appeared at the same time as the monograph⁴, the HAM/3 method was used for the calculation of dipole moments of 97 molecules including fluoro-, 1,1-difluoro-, and trifluoro-ethylenes. However, as indicated by the authors of Ref. 94, this method overestimates the results compared to experiment.

In most cases, the CNDO method gives the dipole moments that are in better agreement with the experimental data than those obtained by the INDO, MNDO, HAM/3, and *ab initio* methods (see Table 4).

This holds for calculations of dipole moments of other fluorine-containing molecules, such as phosphorus fluorides^{4, 24, 105} and nitrogen fluorides.^{4, 106} However, it should be noted that calculations by molecular mechanics are more reliable than quantum-chemical calculations.

V. Conclusion

Quantum-chemical calculations on fluoroalkenes even within the isolated molecule approximation allow one to explain or predict many subtle features of their reactions. A more complete description can be achieved by determination of the structure and stability of possible intermediates⁵ (carbanions, radicals, *etc.*) and by calculation of potential energy surfaces of the reactions.

In calculations of physicochemical parameters of fluoroalkenes, semiempirical and non-empirical methods that make use of experimental molecular geometry lead to better results despite the rapid development of techniques of non-empirical calculations and determination of molecular geometry by a procedure of energy minimisation. Presumably, this is due to the fact that the geometrical parameters of fluoroalkenes (especially of non-symmetrical ones) first of all, bond angles calculated in such a way deviate strongly from the experimental values. Probably, an extension of the basis sets will finally allow one to overcome this problem.

Let us indicate some other problems that are still subjects of discussion, primarily the strength of the π -bonds in ethylene and fluoroethylenes. Our opinion on this point was outlined in the second section of this review.

Another unsolved problem was not considered here but it was extensively discussed in the monograph:⁴ the relative stability of geometrical non-halogenated isomers (in particular, 1,2-alkyl-substituted ones) and 1,2-dihaloethylenes. It was established experimentally that in the first case, the *trans*-isomer is more stable than the *cis*-isomer, whilst in the second case the situation is opposite. However, discussions on the probable reasons for the phenomenon still continue. We hope that all the problems mentioned will be successfully resolved in the near future.

The authors are most grateful to A S Kabankin and L A Piruzyan for a long-lasting and fruitful collaboration, and to I P Beletskaya for valuable advice in the discussion of the paper.

Aliphatic nitro alcohols. Synthesis, chemical transformations and applications

M-G A Shvekhgeimer

Contents

I. Introduction	35
II. Methods for the synthesis of aliphatic nitro alcohols	35
III. Chemical transformations of nitro alcohols	49
IV. Practical use of aliphatic nitro alcohols	64

Abstract. The data on the synthesis, chemical transformations and practical use of aliphatic nitro alcohols published over the last 25 years are described systematically and analysed. The bibliography includes 316 references.

I. Introduction

Aliphatic nitro-derivatives attract considerable attention from researchers, because they are readily accessible and convenient starting compounds for the synthesis of organic derivatives of various classes. The diversity of chemical transformations of aliphatic nitro-compounds provided the basis for the paper 'Aliphatic nitro-compounds as perfect intermediates' published in 1979.¹ Nitro alcohols of the aliphatic series fully conform to this definition. Furthermore, since nitro alcohols contain the hydroxy group, their reactions can involve simultaneously several reaction sites; hence, the range of chemical transformations of these derivatives is even broader.

The results of numerous studies devoted to the chemistry of aliphatic nitro alcohols and published before 1972 have been surveyed quite comprehensively in reviews and monographs.^{2–4} However, no reviews describing systematically the data on the synthesis, transformations and practical use of aliphatic nitro alcohols obtained during the last 25 years have been published so far.

The purpose of this review is to fill this gap. We only briefly outline the preparation of nitro alcohols by nitroaldol condensation (Henry reaction), because its conditions have been described quite comprehensively in previous publications.^{3,4} The studies containing some novelty either in the procedure of condensation of nitro-compounds with carbonyl derivatives or in the use of the target compounds are discussed in greater detail. New data about other known methods for the synthesis of nitro alcohols and new information on their chemical transformations are presented. We also consider most of the studies that mention potential practical applications of these compounds, because this aspect has received little attention in earlier reviews.

II. Methods for the synthesis of aliphatic nitro alcohols

1. Nitroaldol condensation (the Henry reaction)

The Henry reaction consisting of condensation of aliphatic nitro-compounds with aldehydes or ketones is the most general method used widely for the synthesis of aliphatic nitro alcohols. The mechanism of this reaction has not yet been completely elucidated. It is generally accepted that nitroalkanes are condensed with carbonyl compounds according to the following scheme:

a. Reactions of nitromethane and its derivatives with aldehydes

The reaction of nitromethane **1** with formaldehyde **2** catalysed by $\text{Ca}(\text{OH})_2$ makes it possible to prepare both 2-nitropropane-1,3-diol **3**⁵ and 2-hydroxymethyl-2-nitropropane-1,3-diol **4**.⁶

R = H (**3**); CH_2OH (**4**).

The diol **3** has also been prepared from the compounds **1** and **2** at 0–10 °C in the presence of sodium carbonate.⁷

The synthesis of **3** from **1** and an aqueous solution of formaldehyde or paraformaldehyde is carried out most often in the presence of alkali, NaOH ^{8–12} or KOH ,¹³ as catalysts.

Sodium and potassium hydroxides are also used as catalysts to synthesise the triol **4** from MeNO_2 and the aldehyde **2**.¹⁴

The condensation of nitromethane **1** with paraformaldehyde catalysed by sodium methoxide in methanol gives the sodium salt **5**.^{15, 16}

The condensation of MeNO_2 with paraform in the presence of $\text{Bu}_4\text{N}^+\text{Br}^-$ and KF under an inert atmosphere at 18–22 °C for

72 h affords a mixture of the diol **3** (yield 5% – 10%) and the triol **4** (yield 80% – 85%).¹⁶

Treatment of the nitronate **5** with trifluoroacetic acid at low temperatures gives rise to the *aci*-form **6**, which is rapidly converted into the diol **3** and 2-nitroprop-2-en-1-ol.¹⁶

The diol **3** obtained from MeNO₂ and paraformaldehyde in the presence of KF and Bu₄N⁺Br[−] exists as a nitronate **7** stabilised by intramolecular interactions.¹⁷

The condensation of bromonitromethane with formaldehyde **2** in the presence of NaOH in methanol gives the diol **8**.¹⁸

Treatment of nitromethane **1** with bromine in an alkaline medium followed by the reaction with formaldehyde in the presence of NaOH¹⁹ or the condensation of MeNO₂ with formaldehyde followed by treatment with bromine²⁰ afford the same compound **9**, the yield of which is up to 60%.

Nitro alcohols **10** containing a furyl substituent have been obtained by the condensation of MeNO₂ with aldehydes **11** in the presence of sodium hydroxide.^{21, 22}

R	R'	n	Yield (%)	Ref.
H	Me	2	49	21
Me	H	2	78	22
H	H	1	66–73	21, 22
H	Me	1	59–75	21, 22

The reaction of chiral complex **12** with nitromethane has been carried out in the presence of NaOH or KF and gave a mixture of diastereoisomeric nitro alcohols **13a** (1*S*,2*S*) and **13b** (1*S*,2*R*) in a high yield. It was found that the ratio of the resulting isomers varies over a wide range depending on the procedure used and the temperature (see Table 1).²³

Table 1. Reaction conditions and the ratio of the products **13a** and **13b**.

Base	Temperature /°C	Yield (%)	Ratio 13a : 13b
NaOH	20	100	64 : 36
NaOH	−20	95	92 : 8
NaOH	−40	90	97 : 3
KF/Pr ⁱ OH	20	80	40 : 60
KF/Pr ⁱ OH	0	90	88 : 12

When nitromethane was treated with butyllithium (THF, HMPT, −90 to −60 °C), and the product was made to react with aldehyde **12** (THF, −70 to −60 °C, 1.5 h; −45 to −40 °C, 3 h), the isomer **13a** was obtained as the only product.²³

Sodium methoxide has been used as the catalyst in the reactions of nitromethane **1** with both aliphatic²⁴ and aromatic^{25, 26} aldehydes.

R = C₁₃H₂₇, 3-MeOC₆H₄, 4-PhCH₂OC₆H₄ (43%), Ph (59%), 4-MeC₆H₄ (50%), 4-ClC₆H₄ (63%).

Potassium fluoride is an efficient catalyst of the reaction of MeNO₂ with aldehydes.²⁷

R = C₆H₁₃, C₇H₁₅, , .

Me₂C=CH(CH₂)₂C(Me)=CH(CH₂)₂.

Study of the condensation of nitromethane with aldehydes carried out using IR and NMR spectroscopy has shown that the process occurs efficiently in DMF at 20 °C in the presence of a complex of nickel acetate with 2,2'-dipyridyl (Dipy) and gives nitro alcohols **15** in 81% – 87% yields.²⁸

R = , PhCH₂CH₂, 4-NO₂C₆H₄, 4-NCC₆H₄.

The reaction of MeNO₂ with acetaldehyde catalysed by Rh(PMe₃)₃Cl and carried out at 23 °C for 0.5 h affords 1-nitropropan-2-ol in 90% yield.²⁹

Nitromethane readily reacts with aromatic aldehydes in liquid ammonia giving rise to nitro alcohols **16** in good yields.³⁰

Ar = 2-H₂NC₆H₄ (53%), 3,4-(MeO)₂C₆H₃ (98%),
4-Br-3,4-(MeO)₂C₆H₂ (80%), 4-MeC₆H₄ (92%),
3,4-(CH₂O)₂C₆H₃ (83%), 4-BrC₆H₄ (93%), 3-BrC₆H₄ (91%),
3-ClC₆H₄ (75%), 4-MeOC₆H₄ (82%), 1-naphthyl (53%).

Triethylamine has been used as the catalyst in the reaction of MeNO₂ with 4-chloropentanal **17**; this resulted in the formation of nitro alcohol **18** in 42.5% yield.³¹

Difluoronitromethane condenses with trifluoroacetaldehyde on heating in the presence of sodium carbonate. The reaction gives 1,1,1,3,3-pentafluoro-3-nitropropan-2-ol in 38.5% yield.³²

The condensation of difluoronitromethane with aromatic aldehydes has been carried out using KOH as the catalyst.³³

Ar = 2-HOC₆H₄ (47%), 2-ClC₆H₄ (61%), 2-O₂NC₆H₄ (31.5%),
3-O₂NC₆H₄ (56%), 4-MeC₆H₄ (60%), 2,4-(MeO)₂C₆H₃ (53.5%).

It has been reported³⁴ that chlorofluoronitromethane reacts with aliphatic aldehydes without a catalyst.

R = H (83%), Me (55%), Et (73%), Pr (86%).

b. Reactions of nitromethane homologues and their derivatives with aldehydes

It should be noted that even when primary nitro-compounds are used, the synthesis usually affords products resulting from condensation with one formaldehyde molecule.

2-Nitrobutan-1-ol has been obtained in an almost quantitative yield by the reaction of 1-nitropropane with formaldehyde **2** in the presence of Ca(OH)₂ at 30 °C.³⁵

In a number of publications,^{36–39} synthesis of nitro alcohols **19** from nitroalkane **20** and formaldehyde catalysed by an alkali (NaOH or KOH) or by Amberlites IRA-410 has been described (Table 2).

Table 2. Reaction conditions and yields of products in the condensation of the nitro-derivatives **20** with formaldehyde.

R	R'	Catalyst	Time /h	Yield (%)	Ref.
Bu ¹	Me	KOH	—	56.5	36
MeC(NO ₂) ₂ CH ₂	H	NaOH	48	—	37
Et	H	NaOH	5	see ^a	38
C ₁₂ H ₂₅ –C ₁₈ H ₃₇	H	Amberlites IRA-410	—	30	39

^a The reaction also yields EtC(NO₂)(CH₂OH)₂.

Condensation of nitrated butadiene or isoprene oligomers with formaldehyde in the presence of alkaline catalysts gave the corresponding nitro alcohols.⁴⁰

The process of condensation of nitroalkanes with formaldehyde has been optimised by experiment design.^{41,42} It was found that the reaction of paraformaldehyde with nitroethane in the presence of KOH occurs over a period of 2–3 min.⁴¹ The highest yields of nitro alcohols in the reaction between an aqueous solution of the aldehyde **2** and a mixture of C₁–C₄ nitroalkanes are attained when the process is carried out at an RNO₂:CH₂O ratio of 2.5:1 and at a temperature of 50–60 °C for 35–40 min.⁴²

The condensation of 2-nitropropane with paraformaldehyde in the presence of KF affords 2-methyl-2-nitropropan-1-ol in 86% yield.⁴³

2-Nitropropan-1-ol has been obtained in a yield of 62%–74% by the reaction of nitroethane with the aldehyde **2** in the presence of triethylamine.⁴⁴

Tributylphosphine has been used as the catalyst in the synthesis of 2-methyl-2-nitropropan-1-ol from 2-nitropropane and paraformaldehyde.⁴⁵

As a rule, high yields of nitro alcohols are achieved when formaldehyde is condensed with functionally substituted nitroalkanes **21** in the presence of NaOH (Table 3).^{46–48}

Table 3. Reaction conditions and yields of products for the condensation of the nitro-derivative **21** with formaldehyde.

R	R'	Temperature /°C	Time /h	Yield (%)	Ref.

COOEt	Bu	20	2	82 ^a	48

^a Found for the acetylated product.

It can be seen from Table 3 that in the case of fluorine-containing nitroalkanes, approximately the same yields of nitro alcohols are obtained when the reaction is carried out with heating. On the other hand, homologues of ethyl nitroacetate readily react with formaldehyde at room temperature.

Treatment of diethyl fluoronitromalonate with potassium hydroxide gives rise to salt **22**, which reacts with the aldehyde **2** to yield compound **23**; the latter reacts with one more molecule of formaldehyde being thus converted into 2-fluoro-2-nitropropane-1,3-diol in a yield of more than 70%.⁴⁹

Reactions of aldehydes with nitro ketones carried out in the presence of strong bases are substantially complicated by side reactions of the initial compounds and reaction products. To avoid these problems and to obtain the products of nitroaldol condensation in higher yields, a convenient procedure was developed⁴⁸ according to which the condensation of nitro ketones with formaldehyde was carried out in the presence of triphenylphosphine. The intermediate alcohols were isolated as the corresponding acetates after treatment with acetic anhydride. Thus the reaction of nitro ketones **24** with formaldehyde in the presence of triphenylphosphine gave nitro alcohols **25**, which were treated *in situ* with acetic anhydride in the presence of pyridine to give the corresponding acetates **26** (yields 73%–91%).⁴⁸

R, R' = Alk.

1,4-Difluoro-1,4-dinitrobutane reacts with two molecules of the aldehyde **2** in the presence of potassium carbonate giving 2,5-difluoro-2,5-dinitrohexane-1,6-diol in 75% yield.⁵⁰

Some researchers have synthesised nitro alcohols by reactions of formaldehyde with the salts of nitro-compounds prepared previously. The sodium salt **27** prepared from ethyl nitroacetate and the aldehyde **2** under the action of sodium ethoxide has been made to react with a second molecule of **2**; this resulted in the synthesis of compound **28**.⁵¹

The reaction of bis-salts **29** with the aldehyde **2** at 1–3 °C gave bis-salts **30**, which were converted into the corresponding diols **31**. Thus treatment of the salt **30b** with $\text{HONH}_2 \cdot \text{HCl}$ in water at pH 4 gives the diol **31b** in 54.5% yield; treatment of the salt **30a** with 18% hydrochloric acid or with 75% acetic acid affords **31a** in a yield of 9.2% or 6.6%, respectively.⁵²

R = H (a), Me (b).

Under the same conditions, the bis-salt $(-\text{O}_2\text{N}=\text{CHCH}_2\text{CH}_2\text{CH}=\text{NO}_2)_2 2\text{Na}^+$ reacts with two molecules of CH_2O and is thus converted into the salt of bis-hydroxymethyl derivative $[-\text{O}_2\text{N}=\text{C}(\text{CH}_2\text{OH})\text{CH}_2\text{CH}_2\text{C}(\text{CH}_2\text{OH})=\text{NO}_2] 2\text{Na}^+$ in 93.6% yield.⁵²

Whereas the anions of non-conjugated mononitro-derivatives react with formaldehyde only at pH > 7, the dianions of conjugated dinitroalkanes **32** are able to react with the aldehyde **2** giving rise to diols **33** both at pH > 7 (yields 70%–90%) and at pH = 4 (yields 40%–70%).⁵³

n = 0, R = H; n = 1: R = H, R' = H, Me.

The reaction of conjugated nitroalkenes **34** with the aldehyde **2** in the presence of Et_3N in acetonitrile starts with the formation of allylic anions **35**, which are attacked by the aldehyde at the carbon atom carrying the nitro group to give nitro alcohols **36** (yields 60%–94%).⁵⁴

R¹ = H, Bu, PhCH₂; R² = H; R³ = Me, Et, C₇H₁₅, (CH₂)₂COOMe.

Nitroalkenes **37** react successively with lithium phenylthiolate and the aldehyde **2** to afford salts of *aci*-forms **38**, which are converted, on treatment with acetic acid, into mixtures of *erythro*- and *threo*-isomers (in a ratio ranging from 86:14 to 93:7) of nitro alcohols **39** (yields 57%–91%).⁵⁵

R = Me, Et, Pr, Prⁱ, Bu, C₅H₁₁, Ph, PhCH₂CH₂.

The reaction of the nitroalkenes **37** with PhSH and CH_2O in the presence of bases yields mixtures of the *erythro*- and *threo*-isomers of **39** (1:1) together with nitro diols $\text{RCH}(\text{SPh})-\text{C}(\text{CH}_2\text{OH})\text{NO}_2$.⁵⁵

Sodium methoxide has been used as the catalyst in the reaction of 1-(nitromethyl)cyclopentene with paraformaldehyde.⁵⁶

1-Halo-1-nitroalkanes **40** smoothly react with aldehydes **41** in the presence of potassium carbonate at 20 °C, and this leads to halo-substituted nitro alcohols **42** (yields 37%–75%).⁵⁷

R = Alk, CCl₃; R' = H, Cl, Br, Me, Et; X = Cl, Br.

Several nitro-compounds **43** have been condensed with aliphatic or arylalkyl aldehydes **44** in the presence of sodium hydroxide in methanol or ethanol; this resulted in the formation of *threo*-isomers of nitro alcohols **45**, as a rule, in good yields.^{59, 60} However, the reactions of butyraldehyde with nitrobutane (**43**, R¹ = Pr) and nitrooctane (R¹ = C₇H₁₅) gave the corresponding nitro alcohols in yields of 26% and 30% (Table 4).⁶⁰ When the same nitro-compounds **43** were made to react with aldehydes in the presence of KF, the *erythro*-isomers of **45** were obtained.^{59, 60} In some cases, water was added to the reaction mixture.⁶⁰

Table 4. Reaction conditions and yields of the compounds **45**.

^a (R*, R*) *threo*-Isomers are formed; if the reaction is carried out in the presence of KF, the nitro alcohols **45** are mostly formed as (R*, S*) *erythro*-isomers; ^b water was added to the reaction mixture.

Potassium hydroxide has been used as the catalyst in the reactions of myristaldehyde **46** with nitroethane⁶¹ and of unsaturated nitro-compounds **47** with aldehydes **48**;⁶² these reactions gave nitro alcohols **49** and **50** in 64% and 30%–65% yields, respectively.

R¹, R² = H, Me; R³ = Me, Et, Pr, Prⁱ.

A method for the synthesis of nitro alcohols **51** by condensation of aromatic aldehydes with nitroalkanes has been patented.⁶³ According to this method, aldehydes are treated first with sodium hydrogensulfite and then with nitroalkanes in the presence of aqueous sodium hydroxide at 20 °C.⁶³

R = Bu^t, Bu^s; R' = Me, Et.

In the synthesis of 1,1,1-trichloro-3-nitrobutan-2-ol (yield 30%), the initial chloral was also converted first into the hydrogensulfite derivative, and the latter was made to react with nitroethane in the presence of aqueous sodium hydroxide at 20 °C for 12 h.⁶⁴

In the same study,⁶⁴ condensation of primary or secondary nitroalkanes with aliphatic or aromatic aldehydes at 20 °C in the presence of NaHCO₃, K₂CO₃ or NaOH was studied. The yields of the target nitro alcohols **52** were found to depend crucially on the nature of the initial aldehyde (Table 5).

Table 5. Reaction conditions and yields of the nitro alcohols **52**.

Br ₃ C	Me	H	K ₂ CO ₃	0.5	10

Synthesis of 2-nitro-1-phenylpropan-1-ol from benzaldehyde and nitroethane under mild conditions in the presence of bases in DMSO or DMF has been reported.⁶⁵

Condensation of the complex **12** with nitroethane in the presence of NaOH yields a mixture of diastereoisomers **53a,b**; on treatment with hydrogen peroxide, this mixture is converted into a mixture of diastereoisomeric nitro alcohols **54a** (1R*, 2R*) and **54b** (1R*, 2S*) in a ratio of 36 : 64.²³

(a) NaOH, EtOH, H₂O, –40 °C, 0.5 h; (b) NH₄Cl, H₂O.

The reaction of **12** with the nitronate prepared previously from nitroethane resulted in the formation of a mixture of diastereoisomers **54a,b** in a ratio of 77 : 23.²³

Nitro-compounds **55** containing a CF₃ group condense with aldehydes **56** in the presence of potassium fluoride in isopropyl alcohol or without a solvent to give nitro alcohols **57**.⁶⁶

During the last 10–15 years, neutral alumina (Brockmann activity I) has been used as a catalyst in the Henry reaction. In the presence of this catalyst, nitro-compounds **58** condense with various aliphatic aldehydes **59** at ambient temperature.⁶⁷

The reaction of nitro-compound **60** with propanal carried out in the presence of Al₂O₃ at 20 °C affords condensation product **61** as a mixture of *erythro*- and *threo*-isomers in a 54 : 46 ratio and in 22% overall yield.⁶⁸

Nitro alcohols **62** have been prepared by the reactions of primary or secondary nitro-compounds **63** with aldehydes in the presence of neutral Al₂O₃ without solvents.^{66, 69}

The product **64** resulting from interaction of acrolein with two molecules of nitroethane has been synthesised by two procedures: by the reaction of the aldehyde with a fivefold excess of EtNO₂ (yield 39%) or by the addition of one molecule of EtNO₂ to the double bond of the aldehyde followed by condensation of the resulting adduct **65** with a second molecule of the nitro-derivative (yield 89%).⁷⁰

It has been reported⁷¹ that the following nitro alcohols are formed as mixtures of *erythro*- and *threo*-isomers upon reaction of the corresponding aldehydes with nitro-compounds in the presence of Al₂O₃ (Brockmann activity I) at 20 °C for 23 h:

It can be seen from published results^{66, 69} that the condensation of nitro-compounds with aromatic aldehydes in the presence of KF or Al₂O₃ gives the corresponding nitro alcohols in low yields. When the reactions of nitroalkanes **66** with aromatic aldehydes **67** are conducted³⁰ in liquid ammonia, the corresponding nitro alcohols **68** are formed in 53%–98% yields.

R = H, Me; R' = H, Me; Ar = 3-ClC₆H₄, 4-ClC₆H₄, 3-BrC₆H₄, 4-BrC₆H₄, 4-MeOC₆H₄, 4-MeC₆H₄, 2-O₂NC₆H₄, 2-H₂NC₆H₄, 3,4-(MeO)₂C₆H₃, 6-Br-3,4-(MeO)₂C₆H₂,

Nitro alcohols have been obtained in good yields by the condensation of nitromethane, nitroethane or 1-nitropropane with the corresponding aliphatic, aromatic or heterocyclic aldehydes in the presence of KF supported on Al₂O₃ (Scheme 1).⁷²

^a R = Me₂C=CH(CH₂)₂CH(Me)CH₂.

Sodium methoxide⁷³ and sodium ethoxide⁷⁴ have been used as catalysts in the nitroaldol condensation of primary nitroalkanes with functionally substituted aldehydes **69** and **70**.

R, R' (yield, %): MeO, Me (66); EtO, Et (60); PrⁱO, Prⁱ (50); Bu, Prⁱ (46); MeCH=CHCH₂, Prⁱ (20); MeCH=CHCH₂, Pr (20).

R = Me (52%), Et (51.5%), Pr (54%), Prⁱ (28%), Ph (65%).

The reaction of sulfide **71** with acetaldehyde carried out in the presence of potassium *tert*-butoxide (0 °C, 20 min) gives nitro alcohol **72** (yield 95%), whereas the reaction with isobutyraldehyde carried out under the same conditions affords nitroalkene **73** (yield 83%).⁷⁵

Esters of chloronitroacetic acid **74** react with aliphatic aldehydes in the presence of sodium acetate.⁷⁶

R, R' (yield, %): Me, Me (65); Me, Et (92); Et, Me (98); Et, Et (45); PhCH₂, H (71).

The reaction of nitro-compounds **76** with aldehydes in the presence of butyllithium led to γ -nitro alcohols **75** in 75%–80% yields instead of the normal products of nitroaldol condensation.⁷⁷

Ar, R: 4-ClC₆H₄, Et; Ph, Ph; Ph, 4-ClC₆H₄.

This unusual reaction pathway was explained⁷⁷ by the fact that at low temperatures nitro-compounds **76** are doubly deprotonated at the α - and β -positions with respect to the nitro group to give dilithio-derivatives **77**.

The formation of γ -nitro alcohols in the condensation of nitro-compounds with aldehydes in the presence of BuLi is not a specific feature peculiar only to 2-arylnitroethanes. It was found that γ -nitro alcohols are also formed in the reactions of some secondary nitro-compounds with aldehydes in the presence of BuLi or Bu^tLi. For example, 3-nitro-1-phenylbutan-1-ol was synthesised in 50% yield by the reaction of 2-nitropropane with benzaldehyde in the presence of BuLi and Bu^tLi.⁷⁷

The condensation of 1,1,1-trifluoro-2-nitropropane with aliphatic and aromatic aldehydes in the presence of BuLi and Bu^tLi occurs *via* unusual doubly deprotonated products **78** and yields γ -nitro alcohols **79**.⁶⁷

R = C₆H₁₃ (12%), PhCH₂CH₂ (9%), Ph (21%).

Primary nitro-compounds **80**, doubly deprotonated upon treatment with BuLi, react with aldehydes to give products of nitroaldol condensation, namely, β -nitro alcohols **81**.⁶⁶

X, R (yield, %): F, Bu^t (90); H, Bu^t (40); F, Ph (67); H, Ph (32); H, 4-O₂NC₆H₄ (52); F, 3,4-(CH₂O)₂C₆H₃ (40).

The reactions of primary nitro-compounds **82** with aldehydes in the presence of butyllithium and TiCl₃(OPrⁱ) at nitroalkane: aldehyde ratios of 1:1 or 2:1 have been studied in detail. This process was found to afford β -nitro alcohols **83** as mixtures of *erythro*- and *threo*-isomers.⁷⁸

R = Et; R' = 4-O₂NC₆H₄, Ph, 4-MeOC₆H₄, 2-CF₃C₆H₄, 4-MeOCOC₆H₄,

, PhCH=CH, Bu, C₅H₁₁, Bu^t, COOMe;

R = Bu; R' = 4-O₂NC₆H₄.

(a) BuLi, THF, -78 °C, 15 min;

(b) R'CHO, TiCl₃(OPrⁱ), CH₂Cl₂, -78 °C, 1 h; 20 °C, 3.5 h.

The ratio of the *erythro*- and *threo*-isomers formed varies over a wide range. For a nitroalkane:aldehyde ratio of 1:1, it varies from 3.9:1 (in the case of R' = 4-O₂NC₆H₄, R = Bu) to 11.2:1 (in the case of R' = MeOOC₆H₄, R = Et); for a nitroalkane:aldehyde ratio of 2:1, it ranges from 2:1 (R' = COOMe, R = Et) to 8:1 (R' = PhCH=CH, R = Et).⁷⁸

The reaction of nitroethane with benzaldehyde in the presence of butyllithium has been studied systematically using two approaches.⁷⁹ According to one of them, EtNO₂ was treated with BuLi in THF and HMPT at various temperatures and various HMPT/BuLi ratios, and after that, the aldehyde was added at a temperature between -78 and -35 °C, and the reaction mixture was quenched with acetic acid (procedure A). The second approach included treatment of the aldehyde with butyllithium in THF and HMPT at -90 °C and subsequent addition of the nitro-compound at various temperatures and various HMPT/BuLi ratios followed by acidification of the reaction mixture (procedure B). It was found that in both cases, the reaction resulted in the formation of a mixture of β-nitro alcohol **84** and γ-nitro alcohol **85**.

When the reaction was carried out by procedure A at an HMPT/BuLi ratio of 2.6 and at a temperature of -90 to -25 °C, the yields of the compound **84** varied in the range 68.8%–11.3%. In the absence of HMPT, the yield of **84** was 47.3%, and that of the compound **85** was 3% (at -90 °C). At higher temperatures, the yield of **85** increased, whereas the overall yield decreased. The reaction carried out by procedure B without HMPA afforded only the nitro alcohol **84** (yield 56.8%). At HMPT/BuLi ratios greater than 2, the nitro alcohol **85** was formed as the major product (yields 50.8%–72.6%, the yields of **84** formed simultaneously being 3.8%–10.6%).

Triethylamine has been used as the catalyst in the condensation of nitro-compounds with both aliphatic³⁰ and heteroaromatic⁸⁰ aldehydes.

Mixtures of *erythro*- and *threo*-isomers of nitro alcohols **86** are formed when the nitro compound **60** or its derivative **87** is made to react with acetaldehyde or propionaldehyde in the presence of tetrabutylammonium fluoride trihydrate (Table 6).⁶⁹

Table 6. Reaction conditions, yields and isomeric ratios of the nitro alcohols **86**.

R	Nitro-compound	Temperature /°C	Time /h	Yield (%)	Ratio <i>erythro</i> : <i>threo</i>
Me	87	-78–20	15.5	20	56:44
Me	87	0	2.3	89	55:45
Et	87	0	0.75	74	54:46
Me	60	0–6	23	52	62:38

R' = Bu^tMe₂Si.

In a study on the development of the synthesis of β-amino alcohols according to the scheme

it was found^{81–83} that the nitroaldol condensation of nitroalkanes with molecular weights much greater than that of nitromethane in the presence of conventional catalysts gives β-nitro alcohols in low yields. In order to increase the yields of the target compounds, the researchers studied the nitroaldol condensation of aldehydes with silyl ethers **88**, which were obtained from nitroalkanes and chlorotrimethylsilane or *tert*-butyl(chloro)dimethylsilane under the action of Pr₂NLi (LDA), in the presence of tetrabutylammonium fluoride. This resulted in the formation of nitro alcohol derivatives **89** in good or high yields.

R¹ = SiMe₃, SiMe₂Bu^t; R² = C₅H₁₁, R³ = C₆H₁₃ (71–80%);
 R² = C₅H₁₁, R³ = Bu^t (57%); R² = C₅H₁₁, R³ = Ph (75–83%);

 R³ = 4-O₂NC₆H₁₁ (91%); R² = Et, R³ = Pr (82%,
erythro:*threo* = 20:1); R² = Et, R³ = Pr;
 R² = Me, R³ = C₅H₁₁ (*erythro*:*threo* = 20:1); R² = Et,
 R³ = C₅H₁₁ (*erythro*:*threo* = 20:1); R² = C₇H₁₅, R³ = Pr
 (*erythro*:*threo* = 20:1); R² = Me, R³ = C₁₀H₂₁; R² = Me,
 R³ = C₉H₁₉; R² = Et, R³ = Ph (*erythro*:*threo* = 3.5:1).

Silyl ethers of nitro alcohols **90** have been prepared in 30%–40% yields by treatment of 2-nitropropane derivative **91** with aldehydes.⁸¹

R = C₆H₁₃, Bu^t, Ph, 4-MeOC₆H₄, 4-O₂NC₆H₄.

The reaction of the silyl ether **87** with aldehyde **92** gives rise to four isomeric nitro alcohols (overall yield 59%, isomer ratio

58:28:12:2). The isomer **93** was isolated from this mixture in a pure state in a yield of 34%.⁶⁹

The condensation of 1-nitrohex-3-ene **94** with aldehydes catalysed by Amberlyst A-21 occurs successfully at 20 °C; this gives nitro alcohols **95a,b**, their yields being 74% and 71%, respectively.⁸⁴

The reactions of nitroalkanes RCH₂CH(R')NO₂ with 4-ethoxybenzaldehyde carried out in the presence of 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) give rise to the corresponding nitro alcohols 4-EtOC₆H₄CH(OH)C(R')(NO₂)CH₂R (R, R': H, H; H, Me; Me, H).⁸⁵

Nitro alcohols **96** resulting from the condensation of aldehydes **97** with methyl 4-nitrobutyrate in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) have been treated *in situ* with acetic anhydride in the presence of sulfuric acid; the corresponding acetates **98** were prepared in this way in 75% yield.⁸⁶

The reaction of nitroalkenes MeCH(R)CH=CHNO₂ (R = H, Me) with propionaldehyde in the presence of DBN is accompanied by isomerisation of the double bond in the nitroalkene and gives unsaturated β-nitro alcohols EtCH(OH)CH(NO₂)–CH=C(Me)R (R = H, Me).⁵⁴

To synthesise nitro alcohols **99**, a mixture of nitroethane and aldehydes was treated with a mixed acetal of dimethylketene in the presence of [Rh(C₅Me₅)Cl]₂(μ-Cl)₂ and then with tetrabutylammonium fluoride. The reaction conditions and the product yields are listed in Table 7.⁸⁷

Table 7. Reaction conditions and yields of the nitro alcohols **99**.

R	Solvent	Number of equivalents of EtNO ₂	Yield (%)

Ph	THF	10	16
Ph	THF	43	82 ^a
PhCH=CH	THF	43	48
PhCH ₂ CH ₂	THF	43	54

^a The ratio *syn:anti* = 39:61.

c. Reactions of nitroalkanes with ketones

Reactions of nitro-compounds with ketones have been much less studied than the nitroaldol condensation involving aldehydes. This is due to some features peculiar to the reactions with ketones. These reactions are often accompanied by spontaneous dehydration of the adducts yielding nitroalkenes, which enter into the Michael reaction with the initial nitro-derivatives.

Only few studies dealing with the reactions of nitro-compounds with ketones have been published over the last 25 years.

The reaction of phenylnitromethane with acetone in the presence of sodium methoxide at 20 °C for 50 h gave the corresponding nitro alcohol, 2-methyl-1-nitro-1-phenylpropan-2-ol, in a yield of only 10%.⁵⁹

When nitromethane **1** was made to react with ethyl methyl ketone in the presence of sodium methoxide, the product of nitroaldol condensation, 2-methyl-1-nitrobutan-2-ol **100**, was obtained. When this reaction was carried out in the presence of piperidine, 2-methyl-1-nitrobut-2-ene **101** was isolated from the reaction mixture. In the presence of sodium methoxide, **101** reacted with 1,3,5-trioxane being thus converted into nitro alcohol **102**.⁵⁶

The method for the synthesis of β-nitro alcohols from aldehydes and nitroalkanes developed by Colvin *et al.*^{81,82} and described above proved to be inapplicable to nitroaldol condensation between nitroalkanes and ketones. Therefore, a modified procedure for the synthesis of silyl ethers of β-nitro alcohols **103** from 1-nitrohexane and ketones RCOR' was proposed.⁸¹

R = R' = Ph, R, R' = (CH₂)₅;

(a) Me₃SiCl; (b) 1. AcOH; 2. Me₃SiCl–(Me₃Si)₂NH.

When trifluoroacetophenone was treated with nitroethane in the presence of an aqueous solution of potassium carbonate for 5 h, nitro alcohol **104** was formed.⁶

γ-Nitro alcohol **105** was synthesised in 77% yield by condensation of 1-nitropropane with benzophenone in the presence of butyllithium in THF and HMPT at low temperatures.⁷⁹

The reactions of 2-arylnitroethanes **76** with ketones in the presence of butyllithium also afford γ -nitro alcohols **106** rather than the β -derivatives.⁷⁷

R, Ar (yield, %): Me, Ph (70); Ph, 4-ClC₆H₄ (67); (CH₂)₅, Ph (69).

d. Reactions of 1,1-dinitro- and 1,1,1-trinitro-derivatives with aldehydes

In a study dealing with the kinetics and mechanism of the condensation of acetaldehyde with 1,1-dinitroethane or with methyl 2-nitropropionate in DMSO,⁸⁸ it has been found that the addition of the anions derived from nitro-compounds to the carbonyl group of the aldehyde is the rate-determining step of this reaction. The researchers determined the equilibrium and rate constants of the process, which characterise the basicity and nucleophilicity of the nitronate anions. It was found that there exists a normal correlation between the basicity and nucleophilicity of the two anions in DMSO: the more basic anion reacts faster than the less basic one. In the presence of alkali, 1,1-dinitroethane reacts with an aqueous solution of formaldehyde to give 2,2-dinitropropan-1-ol in 80% yield.⁸⁹

Condensation of the potassium salt of 1,1-dinitroethane, formed upon treatment of 1-chloro-1-nitroethane with an aqueous solution of potassium carbonate for 1 h at 25–30 °C, with excess formaldehyde resulted in the formation of 2,2-dinitropropan-1-ol in 20%–25% yield.⁹⁰

2-Fluoro-2,2-dinitroethanol **107** was prepared by the reaction of chlorofluorodinitromethane with potassium iodide and formaldehyde at 70 °C.⁹¹

2,2-Dinitro-3-vinylxypropan-1-ol is formed in 19.2% yield when 2,2,2-trinitroethyl vinyl ether is treated successively with alkaline hydrogen peroxide and with formaldehyde in the presence of sodium hydroxide, and the reaction mixture is then acidified by HCl to pH 2.⁹²

(a) H₂O₂, NaOH, H₂O, MeOH, –4 °C; (b) CH₂O, H₂O; (c) HCl, MeOH, 40 °C.

The ether **109** containing an HC(NO₂)₂ group reacts readily and rapidly with formaldehyde in the presence of sodium hydroxide and is thus converted into hydroxymethyl derivative **110**.⁹³

Compound **111** containing two HC(NO₂)₂ groups reacts with two molecules of formaldehyde in the presence of sodium hydrogencarbonate to give tetrol **112**; under the action of a base, it eliminates a glyoxal molecule giving rise to salt **113**. The latter reacts with the aldehyde **2** to give 2,2-dinitropropane-1,3-diol **114** in an overall yield of 74%.⁹⁴

The compound **111** can also react with formaldehyde without a catalyst yielding the tetrol **112**, which eliminates a dinitromethane molecule and CH₂O even at 20–30 °C being thus converted into aldehyde **115**, which cyclises *in situ* into tetrahydrofuran derivative **116**.⁹⁴

When the dipotassium salt of 1,1,2,2-tetranitroethane **117** is made to react with formaldehyde, this gives tetranitrodiol **118**, which is cleaved on treatment with KOH to give 2,2-dinitroethane salt. This salt reacts with the aldehyde **2** yielding diol **114**.⁹⁵

The sodium⁹⁵ or potassium⁹⁶ salts of dinitromethane react with glyoxal to give salts of 1,1,4,4-tetranitrobutane-2,3-diol **119**. The salt **119** (Y = Na) is converted into the tetrol **112** by the reaction with formaldehyde.⁹⁵ Treatment of the salts **119** (Y = Na or K) with 10% sulfuric acid⁹⁵ or hydrogen chloride⁹⁶ results in the formation of the diol **111** in a yield of 71.8% or 57.2%, respectively.

Potassium salts of fluoro-containing dinitroalkanes **120** or tetranitroalkanes **121** react readily with formaldehyde to give the corresponding nitro alcohols **122** or tetranitro-diols **123**.⁹⁷

R = C₆F₁₃ (36%); C₁₀F₂₁ (62%);

n = 4 (55%), 6 (75%).

Synthesis of 2,2,2-trinitroethanol by the condensation of trinitromethane with formaldehyde in the presence⁹⁸ or in the absence⁹⁹ of CuSO₄ has been reported.

2. Synthesis of nitro alcohols by introduction of a nitro group into hydroxyl-containing compounds

This route for the preparation of nitro alcohols has not found wide application, because the two existing methods for the introduction of a nitro group into compounds containing a hydroxy group suffer from serious drawbacks restricting their use. One of these methods, namely, treatment of halo-substituted alcohols with some metal nitrites, normally permits preparation only of nitro alcohols containing a primary nitro group. In addition, there are some limitations as regards the use of the initial haloalcohols and solvents. The second method, namely, nitration of alcohols, has also found limited use, because only in some cases does it permit the target compounds to be obtained in reasonable yields. The main reaction pathway in this case is the oxidation of alcohols yielding carboxylic acids and the corresponding nitroalkanes.

During the last 25 years, the former method has hardly been used to synthesise aliphatic nitro alcohols. It was not until 1987 that the synthesis of 12-nitrododecan-1-ol (yield 79.5%) by the Meyer reaction of 12-iodododecan-1-ol was reported.¹⁰⁰

Over the period of time considered, only in rare cases has nitration of alcohols been used to prepare nitro alcohols; for example, nitro alcohols **124** have been obtained in this way by treating alcohols **125** with dinitrogen tetroxide.¹⁰¹

R = H; R' = Me, Et, Bu; R = R' = Me.

The reaction of Ph₂C(OH)Et with N₂O₃ or N₂O₄ at 20–25 °C in chloroform affords nitro alcohol Ph₂C(OH)CH(Me)NO₂ in a yield of 47% or 62%. When the same alcohol is treated with N₂O₅ in chloroform or with HNO₃ (20 °C, 1 h; 80 °C, 4 h), nitration involves not only the side chain but also the aromatic ring and the hydroxy group and results in the formation of O₂NC₆H₄C(Ph)(O-NO₂)CH(Me)NO₂ (yields 35% and 70%, respectively).¹⁰²

An original method for the synthesis of nitro alcohol **126** reported in a patent¹⁰³ consists of the transformation of butyne-1,4-diol into 1,4-dihydroxybutan-2-one by the Kucherov reaction followed by replacement of the β-hydroxyl with respect to the carbonyl group by a fluorodinitromethyl group by treatment with fluorodinitromethane.

3. Synthesis of nitro alcohols by introduction of a hydroxy group into compounds containing a nitro group

Syntheses of nitro alcohols by this route can be clearly divided into two groups: (a) formation of a hydroxy group in nitro-compounds from other oxygen-containing groups incorporated in the initial molecule and (b) the formation of nitro alcohols from nitro-compounds containing no oxygen-containing groups.

a. The formation of a hydroxy group from other oxygen-containing groups present in nitro-compounds

The reaction of unsaturated nitro ketones **127** (A = C=CH) or saturated nitro ketones (A = CHCH₂) with lithium aluminium hydride at 20 °C and at a LiAlH₄ : **127** ratio of 1 : 4 involves only transformation of the carbonyl group into a hydroxy group and affords nitro alcohols **128** (yields 64%–95%).¹⁰⁴

R = H, Me; R' = H, Me, Et, Pr; A = C=CH, CHCH₂.

When nitro ketones **129** containing an epoxy group are reduced with lithium aluminium hydride, the structure of the reaction product depends on the LiAlH₄ : **129** ratio. When this ratio is 1 : 4, only the carbonyl group is reduced, and nitro alcohols **130** are formed (yields 67% and 74%); at a ratio of 1 : 2, cleavage of the epoxide ring occurs, in addition to the reduction of the carbonyl group, and the process gives nitro-diols **131**.¹⁰⁴

R = H, Me.

Unsaturated nitro alcohols **132** have been synthesised in 62%–68% yields by the reduction of nitro ketones **133** with lithium aluminium hydride at –15 °C and at an LiAlH₄ : **132** ratio of 1 : 4.¹⁰⁵

R = H, Me, Cl, Br.

Ketone **134** is converted into nitro alcohol **135** in 71% yield on treatment with sodium tetrahydridoborate.³²

The outcome of the reduction of esters **136** with sodium tetrahydridoborate depends on the nature of the radical R; if R = PhCH₂, the reaction gives rise to the nitro alcohol **107** (yield 70%), whereas with R = Me₂CH, hemiacetal **137** is formed.¹⁰⁶

(a) NaBH₄, THF, H₂O, 10–12 °C, 0.5 h;

(b) NaBH₄, (MeOCH₂)₂, 20–25 °C, 0.5 h.

When cyclic α-nitro ketones **138** are treated with sodium tetrahydridoborate, the reduction is accompanied by ring opening and yields nitro alcohols **139**.¹⁰⁷

R = H, n = 0–10 (50%–85%); R = Bu^t, n = 1 (75%).

3-Nitropropanal was converted into 3-nitropropan-1-ol in 89% yield by treatment with the complex BH₃·SMe₂ in Et₂O at 20 °C for 4 h under a nitrogen atmosphere.¹⁰⁸

Nitro alcohol **140** was synthesised in 77.5% yield by the reduction of 5-nitropentan-2-one with diborane in THF.³¹

The reaction of tetrahydrofuran derivatives **141** with borane in THF results in ring opening and formation of diols **142**.^{109, 110}

R¹ = NO₂, R² = H, R³ = OH (35 °C, 72 h, 98%);¹⁰⁹

R¹ = F, R² = H, R³ = OH (25 °C, 24 h, 100%);¹⁰⁹

R¹ = NO₂, R², R³ = O (35 °C, 72 h, 98%).¹¹⁰

Nitro ketone **143** was converted into nitro alcohol **144** in 72% yield on treatment with SnCl₄ and Et₃SiH at 0 °C.⁶⁶

The reduction of the compounds RCOCH(R')(CH₂)₂NO₂ (R, R' = Me, H;¹¹¹ Ph, H; MeO, 2-MeOC₆H₄¹¹²) in the presence of baker's yeast occurs stereoselectively to give (S)-nitro alcohols as the major products; the highest stereoselectivity (99%) is observed in the case of R = MeO, R' = 2-MeOC₆H₄.^{111, 112}

When epoxide **145** (R = Me) is heated in water at 50 °C, the corresponding diol MeCH(OH)CH(OH)CH₂NO₂ is formed in 56% yield.¹¹³ Heating of **145** in aliphatic alcohols leads to ethers **146** (yields 55%–68%).¹¹³

R = H; R' = Me, Et, Prⁱ; R = Me, R' = Me, Prⁱ.

In the presence of triethylamine at 18–20 °C, the epoxide **145** (R = Me) isomerises into the unsaturated nitro alcohol MeCH(OH)CH=CHNO₂ (yield 62%).¹¹³

2,3-Epoxy-1-nitropropane reacts with hydrazines RC₆H₄NHNH₂ (R = 2-NO₂, 4-NO₂) at 20 °C in aqueous ethanol affording 2- or 4-O₂NC₆H₄NHNHCH(CH₂OH)–CH₂NO₂ in 86% yield.¹¹⁴

Epoxides **147** with a more complicated structure have been converted into mixtures of unsaturated nitro alcohols **148** and **149** in four ways: by treatment with triethylamine in aqueous acetonitrile (procedure A); in the presence of alumina in diethyl ether and in dichloromethane (procedure B); at 25 °C over silica gel (procedure C); over aluminium isopropoxide (procedure D) (Scheme 2).¹¹⁵ The reaction conditions and the yields of the alcohols **148** and **149** are listed in Table 8.

Scheme 2

On treatment with hydrohalic acids, 3-fluoro-3-nitrooxetane **150** is converted into nitro alcohols **151** in high yields (96.5% and 93.1%), whereas on treatment with phosphorus trifluoride, it is converted into polymer **152** (yield 82.6%).⁴⁹

X = Cl, Br.

Table 8. Reaction conditions and yields of the nitro alcohols **148** and **149**.

Reactions of alkenes with nitrogen oxides are used most often for the synthesis of nitro alcohols with simultaneous introduction of NO_2 and OH groups to vicinal positions.

The nitro alcohol $C_{12}H_{25}CH(OH)CH_2NO_2$ (yield 10%) and its nitrate $C_{12}H_{25}CH(ONO_2)CH_2NO_2$ (yield 86%) have been prepared by the reaction of $C_{12}H_{25}CH=CH_2$ with N_2O_4 in CCl_4 in the presence of sulfuric acid at $0-5^\circ C$ for 0.5 h.¹²⁵

The nitro alcohol $Ph_2C(OH)CH(Me)NO_2$ has been synthesised by the reactions of the alkene $Ph_2C=CHMe$ with N_2O_4 ($CHCl_3$, $20-25^\circ C$, 6 h), N_2O_3 ($CHCl_3$, $20^\circ C$, 17 h) or HNO_3 (d 1.51, $CHCl_3$, $100^\circ C$, 4 h), the yields of the product being 56%, 46% or 50.8%, respectively.¹⁰³ When the same alkene was treated with N_2O_5 ($CHCl_3$, $18^\circ C$, 12 h), the product $O_2NC_6H_4-(Ph)C(ONO_2)CH(Me)NO_2$ containing a nitro group instead of a hydrogen atom in one of the benzene rings was obtained in 32.2% yield.¹⁰²

The reactions of various alkenes with NO_2 in hexane at $20^\circ C$ have been studied in detail. Nitro alcohols and their derivatives **163–170** were synthesised in this way.¹²⁶

The formation of the compounds **165**, **166** and **168** was explained¹²⁶ in terms of the following scheme:

Diethyl vinylphosphonate **171** readily reacts with N_2O_4 in dichloromethane to give nitro alcohol **172** (yield 34%).¹²⁷

2-Hydroxy-3-nitropropionic acid was synthesised in 60% yield by the reaction of acrylic acid with N_2O_4 in dichloroethane at $18-20^\circ C$ over a period of 10 h.¹²⁸

Nitro alcohol **173** is formed in 23%–25% yield in the reaction of nitrogen oxide with 4-phenylbut-1-ene in various solvents (dichloroethane, tetrachloromethane or benzene) at $20^\circ C$.¹²⁹

Simultaneous introduction of NO_2 and OH groups into alkenes **174** was accomplished by treating them with alkyl nitrites with heating in acetic acid under an inert atmosphere; the yields of nitro alcohols **175** were 20%–33%.¹³⁰

R^1, R^2, R^3 : Ph, Ph, H; Me, Ph, H; Me, COOMe, H; Et, Et, Me.

The synthesis of compound **176** (yield 55%) from alkene **177** was carried out using acetyl nitrate formed *in situ* from Ac_2O and HNO_3 .¹³¹

The reaction of isoprene with acetyl nitrate at $20^\circ C$ affords a mixture of nitroalkenyl acetates **178** and **179** in a ratio of 7 : 3.¹³²

Treatment of unsaturated ketones **180** with nitronium tetrafluoroborate at $-30^\circ C$ in a solution in SO_2 followed by treatment with water gives compounds **181** in low yields.¹³³

$R = Me$ (4%), Pr (17%), Pr^i (34%).

An original method has been proposed¹³⁴ for the synthesis of dichloro-substituted nitro alcohols **182**. It is based on the reaction of trichloronitromethane with aldehydes in the presence of $SnCl_2$.

R = H (67%), Me (76%), Et (82%), Pr (83%), Bu (92%), C₅H₁₁ (85%), Ph (52%), CCl₃ (77%), 4-MeC₆H₄ (57%), 4-ClC₆H₄ (59%), 2-furyl (53%), 2-thienyl (61%).

The reaction of ethyl 4-methylpent-2-enoate **183** with nitril chloride or nitrosyl chloride yields nitrite **184**, which is converted into compound **185** on refluxing with water, the overall yield of the latter being 34%.⁷⁴

III. Chemical transformations of nitro alcohols

1. Reactions involving the nitro group

The reduction of 2-nitrobutan-1-ol in the presence of Raney nickel at 35–40 °C under a hydrogen pressure of 10 atm results in the formation of 2-aminobutan-1-ol in 62%–74% yield.^{44, 135}

The same catalyst is effective in the reduction of nitro alcohols **186** to amino alcohols **187** (Table 9).⁶⁶

Table 9. Reaction conditions and yields of the amino alcohols **187**.

R	R'	Pressure /atm	Temperature /°C	Yield (%)
H	Pr	1	20	52
H	C ₆ H ₁₃	25	50	76
H	Ph(CH ₂) ₂	1	20	79
H	PhCHMe	25	50	82
H	Pr	30	50	59
Me	Pr	30	50	5
Me	C ₆ H ₁₃	25	50	22
Me	Ph(CH ₂) ₂	25	50	53

Raney nickel has also been used to reduce the compounds PhCH(OH)(CH₂)₂NO₂ and Ph₂CHCH(OH)CH₂NO₂ to amino alcohols PhCH(OH)(CH₂)₂NH₂ (yield 49%) and Ph₂CHCH(OH)CH₂NH₂ (yield 18%).⁷⁹

The reduction of the *erythro*-isomers of silyl ethers of nitro alcohols in the presence of Raney nickel occurs stereoselectively; treatment of the reaction mixture with Bu₄N⁺F[−] gives the *erythro*-isomers of amino alcohols **188**.⁸²

R, R': Pr, Et, Prⁱ, Et; C₅H₁₁, Me; C₅H₁₁, Et; Pr, C₇H₁₅; C₁₀H₂₁, Me; C₉H₁₉, Me; Ph, Et.

2-Hydroxymethyl-2-nitropropane-1,3-diol **4** is converted into the amine H₂NC(CH₂OH)₃ (yield 89%) by hydrogenation in the presence of the Pd/C catalyst at 59–63 °C for 4.5 h.¹³⁶

When 4-MeOC₆H₄CH₂C(OH)(Et)NO₂ is reduced with ammonium formate in the presence of Pd/C in THF and MeOH, the amino alcohol 4-MeOC₆H₄CH₂C(OH)(Et)NH₂ is formed in 73% yield.¹³⁷

The amino-diols HOCH₂C(R)(NH₂)CH(OH)C₁₃H₂₇ (R = H, Me) have been synthesised in high yields (83% and 86%) by the reduction of the corresponding nitro-diols with ammonium formate in the presence of Pd/C in MeOH at 20 °C for 16 h under an atmosphere of nitrogen.⁶¹

An active catalyst of reduction, Ni₂B, which is formed *in situ* from NiCl₂·6H₂O and NaBH₄, has been used to convert the nitro alcohol O₂NCMe₂(CH₂)₂CH(OH)Me into the corresponding amino alcohol (yield 76%). The reaction occurs in MeOH at 20 °C over a period of 5 min.¹³⁸

Reduction of nitro alcohols to amino alcohols with hydrogen has also been carried out in the presence of a number of rhodium-containing catalysts. For example, 2-nitrobutan-1-ol has been converted into 2-aminobutan-1-ol by hydrogenation in the presence of di(rhodiumnorbornadienechloride) and Ph₂PCH₂CH(PPh₂)Me at 60 °C under a hydrogen pressure of 67 atm for 20 h.¹³⁹

The reduction of 2-nitrobutan-1-ol to 2-aminobutan-1-ol catalysed by rhodium-, iridium- and palladium-containing systems has been studied in detail (Table 10).¹⁴⁰

Table 10. Hydrogenation of 2-nitrobutan-1-ol.¹⁴⁰

Catalyst	Phosphine	Catalyst: phosphine	Time/h	Temperature/°	Yield (%)

Nitro glycols **189** have been hydrogenated at 80–100 atm in the presence of Ru/C catalyst or Raney Ni–Ru for 2–5 h; this gave amino glycols **190** in 78%–96% yields.¹⁴¹

R = H, Me, Et, CH₂OH.

Hydrogenation of the nitro alcohols 4-RC₆H₄CH(OH).CH₂NO₂ (R = H, Me, Cl) in the presence of PdO₂ in 80% AcOH at 1 atm gives rise to the corresponding amino alcohols RC₆H₄CH(OH)CH₂NH₂ in 59%, 50% and 63% yields, respectively.²⁶

The nitro groups in nitro alcohols and their derivatives **191** and **192** have been reduced to amino groups using LiAlH₄.^{23, 25, 81, 83, 142}

$\text{R}^1 = \text{C}_6\text{H}_{13}, \text{Bu}^t, \text{Ph}, 4\text{-MeOC}_6\text{H}_4, 4\text{-O}_2\text{NC}_6\text{H}_4;$

$\text{R}^2 = \text{SiMe}_3 \text{ or } \text{SiMe}_2\text{Bu}^t; \text{R}^3 = \text{H, Me}; \text{R}^4 = \text{C}_5\text{H}_{11}, \text{Me}.^{81, 83}$

When unsaturated nitro ketones **193** are reduced with a twofold excess of lithium aluminium hydride, the nitro groups are converted into amino groups, whereas the carbonyl groups are reduced to hydroxy groups; thus, the reaction yields amino alcohols **194**.¹⁰⁴

$\text{R} = \text{H} (35\%), \text{Me} (37\%), \text{Et} (38\%).$

Nitro-diols **195** have been converted into amino-diols **196** by treatment with zinc and hydrochloric acid in ethanol.¹⁴³

$\text{R} = \text{C}_7\text{H}_{15} (25\%), \text{C}_9\text{H}_{19} (33\%), \text{C}_{11}\text{H}_{23} (38\%), \text{C}_{13}\text{H}_{27} (40\%).$

Electroreduction of 2-methyl-2-nitropropane-1,3-diol giving 2-amino-2-methylpropane-1,3-diol in 99% yield has been patented.¹⁴⁴

Nitro alcohols or nitro-diols **197** have been converted into the corresponding amino-derivatives **198** by electroreduction at bimetallic electrodes consisting of copper deposited on zinc or cadmium.¹⁴⁵

$\text{R}^1, \text{R}^2: \text{H, Me; Me, CH}_2\text{OH; H, Et; Et, CH}_2\text{OH}.$

Electroreduction of the triol **4** in the presence of sulfuric acid at 75–80 °C and at a current density of 0.1 A cm⁻² for 12–13 h affords amino-derivative H₂NC(CH₂OH)₃ in 40%–50% yield.⁶

The hydrochloride (HOCH₂)₃CNH₂·HCl has been synthesised by electroreduction of the triol **4** at a perforated palladium cathode at 75–80 °C in the presence of 6.5% HCl.¹⁴⁶

Electroreduction of methyl 3-hydroxy-2-nitrobutyrate giving rise to the DL-threonine ester **199** (substance yield 72%–77%; current yield 7%–10%) can be described by the following scheme:^{147, 148}

Treatment of nitro alcohol acetates **200** with tributylstannane in the presence of azobis(isobutyronitrile) in boiling benzene results in the replacement of the nitro group by a hydrogen atom.⁴⁸

The reduction of the nitro group in an acetate of a more complicated structure occurs under the same conditions.⁴⁸

The researchers cited⁴⁸ proposed yet another method for the introduction of a hydrogen atom instead of the nitro group in nitro alcohol acetates **201**. The method involves treatment of **201** with 1,8-diazabicyclo[5.4.0]undec-7-ene in boiling benzene.

$\text{R} = \text{Me} (66\%), \text{Et} (71\%), \text{Pr} (88\%), \text{Pr}^i (83\%), \text{Bu} (78\%).$

2. Reactions involving hydrogen atoms attached to a carbon atom carrying nitro groups

Nitro alcohols containing one or two hydrogen atoms at the carbon atom carrying the nitro group are able to enter into nitroaldol condensation. The reaction of the salt $[-\text{O}_2\text{N}=\text{CHCH}(\text{OH})\text{CH}(\text{OH})\text{CH}=\text{NO}_2^-]2\text{Na}^+$ with formaldehyde at 0–5 °C and pH = 10 in Et₂O gives the tetrol HOCH₂C(NO₂)₂CH(OH)CH(OH)C(NO₂)₂CH₂OH.⁹⁵

The reactions of salts derived from 2-nitropropane-1,3-diol **3** or from 2-nitropropan-1-ol with an aqueous solution of formaldehyde have been studied.¹⁴⁹ Reversible reactions give 2-hydroxymethyl-2-nitropropane-1,3-diol **4** or 2-methyl-2-nitropropane-1,3-diol, respectively.

The equilibrium constants K_1 and K_2 are $(4.3 \pm 0.4) \times 10^{-3}$ and $(3.6 \pm 0.2) \times 10^{-2}$, respectively. The characteristics of these reactions are retained over a broad range of concentrations: $[\text{CH}_2(\text{OH})_2] = 0.058\text{--}3.06\text{ M}$ and $[\text{OH}^-] = 1.8 \times 10^{-2}\text{--}0.36\text{ M}$.

In the presence of Dowex-1 anion-exchange resin, the condensation of nitro alcohols with formaldehyde or acetaldehyde at 20 °C is completed over a period of 1–2 h.¹⁵⁰

$\text{R}^1 = \text{R}^2 = \text{Me}$, $\text{R}^3 = \text{H}$ (63%); $\text{R}^1 = \text{Bu}$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{Me}$ (79%);

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$, $\text{R}^3 = \text{H}$ (91%).

2-Nitroethanol **202** reacts with aliphatic aldehydes in the presence of sodium methoxide to give salts **203** (yields 67%–99%), which are converted into nitro-diols **204** (yields 91%–98%) on treatment with hydrochloric acid.¹⁴³

$\text{R} = \text{C}_7\text{H}_{15}$, C_9H_{19} , $\text{C}_{11}\text{H}_{23}$, $\text{C}_{13}\text{H}_{27}$.

Alumina (Brockmann activity I) has been used as the catalyst in the condensation of nitro alcohols **205** with aldehydes.⁶⁹

R, R' : Me, MeCH(OH)CH₂; Et, (CH₂)₆OH; Et, CH₂OH.

The reaction of the nitro alcohol **202** with benzaldehyde in the presence of triethylamine at 0 °C is completed over a period of 23 h resulting in the formation of DL-*threo*-2-nitro-3-phenylpropane-1,3-diol (yield 98.7%).¹⁵¹

The reaction of furfural with 1-nitropropan-2-ol in the presence of triethylamine gave the corresponding nitro-diol **206** in a yield of only 35%.¹⁵²

The condensation of the nitro alcohol **202** with hexadec-2-enal in the presence of K₂CO₃ or Et₃N at 20 °C affords nitro-diol **207** and a minor quantity of the product of its cyclisation **208**.¹⁵³

When this reaction is carried out in methanol in the presence of K₂CO₃ at 20 °C, the tetrahydropyran derivative **208** (yield 50%) is formed together with compound **209** (yield 12%) (see Scheme 3).¹⁵³

On treatment with butyllithium, compounds **210** were converted into the corresponding lithio-derivatives. Condensation of the latter with carbonyl compounds R¹R²C=O followed by hydrolysis of the condensation products gave nitro-diols **211** in 52%–88% yields.¹⁵⁴

$\text{R}^1, \text{R}^2, \text{R}^3$: H, Prⁱ, H; H, Br, H; H, , H;

 $\text{R}^1, \text{R}^2 = (\text{CH}_2)_5$, $\text{R}^3 = \text{H}$, Me.

A single diastereoisomer of nitro-tetrol **212** was obtained in a similar way from compound **213** and benzaldehyde (yield 73%).¹⁵⁴

(a) BuLi, THF, HMPTA –90 to –40 °C, 3 h;

(b) PhCHO, –90 to –60 °C, 1.5 h; (c) AcONa, H₂O.

Aldehydes have been made to condense with 4-nitrobutan-2-ol in the presence of the Amberlyst A-21 ion-exchange resin at 0 °C for 15 h. This resulted in the formation of nitro-diols **214** (yields 45%–70%).¹⁵⁵

$\text{R} = \text{Me}$, Prⁱ, C₅H₁₁, C₁₀H₂₁, , Ph(CH₂)₂,

(*Z*)-Me(CH₂)₇CH=CH(CH₂)₇, Me(CH₂)₄CH(NO₂)(CH₂)₂.

Dinitro-diols **215** have been prepared in two stages, namely, by the reaction of salts **216** with nitroalkenes **217** and subsequent treatment of the resulting reaction mixtures with formaldehyde in the presence of phosphorous acid at pH 6–5.5.¹⁵⁶

$\text{R} = \text{Me}$; $\text{R}' = \text{Me}$ (45%), Et (42%); $\text{R} = \text{R}' = \text{Et}$ (31%).

The reaction of 1-nitropropane with formaldehyde in the presence of Ca(OH)₂ in water at 30 °C for 1 h followed by treatment of the reaction mixture with bromine in CCl₄ at 20 °C gives rise to 2-bromo-2-nitrobutan-1-ol in 90% yield.³⁵

Scheme 3

When nitro-diol **218** or **219** is treated with an aqueous solution of sodium hydroxide and then with a mixture of fluorine and nitrogen, fluoro-derivative **220** or **221** is formed in a yield of 71% or 68%, respectively.⁵⁰

The potassium salt of 2,2-dinitroethanol is converted into 2-chloro-2,2-dinitroethanol on treatment with chlorine in water at 0–5 °C.¹⁵⁷

When salts of nitro alcohols react with chlorine or bromine, halogenation products are formed:

X = Cl (73.8%), Br (75%).

When the products resulting from reactions of MeNO₂ with aldehydes (CH₂O or Cl₃CCHO) were treated with bromine, 2,2-dibromo-2-nitroethanol¹⁵⁸ or 3-bromo-1,1,1-trichloro-3-nitropropan-1-ol³⁵ were synthesised.

Table 11. Reaction conditions and yields of the compound **8**.

Conditions of nitroaldol condensation				Conditions of bromination		Yield (%)	Ref.
Base	Solvent	T / °C	t / min	T / °C	t / h		
Ca(OH) ₂	H ₂ O	0	30	0	1	74	5
Na ₂ CO ₃		0–10		10	1	80	7
NaOH	H ₂ O	5–10		5–10		86	9
NaOH	MeOH			20	0.5	83	10
NaOH	H ₂ O, DEG ^a	20	60	5–20		98	11
MeONa	MeOH	5		5		86 ^b	20
NaOH	H ₂ O			see ^c			12

^a DEG — diethyleneglycol; ^b CHCl₃, ^c paraform, CCl₄, BrCl.

In a number of patents,^{5, 7, 9–12, 20} it has been proposed to synthesise 2-bromo-2-nitropropane-1,3-diol **8**, which is a known bactericide agent ‘Biocide’, according to the following scheme (the reaction conditions and product yields are listed in Table 11):

Similarly, Cl₃CCH(OH)C(NO₂)Br was prepared from MeNO₂ and Cl₃CCHO;^{5, 7} MeCH(OH)C(NO₂)BrCH(OH)Me was synthesised from MeNO₂ and MeCHO;¹⁰ and MeCH(OH)C-Me(NO₂)BrCH(OH)Me was obtained from EtNO₂ and MeCHO.¹¹

The reactions of salts of nitro alcohols **222** with aryldiazonium cations **223** in water at low temperatures yield arylhydrazones **224**.¹⁵⁹

2-Nitropropane-1,3-diol **3** is nitrated with tetranitromethane in an alkaline medium giving 2,2-dinitropropane-1,3-diol **114**.⁸

However, an attempt to carry out alkaline nitration of the salt **30b** was unsuccessful; the reaction resulted in the formation of diene **225** (yield 21.4%).⁵²

Dinitro alcohol acetates **226** [the compound **226** with $n = 3$ has been obtained by catalytic oxidative nitration of the nitro alcohol O₂NCH(CH₂)₃OH] have been introduced into the Michael reaction with acrolein. This afforded compounds **227**, which were then converted into dinitro-diols **228**.¹⁶⁰

$n = 1, 3$.

The nitro alcohols $\text{O}_2\text{NCH}_2\text{CH}(\text{R}')\text{OH}$ add to α,β -unsaturated ketones in liquid ammonia to give adducts **229** (yields 45%–96%).¹⁶¹

$\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Ph}$, 4- BrC_6H_4 , 4- $\text{O}_2\text{NC}_6\text{H}_4$, ;

$\text{R}^3 = \text{Me}$, Ph , 4- MeC_6H_4 , 4- MeOC_6H_4 ; $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{R}^3 = \text{Ph}$.

Adduct **230** was synthesised by the reaction of the nitro alcohol **202** with 2-(4-methylphenyl)-1-nitroethene under similar conditions (yield 23%).¹⁶¹

The reaction of salts of nitro alcohols **231** with nitroalkenes **232** in aqueous methanol gives adducts **233** in quantitative yields. On treatment with an aqueous solution of hydroxylamine hydrochloride, the adducts **233** are converted into dinitro alcohols **234** in 37%–55% yields.¹⁶²

$\text{R}, \text{R}' = \text{Me}, \text{Et}$.

Chloro-substituted dinitro alcohols **235** have been synthesised by the reaction of the salts **231** with 2-nitroprop-1-ene in aqueous methanol followed by treatment of the resulting adducts **236** with chlorine.¹⁶³

$\text{R} = \text{Me}, \text{Et}$.

3. Reactions involving the hydroxy group

When dinitro alcohols **237** react with compound **238** in the presence of toluene-*p*-sulfonic acid, intermolecular elimination of water occurs to give acetals **239** (yields 73%–100%) as mixtures of *cis*- and *trans*-isomers (in a ratio of 15–35 : 85–65).¹⁰⁹

$\text{R} = \text{F}, \text{Me}, \text{NO}_2$; $\text{R}' = \text{F}, \text{NO}_2$.

Ethers derived from nitro alcohols are often synthesised by reactions of nitro alcohols with halo-derivatives in the presence of bases.

The reaction of 3-nitropropan-1-ol with $\text{Bu}^t\text{Me}_2\text{SiCl}$ carried out in DMF in the presence of imidazoline at 20°C for 15 h gave the ether $\text{O}_2\text{N}(\text{CH}_2)_3\text{OSiMe}_2\text{Bu}^t$ in 91% yield.¹⁰⁸

Ethers **240**, **241** and **242** have been prepared in high yields by the reactions of triol **243** with various halo-derivatives at $20-25^\circ\text{C}$ in the presence of KOH , NaH or Et_3N .¹⁶⁴

R	X	Time /h	Yield (%)
Me	I	2	89
Bu	Br	0.5	78

$\text{R}' = \text{Bu}$ (78%); 4- ClC_6H_4 (63%);

The reaction of 2,2-difluoro-2-nitroethanol **244** with compounds RX in the presence of 5% aqueous sodium hydroxide at $25-30^\circ\text{C}$ affords ethers **245**.¹⁶⁵

R, X (yield, %): $\text{Me}, \text{MeOSO}_2$ (78); $\text{CH}_2\text{CHCH}_2, \text{Cl}$ (75.5); $\text{HC}\equiv\text{CCH}_2, \text{Br}$ (27).

Condensation of the nitro alcohol **107** with allyl bromide or propargyl bromide catalysed by sodium hydroxide has been carried out in the presence of formaldehyde; this led to ethers **246** in 66% or 55% yield, respectively.⁹³

R (time /h): $\text{CH}_2\text{CH}=\text{CH}_2$ (45); $\text{HC}\equiv\text{CCH}_2$ (30).

The role of formaldehyde was to prevent the nitro alcohol **107** from decomposing in the alkaline medium.⁹³

1,3-Dichloropropan-2-ol reacts with two molecules of the nitro alcohol **244** in the presence of 20% aqueous sodium hydroxide to give the diether $(\text{NO}_2\text{CF}_2\text{CH}_2\text{OCH}_2)_2\text{CHOH}$ in a yield of 78.6%.¹⁶⁶

$$\text{244} + \text{XCH}_2\text{COOR} \xrightarrow[\Delta, 4-5 \text{ h}]{\text{K}_2\text{CO}_3, \text{Me}_2\text{CO}} \text{O}_2\text{NCF}_2\text{CH}_2\text{OCH}_2\overset{\text{O}}{\parallel}\text{COR} \quad \text{247}$$

2-Fluoro-2-nitropropane-1,3-diol resulting from the reaction of diethyl 2-fluoro-2-nitromalonate **249** and the aldehyde **2** in the presence of potassium hydroxide has been introduced *in situ* in the reaction with chlorotrimethylsilane in boiling acetonitrile; this gave bis-silyl ether **250**.⁴⁹

$$\begin{array}{ccccc} \text{R}^1\text{R}^2\text{SiCl}_2 & + & \text{HOCHCH}_2\text{NO}_2 & \longrightarrow & \text{R}^1\text{R}^2\text{Si}(\text{OCHCH}_2\text{NO}_2)_2 \\ \text{251} & & \begin{array}{c} | \\ \text{R}^3 \end{array} \text{252} & & \begin{array}{c} | \\ \text{R}^3 \end{array} \text{253} \end{array}$$

Polysiloxanes **255** have been synthesised by the condensation of dichlorosilanes **251** with nitro-diols.¹⁶⁹

Compounds **256** containing one, two or three residues of nitro alcohols **257** are formed in the condensation of **257** with chlorosilanes **258** in the presence of pyridine.¹⁷⁰

<i>n</i>	R ¹	R ²	R ³	X	Yield (%)
3	Me	H	Me	Cl	44
2	Me	H	Me	Cl	66
2	Me	Me	H	Cl	40

NO ₂	NO ₂	2	65–70	72	16
F	F	1	30–35	168	20
NO ₂	Me	1	70–75	72	46
NO ₂	F	1	60–70	72	48

Refluxing of the nitro alcohols **237** with divinyl ether in the presence of HgO and trifluoroacetic acid leads to transesterification yielding vinyl ethers **265**.⁹²

R = Me (64.2%), F (64%), NO₂ (25.9%).

The addition of nitro alcohols to alkenes or to buta-1,3-diene and the addition of alcohols to nitroalkenes have been used to synthesise ethers of nitro alcohols. For example, the reaction of 3-nitropropan-1-ol with 2-methylpropene in CH_2Cl_2 in the presence of sulfuric acid (20 °C, 12 h) gave the ether $\text{Bu}^t\text{O}(\text{CH}_2)_3\text{NO}_2$ (yield 95%).¹⁰⁸

Adduct **266** was obtained by reaction of **107** with 2-methylpent-1-ene at 20 °C in the presence of HgSO_4 or Hg_2SO_4 (yields 74% and 58%, respectively).¹⁷⁸

The reaction of the nitro alcohol **107** with buta-1,3-diene affords a mixture of 1,2-addition product **267** and 1,4-addition product **268** in a ratio of 77 : 23, their total yield being 53%.¹⁷⁸

Two products **269** and **270** resulting from radical C- and O-addition (yields 28% and 70%, respectively) have been synthesised by the reaction of hexan-1-ol with 1-nitroprop-1-ene in the presence of *tert*-butyl peroxide.¹⁷⁹

1,1,1-Trinitroethanol adds to the C=N bond in perfluoroguanidine at ambient temperature to give compound **271**.¹⁸⁰

Acyclic and cyclic acetals containing one or two nitro-alcohol residues are promising compounds for practical purposes.

Acetals **272** have been synthesised by the reactions of the nitro alcohols **237** with 1,3,5-trioxane or with paraldehyde in the presence of sulfuric acid^{181, 182} or sodium hydroxide. The reaction conditions and the yields of products are presented in Table 13.⁸⁹

Mixed acetals **273**^{182, 183} and **274**¹⁸⁴ have been prepared by condensation of three components.

Table 13. Reaction condition and yields of the compounds **272**.

R	R'	Catalyst	Yield (%)	Ref.
F	H	H_2SO_4	—	181
Me	H	NaOH	78	89
Me	H	H_2SO_4	78	182
Me	Me	NaOH	35	89
NO_2	H	H_2SO_4	—	182

R = NO_2 ,¹⁸² F,¹⁸³

The acetal **273** (R = F) was synthesised by the reaction of the nitro alcohol $\text{FC}(\text{NO}_2)_2\text{CH}_2\text{OH}$ with the ether $\text{MeC}(\text{NO}_2)_2\text{CH}_2\text{OCH}_2\text{Cl}$ in the presence of TiCl_4 .¹⁸³

Polycondensation of formaldehyde with the diol $\text{HOCH}_2\text{C}(\text{NO}_2)_2\text{CH}_2\text{CH}_2\text{C}(\text{NO}_2)_2\text{CH}_2\text{OH}$ in the presence of sulfuric acid affords poly(nitroformal).¹⁸⁵

Nitro alcohols add to acyclic^{178, 186} or cyclic^{108, 142, 178} vinyl ethers **275** in the presence of catalysts to give acetals **276** (see Table 14).

The addition of nitro alcohols **277** to 2,3-dihydropyran in THF and HMPT in the presence of butyllithium at a temperature between −90 °C and −40 °C leads to the compounds **209**.¹⁵⁴

R = H, Me.

The nitro alcohol **107** adds to ethoxyacetylene in CH_2Cl_2 at 20 °C in the presence of HgSO_4 ¹⁸⁷ or $\text{Hg}(\text{OAc})_2$ ¹⁷⁸ or in the presence of HgO in CF_3COOH ⁹² giving rise to 2 : 1 adduct **278** (yields 100%, 95%, or 70%, respectively). When this reaction is carried out in the presence of $\text{Hg}(\text{OAc})_2$ in CH_2Cl_2 and hexane at 20 °C, the 1 : 1 adduct **279** is produced in 73% yield in addition to the adduct **278** (yield 27%).¹⁷⁸

Table 14. Conditions for the formation of the acetals **276**.

R ¹	R ²	R ³	Catalyst	Solvent	T / °C	Time / h	Yield (%)	Ref.
$\text{O}_2\text{N}(\text{CH}_2)_3$	$-(\text{CH}_2)_3-$		TsOH	Et_2O	20	5	95	108

The rate of the reaction of 5-substituted furfural derivatives **293** with 2-ethyl-2-nitropropane-1,3-diol in the presence of the KU-2 ion-exchange resin (H-form) has been shown to decrease in the series $\text{NO}_2 > \text{I} > \text{Br} > \text{H} > \text{Me}$. It was assumed that attack by the diol on the protonated formyl group is the rate-determining step of the reaction.¹⁹⁶

$\text{R} = \text{H}$ (66%), Me (70%), Br (84%), I (79%), NO_2 (82%).

Cyclocondensation of mono- and disubstituted 2-nitropropane-1,3-diol derivatives **295** with aldehydes or ketones in the presence of TsOH gave di-, tri- or tetra-substituted derivatives of 5-nitro-1,3-dioxane **296**.¹⁹⁷

$\text{R}^1 = \text{H}, \text{Me}, \text{CH}_2\text{OH}$; $\text{R}^2 = \text{H}, \text{Me}, \text{Pr}, \text{Pr}^i$; $\text{R}^3 = \text{H}, \text{Me}, \text{Pr}, \text{Pr}^i$;
 $\text{R}^4 = \text{H}, \text{Me}$; $\text{R}^5 = \text{H}, \text{Me}, \text{Et}, \text{Pr}^i, \text{Bu}, \text{Ph}, 2\text{-HOC}_6\text{H}_4, 4\text{-O}_2\text{NC}_6\text{H}_4$,
 $\text{PhCH}=\text{CH}$; $\text{R}^4, \text{R}^5 = (\text{CH}_2)_5$.

The compounds **296** were obtained in low yields for $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{R}^3 = \text{R}^4 = \text{R}^5 = \text{Me}$ (27%); $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{R}^3 = \text{Me}$, $\text{R}^4 = \text{R}^5 = \text{H}$ (30%) and $\text{R}^1 = \text{R}^4 = \text{R}^5 = \text{H}$, $\text{R}^2 = \text{R}^3 = \text{Pr}^i$ (32%).¹⁹⁷

1,3-Dioxane derivatives **297** were synthesised from the nitro-diol **206** using acetone dimethyl ketal or benzaldehyde dimethyl acetal as the second reactant.^{152, 198}

$\text{R} = \text{H}, \text{R}' = \text{Ph}$; $\text{R} = \text{R}' = \text{Me}$.

The reaction of **206** with benzaldehyde dimethyl acetal affords three diastereoisomers **297a,b,c** in 55.5% overall yield and in a ratio of 4:1:1.¹⁵²

Refluxing of the nitro-diol $\text{HOCH}_2\text{CH}(\text{NO}_2)\text{CH}(\text{OH})\text{C}_{13}\text{H}_{27}$ with acetone dimethyl ketal in acetone in the presence of toluene-*p*-sulfonic acid results in the formation of 2,2-dimethyl-5-nitro-4-tridecyl-1,3-dioxane in 61.5% yield.⁶¹

Yet another method for the synthesis of acyclic and cyclic acetals of aromatic aldehydes and nitro alcohols consists of the reaction of dichloromethyl arenes with alcohols or 1,3-diols. This

procedure was used, for example, to prepare acetals **298** or **299** from dichloromethylarenes **300** and polynitro alcohols **301** or 2,2-dinitropropane-1,3-diol **114**.¹⁹⁹

$\text{R} = \text{Cl}, \text{Me}, \text{NO}_2$; $\text{Ar} = \text{Ph}, 3\text{-O}_2\text{NC}_6\text{H}_4, 4\text{-O}_2\text{NC}_6\text{H}_4$;

$\text{Ar} = \text{Ph}, 3\text{-O}_2\text{NC}_6\text{H}_4$ (AlCl_3), $4\text{-O}_2\text{NC}_6\text{H}_4$ (FeCl_3).

The reactivity of nitro alcohols decreases in the order $\text{NO}_2 > \text{Cl} > \text{HCCH}_2 > \text{Me}$, i.e. in parallel with their acidity.¹⁹⁹

By refluxing nitro-diol **302** with arylboronic acids **303** in acetone, 2-bora-1,3-dioxane derivatives **304** have been synthesised.²⁰⁰

$\text{Ar} = \text{Ph}$ (90.5%), $4\text{-ClC}_6\text{H}_4$ (67%).

Cyclic compound **305** containing two oxygen atoms and a phosphorus atom in the six-membered ring has been obtained by cyclocondensation of the triol **4** with phosphorous acid.²⁰¹

2-Bromo-2-nitropropane-1,3-diol **8** reacts with dichloro-derivatives **306** at 50 °C to give 5-bromo-5-nitro-2-R-2-oxo-1,3,2-dioxaphosphorinanes **307**.²⁰²

$\text{R} = \text{Me}$ (60%), Cl (28%), PhO (56%), $4\text{-MeC}_6\text{H}_4\text{O}$ (49%),
 $3\text{-MeC}_6\text{H}_4\text{O}$ (42%), $4\text{-O}_2\text{NC}_6\text{H}_4\text{O}$ (60%), OH (39%).

Cyclocondensation of the diol **8** with 2,2,2-trichloro-1,3-dimethyl-1,3,2λ⁵-diazaphosphetidin-4-one **308** gives rise to compound **309**.²⁰³

5-Chloromethyl-5-nitro-1,3,2-dioxathian-2-one **310** was synthesised by the reaction of the triol **4** with thionyl chloride in the presence of pyridine.²⁰⁴

Esters derived from nitro alcohols are usually synthesised either by reactions of nitro alcohols with acid chlorides or anhydrides or by reactions of nitro alcohols with carboxylic acids in the presence of anhydrides of other acids. The preparation

of nitro alcohol acetates has been described in numerous publications. There is no need to consider these studies in detail, because the acetates have been synthesised by conventional procedures, which have been described fairly comprehensively in monographs.^{3, 4}

Syntheses of halocarbonates **311** and **312** (yield 91%) by the reactions of nitro alcohols **313** with carbonyl dichloride or difluoride or by the reaction of 2,2-dinitropropane-1,3-diol **114** with carbonyl difluoride have been reported in patents^{205, 206} and papers.^{207, 208}

Carbonates **314**²⁰⁵ or **315** (yield 64%)²⁰⁸ were prepared by the reaction of nitro alcohol **316** with the chloroformate **311** (R = F, X = Cl) or of 2,2,2-trinitroethanol with carbonyl difluoride.

2,2-Dinitropropane-1,3-diol **114** reacts with two molecules of chloroformate **317** giving rise to diester **318** (yield 83%).²⁰⁹

The exothermic reaction of the nitro alcohols **237** or **202** with chloride **319** in the presence of iron(III) chloride has led to the synthesis of *O*-alkyl *S*-ethyl thiocarbonates **320**²¹⁰ or **321**.

R = F, Me, NO₂;

The three-component reaction involving the nitro alcohol **107**, thiophosgene and Cl₃CSH, taken in a ratio of 3 : 1 : 1, carried out in the presence of a base under conditions of phase transfer catalysis affords compound **322**, which is converted into compound **323** (yield 81%) upon treatment with 1,1,1-trinitroethanol and chlorine.²¹¹

When 2,2-dinitropropanol is made to react with bis(1,2,4-triazol-1-yl) thioketone in acetone in the presence of pyridine at 20 °C, the ester [MeC(NO₂)₂CH₂O]₂C=S is formed in 83% yield over a period of 2 days.²¹² Similarly, the reaction of (O₂N)₃CCH₂OH or the alcohol **107** with bis(1,2,4-triazol-1-yl) sulfoxide yields the corresponding esters.²¹²

R = F, Me, NO₂.

The reaction of 2-nitropropane-1,3-diol with trimethylacetyl chloride in dichloromethane carried out for 3 h at 40 °C and then for 12 h at 25 °C affords the corresponding bis-ester in 95% yield.¹⁵

Esters **324**, which are of interest as monomers, have been synthesised in 60%–70% yields by the reactions of dinitro alcohols **325** with chlorides of α,β-unsaturated acids.^{213–215}

R¹ = H, F, Me; R² = H, Me; R³ = H, Me.

It should be noted that the yield of **324** (R¹ = F, R² = R³ = Me) was as low as 5%.²¹⁴ The reaction of the nitro alcohol **325** (R¹ = Me, R² = H) with acryloyl chloride carried out for 3 h at 20 °C in the presence of TiCl₄ affords the corresponding ester **324** (R¹ = Me, R² = R³ = H) in 93% yield.²¹³

The reaction of perfluoroacryloyl chloride with the nitro alcohol **244** in the presence of triethylamine at –40 to –35 °C follows two competing pathways: esterification of the nitro alcohol giving the ester F₂C=CF₂COOCH₂C(NO₂)₂F₂ (yield 7.9%) and the addition of the nitro alcohol to the double bond of the chloride leading to the ether F₂C(NO₂)CH₂OCF₂–CH(F)COCl (yield 7%).²¹⁶

Esters derived from nitro alcohols and unsaturated dicarboxylic acids have been described in the literature.^{217, 218}

Tris-esters **326** have been prepared by the reactions of the nitro-triol **4** with benzoyl, 4-chlorobenzoyl and toluene-*p*-sulfonyl chlorides in the presence of pyridine.¹⁶⁴

Ar	Y	T / °C	Time / h	Yield (%)
Ph	CO	70	15	51
4-ClC ₆ H ₄	CO	20	30	93
4-MeC ₆ H ₄	SO ₂	0	12	47

R = Me (32%); Prⁱ (22%); Bu^t (77%).

The compounds **339** (R = Me, Et, Pr, Prⁱ, Bu and Bu^t) have also been obtained by another method, namely, the reaction of the nitro-triol **4** with the corresponding 1,3,5-trialkylhexahydro-1,3,5-triazines.²²⁹

The pyrazolidine derivative **340** has been synthesised by the reaction of hydrochloride **341** with 2,2-dinitropropane-1,3-diol **114** (yield 86%) or with the potassium salt of 2,2-dinitroethanol (yield 23.5%).²³⁰

Cyclocondensation of the nitro-diols **302** or **114** with formaldehyde and primary amines leads to hexahydropyrimidine derivatives **342**. The reaction conditions and the yields of reaction products are listed in Table 16.^{200, 231, 232}

Table 16. Reaction conditions and yields of the compounds **342**.

R	R'	Solvent	T / °C	Time / h	Yield (%)	Ref.
Bu ^t	COOEt	EtOH	78	2	25	200
Me	NO ₂	EtOH	5–20		19	231
Bu ^t	NO ₂	MeOH	20	1	29	231
Me ^a	NO ₂	see ^b	20	24	35	232
CH ₂ COOMe ^a	NO ₂	see ^b	20	18	22	232
CH ₂ COOEt ^a	NO ₂	see ^b	20	18	15	232

^a Hydrochlorides of the amines were used; ^b in the presence of AcONa, pH 4.

When the nitro alcohol **202** is treated successively with phosphorus tribromide and sodium thiophenoxide, the corresponding thioether is formed in an overall yield of 73%.²³³

The hydroxy group in nitro alcohols **343** is replaced by aryl groups when **343** are treated with arenes **344** in the presence of sulfuric acid; this yields diphenylmethane derivatives **345**.^{63, 234–236}

On treatment of acetates **346** with sodium tetrahydridoborate in DMSO or ethanol at 20–25 °C for 1.5 h, the acetoxy group is substituted by a hydrogen atom giving nitro-compounds **347** (yields 41%–90%).^{27, 237}

R¹ = C₆H₁₃, C₇H₁₅, ,

Me₂C=CH(CH₂)₂C(Me)=CH(CH₂)₂; R² = R³ = H;²⁷

R¹ = Me, Et, Bu, Ph, MeCH(Et)(CH₂)₃; R² = H, Me;

R³ = H, Me, Et, Pr; R², R³ = (CH₂)₅.²³⁷

The formation of **347** from the acetates **346** involves the intermediate formation of nitroalkenes **348**.²³⁷

4. Reactions involving several sites

Oxidation of nitro alcohols to nitro-carbonyl derivatives can involve simultaneously two reaction sites, namely, the hydroxy group and the hydrogen atom attached to the carbon atom carrying the hydroxy group.

Nitro alcohols **349** have been converted into nitro ketones **350** by treatment with chromium(VI) oxide supported on montmorillonite at –15 °C accompanied by ultrasonic treatment.⁷²

R, R' (yield, %): Me, Me (90); Et, H (76); Prⁱ, Me (93); Prⁱ, Et (90).

Pyridinium chlorochromate has proved to be a good reagent for the transformation of nitro alcohols into nitro ketones. Treatment of nitro alcohols **349** with this reagent in the presence of molecular sieves at 20 °C gave nitro ketones **350** (yields 61%–87%).^{83, 238}

R = Me, CH₂=CH(CH₂)₂; R' = EtCH=CHCH₂; ⁸³ R = Me, Prⁱ,

PCC is pyridinium chlorochromate.

It has been found ²³⁹ that both the rate of the oxidation of EtCH(OH)CH(NO₂)Et with pyridinium chlorochromate on silica gel in CH₂Cl₂ and the yield of the nitro ketone EtCOCH(NO₂)Et formed in this reaction markedly increase upon ultrasonic treatment: without ultrasound the yield of the product is 60% over a period of 1.5–2.5 h at 25 °C, whereas the reaction carried out with sonication is completed over a period of 20 min at –18 °C (yield 71%).

On treatment with K₂Cr₂O₇ or K₂CrO₄ in the presence of Bu₄N⁺HSO₄[–], H₂SO₄ and FeSO₄ at –10 °C, nitro alcohols **351** are readily oxidised to give nitro ketones **352** in high yields (70%–93%), ⁶⁷ and nitro-diols **353** are easily oxidised to nitro diketones **354**. ¹⁵⁵

R¹ = Me, Prⁱ, C₆H₁₃, Ph(CH₂)₂, CH₂=CH(CH₂)₂;

R² = Me, Et, $\begin{array}{c} \text{O} \\ \diagup \quad \diagdown \\ \text{H}_2\text{C} \end{array}$, $\begin{array}{c} \text{Me} \\ \diagup \quad \diagdown \\ \text{O} \quad \text{O} \\ \diagdown \quad \diagup \\ \text{H}_2\text{C} \end{array}$, (CH₂)₂COOMe; R³ = H, Me.

R = Me (53%), Prⁱ (45%), C₅H₁₁ (47%), C₁₀H₂₁ (58%), $\text{Cyclo-C}_6\text{H}_{11}$ (58%),

PhCH₂CH₂ (70%), Z-Me(CH₂)₇CH=CH(CH₂)₇ (58%),

Me(CH₂)₄CH(NO₂)(CH₂)₂ (65%).

3-Chloro-6-nitrohexan-2-one has been synthesised in 75% yield by the oxidation of 3-chloro-6-nitrohexan-2-ol with a solution of Na₂Cr₂O₇ in H₂SO₄ at 10–20 °C for 10 h. ⁵⁸

Heating of 1-nitropropan-2-ol with hydrochloric acid (18%–36%) at 95–107 °C for 5–30 h affords lactic acid in 14%–16% yield. ²⁴⁰

Attempts to dehydrate compounds **356** with phthalic anhydride, P₂O₅ or MeCOCl were unsuccessful: the reactions were accompanied by rupture of the C–P bond. Dehydration of these compounds was accomplished by heating them with thionyl chloride in the presence of pyridine. This gave the corresponding unsaturated compounds **357**. ¹²⁷

R, R' (yield, %): Me, Me (58); Me, Et (69); Et, Prⁱ (59); Prⁱ, Et (53).

Primary and secondary nitro alcohols **358** are readily dehydrated on treatment with cyclohexylcarbodiimide, being converted into mixtures of diastereoisomeric nitroalkenes **359**. ²⁴¹

R	R'	Time /h	Yield (%)	Isomeric ratio Z/E
H	Me	3.5	35	
Me	Me	17	82	70 : 30

2-Furyl	H	24	66	

^a Me₂C=CH(CH₂)₂CH(Me)CH₂.

The methanesulfonyl chloride–triethylamine system has also been used for the transformation of nitro alcohols **358** into nitroalkenes **359** (yields 30%–80%). ^{70, 242}

R = Me, Et, R' = Me, Et; ²⁴² R = Me, R' = PhS. ⁷⁵

The nitroalkene Z-MeCH(NO₂)CH₂CH₂CH=C(NO₂)Me is formed in 80% yield when the nitro alcohol MeCH(NO₂)CH₂–CH₂CH(OH)CH(NO₂)Me is refluxed with MeSO₂Cl and Et₃N in dichloromethane under nitrogen. ⁷⁵

The E-isomers of nitroalkenes **359** were synthesised by dehydration of the nitro alcohols **358** over alumina (Brockmann activity I) at 40 °C. ⁷¹

R	R'	Time /h	Yield (%)
Me	Me	8	75
Me	Et	7	77
Me	(CH ₂) ₄ COOMe	7	76
Me	CH ₂ CH(OH)Me	7	73
EtCH=CH(CH ₂) ₂	Me	7	85
Ph(CH ₂) ₂	Me	9	68
Et	H	48	60
C ₆ H ₁₃	H	50	61
Et	(CH ₂) ₆ OH	7	68
cyclo-C ₆ H ₁₁	C ₅ H ₁₁	24	72

The dehydration occurs selectively: when the molecule contains both primary and secondary hydroxy groups, the secondary group is eliminated preferentially. ⁷¹

It is of interest that the dinitro-diol resulting from acidification of the solution of the salt **30** with hydrochloric acid to pH 1 is dehydrated under the reaction conditions to give triene **360** in 26.7% yield. ⁵²

When a mixture of 2-nitrobutan-1-ol and isoprene is kept at 150 °C, the nitro alcohol is dehydrated, and the resulting 2-nitrobut-2-ene reacts *in situ* with isoprene to give a mixture of [4 + 2]-adducts **361** and **362**.²⁴³

On treatment with potassium hydroxide in Et₂O for 2 h at –15 to –20 °C, the nitro alcohol O₂NCH₂CH(OH)CH₂Cl is converted into the aldehyde O₂NCH₂CHCH₂CHO (yield 21 %).²⁴⁴

The reactions of 1,1,1-trinitroethanol or trinitromethane with formaldehyde in the presence of CuSO₄ followed by treatment of the reaction products with ammonia at 100–105 °C for 8–9 h lead to the same product, 2,2-dinitroethylamine.^{98, 245}

Under conditions of the Mitsunobu reaction (treatment with triphenylphosphine and diethyl azodicarboxylate under an inert atmosphere),²⁴⁶ γ-nitro alcohols **363** are converted into nitroderivatives of cyclopropane **364**.²⁴⁷

R	R'	Yield (%)	Ratio <i>trans</i> : <i>cis</i>
C ₃ H ₁₁	H	82	10 : 1
C ₃ H ₁₁	Me	87	10 : 1
4-PhC ₆ H ₄	H	75	<i>trans</i>
4-MeOC ₆ H ₄	H	92	7 : 1
PhCH ₂ OCH ₂ CH=CH	H	64	<i>trans</i>

Under the same conditions, PhCH₂OCH₂CH(OH)–CH(CH₂OCH₂Ph)CH₂NO₂ is converted into 1,3-bis(benzyl-oxy)-2-nitrocyclopropane in 98% yield (the ratio of the isomers was not determined).²⁴⁷

When hydrochlorides **365** are introduced into the Mitsunobu reaction, they are converted into hydrochlorides of 1-alkyl-3-hydroxymethyl-3-nitroazetidines **366**.²²⁹

R = Me, Et, Pr, Prⁱ, Bu, Bu^t.

When acetates of nitro alcohols **367** and isonitrile **368** are heated in the presence of DBU, **367** are converted into nitroalkenes **369**, while the isonitrile is deprotonated to give carbanion **370**. The nitroalkenes and the carbanion react to give pyrrole derivatives **371**.²⁴⁸

R, R' (yield, %): Me, Me (72); Et, Me (74); Me, Et (76); Et, Et (74); (CH₂)₂COOMe, Me (60); Me, (CH₂)₂COOMe (53).

Pyrrole derivatives **372** have been obtained in high yields (70%–86%) by cyclocondensation of the acetates **367** with alkyl cyanoacetates **373** in the presence of DBU at 20–25 °C.¹⁰⁷

R¹ = Et, (CH₂)₂COOMe; R² = Me, Et, (CH₂)₂COOMe; R³ = Et, Bu^t.

Pyrazole derivatives **374** are formed in the reaction of 2,2-dinitroethanol with diazo compounds **375** in benzene or ether.²⁴⁹

R = OEt (PhH, 50 °C, 6 h, 46%); Me (PhH, 50 °C, 4 h, 64%); Ph (Et₂O, 36 °C, 14 h, 63%).

2-(1-Hydroxy-2-nitroethyl)furan **376** reacts with bromine and sodium methoxide to give 2,5-dihydrofuran derivative **377** in 77.5% yield.¹⁴²

2,4,4-Trimethyl-2-nitromethyltetrahydrofuran (yield 30%) is formed when the nitro alcohol BrCH₂CMe₂CH₂C(OH)(Me).CH₂NO₂ is kept over Al₂O₃ in benzene at 25 °C.²⁵⁰

Treatment of (*S*)-1-nitropentan-1-ol with 30% H₂O₂ and K₂CO₃ in methanol (0 °C, 24 h) followed by the addition of hydrochloric acid results in the formation of (*S*)-4,5-dihydro-5-methylfuran-2(3*H*)-one (yield 7%).¹¹¹

Under the conditions of the Mitsunobu reaction, nitro alcohols **378** cyclise to give either isoxazoline *N*-oxides or dihydro-1,2-oxazine *N*-oxides **379** depending on the mutual arrangement of the nitro and hydroxy groups. When R = PhSO₂, the yield of the corresponding isoxazoline is relatively low; in this case, 1-nitro-1-phenylsulfonylcyclopropane is formed as the main reaction product. For the cyclisation products to be formed in high yields, it is necessary that an electron-withdrawing group or a double bond, which stabilise the *aci*-form **380** of the initial compounds, be present in the α-position with respect to the nitro group.²⁵¹

2-Hydroxy-6-methyl-5-nitrotetrahydropyran has been synthesised in 68% yield by cyclocondensation of acrolein with 1-nitropropan-2-ol in the presence of diethylamine and formic acid at 60–62 °C for 20 h.²⁵²

The reaction of 4-nitrobutan-2-ol with sodium glyoxylate in the presence of Na_2CO_3 resulted in the isolation of compound **381** as two isomers (**a** and **b**), their yields being 32% and 10%, respectively.²⁵³

381a: $\text{R}^1 = \text{R}^3 = \text{H}$, $\text{R}^2 = \text{NO}_2$, $\text{R}^4 = \text{OH}$;

381b: $\text{R}^1 = \text{NO}_2$, $\text{R}^3 = \text{OH}$, $\text{R}^2 = \text{R}^4 = \text{H}$.

Tetrahydro-1,3-oxazine derivatives **382** have been prepared by refluxing compounds **383** with aldehydes **384** in benzene in the presence of sodium hydrogencarbonate.²⁵⁴

R, R' (yield, %): PhCH_2, Me (80); $\text{cyclo-C}_6\text{H}_{11}, \text{Me}$ (60); PhCH_2, Ph (60).

Hydrazone **385** react with carbon disulfide in the presence of potassium hydroxide to give 1,3,4-oxadiazine-2-thiones **386**.¹⁵⁹

$\text{R} = \text{H}, \text{R}' = \text{Me}$ (71%); $\text{R} = \text{Me}, \text{R}' = \text{H}$ (88%), Me (78%).

On heating with sodium hydride, cyclic ketones **387** or **388** containing nitro and 3-hydroxyalkyl groups in the α -position with respect to the oxo group isomerise with ring expansion giving rise to compounds **389** or **390**.²⁵⁵

n	Time /min	Yield (%)
4	45	91
10	30	87

5. Cleavage of nitro alcohols

Under certain conditions, β -nitro alcohols (or β -nitro-diols) are cleaved to give the initial carbonyl derivatives and nitro-compounds (or their salts).

In the presence of alumina at ambient temperature, nitro alcohols **391** are cleaved to nitromethane and ketones **392**.^{250, 256}

$\text{R} = \text{Br}$ (20%),²⁵⁰ NO_2 (72%).²⁵⁶

AcONa , BaO or KNaHPO_4 can be used instead of Al_2O_3 .²⁵⁶

Benzyltrimethylammonium hydroxide cleaves the nitro alcohol $\text{Me}_2\text{C}(\text{OH})\text{CH}(\text{NO}_2)(\text{CH}_2)_2\text{NO}_2$ on refluxing in methanol for 6 h to give acetone and 1,3-dinitropropane (yield 50%).²⁵⁷ This process can be carried out in ethanol, dioxane, THF or DMF in the presence of Na_2CO_3 , Na_3BO_3 , MgO or BaCO_3 .²⁵⁷

Treatment of the alcohol **107** with sodium dichromate and sulfuric acid results in its cleavage giving formaldehyde and fluorodinitromethane (yield 65%).²⁵⁸

When the dinitro-diol **114**¹⁵⁷ or 2,2-dinitropentane-1,3-diol²⁵⁹ is treated with potassium hydroxide in methanol, the salt $\text{K}^+\text{C}^-(\text{NO}_2)_2\text{CH}_2\text{OH}$ and CH_2O or MeCHO are formed.

The reaction of compound **114** with potassium hydroxide and sodium carbonate yields salt **393**, which reacts with chlorine to give 2-chloro-2,2-dinitroethanol (overall yield 48%).¹⁵⁷ Treatment of the dinitro-diol **114** with chlorine fluorosulfonate affords dichlorodinitromethane (yield 15%).²⁶⁰

The decomposition of nitro alcohols **394** in an aqueous buffer solution with μ 1.0 D and pH 6.5–8.4 has been studied at 25.3 $^\circ\text{C}$ by spectrophotometry. The rate constants for the reaction were determined. It was postulated that deprotonation occurs rapidly, while the rupture of the C–C bond is the rate-determining step of the process.²⁶¹

Ar , $10^4 k$ (litre $\text{mol}^{-1} \text{s}^{-1}$): Ph , 3.02 (pH 4.6–8.4); 4-MeC₆H₄, 3.37; 4-MeOC₆H₄, 5.09; 4-ClC₆H₄, 4.22; 4-O₂NC₆H₄, 4.54; 3-ClC₆H₄, 3.79; 3-MeC₆H₄, 3.07.

6. Intramolecular hydrogen bonds in nitro alcohols and nitro-diols

Studies discussing the problems concerning intramolecular hydrogen bonding in nitro alcohols and published before 1977 have been surveyed in a review.²⁶²

The configurations of the *erythro*- and *threo*-isomers of the nitro alcohols $\text{RCH}(\text{OH})\text{CH}(\text{NO}_2)\text{R}'$ ($\text{R}, \text{R}' = \text{Me}, \text{Me}; \text{Pr}^i, \text{Me}; \text{CF}_3, \text{Me}; \text{CCl}_3, \text{Me}; \text{CBr}_3, \text{Me}; 4\text{-O}_2\text{NC}_6\text{H}_4, \text{Et}; 4\text{-O}_2\text{NC}_6\text{H}_4, \text{Pr}^i$) have been established by IR and ^1H , ^{13}C and ^{15}N NMR spectroscopy. It was found that the *erythro*-isomers occur mostly in the *gauche* conformation **A**, and the *threo*-isomers exist predominantly in the *gauche* conformation **B**. These conformers predominate because they are stabilised by intramolecular hydrogen bonds between OH and NO_2 groups.⁶⁴

The conformation equilibria for the alcohols $RCH(OH)CH_2NO_2$ [$R = H$ (**202**), Me, Ph, CCl_3] and for 2-nitropropane-1,3-diol **3** have been studied. In the case of the alcohols, equilibrium conformations **A**¹, **B**¹ and **C**¹ were considered.²⁶³

For the diol **3**, equilibrium conformations **A**², **B**² and **C**² were discussed.

It was found that the nitro alcohol **202** ($R = H$) exists predominantly in conformations **A**¹ and **C**¹. In other cases ($R = Me, Ph, CCl_3$), conformation **C**¹ predominates. The dihedral angle of $100 - 125^\circ$ is in agreement with the synclinal arrangement of the OH and NO_2 groups and with the formation of a hydrogen bond between them.

In the case of the nitro-diol **3**, conformer **A**² with the synclinal arrangement of the CH_2OH and OH groups predominates in the equilibrium. Thus, the interaction between the two hydroxy groups is stronger than that between the OH and NO_2 groups.²⁶³

IV. Practical use of aliphatic nitro alcohols

Possible applications of aliphatic nitro alcohols have been discussed in a large number of publications. Aliphatic monoatomic and polyatomic nitro alcohols and their derivatives both in a pure state and in various compositions are used most widely as biologically active compounds and as components of rocket fuels or explosives. Other applications of these compounds have also been proposed.

2-Bromo-2-nitropropane-1,3-diol **8** is used most often as a biologically active compound known as 'Biocide'. This nitro-diol as well as nitro alcohols of the general formula $R^1R^2C(OH)CR^3(Br)NO_2$ ($R^1 = H$, alkyl, phenylalkyl; $R^2 = H$; $R^1R^2 =$ cycloalkyl; $R^3 = H, Me, Et, Br$) are active against *Staphylococcus aureus* and *Pseudomonas aeruginosa*.²⁶⁴⁻²⁶⁶ The nitro-diol **8** has been used as an antimicrobial additive²⁶⁷ and as a component of agents controlling the amount of slime in wood pulp during the manufacture of paper,^{265,268} antimicrobial compositions controlling *Chlorella*,²⁶⁹ antiulcer compositions²⁷⁰ and compositions controlling the development of *Cosmarium*.²⁷¹

It has been proposed to use the bis-formate of nitro-diol **8** and 5-bromo-5-nitro-1,3-dioxane and its 2-substituted derivatives, resulting from condensation of **8** with aldehydes, as bactericides and fungicides;^{190,191,220} the mixed ester $4-ClC_6H_4OCH_2-C(NO_2)(Br)CH_2OSO_2Me$ has been used as a component of an agent that fully controls the growth of *Erysiphe gramin*.²¹⁹

The nitro-diol **8** has been patented as a deodorant for the toilets of buses and campers,²⁷² as a deodorant for refuse bins²⁷³

and as a component of compositions removing NH_3 , H_2S and $MeSH$ from aircraft toilet waste waters.²⁷⁴

The use of the nitro-diol **8** and 2-chloro-2-nitropropane-1,3-diol as inhibitors of light- and heat-induced paint changes has been patented.²⁷⁵

The polyester obtained by polycondensation of **8** with terephthaloyl dichloride has been claimed as an agent for cotton processing in order to make cotton fabrics resistant against *Escherichia coli* JFO 3134 and *Staphylococcus aureus* JFO 12732 and more comfortable for wearing.²⁷⁶

The nitro alcohols $R^1C(NO_2)(X)CH(OH)R^2$ ($R^1, R^2 = H$, halogen, substituted alkyl; $X =$ halogen) have been patented as components of microbicide agents, in particular, of those active against *Alternaria tenuis*,⁴⁷ *Pseudomonas aeruginosa*,²⁷⁷ *Plasmidiophora brassicae*²⁷⁸ and *Bacillus subtilis*.²⁷⁹

The nitro alcohols $Cl_3CCH(OH)CH(Br)NO_2$,⁷ 2-nitro-1-(2- and 4-pyridyl)propan-1-ols,²⁸⁰ $EtC(NO_2)(Br)CH_2OH$,³⁵ 2-nitro-1-(2- and 4-quinolyl)propan-1-ols and 2-nitro-1-(2 and 4-quinolyl)propane-1,3-diols²⁸¹ have been used as bactericides and fungicides.

2-Hydroxymethyl-2-nitropropane-1,3-diol **4** has been recommended as an agent for treating water infected with *Streptococcus*.²⁸²

$FC(NO_2)_2CH_2OH$ **107** suppresses the growth of *Escherichia coli* or *Staphylococcus aureus*, while 2-chloro-2,2-dinitroethanol exhibits antispasmodic activity.²⁸³

2-Methyl-4-nitropent-3-en-2-ol has been reported to improve blood circulation.²⁸⁴

A broad spectrum of biological activities is exhibited by the nitro alcohols $R,R'CH(OH)C(NO_2)(X)$ ($R, R', X = CCl_3, Me, Cl; H, Pr, Cl; Me, Cl, Cl; Pr^i, H, Br; Bu, H, Br; C_5H_{11}, H, Br; C_6H_{13}, H, Br; Me, Me, Br; Et, Me, Br; CCl_3, Me, Br; H, Et, Br; Me, Et, Br; Me, Br, Br; Et, Br, Br; Pr^i, Br, Br).⁵⁷$

It has been proposed to use formate, methyl carbonate and some other esters of nitro alcohols $RC(NO_2)_2CH_2OH$ ($R = Cl, Br, Me$) as bactericides and fungicides.^{157,285}

The compounds $R^1ZNHC(S)OCH(R^2)CR^3R^4NO_2$ ($R^1, Z, R^2, R^3, R^4 = Ph, SO_2, H, H, H; Ph, SO_2, H, Br, Me; Ph, CO, H, H, H; 4-O_2NC_6H_4, CO, H, Br, Me; 4-O_2NC_6H_4, CO, Me, H, Et; 4-ClC_6H_4, CO, H, H, H; Ph, CO, H, H, Et; 4-O_2NC_6H_4, CO, Me, H, Me; 2-furyl, CO, H, H, H) have been patented as fungicides and bactericides for deodorants, creams and cleaning compositions,²²⁴ while the esters (2-thienyl) $COOCH(R)CH(R')NO_2$ ($R = H, Me, Pr, Pr^i; R' = H, Me, Et) have been used as fungicides and bactericides for deodorants, soaps and creams.²⁸⁶$$

$R = H, Me, Pr, Pr^i; R' = H, Me, Et.$

The nitro alcohols $RR'C(NO_2)(CH_2)_nOH$ ($R, R' = H, Cl, Br, Br; n = 1-3$) and their acetates have been recommended as components of compositions improving the properties of paper, dyes, cosmetics and adhesives.²⁸⁷

The addition of the nitro-diol **8** to a mixture used for the development of photographic materials inhibits contamination of waste waters.²⁸⁸

The nitro alcohols $RC(NO_2)BrCH(R')OH$ ($R = CH_2OH$, lower alkyls; $R' = H$, lower alkyls) increase the stability of dyes in photographic materials with improved photosensitive layers.²⁸⁹ These nitro alcohols combined with isothiazol-3-one derivatives permit high-quality development of photographic materials even at low pH without decreasing the sensitivity.²⁹⁰

The nitro alcohols $RC(NO_2)(Br)CH(OH)R'$ ($R, R' = H, Me, Et) are added to paper pulp in order to improve the properties of photographic paper.²⁹¹$

A film coated by a composition of polyamide with 2-hydroxymethyl-2-nitropropane-1,3-diol **4** becomes more resistant to abrasive wear.²⁹²

The use of the nitro alcohols $R^1R^2C(NO_2)CH(OH)R^3$ [R^1 , $R^2 = H$, C_{1-5} alkyl, CH_2OH ; $R^3 = H$, alkyl (C_{1-5})] as components of toning agents protecting colloidal photographic materials from X-rays has been patented.²⁹³

The nitro-diol **4** has been used as a stabiliser of developers for colour photography.²⁹⁴ The compound **4** and 2-methyl-2-nitropropane-1,3-diol have been recommended as agents increasing light resistance of dyes.²⁹⁵

2-Methyl-2-nitropropan-1-ol can be used for the preparation of polymerisation inhibitors for esters of unsaturated carboxylic acids.²⁹⁶

The nitro alcohols $XX'C(NO_2)CH(R)OH$ ($X, X' = Hal$; $R = H$, alkyl) are used to prevent fur formation.²⁹⁷

2-Methyl-3-nitropropan-2-ol has been used as a plasticiser for cellulose triacetate.²⁹⁸ The same nitro alcohol blended with the product of condensation of urea and formaldehyde imparts permanent-press and wrinkle-resistant characteristics to cotton textiles.²⁹⁹

The nitro-diols $O_2NC(R)(CH_2OH)_2$ ($R = Me, Et, CH_2OH$) react with melamine at 70 °C and pH 9.5–10 to give adhesive resins that join surfaces under elevated pressures at 250–300 °C.³⁰⁰

2-Methyl-2-nitropropan-1-ol has been used to improve adhesion of rubber to a steel cord.³⁰¹

The product of reaction between 2-ethyl-2-nitropropane-1,3-diol and tetraethylenepentamine, which solidifies over a period of 15 min at room temperature, has been recommended as a coating for steel sheets.³⁰²

The nitro alcohols $RC(NO_2)(X)CH(OH)R'$ ($R = H, CH_2OH$, lower alkyls; $R' = H$, lower alkyls; $X = Hal$) have been patented as agents protecting metal working fluids from bacteria and fungi.^{303, 304}

2-Nitropropan-1-ol increases the covering power, the time of hardening and the strength of cements.³⁰⁵

3-Nitrobutan-2-ol has been used as a selective solvent for dearomatisation of directly distilled petrols.³⁰⁶

The nitrate $MeCH(ONO_2)CH(NO_2)Me$ increases the cetane number of diesel fuels.³⁰⁷

Halo-substituted nitro alcohols of the general formula $R^1[CH(OH)]_nC(NO_2)(X)CR^2R^3OH$ [$R^1, R^2, R^3 = H$, alkyl (C_{1-7}); $X = Cl, Br, I$; $n = 0, 1$], in particular, the nitro-diol **8** have been claimed as antimicrobial agents for hydrocarbon fuels.³⁰⁸

Polynitro alcohols and their derivatives are important components of rocket fuels and explosives.

The compound $(O_2N)_2C(F)CH_2OCOOCH_2CF_3$ has been used as a plasticiser for plastic explosives.²⁰⁵

The formate, methyl carbonate and some other esters of $MeC(NO_2)_2CH_2OH$ have been used as plasticisers for rocket fuels;¹⁵⁷ the compound $[FC(NO_2)_2CH_2]_2NCOOCH_2C(NO_2)_2F$ has been patented as a plasticiser for explosive compositions.³⁰⁹

Among the derivatives of polynitro alcohols proposed as plasticisers for high-energy compositions, the following compounds should be noted: $[EtOCOCH_2C(NO_2)_2F]_2Me$,¹⁸⁷ $(RO)_2CHMe$, $MeCH(OR)OCH_2C(NO_2)_2R'$ [$R = CH_2C(NO_2)_2F$, $R' = F, Me, NO_2$]¹⁸⁶ $[RC(NO_2)_2CH_2O]_2CH_2$ ($R = Me$,^{182, 310} F ,³¹¹ NO_2 ¹⁸²), $[RC(NO_2)_2CH_2O] - CH_2[OCH_2C(NO_2)_2R']$ ($R, R' = NO_2, Me$,¹⁸² Me, Et ³¹⁰), $RC(NO_2)_2CH_2OC[CHCOOCH_2C(NO_2)_2R]COOCH_2(NO_2)_2$. $R' (R = R' = H, F, Me, NO_2)$.²¹⁸

The use of the orthoester $[FC(NO_2)_2CH_2O]_2CH - [OCH(Me)C(NO_2)_2F]$ as a co-plasticiser in high-energy compositions has been patented,³¹² the orthocarbonate $[FC(NO_2)_2CH_2O]_3COCH_2C(NO_2)_3$ has been used as a plasticiser and as an energetic explosive.²¹¹

2-Fluoro-2,2-dinitroethanol **107** can be used as a plasticiser and a binding agent for rocket fuels and explosive compositions;⁹¹ the ether $(O_2N)_3CCH_2OC(NF_2)_3$ can be used as a plasticiser and an oxidant for rocket fuels.¹⁸⁰

The following compounds have been patented as energetic binding agents for high-energy compositions: the vinyl ethers $RC(NO_2)_2CH_2OCH=CH_2$ ($R = F, NO_2$)³¹³ and $FC(NO_2)_2 - CH_2C(NF_2)_2CH_2OCH=CH_2$,²¹³ nitroformals synthesised by polycondensation of the tetranitro-diol $[HOCH_2C(NO_2)_2CH_2]_2$ with formaldehyde¹⁸⁵ or by polymerisation of the epoxide $FC(NO_2)_2CH_2OCH_2CHOCH_2$,^{314 314} and esters formed by 2,2-dinitropropane-1,3-diol **114** with oxalic, malonic or fumaric acids.³¹⁵

The polyester resulting from the reaction of the dichloride $[ClCOCH_2CH_2]_2C(NO_2)_2$ with the diol $[HOCH_2C(NO_2)_2CH_2]_2O$ has been patented as a component of energy-producing compositions.³¹⁶

The nitro-derivatives $[RC(NO_2)_2CH_2O]_2C=S$ ($R = F, Me, NO_2$) have been used as intermediate compounds in the synthesis of energetic explosives.²¹²

III. Hydrogenation of FeTi and LaNi ₅ undergoing mechanical milling	76
IV. The direct formation of hydrides during mechanical milling	77
V. Conclusion	77

Abstract. Data on hydrogenation of mechanical alloys and intermetallic compounds formed in the course of mechanical alloying and mechanical milling are generalised. It is shown that mechanochemical methods make it possible to solve a number of problems arising in the hydrogenation of metals and alloys and to synthesise novel hydrides and nanocomposite materials. The mechanism of hydrogenation of mechanical alloys is discussed. The bibliography includes 98 references.

I. Introduction

The diversity of practical tasks associated with the accumulation of hydrogen and the use of metal hydrides and intermetallic compounds (IMC) in various technologies stimulate the development of research directed to the search for novel metal–hydrogen systems with definite structural, kinetic, and thermodynamical characteristics.

This type of research consists of the use of alloys and solid solutions based on the known hydride-forming metals, IMC and composite materials obtained from hydride-forming components containing binders that are inert with respect to hydrogen.¹ LaNi₅, TiFe, and magnesium and its alloys are considered to be the most promising from the viewpoint of the accumulation of hydrogen.^{2,3} These materials are traditionally prepared by alloying and by the methods of powder metallurgy. One substantial problem is the activation of these materials which are usually covered by a layer of oxides and hydroxides, thus preventing the chemisorption of hydrogen at the surface and resulting in long induction periods and low reaction rates in the initial hydrogenation. To achieve the highest reaction rate it is necessary to perform several cycles of hydrogenation and dehydrogenation (cycling), which result in the dispersion of the alloy and the development of its microstructure. The microstructure plays a significant role in further cycling and affects considerably the reaction rate and the amount of absorbed hydrogen.

In addition, traditional methods of preparation of alloys are mainly restricted by thermodynamically stable compounds and solid solutions.

Mechanochemical methods (mechanical alloying, mechanical milling, *etc.*) consist in mechanical treatment of metal powders in high-energy planetary ball mills. This treatment results mainly in plastic deformation of the material under conditions that fix its metastable state. These methods can be applied to the synthesis of metastable phases: amorphous phases,⁴ supersaturated solid solutions, non-stoichiometric intermetallic compounds,⁵ quasi-crystals,^{6,7} and composites with different microstructure and composition including those with non-interacting components.⁸ These phases often exhibit unusual physicochemical properties and enhanced reactivity.^{8,9} Mechanical alloying, as shown in the present review, can be a promising method for the preparation of materials with high reactivity with respect to hydrogen.

II. Magnesium systems

1. Problems arising in the hydrogenation of magnesium and its alloys

Magnesium and its alloys are promising materials for the accumulation of hydrogen. The stoichiometric hydrogen content in magnesium hydride is 7.6 mass % (Table 1), which exceeds its content in other known hydrides and also in gas cylinders.^{10,11} However, the relatively high thermal stability of magnesium hydride (equilibrium hydrogen pressure of 0.1 MPa is achieved at ~560 K), insufficiently high rates of hydrogenation of magnesium and dehydrogenation of MgH₂, long-lasting activation, and incomplete conversion of magnesium into the hydride (which decreases the hydrogen content to 5 mass %) have stimulated the appearance of research projects aimed at the possibility of improving the above-mentioned characteristics.

It has been established to date that the formation of magnesium hydride is connected with the processes of formation and growth of MgH₂ nuclei. For the majority of metal–hydrogen systems, the first stage of the interaction of hydrogen with a metal is characterised by the formation of a solid solution of hydrogen in a metal, in which nuclei of the hydride phase are crystallised.¹² The formation of solid solutions of hydrogen is not typical of magnesium, or more precisely, their concentrations are low.^{13–15} The hydride nuclei appear at the surface of magnesium particles; when the nuclei overlap, the reaction rate is controlled by diffusion processes. ‘Diffusion retardation’ then occurs, which prevents the complete conversion of magnesium into the hydride. In the first cycle of hydrogenation, the extent of conversion does

Table 1. Characteristics of hydrogen storage systems.^{10, 11}

Method of storage	Hydrogen content		Hydride density /g cm ⁻³	Accumulated energy		Hydrogenation rate
	(mass %)	/10 ²² at cm ⁻³		/kJ g ⁻¹	/kJ cm ⁻³	
H ₂ , gas 20 MPa, 300 K	1.2 ^a	0.9	—	142.7	2.13	—
H ₂ , liquid	≤ 12 ^a	4.2	—	142.7	9.96	—
LaNi ₅ H ₆	1.4	5.5	6.2	2.0	13.04	High
TiFeH ₂	1.9	6.3	5.5	2.7	14.93	"
MgH ₂	7.6	6.6	1.5	10.8	15.64	Low
MgNiH ₄	3.6	5.8	2.7	5.1	13.75	High
Gasoline	—	—	—	48	38	—

^a With account of the mass of the storage system.

not usually exceed 0.9, in subsequent cycles it does not exceed 0.6–0.7.^{16–18}

Kinetic characteristics of hydrogenation processes in the first cycle differ substantially from those in the later cycles. The surface layer of magnesium oxide, which is always present on the original metal particles before the first hydrogenation, inhibits the formation of magnesium hydride nuclei, because no dissociative adsorption of hydrogen on this layer occurs.¹⁹ Therefore, the rate of hydrogenation of magnesium in the first cycle is determined by the processes of destruction of the oxide film and formation of a metallic surface with hydrogen chemisorption ability.^{19–21} A model of the first cycle of hydrogenation of magnesium taking into account the dynamics of the destruction of the oxide film and kinetics of the nucleus growth has been proposed.²²

During activation through cycling, exfoliation of the oxide film occurs. The initial reaction rate is determined by the dissociative chemisorption of hydrogen on a pure metal surface, and the nucleus growth occurs due to the surface diffusion within the layer of the chemisorbed hydrogen.²³ An increase in the number of nuclei with an increase of ΔP (the difference between the pressure in the reactor and the hydrogen equilibrium pressure for magnesium hydride at the temperature of the experiment), which is a driving force of the reaction, or the introduction of catalysts accelerates the initial stage of hydrogenation, leads to the faster formation of the continuous layer of the hydride, and to a change over to diffusion conditions at lower conversion rates.²⁴ It was shown by experiments on the movement of the Kirkendall mark that hydrogen atoms or ions are the diffusing species.²⁵

The rate of decomposition of magnesium hydride depends on the dynamics of the formation and growth of nuclei of magnesium metal.²³ The desorption of hydrogen from the surface of the solid reaction product, metallic magnesium, is the limiting stage of the reaction; for this reason, the size of the Mg/MgH₂ interface plays a significant role.

Thus, the rate of magnesium hydrogenation in the first stage and the rate of decomposition of magnesium hydride are determined by the processes of adsorption (or desorption) of hydrogen on the metal surface (in the first hydrogenation, by the formation of the metal surface), by the rates of formation and growth of nuclei of the reaction product, and after the creation of the continuous layer of MgH₂ in the hydrogenation, by the rate of diffusion of hydrogen through the hydride. Hence, changes in the kinetics of hydrogenation and dehydrogenation can be achieved by controlling these stages.

In the majority of studies dealing with the improvement of kinetic and thermodynamic characteristics of magnesium in the interaction with hydrogen, its alloys with other metals have been used. However, it should be noted that in the case of magnesium, the choice of these metals is rather limited for the enthalpy of mixing of magnesium with many elements of the Periodic Table is positive.

To date, only two magnesium intermetallic compounds are known that absorb hydrogen reversibly, *viz.*, Mg₂Ni and

Mg₅₁Zn₂₀, and the corresponding hydrides, MgNiH₄ (Ref. 26) and Mg₅₁Zn₂₀H_{*y*} (*y* = 90–95).²⁷ The hydride Mg₂NiH₄ is regarded as a promising one for the accumulation of hydrogen, because it interacts with hydrogen at a high rate at temperatures of about 473–573 K and $P_{H_2} \approx 0.5–1.0$ MPa,²⁸ although its hydrogen capacity is less than that of magnesium (see Table 1). At the first stage of hydrogenation of Mg₂Ni under the conditions ensuring fast heat removal and at rather high hydrogen pressures, chemisorption of hydrogen on the surface of IMC with an effective activation energy of 14.0 ± 0.8 kJ mol⁻¹ is the limiting stage.²⁹ However, due to high rates of hydrogenation and dehydrogenation, the processes of heat and mass transfer play a significant role and may become limiting, especially if this IMC is used on a technological scale. The creation of composite materials containing inert metallic fillers is the way to solve the problems of heat and mass transfer,³⁰ but this further decreases the hydrogen capacity of an accumulator.

The interaction of IMC of magnesium and of some other elements, such as rare earth metals, Cu, Al, Ca, with hydrogen leads to the decomposition of the intermetallic compound to form a mixture of two hydrides or a hydride and a metal (or another IMC). This process was termed hydrogenolysis,^{31, 32} in general it can be represented by the equation

where A, B are elements constituting the IMC; *n* = 0 if the second element does not give a hydride.

Hydrogenolysis can be reversible, as in the case of Mg₂Cu,³³ and irreversible, as for most IMC of magnesium with rare earth metals and Al.^{11, 32, 34–40} The reversibility is determined by the relationship between the values of the heat of formation of the binary hydride and the initial IMC. The mechanism of hydrogenolysis has not been studied in detail. No complete separation of hydrides or a hydride and a metal (IMC) resulted from hydrogenolysis occurs. The material obtained is composed of particles with a developed interface between its constituents^{35, 36} which determines the reactivity of these particles in further hydrogenation–dehydrogenation cycles.

Of the systems that undergo hydrogenolysis, the main attention has been paid to IMC of magnesium with rare earth metals. Hydrogenolysis results in a non-stoichiometric hydride LnH_{*x*}, which plays the role of a ‘hydrogen pump’, which facilitates the delivery of hydrogen to the magnesium surface and thus accelerates hydrogenation.^{35–37, 41} However, no significant enhancement of the kinetics of dehydrogenation of these reaction mixtures occurs in comparison with pure MgH₂.^{34–36, 40} In order to accelerate dehydrogenation, it is necessary to introduce elements that facilitate the processes of hydrogen desorption and the formation of the metallic phase nuclei, for example, *d*-metals.^{34, 37, 42–44} These additives form a separate phase as a result of cycling. After hydrogenolysis the material is a virtually multi-phase system, its features being typical of those for multi-phase alloys.

Two- and multi-phase systems are alloys of magnesium with other elements, the composition of which does not correspond to the stoichiometric composition of intermetallic compounds. These can be alloys with Ni, Cu, rare earth, and some other metals.

Hydrogenation of alloys of magnesium with rare earth metals yields a mixture of binary hydrides, as in the case of hydrogenolysis of IMC. The compositions formed differ, first of all, in specific features of the microstructure and in the size of the magnesium/lanthanide hydride interface. In the decomposition of a non-stoichiometric alloy, the interface is, as a rule, smaller than that in hydrogenolysis of IMC, which results in a decrease in the rates of the interaction of these systems with hydrogen.

The alloys Mg–Ni and Mg–Cu are two-phase systems containing magnesium and IMC Mg₂Ni or Mg₂Cu. Hydrogenation of these alloys can be carried out in two versions: under conditions where both phases are hydrogenated and under conditions where only magnesium is hydrogenated and the intermetallic compound serves only as a catalyst. However, in both cases dissociative hydrogen adsorption takes place on clusters of the *d*-element resulting from segregation occurring in the course of hydrogenation–dehydrogenation.[†] Studies of the surface of alloys by ferromagnetic resonance,⁴⁵ X-ray photoelectron and Auger spectroscopy^{46,47} gave reason to adopt a model of the structure of the surface of the alloy and the scheme of the initial stage of hydrogenation, which accounts for the catalytic activity of transition metals.^{47–49} The essence of the model is as follows:

1. Activation of the material in hydrogenation–dehydrogenation cycles leads to dispersion of the sample, that is, to the formation of a new clean surface.
2. In the interaction with traces of oxygen and water, clusters of a *d*-element are formed on this surface (the so-called oxidative segregation).
3. Dissociative chemisorption of hydrogen takes place on the clusters of the *d*-element.
4. The hydrogen atoms formed diffuse into the bulk of the material along the metal/oxide interface.

The course of the reaction, as was mentioned above, depends largely on the size of the magnesium/catalyst interface and accordingly, on the size of magnesium particles in the alloy.

The size of magnesium crystallites determines the degree of its conversion into the hydride. The process of nucleation is accelerated under the action of catalytic additives, which leads to faster formation of a continuous layer of the hydride and to a change to the diffusion control of the reaction.²⁴ In the case of larger magnesium particles, these processes slow down and practically completely stop the reaction long before complete conversion. The portion of magnesium that does not enter the reaction decreases and the hydrogen content increases with a decrease in the size of particles in the alloy.

Hence, the main problems in the creation of two- and multi-component materials for accumulation of hydrogen are, first, the choice of a catalyst and determination of its optimum concentration at which the maximum hydrogen content is achieved over a given time and second, the creation of the microstructure of the sample ensuring the maximum magnesium/catalyst interface.

In addition, the problem of activation exists for all the alloys. The rate of the first hydrogenation is determined by the rate of the rupture of the oxide film, by the rates of the formation and growth of magnesium hydride nuclei. The effect of additives reduces most commonly to a decrease in the induction period and to an increase in the rate of the first hydrogenation as compared to analogous characteristics for pure magnesium,^{17,24,50,51} however, the duration of the first cycle remains too high.

[†] Segregation processes occur due to the presence of traces of oxygen and water in the hydrogen.

2. The interaction of mechanical alloys of magnesium with hydrogen

A new approach to the creation of two- and multi-component systems interacting with hydrogen has been proposed.^{52–55} It is based on the use of mechanical alloying. In the initial stage of processing of a mixture of metal powders (in ~5 min) in centrifugal planetary mills, composites are formed with a considerable interface similar to those resulting from hydrogenolysis of IMC, but the hydrogenolysis stage is excluded. These composites were termed mechanical alloys (MA). A typical (rather porous) structure of a particle of a mechanical alloy with uniformly distributed particles of a metal catalyst within the magnesium matrix is shown in Fig. 1.⁵⁵ Wide angle X-ray scattering (WAXS) of these materials did not reveal the formation of either intermetallic compounds or solid solutions.

The processes of hydrogenation and dehydrogenation have been studied for the systems Mg–Ce;⁵⁶ Mg–Fe, Mg–Co, Mg–Ti, Mg–V, Mg–Nb, Mg–Cr, Mg–C, Mg–Si;^{52–54,57–59} Mg–Ni;^{29,52,53,60–63} Mg–TiO₂;^{64–66} Mg–V₂O₅, Mg–Cr₂O₃;⁶⁶ Mg–MnO₂; Mg–Fe₂O₃, Mg–NiO;⁶⁷ Mg–MmM'₅ (MM'₅ is IMC of the type LaNi₅, Mm is a mischmetal, M' is Ni with admixtures of Al, Co, and Mn),^{68,69} Mg–FeTi,⁷⁰ etc.

Figure 1. A particle of mechanical alloy Mg–Ni at a fracture; the image in the Ni *K_α* radiation.

Thus, mechanical alloying allows the considerable extension of the range of systems under study including mixtures that could not be alloyed by traditional methods, such as Mg–Fe, Mg–Ti, Mg–Nb, and Mg–Cr with positive enthalpy of mixing of the components, or mixtures of magnesium with oxides. It is also very difficult to prepare from the latter composites with homogeneous distribution of the components by traditional alloying methods.

The additives to magnesium used in mechanical alloys differ in their nature. Thus the above-mentioned additives can be divided into six groups.

1. Ni forms with magnesium the intermetallic compound Mg₂Ni, which can absorb and liberate hydrogen.
2. Ce, Nb, and Ti form hydrides CeH₃, NbH₂, and TiH₂, which can serve as 'hydrogen pumps' due to the change in stoichiometry.
3. MmM' and FeTi are intermetallic compounds, which absorb hydrogen reversibly under milder conditions compared to magnesium.
4. Fe, Co, and Cr are metal catalysts, which do not form hydrides themselves under the conditions studied.

Figure 2. Kinetics of the first hydrogenation of magnesium and its mechanical alloys.

5. Si and C form with magnesium compounds with predominantly covalent bonds.

6. Metal oxides.

All the types of catalytic additives accelerate remarkably the first hydrogenation as compared to that of pure magnesium^{52,67} (Fig. 2). The character of the action of additives (except for Si and C) seems to be the same and consists in the acceleration of the stage of chemisorption of hydrogen on the surface of a catalyst. It is of note that mechanical alloys Mg–Ni are hydrogenated during the first cycle faster than the corresponding ordinary alloys Mg–Ni (Fig. 3).⁶¹

Figure 3. Kinetics of the first hydrogenation of mechanical alloys of magnesium with nickel.

[Ni] (mass %): (1) 60, (2) 53, (3) 35, (4) 1; (1–4) at $P_{\text{H}_2} = 1.8 \text{ MPa}$, $T = 583–593 \text{ K}$; (5) ordinary alloy of Mg with 25 mass % of Ni at $P_{\text{H}_2} = 2.1 \text{ MPa}$, $T = 673 \text{ K}$.

The rate of the first hydrogenation depends on the nature and concentration of the catalyst, but in almost all the systems examined, the reaction begins at the maximum rate (see Figs 2, 3). This means that the surface of the catalyst in mechanical alloys, unlike that in traditional alloys, is accessible to hydrogen.

X-ray photoelectron spectroscopic studies^{29,71} of the surface of MA have shown that it is covered with a layer of organic impurities and oxygen-containing magnesium compounds. The thickness of this layer is small, and it does not seem to affect the hydrogenation process. The profiles of concentration of the elements for magnesium MA containing 50 mass % Ni are shown in Fig. 4. The surface layer (3–5 nm) contained neither metallic magnesium, which appeared at a depth of 40 nm, nor nickel, which appeared at a depth of $\sim 4–10 \text{ nm}$ in the oxidised state and at a depth of 40 nm in the metallic state. The presence of oxygen throughout the entire layer provides evidence for the destruction of the surface MgO film and its dispersion in the matrix. Carbon-containing impurities also penetrate into the bulk upon mechanical alloying.

Figure 4. The dependence of the chemical composition on the etching depth (h) for a mechanical alloy of Mg with 50 mass % of Ni. (1) Mg, (2) Ni, (3) O, (4) C, (5) Ni/Mg.

The chemical state of the elements in the near-surface layer of MA differs significantly from that in the original metals. The contour of the nickel $2p_{3/2}$ line at a depth of 40 nm corresponds to metallic nickel and to the nickel implanted into an inert matrix as isolated atoms. In addition, charge transfer from magnesium to non-bonding levels of the nickel atoms has been observed. In this case, a portion of magnesium is in the state to which the formal oxidation degree of +1 can be ascribed. The chemical state of oxygen also differs from that in the original metals and MgO , which might be due to defectiveness of the surface layer of MA.^{29,71} The nickel atoms resulting from the chemical interaction between Mg and Ni in the course of mechanical alloying bear an excessive electron density and are active catalysts of hydrogen dissociation. The nickel atoms are, probably, present not only in the surface layer, but also in the bulk of the sample forming a

supersaturated solid solution around the nickel particles upon dispersion of nickel within the matrix.

Other MA of magnesium with metals and IMC, even those having a positive enthalpy of mixing, seem to have a similar structure. This can be indirectly proved by the fact that the initial hydrogenation rate of mechanical alloys Mg–Fe and Mg–Ni depends linearly on the square of the concentration of the catalyst in MA.⁵⁹

Hence, disordering of the surface layer, the rupture of the oxide film, and dispersion of the catalyst take place in mechanical alloys. Disorder of the surface layer makes the catalyst accessible to hydrogen, which is the main reason for the rapid first hydrogenation of MA as compared to that of alloys and mixtures of the same composition.^{29, 71}

It should be noted that this surface structure is quite stable over a long period: the initial rate of hydrogenation of MA that have been stored in air for 9–12 months did not differ from that of freshly prepared samples.²⁹

The high reactivity (with respect to hydrogen) of mechanical alloys of magnesium with transition metal oxides may also be accounted for by the presence of metallic particles and partially reduced metal oxides at the surface formed in the course of mechanical processing.^{64–67} The efficiency of the action of metal oxides as catalysts depends on the ease of their reduction.⁶⁶

For the majority of systems examined (except for Mg–Ce and, under special experimental conditions that will be considered below, Mg–Fe and Mg–Co), magnesium hydride (the second phase, catalyst) is the product of the first hydrogenation. The degree of conversion of magnesium into the hydride, as in two-phase systems, in these MA depends on their microstructures. A model of a microstructure reflecting qualitatively the initial stage of hydrogenation is presented in Fig. 5: MgH_2 is formed around the catalyst particles. It is difficult for hydrogen to penetrate through the layer of hydride; that is why the reaction slows down with an increase in the thickness of the layer. The thickness of the hydride layer, which depends on the distance between particles of the catalyst, decreases with an increase in the concentration of the catalyst, and the degree of conversion also increases. However, the hydrogen content (mass %) in the alloy decreases due to the large mass of catalyst. It has been found experimentally^{59, 63} that the optimum catalyst content was in the range of 2 mass %–25 mass %.

Figure 5. A model of the microstructure of mechanical alloy Mg–Ni (a) and the illustration of the effect of the Ni concentration on the degree of conversion (b).

In subsequent cycles, MA retain high rates of hydrogenation and dehydrogenation (Figs 6, 7) and rather high hydrogen capacity.⁵²

In the case of the Mg–Ni mechanical alloy, the intermetallic compound Mg_2Ni is formed after 3–4 cycles of hydrogenation–dehydrogenation, mainly according to the equation⁶¹

Further, kinetic characteristics of the system do not differ from those of the ordinary two-phase system Mg–Ni or the intermetallic compound Mg_2Ni .^{29, 63}

Kinetic characteristics of the mechanical alloy Mg–Ce in the cycling are also comparable with those of hydrogenation and dehydrogenation obtained in the hydrogenolysis of Mg– CeH_x mixtures (Fig. 8).⁵⁶ This shows that the size of the interface in MA has the same order of magnitude as the interface in the mixtures obtained in the hydrogenolysis.

As for MA composed of thermodynamically immiscible components, one could expect rapid destruction of a sample in repeating hydrogenation–dehydrogenation cycles due to exfoliation of the system. However, these systems appeared to be rather stable in cycling. A mechanical alloy Mg–Fe retains its hydrogen capacity for ~ 70 cycles, and the rate of hydrogenation even

Figure 6. Kinetics of hydrogenation for the fifth cycle, $P_{\text{H}_2} = 1.5$ MPa, $T = 625$ K.

gradually increases;⁵⁹ a mechanical alloy Mg–TiO₂ retains its kinetic characteristics at least up to the 39th cycle⁶⁴ (there are no data on longer cycling).

It was shown^{59, 72} that complex competing processes including sintering and dispersion of the sample occur in a Mg–Fe system in the hydrogenation–dehydrogenation. Hydrogen undergoes dissociation on iron and it further diffuses into the bulk of the sample along the interface and grain boundaries to form an Mg/Fe adsorption layer at the interface in which rather high mobility of both hydrogen and metals is observed. Some experiments on the annealing of a contact pair Mg/Fe using a microprobe analysis have shown that the principal possibility is for iron to diffuse along the surface of magnesium in a hydrogen atmosphere.^{59, 72} This favours an increase in the Mg/Fe contact area and in the hydrogenation rate. When a definite hydrogen concentration in the adsorption layer at the interface Mg/Fe is achieved, a ternary hydride of the composition Mg₂FeH₆ crystallises at a noticeable rate, which was observed at $T \geq 615$ K. At hydrogen pressures exceeding the equilibrium pressure over MgH₂, catalytic hydrogenation of magnesium occurs in parallel, often at a higher rate; the synthesis of Mg₂FeH₆ can also occur according to the equation

However, since the equilibrium hydrogen pressure for Mg₂FeH₆ is lower than that for magnesium hydride⁵⁷ (Fig. 9), the synthesis of the latter was successfully accomplished directly from the elements. This reaction has been described in detail.^{59, 72}

Analogous processes seem to occur in the hydrogenation of a mechanical alloy Mg–Co. This system does not belong to immiscible ones; however, for this system only one intermetallic compound MgCo₂ is known, which does not absorb hydrogen under ordinary hydrogenation conditions. In the hydrogenation of mechanical alloys in this system, two hydrides, *viz.*, Mg₂CoH_x ($x = 4-5$) and Mg₃CoH₅, were detected^{58, 59} which, like Mg₂FeH₆, can be synthesised from the elements (without the intermediate stage of formation of magnesium hydride). Decomposition of ternary magnesium–cobalt hydrides gave a previously unknown IMC with composition close to Mg₂Co and having a cubic structure. This compound interacts with hydrogen even at room temperature to form solid solutions and at elevated temperatures to form ternary hydrides (Table 2).

It should be noted that ternary magnesium–iron and magnesium–cobalt hydrides could not be detected for a long time due to the lack of hydride-forming IMC in the systems Mg–Fe and Mg–Co. Yvon *et al.*⁷³ considered the hydride Mg₂NiH₄ as a complex compound composed of the Mg²⁺ cation and the [NiH₄]⁴⁻ anion. Assuming that the 18 electron rule, which determines the content of a ligand (H in this case), is valid for these complexes, they have predicted the possibility that hydrides Mg₂FeH₆ and Mg₂CoH₅ exist. Research by these authors in

Figure 9. Temperature dependence of equilibrium pressures of hydrogen over the hydride phases MgH₂ (1) and Mg₂FeH₆ (2).

Table 2. Crystallographic data for novel ternary hydrides and intermetallic compounds.

^a The temperature of a reversible phase transition of Mg₂CoH_x from the low-temperature modification to the high-temperature one is 470 K, ΔH for the phase transition is ~ 2 kJ mol⁻¹.^{58, 59}

1984–1985 aimed at synthesising these hydrides was successful.^{74, 75} At the same period, the hydrides were found in the hydrogenation of mechanical alloys.⁷⁶ The lack of a method for the preparation of a material with a large Mg/Fe and Mg/Co interface caused the authors^{74, 75} to use a mixture of pressed metal powders. The reaction had to be conducted for weeks under drastic conditions, nevertheless, complete conversion of these mixtures into the hydrides was not achieved. Neither the second hydride Mg₃CoH₅ existing in the Mg–Co system nor the intermetallic compound Mg₂Co could be isolated and identified.

The magnesium–iron and magnesium–cobalt ternary hydrides were examined as catalysts for the hydrogenation of unsaturated hydrocarbons. These catalysts manifested catalytic activity comparable with that of catalysts based on platinum-group metals, and high selectivity in processes of partial reduction

Table 3. Catalytic characteristics of ternary hydrides and traditional catalysts.⁵⁹

Catalyst	Degree of conversion (%)	Selectivity (%)
Compound to be hydrogenated is acetylene

of acetylene derivatives and compounds with several double bonds (Table 3).^{59, 77}

Hydrogenation and dehydrogenation of MA containing, for example, two or more IMC can be more complicated. Depending on the composition of MA, cycling can result in the interaction between the components, their decomposition, and the formation of other phases, which can be both hydride-forming and hydride-non-forming. Thus a study of hydrogenation of a MA containing 66.6 mass % of La₂Mg₁₇ and 33.3 mass % of LaNi₅ has shown⁷⁸ that several hydrogenation–dehydrogenation cycles result in their decomposition and the formation of Mg, Mg₂Ni, and LaH_x ($x = 2.00–2.99$). Then, depending on the temperature and hydrogen pressure used in hydrogenation, hydrogen is absorbed either by magnesium or by magnesium and Mg₂Ni, and LaH_x serves as a ‘hydrogen pump’. After 20 cycles, the sample was a conglomerate of all the phases with a granule size of $\sim 0.2 \mu\text{m}$. Although these MA have lower hydrogen capacity as compared to that of pure La₅Mg₁₇, the rates of their hydrogenation and dehydrogenation are higher in the first cycles and depend, other conditions being the same, on the duration and intensity of mechanical processing. Thus MA obtained under the most drastic conditions (at an acceleration of 130 m s^{-2} for 25 min) absorbs 3.5 mass % of hydrogen (90% of full capacity) in less than 1 min at 523 K and liberates the same amount in 6 min, whereas under the same conditions it takes 2.5 h for pure La₅Mg₁₇ to absorb 4.9 mass % of hydrogen (also 90% of its full capacity) and 3 h to desorb it.⁷⁸ This was explained⁷⁸ by the small size of MA particles ($\sim 10 \mu\text{m}$), their multi-phase composition and catalytic activity of one or two components. It was thus concluded that a solution of the problem of improvement of the kinetic characteristics of hydrogenation and dehydrogenation lies in the creation of analogous composite materials.

3. Hydrogenation of Mg₂Ni obtained by mechanical alloying and mechanical milling

The intermetallic compound Mg₂Ni interacts with hydrogen at a high rate at 473–573 K and a hydrogen pressures of 0.5–1.0 MPa; however, a problem of activation exists. From 10 to 20 cycles of hydrogenation–dehydrogenation are necessary for activation⁷⁹ in the course of which dispersion of the material and the formation of a metallic surface occur. These difficulties can be avoided if Mg₂Ni is subjected to mechanical milling or is synthesised by mechanical alloying using the same procedure as for the synthesis of MA but increasing the duration of the treatment. It was shown^{80, 81} that mechanical alloying of a mixture of Mg and Ni powders gives nanocrystalline Mg₂Ni with the size of crystallites of about 20–30 nm. This material interacts rapidly with hydrogen, and reproducible rates of hydrogenation are achieved even by the second cycle (Fig. 10). If a small amount of palladium (less than 1 mass %) is added to the reaction mixture during mechanical alloying, the thus modified Mg₂Ni absorbs hydrogen at room temperature (Fig. 11).^{80–83} An analogous result was obtained without addition of palladium.⁸⁴ However, in this case

Figure 10. Kinetics of hydrogenation of nanocrystalline Mg₂Ni prepared by mechanical alloying at $T = 573 \text{ K}$, $P_{\text{H}_2} = 1.16 \text{ MPa}$; (1) the first cycle; (2) the second and subsequent cycles. The x values in the formula Mg₂NiH_x are shown in the y-axis.

Figure 11. Kinetics of hydrogen sorption by nanocrystalline Mg₂Ni modified with palladium during mechanical alloying (room temperature, $P_{\text{H}_2} = 1.2 \text{ MPa}$, without activation). The x values in the formula Mg₂NiH_x are shown in the y-axis.

hydrogenation of Mg₂Ni was performed immediately after its mechanical milling without exposure to air (Fig. 12). Mechanical milling implies practically the same procedure as mechanical alloying except that the initial material is not a mixture of metal powders but an intermetallic compound obtained by traditional alloying. As is shown by Fig. 12, the reaction rate and the amount of absorbed hydrogen increase as the duration of mechanical

Figure 12. Kinetics of hydrogen sorption for Mg₂Ni (285 K, $P_{\text{H}_2} = 2 \text{ MPa}$) after its mechanical milling in an argon atmosphere for 30 (1), 5 (2), 1 min (3), and without milling (4). The ratio of hydrogen atoms to metal atoms in Mg₂NiH_x is shown in the y-axis.

milling is increased, which can be due to gradual dispersion of the sample and the formation of pure metal surface during this milling. However, at room temperature hydrogenation does not go to completion; the hydrogen content corresponds to the formula Mg_2NiH_x ($x \approx 2$). This might be connected with the fact that as the temperature decreases, following the formation of a hydride layer on the surface of particles, the diffusion of hydrogen through this layer, the rate of which can be small at room temperature, becomes the limiting stage. The 'diffusion retardation' occurs similarly to that observed in the hydrogenation of magnesium. Moreover, at $T < 515 \text{ K}$ Mg_2NiH_4 exists as a low-temperature modification, the structure of which is the monoclinic distortion of a cubic high-temperature modification.⁸⁵ The latter normally results from hydrogenation at temperatures above the temperature of phase transition. The explanation of this fact calls for additional studies.

III. Hydrogenation of FeTi and LaNi_5 undergoing mechanical milling

As compared to magnesium systems, LaNi_5 and FeTi are low-temperature accumulators of hydrogen. They absorb hydrogen at room temperature. However, commercial polycrystalline samples covered with oxygen-containing compounds require, as a rule, preliminary activation. For instance, the procedure for activation of FeTi consists of heating the sample in a vacuum to 673–723 K and subsequent annealing in hydrogen at a pressure of $\sim 0.7 \text{ MPa}$ followed by cooling to room temperature and increase in the hydrogen pressure to 3.5–6.5 MPa.⁸⁶ This procedure is repeated several times so that hydrogenation is reproducible.

Activation of LaNi_5 proceeds much more easily than in the case of FeTi, but this is still required and consists of a prolonged exposure of the sample at high hydrogen pressure (about 5.0 MPa) at room⁸⁷ or elevated ($\sim 623 \text{ K}$) temperatures in vacuum.⁸⁸

Mechanical milling of these intermetallic compounds in ball mills allows omission or simplification of the activation procedure. The kinetic curves of hydrogen sorption for mechanically milled FeTi are presented in Fig. 13.⁸⁴ After mechanical milling, contact of the sample with air was excluded. It is seen that in this case hydrogenation starts at the maximum rate, and the degree of conversion depends on the duration of the treatment. If the sample was exposed to air after mechanical milling and prior to hydrogenation, activation was necessary, but it occurred much more easily than for ordinary alloys: it is sufficient to heat the sample at 673 K in vacuum for 30 min.⁸⁹

If FeTi is modified with a small amount of palladium, which is added during mechanical milling, neither annealing of the sample nor preliminary exposure of the sample to hydrogen are required.

Figure 13. Kinetics of hydrogen sorption for FeTi (283 K, $P_{\text{H}_2} = 2 \text{ MPa}$) after its mechanical processing in an argon atmosphere for 24 (1), 3 h (2), 30 min (3), and without processing (4). The ratio of hydrogen atoms to metal atoms in FeTiH_x is shown in the y-axis.

This sample immediately absorbs hydrogen at room temperature.^{81, 83, 90}

Isotherms of 'pressure–composition' at room temperature without preliminary activation of samples were obtained⁹¹ for amorphous and nanocrystalline FeTi formed upon mechanical alloying. It was shown that the shape of the isotherms is very 'sensitive' to the microstructure of the samples and changes significantly after their annealing. The relaxation of structural defects and mechanical strains upon annealing leads to a decrease in the solubility of hydrogen in both cases and to a change in the length and slope of the plateau in the isotherm of nanocrystalline FeTi. The shape of the adsorption isotherm of the initial nanocrystalline powder indicates the significant contribution of an amorphous component. This fact together with the electron microscopy and WAXS data allowed the authors⁹¹ to draw the following conclusion: the microstructure of particles of nanocrystalline FeTi formed upon mechanical alloying is nanocrystallites with a highly disordered intercrystallite region; the portion of this structure in the bulk material is 20%–30%. It should be emphasised that these data give direct evidence that the degree of disorder and mechanical strains affect the character of the hydrogen absorption in the sample. During preliminary activation, which is required for hydrogenation of intermetallic compounds not doped with palladium the relaxation processes have, as a rule, already occurred, which prevents the unambiguous interpretation of the results.

Analogous kinetic data have been obtained for LaNi_5 .^{81, 83} The kinetic curves for hydrogenation of mechanically milled samples of LaNi_5 — one of which was hydrogenated immediately after mechanical milling, another was kept in air for a long period, and the third was prepared with the addition of palladium — are presented in Fig. 14.

Figure 14. Kinetics of hydrogenation of LaNi_5 milled mechanically at $T = 313 \text{ K}$ and $P_{\text{H}_2} = 1.5 \text{ MPa}$;

(1) the sample kept in air for several months; (2) the sample immediately after mechanical activation; (3) the sample modified with palladium. The x values in the formula LaNi_3H_x are shown in the y-axis.

Hence, mechanical milling of intermetallic compounds Mg_2Ni , FeTi, and LaNi_5 yields a metallic surface, on which dissociative adsorption of hydrogen occurs. However, upon contact of these samples with air the surface is rapidly oxidised and the kinetic characteristics of hydrogenation are impaired. Modification with palladium (one of the best catalysts for the dissociative adsorption of hydrogen) during mechanical milling of these intermetallic compounds allows hydrogenation to be carried out at room temperature without preliminary activation.

IV. The direct formation of hydrides during mechanical milling

The formation of metal hydrides is possible during mechanical milling.^{92–96} To this end, mechanical milling is run in a hydrogen atmosphere at elevated pressure. In this way, binary hydrides of the compositions $\text{TiH}_{1.9}$, $\text{ZrH}_{1.66}$ and MgH_2 have been prepared and characterised by WAXS analysis, differential thermal analysis, and electron microscopy.^{92–95} It is remarkable that magnesium usually absorbs hydrogen in noticeable amounts only at temperatures above 573 K, whereas hydrogenation concurrent with mechanical milling yields magnesium hydride without heating. To date it remains unclear which factor is determining in the formation of hydrides during mechanical milling in a hydrogen atmosphere. It might be crushing, plastic deformation, the formation of a fresh metal surface, local increase in temperature upon collision of grinding bodies, *etc.* Most likely, all these processes contribute to the formation of hydrides.

Mechanochemical processes are known to be non-equilibrium ones and often occur *via* metastable states. This is the case in the hydrogenation of ZrNi during its mechanical milling in a hydrogen atmosphere.⁹⁶ This process includes the stages differing from those in the traditional hydrogenation, namely, the consecutive formation of the hydride phases ZrNiH and/or ZrNiH_3 followed by their amorphisation, and then the decomposition of the amorphous phase to ZrH_2 and metastable hydride $\alpha\text{-Zr}_{1-\delta}\text{NiH}_x$. As a result, composite particles composed of amorphous ($\alpha\text{-Zr}_{1-\delta}\text{NiH}_x$) and crystalline ($\alpha\text{-ZrNiH}_3$ and/or ZrH_2) hydride phases are formed according to the hydrogen pressure used, which varies from 0.1 to 1.0 MPa. Particles resulting from mechanical processing in a hydrogen atmosphere appeared to be much smaller in size (0.5–1.0 μm at a hydrogen pressure of 1.0 MPa) than those obtained under similar conditions in an argon atmosphere (50 μm) due to the higher fragility of the hydride phases as compared to that of ZrNi .

Taking this into account, it was concluded⁹⁶ that mechanical processing in a hydrogen atmosphere can be a promising method for the creation of hydrogen-accumulating materials with a very large interface between the amorphous and crystalline phases and for the creation of hard magnets with anisotropic nanosized grains, which can be obtained by consecutive hydrogenation, amorphisation, and dehydrogenation with simultaneous crystallisation.

When mechanical milling of Mg_2Ni was carried out in a hydrogen atmosphere at a pressure of 1.0 MPa in a 'Fritsch P7' ball planetary mill at a rotation rate of 400 rev min^{-1} , the sorption of hydrogen was also detected.⁹⁷ According to the WAXS data, the samples obtained corresponded to the α -phase, a solid solution of hydrogen in the intermetallic compound $\text{Mg}_2\text{NiH}_{0.3}$. The latter is usually formed in the initial stages of hydrogenation and at higher hydrogen concentrations, the formation of Mg_2NiH_4 begins.⁹⁸ However, upon hydrogenation during mechanical milling, the amount of hydrogen absorbed exceeded significantly that corresponding to the formula $\text{Mg}_2\text{NiH}_{0.3}$. For instance, after processing for 80 h this amount achieved 1.6 mass % ($\text{Mg}_2\text{NiH}_{1.8}$) without noticeable changes in X-ray patterns. In this case, a correlation between the value of specific surface of the sample and the hydrogen content in the sample was observed (Fig. 15). The authors⁹⁷ associate this fact not only with the disintegration of the sample, but also with the formation of a nanocrystalline composite material during mechanical milling composed of crystalline particles with this phase disordered at the grain interface where hydrogen can occupy more sites than in the crystalline phase. The thickness of this disordered phase might be only several nanometers and is not observed in X-ray patterns.

In our opinion, the data given in Ref. 97 do not rule out the principal possibility for the formation of the hydride Mg_2NiH_4 during mechanical milling since the investigations were performed in a low-energy 'Fritsch P7' apparatus. Under more drastic

Figure 15. The correlation between the specific surface of the samples (s) prepared by hydrogenation of Mg_2Ni during mechanical milling and the hydrogen content in the samples.

τ / min: (1) 5, (2) 15, (3) 60, (4) 300, (5) 7800.

conditions (more powerful mills, higher hydrogen pressure), hydrogenation can occur to reach the stage of formation of the ternary hydride, which, probably, would be a metastable phase. In any case, the formation of a solid supersaturated solution of hydrogen in Mg_2Ni at the grain interface⁹⁷ indicates that the processes of traditional hydrogenation and hydrogenation during mechanical milling differ in the initial stages.

V. Conclusion

The above review of published data on the interaction between hydrogen and mechanical alloys and intermetallic compounds undergoing mechanical milling allows the following conclusions to be drawn.

Mechanical alloying is a promising method for the preparation of materials with high reactivity with respect to hydrogen.

As compared to traditional methods for the preparation of alloys and intermetallic compounds, mechanical alloying is substantially less time- and energy-consuming. There is no need for high temperatures. Depending on the apparatus design, the process of mechanical alloying takes from several minutes to several hours to yield homogeneous materials or composites with a sufficiently uniform phase distribution, while in the case of traditional alloying, as a rule, special prolonged homogenising annealing is necessary. This is especially important for obtaining alloys of metals differing considerably in their specific densities.

Mechanical alloys formed in the early stages of mechanical alloying are metastable systems with a large interface where the 'atomic' contact of metals occurs and their chemical interaction is possible. This interaction consists of both electron transfer from one element to another thus increasing the catalytic activity of the metal-catalyst and the reduction of oxides used as the second phase in magnesium systems thus creating centres of hydrogen adsorption.

A highly disordered specific structure of the MA surface with a catalyst dispersed in the form of atoms in the near-surface layer is responsible for the high hydrogenation rate in the first cycle. This structure is stable to oxygen and the operation with the sample in air does not require any special conditions.

The possibility to vary the microstructure during mechanical alloying allows the reaction rate and hydrogen capacity of MA to be varied.

The method of mechanical alloying provides a possibility to create composites from non-interacting components, which favours the synthesis of novel hydrides and IMC in the reaction of these MA with hydrogen.

Mechanochemical synthesis or mechanical processing of intermetallic compounds results in a material with nanosized particles and a pure metal surface, which excludes the necessity for its activation before hydrogenation. Despite the fact that this surface is prone to rapid oxidation, the activation of these materials after their contact with air still proceeds much more easily than that of ordinary IMC. If catalytic centres of hydrogen adsorption are created at the surface of IMC, for example, by the introduction of a small amount of palladium during mechanical alloying, high hydrogenation rates can be achieved at room temperature without preliminary activation, as in the case of Mg_2Ni , FeTi , and LaNi_5 .

Some hydrides can be formed directly during mechanical processing in a hydrogen atmosphere. In this case, due to the non-equilibrium character of mechanochemical processes, metastable hydride phases and nanocomposites can be formed, which opens up new prospects for the synthesis of novel materials.

Of course, mechanical alloying does not solve all the problems associated with the hydrogenation of metals and alloys; all the potentialities of mechanical alloying have not been exhausted. The major part of the investigations dealt with magnesium systems for which mechanical alloying is the efficient method of preparation of materials with high reactivity towards hydrogen, and which has practically no alternative in the case of immiscible components. Examination of other systems has only just started, though for these systems the possibility of solving the problem of activation by means of mechanical processing has already been shown. Studies of the synthesis of nanocomposites that could possess high reactivity and high hydrogen capacity by mechanical processing seem to be promising. Unfortunately, it should be noticed that by now the problems concerning cycling of MA and IMC milled mechanically have not been sufficiently covered in the literature; little attention has been paid to processes of dehydrogenation, etc. We hope that these problems will find their researchers in the future.

IV. Vapour pressure of water over the surface of gas hydrates in mixtures of volatile inorganic hydrides	85
V. The formation of mixed hydrates in inorganic hydrides and atmospheric air	87
VI. Conclusion	91

Abstract. The conditions of formation and structural features of gas hydrates are considered. The existing physicochemical models of formation of gas hydrates are analysed and an algorithm for calculating the parameters which influence the efficiency of gas purification is proposed. Theoretical values of dissociation pressure and water vapour pressure over the surface of mixed hydrates in mixtures of volatile inorganic hydrides are given as well as the distribution coefficients of the components between phases in the process of their formation. It is shown that the appearance of impurities in the form of gas hydrates in hydrides can markedly affect the efficiency of their refinement. The bibliography includes 43 references.

I. Introduction

The chemical nature of impurities determines their behaviour in the processes of separation and refinement of substances. In studies of suspended particles of submicro-size it was established that the transition of the same compound from the molecular to the heterogeneous form substantially alters its behaviour as an impurity in these processes. Therefore, suspended particles of submicro-size are regarded as a new class of impurities in substances of high purity. The interaction of impurity components (especially, water) with the main substance yielding donor–acceptor complexes or new chemical compounds substantially broadens the array of impurities in the substance under purification. At the same time, the appearance of a ‘new’ impurity component may be due to the formation of molecular complexes, that are bound only by van der Waals forces. Certain complexes of this kind known as gas hydrates and suspended submicro-size particles may also be attributed to a new class of impurities in ultrapure substances. It is interesting to study their structure, the formation conditions, and behaviour in the process of gas refinement. The aim of this paper is to analyse the existing physicochemical models of gas hydrate formation and to devise algorithms for calculating their parameters which affect the efficiency of gas refinement: the pressure of saturated water

vapour over the surface of hydrates and dissociation pressure as well as distribution coefficients of gas mixture components between the gas and solid phases.

Gas hydrates were first detected and given this name as early as 1810 when Davy synthesised a chlorine gas hydrate. Nikitin suggested¹ that gas hydrates are solid solutions. Several reviews and monographs have been published^{2–7} which present in detail both historical aspects and physicochemical data on gas hydrates.

At present, over 120 gas hydrates are known. Many of them have found practical uses: for example, gas hydrates of Freon 12 are applied to desalinating sea water and in the concentration of heavy water.⁸

Gas hydrates formed in gas mains can block the transportation of natural gas resulting in pipeline failures.⁵ In addition, gas hydrates can be formed in the process of purification of volatile substances under high pressure and change the solubility of the water impurity in such substances.⁹

Clathrate compounds are formed by the inclusion of one species of molecules called ‘guests’ into the cavities of a crystalline network built of molecules of another species called ‘hosts’. The term ‘inclusion compounds’ was introduced by Schlenk, and the term ‘clathrate compounds’ was proposed by Powell.¹⁰ Originally, only compounds with cellular cavities were regarded as clathrates. Nowadays, both terms are synonyms defining the compounds in question irrespective of the type of cavities. Their major difference from common chemical compounds consists in their reacting components (‘host’ and ‘guest’) being generally coordinatively saturated compounds and their interaction is, as a rule, based on van der Waals forces. Therefore, the clathration is accompanied by a slight gain of energy and plays a crucial role only when no chemical reactions take place. The crystalline lattice of the ‘host’ per se is thermodynamically unstable if it is not filled with a minimum number of gas molecules, and thus cannot exist in the ‘pure’ form. This peculiarity distinguishes it from the crystalline lattice of ice.

II. Structure of gas hydrates

All the known gas hydrates have basically one of the following structures: I, II and H. The structures I and II are characterised respectively by a cubic symmetry (space group $Pm\bar{3}n$, $Fd\bar{3}m$) and the structure H, by hexagonal (space group $P6/mmm$) symmetry. Structure H was discovered in 1987.² Some compounds possess a different structure; for example, Br_2 and Me_2O have tetragonal (space group $P4_2/mnm$) symmetry, while Me_3CNH_2 has cubic (space group $I\bar{4}3d$) symmetry.

Received 26 November 1996

Uspekhi Khimii 67 (1) 87–99 (1998); translated by V D Gorokhov

There are five fundamental types of cavities in the crystalline network of which structures I, II, and H are constructed. The basic characteristics of these cavities are presented in Table 1.

Table 1. Structural properties of clathrate hydrates.²

Parameter	Structure I	Structure II	Structure H
Space group	<i>Pm3n</i>	<i>Fd3m</i>	<i>P6/mmm</i>
Unit cell parameters / Å			
<i>a</i>	12.03	17.31	12.26
<i>c</i>	—	—	10.17
Number of water molecules per unit cell	46	136	34
Number of cavities in the unit cell with D_{mean} / Å			
7.8	2	16	3
8.7	6	0	0
9.4	0	8	0
7.8	0	0	2
10.7	0	0	1
Composition of the structure			
all cells are occupied	$M \cdot \frac{23}{4} \text{H}_2\text{O}$	$M \cdot \frac{17}{3} \text{H}_2\text{O}$	see ^a
large cells are occupied	$M \cdot \frac{23}{3} \text{H}_2\text{O}$	$M \cdot 17 \text{H}_2\text{O}$	$M \cdot 34 \text{H}_2\text{O}$

^a Structure H is stabilised only due to filling of the smallest cavities with xenon and hydrogen sulfide.

Gas molecules intercalating into structures I, II, and H differ substantially in size and shape. There is a relationship between the maximum van der Waals diameter of gas molecules and the lattice structure. Gas molecules will not occupy the cavities if their van der Waals diameter is larger than the free diameter of these cavities. The latter is roughly equal to the difference between the geometric size of the cavity indicated in Table 1 and the van der Waals diameter of the oxygen molecule (2.8 Å). For example, when the van der Waals diameter of a gas (d_g) is in the range from 4.2 to 5.5 Å, the gas hydrate with structure I is formed; when $3.8 < d_g < 4.0$ Å or $5.6 < d_g < 7.0$ Å, structure II is formed, and when $d_g = 8.2$ –8.3 Å, structure H is formed.²

Certain gas hydrates include more than one substance as their ‘guests’. If different compounds occupy cavities randomly, a mixed gas hydrate is formed. When large cavities are filled with gas molecules of large size and small cavities are occupied by those of small size, double hydrates are formed. All hydrates with structures H and II for relatively large gas molecules (> 6.8 Å) are of the double type. In such hydrates, the ‘auxiliary’ gases, xenon and hydrogen sulfide, occupy small cavities and stabilise the crystal.

III. Physicochemical models of gas hydrate formation

1. An ideal solution model

First, a model of ideal solutions has been used by van der Waals for a description of the non-stoichiometric nature of clathrate crystals.¹¹ Initially, it was used for clathrates of hydroquinone with cavities of only one type. However, the equations derived for this molecule had to be modified considerably because of the specificity of gas hydrates (the presence of cavities of different size and shape in structures I and II, crystalline lattices of water molecules, *etc.*). The modifications were first done by Barrer and Stuart¹² and then by van der Waals and Platteeuw.¹³

By assuming that only one molecule occupies each cavity, van der Waals obtained the following expression for the distribution function for an ensemble of molecules of water W and gas M forming a clathrate crystal:

$$Z = \exp\left(-\frac{F_0}{kT}\right) \sum_{N_{M_1}} \prod_{i=1}^2 \left[N_{M_i} B_{M_i} A_M \frac{N_i!}{(N_i - N_{M_i})! N_{M_i}!} \right], \quad (1)$$

where F_0 is the free energy of water molecules in an empty clathrate lattice; N_{M_1} and N_{M_2} are the numbers of gas molecules in the respective cavities; B_{M_i} is the molecular distribution function of molecules M in cavities i ; A_M is the absolute activity; and N_1 and N_2 are the numbers of large and small cavities, respectively. For Eqn (1), it is assumed that, first, F_0 is independent of the extent of cavity filling and the nature of gas M and, second, the value of B_{M_i} is the same for each cavity of the i th type and is independent of whether or not the cavity is occupied. The first condition is not strictly true for large gas molecules nor is the second condition, for strongly polarised gas molecules.

In the case of an equilibrium distribution of gas molecules M over cavities, all the known thermodynamic functions are included in Z in accordance with the following equation:

$$kT d(\ln Z) = \frac{U}{T} dT + PdV + N_M kT d(\ln A_M) - \mu_W dN_W, \quad (2)$$

where U is the internal energy, $N_M = N_{M_1} + N_{M_2}$ is the equilibrium number of intercalated gas molecules with activity A_M , μ_W is the chemical potential and N_W is the number of water molecules in the clathrate lattice.

Using the method of molecular dynamics, Rodger has attempted to establish how far the assumptions underlying the cellular theory of gas hydrates are valid.¹⁴ It was shown that one of the approximations, according to which the free energy of the ‘water crystal’ is independent of the presence of ‘guest’ molecules in the cell structure, does not hold for gas hydrates. Analysis of the results obtained suggested that the conditions of gas hydrate formation may equally depend on kinetic and thermodynamic factors.

Disregarding the kinetic factors, Eqns (1) and (2) may be transformed to yield an expression for the determination of the chemical potential of water molecules in the equilibrium distribution of ‘guest’ molecules over the cavities of a gas hydrate:^{12, 13}

$$\mu_W = \mu_W^0 + kT \sum_i n_i \ln(1 - Q_i), \quad (3)$$

where μ_W^0 is the chemical potential of an empty hydrate lattice, n_i is the ratio of the number of i -type cavities in the elementary cell to the number of its constituent water molecules, Q_i is the fraction of gas-filled cavities calculated using the known Langmuir formula:

$$Q_i = \frac{C_{M_i} f_M}{1 + C_{M_i} f_M}, \quad (4)$$

where, C_{M_i} are the Langmuir coefficients depending on temperature and pressure (the latter dependence is very weak), f_M is the gas fugacity.

It was shown¹⁵ that one should take into account the fugacity of gas molecules in calculations. Sufficient accuracy in the calculation of this parameter is achieved using the Redlich–Quong equation.

Equation (3) makes it possible to determine the minimum value of the fraction of filled cavities, and in combination with Eqn (4), it allows the estimation of the minimum pressure of gas M (dissociation pressure P_{dis}) necessary for the hydrate stabilisation at a given temperature.

The results of studies^{16–18} demonstrate that there is also a maximum pressure under which gas hydrates may exist in a steady state (15 000–20 000 atm). With hydrates of tetrahydrofuran and SF₆ as examples it was shown¹⁸ that at 77 K and 10 000–20 000 atm they are transformed to a denser modification with a 19% decrease in volume.

Barrer and Stuart¹² have derived an expression for the determination of the saturated vapour pressure over the surface of gas hydrate for the case of thermodynamic equilibrium of a gas hydrate with water vapour:

$$P_W = P_W^0 - \sum_i n_i \ln(1 + C_{M_i} f_i), \quad (5)$$

where P_W^0 is the saturated vapour pressure (dependent on temperature and the structural type) over an empty clathrate lattice. Using the experimental data for the most thoroughly studied hydrates of methane (structure I) and propane (structure II), the authors of Ref. 19 showed that the dependence $P_W^{0(I,II)}$ is satisfactorily (with an error of $\sim 3.5\%$) described by two three-membered equations for the temperature range 260–290 K

$$\ln P_W^{0(I)} P = -128.0009 + 22.0937 \ln T - \frac{193.6439}{T}, \quad (6)$$

$$\ln P_W^{0(II)} P = -111.0433 + 20.2241 \ln T - \frac{690.3979}{T}. \quad (7)$$

Thus, if the Langmuir coefficients are known, Eqns (5)–(7) permit us to calculate the pressure (or fugacity) of gas hydrate dissociation or the saturated water vapour pressure above its surface.

In recent years, more accurate models for the thermodynamic description of gas hydrates have been developed.^{7,10} It has been shown that the most important factors to be taken into account in the construction of such models are the interactions of intercalated molecules (interaction of a ‘guest–guest’ type). The refinement of a thermodynamic description of gas hydrates is made in a way analogous to that used in the theory of solutions when a model of a regular solution is considered instead of a model of an ideal solution. The model thus obtained is called the ‘regular clathrate model’. It should be emphasised that at higher degrees of filling of cavities in the hydrate network and similarity of parameters characterising the ‘guest–guest’ interactions for different gases (*e.g.*, in narrow groups of gas mixtures such as natural gas, hydrides, *etc.*), their contributions to the formulae describing the interaction of intercalated molecules are virtually constant and independent of the gas phase composition. In this case, the ‘guest–guest’ interaction may formally be included in μ_0 (Ref. 7). It is for this reason that the possibilities of practical application of the ideal gas hydrate model are noticeably extended. Therefore, this paper discusses in sufficient detail the model of an ideal gas hydrate rather than a model of a regular clathrate, which is more complex and cumbersome for practical calculations.

2. Calculation of Langmuir coefficients

In order to determine the Langmuir coefficients, van der Waals and Platteeuw²⁰ used a spherical cell model. By substituting the mean cavity radius R_i formed by Z_i water molecules for the mean cell radius formed by the neighbouring molecules in liquid, these authors obtained the equation

$$C_{M_i} = \frac{4\pi}{kT} \int_0^{R_i} \exp\left(-\frac{W(r)}{kT}\right) r^2 dr, \quad (8)$$

where $W(r)$ is the radial potential function derived using the interaction potential of the gas molecules with the surrounding water molecules and r is the radial distance of the intercalated gas molecule from the cavity centre.

The energy of gas–water interaction is usually determined by the Lennard-Jones potential. The interaction between gas molecules in the hydrate cavities may be disregarded, as it is insignificant compared to the gas–water interaction and the accuracy of its determination is low (20%–40%).²¹

Calculations of the dissociation pressure by Eqns (3) and (8) using Kihara’s potential (*e.g.*, in studies^{22,23} for methane, nitrogen, ethane, and propane) agree well with the experimental values

of dissociation pressure of the corresponding gas hydrates. As regards the parameters of Kihara’s potential, preference was given to those values which gave the best fit of the μ_W values calculated by Eqns (3) and (4) and found in experiments. The model for calculating the Langmuir coefficients was further improved in studies^{24–27} to allow a more adequate description of experimental data.

To calculate the Langmuir coefficients of a spherical gas molecule in a real non-spherical hydrate cavity, the following equation was proposed:²⁴

$$C_{M_i} = \frac{1}{kT} \int_0^{2\pi} \int_0^\pi \int_0^{R_i} \exp\left(-\frac{W}{kT}\right) r^2 \sin \theta dr d\theta d\varphi, \quad (9)$$

where $W = W(r, \theta, \varphi)$ is the interaction potential in the cavity. To estimate it, the spherical Kihara potential was used, because this potential is believed to permit a better prediction of hydrate equilibria than other potentials do.^{24,25} Kihara’s potential has the following form:

$$F(x) = \infty \quad \text{at } x < 2a, \\ F(x) = 4\epsilon \left[\left(\frac{\sigma}{x-2a} \right)^{12} - \left(\frac{\sigma}{x-2a} \right)^6 \right] \quad \text{at } x > 2a, \quad (10)$$

where $F(x)$ is the potential energy of a binary interaction for a distance x between the water and gas molecules, ϵ is the potential well depth, σ is the distance between molecular centres for which $F(x) = 0$ and a is the nuclear radius of interaction between water and gas molecules. When the distribution of cavity-forming water molecules is known, the summation of binary interactions of a gas molecule with each water molecule allows the estimation of the interaction potential in the cavity $W(r, \theta, \varphi)$ for selected coordinates of the gas molecule.

The spherically symmetrical, smoothed potential derived from the cell model, $\langle W(r) \rangle$, is expressed through Kihara’s parameters in the following manner:

$$\langle W(r) \rangle = 2Ze \left[\frac{\sigma^{12}}{R^{11}r} \left(B^{10} + \frac{a}{R} B^{11} \right) - \frac{\sigma^6}{R^5 r} \left(B^4 + \frac{a}{R} B^5 \right) \right], \quad (11)$$

where Z is the coordination number and R is the radius of the cavity.

$$B^n = \frac{1}{n} \left[\left(1 - \frac{r}{R} - \frac{a}{R} \right)^{-n} - \left(1 + \frac{r}{R} - \frac{a}{R} \right)^{-n} \right],$$

n is 4, 5, 10 and 11.

By comparing the results of calculations using Eqns (9), (10), and (11), the radius and coordination number were determined for each cavity,²⁴ which allow the use of $\langle W(r) \rangle$ for the approximation of the interaction potential in a cavity for all distances at which the potential is negative or ‘slightly positive’. In this case, the coordination number of an equivalent spherical cavity is not necessarily equal to the real coordination number of the cavity (Table 2).

The effects of the second and third layers of water molecules in the hydrate lattice on the accuracy of calculation of Langmuir constants were studied.²⁵ It is assumed that the binary interaction between a gas and a water molecule is described by the quasi-spherical Kihara potential (10). The characteristics of smoothed potential in the form of Eqn (11) were obtained, as before,²³ by comparing the results of calculations by Eqn (11) with the results of the summation of the binary interactions. The data reported in Ref. 28 on the distribution of water molecules in a hydrate cell were used for the estimation of the effects of the second and third levels of water molecules. When the effective radius and coordination number of the second and third levels of water molecules were introduced, it was assumed that the gas and water molecules interact only due to the attractive forces. To determine the effective radius of the second level (R_{2i}), the following expression was used:

Table 2. Effective radii of shells of water molecules for various types of cavities in gas hydrates.

Cavity	First shell ²²		First shell ²³		Second shell		Third shell	
	$R_i, \text{\AA}$	Z	$R_i, \text{\AA}$	Z	$R_i, \text{\AA}$	Z	$R_i, \text{\AA}$	Z
Structure I								
Small cavity	3.95	20	3.875	20	6.593	20	8.056	50
Large cavity	4.3	24	4.152	21	7.078	24	8.285	50
Structure II								
Small cavity	3.91	20	3.870	20	6.667	20	8.079	50
Large cavity	4.73	28	4.703	28	7.464	28	8.782	50

$$\frac{Z}{(R_{2i})^6} = \sum_j \frac{Z_j}{(r_j)^6}, \quad (12)$$

where Z_j is the number of the second level molecules at the distance r_j from the cavity centre. The effective radius of water molecules at the third level R_{3i} was determined similarly. However, whereas the second layer of water molecules may be correctly described using the crystallographic data, it is not always possible to distinguish the third and subsequent layers. Therefore, the contribution from the third level is determined by those from the subsequent layers of water molecules. The results of calculation of the effective radius for the second and third layers are presented in Table 2. The calculation of the smoothed interaction potential between gas and water molecules by Eqn (11) for the three water layers has shown²⁵ that although the contributions from the molecules of more distant layers are small compared to that of the first-layer molecules and make up only a few percent, nonetheless their consideration leads to a nearly tenfold increase in the Langmuir constant. Consequently, accurate calculation of the Langmuir constants requires consideration of no less than three layers of water molecules.²⁵

To make it possible to use the parameters of Kihara's potential obtained by independent calculations based on the data on viscosity and the second virial coefficient in Eqn (11), it was proposed^{26,27} to introduce a correction factor into Eqn (8) to account for the irregularity of the shape of gas molecules and the cavity. To this end, it was proposed to calculate the Langmuir constant by the following equation:

$$C_0 = CQ, \quad (13)$$

$$Q = \exp \left\{ -A_0 \left[U \left(\frac{\sigma}{R-a} \right) \frac{\varepsilon}{rT} \right]^n \right\}, \quad (14)$$

where C is calculated by Eqn (8), A_0 and n are empirical constants depending on the cavity type, and U is the empirical parameter taking into account the shape of the gas molecules. For small and spherical molecules, $U = 0$. The largest deviation of the coefficient Q from 1 is observed for the gas molecules localised in large cavities of structure I, which are the most asymmetrical. The results of calculations of the dissociation pressure for a number of substances based on the above model agree well with the reported experimental data.^{26,27} The Q value may also be larger than 1. Relatively high Q values are observed for small Langmuir constants (for large gas molecules). This may be explained by strong fluctuations of the cell potential $W(r, \theta, \varphi)$.²⁶

The method of molecular dynamics was used²⁹ to study the potential field in a small cavity of type I gas hydrate. The thermal motion of 'host' molecules of the lattice was found to change the natural potential in the cavity and to result in its substantial anisotropy and temperature dependence. An equation for the potential in the form of a polynomial of the sixth power was proposed and its parameters were determined for methane. It was shown that Kihara's potential may also be applied using the dependence of parameters a and R on angles θ and φ . The form of these dependences can be determined from the results of simulation by the method of molecular dynamics.

Thus, a system of Eqns (8), (11), (13), and (14) makes it possible to calculate the Langmuir constants necessary for determination of the conditions for the existence of gas hydrates by the Eqns (3)–(5).

3. Calculation of gas hydrate parameters for argon, krypton and xenon

Using the model of ideal solutions for the calculation of the conditions for the existence of gas hydrates and the spherical cell model for the determination of the Langmuir constants, an algorithm for the computation of parameters of gas hydrates in the separation and refinement of gases was derived and the corresponding programs for an IBM PC were developed.³⁰

To check the applicability of Eqns (8) and (11)–(14) for the determination of the Langmuir constants, these were calculated³⁰ for the gas hydrates of argon, krypton, and xenon because of the availability of experimental data on these compounds.³¹

The calculation of the Langmuir constants within the framework of the above model requires that the parameters of Kihara's potential for the substances under study be known. The literature data on these parameters are contradictory; in some cases, the discrepancy reaches 50%–100%. The authors of Ref. 32 have used the parameters of Kihara's potential reported in Ref. 27, whereas in another study,³¹ double hydrates were used for the experimental determination of the Langmuir constants. In the latter work, the absorption of the above-mentioned gases in structure II of CHCl_3 hydrate under different gas pressures was investigated. All large cavities were occupied by CHCl_3 , while the inert gas filled the small cavities. The linear dependence obtained between the pressure and the volume of the gas absorbed confirmed once again the applicability of the Langmuir isotherm. Figure 1 shows the plots of the dependence of the logarithm of the Langmuir constant for argon, krypton, and xenon on $1/T$. All the

Figure 1. The temperature dependence of the Langmuir constants for argon (1), krypton (2), and xenon (3). The solid line corresponds to the theoretical calculations, the points represent the experimental data.

dependences proved to be linear thus allowing the determination of the enthalpy of dissociation for each gas in 12 water cavities, and the results obtained coincided with the theoretical data.³¹ Figure 1 also shows the results of calculations based on the above model. However, the parameters of Kihara's potential differ from those reported²⁷ (Table 3) by the magnitude of the error of their determination (5%–7%). The use of accurate ε and σ values results in underestimation of the Langmuir constants for krypton and xenon by more than an order of magnitude.

To check the applicability of Eqns (5)–(7) for the calculation

Table 3. Parameters of Kihara's potential used to calculate the Langmuir constants.

$a/\text{\AA}$	<u>0.217</u> 0.217	<u>0.232</u> 0.217	<u>0.252</u> 0.252

Note. Numbers above the line are potential parameters given in Ref. 26, those below the stroke are parameters used by us. For all gases in all cases we assumed $U = 0$.

of the vapour pressure of water above the surface of hydrates, calculations were performed³⁰ for the hydrates of the same inert gases under their dissociation pressure. As follows from the above-mentioned theory of gas hydrate formation, under the pressure of hydrate dissociation, the pressure of water vapour above its surface is equal to that above the ice surface at the same temperature. For example, at 273 K the pressure of water vapour calculated by the algorithm mentioned is 0.54, 0.53, and 0.57 kPa for argon, krypton, and xenon, respectively. The literature data value for the same parameter for ice is 0.6 kPa,³² i.e. fairly good agreement is observed between the theoretical and experimental results.

Thus, the theoretical model of gas hydrate formation allows an accurate calculation of the dissociation pressure of a hydrate-forming gas and the minimum content of water at which the formation of hydrates is still possible. In the refinement of some substances, e.g., Freons and volatile inorganic compounds capable of forming gas hydrates in the vapour phase, their effect on the efficiency of this process may be substantial.^{33–36}

IV. Vapour pressure of water over the surface of gas hydrates in mixtures of volatile inorganic hydrides

In volatile inorganic hydrides, the content of water and some other impurities should not exceed a certain level. Demands for higher purity of substances and a larger set of impurities to be controlled make it necessary to consider the possible presence of different forms of water.

Under elevated pressures, the impurity of water can form finely dispersed, solid gas hydrates with some volatile inorganic hydrides.¹⁵ The presence of gas hydrates in the vapour phase may lead to incorrect determination of the water concentration in a given gas.³⁴

Using the algorithm for the calculation of the parameters of gas hydrates,³⁰ the pressure of water vapour above the surface of methane and hydrogen sulfide hydrates for different temperatures and gas pressures was calculated³⁴ (Table 4). For these compounds, the temperature dependences of dissociation pressure of

gas hydrates and the parameters of Kihara's potential have been studied in sufficient detail.²⁷

Analogous calculations for other hydrides are problematic due to the absence of the respective parameters of Kihara's potential. Therefore, the Lennard-Jones potential was used³⁴ to calculate the Langmuir constants by Eqn (4).

To check the applicability of the Lennard-Jones potential for this purpose, the Langmuir constants were calculated for the gas hydrates of argon, krypton, and xenon, because the experimental values of the constants are known.² The parameters of the Lennard-Jones potential necessary for such calculations are presented in Table 5. The use of literature values of ε and σ leads to the underestimation of the Langmuir constants for all gases by more than one order of magnitude. Therefore, to calculate the Langmuir constants, preference was given to the values of ε and σ , which are within the range of their error estimates. For water, the following parameters were used: $\varepsilon_{\text{W}}/k = 102.1$ K, $\sigma_{\text{W}} = 3.564$ \AA.²⁷ When calculating ε and σ for the cases of cross-interaction of water molecules with molecules of hydrides, the Lorentz–Berthelot rule was used:³⁴

$$\varepsilon_0 = (\varepsilon_{\text{W}}\varepsilon)^{1/2}; \sigma_0 = \frac{1}{2}(\sigma_{\text{W}} + \sigma),$$

where ε_0 and σ_0 are parameters describing the gas–water interaction.

Analogous formulae were also used for the calculation of the vapour pressure of water above the surface of hydrates of some volatile inorganic hydrides. The results of calculations for gas hydrates of arsine, hydrogen selenide, and phosphine, as well as methane, characterised by structure I are given in Table 4 as examples.³⁴ Comparison of the results of calculations for hydrogen sulfide and methane shows that the deviation of values derived using the interaction potentials of Kihara and Lennard-Jones does not exceed 10%. The percentage of water in gas given in the table, which is equal to the ratio of water vapour and gas pressures, determines the minimum content of water in the molecular form at which the formation of gas hydrates is possible under given conditions. If the concentration of molecular water exceeds the indicated value, it is decreased owing to the formation of hydrates and tends to reach the level given in the table. Consequently, the given value of water concentration determines the maximum concentration of water in the molecular form for specified conditions.

The results of calculations presented in the tables indicate that if one disregards the formation of hydrates and takes into account only the condensation of water to form ice, then the value of the vapour pressure of water and hence the concentration of molecular water may be overestimated by a factor of 1.5 or more. With a decrease in temperature, the ratio of the vapour pressure of water above the ice surface to that of gas hydrate increases (Table 6) with a concomitant increase in the scatter of values of this parameter for different hydrides (except for arsine and hydrogen sulfide), which becomes significant at temperatures below 273 K. It seems so far impossible to calculate this parameter for a wider temperature range since the required initial data are unavailable. Nonetheless, this parameter may be estimated using the equations given in Ref. 34 by approximating the data shown in Table 6 by the least-squares method.

For arsine and hydrogen sulfide at $T < 273$ K

$$\ln\left(\frac{P_2}{P_1}\right) = \frac{189.1}{T} - 0.328, \quad (15)$$

for phosphine at $T < 273$ K

$$\ln\left(\frac{P_2}{P_1}\right) = \frac{613.4}{T} - 1.879, \quad (16)$$

for hydrogen selenide at $T < 273$ K

$$\ln\left(\frac{P_2}{P_1}\right) = -\frac{49.5}{T} + 0.587, \quad (17)$$

Table 4. Results of the calculations of water vapour pressure over the surface of various hydrates.

294	1.08	1.11	1.16	1.11

for all hydrides at $T > 273$ K

$$\ln\left(\frac{P_2}{P_1}\right) = \frac{940.6}{T} - 3.089, \quad (18)$$

where P_1 and P_2 are the pressures of water vapour above the gas hydrate surface at the pressure of saturated hydride vapour and at the pressure of dissociation, respectively. Thus, for phosphine at 200 K, this parameter and hence the ratio of the real concentration to its theoretical value is 3.28.

In addition, the presence of water in the form of a finely dispersed phase requires the use of an appropriate purification technique. Specifically, this concerns the formation of double or mixed hydrates, when other hydrides or gases may be intercalated as impurities into the crystalline lattice of gas hydrates.

Thus, the above data indicate that the appearance of impurities in hydrides in the form of gas hydrates can substantially affect the process of their refinement.

V. The formation of mixed hydrates in inorganic hydrides and atmospheric air

A large contribution to the development of theory and experimental techniques for studying mixed gas hydrates was made by Nikitin¹ who proposed and developed a method of isomorphous co-precipitation in mixed hydrates of rare components from the gas phase irrespective of their concentration. It was shown that there is no need to apply high pressures to form gas hydrates of a large number of gases, since the gas in question under a partial pressure lower than the pressure of its hydrate dissociation, can form a gas hydrate in the form of an isomorphous mixture with hydrates of other gases. Based on the results obtained and general theoretical concepts, Nikitin formulated the ‘analogy rule’, according to which two substances having the same van der Waals forces and commensurable molecules should form with a third substance analogous molecular compounds possessing similar stability and the ability to form mixed crystals with each other.

Thus, taking into account the ‘analogy rule’ and the law of isomorphous co-precipitation, it may be inferred that a mixed hydrate can contain different quantities of the all gas phase components that can form isomorphous structures.

Let us consider the methods employed for the quantitative assessment of the conditions for formation of mixed gas hydrates.

1. The effect of gas mixture composition on conditions of gas hydrate formation and vapour pressure of water above its surface

One of the critical parameters characterising the process of gas hydrate formation at a given temperature is its dissociation pressure P_{dis} . The dissociation pressure determines the minimum pressure of a gas mixture at which the hydrate is thermodynamically stable. To carry out processes of refinement of substances that form gas hydrates, one should know the dependence of the dissociation pressure of gas hydrates and the vapour pressure of water over their surface on the composition of gas mixture. This dependence may be determined using the model proposed by Barrer and Stuart.¹²

The application of the model of ideal solutions for the case of thermodynamic equilibrium yielded an equation for the calculation of the pressure of saturated water vapour over the surface of a gas hydrate formed by a mixture of gases $M_1, M_2, \dots, M_i$.¹²

$$\ln\left(\frac{P_W}{P_W^0}\right) = \frac{1}{m(n+1)} \left[n \ln\left(1 - \sum_i Q_{1i}\right) + \ln\left(1 - \sum_i Q_{2i}\right) \right], \quad (19)$$

where P_W is the pressure of saturated vapour over the hydrate surface; P_W^0 is the pressure of saturated vapour above an empty clathrate lattice (which depends on the structural type and temperature; these may be found in Ref. 32); m is the number of water molecules per cavity; n is the ratio of large-to-small cavities in the elementary crystalline hydrate cell ($n = 3, m = 5.75$ for structure I hydrates and $n = 2$ and $m = 5.67$ for structure II hydrates³²); Q_{1i} and Q_{2i} are the fractions of small and large cavities filled with gas M_i .

The filling of cavities in gas hydrates is well described by the Langmuir adsorption isotherm:¹⁵

$$Q_{ji} = \frac{C_{ij}f_i}{1 + \sum_i C_{ij}f_i}, \quad (20)$$

where $f_i = \phi_i P_i$ is the fugacity of gas M_i , ϕ_i is the fugacity coefficient, P_i is its pressure and C_{ij} are the Langmuir coefficients calculated using the spherical cell model.³²

The model used for calculating the fraction of filled cavities in mixed gas hydrates describes well the experimentally found (most probably, derived in an indirect way)⁵ compositions of equilibrium phases formed by hydrates of natural gas (Table 7).

Table 7. Composition of the equilibrium phases formed by natural gas ($T = 269.5$ K; $P = 4150$, $P_W^h = 0.455$, $P_W^h = 0.367$ kPa).

^a Found experimentally.

Since an empty hydrate lattice cannot be formed directly from water or ice, the following relation² is valid: $P_W^0 > P_W^{l,s}$, where $P_W^{l,s}$ is the pressure of saturated water vapour above the surface of liquid (l) or ice (s). It follows from Eqn (19) that the intercalation of the gas forming the hydrate into the hydrate lattice cavities reduces the pressure of water vapour above the hydrate surface. As soon as it becomes equal to or lower than $P_W^{l,s}$, crystalline lattice formation becomes possible. Thus, the dissociation pressure is determined from the condition

$$P_W = P_W^{l,s}. \quad (21)$$

By substituting (19) and (20) into (21), one obtains an expression for the calculation of the dissociation pressure:³⁵

$$\ln\left(\frac{P_W^{l,s}}{P_W^0}\right) = \frac{1}{m(n+1)} \left[n \ln\left(1 + \sum_i C_{li}f_i\right) + \ln\left(1 + \sum_i C_{2i}f_i\right) \right]. \quad (22)$$

Equation (22) was solved for the dissociation pressure by numerical methods on a PC. The computations were performed for gas mixtures of different composition containing hydrides of arsenic, phosphorus, sulfur, and selenium, as well as krypton at different temperatures of hydrate formation. In the calculations by Eqn (22), it was assumed that $P_W^{l,s} = 2.52$ kPa at $T = 294$ K and $P_W^{l,s} = 0.092$ kPa at $T = 252$ K.³² The results of calculations are presented in Fig. 2.

As is seen from the Figures showing a ternary gas mixture (two hydrides and water), in all cases when values of P_{dis} of individual components are different, the dissociation pressure depends substantially on the fraction of the main substance and the temperature of hydrate formation. With the decrease in the amount of the main component, P_{dis} varies monotonically from the value of dissociation pressure of a pure major component to that of a pure component, which serves as an impurity (Fig. 2a, curves 1–4; Fig. 2b, curve 1).

For four-component systems, the content of the second component was arbitrarily taken to be equal to 10% of that of the main substance, and this ratio was maintained constant. The portion of the major component varied in the same way as in the case of ternary systems, though at the expense of the fourth component. The character of changes in the dissociation pressure was analogous to that in the first case, though at definite ratios of concentrations of the second and the fourth components (this ratio varies for different systems and depends on the temperature and P_{dis} of each component) extrema may appear in the curve of dependence of P_{dis} on composition (Fig. 2a, curve 2).

Figure 2. Dissociation pressure of gas hydrates vs. concentration of the main component of a gas mixture for different systems at 252 K (a) and 294 K (b).

(a): (1) $H_2S + H_2Se + H_2O$; (2) $H_2S + H_2Se + H_2O + Kr$; (3) $AsH_3 + PH_3 + H_2O + Kr$; (4) $AsH_3 + PH_3 + H_2O$;
(b): (1) $H_2S + H_2Se + H_2O$; (2) $H_2S + H_2Se + H_2O + Kr$.

Thus, the presence in a gas mixture of components with lower and higher values of dissociation pressure than that of the main substance under purification may substantially alter the conditions of formation of hydrates and in some cases prevent their formation in the process of purification.

The maximum concentration of water in a gas mixture containing gas hydrates is determined by the pressure of saturated water vapour above the hydrate surface.³⁴ Let us consider the influence of gas mixture composition on the pressure of water vapour above the surface of a gas hydrate.

Under real conditions, the composition of a gas mixture changes due to changes in the partial pressures of its components.^{33, 35, 36}

Let us consider first a ternary gas system comprising two hydrides and water. The variation of partial pressures occurs in the following manner:^{35, 36} first, the pressure of a major component, equal to the pressure of its saturated vapour at a given temperature, is assumed to be constant, while the partial pressure of an impurity component increases from zero to a maximum value equal to the pressure of its saturated vapour at this temperature. After the maximum partial pressure of impurity is reached, further decrease in the proportion of the major substance is possible only owing to the reduction of its partial pressure. In this situation, the pressure of the impurity component is maintained constant. As a result, the total pressure of the gas mixture first increases and then decreases. The vapour pressures of water above the hydrate surface calculated for this case by Eqn (19) are presented in Fig. 3.³⁶

Figure 3. Pressure of water vapour above the surface of gas hydrates vs. concentration of the main component of a gas mixture at 252 K (a) and 273 K (b).

(a): (1) $AsH_3 + PH_3 + H_2O$; (2) $AsH_3 + PH_3 + H_2O + Kr$; (3) $H_2S + H_2Se + H_2O$; (4) $H_2S + H_2Se + H_2O + Kr$;
(b): (1) $AsH_3 + PH_3 + H_2O$; (2) $AsH_3 + PH_3 + H_2O + Kr$; (3) $H_2S + H_2Se + H_2O$; (4) $H_2S + H_2Se + H_2O + Kr$.

As seen from the Figures, there is a minimum in P_W corresponding to the maximum value of the total pressure of the gas mixture. This is due to the maximum filling of hydrate cavities by gas molecules resulting in higher stability of the clathrate lattice and a lower pressure of water vapour above its surface.

In the calculations of four-component systems, the content of the second component was also arbitrarily assumed to be equal to 10% of the content of the main substance (see above), and this ratio was maintained constant.³⁵ As the temperature of the gas mixture was higher than the critical temperature of the fourth component (krypton), the total pressure increased monotonically with the decrease in the level of the major component, and the vapour pressure of water over the surface of mixed hydrate was substantially decreased (Figs 3 *a* and 3 *b*, curves 2 and 4).

Thus, the increase in the pressure of a gas mixture due to the addition to it of a component which does not condense at a given temperature, allows a significant decrease in the content of molecular water in the gas mixture.

2. Distribution coefficients of constituent molecules of a gas mixture in the cavities of mixed hydrates

In the process of separation and refinement of multicomponent systems $M_1, M_2, \dots, M_i$, mixed hydrates may be formed at appropriate temperatures and pressures. This is accompanied by redistribution of gas mixture components between the gas hydrate and the gas mixture. The gas hydrate (or the gas mixture) is enriched or depleted in one or several components because of differences in the composition of equilibrium phases: gas phase and solid phase (on an anhydrous base).³⁰ In order to estimate the purification efficiency, it is necessary to know the composition of gas hydrates, which is determined by distribution of molecules of the major substance and impurities in the cavities.

The distribution of the hydrate-forming molecules in the cavities of a gas hydrate is characterised by the distribution coefficient^{33, 36}

$$K_i = \frac{Q_i P_s}{P_i \sum_i Q_i}, \quad (23)$$

where Q_i is the fraction of hydrate cavities filled with molecules M_i , P_s is the total pressure of the gas mixture, and P_i is the partial pressure of M_i molecules in the gas phase.

The fraction of filled cavities is determined from the Langmuir isotherm [Eqn (20)]. If n_j is the fraction of type j cavities in the gas hydrate, then

$$Q_i = \sum_j n_j Q_{ij}. \quad (24)$$

To characterise the redistribution of gas mixture components upon formation of gas hydrates, it is convenient to use the relative distribution coefficient^{33, 36}

$$K_{i1} = \frac{K_i}{K_1}, \quad (25)$$

where the mixture component with $i = 1$ is arbitrarily assumed to be the major substance (the one to be purified).

By substituting Eqn (23) into Eqn (25) the following relation is obtained:

$$K_{i1} = \frac{Q_i P_1}{Q_1 P_i}. \quad (26)$$

The relative distribution coefficient makes it possible to assess whether the gas hydrate will be enriched (when $K_{i1} > 1$) or depleted (when $K_{i1} < 1$) in impurities from the substance subject to purification. It follows from Eqns (24) and (26) that the relative distribution coefficient may substantially depend on the conditions of hydrate formation and the impurity concentration in the gas mixture.

The dependences of relative distribution coefficient on the conditions of gas hydrate formation were studied³⁶ in mixtures containing inorganic hydrides of arsenic, sulfur, selenium, phosphorus and antimony, as well as methane and nitrogen.

Under real conditions, the composition of a gas mixture changes as a result of changes in the partial pressures of the components of a mixture.

Let us consider first a ternary gas mixture containing two hydrides and water. In the temperature range studied (250–290 K), the pressure of water vapour is negligible in comparison with the total pressure of the gases³⁴ and hence may be disregarded. Thus, the total gas pressure is determined by the partial pressures of the hydrides. If the partial pressure of the major component (equal to the pressure of its saturated vapour at a given temperature) is assumed to be constant, then the decrease of its fraction in the mixture may occur at the expense of an increase in the partial pressure of the impurity component, up to its maximum level (equal to the pressure of its saturated vapour at a given temperature). This results in an increase in the total pressure of the gas mixture. The increase in the partial pressure of impurity above its maximum level leads to condensation of the impurity component. Thus, further decrease in the fraction of the major substance is possible only at the expense of a decrease in its partial pressure, the pressure of the impurity component being maintained constant. This results in the reduction of the total pressure of the gas mixture. The relative distribution coefficients calculated for this case by Eqn (26) are presented in Fig. 4 *a, b*. The

Figure 4. Relative distribution coefficient vs. concentration of principal (*I*) and the second (*II*) components of gas mixture for the systems: $\text{AsH}_3 + \text{PH}_3 + \text{H}_2\text{O}$ (*a*), $\text{H}_2\text{S} + \text{H}_2\text{Se} + \text{H}_2\text{O}$ (*b*), $\text{AsH}_3 + \text{CH}_4 + \text{H}_2\text{O} + \text{PH}_3$ (*c*) at 252 K (*I*), 273 K (*2*) and 294 K (*3*).

Langmuir constants, which are required for the determination of the fraction of the cavities filled from Eqn (20), were calculated using the spherical cell model.³²

As is seen from these figures, in all cases the relative distribution coefficient depends substantially on the fraction of the main substance. This is due to the fact that changes in the partial pressures (fugacity) of the components of the gas mixture result in redistribution of molecules of different gases between the gas hydrate cavities according to Eqn (20). The presence of extrema in curves 1–3 shown in Fig. 4a and inflection points in all curves of Fig. 4b may be explained by non-monotonic changes in the fugacity of the components of the mixture upon the non-monotonic changes in the total pressure of the gas mixture.³⁷ Incidentally, depending on the fraction of the components of the mixture, the relative distribution coefficient of the second component may be either > 1 , *i.e.* the hydrates accumulate predominantly the impurity from the substance subject to purification, or < 1 , *i.e.* the hydrates accumulate mostly the major substance.

In calculations of four-component systems, the content of the second component was arbitrarily assumed to be equal to 10% of that of the main substance, and this proportion was maintained constant. The fraction of the main component varied in the same manner as in the case of ternary systems, though at the expense of changes in the concentration of the fourth component. If the temperature of the gas mixture is below the critical temperature of the third component, then the total pressure is first increased and then decreased as the fraction of the main component is increased. This leads to the formation of extrema in curves 1–3 (Fig. 4c). If the temperature of the gas mixture is above the critical temperature of the fourth component, the total pressure of the mixture grows monotonically with the decrease in the fraction of the main component. In this case, the relative distribution coefficient of the second component changes monotonically (Fig. 4a, curves II). Figure 4a shows that in this case, too, K_{21} may be either > 1 or < 1 , depending on the fractions of the gas mixture components.

If the total pressure of the gas mixture remains invariant despite changes in its composition, the partial pressure of each component is subject to variation. Then, the dependence of the relative distribution coefficient of the second component on the fraction of the main component in the gas phase is virtually linear for different mixture compositions and conditions of hydrate formation (Fig. 5).

Figure 5. Relative distribution coefficient *vs.* concentration of the main component of a gas mixture for the systems: $\text{H}_2\text{S} + \text{H}_2\text{Se} + \text{H}_2\text{O}$ (a), $\text{AsH}_3 + \text{SbH}_3 + \text{H}_2\text{O} + \text{PH}_3$ (b, 1, 2), and $\text{AsH}_3 + \text{SbH}_3 + \text{H}_2\text{O}$ (b, 3, 4).

(a)	1	2	3	(b)	1	2	3	4
T/K	294	252	294	T/K	294	252	294	252
P_s/kPa	930	230	150	P_s/kPa	1520	500	1520	500

The above data indicate that under the same conditions of hydrate formation the relative distribution coefficient depends substantially on the ratio of components in gas mixtures, and in some cases it may differ greatly from unity (see, *e.g.*, Fig. 4b). Hence, substantial enrichment or depletion of the main component in the impurities present may already occur at the stage of hydrate formation. Separation of gas hydrates from the gas mixture allows additional purification of the main substance or air–gas mixtures.

3. Concentration of technogenic impurities in atmospheric gas hydrates

The atmosphere continuously receives strong fluxes of gases containing deleterious compounds, such as sulfur and carbon dioxides, carbon and nitrogen monoxides, chlorinated organic compounds, *etc.* Such noxious compounds are released by natural and industrial sources. Nowadays, the natural and anthropogenic fluxes are commensurable, though in some instances the latter may dominate.⁴⁰ Such compounds are either uniformly dispersed in space or concentrated on some carriers (aerosols, various colloidal particles, *etc.*). Concentration of hazardous impurities on specific carriers may lead, on the one hand, to environmental cleaning by the ‘storage’ of such impurities in relatively small quantities of microparticles. On the other hand, these ‘stores’ are a serious threat to biosystems, since such a redistribution of minor components in atmospheric air may radically affect various physicochemical processes in the biosphere.⁴¹ The role of carriers in which the components of gas mixtures can be concentrated may be played by water molecules, water-based clusters, or gas hydrates.^{35, 41}

When technogenic impurities are released into the atmosphere in quantities sufficient for the formation of gas hydrates, it is necessary to know their composition and the conditions of their stability at a given temperature.

The use of Eqn (22) makes it possible to determine whether or not gas hydrates are formed under given conditions.

Knowing the fraction of cavities filled with molecules of a gas mixture, one can determine their concentration in the gas hydrate. Since, on average, there are 5.75 water molecules per cavity in structure I hydrate and 5.67 water molecules per cavity in structure II hydrate,⁵ then we obtain for structure I

$$c_i = \frac{Q_i}{5.75}, \quad (27)$$

and for structure II

$$c_i = \frac{Q_i}{5.67}. \quad (28)$$

Let us consider an air mixture (with nitrogen and oxygen as the main components) containing sulfur and carbon dioxides, nitrogen monoxide, Freon 12 and chloroform as impurities.^{42, 43} The results of calculations performed using the above equations allowing the determination of relative distribution coefficients and the concentrations of impurities in gas hydrates are presented in Table 8.

For the temperature range under study, $P_W^s = 0.2566$ kPa at 263 K and $P_W^s = 0.6067$ at 273 K. The gas mixtures indicated above do not form any gas hydrates at 273 K, because condition (21) is not fulfilled, whereas in all other cases the formation of gas hydrates is possible. When the temperature increases, the probability of hydrate formation decreases. It is of note that the hydrates formed will contain predominantly the impurity components. Gas hydrates concentrate preferentially the compounds with minimum dissociation pressures at given temperature. For example, at 273 K the dissociation pressures of nitrogen, sulfur dioxide, and chloroform are 11 000, 18.7, and 3.5 kPa, respectively. In addition, the extent of concentration of individual impurity in a hydrate or the relative distribution coefficient (relative to the coefficient of nitrogen distribution) depends substantially on the composition of a gas mixture, temperature,

and pressure. This is due to the redistribution of gas mixture molecules among hydrate cavities according to the Langmuir coefficients determined by the character of the van der Waals interaction.

Thus, gas hydrates may be formed under the conditions of the environmental presence of technogenic impurities over a wide range of ambient temperatures (the temperate climate zone). Such gas hydrates become sites of predominant concentration of typical technogenic impurities.

VI. Conclusion

The appearance of impurities in the form of gas hydrates in gases undergoing cleaning may significantly influence the process of their refinement: at the stage of hydrate formation the content of water in the gas phase decreases accompanied by changes in its composition due to redistribution of components between the solid and gas phase.

The presence in a gas mixture of components with higher or lower values of dissociation pressure than that of the principal substance subject to purification may change substantially the conditions of gas hydrate formation and in some instances even prevent their formation in the process of purification.

The relative distribution coefficient for the same conditions of hydrate formation depends appreciably on the ratio of the components in the gas mixture and in some cases it differs markedly from unity. Therefore, even at the stage of hydrate formation, the substance can be considerably enriched or depleted

in impurities. Thus, the separation of gas hydrates from the gas mixture may provide additional purification of the major substance or air–gas mixtures.

The existing models which simulate gas hydrate formation allow an accurate determination of the dissociation pressure of a hydrate-forming gas, the minimum water content at which the formation of hydrates is still possible, as well as the distribution coefficients of molecules of a gas mixture over the cavities of gas hydrates.

The computational results provide evidence that gas hydrates can be formed under environmental conditions (in the range of temperatures characteristic of the temperate climate zone). Under these conditions, they predominantly accumulate deleterious impurities released into the atmosphere from technogenic exhausts. Concentration of such impurities becomes hazardous for biological systems.

Thus, the gas hydrates formed in the vapour phase in the process of refinement of gases (Freons, volatile inorganic hydrides, *etc.*) as well as the suspended particles of submicro-size form a new class of impurities in ultrapure substances, and it is necessary to account for their influence on the processes of refinement of gases.

III. Models using the Monte Carlo method	101
IV. Molecular dynamics models	105
V. Conclusions	107

Abstract. The basic problems of computer simulation of mass and charge transfer in electrochemical processes such as electrocrystallisation and corrosion of metals are analysed. Three main approaches to the simulation of electrochemical problems are considered: the Ising (lattice gas) model, molecular dynamics (MD) and Monte Carlo (MC) methods. The principal equations used in simulation techniques and examples of the simulation of particular systems are presented. The bibliography includes 136 references.

I. Introduction

Computer simulation plays an important role in the solution of many physical problems. Certainly, the use of graphical two- (2D) and three-dimensional (3D) models obtained by computer simulation is interesting not only for physicists but also for chemists.¹ Primarily, these are simulation of phase transitions in chemical systems, construction of 'phase portraits' changing in time for these systems, and predictive assessment of the evolution of hierarchic near-the-surface crystal-electrolyte structures exposed to external factors. In computer simulation of electrochemical problems, reactions involving charge transfer are included in kinetic schemes along with chemical steps. The prerequisite for concentration and charge gradients to appear is the formation of fluctuations of the material density in the vicinity of reaction sites on the surface, where chemical reactions occur. Therefore, simulation of a metal–electrolyte interface is done taking account of the collective local degrees of freedom of a system.^{2,3} Computer simulations of the dynamics of surface electrochemical processes are based on the lattice gas model (the Ising model) as well as on molecular dynamics (MD) and Monte Carlo (MC) methods. The simulation techniques are well developed and the corresponding application software is available.⁴

II. Lattice gas models

Corrosion-electrochemical systems described by computer simulations can be tentatively divided in two groups: processes involving the formation of a new crystalline phase on the

substrate — crystallisation (i) and processes of dissolution — decrystallisation (ii).

Gilmer's approach is quite sufficient if the 'rigid' 2D-lattice Ising kinetic model is used for the computer-assisted description of the formal kinetics of growth and dissolution of ideal crystal lattices.^{5,6} The following assumptions are made: (1) the atoms removed from the surface can only enter multi-centre adsorption states with maximum stability (S-positions); (2) the order of occupying the adsorption cells is fulfilled according to which cell can contain no more than one atom; (3) the van der Waals metal–metal (M–M) interaction is approximated by a pair Mie potential of the type $U(r) = A/r^n - B/r^m$, where A and B are constants characterising the attractive and repulsive forces, respectively, r is the distance between the particles, and $n > m > 0$. The Hamiltonian for a simple cubic Ising lattice taking account of interaction between the closest neighbours (NN) has the form:⁷

$$H = -J \sum_{\langle ij \rangle} \sigma_i \sigma_j, \quad (1)$$

where J is the exchange energy; σ_i and σ_j are variables of the occupancy of cells i and j , respectively; the term $\sigma_i = \pm 1$ 'controls' the second assumption of the Ising model, and the symbol $\langle ij \rangle$ shows that summation is carried out over pairs of the closest neighbours. The formation of a step on this lattice (Fig. 1) is always accompanied by the formation of centres possessing excess charge and deficiency of mass, kinks, which are the most adsorption-active cells on a crystal surface (the TLK-model, from terrace T, step L, kink K). In these models, the solid is a Kossel–Stransky crystal.⁸

The pair potential can be written in a form convenient for practical use:

$$U(r_{ij}) = \frac{E_1 [a(B_a/r_{ij})^m - b(C_{lat}/r_{ij})^n]}{b - a}, \quad (2)$$

where E_1 is the depth of the potential well; the a and b constants are the degrees of 'far-range action' and 'hardness' of the potential, respectively; B_a and C_{lat} are constants of attraction and repulsion interaction, respectively; and r_{ij} is the distance between the reacting particles i and j . The potential most commonly used for computer simulation of electrochemical systems is the Lennard-Jones potential, while the Buckingham potential

[†] A defect-free crystal constructed according to Drude–Sommerfeld⁹ (from ions oscillating in equilibrium positions with a Debye frequency of $\mu_D = 10^{13} \text{ s}^{-1}$ near the equilibrium positions, and an electron subsystem).

Figure 1. Typical stepped configurations on the (100) face of a simple cubic lattice; (a) $T = 0$ K; (b) $T > 0$ K.

and the anharmonic Morse potential are used more rarely. These potentials are written as follows:
the Lennard-Jones potential (pair potential 6–12)

$$U_{LJ}(r_{ij}) = 4E_1 \left[-\left(\frac{C_{lat}}{r_{ij}}\right)^6 + \left(\frac{B_a}{r_{ij}}\right)^{12} \right], \quad (2a)$$

the three-parameter Buckingham potential (if repulsion is determined by overlapping of wave functions)

$$U_B(r_{ij}) = 4E_1 \left[-\left(\frac{C_{lat}}{r_{ij}}\right)^6 + B_a \exp\left(-\frac{C_{lat}}{r_{ij}}\right) \right], \quad (2b)$$

and the Morse potential

$$U_M(r_{ij}) = \delta \{ \exp[-2\alpha(r_{ij} - C_{lat})] - 2\exp[-\alpha(r_{ij} - B_a)] \}, \quad (2c)$$

where δ and α are empirical constants. The energy E_1 is determined by the nature of interaction of particles and is as high as ~ 10 eV for the ionic bond, $\sim 1-5$ eV for the metal bond, ~ 0.5 eV for the hydrogen bond and ~ 0.1 eV for the van der Waals interaction.

The pair interaction potentials (2a) and (2b) are used in the case of nonspecific physical adsorption, when $E_1 < 0.5$ eV. The adsorption energy E_{ads} can be calculated from a relation obtained by integration of the Lennard-Jones potential (2a) assuming that atoms (the number of which in unit volume of a crystal equals the Avogadro number, N_A) form an averaged ‘jelly’-background with mean parameters E_1 and C_{lat}

$$E_{ads} = \frac{\pi}{3} N_A E_1 B_a^3 \left[\left(\frac{C_{lat}}{r_{ij}}\right)^3 - \frac{1}{15} \left(\frac{C_{lat}}{r_{ij}}\right)^9 \right]. \quad (3)$$

Models of the liquid mercury surface in contact with an electrolyte are in satisfactory agreement with the relationship (3).¹⁰ An ideal flat condenser is formed in this case. The minimal distances between the particles

$$l \equiv r_{ij \min} \simeq \frac{C_{lat}}{\sqrt[6]{5}}$$

have to be smaller for flat condenser models than for an actual surface M. Hence, it is necessary to take into account both the crystallographic features of adsorption and changes in the electronic structure of an adsorbate–adsorbent system (mixing of wave functions of valence electrons of the adsorbed particles with those of the metal adsorbent occurs).

The stability of two-dimensional lattices (usually, tetragonal, trigonal and hexagonal lattices incorporating 32×32 , 64×64 , 128×128 , 256×256 etc. cells are analysed) depends on the total energy of the system. The dynamically unstable tetragonal lattice is transformed into the trigonal lattice, which is more energetically stable.¹¹ Dimers of a tetragonal lattice with antiparallel spins oriented along a particular crystallographic direction are rearranged in a simultaneous cooperative act¹² into a more stable Ising structure (Fig. 2). As a result, the density of dimers increases.

Figure 2. Transformation of simple tetragonal lattice (a) into triangular lattice (b).

The rearrangement occurs in the sequence: self-organising $\rightarrow$ high order $\rightarrow$ low entropy^{13,14} and results in the generation of a low-entropy surface structure. The kinetics of destruction of two-dimensional lattices can follow their reversible nature, i.e., transition of rows or separate intermediates into solution with restoration of the coverage provided that the concentration of the surfactant in solution is sufficient. The equation for the destruction rate (current I) has the ‘Arrhenius form’ determined by the degree of coverage of the crystal with surfactant particles, θ_{surf} , which in turn depends on the external factors and internal state of the crystal surface – electrolyte system:

$$I = v_i(\theta_{surf}) \theta_{surf}^n \exp \left[-\frac{E_a(\theta_{surf})}{kT} \right], \quad (4)$$

where $v_i(\theta_{surf})$ is the pre-exponential frequency factor (vibration frequency of i th metal surface particles, $10^{13}-10^{14}$ s⁻¹), n is the order of the reaction between the adsorbed particles, and $E_a(\theta_{surf})$ is the activation energy of interaction of passivating particles in 2D-structures. The $E_a(\theta_{surf})$ dependence is nonlinear: at $\theta \leq 0.2$, the interaction of the surfactant particles in the adsorbed layer can be neglected, but at $\theta > 0.8$ (under conditions of rapid increase in the B_a constant), an attraction correction should be made to determine $E_a(\theta_{surf})$. Usually, $E_a(\theta_{surf}) = E_b - \Delta H_{ads}$, where E_b is the bonding energy of the surfactant particles and ΔH_{ads} is their heat of adsorption on the crystal surface. The pre-exponential terms of kinetic equation (4) take account of the adsorption isotherm of a surfactant on the crystal surface, that is calculated within the scope of the Ising lattice model.¹⁵ This determines changes in the rate of reorganisation of surface intermediates and, as a result, the current I across the interface.

Further, it is worthwhile to consider, within classical concepts, the interaction of a 2D-film with a substrate leading to the formation of some new phases (layers). For example, this interaction is typical of the inhibition of metal dissolution.¹⁶ If only the potentials of pair interactions ‘a particle in film – a particle in substrate’ are taken into account additively, then, according to Heitler and London,¹⁷ the pair potential is expressed as:

$$U(r) = \sum_i U_i(r) = -\frac{K_L}{r^6}, \quad (5)$$

where $K_L = (3/4)\hbar v_0 \varepsilon^2$ is the London constant, $\hbar = h/2\pi$ is the Planck constant, v_0 is the characteristic frequency of vibration of charged particles, and ε is the polarisability of particles. Then, according to Ref. 18, one can write:

$$U(r) = - \int K_L r_{ij}^{-6} N_A dV, \quad (5a)$$

where N_A is the number of particles per unit molar volume of the metal, dV is an element of the solid phase volume (in a particular case, the volume of the adsorbed particle) at a distance r_{ij} from a particle given by the r coordinate in the first near-surface layer of the substrate. If $N_A = \text{const}$, then

$$U(r) = -\frac{N_A \pi K_L}{6l^3}, \quad (5b)$$

where l is the shortest distance between the adsorbate and adsorbent particles. In the flat condenser model, the adsorbate and adsorbent are independent layers, and if the surfactant layer penetrates into the substrate, then to estimate $U(r)$ it is necessary to integrate over the depth l of the substrate. Integration gives

$$U(r) = -\frac{\Gamma_{\text{surf}, M}}{12\pi l^2}, \quad (5c)$$

where $\Gamma_{\text{surf}, M} = \pi^2 N_A^2 K_L$ is the Hamaker constant.¹⁹ For example, such penetration occurs in the case of hydrogen adsorption. The size of the cell is close to that of the adsorbed hydrogen atom, that is, the use of the Ising model for the estimation of hydrogen adsorption is substantiated. If an electrical double layer appears and charges are transferred between the inhibiting surfactant film and the substrate, $\Gamma_{\text{surf}, M}$ can be calculated by summing pair potentials for three-dimensional elements

$$\Gamma_1 = \frac{3}{4} \pi^2 N_{A, \text{surf}}^2 \varepsilon_{\text{surf}}^2 E_{i, \text{surf}}, \quad (6)$$

where $N_{A, \text{surf}}$ is the number of surfactant particles in unit molar volume of the film and $\varepsilon_{\text{surf}}$ and $E_{i, \text{surf}}$ are the polarisability of surfactant particles and the ionisation potential in the surfactant film, respectively. After the film–substrate interaction has occurred, the Hamaker constant in equation (5c) is determined by a superposition of constants for the film (Γ_{surf}) and the metal (Γ_M)

$$\Gamma_{\text{surf}, M} = \Gamma_{\text{surf}} - 2\sqrt{\Gamma_{\text{surf}} \Gamma_M} \left(\frac{2\sqrt{E_{i, \text{surf}} E_i}}{E_{i, \text{surf}} + E_i} \right) + \Gamma_M, \quad (7)$$

where E_i is the ionisation energy of the metal.

If the ionisation energies in the inhibiting film and in the metal become equal, $E_{i, \text{surf}} \simeq E_i$, relation (7) can be simplified

$$\Gamma_{\text{surf}, M} = (\sqrt{\Gamma_{\text{surf}}} - \sqrt{\Gamma_M})^2. \quad (8)$$

According to Frumkin,²⁰ the lateral interactions of adsorbed particles

$$E_a(T, \theta_{\text{surf}}) = E_b + \Delta E_{\text{lat}}(T, \theta_{\text{surf}})$$

in a two-dimensional adsorption structure can also be of chemical or physical nature, and $E_a(T, \theta_{\text{surf}})$ can be > 0.5 eV or < 0.5 eV. The Frumkin's correction factor $\Delta E_{\text{lat}}(T, \theta_{\text{surf}})$ decreases with an increase in temperature and increases for $\theta_{\text{surf}} \geq 0.2$. Interactions in 'surfactant particles in solution – a surfactant in an inhibiting film' and 'surfactant particles in solution – substrate atoms' systems result in the formation of defects in the covering surfactant film because of the non-equivalence of energetic positions of the substrate atoms.

The interaction of particles in the 2D-structure of the covering film determines a hierarchy of defects and 3D-islands of the surfactant, which depends strongly on the structural features of

the substrate. Within the scope of the linear elasticity theory, the contact of films with metal surfaces is considered taking account mostly of two parameters: the module of elasticity and the differences in the crystallographic parameters of film and substrate lattices. If the lattice parameter of an adsorbed covering 3D-film is larger than that of the substrate, the relaxation of strain in the film ends with the formation of discrepancy dislocations, and it is not deteriorated; in the absence of strain relaxation, the film is deteriorated.

Computer simulations use models that combine simultaneous formation of 2D- and 3D-structures on heterogeneous substrates. Analytical solutions of equations that describe inhibiting 2D-structures (on singular substrates) and 3D-islands on surfaces with uniformly distributed defects of the same nature are only possible in the lattice gas model.

The adsorption of an inhibitor on a non-uniform metal surface can be accompanied by the formation of both two-dimensional films and three-dimensional structures. The former case is less probable than the latter, but exact solutions are possible for it within the scope of the models considered. In the 2D-case, for the adsorption of light particles (H, O, N, CO, etc.) on singular single-crystal planes, the discreteness of charges of single, strongly bonded substrate atoms in an ensemble is described relatively accurately. However, it is impossible to simulate the behaviour of a big particle on the surface within the Ising model. The situation is similar to that when one has to play chess using chesspieces larger not only than the board squares but also than the board itself. Models are required that take into account the direction (correlated with the surface structure) of particle movement along the crystal surface (along definite preferred trajectories) and the presence of periodic extended surface and subsurface defects. When complex particles (large inorganic and/or organic molecules) are adsorbed, the field of extended surface and subsurface defects creates conditions for the formation of 3D-phase islets.^{21, 22} The three-dimensional adsorbed formations of inhibiting particles interact with each other both through the substrate and directly, creating their own hierarchic structure.

The study of the phase transition upon metal dissolution in the presence of surface 2D-films is an example of the classical approach to the consideration of the corrosion problem. Inhibiting layers on a non-uniform metal surface are formed more commonly as a superposition of 2D-films and 3D-structures. Two-dimensional films are formed on surfaces of crystallite (grain) terraces, which are, as a rule, non-singular stepped high-index planes. The expanse (surface area) of terraces on such stepped surfaces is sufficiently large to be treated as main structural elements (as regards surface area). The lattice gas model is quite applicable for the description of the adsorption of a metal dissolution inhibitor on densely packed ideal terraces. The corresponding Hamiltonian contains terms describing not only the surfaces of the metal and adsorbed particles of a surfactant but also exchange energies of their interactions, i.e., the usual Ising Hamiltonian (1) becomes more complex

$$H = -E_{NN} \sum_{NN} \sigma_i \sigma_j - E_{NNN} \sum_{NNN} \sigma_i \sigma_j, \quad \sigma_i = \pm 1. \quad (9)$$

It contains exchange energies of interaction not only between the closest neighbours NN , but also between the next to the closest neighbours NNN . If one limits the consideration to $NN = 1$ and $NNN = 2$ and designates the NN - and NNN -interactions as E_1 and $E_2 = RE_1$, $R < 0$, then the parameter for the critical temperature (T_c) for the formation of a new phase on the surface is

$$\sinh \frac{2E_1}{kT_c} \sinh \frac{2E_2}{kT} = 1 \quad \text{or} \quad -\frac{2kT}{E_1} \ln \left(\tanh \frac{E_1}{4kT_c} \right) = \frac{E_2}{E_1}.$$

'Loose' steps and kinks on the steps have different adsorption characteristics from the terraces. Only in rare situations can adsorption be regarded as physical adsorption. The strength of bonds of adsorbed particles with kinks is high. The behaviour

(kinetics of movement and inhibition) of steps is described in terms of dislocation dynamics.

The formation of inhibiting covering 2D-films can be considered both from the viewpoint of the classical nucleation theory and taking account of the quantum-chemical nature of interaction in the adsorbate – adsorbent system.²³ In the classical variant, the surfactant particles that are adsorbed and form a uniform film are treated in the mean field approximation. The ratio of the density of this film (ρ) to the activity of spherically symmetrical particles in it (a_{surf}) is described by the equation:

$$\frac{\rho}{a_{\text{surf}}} = A \left\langle \exp \left(- \frac{E_{\text{attr}}(T, \theta_{\text{surf}})}{kT} \right) \right\rangle,$$

where $A = v_i(\theta_{\text{surf}}) \exp(\Delta S/k)$ is the Einstein configurational term, ΔS is the entropy change in the adsorption ensemble, and $E_{\text{attr}}(T, \theta_{\text{surf}})$ is the attraction potential. When a uniform temperature-independent field of the inhibiting film is created, $E_{\text{attr}}(T, \theta_{\text{surf}})$ can be approximated by the mean field potential $E_{\text{mf}}(\theta_{\text{surf}})$, or $E_{\text{attr}}(T, \theta_{\text{surf}}) \simeq E_{\text{mf}}(\theta_{\text{surf}})$.

The classical models of new phase growth on a crystal surface (they can be divided in three groups, Fig. 3) are based on the formation of 2D-films and insular 3D-structures. According to the FVdM model, the growth of inhibiting films occurs by a mechanism involving a ‘carpet’ of a 2D inhibitor layer ‘unrolling’ over the crystal surface; the VW model assumes that flat disks arise and then coalesce; the SK theory involves a combination of 2D-films and 3D-islets. There is also a variant of the VW model in which the new phase grows as a column composed of adsorbed particles (see Fig. 3). This is the ‘solid on solid’ model, whose distinguishing feature is a high process rate (in a particular case, high cathodic current density, i_c), low supersaturation of reacting particles in the near-electrode layer $\Delta\gamma^\neq$, and high force field of the surface (subsurface) active centre where the new phase appears.

Figure 3. Scheme of growth of 2D and 3D structures on a crystal surface; (a) the Frank – Van der Merve model (FVdM); (b) ‘column’; (c) the Stransky – Krastanov (SK) model; (d) the Volmer – Weber (VW) model.

The estimated specific surface energy change, $\Delta\sigma$, is the criterion of applicability of these models. Under conditions of heteroepitaxial growth of covering films (where the pseudomorphism mechanism operates), if the structure of the covering film is analogous to that of the structure of the substrate or maintains its symmetry upon minimisation of $\Delta\sigma$, the FVdM mechanism operates. Thus, at $\Delta\sigma = 0$ the FVdM mechanism, at $\Delta\sigma > 0$ the VW mechanism, and at $\Delta\sigma < 0$ the SK mechanism operates. The latter model (SK) is used in computer simulations more commonly than the two others. The growth models considered above (see Fig. 3) provide a reasonably good description of the structures observed in experiments.^{24,25} The phase transition considered in classical models is initiated by changes in surface tension, which appear because of disagreement between the lattice spacing of the substrate and the adsorbate.

Presently, the main difficulty in making a complete quantitative description of metal – electrolyte systems is the adequate

representation of periodic 2D-structures at the level of regularly spaced particles (atoms, surfactant molecules) and accounting for the quantum-chemical nature of the interaction between the 2D-film and the substrate. The interaction mentioned above is described by model Anderson – Ising – Hubbard Hamiltonians²⁶ for each particular system ‘M – inhibiting surfactant – electrolyte’. It should be noted that calculations using model Hamiltonian methods are often rather complicated, and Hamiltonians for electrochemical systems contain many uncertain parameters.

Let us analyse the 2D-nucleation process. We shall take the topological principle as the base and consider a series of main models, gradually complicating the dimensionality. It is reasonable at the beginning to give a description of a lattice gas model for singular defect-free surface crystals. Nucleation can also be considered in a classical approximation in which joining and formation of films occurs from fragments larger than separate atoms and molecules, surface clusters. In the lattice gas model, the degree of coverage of a crystal surface by inhibiting surfactant particles is expressed by the formula²⁷

$$\theta_{\text{surf}} = \frac{1}{N_s} \sum_{i=1}^{N_a} \langle C_i \rangle_T, \quad (10)$$

where N_s and N_a are the number of lattice points of substrate atoms and the number of occupied points, respectively; C_i is the variable of coverage ($C_i = 1$ if the surface points N_s are occupied and $C_i = 0$ if these points are not occupied). In formula (10), θ_{surf} is the molar fraction of occupied active centres on the crystal surface, and angle brackets henceforth denote statistical averaging over the main system state at a certain temperature T .

The variable of coverage $C_i \equiv \sigma_i$ determines the Boltzmann factor

$$B = \exp \left(- \beta \sum_{i,j} \sigma_i \sigma_j \right),$$

where $\sigma_i = \pm 1$, $i \neq j$, $\beta = T^{-1}$. Equation (10) follows from the main relationship for the variable of coverage (S) in the Ising model

$$S = \frac{1}{N_s^d} \sum_{i=1}^{N_s^d} \sigma_i,$$

where $d \geq 2$ is the fractal dimensionality ($d = 2$ in the two-dimensional model).

Summation in equation (10) is performed over all lattice points whose size is close to that of the adsorbing surfactant particles. When the sizes of adsorption cells are close to those of adsorbate particles, the Ising 2D-model employs a diagram technique.²⁸ At a certain average temperature T , the surfactant forms a monolayer, whose particles are bonded to the substrate particles with an energy E_b . This energy is determined by the sum of correlation functions of the spin on the crystal surface and the spins of the adequately conjugated surfactant monolayer with the surface layer of the substrate. The loss of mechanical stability of the flat frontier of growth (dissolution) of crystal surfaces results in the formation of a surface with a cellular structure. In this process, the growth of cells during self-organising is accompanied by avalanche-like changes in the overall distribution of spins.²⁹

The energies of pair additive interactions of the neighbouring (E_{NN}), next-to-neighbouring (E_{NNN}) and third-to-neighbouring (E_3) adsorbed particles occupying highly coordinated s -states can be defined as shown in Fig. 4. In the case of unpaired interactions, the energy is $-2E_{NN} - E_{NNN} - E_t$ (E_t is the energy of interaction of the neighbouring, NN , and closest-to-neighbouring, NNN , points). The total (configurational) energy of the three-particle (i, j, k) system (potential as in the 2D lattice gas model) is:

$$U_0 = -E_b \sum_{i=1}^{N_a} C_i - \sum_{i \neq j} E_{ij} C_i C_j - \sum_{i \neq j \neq k} E_t C_i C_j C_k, \quad (11)$$

where $E_{ij} = E_{NN}$, E_{NNN} , or E_3 , if i and j are the neighbouring, the next-to-neighbouring, and third-to-neighbouring sites, respectively; C_i , C_j and C_k are variables of occupation. The second

Figure 4. Energies of interaction of an adsorbed particle with a tetragonal (a) and centred rectangular lattice (b).

term in equation (11) describes all pair interactions, and the third term, all triple interactions. The prenucleation situation in the case of a centred rectangular lattice is analogous to that in the case of a square lattice (Fig. 5).

Figure 5. Completed ordered 2D-phases at $T = 0$ K; (a) $c(2 \times 2)$, $R < 0.5$; (b) L , $R > 0.5$; (c) $D_{0.25}$, $R > 0$; (d) $D_{0.25}$, $R > 0.5$.

The formation of condensed 2D-layers in the lattice gas model is described by statistical mechanics methods. Phases with low density (see Fig. 4) randomly distributed on a crystal surface are transformed into condensed phases due to the action of chemical and van der Waals forces. For example, on the (100) plane of a body-centred cubic (BCC) crystal (c) completed 2D-phases of various dimensionality are formed (see Fig. 5): $c(2 \times 2)$, L - and D -phases ($0 < R < 1$ is a dimensionless factor of confidence showing the divergence between experimental and calculated data). It should be noted that the Ising model for electrochemical contacts with charge transfer provides a good description of the results of *in situ* experiments performed by scanning tunneling electron microscopy in an electrolyte to study the initial steps of electrodeposition³⁰ and adsorption of solution particles on densely packed cubic crystal planes.³¹

Due to diversity of types of adsorption cells (Fig. 6) on the surface of the (100) plane, a type of unlimited percolation cluster can be formed in a 2D-structure.³² The kinetics of its formation is determined by the probability of sticking of the surfactant particles to the crystal surface (S), which is described by the equation:

Figure 6. Types of adsorption cells on the (100) face of a body-centred cubic crystal. Here c and p are centred and primitive surface elementary cells, respectively; the black circle indicates a cell covered by an adsorbed particle.

$$S = S_0 K(E_{ij}, c_s) c_s^n,$$

where S_0 is the initial sticking coefficient (at the degree of coverage $\theta_{\text{surf}} = 0$), K is the configurational factor determining the form of the adsorption ensemble (e.g., $K = \pi$ for a dome-shaped ensemble and $K = 16\pi/3$ for a spherical ensemble), E_{ij} is the energy of interatomic (inter-particle) interaction, $c_s = f(N_s)$ is the surface concentration of vacant cells (unoccupied positions), which depends on the number of surface atoms of the substrate (total number of cells) N_s , and $n \simeq 0.3$ is a constant (degree) of nucleation of particles involved in the cluster.³³

Computations of the probability of sticking usually employ relationships of the Arrhenius type

$$S = S_0 (1 - \theta_{\text{surf}}) \exp\left(-\frac{E_{\text{ads}}}{RT}\right), \quad (12)$$

where E_{ads} is the activation energy of adsorption of the surfactant particles on the metal surface. A particular dynamic three-dimensional percolation cluster with a high specific surface area is formed on the electrode surface. A percolation cluster can appear upon deposition of particles on the surface in the mode of underpotential deposition,³⁴ in the formation of composite electrochemical coatings^{35,36} and oxide structures.^{37,38} In these cases, the subsurface layer behaves as a dynamic 3D-electrode.

If a model takes into account only the flux of surfactant particles hitting the crystal surface and sticking to it and ignores the possibility of their diffusive movement (when the magnitudes E_b are high) along the surface, the coalescence of islets of condensed phases according to the VW model results in the formation of condensed layers. The particles in adsorbed layers interact through repulsive and attractive forces, which differently depend on the distance. As the distance decreases, the repulsive forces grow more quickly than the attractive forces.

Within the lattice gas model with account of the U_0 energy [from equation (11)], the adsorption energy E_{ads} can be determined as follows:

$$E_{\text{ads}} = \frac{\langle U_0 \rangle_T}{N_s} = -E_b \theta_{\text{surf}} - \frac{1}{N_s} \sum_{i \neq j} E_{ij} \langle C_i C_j \rangle_T - \frac{1}{N_s} \sum_{i \neq j \neq k} E_{ijk} \langle C_i C_j C_k \rangle_T, \quad (13)$$

where N_s is the number of active lattice points to be occupied.

Equation (13) is written for a canonical ensemble at fixed independent T and θ_{surf} . If interaction of adsorbed particles occurs in a covering 2D-film, a term describing this should be added to equation (13), namely, $\mu_{\text{surf}}N_a$ (where μ_{surf} is the chemical potential of particles in the 2D-film, and N_a is the number of occupied points on the crystal surface). In the Ising model, the Hamiltonian for a crystal growing in an equilibrium mode has the form:³⁹

$$H = 2E_b \sum_{\langle i,j \rangle} [C_i(1 - C_j) + (1 - C_i)C_j] + \mu \sum_i C_i, \quad (14)$$

where E_b is the energy of cleavage of the interatomic bond between the closest NN -neighbours, summation $\langle i,j \rangle$ is carried out over pairs of NN -neighbours, and $\mu < 0$ is the energy of formation of a commensurate adsorbed 2D-phase 'not linked with the surface layer of the crystal'. The Hamiltonian for a system in which non-commensurate 'linked' films are formed from adsorbed layers, or the crystal lattice grows further, is more complex because it includes terms describing the interaction in 'linked' layers

$$H = U_0 - \mu_{\text{surf}}N_a = -(E_b + \mu_{\text{surf}}) \sum_{i=1}^N C_i - \sum_{i \neq j} E_{ij} C_i C_j - \sum_{i \neq j \neq k} E_i C_i C_j C_k. \quad (15)$$

At $T = \text{const}$, the dependence of μ_{surf} on θ_{surf} is described by the adsorption isotherm

$$\mu_{\text{surf}} = \frac{1}{N_a} \left(\frac{\partial F}{\partial \theta_{\text{surf}}} \right)_T, \quad (16)$$

where F is the Helmholtz free energy of the system

$$F = -kT \ln \text{Tr} \exp \left[-\frac{H\{C_i\}}{kT} \right], \text{Tr} = \sum_{i=1}^n a_{ii}, C_i = 0.1,$$

where the trace Tr means summation over all configurations (see Fig. 4). The condition $C_i = 0.1$ imposed on the Hamiltonian $H\{C_i\}$ means the absence of attraction–repulsion interactions in surface 2D-phases of adsorbed surfactant particles. In the Ising model taking account of the second limitation (see above), the variable of coverage C_i is given by the formula

$$C_i = \frac{1 - \sigma_i}{2}, \sigma_i = \pm 1,$$

where the spin is $\sigma_i = \pm 1$.

For particles of an adsorbing surfactant of the same type which do not interact, equation (13) is simplified when the temperature of the crystal increases to temperatures for desorption of the surfactant from the surface ($T \rightarrow \infty$):

$$E_{\text{ads}}(T \rightarrow \infty) = \quad (17)$$

$$= -E_b \theta_{\text{surf}} - 0.5 \theta_{\text{surf}}^2 \sum_{i \neq j} E_{ij} - 0.33 \theta_{\text{surf}}^3 \sum_{i \neq j \neq k} E_i,$$

where $\theta_{\text{surf}}^2 = \langle C_i C_j \rangle$, $\theta_{\text{surf}}^3 = \langle C_i C_j C_k \rangle$.

If the following designations are introduced: the Jackson–Temkin parameter

$$\beta_{\text{JT}} = 0.5 \frac{E_b}{kT},$$

$$m = \tanh \beta_{\text{JT}}, \quad \beta_{\text{JT}} = \ln \frac{1+m}{1-m} = \ln \frac{1-\theta_{\text{surf}}}{\theta_{\text{surf}}},$$

from equation (16) we obtain the Langmuir isotherm in the form

$$\frac{\mu_{\text{surf}} + E_{\text{ads}}}{kT} = \ln \frac{\theta_{\text{surf}}}{1 - \theta_{\text{surf}}}, \quad (18)$$

where the bond energy $E_b = 2(\mu_{\text{surf}} + E_{\text{ads}})$.

The anti-logarithm of isotherm (18) shows that the activation energy $\mu_{\text{surf}} + E_{\text{ads}}$ in the expression $\exp[(\mu_{\text{surf}} + E_{\text{ads}})/kT]$ is responsible for overcoming the potential difference in the double layer formed on the electrolyte side at the metal–electrolyte interface. This energy is related to variations in the Fermi energy of the metal, E_F , in the case of non-commensurate interaction in a film–substrate system and degree of solvation of surfactant particles in different phases that change the charge during the phase transition.

The Hamiltonian that describes the adsorption of surfactant particles within the Anderson–Newns model has the form:^{40, 41}

$$H = H_{\text{surf}} + H_M + H_{\text{surf-M}}, \quad (19)$$

where H_{surf} and H_M are Hamiltonians of the adsorbed particle and the pure substrate (metal), respectively; $H_{\text{surf-M}}$ is the Hamiltonian of the bond between them. The sum $H_{\text{surf}} + H_{\text{surf-M}}$ in operator (19) is usually replaced by a Hamiltonian taking the adsorption of the surfactant into account

$$H = H_M + H_{\text{ads}}, \quad (20)$$

where

$$H_{\text{ads}} = -kT \sum_{l,v} \ln \{ 1 + \exp[-\beta_{\text{JT}}(E_{l,v} - \mu_{\text{surf}})] \}.$$

Summation is done over all occupied adsorption cells N_s . Summation over l reflects the one-centre (on top) positions of the adsorbed surfactant particles, while summation over v corresponds to their bridging positions for a potential of the form

$$E_{l,v} = \sum_j \alpha_{lvj},$$

where α_{lvj} is the constant of attraction–repulsion interaction between the surfactant and the metal surface.

When estimating the degree of coverage within the Ising model, one performs summation over all adsorption cells $\{l,v\}$, and formula (10) is reduced to a more concrete expression

$$\theta_{\text{surf}} = \left\langle \sum_{l,v} \frac{1}{\exp[(E_{l,v} - \mu_{\text{surf}})/kT] + 1} \right\rangle.$$

In almost all cases, the surfactant particles adsorbed on a crystal surface induce reorganisation in first near-surface layers (phase transition of second order, without a heat effect or change in the specific volume). If the electronic subsystem of the crystal lattice is only slightly affected by surfactant adsorption, computer simulation can use the Hamiltonian (15) in the form:^{40, 41}

$$H = 0.5 \sum_{i \neq j} E_{ij} \langle C_i C_j \rangle_T + \sum_{i,j} C_i U(r_i^0 - r_i), \quad (21)$$

where E_{ij} is the energy of inter-particle interaction (adsorbate–adsorbent); U is the interaction potential, r_i^0 and r_i are the coordinates of a surface atom of the adsorbent before and after the reorganisation, respectively.

It should be noted that in electrolytes, the system 'metal surface–covering surfactant film' interacts with the solvent. The efficiency of interaction depends on the degree of coverage θ_{surf} . At $\theta_{\text{surf}} \ll 1$, it is necessary to take the predominating effect of interaction of particles in the film into account. Kornyshev and Schmickler⁴² introduce into Hamiltonian (19) an additional term of the type $E_{\text{sol}}(q_a) \langle C_i C_j \rangle_T$, where $E_{\text{sol}}(q_a)$ is the energy of interaction of an adsorbed particle with a mean charge q_a with the solvent.

In accordance with the classical concepts, the adsorbed particles have vibrational, translational and rotational degrees of freedom. The potential part of the total energy of these slow movements is determined by the electronic part of the Hamilto-

nian. As new physical aspects of interaction in the adsorbate–adsorbent system are discovered, the structure of the model Hamiltonian changes.

The van der Waals attraction or repulsion is caused by overlapping and orthogonalisation of wave functions of electronic states for the substrate and the adsorbed atom. The interaction between the adsorbed particles can be of at least four types:⁴³ electrostatic (Coulomb or dipole–dipole), due to overlapping of orbitals of adsorbed atoms or through phonons of the substrate by direct interaction ($\theta_{\text{surf}} \leq 1$) and by indirect interaction through electronic states of the metal. For covering layers of a surfactant with very low degrees of coverage ($\theta_{\text{surf}} \ll 1$), the Anderson's model Hamiltonian is constructed using Hubbard operators.⁴¹ The use of these operators makes it possible exactly to take into account the correlation of electrons on a doping (adsorbed) atom and to overcome the difficulties related to the need to combine the quantum character of an electronic subsystem with a classical representation (the Drude–Sommerfeld model⁹) of the crystal lattice.

A Hamiltonian for an adsorbate–adsorbent system in which reorganisation of the metal surface induced by adsorbed particles occurs has the form⁴⁴

$$H = U - \mu_{\text{surf}} \sum_{i=1}^{N_a} \langle C_i \rangle, \quad (22)$$

where the operator C_i equals unity if the act of adsorption has occurred, and $C_i = 0$ otherwise. The interaction potential in equation (22) can be presented as a sum of four terms

$$U = U_0 + U_M + U_{\text{surf}} + U_{M-\text{surf}}, \quad (23)$$

where U_0 is the potential from the 2D-lattice gas model for adsorbed surfactant particles with no account of reorganisation of the metal surface [see equation (11)], U_M is the potential reflecting pair interactions of atoms in the bulk and on the surface of a crystal M; U_{surf} and $U_{M-\text{surf}}$ are potentials composed taking account of the following effects of the substrate: lateral, dipole–dipole, those occurring due to overlapping of orbitals of adsorbed surfactant particles, electronic, and phononic.

In the case of 3D-nucleation at the interface, simulation requires ‘cutting’ of a definite volume including particles in the near-surface layer of the crystal, on the surface, and in the electrolyte. In this respect, lattice models have wider ‘possibilities’ in comparison with models based on the use of numerical methods. The cluster approach in the lattice gas model has been used for constructing equations that describe an equilibrium distribution of molecules in a multicomponent solution taking account of orientationally directed interactions.⁴⁵ To solve this problem, commensurate and non-commensurate layers of a surfactant are considered. The degree of commensurability depends on the sizes of surfactant particles and is primarily determined by the mean distance from adsorbing surfactant particles to the nearest adsorption points. Simulation of commensurability is performed by minimising the energy of additive interactions of atoms between each other $E(r_i - r_{i-1})$, which is very sensitive to the size of particles. If a commensurate phase of a protective inhibitor film has formed on a metal crystal surface ($\theta_{\text{surf}} \simeq 1$) that displays cooperative properties upon corrosive action of the medium, Hamiltonian (22) can describe the well-known Frenkel–Kontorova model⁴⁶

$$H = \sum_i [E(r_i - r_{i-1}) + U(r_i)], \quad (24)$$

where r_i is the coordinate of the i th atom and $U(r_i)$ is the periodic potential of substrate surface atoms in the form

$$U(r_i) \sim A \sin \frac{2\pi r_i}{\lambda},$$

where A and λ are the amplitude and length of the potential disturbance wave, respectively. The periodic potential of the lattice, which is the sum of local potentials $U(r_i - r_{i-1})$ of additive interactions of the particles, equals

$$U(r) = \sum_i U(r_i - r_{i-1}).$$

For simplification, one can accept

$$U(r) = U(r + 1)$$

and consider the action of this potential in a commensurate ‘cross-linked’ subsurface layer of the metal. Additive interactions $E(r_i - r_{i-1})$ occur in a commensurate M–surfactant ‘sandwich’. In the physical sense, Hamiltonians (24) are practically equivalent for 3D- and 2D-layers. In this model, a monolayer of a surfactant undergoes the action of the periodic potential of the substrate that is a plane of an ideal crystal, while particles of the adsorbate (surfactant) in the 3D-structure elastically interact with each other. Naturally, a Hamiltonian of the type (24) describes a very limited number of real cases, since rather strict limitations are imposed on it: the similarity of sizes of metal atoms and surfactant particles, of the electrical and vibrational characteristics of the metal and the surfactant. Perhaps, covering of the surface of a single crystal of a 3d-metal (Fe, Co, Ni) with atoms of noble 4d- or 5d-metals (Ru, Rh, Pd, Os, Ir, Pt) corresponds to this model.

When a real crystal surface is represented by a combination of steps and terraces (Fig. 7), Hamiltonian (24) becomes more complicated, as it includes terms corresponding to covering of both the steps and the terraces and can be expressed⁴⁷ by parameters for a partial coverage of the adsorption centres

$$n(i, j) = \left(\frac{N_a}{N_s} \right)^d,$$

where $2 < d < 3$ is the dimensionality.

Figure 7. A model (a) and an energy diagram (b) for surfactant adsorption on a metal surface.

The complicated Hamiltonian has the form:

$$H = E_1 \sum_{j=1}^M n(1, j) - E_L \sum_{j=1}^M n(L, j) - E \sum_{i=2}^{L-1} \sum_{j=1}^M n(i, j) - \quad (25)$$

$$- 0.5 E_{\text{surf-surf}} \sum_{j=1}^M \{ n(1, j) [n(1, j-1) + n(1, j+1) + n(2, j)] +$$

$$+ n(L, j) [n(L, j-1) + n(L, j+1) + n(L-1, j)] +$$

$$+ \sum_{i=2}^{L-1} n(i, j) [n(i, j-1) + n(i, j+1) + n(i+1, j) + n(i-1, j)] \},$$

where E_1 , E_L , and E are energies of M-surfactant bonds at the end, at the beginning of a step, and on a terrace, respectively; $E_{\text{surf-surf}} = \mu_{\text{surf}} N_a$ is the energy of mutual repulsion in the adsorbate-adsorbent system. In relationship (25), the length of terraces is L , the length of steps is M , and the following condition is fulfilled: $M \gg L$. The step height is h , and the negative slope of the step face to the singular surface is $-\theta$ (see Fig. 7). A change in the sign of θ changes the dynamics of movement of the steps:⁴⁷ in one case, the adsorbed surfactant particles are forced back by the moving step, and in the other, they are absorbed in the crystal. The equidistant steps of finite length M take up the adsorbed surfactant particles, and the degree of coverage in a certain row l is determined by the relationship

$$\theta_{\text{surf}} = \langle n(l) \rangle_T = \frac{1}{M} \sum_{j=1}^M \langle n(l, j) \rangle_T. \quad (26)$$

As regards the retention of translational invariance in a bulk near-surface surfactant layer, since high-index planes of a single crystal with surface defects in the form of rectangular steps (without kinks) are considered, summation can be done over the index j of the coordinate y . Full coverage ($\theta_{\text{surf}} = 1$) of the terrace by the adsorbate is calculated using the formula

$$\theta_{\text{surf}} = \frac{1}{LM} \sum_{l=1}^L \sum_{j=1}^M \langle n(l, j) \rangle_T = \frac{1}{L} \sum_{l=1}^L \theta_{\text{surf}}. \quad (27)$$

The magnitude of θ_{surf} is considered to be a constant in this case.

The results of computer simulation using equations (25)–(27) agree satisfactorily with experimental data for well-characterised stepped planes of noble metal single crystals.⁴⁸ The growing steps maintain their faces in solutions where $\theta_{\text{surf}} \ll 1$. In the model of single step growth, the flux of surfactant from the terrace (J) that has higher kinetic coefficient or higher partial rate of direct reduction i_c [see relationships (29)] predominates. The flux of surfactant from the front terrace predominates,⁴⁹ i.e. $J_2 > J_1$ (see Fig. 7a).

Simulation of non-equilibrium single atomic steps showed⁵⁰ that the critical supersaturation

$$\Delta \gamma_c^\# = \ln \frac{c_{\text{surf},c}}{c_{\text{surf},0}}$$

[where $c_{\text{surf},0}$ and $c_{\text{surf},\text{crit}}$ are the equilibrium and critical (causing a phase transition) surfactant solution concentrations, respectively, at which the step starts growing linearly] depends on its inverse length M^{-1} for lattice spacing $k < 300$. Figure 7a shows a tetrahedral lattice with $\{Ik\}$ surface, where I is the number of steps and k is the lattice spacing (number of lattice sites along axis x on a densely packed terrace). As k grows, the surface ever more approximates a singular plane. At $k > 500$, critical supersaturation in the vicinity of the interface is not observed. However, actual steps in solutions containing surfactants have no distinct crystallographic faceting and non-uniformly move over the surface.

A particle that is adsorbed disturbs the electron density at the metal surface when it approaches the substrate. This disturbance propagates according to the law

$$\bar{n} = \bar{n}_0 + K_a \exp(-K_p z),$$

where $\bar{n}_0$ is the mean bulk concentration of electrons, K_a and K_p are coefficients of intensity and decay of electron density, and z is the coordinate on an axis normal to the metal surface. The magnitudes of K_a and K_p are determined by the nature of the metal, primarily by the work function of an electron and the Fermi level.

The interaction energy of the particles adsorbed on the substrate [$E_{ij} = E_{ij}(T, \theta_{\text{surf}}) = E_{\text{surf-surf}}(r)$] is determined by Friedel oscillations of electron density and depends on the shape of the Fermi surface⁵¹

$$E_{\text{surf-surf}}(x) \sim \frac{\sin(2\vec{k}_F r + m)}{r^n}, \quad (28)$$

where $\vec{k}_F$ is the Fermi wave vector, r is the distance between interacting surfactant particles, and the constants m and n depend on the nature of the metal. The Fermi surface, i.e., the surface of constant energy in a multidimensional space, is described by the $\vec{k}_F$ vectors, local Fermi levels (energies) E_F . At 0 K, all states 0.07 eV lower than E_F will be occupied, while the states higher than E_F by the same value will be vacant. The function $\phi = m/r^n$ is introduced in equation (28) to take into account the additional indirect (exchange of electrons in the surfactant-metal system through the conduction band of the substrate) contribution into the energy of the surfactant-surfactant interaction. The values of m and n depend on the shape of the Fermi surface. In terms of graphical 3D-models, the Fermi surface characterises a definite metal with fixed topology and constant energy in inverse space (in a particular three-dimensional case, in an inverse lattice; for example, see Ref. 52) with wave vector $\vec{k}_F$ of the electron angular momentum. A classical surface of a solid is a direct analogue of the quantum-mechanical Fermi surface for conductivity electrons in inverse space.⁵³ The Fermi surface is transformed to a usual classical surface as the relativistic mass of electron increases. Transition to a state of Fermi surface instability is accompanied by a second-order phase transition and, eventually, desorption of the surfactant from the crystal surface.⁵⁴ For an amorphous material, the Fermi surface is spherical, i.e. analysis of the Fermi surface topology affords the possibility of predicting the high chemical resistance (low corrosion rate) of solids in an amorphous state.

The Fermi surfaces of compounds that exist in the crystalline state contain cylindrical regions. In this case, the energy of interaction in the direction perpendicular to the cylinder axis (when $m = 0, n = 2$) is inversely proportional to the square of the distance r between the interacting particles

$$E_{\text{surf-surf}}(r) \sim \frac{\sin(2\vec{k}_F r)}{r^2},$$

while for planar regions of the Fermi surface, in the direction perpendicular to them (when $m = 0, n = 1$),

$$E_{\text{surf-surf}}(r) \sim \frac{\cos(2\vec{k}_F r)}{r}.$$

In Hubbard's model,^{41, 55} the penetration depth of the electric field of an adsorbed particle into a metal substrate depends on the Thomas-Fermi length of shielding⁹

$$l_{\text{TF}} = \left(\frac{E_F}{6\pi\bar{n}_0|e^-|^2} \right)^{1/2},$$

where n_0 is the bulk concentration of electrons in the conduction band. Such adsorbents as Fe, Ru and Os, which have considerably higher Fermi energies than Cu, Ag and Au, have better chemisorption characteristics with respect to particles that are adsorbed with charge transfer. In the series of transition d -metals, elements occupying the middle of a series have higher E_F than the elements with d -shells filled (Cu, Ag, Au).

The chemisorption activity of transition metals is considerably affected by light particles implanted in the near-surface layer; either these particles are local harmonic oscillators, or they create their own sublattice as a result of self-organisation (provided that they have high diffusion mobility). Absorption of hydrogen by the near-surface layer of the metal or 'poisoning' of the metal by other light chalcophilic elements change both the E_F and $\bar{n}_0$. Programmes are available for modelling the ionic implantation into crystals, which provide the possibility of building concentration profiles⁵⁶ and subsequently of assessing changes in the corrosion resistance of the crystals subjected to a treatment.

On translation-invariant substrates, the adsorption of solution particles (the primary act in metal dissolution) can be rather strictly described (in analytical form) within the Ising model. The formation of ordered adsorption structures determines the kinetics of the corrosion dissolution of a metal whose surface is homogeneous (and/or the structural defects of the near-surface layer of the metal are blocked). For computer simulation purposes, the rates of partial cathodic and anodic reactions (cathodic and anodic current densities, i_c and i_a) occurring in non-saturated solutions can be expressed by equations that follow from formula (4),

$$i_c = v_i \exp \frac{\mu_e}{kT}, \quad (29)$$

$$i_a = v_i \exp \frac{-n_{\text{ads}} E_b}{kT}, \quad (30)$$

where v_i is a frequency factor (of the order of the Debye frequency, 10^{13} s^{-1}), μ_e is the equilibrium chemical potential in solution, n_{ads} is the number of bonds of an adsorbed atom with other lattice atoms and E_b is the energy required for the cleavage of one M–M bond. In the absence of charge transfer, the equilibrium chemical potential μ_e and the chemical potential of surfactant particles on the interface, μ_{surf} , are related to the solution concentration c_{surf} and activity a_{surf} by the equation

$$\mu_{\text{surf}} - \mu_e = kT \ln \frac{c_{\text{surf}}}{c_e} = kT \ln \frac{a_{\text{surf}}}{a_e},$$

where c_e and a_e are the equilibrium concentration and activity of the surfactant in solution, respectively.

When a quasi-equilibrium stationary state accompanied by inter-phase transfer of charged particles has been established in a system, the well-known Nernst equation, which describes the inter-phase distribution of particles, is applicable in the thermodynamic description:

$$\mu_e = 0.5WE_b + \frac{RT}{nF} \ln \frac{c_{\text{surf}}}{c_e}.$$

Here W is the number of the closest neighbours of an atom (in bulk metal, $W = 12$ for a face-centred lattice and $W = 8$ for a body-centred lattice), n is the number of electrons transferred in an elementary discharge act, and F is the Faraday constant. The factor of 0.5 is introduced in the first term of the right-side expression (the two-particle potential $\mu_0 = 0.5WE_b$) in order to avoid counting the interaction of each pair of particles twice.

The coordination number W is determined by the topology of an adsorbed particle on the crystal surface. The magnitude of W on the crystal surface is considerably smaller (by a factor of two in a semi-crystalline position) than in the crystal bulk. The adsorption energies expressed according to Kaishev–Stransky⁵⁷ for different crystal faces (ΔE_{ads}) and the energies of semi-crystalline positions ($E_{1/2}$) depend strongly on the reticular density of the surface (the packing density of surface atoms) of the crystal, S_{hkl} . The magnitude of ΔE_{ads} for atomic-planar F -faces is 0.3 to 0.5 of the heat of sublimation ΔH ; the $E_{1/2}$ values increase along the series: body-centred, face-centred, hexagonal close packed crystal.

Analysis of equations (29) and (30) shows that the frequency factor

$$v_i = k_0 a_a^0 \equiv k_0 a_k^0,$$

[here $k_0 = (kT/2\pi h)(z^\# / z)$, where h is the Planck constant, $z^\#$ and z are the partition functions per unit volumes of the active complex and the reagents in the electrolyte, respectively] most strongly depends on the activities of the cathodic and anodic surface complexes a_c^0 and a_a^0 , which change in parallel with the concentration of Ox- and Red-particles in solution. The smaller W the easier it is to block the crystal surface element (cell) by an inhibiting surfactant. Conversely, adsorbed (mostly, semi-crystalline) particles have higher tendency to ionisation (dissolution). The excited state of an atom undergoing ionisation exists for a sufficiently long time ($\leq 10^{-8} \text{ s}$), that rapid transition of the surface atom to an unstable state is necessary. The characteristic times of electrochemical reactions ($\sim 10^{-11} \text{ s}$) are considerably longer⁵⁸ than the characteristic times of redistribution of bound charges of the solvent at the interface ($10^{-14} - 10^{-15} \text{ s}$). Hence, metal dissolution becomes possible. Increasing the electrochemical dissolution rate (decreasing the time t to $10^{-12} - 10^{-13} \text{ s}$) by application of anodic current to an activated surface considerably decreases the contribution of surface defects to the overall balance of mass loss by the crystal due to dissolution. This provides the opportunity to use the classical formal kinetics approach based on the Langmuir isotherm (18) in the computer simulation. It is assumed in equations (29) and (30) that the dependence of the equilibrium concentration c_e on the surface coverage by adsorbed particles obeys the Langmuir isotherm.

According to the classical concepts, an act of dissolution is preceded by the transition of a surface atom to a metastable state, which occurs with a frequency differing from the Debye frequency ν_D (which is characteristic of the bulk of the crystal), $\nu_i = 10^{13} - 10^{14} \text{ s}^{-1}$. This frequency ν_i [the pre-exponential factor in kinetic equations (4) and (29)] depends on the Debye frequency ν_D according to the formula

$$\nu_i = \nu_D \exp \left(\frac{-\Delta G}{RT} \right) = \nu_D \exp \left(\frac{\Delta S}{k} \right) \exp \left(\frac{-\Delta H}{RT} \right), \quad (31)$$

where the product $\nu_D \exp(S/k)^\ddagger$ is an insignificant deviation of a local volume of the system from the equilibrium state; ΔG , ΔS , and ΔH are the Gibbs free energy, the entropy and the enthalpy, respectively, required for the transfer of the atoms under consideration to the peak of the potential barrier between two equilibrium states of the structure.

Thus, in covering layers (commensurate or non-commensurate) on the surface and in the crystal bulk, a certain phonon mismatch (mechanical resonance) appears, which is, strictly speaking, the origin of phase transitions in these layers.

III. Models using the Monte Carlo method

In its canonical distribution variant, the MC method, which is based on statistical sampling of configuration mean values, calculates the mean values ($\bar{M}$) according to the formula

$$\bar{M} = \frac{\sum_i M_i \exp(-E_i/kT)}{\sum_j \exp(-E_j/kT)} = \sum_i M_i P_i,$$

where M_i is one of physical characteristics of the i th configuration, E_i is its energy, and P_i is the probability that the i th configuration would appear.

$$P_i = \frac{\exp(-E_i/kT)}{\sum_j \exp(-E_j/kT)}.$$

[‡] The Einstein formula describing the fluctuation probability in the first near-surface metal layer.

The MC method is a method of numerical experiment; it is versatile and provides highly reliable results.⁵⁹ The MC technique can be used for the 2D Ising model for which exact solutions can be obtained,⁶⁰ in particular, for the formation of fluctuations of material density (drops) at the interface.^{61,62} The stability of mesoscopic water clusters (small drops) and thin films is being studied intensively.⁶³ Ultra-thin water films on solid surfaces form crystal-like structures. The nucleation of small water clusters in the electrolyte bulk far from the interface occurs on ions of dissolved salts. The instability range of small water clusters results from the relative weakness of long-range electrostatic interactions. Large clusters form mesoscopic bubbles in polar liquids. Their shape is calculated using the MC method.⁶⁴ Calculations in independent sets (several hundred MC steps per adsorption cell) make it possible to access continuous thermodynamic functions of continuous thermodynamic variables. A stable state of a multi-particle system containing N particles corresponds to a minimum of the functional of inter-particle effective (resulting in the formation of chemical bonds) potentials $U_{\text{ef}}(r_i, r_j)$ of the type (2)

$$U_{\text{ef}}(r_i, r_j) = \int \dots \int [\exp(\beta_{\text{JT}, E_b}) - \exp(\beta_{\text{JT}, U_{\text{ef}}})]^2 dr_1 \dots dr_N.$$

Here the Jackson–Temkin parameter is

$$\beta_{\text{JT}, E_b} = \frac{-0.5E_b(r_1, \dots, r_N)}{kT} \text{ and } \beta_{\text{JT}, U_{\text{ef}}} = \frac{-0.5 \sum_{i < j}^N U_{\text{ef}}(r_i, r_j)}{kT}.$$

Naturally, the order in which problems are solved by MC simulation depends on the level of development of mathematical methods and computational means. Using the simplest pair potentials, electrochemical problems on the adsorption of chalcophilic particles on various faces of single crystals of noble transition metals were solved. Complication of the pair potentials is required if the act of adsorption involves more complex particles, such as water molecules.^{65,66} In this case, the effective potential $U_{\text{ef}}(r_i, r_j)$ also becomes more complex. For example, the Raman–Stillinger potential⁶⁷ contains a spherically symmetric term [Lennard-Jones potential (2a), $U_{\text{LJ}}(r_{ij})$] and an electrostatic potential [$U_{\text{el}}(r_i, r_j)$] of point charges displaced from the geometric centre of the molecule

$$U_{\text{ef}}(r_i, r_j) = U_{\text{LJ}}(r_{ij}) + \sigma(r_{ij})U_{\text{el}}(r_i, r_j). \quad (32)$$

Here $\sigma(r_{ij})$ is a smoothing function for correction of the interactions at small interatomic distances.

Lattice gas models can be realised in the 3D variant for the estimation of phase transformations at interfaces: these are Brunauer–Emmett–Teller generalised kinetic models, both in discrete and diffusion forms.⁶⁵ For example, problems on the absorption of electrolytic hydrogen by crystals are solved by numerical MC methods in three-dimensional systems⁶⁶ using 3D lattices with $> 10^6$ positions for occluded hydrogen and with variable parameters of the Gaussian distribution of equilibrium states and middle points between them. Subsequently, more complex systems were studied, such as M–chalcophilic particles, adsorption of CO, H₂O and halides, co-adsorption of CO and hydrogen on noble metal surfaces.^{67,68}

In early studies on the simulation of water adsorption on metal electrodes by the MC method,^{69,70} the crystal surface was simulated as a hard wall of a ‘jelly’-metal. The surface charge was distributed uniformly, and the interface was simulated as a ‘flat condenser’, d being the distance between the plates; the ions located in the water layer were approximated by spherically symmetrical particles.⁷¹ The inter-ionic interaction was described within the Poisson–Boltzmann model

$$U(r_{ij}) = \frac{n_i n_j |e^-|^2}{4\pi\epsilon_0\epsilon_r r_{ij}} \text{ for } r_{ij} > d,$$

$$U(r_{ij}) = \infty \text{ for } r_{ij} < d,$$

where r_{ij} is the distance between ions i and j ; n_i and n_j are the concentrations of ions (of the kind i and j , respectively); ϵ_0 and ϵ_r are the dielectric constants of the solvent and the solution, respectively; and the interaction between the solvent layer and the ‘jelly’-metal surface was described as

$$U(r_{ij}) = \frac{q_i n_i |e^-| \Delta z_i}{2\epsilon_0\epsilon_r}.$$

Here q_i is the surface charge density; Δz_i is the normal distance (along the z axis) between the charged surface of the ‘jelly’-metal and an ion with a radius of r_i . It should be noted that Δz_i is the major factor determining the formation of commensurate and non-commensurate covering adsorbed layers.

When an interface is simulated, a cylinder, which contains a certain number of chalcophilic particles, is ‘cut out’ of the electrolyte so that some of the particles are located at the interface. For example, various models of hydrogen bond networks in 3D water have been constructed using the MC method. Three variants of the model were considered in Ref. 72: with 125 and 343 particles in the unit cell and with two different starting conditions. The differences between the variants are almost not discernible in the pair correlation functions, *i.e.* atom–atom radial distribution functions, which reveal the specifics of orientation order at sufficiently long distances (> 10 nm). The use of radial distribution functions is caused by the impossibility of obtaining exact solutions from equations, which operate in terms of particle coordinates and atom–atom interaction potentials. When one starts calculations, it is important to make a correct selection of the pair potential $U(r_{ij})$, which is different in adsorption 2D layers and in the bulk of the liquid phase. A model Hamiltonian of the system should certainly involve the mapping effects (for transition metals, the distance from the mapping plane to the crystal surface, which correlates with reticular density variation and decreases on changing from a ‘loose’ face to a densely packed one), the reconstruction of the near-surface metal layer due to adsorption and the evolution of non-equilibrium defects in this layer under the action of an electrolyte.

In the Kossel–Stransky model (TLK model), equations resembling (29) are used at moderate solution oversaturations for computer MC calculations of growth and dissolution of crystals under the above assumptions.^{73–75} During the growth of an ideally smooth surface of a cubic crystal, the sticking probability of the particles that are deposited, P_a , is determined by the product of the probability of existence of n closest neighbours at one cell [$P_g(n)$] and the probability that the electrode potential E assumes a certain value, $P_\eta(E)$

$$P_a(n, E) = P_g(n)P_\eta(E).$$

In metal corrosion, the probability of detachment of an atom from the first (n_1) and second (n_2) closest neighbours $P(n_1, n_2)$ for the {001} faces of a cubic crystal depends on the energy of cleavage of M–M bonds due to corrosion according to an Arrhenius-type equation:⁷⁶

$$P(n_1, n_2) = v_i(n_1, n_2) \exp \frac{-E_b(n_1, n_2)}{RT}.$$

The bond energy, $E_b(n_1, n_2) \equiv n_{\text{ads}} E_b$, depends on solution under-saturation, as well as on the charge, ion size and concentration of an inhibitor if present. The physical meaning and structure of the equation presented above are similar to those of equation (30): the activation energy (energy of cleavage of one M–M bond) is $E_b(n_1, n_2) = n_2 E_2 - n_1 E_1 = -n_{\text{ads}} E_b$, and the frequency factor $v_i(n_1, n_2)$ is determined by equation (31). The values of E_1 and E_2 (bond energies for the first and second closest neighbours, respectively) can be calculated using pair potentials.

The MC method can be used for the computer description of both the development of local forms of corrosion (formation and

growth of a single pit) and the evolution of non-singular (diffusion) surfaces of crystals with surface defects in the form of steps and kinks. The growth of an ideally smooth (singular) single crystal surface is simulated by the MC method within the cellular automata model,⁷⁷ which takes the adsorption of discharging particles, their movement on the surface, incorporation, chemical reactions and desorption into account.^{78,79} The discrete growth of a new monolayer in a unit cell (Fig. 8) starts from the centre (single cell). A single cell is filled by an adsorbing particle in the case if two neighbouring sites are also vacant. The process is controlled⁸⁰ by a pair correlation function $\sigma(r, t)$, which changes with time (provided that the adsorption acts occur randomly)

$$\sigma(r, t) = \frac{-0.5 \exp(-2A) \sum_{n=0}^{\infty} (-2A)^{2n+r+1}}{(2n+r+1)!},$$

where $A = 1 - \exp(-t)$.

Figure 8. Types of elementary cells; (a) square (Neumann vicinity); (b) hexagon; (c) rhombus (Moore vicinity).

The distribution of adsorbed particles in a lattice that consists of cells with N_{ac} active centres on the surface has the dispersion $N_{ac}A \exp(-4A)$ at high N_{ac} . The cellular automata model is applicable to the description of selective dissolution of crystals occurring by generation of dissolution steps.⁸¹

The computer simulation of changes in the morphology of a pit growing at a dislocation exit on an 'atomically-smooth' surface is based on the concept that atoms with higher energies are preferentially removed from the crystal. In the first step, a 2D nucleus of the pit is formed. In the model suggested in Ref. 82, the authors considered the bonding of the atom being removed with the neighbouring metal atoms located in four types of positions at the closest distances. Computer calculations determine the energy of each atom along the perimeter of the 2D nucleus and select the atom with the weakest bonding to the substrate. After removal of this atom, the calculation of energies of perimeter atoms is repeated.

It has to be noted that this approach ('removal' of the most weakly bound atoms from the near-surface layer of a crystal) is also quite acceptable for the computer simulation of alloy corrosion or dissolution of high-index surfaces of pure metals.⁸³ Numerous experiments on the study of alloy corrosion⁸⁴ show that the most electronegative component is the first to be removed from the surface during alloy dissolution. For example, in modelling of the dissolution of an Fe–Cr alloy,⁸⁵ the percolation process is taken into account; this process can be visualised as follows in the 2D variant:

Here P_{dis} is the dissolution probability. At step *a*, the surface contains oxidised atoms of both iron and chromium. Removal of an iron atom from the surface (step *b*) results in the formation of a continuous surface coating by chromium, *i.e.*, a percolation 2D cluster is formed. The percolation leading to enrichment of the surface by chromium atoms results in surface passivation, structural stabilisation of the alloy and a decrease in the dissolution rate. A similar procedure of 'removal' of the most weakly bound atom in the 3D model of metal corrosion makes it possible to simulate the movement of dissolution steps on high-index crystal planes.

Eventually, corrosion stabilises the surface layers of crystals. The stabilisation occurs not only by percolation but also by forming a near-surface layer with particular grain composition. Problems of grain growth in near-surface metal layers were successfully solved using recrystallisation MC models.⁸⁶

In the scheme of layered growth (dissolution) by the FVdM mechanism, the computer simulation of the TLK model (Fig. 9) uses a MC principle in the random formation of the growth (dissolution) centres.⁸⁷ This eventually results in the formation of a quasi-stationary surface topography characterised by the Gaussian distribution of layer coverage. The mean rate of tangentially moving atom chains ($\bar{V}$) is proportional to the degree of surface coverage by adsorbed atoms (θ_{ads})

$$\bar{V} = \frac{L}{t} \theta_{ads},$$

where L is the distance between atom chains (steps) and t is the time of incorporation of an adsorbed particle into a step. Of course, the rate $\bar{V}$ also depends on the density of active centres on the step, N_{ac}

$$\bar{V} = \frac{L}{N_{ac} \Delta t},$$

where $\Delta t = t/N_s \theta_{ads}$ is the time (the Monte Carlo time) till a successful attempt to incorporate an adsorbed particle at a functioning active centre and N_s is the number of substrate surface atoms. It is important that the Monte Carlo time Δt matches the increment of real time (or time step in numerical simulation).⁸⁸ Of major importance are the transition probabilities $P_a(n, E)$ describing a system in the MC model. The sums

$$\sum_1^n P_a(n, E)$$

determine the trajectories of the system transition into the equilibrium state. The main mechanism of the growth of adsorbed layers in the MC model is diffusion of an adsorbed particle until it incorporates itself in an active centre. The role of active centres is usually played by kinks.

Figure 9. Scheme of increase in the crystal surface in the TLK model by the mechanism of anisotropic growth of 'orthogonal strings' (atomic chains); AC is the active centre.

The model of consecutive coverage by monolayers (see Fig. 9) is not the only one or the simplest one of TLK models. The following models have also been considered:^{75,89} the random deposition model in which an adsorbing particle striking the crystal surface is instantly attached to a stable position of a tetragonal lattice (substrate); the model of locally-perfect layer-by-layer growth on a tetragonal lattice in whose each cell 'perfect' (not correlated with other cells) layer-by-layer growth of a non-commensurate phase occurs; the local islets model in which the diffusing adsorbed particles are attached in highly-coordinated positions on a crystal surface.

For the stepped surface in the TLK model (see Fig. 7), the flux of adsorbing particles striking the crystal surface should consist of, at least, three components:⁹⁰

$$J = J_S + J_i + J_r,$$

where J_S is the flux of surfactant particles attaching themselves to a step; J_i is the flux of surfactant particles directed to active centres (2D-islets); and J_r is the flux of desorbing surfactant particles.

The MC method was used for the surface of a simple cubic crystal in a study of surface covering with an epitaxially growing film.^{90,91} It was shown that concentration oscillations appearing in the simulation of layer-by-layer film growth mechanism do not correspond to the exact filling of monolayers. As the length of surface migration of adsorbed atoms, λ ($\lambda < L$), increases, the oscillation region shifts from the region of high degree of coverage, $\theta_{\text{surf}} > 1$, to the region of small degree of coverage, $\theta_{\text{surf}} < 1$. It should be noted that concentration oscillations near the electrode surface in homogeneous nucleation have been reported as early as in Refs 92 and 93, which dealt with an MC simulation of polynuclear crystal growth. Concentration oscillations in solution give rise to non-uniformity of layer growth in galvanic coatings.

The electrodeposition of metals was studied using computer simulation methods.^{94,95} It was assumed that the new phase growth occurred under the conditions of simultaneous coverage of adsorption cells with various particles and that depolarisation on both components occurred due to changes in the free energies of the components.⁹⁶ In a model predicting the alloy composition, the shift of the equilibrium potential for each component of a two-component alloy was used as the main characteristics for computer simulation^{94,95}

$$E_i = \frac{RT}{nF} \ln c_i - (1 - c_i)^2 E,$$

where c_i is the molar fraction of the i th component in the alloy, $E = \Delta H/nF$, and ΔH is the integral enthalpy of mixing. In computer simulation of the formation of binary alloys AB in an electrochemical process by the VW mechanism, the work of formation of 2D-nuclei is determined taking account of the energy of elastic deformation of the crystal lattice

$$W_{hkl} = 6\pi \left(\frac{r_A - r_B}{r} \right)^2 r^3 \frac{c_B(1 - c_B)}{k_1 + k_2 C_B},$$

where r_A and r_B are the atomic radii of metals A and B, $r = (r_A + r_B)/2$ is the mean atomic radius, k_1 and k_2 are coefficients:

$$k_1 = \frac{3}{4} G_A + K_B,$$

$$k_2 = \frac{3}{4} K_B + G_A - \frac{3}{4} K_A - G_B,$$

G_A and G_B are the shear moduli of metals A and B, K_A and K_B are the deformability (compressibility) coefficients of metals A and B, respectively.

MC computer simulation was used in studies of the electrochemical growth of crystals, both in the form of islets⁹⁷⁻⁹⁹ and in vicinal form (pack of monoatomic steps).^{83,100,101} It was shown that surface evolution is in good accord with morphological

patterns of the growth of continuous galvanic deposits and with the structural features of insular coatings. For example, computer simulation using Lennard-Jones potentials (2a) showed⁹⁸ that on the surface of a crystal with a simple cubic lattice, subcritical size nuclei of the new phase have body-centred cubic structure, while after reaching the critical size, they have face-centred cubic (FCC) structure. This result totally agrees with experimental estimates of actual heteroepitaxial systems 'crystal surface – galvanic deposit'.

The use of the vicinal growth model on a crystal surface¹⁰² assumes correlated movement of not only monoatomic steps but also [taking account of equation (4)] electrochemically active adsorbed particles. The energy of the diffusion barrier $E(\theta_{\text{surf}})$ is expressed as the sum

$$E(\theta_{\text{surf}}) = E_s(\theta_{\text{surf}}) + nE_N(\theta_{\text{surf}}),$$

where $E_s(\theta_{\text{surf}})$ and $E_N(\theta_{\text{surf}})$ are contributions of interaction with the surface and with the closest neighbours, respectively; $n = 1-4$. The rate of movement of vicinals during crystal dissolution primarily depends on their height.¹⁰³⁻¹⁰⁶ Splitting of vicinals from a chain of atoms, which belong to a step and are transferred into solution, occurs in a correlated way. Consideration of corrosion of a crystal face having linearly-stretched defects is possible either in the classical variant or with account of wave cooperative features of the interaction of adsorbed particles and surface atoms on the interface.¹⁶

In the classical Kossel-Stransky's theory of attachment (separation) of particles to a monoatomic step of a crystal, the rates (currents) of the direct and reverse processes ($\vec{i}$ and $\vec{i}'$, respectively) obey equations of the type (31)

$$\vec{i}(\vec{i}') = v_D \exp\left(\frac{\Delta S}{k}\right) \exp\left[\frac{-(E_a + \Delta E_{\text{lat}}(T))}{kT}\right], \quad (33)$$

in which $E_a + \Delta E_{\text{lat}}(T) = \Delta H$, $\Delta E_{\text{lat}}(T)$ is the energy of lateral interaction of particles in a step (the Frumkin correction factor). An equation has been suggested for the estimation of the rate of movement of a single monoatomic step (V_L) containing kinks:

$$V_L = 0.5 \exp \frac{\Delta G^\ddagger}{RT} a_0 \left(\frac{2\text{ch}(3\sigma_L)}{RT} - 1 \right) \left(\exp \frac{\Delta \mu}{RT} - 1 \right), \quad (34)$$

where $\Delta G^\ddagger$ is the free activation energy of dissolution in a kink on the step; a_0 is the activity of the substance in a saturated solution; σ_L is the specific free surface energy per atom located in the step; $\Delta \mu$ is the difference between the chemical potentials of the material of the crystal that is dissolved in supersaturated and saturated solutions.

Estimates using equation (34) show that an increase in σ_L should increase the rate of step movement, V_L . If a step and/or kinks on crystal steps in a Kossel-Stransky crystal are blocked by a corrosion inhibitor, σ_L and probabilities of detachment of an atom from the surface, $P(n_1, n_2)$, change. The reasons for this are as follows: first, a decrease in the number of 'free bonds' of an atom in a certain position; second, a decrease in the number of bonds between the inhibitor atoms and the crystal lattice; third, attenuation of electronic vibrational modes (changes in the electronic and phonon spectra of the surface atomic layer of the crystal) due to the adsorption of solution particles. The attenuation of vibrations due to the inhibiting adsorption of small chalcophilic particles is stronger in the direction tangential to the surface than in the perpendicular direction.¹⁰⁷ The decrease in the probability of exit of an atom from a kink due to dissolution inhibition can be determined from the equation

$$\frac{\Delta P(n_1, n_2)}{P(n_1, n_2)} = 1 - K \exp(n_{M-M} + n_{\text{surf-M}} + n'_{M-M}), \quad (35)$$

where K is the metal deformability constant; $n_{\text{surf-M}}$ is the number of bonds between the inhibitor particles and the lattice atoms; n_{M-M} and n'_{M-M} are the numbers of free bonds of an atom in a

typical lattice position with and without an inhibitor, respectively. According to equations (2) and (34), each bond has distinct energetic characteristics, and the maximum contribution to its realisation in inhibiting adsorption is made by the electronic interaction in the adsorbate–adsorbent system [the third term $H_{\text{surf-M}}$ in Hamiltonian (19)]. In an adsorbed dipole, the attenuation of stretching vibrations of the M–surfactant bond is primarily caused by changes in the density of states at the Fermi level of the transition metal, E_F , due to the adsorption of an inhibiting particle.

Simulation of adsorption by MC methods showed⁴⁷ that mutual attraction of particles on a stepped surface strongly affects the adsorption isotherm, which leads to the separation of the system into phases with low and high degree of coverage. For example, the authors¹⁰⁸ who made a calculation of the effective interaction potential of the simplest adsorbing particle (hydrogen) also noted that the Hamiltonian for the full energy of an adsorbed hydrogen atom similar to Hamiltonian (20) consists of the energy of hybridisation of one-electron states with d -electrons of the adsorbent, the adsorption energy of hydrogen on a uniform surface, and the short-range attraction forces between the adsorbed atoms and the ion framework of the metal. The Hamiltonian for a hydrogen molecule desorbing from a metal surface and not bound to it by chemical forces is expressed by the sum (in atomic units)

$$\hat{H}_{H_a H_b} = \underbrace{-0.5\nabla_1^2 - r_{1a}^{-1}}_{\text{Hamiltonian of the atom } H_a} + \underbrace{-0.5\nabla_2^2 - r_{2b}^{-1} - r_{1b}^{-1} - r_{2a}^{-1} - r_{12}^{-1}}_{\text{Hamiltonian of the atom } H_b} - \underbrace{R_{ab}^{-1}}_{\text{Hamiltonian of the molecule } H_a H_b}. \quad (36)$$

Here the subscripts 1 and 2 signify the arbitrary numbers of 1s electrons of the H_a and H_b atoms; r_{1a} , r_{2a} and r_{1b} , r_{2b} ; r_{12} and R_{ab} are the electron–nucleus, nucleus–nucleus distances and the distance to the adsorption point, respectively.

When atoms H_a and H_b are remote from each other, they can be considered non-interacting, and the electronic state of each of them can be described by wave functions $G_a(1)$ and $G_b(2)$ of isolated atoms H_a and H_b

$$\begin{aligned} G_a(1) &\equiv 1S_a(1) = \frac{1}{\sqrt{\pi}} \exp(-r_{1a}), \\ G_b(2) &\equiv 1S_b(2) = \frac{1}{\sqrt{\pi}} \exp(-r_{2b}). \end{aligned} \quad (37)$$

The spins in the H_2 molecule are anti-parallel; hydrogen atoms adsorbed on a metal (with parallel spins) interact through van der Waals forces (repulsion).

A thermodynamic estimation of surface states shows that the lowest equilibrium chemical potential μ_e for surface states is realised for the most loosely packed {110} FCC and {111} BCC faces. This ensures their preferential filling with adsorbed particles within the model of hard spheres with uniform charge ('jelly'-spheres).

Results of computer simulation by methods of statistical selection of configurations (MC method) based on the concepts described above, with the assumption that E_b in a crystal does not depend on the direction $\langle hkl \rangle$, lead to certain conclusions on new phase formation on singular and low-index single crystal faces. This approach is quite satisfactory for the problem of corrosion inhibition, since films formed on the surface are two-dimensional and comply to the pre-phase formation condition. For example, on a face-centred crystal under monoepitaxy conditions (direct continuation of the solid phase lattice into solution) and with the Jackson–Temkin parameter $\beta_{JT} = 0.5E_b/kT = 0.3$ ($\Delta\mu \simeq 0.01kT$ for crystal growth from solution), the rate of new phase formation depends considerably on the reticular density of the face.^{92,93} It is lower on the most densely packed (111) FCC face than on the 'loose' (110) FCC face. According to Gilmer,^{5,6} this follows even from simple geometric considerations: an atom adsorbed on the (111) face of an FCC crystal is bound to three substrate atoms, as

compared to four on the (001) FCC face and five on the (011) FCC face, *i.e.* the reverse process (dissolution) on an FCC crystal will not occur as easily on the densely packed (111) face as on the 'loose' (110) face.

IV. Molecular dynamics models

The molecular dynamics (MD) method is less widespread than the MC method. Both methods provide information on the structures of phases interacting in electrolytes; it is impossible to obtain such data by statistical methods. The MD method is based on calculations of trajectories for separate adsorbed particles on a crystal surface and for groups of interacting atoms. The calculation of new positions occupied by the particles moving on the surface is made using classical equations of motion. Pair potentials (2b) are used; for densely packed structures, the Lennard-Jones potential summed over all atom pairs

$$U_{LJ}(r_{ij}) = \sum_{i < j} U(r_{ij}) = \sum_{i < j} 4E_L \left[\left(\frac{B_a}{r_{ij}} \right)^{12} - \left(\frac{C_{lat}}{r_{ij}} \right)^6 \right], \quad (38)$$

where $r_{ij} > 2.5(C_{lat}, B_a)$, is used most commonly. If $r_{ij} \leq 2.5(C_{lat}, B_a)$, potential (38) is complicated by introducing a Coulombic correction when solving electrochemical problems^{109,110}

$$\sum_{i < j} U(r_{ij}) = \sum_{i < j} 4E_L \left[\left(\frac{B_a}{r_{ij}} \right)^{12} - \left(\frac{C_{lat}}{r_{ij}} \right)^6 \right] + \frac{n_i n_j |e^-|^2}{4\pi\epsilon_0 \epsilon_r r_{ij}}.$$

For loose structures, the Stillinger–Weber (SW) potential,¹¹¹ which takes three-particle interactions into account, is used. The SW potential for a triplet of atoms (i, j, k) has the form¹¹² (if $B_a = C_{lat}$)

$$U_{CB}(r_{ijk}) = f\left(\frac{r_{ij}}{\sigma}\right) f\left(\frac{r_{ik}}{\sigma}\right) \left(\cos \theta_{ijk} + \frac{1}{3} \right)^2.$$

In this expression, the smoothing nonparametric function $f(r/\sigma)$, which is common at small interatomic distances r , approaches zero at $r \rightarrow 1.8\sigma$, and θ_{ijk} is the internal angle of the triplet.

The diffusion coefficient of adsorbed particles on the crystal surface is calculated using the Einstein's equation

$$D_{\text{surf}} = \frac{\{ \langle [\vec{R}_i''(t_2) - \vec{R}_i''(t_1)]^2 \rangle_i \}_c}{4(t_2 - t_1)},$$

where $\vec{R}_i''(t_1)$ and $\vec{R}_i''(t_2)$ are radius-vectors of the i th surface-adsorbed surfactant particle at instants t_1 and t_2 after the equilibrium state has been reached; $\vec{R}_i'' = (x_i, y_i)$ are vector projections on the 2D crystal surface; the angle brackets $\langle \dots \rangle_i$ and braces $\{ \dots \}_i$ mean statistical averaging over all i particles (on the surface and in the bulk of the 3D layer at the metal–electrolyte interface). A diffusing surfactant particle comes to an equilibrium position on the crystal surface by crossing the quasi-stable bridging positions. This crossing occurs through thermal activation. The minimum path, $l_{\min}$, that has to be overcome along a crystal surface with a surface concentration of active lattice sites N_s (10^{18} – 10^{19} m⁻² for cubic crystals) is controlled by the well-known 'directed movement of a salesman' relationship

$$l_{\min} = \frac{1}{N_s} + \frac{1}{L_l} \frac{2[2P_a(n, E) - 1]}{N_s^2},$$

where L_l is the characteristic size of the substrate tetragonal lattice and $P_a(n, E)$ is the probability of occupying a point by the i th surfactant particle to be adsorbed.

The equations for D_{surf} and $l_{\min}$ presented above are also valid under conditions of self-diffusion of particles, adsorbed on a metal crystal, along its surface. Adsorbed surfactant particles (including large organic molecules) can form structures 'cross-linked' with the near-surface metal layer. Calculation by the MD method of the height of surface barriers upon intrusion of surfactant particles into thin channels (pores) of a metallic adsorbent makes it possible

to assess the steric factor.¹¹³ The surface layer itself is considered within the MD method as a non-commensurate ‘cross-linked’ adsorption layer of particles of the same type as the crystal atoms.

Finally, the MD method determines the position of a surface-adsorbed particle with a local minimum of potential energy. Along one of the pathways for the formation of adsorption layers, minimisation of energy as a function of position of the adsorbed particle occurs through thermal activation. An increase in temperature accelerates the attainment of low-entropy surfactant state (self-organisation) on the crystal surface. Computer simulation by the MD method showed¹¹⁴ that in the temperature range close to the melting point, non-commensurate and adsorbed surfactant layers are transformed to a particular state that precedes melting. In this case, a correction for the attraction of particles, $\Delta E_{\text{attr}}(T, \theta_{\text{surf}})$, similar to the Frumkin’s correction factor²⁰ for the description of adsorption in the double electric layer, should be introduced to the Arrhenius equation for the diffusion coefficient

$$D_{\text{surf}}(T) = D_0 \exp \left\{ \frac{-[E_a + \Delta E_{\text{attr}}(T, \theta_{\text{surf}})]}{kT} \right\},$$

The value of $\Delta E_{\text{attr}}(T, \theta_{\text{surf}})$ depends on the degree of coverage of the crystal surface by surfactant particles and on the force of interaction of these particles between each other.

Combining the MD and MC methods provides a possibility of separating the first-kind phase transition as such¹¹⁵ from processes of rapid but continuous changes in the physical parameters measured. This possibility is particularly important in the simulation of non-commensurate surfactant particles on crystal surfaces in the electrochemical contact with an electrolyte. Computer simulation by the MC method (using the Lennard-Jones potential) of the near-surface layer of the (100) face of a FCC crystal showed¹¹⁶ that the temperature of non-commensurate first surface atomic layer is lower than that in the bulk of the crystal. Thus, non-commensurate adsorption layers stabilise or ‘slow down’ the near-surface crystal layers thus increasing its dynamic stability in a corrosive medium.

The MD method is widely used in the description of the movement of light particles (particularly, hydrogen¹¹⁷) on the surface and in the bulk of metal crystals.¹¹⁸ The diffusion of hydrogen is simulated by the MD method taking account of the reticular density of near-surface metal layers.¹¹⁹ It was found that light surfactant particles quickly form commensurate and non-commensurate phases on the crystal surface. As MD simulation shows,¹²⁰ non-commensurate islets are formed from particles in the first stage, in agreement with the VW model (see Fig. 3). In the crystal bulk, the hydrogen atoms which get into the metal due to an electrochemical process occupy tetra- or octahedral interstices. Comparison of results obtained using lattice gas models with MD results^{121, 122} makes it possible to identify reliably the topology of hydrogen absorbed by the crystal.

The vast majority (95%) of atom jumps from one interstice to another in the crystal bulk occur in a non-correlated Brownian way. For example, the movement of adsorbed hydrogen on the surface of a metal saturated with hydrogen occurs in a directed (correlated with the potential energy surface) way, along valley bottoms of the potential pattern. Computer simulations of this process virtually always use the lattice gas model, and calculations using this model are carried out by the MC method.¹²³

Hydrogen absorbed by a metal crystal changes the hierarchy of internal defects of various dimensionality, particularly near interfaces.^{123–125} 2D-Models of external and internal interfaces of polycrystals that form a lattice of coinciding points or densely-packed hexagons are used for the description of changes in macroscopic deformation characteristics, as well as the evolution of dislocation ensembles in terms of the monoatomic steps model by Frenkel–Kontorova.^{126–128} Computer simulation of dislocation rearrangements on a metal surface in the 3D-variant and assessment of the topology of the electric pattern of the process¹²⁹

make it possible to predict the adsorption coverage of not only singular but also diffuse surfaces.

The pair potentials used in MD computer simulations are relatively simple. For example, the following potentials are used in the description of hydrogen behaviour in palladium:¹²¹

$$U_{\text{Pd-Pd}}(r) = \begin{cases} \sum_{S=0}^6 K_S r^S, & r < r_0 \\ 0 & r \geq r_0 \end{cases}, \quad (39)$$

$$U_{\text{Pd-H}}(r) = \begin{cases} K_S \exp\left(-\frac{r}{\rho}\right), & r < r_1 \\ 0, & r > r_1 \end{cases},$$

$$U_{\text{H-H}}(r) = U_{\text{Pd-H}}(r),$$

where K_S is the volume factor characterising the height of the energy barrier (when a hydrogen atom passes through it) of a surface Pd-cluster (up to six Pd atoms); r is the interstice (pore) radius; r_0 is the radius of pore ‘cutting’ in the formation of a 2D lattice of surface Pd atoms; r_1 is the radius of an adsorbed hydrogen atom (it is smaller than that of a hydrogen atom, $r_{\text{H}} = 0.46$ nm, and depends on the nature of the transition metal adsorbent); the constants for palladium are as follows: $\rho = 0.05$ nm, $r_1 = 0.38$ nm, $K_S = 15.3$ eV.

The MD method is successfully used for the simulation of the co-adsorption of chalcophilic particles on surfaces of transition metal single crystals;^{128–130} it is also convenient for the simulation of water/metal interfaces.¹³¹ In early studies, lattice 3D-models of H₂O adsorption on a homogeneous metal surface (Hg) were calculated by the MC method using asymmetric multi-particle pair potentials.^{132–134} All calculation models are based on the Gouy–Chapman theory of the double layer structure. In analytical form, the pair potentials for the system water–platinum are represented as follows:

$$U_{\text{H}_2\text{O-Pt}} = U_{\text{O-Pt}}(r_{\text{O-Pt}}, \vec{R}_{\text{O-Pt}}) + U_{\text{H-Pt}}(r_{\text{H-Pt}}) + \quad (40)$$

$$+ U_{\text{H-Pt}}(r_{\text{Hb-Pt}}),$$

$$\text{where } U_{\text{O-Pt}} = [1894 \exp(-1.1004r) - 1886.3 \exp(-1.0966r)] f(\vec{R}) + 10^6 \exp(-5.3568r) [1 - f(\vec{R})],$$

$$U_{\text{H-Pt}} = 1.7142 \exp(-1.2777r),$$

where $f(\vec{R}) = \exp(-0.5208 \vec{R}^2)$, r is the distance between adsorption cells on the metal surface (pore radius), $\vec{R}$ is the projection of the vector of displacement of an adsorbed H₂O molecule on the metal surface; $\vec{R}$ and r are expressed in nm, and the potentials are in eV. In adsorbed water layers on single crystal faces, a periodic structure with a definite oscillation period was observed. The interaction energy $E_b \equiv U_{\text{H}_2\text{O-M}}$ for water–metal contacts is 51.1 (Al), 33.7 (Ni), and 36.6 kJ mol^{−1} (Cu). Based on results of MD simulations,¹³¹ four main configurations can be suggested for the geometry of a water molecule on an ideal metal ‘jelly-surface’ (Fig. 10); they do not differ much from the well-known Okamoto’s model¹³⁵ in which water molecules, whose ‘oxygen ends’ form an angle of 10–35° with the crystal surface.

Consideration of this process within the Ising model suggests the formation of periodic surface low-entropy water structures¹³⁶

Figure 10. Variants of location of adsorbed water molecules on an ideal metal surface (according to results of the MD method).

Figure 11. Schematic crystallographic model of adsorbed water on the (110) surface of a face-centred crystal.

(Fig. 11). On stepped crystal surfaces, water structures with a certain fractal dimensionality are formed.¹²⁴

It has been shown³¹ that water molecules are displaced from 'loose' steps to densely packed terraces by HSO_4^- or SO_4^{2-} ions, which have larger surface areas; a portion of water molecules are moved into the second adsorption layer.

V. Conclusions

Physicochemical patterns obtained by computer simulation of corrosion-electrochemical processes on metal–electrolyte interfaces satisfactorily describe many features of these complex phenomena. The computer models used now have good predicting ability. Although model Hamiltonians for the systems in question have many drawbacks, consideration of the main physical features of crystallisation – decrystallisation mechanisms provides the possibility to determine the types of materials that would be most stable in corrosive environments, to obtain information on the kinetics of corrosion-electrochemical processes, to predict the character of anticipated metal degradation and the structure of a galvanic coating to be formed.

Irrespective of the simulation method, the main direction of studies on computer simulation of electrochemical processes is related to the description of collective phase transitions. The speed and amount of memory available in modern computers make it possible to take into account not only the behaviour of separate particles in an ensemble (nearest environment) and the evolution of ensembles (clusters) in translation-invariant structures on the surface, but also mass and charge transfer of a material in a continuous medium. Therefore, the computer description of the behaviour of commensurate (floating) and non-commensurate (cross-linked) adsorption layers is based on non-linear relationships, which take into consideration the wave character of processes in these layers. One of the features of computer simulations is that they take into account correlated movements of adsorbed particles on the crystal surface involved in the formation of certain structures of adsorbed layers with fractal dimensionality and in adsorption-induced rearrangements (second-order phase transitions) in the crystal near-surface layer. It is believed that the development of mathematical methods and the coming of new-generation computers will make it possible to simulate the cooperative behaviour of resonance-linked double electric layers on the sides of the crystal and the electrolyte (the Frumkin double plane-parallel capacitor).

Abstract. Basic advances and prospects of further research in the field of the chemistry of nanoparticles are considered. The principal factors determining the unusual physicochemical properties of semiconductor nanoparticles are discussed. It is pointed out that the kinetics of chemical transformations on the surface and in the bulk of nanoparticles differs from that in infinite space. The classical equations of chemical kinetics can be used for the description of the processes on the surface of nanoparticles down to a size that exceeds the size of the reacting molecules by an order of magnitude. The large relative fraction of surface atoms in nanoparticles determines the size dependences of the melting temperature and pressure at which the crystal lattice of a semiconductor rearranges (*i.e.*, a phase transition occurs in the semiconductor crystal). Because of the comparable size of nanoparticles and the delocalisation radii of charge carriers non-linear optical effects arise and the redox properties and optical characteristics of nanoparticles become dependent on their size. The bibliography includes 219 references.

I. Introduction

It is usually assumed that the properties of solid semiconductors are independent of their size. However, this assumption is only valid for the solids containing a macroscopic number of atoms. Recent studies have shown that if the characteristic size of semiconductor particles is less than 10 nm, then many of their physicochemical properties appear to be essentially different from analogous properties of macroscopic objects. This is related to the fact that semiconductors are characterised by high energies of intermolecular interactions and a macroscopic crystal can be considered as one large molecule when its electronic properties are described. The electronic excitation of semiconductor crystals results in the formation of a loosely coupled electron–hole pair. In semiconductors, the size of the delocalisation area of such a pair can be many times larger than the lattice constant. The decrease in the size of a semiconductor crystal down to a size comparable with the delocalisation area of the electron–hole pair affects its electronic characteristics. The blue shift of the excitonic absorp-

tion band of a semiconductor crystal with decreasing its size is a remarkable manifestation of this effect.^{1–3} For CdS, which is the best studied semiconductor material, the blue shift of the excitonic absorption band is observed beginning from a crystal size of 5–6 nm. Ultrasmall semiconductor crystals are known in the literature as nanocrystals, particles with quantum size effect, or nanoparticles. The intensive studies of physicochemical properties of nanocrystals that have been carried out during the last decade have revealed a large number of other their unusual characteristics, such as the size dependence of the radiative lifetime of the electronic excitation, melting temperature, pressure needed for the rearrangement of the crystal structure (*i.e.*, for a phase transition to occur in the crystal), and character of the kinetics of chemical processes on the surface of nanoparticles.

Unusual physicochemical properties of nanoparticles are due to three main reasons. First, as has been noted above, the size of nanoparticles is comparable to the Bohr radius of the excitons in semiconductors. This determines the optical, luminescent, and redox properties of nanoparticles. Second, the surface atoms constitute a considerable fraction of the total number of the atoms of the nanoparticle. For example, a 5-nm CdS nanocrystal has about 15% of the atoms on the surface. The surface atoms contribute largely to the thermodynamic characteristics of solids and determine to a considerable extent the melting temperature and structural transitions for nanoparticles. Third, the natural size of the nanoparticles is comparable with the size of molecules. This determines the peculiarities of the kinetics of chemical processes on the surface of nanoparticles.

Most of the studies of semiconductor nanoparticles are of interdisciplinary character and are devoted to investigation of their colloidal solutions. To date, nanoparticles of ZnO, Fe₂O₃, SiO₂, MoS₂, CdS, HgS, GaP, Cd₃P₂, BiI₃, PbI₂, and a number of other semiconductors have been synthesised and investigated. For several semiconductor nanoparticles, the structure of the electronic bands and electrochemical characteristics, optical properties and photochemical reactions, processes of charge separation and recombination, mechanical and thermal properties, regularities of reactions of the molecules adsorbed on the surface have been investigated.

In this review, the major achievements in the chemistry of semiconductor nanoparticles are considered. Methods for the synthesis of nanoparticles, quantum size effects characteristic of semiconductor nanoparticles, photocatalytic processes with participation of semiconductor nanoparticles and films prepared on their base are considered. The primary attention is given to the prospects of the use of the nanostructures to implement practically important processes of photomineralisation of environmentally

hazardous organic compounds. In the concluding section of this review, a brief outline of feasible lines for further development of nanochemistry is given.

II. Methods for the synthesis of nanoparticles

Methods for the synthesis of nanoparticles can be divided into three main groups.

1. Synthesis of semiconductor nanoparticles in solutions of the corresponding salts by controlled addition of anions (or cations) or by hydrolysis.^{4–19}

2. Preparation of nanoparticles as a result of phase transformations.^{20–22}

3. The synthesis of nanoparticles in aerosols.^{23–25}

The radiation-chemical method for the synthesis of nanoparticles is also known.³ Methods for the synthesis of complex multicomponent nanoparticles have been developed. Most of the semiconductor colloidal systems studied to date have been obtained by synthesising the semiconductor nanoparticles in homogeneous solution.

Commercial colloidal solutions containing the SnO₂ nanoparticles (with an average diameter of 3 nm) are available from Johnson Matthey (USA). A Degussa P25 TiO₂ powder containing 80% of anatase and 20% of rutile is often used in photocatalysis.²⁶

1. Synthesis of semiconductor nanoparticles in colloidal solutions

The semiconductor nanoparticles are prepared by chemical synthesis in homogeneous solutions,^{4–7} in micelles, vesicles, and Langmuir–Blodgett films,^{8–11, 27, 28} in polymers,^{12–14} in glasses,^{15, 16} in zeolites,^{17–19} and in β -cyclodextrin.²⁹

The easiest and most common method for the preparation of semiconductor nanoparticles is the synthesis from the starting reagents in solution by arresting the reaction at a definite moment.^{4–7} Nanoparticles of metal sulfides are synthesised by a reaction of a water-soluble metal salt and H₂S (or Na₂S) in the presence of an appropriate stabiliser such as sodium metaphosphate. For example, the CdS nanoparticles can be synthesised by mixing Cd(ClO₄)₂ and Na₂S solutions:

The growth of the CdS nanoparticles in the course of reaction is arrested by an abrupt increase in pH of the solution.

Colloidal particles of metal oxides can be obtained by hydrolysis of the corresponding salts. For example, the TiO₂ nanoparticles are readily formed in the hydrolysis of titanium tetrachloride

Unfortunately, most of the colloidal solutions of nanoparticles have low stability towards coagulation and possess a large size dispersion. Coagulation can be prevented by passivation³⁰ of the surface of nanoparticles by hydroxyl ions,³¹ amines,³² or ammonia.¹³ Yet another procedure for the stabilisation of colloidal solutions of nanoparticles is the coating of their surfaces with polyphosphates³³ or thiols.^{34–38} As a result, one can obtain a stable colloidal solution of nanoparticles, isolate the nanoparticles as a powder, and then prepare a colloidal solution again by dispersing the powder in a solvent.

Usually, the methods for the synthesis of nanoparticles discussed above result in a nonuniform size distribution. It is possible to decrease the width of this distribution by monitoring the synthetic procedures and using high-pressure liquid chromatography and capillary electrophoresis.^{39, 40} In the latter case, the separation of nanoparticles is achieved due to the different charge/size ratios for nanoparticles of different sizes.

Small monodisperse semiconductor clusters can be obtained by performing the synthesis inside zeolite cages.^{17–19, 41, 42} Thus Cd₄S₄ clusters were synthesised inside zeolite Y.^{17–19}

It is possible to synthesise larger semiconductor nanoparticles of fixed size by introducing additional molecules to a small initial cluster stabilised by organic ligands in a colloidal solution.^{7, 43–47} For instance, it was found that the size of CdS clusters coated with thiophenolate ions can be increased if a metal sulfide is added to the solution.⁴⁵ Such a polymerisation of inorganic compounds appeared to be applicable to the synthesis of large semiconductor clusters of strictly fixed size from small particles. Wang and Herron⁴⁸ succeeded in obtaining the [Cd₂₀S₁₃(SC₆H₅)₂₂]^{8–} clusters containing 55 cadmium and sulfur atoms from the pyramidal [Cd₁₀S₄(SC₆H₅)₁₆]^{4–} clusters containing 30 cadmium and sulfur atoms.³⁴ The introduction of additional five sulfide ions leads to the fusion of two small clusters into one larger cluster. The process of the formation of a large cluster from two small ones can be illustrated by the following scheme:

The pyramidal structure of the [Cd₂₀S₁₃(SPh)₂₂]^{8–} clusters was confirmed by X-ray analysis. Further addition of sulfide ions made it possible to obtain the Cd₃₂S₁₄(SC₆H₅)₃₆ tetrahedral clusters containing 82 cadmium and sulfur atoms.⁴⁶

Usually, it is assumed that the nanoparticles containing several hundreds of atoms have a spherical or ellipsoidal shape. However, recent investigations have shown that the nanoparticles often have clearly defined facets and their shape is analogous to that of macroscopic crystals.^{49, 50}

The shape and size of nanoparticles is determined by electron microscopy. For a rough estimation of the size of nanoparticles, it is also possible to use the optical spectra of colloidal solutions. These estimates are based on the dependence of the position of the excitonic band of nanoparticles on their size. However, overestimated values are obtained for small nanoparticles⁴⁸ (this problem is discussed in more detail below).

2. Dispersion of macroscopic particles in solutions

It is possible to obtain semiconductor nanoparticles by sonication of colloidal solutions of large particles. Nanoparticles of layered semiconductors are also formed upon mere dissolution of large particles in an appropriate solvent, which was observed for MoS₂ and WS₂.²⁰ Layered MoS₂-type semiconductors are characterised by a weak van der Waals interaction between separate S–Mo–S layers. In the course of dissolution, the solvent molecules penetrate between the layers of the semiconductor and destroy large particles. In the case of MoS₂, the process of destruction can proceed until the formation of a two-layer particle. No further stratification of the semiconductor occurs, since the formation of single-layer particles is accompanied by a considerable increase in the free energy of the system.^{20, 21, 30}

Sonication of a disperse system of large semiconductor particles can also result in the formation of nanoparticles. The nanoparticles of MoS₂, WS₂,^{20, 21} PbI₂,⁵¹ and α -Fe₂O₃^{52, 53} were obtained by this procedure.

Nanocrystals of layered PbI₂-type semiconductors have a disk-like shape and discrete ‘magic’ sizes of the disks.⁵¹ For these semiconductors, a stable nanoparticle of a minimum size is assumed to be the smallest crystallite conserving the hexagonal symmetry of the macroscopic crystal. Such a crystallite is composed of two seven-atom iodine layers and two lead layers. Large stable nanoparticles are obtained from this ‘seed’ by the layer-by-layer addition of extra iodide ‘caps’ symmetrically around the perimeter. An analogous structure is also assumed for MoS₂ nanoparticles.^{30, 54}

3. Gas-phase synthesis of nanoparticles

The gas-phase synthesis of TiO₂ and Si nanoparticles was carried out by Visca and Matijevic⁵⁵ and Fojtik *et al.*⁵⁶ Thus the Si nanoparticles are formed in 67% yield in the combustion of SiH₄

under oxygen-deficient conditions as a result of thermolysis of SiH_4 .

An interesting method for the gas-phase synthesis of nanoparticles of various materials has been suggested:^{23–25} the nanoparticles were obtained by pulsed laser vapourisation of metals in a chamber filled with a known amount of a reagent gas and by controlled condensation of nanoparticles onto the support. A schematic view of the installation for the synthesis of nanoparticles is given in Fig. 1. As the metal atoms diffuse from the target to the support, they interact with the gas to form the desired compound (for instance, oxide in the case of oxygen, nitride for nitrogen or ammonia, carbide for methane, *etc.*).

Figure 1. Schematic view of the installation for the synthesis of nanoparticles by laser vapourisation of metals.

The pulsed laser vapourisation of metals in the chamber is a modification of the known method for the synthesis of metal compounds in a diffusion cloud chamber and makes it possible to prepare nanoparticles of mixed molecular composition, such as mixed oxides/nitrides and carbides/nitrides or mixtures of oxides of different metals. Along with the reagent gas, the chamber contains an inert gas, such as He or Ar, at a pressure of 10^{-2} –1 Torr, which favours the establishment of steady convection between the heated bottom plate and cooled top plate. In an experiment with a single pulse of a Nd:YAG laser (532 nm, 15–30 mJ pulse⁻¹, 10^{-8} s), over 10^{14} metal atoms are vapourised. A new compound is formed due to the reaction between the ‘hot’ metal atoms and the gas molecules, which is accompanied by the energy loss of the molecules formed by collisions with the inert gas atoms. The metal atoms that did not enter into reaction and the molecules of the new compound are carried by convection to the nucleation zone on the cooled top plate. By changing the composition of the inert gas and the reagent gas in the chamber and varying the temperature gradient and laser pulse power, it is possible to control the elemental composition and size of nanoparticles that are obtained.

4. Synthesis of nanoparticles of mixed composition

The high efficiency of recombination of the light-generated electrons and holes presents obstacles to the practical application of the semiconductor nanoparticles in photocatalysis. In this connection, the semiconductor nanocrystal hetero-structures composed of semiconductors with different structures of the electronic levels are of considerable interest. With these structures, it is possible to attain high quantum yields of charge separation. The nanoparticles schematically shown in Fig. 2 belong to this class of hetero-structures. The structures analogous to that shown in Fig. 2a are known for CdS/TiO₂,^{57–60} CdS/ZnO,^{57,61} CdS/AgI and CdS/HgS,^{62,63} Cd₃P₂/TiO₂ and Cd₃P₂/ZnO,⁶⁴ and AgI/Ag₂S.⁶⁵ For CdS/TiO₂, photoexcitation into the absorption band of CdS results in the electron transfer from CdS to TiO₂, while the hole remains in CdS. These structures are also of interest as nanoscale rectifier units for molecular electronics.⁶⁶

Figure 2. Schematic view of hetero-nanoparticles of different structure. (a) and (b), see text; CB stands for conduction band; VB stands for valence band.

The formation of hetero-structures of the ‘core–shell’ type (see Fig. 2b) has been demonstrated using the CdSe/ZnS and ZnS/CdSe nanoparticles as an example.⁶⁷ These nanoparticles are obtained by controlled precipitation of semiconductor molecules of one type (‘shell’) on the pre-synthesised nanoparticles of another type (‘core’). The synthesis of the shell is carried out in colloidal solution by methods analogous to those for the synthesis of one-component nanoparticles considered above. The crystalline shells grow on the nanocrystal core despite the fact that the lattice constants in CdSe and in ZnS differ by 13%.

The following ‘core-shell’ type nanoparticles have also been synthesised: HgS/CdS,⁶³ ZnS/ZnO and ZnO/ZnSe,^{68,69} TiO₂/SiO₂ and TiO₂/SnO₂,⁷⁰ and TiO₂/ZnO.⁷¹ These hetero-nanoparticles can, in turn, be coated with a layer of one more semiconductor. Below we shall consider the use of nanocrystal hetero-structures in photocatalysis.

5. Preparation of nanostructured semiconductor films

Thin films of semiconductor nanoparticles are of considerable practical interest. Synthesis of these films is carried out by precipitation of pre-formed nanoparticles from colloidal solutions onto the supports, by direct precipitation of semiconductor molecules onto the support, and by oxidative hydrolysis of the corresponding metal salts at the anode. Usually, the films are 0.1–1 μm thick. The following films of semiconductor nanoparticles are known: SnO₂,⁷² ZnO,^{61,73} TiO₂,⁷⁴ WO₃,^{75,76} and Fe₂O₃.⁷⁷ The SnO₂, ZnO, TiO₂, and WO₃ films were obtained by precipitation of nanoparticles. Direct precipitation of semiconductor molecules onto the support is used to prepare films of nanoparticles of semiconductors on the basis of Group II–VI elements.

Oxidative hydrolysis of TiCl₃ at pH 2.3 and a platinum anode potential of 0 V vs. saturated calomel electrode (SCE) results in the formation of nanoparticles with an average diameter of 1–2 nm on the anode surface.⁷⁸

Nanostructured films containing nanoparticles of different semiconductors can be prepared by coprecipitation. A schematic view of such a film supported by the optically transparent electrode is given in Fig. 3. Yet another method for the preparation of such films consists in wetting of a plate coated with a film of a certain type of nanoparticles with a solution containing metal ions followed by wetting of the plate with a solution containing sulfide ions. This procedure was used for the synthesis of films containing ZnO and CdS nanoparticles.^{61,79}

Figure 3. Schematic view of the process of photostimulated charge separation in the nanostructured film composed of TiO₂ and SnO₂ nanoparticles adsorbed on an optically transparent electrode (OTE).

III. The quantum size effects

1. Specific features of the kinetics of chemical processes on the surface of nanoparticles

Surface reactions determine the behaviour of nanoparticles in colloidal solutions and the possibility of using the semiconductor nanoparticles in photocatalysis. For reagents adsorbed on the surface of nanoparticles, a chemical reaction cannot be considered as a process occurring in an infinite volume with a constant average density of the molecules. This is associated with the fact that the surface area of nanoparticles is rather small and comparable with the size of the reagents. In such a system, the kinetics of a bimolecular chemical reaction differs from the classical kinetics.

The mathematical approach to the classical, or deterministic, chemical kinetics ignores fluctuations in the concentration of reacting molecules. However, the nanoparticles composed of a small number of reacting molecules are characterised by relatively large fluctuations in the number of reagents. This results in different changes in the concentration of reagents on the surface of different nanoparticles with time; the general kinetic law for a macroscopic sample can be obtained by averaging the kinetics over all nanoparticles. A mathematical description of the processes occurring in such systems is based on the use of a stochastic approach, which takes into account the statistical fluctuations in the number of reacting molecules.⁸⁰

General regularities in the kinetics of diffusion-controlled reactions for a small number of reacting molecules have been analysed.^{81,82} The kinetics of a bimolecular reaction was analysed assuming that the reaction can be characterised by the rate constant k , which is the same for all the reagent pairs. The results of these studies can be used for the analysis of the kinetics of reactions occurring on the surface of nanoparticles.

For a reaction

the kinetics of the loss of the reagents is described by the following equation:⁸³

$$\frac{\bar{N}(t)}{\bar{N}(0)} = \sum_{n=1}^{\infty} B_n \exp\left[-\frac{1}{2}n(n-1)kt\right] \quad (3)$$

where $\bar{N}(t)$ and $\bar{N}(0)$ are the current and initial concentrations of the reagents on the surface of nanoparticles averaged over the sample containing a macroscopic number of nanoparticles,

$$B_n = \frac{(2n-1)}{2^n} \frac{\exp[-\bar{N}(0)]}{\bar{N}(0)} \sum_{j=n}^{\infty} \frac{\bar{N}(0)^j}{(j-n)!} \frac{\Gamma[(j-n+1)/2]}{\Gamma[(j+n+1)/2]},$$

$$j = n, n+2, n+4, \dots$$

and $\Gamma(x)$ is the gamma function.

The assumption in Eqn (3) that the rate constant k is the same for all the reagent pairs may appear to be invalid for small nanoparticles. Actually, it was shown⁸⁴ that Eqn (3) is only valid for nanoparticles the size of which exceeds that of the reagents by at least an order of magnitude. In Fig. 4, the results of the analysis of the kinetic curves of the reaction occurring on the surface within a circle of radius R are presented as an example. The analysis was performed using Eqn (3) and the curves were calculated by the Monte Carlo method for various size of the reagent particles and the circle. The triplet-triplet annihilation of molecules recombining at a distance of R_{ef} was considered as a model reaction. It can be seen that for $R < 10R_{ef}$ the k value becomes dependent on the radius of the circle and, hence, Eqn (3) is no longer valid for small radii R .

Figure 4. The dependence of the rate constant for the triplet-triplet annihilation on the circle radius for different effective radii of the triplet-triplet annihilation.

R_{ef} / Å: (1) 4.3; (2) 2.9; (3) 2.3.

The Monte Carlo method can also be used for the description of the kinetics of processes on the surface of nanoparticles. The number of reagent molecules on the surface of each nanoparticle is small, and calculations of the reaction kinetics by the Monte Carlo method do not require much effort. The parameters of the process used in the calculations are chosen so as to achieve the best agreement between the calculated and experimental kinetic dependences.^{84,85}

Only a few processes occurring on the surface of nanoparticles have been studied to date. The triplet-triplet annihilation of the zinc tetraphenylporphyrin (ZnTPP) molecules adsorbed on the surface of disk-like MoS₂ nanoparticles, whose size did not exceed 2 nm, has been studied.⁸⁶ The annihilation of the triplet molecules occurs by an exchange mechanism and its efficiency (w) is determined by the distance between the reagents (r)^{87,88}

$$w(r) = v \exp\left(\frac{-2r}{a}\right), \quad (4)$$

where v and a are the parameters of the process.

Typical curves of the decay of triplet-excited molecules on the surface of MoS₂ nanoparticles and the results of their analysis by the Monte Carlo method are shown in Fig. 5. This analysis appeared to be very 'sensitive' to the parameters of the interaction

Figure 5. The decay curves of triplet-excited ZnTPP molecules on the surface of the MoS₂ nanoparticles. The average number of the triplet-excited ZnTPP molecules on the surface of the MoS₂ nanoparticles is equal to 6.4 (1) and 22 (2); the lines correspond to the experimental data, the dots correspond to the results of the Monte Carlo calculations.

between the triplet molecules and their diffusion over the surface of MoS₂ nanoparticles. The following values of the parameters were obtained: $\nu = 10^6 \text{ s}^{-1}$ and $a = 3 \text{ \AA}$, and the diffusion coefficient of the zinc porphyrin molecules over the surface (D) was found to be equal to $10^{-8} \text{ cm}^2 \text{ s}^{-1}$.

Quenching of the singly excited molecules of ZnTPP and its metal-free analogue (H₂TPP) by various quinones (Q) on the surface of the MoS₂ nanoparticles has been studied.⁸⁴ The kinetics of the processes was analysed by both the Monte Carlo method and kinetic equations⁸⁵ derived for the reactions occurring on the surface of the disk-like nanoparticles. The decay curves of the singlet-excited H₂TPP molecules in the reaction with duroquinone (DQ)

are shown as an example in Fig. 6.

The theoretical decay curves (dots in Fig. 6) calculated by the Monte Carlo method are in good agreement with the experimental ones.

Figure 6. The kinetics of the luminescence decay of the singlet-excited H₂TPP molecules on the surface of the MoS₂ nanoparticles; (1) in the absence of the quencher; (2) each nanoparticle is capped, on the average, with five duroquinone molecules; (3) the shape of the excitation light pulse. The dots on curve 2 correspond to the results of the Monte Carlo calculations.⁸⁴

The detailed kinetic analysis of bimolecular processes of electron and energy transfer on the surface of nanoparticles of various shapes has been carried out.^{84, 89} It has been possible to obtain an analytical solution of the kinetic problem only for the reactions occurring on the surface of planar disk-like nanoparticles. It has been shown that the corresponding equations derived for the disk-like nanoparticles can be applied to nanoparticles of different (*viz.*, cubic, spherical, and tetrahedral) shape.

The kinetic equations for the processes of electron and energy transfer on the surface of nanoparticles are rather complicated. For example, the kinetics of electron transfer from a donor to acceptors on the surface of disk-like nanoparticles is described by the following equation:⁸⁵

$$\frac{N(t)}{N(0)} = \quad (6)$$

$$= \frac{2}{R^2} \int_0^R r_0 \exp \left\{ -\bar{n} \left[1 - \exp \left\{ -\frac{1}{\pi(R^2 - d^2)} f(r_0, t) \right\} \right] \right\} dr_0,$$

where $\bar{n}$ is the average number of the acceptor molecules on each surface of a disk-like nanoparticle, d is the sum of the donor and acceptor radii,

$$f(r_0, t) = \int_d^{R+r_0} \left\{ 1 - \exp[-w(r)t] \right\} 2r \varphi_{\max} dr, \quad (6a)$$

$w(r)$ is the function describing the dependence of the probability of the electron transfer from the donor to the acceptor on the distance between them, and the meaning of other parameters is evident from Fig. 7.

Figure 7. Disk-like (a), spherical (b), square (c), and pyramidal (d) nanoparticles. The acceptor (1) and donor (2) species.

The use of the kinetic equations similar to Eqn (6) for the description of the processes on the surface of nanoparticles requires time-consuming calculations. In this connection, the problem of applicability of simpler kinetic equations derived for the processes occurring on the unbounded surface to nanoparticles appears to be important.⁸⁹

To solve this problem, an analysis according to the following scheme was performed in considering specific equations used for the description of the processes occurring with participation of nanoparticles. First, the decay curves of the reagents on the surface of nanoparticles were calculated by the Monte Carlo method. Then, these curves were considered as 'experimental' kinetic curves and were used to find the characteristics of the process using the corresponding kinetic equations. The coincidence between the calculated characteristics and the

corresponding parameters used in the calculations of the kinetic curves by the Monte Carlo method served as the criterion of the applicability of the kinetic equations for the description of the processes occurring on the surface of nanoparticles.

It was shown^{84,89} that the classical equations of chemical kinetics can be used to determine the parameters of the processes occurring on the surface of nanoparticles down to their characteristic linear size that is 2–7 times larger than the size of reacting molecules or effective radii of the interaction between them. The application of the classical equations of chemical kinetics to nanoparticles of smaller size results in considerable errors in the calculations of characteristics of the processes. For small nanoparticles, the parameters of chemical reactions can be calculated using the corresponding equations for the nanoparticles or by the Monte Carlo method.

The following equation is an analogue of Eqn (6) for an unbounded surface and the $w(r)$ function defined by Eqn (4):

$$\frac{N(t)}{N(0)} = \exp \left[-c \left(\frac{\pi a^2}{4} \ln^2 vt - \pi d^2 \right) \right], \quad (7)$$

where c is the surface concentration of an acceptor. The possibility of using Eqn (7) to analyse the kinetic curves on the surface of disk-like nanoparticles of various size has been considered.⁸⁹ It was shown that Eqn (7) can be used for calculating the parameters of interaction between the reagents (a and v) down to the disk size 7 times greater than the sum of the donor and acceptor radii.

2. The effect of the nanoparticle size on their optical and luminescent characteristics

a. Dependence of the optical and luminescent characteristics of nanoparticles on their size

It seems evident that the excitation energy of small semiconductor crystals must differ from that of a large semiconductor. In fact, the energy of the electronic excitation of an isolated molecule is usually considerably higher than the energy of the interband transition in the corresponding macroscopic semiconductor. Hence, a size range must exist in which the low energy of the electronic excitation of a crystal changes smoothly to the high value characterising the individual molecule on going from the crystal to the molecule. For semiconductor crystals, such a transition occurs in the nanometric range. So far, the effect of the nanoparticle size on their optical spectra has been found for many types of semiconductors.^{3,38,90–108} The optical spectra of CdSe nanoparticles of various size are shown in Fig. 8a as an example.¹⁰⁸ It can be seen that the absorption band of nanoparticles does shift to the shorter wavelength (blue) region as their size decreases.

The quantitative dependence of the minimum electronic excitation energy of a nanoparticle on its size can be approximately calculated taking into account the relation between the uncertainty in the position (Δx) and the uncertainty in the momentum (Δp) of the exciton in a macroscopic crystal and in a nanoparticle:

$$\Delta p \Delta x \geq \frac{\hbar}{2}. \quad (8)$$

The delocalised exciton has no fixed position in the periodic potential of the macroscopic crystal, whereas its energy (E) and momentum ($p = \hbar k$) are strictly fixed, and at small k

$$E = \frac{\hbar^2 k^2}{2\mu}, \quad (9)$$

where μ is the effective mass of the exciton.¹⁰⁹ For a nanoparticle, the uncertainty in the position of the exciton depends on the characteristic size of the nanoparticle

$$\Delta x = d.$$

Figure 8. The absorption spectra of the CdSe nanoparticles of various size (a) and the dependence of the energy at the maximum of the absorption band of the CdSe nanoparticles on their radius (b).

(a): R /nm: (1) 2.1; (2) 2.3; (3) 2.7; (4) 3; (5) 4; (b) the line corresponds to the $1/R^2$ dependence.

Assuming that the relation between the energy and momentum is independent of the particle size, the exciton energy will change in inverse proportion to the square of the characteristic size of the nanoparticle.

A more rigorous analysis of the effect of the size on the energy of excitonic excitation of spherical nanoparticles (E_n) gives the following relationship:

$$E_n = E_m + E_l, \quad (10)$$

where E_m is the energy of the interband transition in a macroscopic semiconductor, E_l is the energy of exciton localisation in the nanoparticle:

$$E_l = \frac{\hbar^2 n^2}{8R^2\mu} - \frac{1.78e^2}{\epsilon R} - 0.248E_R^*, \quad (11)$$

where n is an integer, R is the radius of the nanoparticle, $\mu = (m_e^{-1} + m_h^{-1})^{-1}$ (m_e and m_h are the electron and hole effective mass, respectively), ϵ is the dielectric constant of the semiconductor, and E_R^* is the effective Rydberg energy.^{1,2,110} The first term on the right of the equation is predominant, and its nature was considered above, the second term takes into account the Coulomb interaction between the electron and hole inside the nanoparticle, and the third term is responsible for the spatial correlation. The n values larger than 1 in Eqn (11) correspond to the exciton transitions to higher excited states (see Fig. 8a).

In the case of anisotropic semiconductors, the electron and hole effective masses depend on the direction of motion and Eqn (11) becomes more complex with allowance for this anisotropy⁵¹

$$E_{n_x, n_y, n_z} = \frac{\hbar^2}{8} \left(\frac{n_x^2}{\mu_x L_x^2} + \frac{n_y^2}{\mu_y L_y^2} + \frac{n_z^2}{\mu_z L_z^2} \right) - \frac{1.78e^2}{\epsilon R} - 0.243E_R^*, \quad (12)$$

where n_x , n_y , and n_z are integers; μ_x , μ_y , and μ_z are the effective masses of the exciton along the corresponding directions, and L_x , L_y , and L_z are the dimensions of the nanoparticle.

The dependence of the energy at the maximum of the absorption band of CdSe nanoparticles on their radii calculated from the data in Fig. 8a is shown in Fig. 8b. It can be seen that the exciton energy of nanoparticles is well described by the $1/R^2$ dependence.

The effective mass approximation and, hence, Eqn (11) become inapplicable for small nanoparticles. The observed values of the exciton energies of nanoparticles appear to be lower than those predicted from Eqn (11). A more exact expression for the exciton energy can be found by quantum-chemical methods.^{111, 112} However, quantum-chemical calculations cannot also be applied to very small nanoparticles. The lower confidence level of the exciton energy calculations varies for different semiconductors. In the case of the effective mass approximation, it is determined by the value of the Bohr radius of the exciton. The dependence of the energy of the first excitonic CdS band on the nanoparticle size and the results of the corresponding calculations performed in the effective mass approximation⁴⁸ and by quantum-chemical methods¹¹³ are shown in Fig. 9 as an example.

Figure 9. Dependence of the energy of the first excitonic band of CdS on the nanoparticle size and the results of the corresponding calculations performed in the effective mass approximation (1)⁴⁸ and by quantum-chemical methods (2).¹¹³

Equation (11) is often used for the estimation of the size of nanoparticles. Usually, the last two terms on the right side of this equation are neglected. For the first excitonic transition we have

$$R = \frac{\hbar}{\sqrt{8\mu E_1}}. \quad (13)$$

As was mentioned above, the effective mass approximation and, hence, Eqn (13) is inapplicable for very small nanoparticles. The use of Eqn (13) results in overestimation of the size of nanoparticles; the smaller the true size of nanoparticles the larger the overestimation.

Another manifestation of the size effect in the optical characteristics of nanoparticles is the blue shift of their optical spectrum, which occurs when an excess electron is injected into the nanoparticle.^{114–121} Three different reasons may account for the shift: first, the increase in the exciton energy due to the influence of the electric field of the excess electron;^{119, 121} second, the effect of filling the lowest vacant state with the excess electron whose excitation to a higher vacant state requires higher energy;^{122, 123} and third, a decrease in the oscillator strength of the excitonic transition due to the effect of trapped electrons and holes.^{13, 124}

Recombination of light-generated charges results in luminescence of nanoparticles. In this case, the blue shift is also observed

as the nanoparticle size decreases. The luminescence of ZnO,^{61, 68, 68, 117} ZnS,^{125–127} CdS,^{128–136} and CdSe^{137, 138} has been studied in detail.

The luminescence spectra of colloidal CdS solutions are shown in Fig. 10. It can be seen that the decrease in the nanoparticle size results in a shift of the luminescence spectra towards the short-wavelength region. The kinetics of the luminescence decay of nanoparticles is nonexponential and the characteristic time of decay for nanoparticles of the same size depends on the luminescence wavelength. The shorter-lived luminescence corresponds to a higher energy of the emitted light quantum. The dependence of the lifetime of the excited state on the wavelength is explained by the contribution of the Coulomb interaction between the electron and hole to the energy of the emitted light quantum.¹³⁹

$$\hbar\nu = E - (D_+ - D_-) + \frac{e^2}{\epsilon R_h}, \quad (14)$$

where E is the minimum excitation energy of nanoparticles, D_- and D_+ are the depths of the electron and hole traps, respectively, and R_h is the distance between the electron and hole. If the electron–hole recombination follows the tunnel mechanism, then the pairs with small R_h emit light faster and at higher energies than the pairs with larger R_h .

Figure 10. The luminescence spectra of colloidal solutions of CdS nanoparticles in acetonitrile.¹³¹

Average size of nanoparticles /nm: (1) 2.5; (2) 3; (3) 3.7; (4) > 4.2.

b. Dependence of the intensity of electronic transitions and radiative lifetimes on the nanoparticle size.

The increase in the volume-normalised oscillator strength of the excitonic absorption with the decrease in the size of nanoparticles^{110, 140–143} is one more manifestation of the quantum size effect. This is associated with the increase in the overlap integral of the electron and hole wave functions with the decrease in the size of nanoparticles.

For large spherical semiconductor particles ($R \gg a_B$, where a_B is the Bohr radius), the overlap integral of the wave functions is independent of the particle size and the oscillator strength of excitonic absorption (f) is determined by the macroscopic dipole moment of the transition. Assuming that the exciton moves coherently throughout the particle, the number of energy levels in the excitonic band is equal to $(R/a_B)^3$ (see Ref. 110). In the low-temperature limit, the integrated oscillator strength of all $(R/a_B)^3$ levels is concentrated in the lowest excitonic transition. The oscillator strength of the particle increases linearly as the volume increases

$$f \propto \left(\frac{R}{a_B} \right)^3,$$

whereas the volume-normalised oscillator strength (f/V) remains unchanged.

For nanoparticles ($R \leq a_B$), the overlap integral of the electron and hole wave functions increases as the nanoparticle size decreases. As a result, the oscillator strength of nanoparticles depends only slightly on their size, while the volume-normalised oscillator strength increases with decrease in the nanoparticle size

$$\frac{f}{V} \propto \left(\frac{a_B}{R}\right)^3.$$

As is known, the oscillator strength determines the radiative lifetime of excited state at low temperatures, while the volume-normalised oscillator strength determines the light absorption coefficient. It follows from the analysis performed above that the radiative lifetime of the exciton decreases while the absorption coefficient increases linearly as the nanoparticle volume increases. For typical semiconductor crystals, the excitonic band width is of the order of 0.15–0.3 eV. The possibility for the integrated oscillator strength to be concentrated on the transitions whose widths are of the order of 10^{-3} – 10^{-4} eV with the decrease in the nanoparticle size results in a giant increase in the excitonic absorption of nanocrystals. These effects have been observed experimentally.^{2, 13, 108, 143} However, complete quantitative agreement between the experimental data and the theoretical concepts of the light absorption by nanoparticles cannot be achieved because of the difficulties in obtaining nanoparticles of fixed size and the effect of surface defects on the processes of light absorption and emission by nanoparticles.

3. Redox properties of semiconductor nanoparticles

Evidently, changes in the nanoparticle size resulting in the change in the energy of formation of electron–hole centres affect the redox properties of light-irradiated semiconductor nanocrystals. It seems most likely that the conduction and valence bands may be shifted towards more negative and more positive potentials, respectively, by decreasing the size of semiconductor nanoparticles. The energy diagram for CdTe nanocrystals¹⁴⁴ is shown in Fig. 11 as an example. It can be seen that the decrease in the size of nanoparticles affects more strongly the position of the energy level of the electron centre than that of the hole centre.

Figure 11. The energy diagram of the CdTe nanoparticles. Average size of the nanoparticles /nm: (1) 1; (2) 1.25; (3) 1.75; (4) 2; (5) ∞ (the last corresponds to the macroscopic crystal).

According to the modern theoretical concepts of the electron transfer,^{87, 145, 146} an appreciable change in the position of the energy level of the electron centre may result in a considerable change in the rate of redox processes occurring with the participation of nanoparticles. The dependence of the rate constant for the luminescence quenching of light-irradiated MoS₂ nanoparticles by oxygen molecules on the particle size^{30, 54} is shown in Fig. 12. The processes occurring in the MoS₂ nanoparticles upon their irradiation by light are described by the following scheme:

Figure 12. Dependence of the rate constant for the oxygen quenching of the luminescence of light-irradiated MoS₂ nanoparticles on their size.

Photogeneration of charge carriers:

stabilisation of charge carriers in shallow traps:

recombination luminescence:

luminescence quenching:

The luminescence of MoS₂ nanoparticles is due to the recombination of electrons trapped into shallow traps (e_t^-) and holes (h_t^+). In the presence of oxygen, luminescence quenching is observed due to the electron transfer from the trap to O₂. A decrease in the size of MoS₂ nanoparticles results in an increase in the energy of the trapped electrons and, hence, in an increase in thermal effect of the process. According to the modern concepts of electron transfer in the condensed phase,^{87, 145–147} the reaction rate of the electron transfer from the trap to the oxygen molecule must also increase in this case.

It is of note that the potential of the bottom of the conduction band of the macroscopic MoS₂ semiconductor is equal to 0.2 V vs. SCE, while the reduction potential of the oxygen molecule is equal to 0.82 V vs. SCE.¹⁴⁸ Comparison of these values shows that the photoreduction of oxygen using a macroscopic MoS₂ crystal is thermodynamically impossible.

The dependences analogous to that shown in Fig. 12 were found for the luminescence quenching of MoS₂ nanoparticles by methyl viologen and nitrobenzene.^{30, 54}

A dependence of the quenching efficiency of singlet-excited ZnTPP molecules by CdS nanoparticles on the nanoparticle size was found by Chrysochoos.¹⁴⁹ Analysis of experimental data¹⁴⁹ has shown⁸⁴ that the rate constant for quenching (k_q) changes from 0 to 10^{12} mol litre⁻¹ s⁻¹ as the localisation energy of the exciton in the CdS nanoparticles changes from 0.7 to 0.5 eV. From the results shown in Fig. 9 one can easily estimate that the change in the nanoparticle size from ~ 0.8 to ~ 1.2 nm corresponds to this range of the change in the localisation energy of the exciton. Large values of the quenching rate constant ($\sim 10^{12}$ mol litre⁻¹ s⁻¹) indicate that it was quenching of the porphyrin molecules adsorbed on the surface of CdS nanoparticles that has been observed by Chrysochoos.¹⁴⁹

4. Dependence of thermodynamic parameters of nanocrystals on their size

As has been mentioned above, a considerable portion of the atoms of nanoparticles is on the surface and it increases as the nanoparticle size decreases. Correspondingly, the surface atoms make a large contribution to the nanocrystal energy. In this connection, the dependence of the melting temperature of nanoparticles on their size shown in Fig. 13 for CdS¹⁵⁰ becomes understandable. In fact, the surface energy of a liquid is always lower than the surface energy of the corresponding crystal. A decrease in the size of nanoparticles leads to an increase in the proportion of the surface energy and, hence, to a decrease in the melting temperature of nanocrystals. As can be seen from Fig. 13, this decrease can be considerable.

Figure 13. Dependence of the melting temperature (T_m) of CdS nanoparticles on their size.¹⁵⁰

The geometry of the crystal lattice of a macroscopic crystal can be changed by applying hydrostatic pressure to the crystal, which results in closer crystal packing. An analogous transformation can also be performed for nanocrystals. Thus, the application of hydrostatic pressure to the CdSe nanocrystal with the wurtzite type structure (hexagonal crystal lattice) results in the change to the sphalerite type structure (face-centred cubic crystal lattice). As a result, a less ordered surface with high surface energy is formed. Therefore, one should expect that increased pressure (P) is necessary for changing the crystal lattice geometry as the nanocrystal size decreases because of the large fraction of surface centres characteristic of nanocrystals. These are just the dependences of P on the nanoparticle size that were found for CdSe,¹⁵¹ CdS,¹⁵² InP, and Si.¹⁵³ However, in the case of colloidal solutions of nanoparticles it could be expected that both the magnitude and

Figure 14. Dependence of hydrostatic pressure necessary for the phase transition to occur on the size of the CdSe nanoparticles.¹⁵⁰

sign of the effect must be strongly dependent on the nature of the solvent molecules coordinated on the surface of nanoparticles and thus affecting the surface energetics in both structural modifications of nanocrystals. The dependence of P on the size of CdSe nanoparticles¹⁵¹ is shown in Fig. 14 as an example.

IV. Photocatalytic processes with the participation of semiconductor nanostructures

Unusual physicochemical properties of semiconductor nanoparticles gave rise to various speculations concerning their practical implementations. Sensors and systems of light energy storage, electronics and photodetoxication of waste waters, non-linear optics and catalysis, and lithography and lasers (see, for example, Refs 154 and 155) are considered as possible fields of uses of semiconductor nanoparticles. However, in most cases it is premature to discuss practical application of semiconductor nanoparticles. Only investigations in the field of photocatalysis carried out so far make it possible to consider the possibilities of practical use of nanoparticles.

1. The use of semiconductor nanoparticles in photocatalytic processes

As has been mentioned above, a decrease in the size of semiconductor nanoparticles results in a shift of the conduction and valence bands towards more negative and more positive potentials, respectively. It seems to be tempting to use the possibility of controlling the redox properties of nanoparticles by changing their size in photocatalytic systems of water decomposition and the synthesis and destruction of organic compounds. Additionally, the fact that nanoparticles have a large specific surface area is of importance for carrying out photocatalytic processes on the surface of semiconductors. And finally, the small size of semiconductor nanoparticles can provide high efficiency of detrapping of light-generated electrons and holes, thus increasing the probability of a photocatalytic process on the surface of the semiconductor.

However, it should be noted that the semiconductor nanoparticles used in photocatalytic studies are, as a rule, rather large ($\sim 10^2$ nm) and no pronounced quantum size effects are observed for them. A correlation between the photocatalytic activity of TiO₂ nanoparticles and their size was found only in one study.¹⁵⁶ High quantum efficiencies of photocatalytic processes with the participation of nanoparticles are achieved by designing specifically ordered structures based on these particles.

The idea of using nanoparticles for photocatalytic water decomposition was first proposed by Henglein¹⁵⁷ and Duong-hong *et al.*,¹⁵⁸ who have demonstrated the possibility of photoreduction of methyl viologen in colloidal solutions of semiconductors. The photoreduction of methyl viologen on the surface of nanoparticles was studied by laser flash photolysis in colloidal solutions of TiO₂^{158–166} and metal chalcogenides.^{65, 167–170} Photoreduction of various dyes by nanoparticles has also been studied.^{171–175} Photoexcitation of nanoparticles results in one-electron reduction of dye molecules followed by the formation of a leuco-product.

The possibility of using nanoparticles in photocatalytic synthesis of organic compounds was demonstrated for the first time by Kraeutler *et al.*^{176–178} Photocatalytic synthesis of an amino acid and the Kolbe reaction were carried out by the interband excitation of TiO₂ nanoparticles coated with platinum. Later, *cis-trans* isomerisation of styrene derivatives upon photoexcitation of CdS nanoparticles was reported.^{179, 180} The process of isomerisation includes the formation of alkene radical cation on the surface of nanoparticles. Photocatalytic processes of oxidation of a number of alkanes, arenes, amines, and alcohols on the surface of nanoparticles are also known.^{181, 182}

Light-generated holes can be used in photooxidation of various substrates on the surface of nanoparticles until their complete destruction.^{131, 160, 168, 172, 183–188} The use of semicon-

ductor nanoparticles for photochemical purification of water from various contaminants seems to be rather tempting and attracts particular interest of researchers in recent years. Systems based on TiO₂ seem to be the most promising for photocatalytic mineralisation of organic compounds in waste waters.

Of the three major structural modifications of TiO₂ (rutile, anatase, and brookite), anatase is the most photocatalytically active. The difference in the photocatalytic activity of different TiO₂ modifications is most likely due to their different crystal structures. Anatase has a bandgap of 3.2 eV and UV radiation needs to be applied for the electronic excitation of this compound; hence, only a small portion of the sun light can be used for the photocatalytic processes involving anatase to occur. Nevertheless, among a wide variety of semiconductor materials, TiO₂ is most often used as a photocatalyst due to the high oxidation ability of its photogenerated holes ($E = 2.9$ V vs. NHE at pH 0), its stability in aqueous solutions, safety for living organisms, and low price.

Titanium dioxide has long been used in paint industry as the photocatalyst in the oxidation of organic substances. This property of TiO₂ has determined its wide use as the white pigment.¹⁸⁹ Later, attempts were made aimed at using TiO₂ for photodecomposition of water.^{190, 191} However, its efficiency appeared to be low because of a low quantum yield of charge photoseparation. Recently, the problems of the environment protection forced many researchers to direct their attention again to the systems based on TiO₂ and to make efforts to use TiO₂ for photocatalytic mineralisation of ecologically hazardous organic compounds both in aqueous media and gases.

The scheme of the photocatalytic process involving semiconductor nanoparticles is shown in Fig. 15. The absorption of a light quantum with an energy of $h\nu$, that exceeds the bandgap of the semiconductor, results in the primary charge separation. In this case, the nanoparticle can be considered as a short-circuit electrode initiating the processes of oxidation and reduction of the substrate molecules adsorbed on the surface. The oxidation and reduction of non-adsorbed substrate molecules is possible if the primary electrons and holes are transformed into stable intermediates on the surface of nanoparticles.

Figure 15. Schematic view of charge separation processes in a semiconductor nanoparticle.

Good results have been obtained for the detoxication of waste waters containing hydrocarbons, phenols, chloroaromatic compounds, surfactants, and nitro compounds (see, for example, reviews^{192–196} and references cited therein). A typical example of photocatalytic mineralisation is the oxidation of the dichloroacetate ion by oxygen in water:

The detailed mechanism of the processes of the photoreduction of acceptors and photooxidation of donors with the participation of TiO₂ nanoparticles includes a large number of events occurring both in the bulk and on the surface of nanoparticles; the basic events are outlined below (see also Fig. 16).¹⁹⁶

Figure 16. Schematic view of processes of photoreduction of acceptors and photooxidation of donors by TiO₂ nanoparticles.

Photostimulated generation of electrons and holes in the conduction and valence band, respectively

charge carrier migration to the surface of the nanoparticle

charge carrier trapping by acceptor centres and into shallow traps (ST)

charge carrier recombination (radiative and nonradiative)

It is usually assumed that the photooxidation of organic substrates in aqueous suspensions of TiO₂ can occur by both the direct interaction of the holes with the substrate molecules and the formation of the OH· radicals in the reaction of the holes with H₂O or OH⁻.

The prospects of the use of semiconductor nanoparticles in photocatalysis have stimulated studies of the possibility of spectral sensitisation of nanoparticles and modification of their surface by noble metals. In the photocatalytic systems of water decomposition, the metal deposited on the surface of nanoparticles acts as the catalyst of the photosplitting of water to produce hydrogen gas. The effect of coating the surface of TiO₂ nanoparticles with platinum^{197, 198} and other noble metals and metal oxides^{199–202} on the quantum yield of water photodegradation has been studied.

Sensitisation of semiconductors is widely used for expanding the spectral sensitivity region of these materials. Thus, TiO_2 has a bandgap of 3.1 eV and its use in a photocatalytic system is only expedient in the case of expanding the spectral sensitivity region of the system into the visible region. Sensitisation of TiO_2 nanoparticles is performed with the participation of both singlet^{203–206} and triplet^{207–209} excited dye molecules.

Semiconductor hetero-nanoparticles can be of considerable practical interest. The processes of charge separation in mixed CdS/TiO_2 semiconductor nanoparticles⁷⁹ and in the ZnO nanoparticle coated with a ZnS layer²¹⁰ are depicted schematically in Fig. 2. Production of large-bandgap hetero-nanoparticles can favour their spectral sensitisation. Additionally, as has been mentioned above, multicomponent nanoparticles are of interest, since it is possible to increase the efficiency of charge photo-separation because of the effective spatial separation of the electrons and holes in such structures. There are only a few experimental data^{211,212} on the photocatalytic activity of hetero-nanoparticles analogous to those shown in Fig. 2. The possibility of increasing the quantum yield of charge separation in such hetero-nanoparticles has been demonstrated experimentally. In Fig. 17, the short-lived optical spectra of colloidal solutions of CdS and TiO_2 nanoparticles in CH_3CN generated by a laser pulse upon the excitation of CdS by light⁵⁸ are shown as an example. The short-lived optical absorption in the 500–750 nm region is caused by the electrons trapped by the Ti^{4+} centres of titanium dioxide. As can be seen from this picture, the excitation of CdS in CdS/TiO_2 nanoparticles leads to the electron transfer from CdS to TiO_2 .

Figure 17. The absorption spectra of colloidal solutions of nanoparticles in CH_3CN after a laser pulse ($\lambda = 355 \text{ nm}$, $\Delta\tau = 0 \text{ ps}$). The concentration of nanoparticles in solution /mmol litre⁻¹: (1) 0.75(CdS) + 1.15(TiO_2); (2) 0.75(CdS); (3) 1.15(TiO_2).

The high photocatalytic activity of nanoparticles of the ‘core–shell’ type has been demonstrated in the example of the photo-oxidation of I^- and SCN^- anions by $\text{SnO}_2/\text{TiO}_2$ nanoparticles.⁷⁰ It was found that the quantum efficiency of the photooxidation of I^- anions by $\text{SnO}_2/\text{TiO}_2$ nanoparticles is 2–3 times higher than the quantum efficiency of the photooxidation by $\text{SiO}_2/\text{TiO}_2$ or TiO_2 nanoparticles. The use of systems of the ‘core–shell’ type is also promising in view of cutting the costs of hetero-nanoparticles if inexpensive materials are used for the synthesis of the cores for such structures.^{63, 67, 71, 210, 213, 214}

2. Photocatalysis based on nanostructured films of semiconductors

Colloidal solutions of nanoparticles are suitable objects for the demonstration of the possibility of their use in photocatalysis. However, the practical use of colloidal solutions is difficult because of the need to separate nanoparticles from the solution after the completion of the photocatalytic process. Thin layers of

nanoparticles adsorbed on a carrier seem to be much more promising, especially the films composed of hetero-nanoparticles shown in Fig. 3. These films have many advantages over films composed of nanoparticles of the same nature, namely, the expanded spectral sensitivity region of the large-bandgap semiconductor nanoparticles, increased quantum efficiency of charge photoseparation,²¹⁵ and high efficiency of spectral sensitisation of films by dyes.²¹⁶

An idealised illustration of photocatalytic processes occurring on the surface of a conducting electrode with the participation of films composed of heteronanoparticles is exemplified in Fig. 3 with $\text{TiO}_2/\text{SnO}_2$ films. The position of the bottom of the SnO_2 conduction band is lower than that of the TiO_2 conduction band (0 and -0.5 V vs. NHE at pH 7, respectively). This causes the light-generated electrons to transfer from TiO_2 to SnO_2 . The holes move in the opposite direction and are accumulated on the TiO_2 nanoparticles. As a result, an increase in the quantum efficiency of charge photoseparation and, hence, in the efficiency of the oxidation of donor molecules in solution can be observed in the structure under consideration. High efficiency of the $\text{TiO}_2/\text{SnO}_2$ film was demonstrated experimentally in the example of photocatalytic degradation of dyes (Acid Orange 7 and Naphthol Blue Black).^{217,218} The overall processes occurring at the anode and cathode can be described by the following scheme:

at the photoanode

at the cathode

Porous nanostructured films possess high adsorption capacity to organic dyes and organometallic compounds. Large specific surface area of such films allows adsorption of a considerable amount of a dye. The use of these properties of the nanostructured films makes it possible to increase substantially their photocatalytic efficiency due to sensitisation into the visible region.^{72, 219}

V. Conclusion

Some interesting peculiarities in the solution behaviour of the ultrasmall semiconductor particles containing several hundreds of atoms have been revealed in the studies of their properties. Unusual physicochemical properties of semiconductor nanoparticles depend on three main factors. First, the size of nanoparticles is comparable with the molecular dimensions. This determines the difference between the kinetics of chemical transformations on the surface or in the bulk of nanoparticles and the kinetics of chemical transformations in infinite space. The classical equations of chemical kinetics can be used for the description of the processes on the surface of nanoparticles down to a size that exceeds the actual size of the reacting molecules by an order of magnitude. The processes occurring on the surface of smaller nanoparticles can be described by the Monte Carlo method or by the methods of stochastic kinetics.

Second, the surface atoms constitute a considerable proportion of the total number of atoms of a nanoparticle. This strongly affects the thermodynamic characteristics of nanoparticles and determines the size dependences of melting temperatures and pressures at which the crystal lattice of a semiconductor rearranges (*i.e.*, phase transition occurs).

And, finally, third, the non-linear optical effects arise and the energies of excitonic transitions in nanoparticles, oscillator strengths, and redox characteristics become dependent on the nanoparticle size as the latter becomes comparable with the delocalisation area of charge carriers.

Intensive investigations in the field of the chemistry of semiconductor nanoparticles have been carried out during the last decade. The major efforts of researchers are directed to the development of methods for the synthesis of nanostructures with controlled characteristics and investigation of their photocatalytic properties. Considerable progress has been achieved in the demonstration of the possibility of the use of semiconductor nanostructures for photocatalytic mineralisation of various environmentally hazardous compounds. In our opinion, the most promising lines in the study of semiconductor nanoparticles in the coming years will be associated with the development of methods for the synthesis of nanoparticles with predetermined geometric characteristics, studies of the mechanisms of chemical transformations at the liquid–solid interface in colloidal solutions of nanoparticles, practical implementation of nanoparticles and films produced on their basis in photocatalysis, and design of complex ordered systems for electronics.

V. Losses in photochemical lasers	131
VI. Tunable photochemical lasers	133

Abstract. Reactions of proton phototransfer in organic compounds and photochemical lasers based on these reactions are considered. A principle of operation of a photochemical laser is described. Selection criteria of acid-base systems to serve as active media in photochemical lasers are determined. A list of acid-base laser systems, conditions of their fabrication, and emission characteristics are collated. Specific losses in photochemical lasers are analysed. Methods of expanding the spectral range of tunable emission in the photochemical lasers are described. The bibliography includes 134 references.

I. Introduction

Laser radiation is the emission of light upon transition of excited molecules to the ground electronic state. The emission of light is stimulated by an external electromagnetic field under the conditions of an optical resonator. The phenomenon of light amplification by the effect of stimulated radiation emission is called laser action, which stems from the abbreviation of the expression 'light amplification by stimulated emission of radiation'. Among numerous types of lasers used in the different fields of science and technology, those based on organic compounds (dyes) occupy a special place.¹ The advantages of the dye lasers over the others include the possibility of fine and continuous tuning of the laser radiation wavelength over a wide range (up to 100 nm), a high coefficient of emitted light amplification by the active medium, and the possibility of obtaining multiband radiation.² The latter is employed for the solution of a number of practically important problems (in particular, atmospheric probing, multipulse multi-colour spectroscopy, *etc.*). Dye lasers are the main source of pico- and femtosecond pulses.³ The possibility of achieving the femtosecond pulses is determined by the existence of highly effective amplification medium with a broad range of laser radiation tuning. A significant increase in the spectral range of tuning, up to 220 nm,⁴ can be attained in the dye lasers with adiabatic photochemical reactions.

A dye produces stimulated light emission in the spectral range of its fluorescence. The excited dye molecules may be generated in two ways: (1) as a result of direct excitation from the ground state through absorption of a photon or under electron impact; (2) as a result of an adiabatic photochemical reaction (photochemical laser). The regularities of radiation for the first type of dye laser are considered in numerous reviews and original papers.^{5–11} The reactions of electron and proton phototransfer belong to the best studied adiabatic photochemical reactions of organic compounds.¹² The electron phototransfer reactions result in the formation of excited charge-transfer complexes (exciplexes).¹³ The radiative transition in exciplexes is partially forbidden, therefore, the generation of laser radiation by the products of electron phototransfer reactions and, consequently, photochemical lasers based on these reactions are hardly probable.¹⁴ The radiative transition in excited products of numerous proton phototransfer reactions is permitted.¹⁵ These excited products are the potential generators of the laser radiation.

II. An operation scheme for a photochemical laser based on proton phototransfer reactions

Proton phototransfer reactions in organic compounds occur according to static and dynamic mechanisms. In the former case the reaction occurs 'instantaneously' in the excitation of a hydrogen-bonded complex of a proton donor with acceptor, which is formed in the ground state.

In the latter case, the interaction between the excited molecule of an aromatic compound and a molecule of a base or acid is realised. Fluorophores that can participate in the acid-base interaction may be divided into two groups. Proton-donor fluorophores ArXH constitute the first group, their acidity being increased upon excitation. A reaction with a base B in the ground state occurs according to the scheme

The majority of compounds of this group possess an aromatic radical Ar bound by a single bond to the proton-donor group XH (X = O, S, NR, and NR₂⁺).^{16–19} The kinetic and thermodynamic parameters of reaction (2) and spectral-kinetic characteristics of the forms ArXH and ArX[−] for the known laser acid-base systems are listed in Table 1.

Proton-acceptor fluorophores constitute the second group, their basicity is increased upon excitation

In this type of base, the π -system is linked by a double bond to the proton-acceptor centre. The proton-acceptor centre can be exocyclic or endocyclic.

Aromatic carbonyl compounds (aldehydes and ketones) and their imine derivatives belong to the organic bases with an exocyclic proton-acceptor centre. Organic carbonyl compounds are weak bases.²⁸ Their basicity is increased in the excited state.²⁹ The protonation rate constants for aminocoumarins in the excited state in solution are close to the diffusion rates.²⁹ The rate constants for the protonation of pyridine and oxazole derivatives in the excited state by carboxylic acids are one or two orders of magnitude smaller than the rate constants for the diffusion-limited reactions, respectively.^{30,31} The photoprotonation of pyridine and oxazole derivatives occurs either according to the

static [reaction (5)] or dynamic [reaction (4)] mechanism.^{30,31} The kinetic and thermodynamic parameters for the reactions (4) and (5) and spectral-kinetic characteristic of the forms B and BH^+ for the known laser acid-base systems are listed in Table 2.

Aromatic C-bases possess low basicity. These compounds are protonated in the ground state only in concentrated strong acids. The acid-base interaction in the excited state leads to quenching of the fluorescence. No excited products are generated in this reaction.^{43,44}

In numerous organic compounds, the proton-donor and proton-acceptor groups are linked by an intramolecular hydrogen bond.^{45–48} The proton-donor and proton-acceptor ability of these reaction centres of the molecule is increased upon excitation of these compounds, which results in the intramolecular proton phototransfer. This type of reaction can be assigned to the stationary proton phototransfer. The kinetic and thermodynamic parameters for the reactions of intramolecular proton phototransfer as well as spectral-kinetic characteristics for the known laser systems of this type are listed in Table 3.

Table 3. Parameters of reactions of intramolecular proton phototransfer in dye molecules for photochemical lasers and spectral-luminescence characteristics of the initial form (N) and its tautomer (T).

Intramolecular proton phototransfer reactions leading to species with effective fluorescence are wide-spread (see Tables 1 and 2). Compounds that give products with a high quantum yield of fluorescence of the intramolecular proton phototransfer product are scarce.^{59,61–64} The fluorescent reaction products of the proton phototransfer, as with usual fluorophores, under appropriate conditions can amplify the light passing through the solution.

In a number of studies that were performed over the period from 1960 to 1964, the possibility of the light amplification by the dye solutions has been demonstrated,⁶⁵ and the principles of generation of laser radiation (lasing) as a result of electron-vibrational singlet–singlet transitions in anthraquinone molecule have been discussed.⁶⁶ Certain theoretical calculations on lasing taking into account the vibrational structure of the electronic levels of dyes were carried out.^{67,68} The processes that occur in the excitation of complex molecules, including the processes of stimulated light emission, were analysed in detail.^{69,70} Slight amplification of light upon photoirradiation of a solution of perylene in benzene was detected in 1964.⁷¹

The lasing of organic compounds was first observed independently by two research groups.^{72,73} Chronologically, the first dye laser was created by Sorokin and Lankard⁷³ in 1966. Excitation of an ethanolic solution of phthalocyanine complex with aluminium chloride by the radiation of a ruby laser induced laser radiation resulting from electronic transitions in the organic ligand of the metal complex. Currently, dye lasing with a high conversion efficiency (71% for the Rhodamine 6G in EtOH⁷⁵ and 78% for the dye LKK-756 in MeCN⁷⁶) can be obtained in a spectral range from 322 nm⁷⁴ to 1800 nm.¹⁰ Arylazole, coumarin, xanthene, oxazine, and polymethine dyes are the most efficient laser dyes.⁷ Active media for the dye lasers are liquid solutions of dyes,^{1–5} solid solutions in polymers,⁷⁷ and gaseous mixtures of dye vapour with buffer gases.⁷⁸

A solution of an organic compound can generate laser radiation (lase) if its optical density $[-k_a(v)x]$ at some frequency v is less than zero (negative absorption).⁷⁹

$$\ln \left[\frac{I_0(v)}{I(v)} \right] = -k_a(v)x,$$

where $I_0(v)$ and $I(v)$ are the radiation flux intensities before and after the light has passed through the layer of a solution with a thickness x , $k_a(v)$ is an amplification coefficient of the medium.

In the simplest case of a two-level scheme, $k_a(v)$ is described by the equation

$$k_a(v) = \frac{h\nu}{v} [N_2 B_{21}(v) - N_1 B_{12}(v)],$$

where N_1 and N_2 are the population of the lower (1) and upper (2) levels, $B_{12}(v)$ and $B_{21}(v)$ are the probabilities of absorption and stimulated emission (Einstein's coefficients for induced transitions), respectively, v is the velocity of light in the medium. More often, a cross-section of stimulated transition is used instead of $B(v)$

$$\sigma(v) = \frac{h\nu}{v} B(v).$$

The Einstein coefficients, cross-sections of absorption and stimulated emission are the same, *i.e.*,

$$B_{12}(v) = B_{21}(v) \text{ and } \sigma_{21}(v) = \sigma_{12}(v).$$

The condition for lasing

$$k_a(v) = N_2 \sigma_{21}(v) - N_1 \sigma_{12}(v) = \sigma_{21}(v)(N_2 - N_1) > 0$$

is fulfilled when $N_2 > N_1$, *i.e.*, in the presence in the system with an inverted (relative to thermal population) level population. This cannot be achieved in the two-level system with optical pumping. The currently known laser systems lase according to three- (1–3)

Figure 1. The energy level diagram of a laser dye molecule.

and four-level (1–4) schemes (Fig. 1). Optical transitions occur between the levels 1–2 and 3–4. The system is excited from the lower vibrational sublevel of the main electronic state (level 1) to higher vibrational sublevels of the first excited electronic state (level 2). The lower laser level (level 4) consists of higher vibrational sublevels of the ground electronic state of the dye, the upper laser level (level 3) is a zero vibrational sublevel of the first excited electronic state. The transitions between the levels 2–3 and 4–1 are radiationless (the rate constant of these processes is $\sim 10^3$ ns⁻¹). They represent vibrational relaxation in the excited and ground electronic states, respectively. As the higher vibrational sublevels of the ground state are virtually unoccupied at room temperature, the concentration of excited molecules at the level 3 (N_3) exceeds that of molecules at the level 4 (N_4) upon excitation of the system even by light of relatively low power. In this case, an inverted population of the levels 3 and 4 is observed in the system ($N_3 > N_4$). An inverted population of the zero vibrational sublevels of the ground and excited states cannot be achieved. In addition to these processes, optical transitions from the level 3 to the highest singlet states of the molecule (level 5), intersystem transitions to the triplet state (level 6) and optical transitions from the level 6 to the highest triplet level of the molecule (level 7) as well as photochemical decay of the dye occur in the dye lasers. For the system that is described by this scheme the amplification coefficient is determined by the equation

$$k_a(v) = N_2[\sigma_{34}(v) - \sigma_{35}(v)] - N_1\sigma_{12}(v) - N_6\sigma_{67}(v) - \sum_i N_{p_i}\sigma_{p_i}(v) - k_w(v), \quad (6)$$

where the number in subscript indicates the number of the level, N_{p_i} is the population of levels, $\sigma_{p_i}(v)$ is the cross-section of absorption of photoproduct p_i at a frequency v , $k_w(v)$ is the constant loss coefficient. Spectral criteria for the selection of a dye to produce efficient lasing have been formulated by Simonov⁸⁰ and Denisov and Uzhinov⁸¹.

The idea of creating an inverted electronic state population as a result of the adiabatic reaction of organic compounds in excited state was suggested practically simultaneously by Derkacheva⁸² and Kuz'min⁸³ (3 years before the appearance of the first dye laser⁷³). It was assumed that photochemical reactions of dissociation, isomerisation, complexation, dimerisation, and polymerisation and redox processes can be adiabatic.⁸³ In the four-level scheme suggested,^{82,83} the ground and excited states of the initial form of the dye involved in the reaction correspond to levels 1 and 2 (see Fig. 1). The excited and ground state of the proton phototransfer product correspond to levels 3 and 4. In this case, the direct reaction in the excited state and the reverse reaction in the ground state play the roles of radiationless relaxation processes (transitions between the levels 2–3 and 4–1), respectively. The change in the equilibrium constant in the excited state compared to the ground state is crucial for lasing.

Derkacheva⁸² has considered the mechanism of lasing of products of photoprolytic reactions of phenols in water, which occur according to the following scheme.

The value k_{34}^{-1} is the lifetime of the excited product of the photoreaction. It was considered^{82,83} that the attainment of an inverted population between the zero vibrational sublevels of the excited and the ground states of RO^- is a prerequisite for lasing. The difference in populations of these states under steady-state conditions is determined by the equation⁸²

$$\begin{aligned}
 [\text{RO}^{-*}] - [\text{RO}^-] = [\text{ROH}] & \left[\frac{\alpha k_{23}/k_{34}}{1 + k_{32}[\text{H}_3\text{O}^+]/k_{34}} \times \right. \\
 & \left. \times \left(1 - \frac{1}{k_{41}[\text{H}_3\text{O}^+]/k_{34}} \right) - \frac{k_{14}}{k_{41}[\text{H}_3\text{O}^+]} \right],
 \end{aligned}$$

where $\alpha = [\text{ROH}^*]/[\text{ROH}]$.

The following two conditions should be fulfilled to ensure an inverted population in the reaction product ($[\text{RO}^{-*}] > [\text{RO}^-]$): (1) $[\text{H}_3\text{O}^+] > k_{34}/k_{41}$; (2) sufficiently intense excitation, which determines the value of α , as well as large value of k_{23} , which provides for the high formation rate of the excited molecules of the deprotonated form. In the case of acid dissociation of the excited 2-naphthol, the first condition is fulfilled at $\text{pH} < 1.7$ ($[\text{H}_3\text{O}^+] > 0.02 \text{ mol litre}^{-1}$), and the second condition if sufficiently powerful excitation sources are employed.⁸²

More recent studies have shown that the mechanism of lasing suggested earlier^{82,83} is invalid. Currently, it is believed that an inverted population between the zero vibrational sublevels of the excited state and the vibrational sublevels (excluding zero sublevel) of the dye ground state is the prerequisite for lasing in organic compounds.⁷⁹ This is also a prerequisite for the radiation of a photochemical laser. However, in this case the inverted population can also occur between the zero vibrational sublevels of the excited and ground states of the lasing species.

Due to spectral overlap of the stimulated emission of the components, the initial form influences significantly the emission by the photochemical reaction product, and *vice versa* the product influences the emission by the initial form. Thus, the properties of both components of an acid-base system determine the radiation characteristics of the photochemical laser. The energy diagram of the photochemical laser is a combination of 7-level schemes for the initial compound and the photoreaction product. In a general case, the diagram contains 14 levels (Fig. 2). The amplification coefficient of the active medium in such a laser is determined by the equation²²

$$\begin{aligned}
 k_a(\nu) = N_3[\sigma_{31}(\nu) - \sigma_{35}(\nu)] - N_1\sigma_{12}(\nu) - N_6\sigma_{67}(\nu) + \\
 + N_{3'}[\sigma_{3'1'}(\nu) - \sigma_{3'5'}(\nu)] - N_{1'}\sigma_{1'2'}(\nu) - \\
 - N_{6'}\sigma_{6'7'}(\nu) - \sum_i N_{p_i}\sigma_{p_i}(\nu) - k_w(\nu),
 \end{aligned} \quad (7)$$

where the quantities corresponding to the photoreaction product are primed.

Figure 2. The energy level diagram of the components of a photochemical laser.

Analysis of the features of laser radiation of a system with an intermolecular proton transfer reaction at steady-state excitation⁸⁴ shows that the system is described by two pairs of electronic-vibrational levels for the initial form (1, 2) and the photoreaction product (1', 2'), respectively; the transitions to the triplet levels are absent and the concentration of the reaction product in the ground state $N_{1'}$ is taken to be equal to zero.⁸⁴ When the intensity of excitation (I_e) is higher than the threshold for the photoreaction product (I'_t) and lower than the threshold for the initial form (I_t) and the laser radiation is generated only by the photoreaction product at a frequency ν' , its radiation power is increased with the intensity of excitation up to the maximum value $I'_{\max}$ at $I_e = I_t$. On further increase in I_e , the passage of the system into a two-band generation mode occurs with frequencies ν' and ν :

$$I'(\nu') = I'_{\max}(\nu') - \frac{\sigma_{2'1'}(\nu')}{\sigma_{2'1'}(\nu')} I(\nu),$$

$$I(\nu) = C(I_e - I_t),$$

$$I'_{\max} = \frac{\sigma_{12}(\nu)(N - k_w(\nu)/\sigma_{2'1'}(\nu')) + k_w(\nu)}{k_w(\nu')\sigma_{21}(\nu)[1 + \exp(h(\nu' - \nu_{00})/kT)](k_{22'} - k_{22}^{\min})},$$

$$k_{22'}^{\min} = \frac{k_w(\nu')\sigma_{21}(\nu)k_{2'1'}}{\sigma_{2'1'}(\nu')},$$

where C is a coefficient, N is an analytical dye concentration, ν_{00} is the frequency of the 0–0-transition in the reaction product, $k_{22'}^{\min}$ is a minimum rate of the proton transfer reaction in the excited state, which provides the appearance of lasing of the product. The coefficient c is independent of pump power.

If fluorescence spectra of the initial form and the reaction product do not overlap at the frequencies of lasing ν and ν' [$\sigma_{21}(\nu') = \sigma_{2'1'}(\nu) = 0$], then the laser radiation power for the photoreaction product is independent of I_e if $I_e \geq I_t$. It was concluded⁸⁴ that $I'_{\max}$ is proportional to the rate constant for the proton transfer reaction in the excited state. If fluorescence spectra of the initial form and the product overlap at the frequency of lasing of the initial form [$\sigma_{21}(\nu') = 0$, $\sigma_{2'1'}(\nu) > 0$], then participation of the reaction product in the lasing of the initial form leads to an increase in amplification at the frequency of its lasing. For $I_e \geq I_t$, this leads to the situation, where the power of laser radiation at the frequency ν increases faster than in the previous case, but at the frequency ν' the power drops until the ceasing of generation at

$$I(\nu) = \frac{I'_{\max}(\nu')\sigma_{2'1'}(\nu')}{\sigma_{2'1'}(\nu)}.$$

In other words, two thresholds (upper and lower) in the lasing of the photoreaction product should be observed for such a system. The range of I_e , where two-band laser radiation exists, is the wider the smaller $\sigma_{2'1'}(\nu)$ and the larger $k_{22'}$. Analysis of changes in the generated power of laser radiation at frequencies ν and ν' provided $N_{1'} > 0$ has shown⁸⁴ that at $I_e > I_t$ and $\sigma_{21}(\nu') = \sigma_{2'1'}(\nu) = 0$ the generation threshold at the frequency ν depends on the acidity of the medium due to absorption of the excitation radiation by the photoreaction product $N_{1'}\sigma_{1'2'}(\nu_p)I_p$. A limiting value for the ratio of the rate constants for the direct reaction in the excited state and the reverse reaction in the ground state exists

$$\frac{k_{22'}}{k_{1'1}} = \frac{a}{\sigma_{1'2'}(\nu)},$$

where coefficient a is independent of I_e . If this ratio is greater than the limiting value, the generation threshold for laser radiation of initial form becomes infinitely large.

Neglecting the terms that correspond to the absorption of light by the products of irreversible reactions of photodecay and constant losses in the resonator, Kasha and co-workers^{53,85–87} derived an expression similar to (7) for the change in the

amplification coefficient of a photochemical laser based on the reaction of intramolecular proton phototransfer of 3-hydroxy-flavone in methylcyclohexane. In the approximation of a fast proton transfer reaction in the excited ($k_{3'3} < 8$ ps) and ground states and neglecting the induced absorption $S_n \leftarrow S_1$ [$\sigma_{35}(v) = 0$], $T_n \leftarrow T_1$ [$\sigma_{67}(v) = 0$], $S_n' \leftarrow S_1'$ [$\sigma_{3'5'}(v) = 0$], and $T_n' \leftarrow T_1'$ [$\sigma_{6'7'}(v) = 0$], they obtained an amplification coefficient of the active medium equal to 10 cm^{-1} at an excitation power of 500 kW ($\lambda = 337 \text{ nm}$) and dye concentration of $1.64 \text{ mmol litre}^{-1}$ (Ref. 53).

Radiation kinetics of a photochemical laser based on a binary mixture of dyes, 2-(biphenyl-4-yl)-6-phenylbenzoxazole and 2-(2-hydroxyphenyl)benzoxazole, was studied^{58,88} in the generation band of the first dye and a bifluorophore comprising these two dyes bound chemically. The solution of a direct kinetic problem to describe the radiation kinetics was attempted.⁸⁸ Using literature data on the optical properties of dyes, and experimental characteristics of the exciting radiation (308 nm) and optical resonator, and neglecting the light absorption by the singlet- and triplet-excited molecules, it was concluded⁸⁸ that the laser pulse duration of the first dye should be much smaller in the presence of the second dye. The results of calculation were in agreement with experiment. The laser pulse duration was 3.3 ns in the absence of the second dye and 80 ps in the presence of the second dye. It was assumed in the calculation⁸⁸ that the induced absorption in this system corresponds to absorption of a tautomer of the second dye in the ground state [$\sigma_{1'2'}(v) > 0$]. However, the induced absorption in 2-(2-hydroxyphenyl)benzoxazole was later assigned to $T_n \leftarrow T_1$ absorption of the dye [$\sigma_{67}(v)$].^{89,90}

The dynamics of lasing of the product of the intramolecular proton transfer in salicylamide and derivatives of 2-(2-hydroxyphenyl)benzoxazole in DMF⁴⁸ was described by the system of differential equations based on a previously employed model.^{53,85–88} It was assumed in the calculation that the rate constants for the direct proton transfer in singlet excited state of initial form ($k_{22'}$) and reverse proton transfer in triplet excited state ($k_{6'6}$) are equal to 10^{12} and 10^9 s^{-1} , respectively. Absorption by the excited singlet state [$\sigma_{35}(v) = \sigma_{3'5'}(v) = 0$] was neglected. The values calculated $\sigma_{1'2'}(v) = 8.0 \times 10^{-19} - 2.3 \times 10^{-17} \text{ cm}^2$ correlate linearly with a cross-section of stimulated emission of the tautomer at a frequency of the spectral maximum of lasing (this was estimated from the fluorescence spectrum). It was concluded⁵⁸ that the rate of reverse proton transfer in the ground state ($k_{1'1} = 1.50 \times 10^8 \text{ s}^{-1}$) and light absorption by the reaction product in the ground state are the main factors determining lasing of the product of intramolecular proton phototransfer of 2-(2-hydroxyphenyl)benzoxazoles and salicylamide.

III. Selection criteria of acid-base systems for active media in photochemical lasers

The cross-section of stimulated emission (σ_{34}) is the main criterion, which determines the possibility of lasing by an organic compound on a certain frequency. The cross-section should exceed the threshold value estimated according to the following formula¹¹

$$\sigma_{34}^{-1} = 8\pi n^2 c v_f^2 \Delta v_f \tau_f,$$

where n is the refractive index of the medium, c is the velocity of light, τ_f is the radiative lifetime of fluorescence, v_f and Δv_f are the frequency of maximum and the peak halfwidth of the fluorescence spectrum, respectively.⁸⁰ Analysis of cross-sections of stimulated emission for the known laser dyes allows one to determine the threshold value σ_{34} for the existence of lasing in organic compounds as $\sigma_{34} > 5 \times 10^{-17} \text{ cm}^2$ (Ref. 91). Spectral criteria for the occurrence of lasing in organic compounds were suggested⁸¹ taking account of the relation between the cross-section of stimulated emission and spectral characteristics of a laser dye. Quantum-chemical criteria for the occurrence of laser radiation in organic compounds were also formulated.^{92,93}

Along with cross-section σ_{34} the product of a photochemical reaction, thermodynamic and kinetic parameters of the reaction determine the efficiency of photochemical laser radiation. There are no rigorous quantitative criteria for the selection of lasing systems with proton phototransfer reactions. The following spectral-kinetic criteria for the selection of systems for the photochemical laser were suggested based on the analysis of the known laser systems with proton phototransfer reactions.^{9,15}

1. The initial compound (which absorbs light and in which the proton phototransfer reaction occurs) should absorb light strongly in excitation spectral range. The extinction coefficient should be greater than $10^4 \text{ litre mol}^{-1} \text{ cm}^{-1}$ at the excitation frequency.

2. The proton phototransfer reaction should be fast and efficient (*i.e.*, with low efficiency of competing radiationless deactivation processes). The rate constants for the intermolecular and intramolecular proton phototransfer should be greater than $10^8 \text{ litre mol}^{-1} \text{ s}^{-1}$ and 10^9 s^{-1} , respectively.

3. The product of the proton phototransfer reaction should possess intense fluorescence. The fluorescence quantum yield should be greater than 0.2.

4. The acid-base properties of the dye should be changed significantly ($\Delta pK_a > 1$) upon excitation to provide for the direct reaction of the proton transfer in the initial excited form of the dye and reverse reaction of the proton transfer in the product in the ground state.

5. The radiative transition in the product of the proton phototransfer reaction should possess a short radiative lifetime of fluorescence ($\tau_f < 10 \text{ ns}$).

6. The rate of the reverse proton transfer reaction in the ground state should be significantly higher than the overall rate of the direct reaction of proton phototransfer in the excited state and the formation of the product of proton transfer in the ground state resulting from deactivation of the excited state.

7. The absorption spectra $S_n \leftarrow S_0$, $S_n \leftarrow S_1$ and $T_n \leftarrow T_1$ of the initial form of the dye and reaction product of proton phototransfer should possess minimum overlap with the fluorescence spectrum of the proton phototransfer product. The absorption coefficient at the frequency of lasing should not be higher than 0.01 cm^{-1} .

8. The steady-state concentration of molecules in the triplet state of the initial form of the dye and the proton phototransfer product should be low, which is ensured by a low rate constant for intersystem crossing from the S_1 state and a large rate constant for intersystem crossing from the T_1 state.

9. The initial form of the dye and the product of the proton phototransfer reaction should be photochemically stable.

The majority of dyes listed in Tables 1–3 fulfil the above-mentioned requirements. 2-Naphthol, potassium 7-hydroxynaphthalene-1,3-disulfonate, 1,3-disulfo-7-naphthylammonium hydrogensulfate, and sodium salicylate are the exceptions. The extinction coefficients for these compounds at the excitation wavelength are smaller than $10^4 \text{ litre mol}^{-1} \text{ cm}^{-1}$. The radiative lifetime of fluorescence of the proton phototransfer products is greater than 10 ns. In spite of this, the reaction products of proton phototransfer of these compounds, except for the deprotonated form of 2-naphthol, lase. This is due to the fact that the numerical value of the criterion 5 permits selection of lasing dyes among all fluorophores. Aqueous 2-naphthol solution is also a useless laser system because the rate constant for the proton phototransfer for 2-naphthol in water is significantly smaller than $10^8 \text{ litre mol}^{-1} \text{ cm}^{-1}$. The overlap of the absorption and fluorescence spectra will be the smaller the higher Stokes' shift of fluorescence. In the formation of the lasing form as a result of reaction in the excited state, Stokes' shift is increased significantly (see Tables 1–3).

IV. Acid-base laser systems

Schaefer⁹⁴ was the first to report in 1968 on a photochemical laser based on a product of intermolecular acid photodissociation reaction of sodium 8-acetylaminopyrene-1,3,6-trisulfonate. In the ground state in basic solution the dye exists in the form of a trianion. In the excited state, the trianion dissociates to form a tetraanion. In the excitation by a lamp the laser radiation in a neutral solution is observed for the trication and in a basic solution for the tetraanion. The laser radiation spectrum in basic solution is shifted to longer wavelengths by 125 nm compared to the spectrum in neutral solution. The duration of the radiation pulse in basic solution (1400 ns) is greater than in neutral solution (250 ns).⁹⁵

Laser radiation was obtained in 1970 from an ethanolic solution of sodium salicylate upon laser-induced excitation.⁹⁶

The species that lased was not identified. However, the data then available and current data on fluorescence of sodium salicylate in ethanol allow assignment of this radiation to the product of intramolecular proton phototransfer to the oxygen of the carboxy group.⁹⁷ For the first time lasing of a product of intramolecular proton phototransfer and identification of a radiating species was reported⁹⁸ in a study of stimulated emission of 2-(2-tosylaminophenyl)-5-phenyl-1,3,4-oxadiazole and 2-(2-tosylaminophenyl)-benzoxazole in ethanol. The lasing species results from the intramolecular proton phototransfer from the nitrogen of the amino group of the phenyl ring to the nitrogen atoms of the oxadiazole and oxazole rings, respectively. The photochemical lasers known to date based on intermolecular and intramolecular reactions of proton phototransfer of organic compounds are listed in Tables 4 and 5.

Table 4. Characteristics of photochemical lasers based on intermolecular proton phototransfer reactions of organic compounds.

V. Losses in photochemical lasers

The efficiency of dye lasing is determined by the relationship between the light amplification and losses. The losses are classified as constant and induced losses. The former are the losses in the resonator and at the mirrors. In dye lasers overabsorption of the laser radiation by the dye in the ground state (for a photochemical laser, by the components of acid-base interaction) belong to the constant losses in addition to those mentioned above. The constant losses are time independent. The induced losses in dye lasers are related to the absorption of lasing by short-living intermediate species produced by the excitation light.

Induced losses in photochemical lasers unlike ordinary lasers may occur due to photoprotolytic reactions. Let us consider these induced losses.

1. Absorption of the laser radiation by the product of a photochemical reaction in the excited singlet [terms $N_3\sigma_{35}(v)$ and $N_3'\sigma_{3'5'}(v)$ in the equation (7)] and triplet [terms $N_6\sigma_{67}(v)$ and $N_6'\sigma_{6'7'}(v)$] states of the components of the acid-base interaction.

Acid-base systems with simultaneous lasing of the initial compound and the photoreaction product are the most valuable from the practical viewpoint. In the selective resonator of such a system, it is possible to attain laser radiation tuned over a wide spectral range, which exceeds the range of tuning for the individual components of the acid-base system. Lasing of the initial compound and the reaction product separately does not necessarily imply their simultaneous lasing. Thus 2-heteryloxazoles and their cations fluoresce efficiently and lase separately.⁴⁰ However, solutions with simultaneous efficient fluorescence of both the initial heteryloxazole and cation, do not lase at certain ratio of the components. As the concentration of a proton donor (acetic acid) in ethanolic solutions of 2-heteryloxazoles is increased, the quantum yields of fluorescence of the initial form are decreased, and a band of fluorescence of a protonated form resulting from the proton phototransfer appears in the longwave region of the spectrum,³⁰ and the efficiency of laser radiation of the initial form drops to zero at low concentrations of acetic acid. At certain concentrations, both forms do not lase. At higher acetic acid concentrations, the laser radiation of the photoreaction product appears and the efficiency of this radiation increases with the increase in the acid concentration.¹¹⁶ Both the neutral and the protonated forms of 2-heteryloxazoles cause additional losses, which decrease stimulated emission by the corresponding conjugated acid-base form. For this reason, it is impossible to produce two-band laser radiation in solutions of 2-heteryloxazoles. The losses due to the neutral form in the lasing by the cations result from the $S_n \leftarrow S_1$ absorption of the neutral forms. The losses due to the cations in the lasing by the neutral forms, in addition to $S_n \leftarrow S_1$

absorption in the region of stimulated emission of the neutral forms, may result from slow dissociation of the cations in the ground state.¹¹⁶

2. Light absorption by decay products of a lasing species.

Reactions of electron photosplitting are typical of the aromatic compounds with the electron-donor group (OR, NR₂, O⁻). The thus formed solvated electron has a broad absorption spectrum,¹³¹ which can overlap with that of laser radiation of a photochemical laser. Thus flash lamp excitation of an aqueous solution of sodium 8-hydroxypyrene-1,3,6-trisulfonate (SHPTS) induced losses in the photochemical laser that are related to the absorption of the laser radiation from the deprotonated form of SHPTS by the hydrated electron produced from this excited form.¹³² The light absorption by the hydrated electron leads to a decrease in the efficiency and narrows the lasing spectrum of SHPTS. In the laser excitation, the induced losses in this laser are small.¹⁰¹ A decrease in the hydrated electron concentration due to its interaction with electron acceptors results in a decrease in these induced losses and an increase in the laser radiation efficiency of SHPTS in the lamp excitation.¹³²

If the 7-aminonaphthalene-1,3-disulfonate dianion is formed in acidic solutions by the reaction of an acid photodissociated monoanion with the protonated amino group, the efficiency of the lasing upon pulse photoexcitation is considerably higher compared to that upon direct excitation from the ground state in neutral solutions.²² This increase in efficiency is rationalised as a decrease in losses, due to the induced $T_n \leftarrow T_1$ absorption of light by the 7-aminonaphthalene-1,3-disulfonate dianion upon protonation of the amino group of the dianion triplet ($\sigma_{67} < \sigma_{6'7'}$) in acidic solutions and a decrease in losses, caused by the light absorption by the hydrated electron, as a result of the effective reaction of the electron with the proton.

VI. Tunable photochemical lasers

Systems with intermolecular relaxation processes that allow excitation of two or several different lasing species are promising for designing lasers tunable over a wide spectral range. This can be achieved in systems with electron energy transfer if both the donor and acceptor lase and in systems with fast reversible photochemical reactions provided both the initial species and the reaction product lase simultaneously.⁹ Favourable relative disposition of the spectra of laser radiation of the components in binary systems with energy transfer and in systems with photoprotolytic reactions enables generation of laser radiation over a wide spectral range in a selective resonator.

The acid-base systems with simultaneous laser radiation of both photoprotolytic forms are few. In the majority of photo-

Table 6. Characteristics of photochemical lasers based on binary dye systems.

Binary dye system	c_1 /mmol litre ⁻¹	c_2 /mmol litre ⁻¹	$\lambda_1 - \lambda_2$ or λ /nm

	0.4	0.9	520
	0	1.0	524

Note. The following designations are adopted: c_1 is the concentration of the first component of the binary dye system, c_2 is the concentration of the second component of the binary dye system, $\lambda_1 - \lambda_2$ is the range of tuning of lasing, λ is the wavelength of spectral maximum of laser radiation. The data for the first five binary dye systems are taken from Ref. 134, for the next system from Ref. 133, and for the two last systems from Ref. 56. ^a The component that undergoes proton phototransfer reaction. ^b The component that forms a hydrogen-bond complex in the excited state.

chemical lasers (see Tables 4 and 5), stimulated light emission by the reaction product only is observed. This narrows substantially the possibility for creation of an increased range of tunable radiation in dye lasers. Binary mixtures were suggested to overcome this difficulty. In these mixtures, one or both components participate in photoprotolytic reactions.^{133,134} Realisation of a large Stokes' shift of fluorescence, due to adiabatic reactions of proton phototransfer allows the selection of binary solutions where the fluorescence band of one of the components lies in the spectral range between the absorption band and the fluorescence band of the second component. This allows one to create active media of lasers with an expanded range of the laser radiation tuning within the limits of the total luminescence band of the binary mixture components.

To increase substantially the tuning range of laser radiation in binary mixtures with photoprotolytic reactions it is necessary that first, the fluorescence bands are shifted relative to each other to make the total amplification band noticeably wider than the amplification bands of the individual components. Second, the energy transfer between components should not occur, that is, the absorption band of one component should not overlap with the fluorescence band of the other component. These requirements can be met if systems with a high Stokes' shift of fluorescence are used, e.g. systems with photoprotolytic reactions.¹³⁴ In coherent excitation, compounds should possess substantial absorption at the excitation wavelength. In lamp excitation the absorption spectra of the components should have minimum overlap to utilise efficiently the pump energy. For some binary mixtures of this type, broadening of the tuning range or shift of the maximum of laser radiation is observed at a certain ratio of the components (Table 6).

The spectrum of stimulated emission of 2,2'-bipyridyl-3,3'-diol in which intramolecular proton phototransfer occurs exhibits a blue shift in dioxane upon addition of 7-ethylamino-6-methyl-4-trifluoromethylcoumarin.⁶³ This effect depends on the relative concentration of the components. If spectra of laser radiation of components of a binary mixture are far removed from each other, the mutual influence of the components on the spectral position of their laser radiation is absent. The spectrum of stimulated emission of a mixture of 1,4-bis(2-methylstyryl)benzene (0.8×10^{-3} mol litre⁻¹) and 3-hydroxyflavone (3×10^{-3} mol litre⁻¹) which undergoes intramolecular proton phototransfer, exhibits two peaks at 420 and 535 nm in dioxane.¹³³ These maxima coincide with those of stimulated emission of the individual components in the same solvent and their relative intensities depend on the relative concentrations of the components. A similar picture is observed for a solution of 4,4'-diphenylstilbene (1.2×10^{-3} mol litre⁻¹) and 3-hydroxyflavone (1.64×10^{-3} mol litre⁻¹) in dioxane. Two maxima at 408 and 535 nm,¹³³ which correspond to the stimulated emission of individual components, are observed in the spectrum of stimulated emission of a mixture.

Abstract. The crystal structures of inorganic compounds comprising cationic complexes containing oxygen atoms coordinated tetrahedrally to metal atoms, or oxocentred groups [OM₄], are considered. The linking of the [OM₄] tetrahedra in the structures has been analysed and cationic complexes of different structures have been identified. The rules governing the linking of the [OM₄] tetrahedra have been formulated and the cationic complexes have been subjected to a detailed systematic treatment on their basis. Data on the statistics of the bond lengths and bond angles in the [OM₄] tetrahedra are presented. The bibliography includes 317 references.

I. Introduction

One of the approaches to the description of crystal structures is the identification in the latter of cations as the central atoms and of anions as ligands. However, a number of crystal structures can also be considered from the standpoint of the coordination of anions^{1–7} and in particular of oxygen atoms (Al₂O, Al₃O,^{8,9} Mg₂O, Mg₃O,^{10–13} Li₃O, Li₄O, Li₅O,^{14,15} Na₃O, Na₄O, K₃O, K₄O,^{16,17} *etc.* clusters). Some workers^{18–21} have used this approach for the description of crystal structures, identifying in the latter individual atomic groups formed by anions as the central atoms and by cations as the ligands. The development of this approach constitutes the subject of the crystal chemistry of compounds with oxocentred complexes, within the framework of which one considers ‘additional’ oxygen atoms — atoms which do not enter into the composition of the traditional anionic complexes [T_mO_m] (T = Si, Ge, B, S, P, V, As, Se, *etc.*) and water molecules — as the coordination centres. We emphasise that the proposed method applies only to cationic complexes and does not alter the classification of structures based on the type of anionic groups. In most cases, the ‘additional’ oxygen atoms are involved in the tetrahedral coordination of metal atoms and oxygen is thus

the central atom in cationic [OM₄]ⁿ⁺ complexes. We may note that the coordination of the ‘additional’ oxygen atom in the complex originally studied structurally was not as a rule analysed, but sometimes an oxocentred complex based on [OM₄] groups was identified in connection with the main alternative description of the structure. For example, Sahl²² described the structure of lanarkite Pb₂O(SO₄) on the basis of chains of [OPb₂], consisting of edge-linked [OPb₄] tetrahedra and sulfate groups [SO₄]. Apparently the first systematic study on this topic is that of Bergerhoff and Paeslack,¹⁹ where the authors specified only ‘additional’ oxygen atoms as the centres for a series of tetrahedral complexes based on [OM₄] groups. The calculation of the stoichiometric cation/additional oxygen atom ratios, which are sometimes appreciably greater than unity, serves as the crystal-chemical basis for this approach. Thus in the structure of dolerophanite Cu₂O(SO₄),^{23,24} the ratio is 2, which provides grounds for considering the ‘additional’ oxygen atom as the coordination centre. Six oxocentred complexes based on [OM₄] tetrahedra have been identified:¹⁹ a single tetrahedron, a chain, three types of layers, and one framework. Such a small structural diversity of [OM₄] complexes is due to the fact that at the time when the above communication was written¹⁹ (1968) few structures with ‘additional’ oxygen atoms were known. Later Carre *et al.*²⁰ analysed a series of compounds with complexes based on oxocentred [OLa₄] tetrahedra. They specified²⁰ five different types of complexes considered as derivatives of the oxocentred [OLa] layer. Bengtsson and Holmberg²¹ published a review on the structural chemistry of crystalline and amorphous media containing [OPb₄] tetrahedra. Oxocentred [OPb₄] tetrahedra have been found in glasses of the PbO–PbF₂ system.^{25–27} They produce a three-dimensional framework made up of O–Pb–O linkages and performing in essence a function analogous to that of the [SiO₄] tetrahedra in silicate glasses. The [OCu₄] tetrahedra are well known in organometallic chemistry as the central groups in copper(II) μ_4 -oxo-complexes.^{28–37} Ten types of [OCu₄] complexes have been identified^{38–41} and their characteristic features have been noted: the cationic nature of [OM₄] tetrahedral complexes; owing to the large size of the central atom and its relatively low charge (2–), the tetrahedra are linked to one another not only *via* common corners but also *via* their edges and there is also a possibility of corners common to more than two tetrahedra (this accounts for the exceptional diversity of the types of complexes).

Uspekhi Khimii 67 (2) 155–174 (1998); translated by A K Grzybowski

Inorganic compounds incorporating an oxygen atom with tetrahedral coordination involving metal atoms are examined in the present review and a systematic crystal-chemical description of the ways in which the oxocentred $[\text{OM}_4]$ groups are linked together to form cationic $[\text{OM}_n]$ complexes is given.

II. The bond lengths in $[\text{OM}_4]$ complexes and the physical properties of compounds with $[\text{OM}_4]$ tetrahedra

The identification of the oxocentred cationic $[\text{OM}_4]$ complexes as structural units of a special type arose because of the high strength of the O–M bonds in these groups. Table 1 presents the average M–O distances (M = Cu, Sn, Pb, La) in structures with tetrahedrally coordinated ‘additional’ oxygen atoms O_A and the anionic $[\text{TO}]_n$ complexes formed by the central atom T and the oxygen atoms O_T as the ligands $\{[\text{TO}_3], \text{T} = \text{Se, As}; [\text{TO}_4], \text{T} = \text{S, Cr, V, P, Ge}; [\text{TO}_6], \text{T} = \text{Mo, Re}\}$. Thus the average M– O_A and M– O_T distances are 1.93 and 1.99 Å respectively for M = Cu, 2.23 and 2.42 Å for M = Sn, 2.33 and 2.69 Å for M = Pb, and 2.42 and 2.60 Å for M = La. We may note that bonds longer than 2.1 Å were not taken into account in calculating the Cu–O bond lengths.

The O_A –M bond is on average shorter than O_T –M, which suggests a high bond strength in the oxocentred tetrahedral complexes and influences the physical properties of the chemical compounds.

We shall consider as an example the crystal structure of georgbokiite $\text{Cu}_5\text{O}_2(\text{SeO}_3)_2\text{Cl}_2$ (Fig. 1). In this structure, there are isolated groups (SeO_3) with Se atoms involved in ternary

Figure 1. The crystal structure of georgbokiite $\text{Cu}_5\text{O}_2(\text{SeO}_3)_2\text{Cl}_2$ in projection onto the yz plane.⁴² (a) Representation in terms of the coordination polyhedra of copper; (b) ‘ball-and-stick’ representation.

‘pyramidal’ coordination. According to traditional crystal-chemical ideas, this structure is considered from the standpoint of the coordination of copper and selenium atoms. Three crystallographically nonequivalent copper atoms form coordination polyhedra with different structures and compositions: $\text{Cu}(1)\text{O}_3\text{Cl}_2$ — trigonal bipyramid; $\text{Cu}(2)\text{O}_4\text{Cl}_2$ and $\text{Cu}(3)\text{O}_5\text{Cl}$ — octahedra. Only the equatorial CuO_4 fragments are indicated in Fig. 1a for the octahedra as the most stable groups. The $\text{Cu}(3)\text{O}_4$ squares are linked *via* their edges, forming infinite CuO_2 chains, extended

Table 1. The M–O bond lengths for the ‘additional’ oxygen atom O_A in the $[\text{OM}_4]$ tetrahedra and the O_T oxygen atom in the $[\text{TO}_3]$ triangular groups, $[\text{TO}_4]$ tetrahedra, or $[\text{TO}_6]$ octahedra.

Note. The space group is indicated for compounds existing in several polymorphic modifications. The table presents the average bond lengths and the limits of their variation (in brackets) in the crystal structure. The error in the determination of the bond lengths does not exceed 0.01 Å.

along the x axis and joined together into a layer parallel to the xz plane. The layers are combined into a framework *via* the Cu(1)O₃Cl₂ polyhedra. Thus, from the standpoint of traditional ideas, the most stable fragment in the structure of georgbokiite is a chain, parallel to the x axis, made up of edge-linked CuO₄ squares. However, in the study of thermal deformations of georgbokiite it was found that the z and y axes are respectively the directions of minimum and maximum thermal expansions, the average expansion occurring along the x axis.⁷³ Furthermore, one of the cleavage planes (yz) in the test compound is perpendicular to the direction of the CuO₂ chains.

Analysis of this structure from the standpoint of the crystal chemistry of oxocentred complexes showed that the 'additional' oxygen atoms are tetrahedrally coordinated to copper atoms (Fig. 1b). By being alternately corner- and edge-linked, the [OCu₄] groups form oxocentred [O₂Cu₅] chains extended parallel to the z axis (Fig. 2). The thermal expansion is a minimum precisely along this direction and both cleavage systems (xz and yz) are parallel to the latter. The maximum refractive index, corresponding as a rule to the direction of the densest rows of atoms, corresponds also to the direction of the z axis.^{74, 75}

Figure 2. The oxocentred [O₂Cu₅] chains in the structure of georgbokiite and the figure representing its thermal expansions.

α_{22} and α_{33} are the axes of the figure representing the thermal expansion coefficients; N_g' and N_m are the axes of the optical indicatrix in the yz plane.

Thus the identification of oxocentred groups in the structures makes it possible to treat more clearly the anisotropy of the thermal expansion and of other physical properties of georgbokiite than in the traditional approach. Henceforth, in numerating the ways in which the [OM₄] groups can be linked together to form a cationic complex, we shall make use of polyhedral images similar to that presented in Fig. 2. Images of the structures from the point of view of the classical approach (Fig. 1) may be found in the original studies indicated in the references.

III. Systematic treatment of cationic complexes based on [OM₄] tetrahedra and the principles governing their descriptions

In traditional crystal chemistry, [TO₄] tetrahedra are as a rule corner-linked and one corner belongs to not more than two

tetrahedra.^{76, 77} The linking together of the tetrahedra *via* their edges (let alone faces) is encountered very rarely. For example, edge-linking of the tetrahedra in silicate anions has been established in the fibrous modification of silicon dioxide⁷⁶ and in certain beryllsilicates.⁷⁸ The formation of 'knotted' linkages,^{77, 78} i.e. the linking together of several tetrahedra by one corner, is also an exceptional case and the 'knot' consists as a rule of not more than four highly distorted tetrahedra.

In describing the crystal structure using [OM₄] tetrahedra, the possibility of their edge-linking is postulated and one M corner can belong to more than two tetrahedra.

In the present review, oxocentred [OM_x] complexes are represented as an assembly of [OM₄] tetrahedra.

There are several classifications of polyhedral structural units.^{76, 79, 80} The classification based on Liebau features,⁷⁶ constructed on the basis of a traditional systematic treatment of silicates devised by Machatschki, Bragg, *etc.*, is the most general. The Liebau classification involves both different geometrical types of coordination polyhedra and various ways of linking them together (*via* corners, edges, and n -corner faces). However, it bears features of the structure of silicate anions, for the classification of which it has in fact been created. For a more complete classification of polyhedral edge-linked and face-linked structural units, this system requires a series of amplifications, which are unimportant for silicates. The principal characteristics of the systematic treatment employed are described briefly below and an account is given of the main principles governing this description of structures made up of oxocentred fragments. The problems of the classification of polyhedral structures have been described in greater detail in another communication.⁸¹

Features of the systematic treatment. 1. The coordination of the central atom is a parameter which includes both the coordination number of the central atom and the geometry of the coordination polyhedron. The recommendations given by Parthé and coworkers^{79, 80, 82} are employed in the determination of the values of the parameters. In particular, the designation $4t$ was adopted for tetrahedral groups.

2. The dimensionality of the complex D is the number of dimensions in which the complex is of infinite extent. The following values are possible: 0 (finite complexes), 1 (chain complexes), 2 (layered complexes), 3 (framework complexes).

3 and 4. The linkedness of the tetrahedra in the complex ML and the linkedness of the tetrahedron L .

The parameter ML indicates the way in which it is possible to construct the specified complex by adding individual single polyhedra. It is determined as the following hierarchical series of values: $3 > 2$, $3 > 1$, 2 , $3 > 2 > 1$, $2 > 1 > 0$. Here it is necessary to make use of Wells's rule: if an edge (or face) is shared by two tetrahedra, then its corners (and edges) are not considered to be shared by these two tetrahedra. The value of L reflects all the ways of linking together the polyhedra in the complex. The linkedness L is equal to the number of corner atoms shared by two coordination polyhedra:¹⁰ $L = 0$ for an isolated polyhedron, $L = 1$ for corner-linking, $L = 2$ for edge-linking, and $L = 3$ and above for face-linking.

5. The connectedness s of the polyhedra of a coordination polyhedron is equal to the number of polyhedra with which the given polyhedron shares corners, regardless of their linkedness.^{76, 82}

6. The branchedness of the complex B . The finite structural units and single chains[†] are called unbranched if they contain no subunits linked to more than two other subunits.⁸² Otherwise they are called branched. Furthermore, complex structural complexes, which may be regarded as made up of unbranched (branched) finite fragments or unbranched (branched) single chains, are described as unbranched (branched). The branchedness B of a cationic complex of infinite extent (*i.e.* with $D > 0$) is a property of its fundamental chain. The fundamental chain is defined as the

[†] A chain consisting of secondary tetrahedra is called single.

chain from which the cationic complex may be constructed by its successive addition.⁸² The fundamental chain consists of a single chain (made up of only secondary polyhedra) and branches. Liebau⁷⁶ suggested that unbranched, open-branched, loop-branched, mixed-branched, and hybrid complexes, designated respectively by the symbols uB , oB , lB , olB , and hB , be distinguished.

7. The periodicity P . The term periodicity of a structural fragment of infinite extent is the number of structural subunits (excluding branches) constituting the period of the chain from which this fragment may be constructed by the successive addition of subunits to one another.⁸² For finite ring complexes, the number of polyhedra constituting the ring is specified as the periodicity. Liebau⁷⁶ calls this parameter the ring periodicity.

8. The multiplicity M of the complex is the term given to the number of single polyhedra, chains, or layers, which, by linking to one another, form a complex with the same dimensionality as the initial complexes.⁸²

9. The ratio $n:m$ for the complex $[A_nB_m]$, where A is the central atom and B is the ligand.

Formula and diagram of connectedness. The following is the connectedness formula: $(s: L_1 - s_1; L_2 - s_2 \dots L_n - s_n)$, where $L_1, L_2, \dots, L_n$ are specific values of linkedness, while $s_1, s_2, \dots, s_n$ are specific values of connectedness for the given polyhedron with others in accordance with the values of linkedness indicated ahead of them. The formula of the connectedness of this polyhedron shows how many polyhedra are linked to the given polyhedron and in what way. It is convenient to employ the so called diagram of connectedness constructed on the basis of the Schlegel diagram for the given polyhedron. The latter represents a planar image of the edge network of any kind of convex polyhedron. For the tetrahedron, the Schlegel diagram represents the view from above on to a regular tetrahedron placed on one of its triangular bases. The Schlegel diagrams were first introduced into crystal chemistry by Hoppe and Köhler.⁸³

Henceforth we shall use the following ways of representing the elements of connectedness.

1. The corner designated by a circle links the given polyhedron to another. If the corner links the given polyhedron to more than one other polyhedron, then the number of such polyhedra is indicated next to the corner.

2. The edge identified by a semibold line is common to two polyhedra.

The connectedness diagrams will be referred to as equivalent if the relative disposition of the linkage corners and/or edges in them is the same (or is mirror-symmetrical).

Classification of the polyhedra in a polyhedral complex. For the crystal-chemical description of the coordination polyhedra, constituting the given complex it is necessary not only to indicate the geometrical characteristics but also to define the way in which they are joined together. Wells^{84–86} suggested that polyhedra with the same relative disposition as the elements of connectedness be referred to as topologically equivalent. Within the framework of the approach employed, this means that polyhedra with equivalent connectedness diagrams are referred to as topologically equivalent polyhedra in the complex.

It is essential to note that the description of the disposition of the elements of connectedness in the polyhedron (with the aid of the connectedness diagram) is still insufficient to define the position of the polyhedron in the complex. In the same structure, topologically equivalent polyhedra may have different environments comprising polyhedra with which they have common linkage corners. In such cases we speak of configurationally nonequivalent polyhedra (more rigorous definitions have been given elsewhere⁸¹).

Configurationally equivalent polyhedra are always topologically equivalent, but topologically equivalent polyhedra may be configurationally nonequivalent. Crystallographically equivalent polyhedra are always topologically and configurationally equivalent.

Thus, from this standpoint, a polyhedral cationic complex consists of n types of configurationally equivalent and m classes of topologically equivalent polyhedra. In the general case, we have $m < n$. The classification of the polyhedra in the structure is based on the order of hierarchical equivalence ratios: configurational – topological – crystallographic.

Additional features of the systematic treatment. 10. The number of configurational types of polyhedra in the complex and their ratio.

11 and 12. The diagrams and formulae of the connectedness of the configurational types of polyhedra.

Crystal-chemical formulae. When the formula of the complex is written, the system recommended by Liebau *et al.*^{76, 82} is used to characterise it structurally. The following parameters are indicated in braces before the chemical formula of the complex written in square brackets: $\{B, M_\infty^D\}$. The following designations are adopted for finite structures ($D = 0$): $\{f\}$ — for a chain of finite length, $\{r\}$ — for a ring polyion, $\{c\}$ — for a cage.^{79, 82}

IV. Types of cationic [OM₄] complexes

1. General remarks

The structures of oxocentred complexes are described in terms of the [OM₄] tetrahedra in accordance with the following main principles. Taking into account the features of the classification formulated in the previous section, the type units of oxocentred [OM₄] structural units are treated systematically. All the known crystal structures in which the complex has been found are indicated for complexes of each type. Some of these structures are considered as examples and are described from the standpoint of the crystal chemistry of compounds with oxocentred groups.

For convenience we introduced a numbering of the types of structural units within each dimensionality. A capital Latin letter is placed before the number of the complex indicating its dimensionality: I — finite (*islands*), C — one-dimensional or chain (*chains*), L — two-dimensional or layered (*layers*), F — three-dimensional or framework (*frameworks*).

2. Finite oxocentred complexes.

Tables 2 and 3 as well as Fig. 3 present the main types of finite oxocentred complexes, the crystal structures in which these complexes have been found, and a topological description of the latter.

1I. The individual [OM₄] tetrahedron. The oxocentred [OM₄] tetrahedron is known in organic crystal chemistry,^{28–37} for example $M = \text{Cu}$, Be , or Zn . Among inorganic compounds, a single [OM₄] tetrahedron can be identified, in particular, in the crystal structure of ponomarevite $\text{K}_4\text{Cu}_4\text{OCl}_{10}$,^{87–89} which con-

Table 2. Classification of the types of finite oxocentred complexes based on the [OM₄] tetrahedron.

Num- ber	L	Para- meter	n	O:M	Type of complex	m	p	Connect- edness formula

tains tetranuclear clusters [Cu₄OCl₁₀] formed by oxygen as the central atom involved in tetrahedral coordination.

I2. The binary group {*f*}[O₂T₇]. This oxocentred complex consists of two [OM₄] tetrahedra linked by one common corner and it is therefore ‘reverse’ analogue of the diorthosilicate group [Si₂O₇].

I3. The chain fragment {*f*}[O₄M₁₃] made up of four tetrahedra and discovered in the crystal structure of the compound Cu(Cu₁₃O₄)(SeO₃)₂Cl₁₆.¹¹⁴ The fragment consists of four [OCu₄] tetrahedra linked in succession *via* their corners. In the structure of

**Figure 3.** The types of finite oxocentred complexes. A, B — tetrahedra belonging to different topological types.

the given compound, there are copper atoms which do not enter into the oxocentred tetrahedra.

I4. The binary group {*f*}[O₂M₆] consists of two tetrahedra having one common edge. The presence of the complex [O₂Cu₆] having this structure has been established in the crystal structure of the exhalation mineral fedotovite K₂Cu₃O(SO₄)₃.^{46, 47}

I5. We identified the chain fragment {*f*}[O₄M₁₀] with an edge-linkage made up of four tetrahedra in the crystal structure of Sr₂Bi₃V₃O₁₄ solved by Boje and Müller-Buschbaum.¹¹⁸ From the standpoint of the approach employed, the formula of this compound is written as Sr₂Bi₃O₂(VO₄)₃.

I6. An oxocentred complex made up of four [OM₄] tetrahedra in which each tetrahedron is edge-linked to three others, was first noted by Keller in the compounds Pb₉O₄Br₉¹¹⁹ and TiPb₈O₄Br₉.¹²⁰ Later Riebe and Keller¹²¹ noted that in a complex having this structure the M atoms not involved in the linking of the tetrahedra may be replaced by hydrogen.

It is of interest that the complex [O₄Pb₄], having a similar structure but incorporating only Pb atoms participating in the linking of the tetrahedra, has been discovered in the gas phase,^{128, 129} while the complexes [(OH)₄M₄] (M = Mg, Co, Ni, Cd, Pb) have been found in aqueous solutions.^{130–132}

Table 4 presents the finite complexes formed from the complex I6 for different degrees of substitution *n*.

Table 4. Finite oxocentred complexes formed from complex I6 as a result of the substitution *n*(O + M) → *n*(OH).

3. Oxocentred chain complexes

Oxocentred chains can be conveniently classified in terms of the types of single chains from which they are constructed. The linking of single chains leads to the formation of multiple structural units. All the oxocentred chains can be divided into families in terms of their multiplicity and linkedness. Tables 5 and 6 present the types of oxocentred chain complexes based on the $[\text{OM}_4]$ tetrahedra and the chemical compounds in the structures of which such complexes have been found.

Table 5. Classification of the types of oxocentred chain complexes based on the $[\text{OM}_4]$ tetrahedron.

C1. The single-period chain $\{uB, 1^1_\infty\}[\text{OM}_3]$ (Fig. 4). In this chain, the tetrahedra are linked only *via* the corners with a periodicity 1. This polyion is an analogue of the metagermanate chain $[\text{GeO}_3]$.

C2. The $\{uB, 2^1_\infty\}[\text{O}_2\text{M}_5]$ double chain. The linking of two C1 chains *via* free corners leads to the formation of the C2 double chain. Such a fragment can be identified in chemical compounds belonging to the ludwigite structural type. In the crystal structures of these compounds, there is also an 'additional' oxygen atom with a tetragonal-pyramidal coordination, as well as metal atoms which do not enter into the tetrahedral oxocentred complex.

C3. The $\{uB, 2^1_\infty\}[\text{OM}_2]$ double chain. The linking of two C1 chains to one another *via* the edges leads to the formation of a type C3 oxocentred chain. The main type of linkedness *ML* for this double chain is 2, although for the fundamental chain *ML* = 1. The C3 chain may be identified in oxoborates with the warwickite structural type. In contrast to ludwigite, in the warwickite structural type all the 'additional' oxygen atoms are involved in tetrahedral coordination and all the metal atoms enter into the oxocentred complex. Chains of analogous structure have been found in the structures of the diorthosilicates of the cuspidine and epistilite groups (innelite, lomonosovite, murmanite, *etc.*). In such compounds, the 'additional' oxygen, not entering into

Figure 4. The types of oxocentred chain complexes (C1–C6). *A, B* — tetrahedra belonging to different topological types.

anionic complexes, may be substituted by fluorine with its similar properties. The nature of the substitution can be both statistical and ordered. The structural similarity of oxoborates and the cuspidine-group diorthosilicates was first pointed out by Belov.⁷⁷

C4. The $\{uB, 3^1_\infty\}[\text{O}_3\text{M}_5]$ triple chain. As a result of the addition of yet another single C1 chain to a C3 chain, a triple oxocentred C4 chain is formed. Such a chain was first identified by Carre *et al.*²⁰ in the crystal structure of $\text{In}_6\text{La}_{10}\text{O}_6\text{S}_{17}$.¹⁸⁰

The C1, C3, and C4 chains may be assigned to a single family with the general formula $\{uB, n^1_\infty\}[\text{O}_n\text{M}_{n+2}]$, where *n* is the multiplicity of the chain.

C5. The $\{uB, 1^1_\infty\}[\text{O}_2\text{M}_6]$ single chain. This chain is topologically equivalent to the C1 chain, different from the latter by the periodicity (*P* = 2). In terms of its structure, the C5 chain is a reverse analogue of the pyroxene chain in the silicate. The difference consists in the fact that the corners not involved in the linking of the tetrahedra into the C5 chain are turned in opposite directions relative to the plane of the chain, whereas in pyroxenes they are turned in one direction. A C5 complex has been detected, in particular, in the crystal structure of the exhalation mineral kamchatkite $\text{KCu}_3\text{O}(\text{SO}_4)_2\text{Cl}$ (Fig. 5).^{43, 44}

Figure 5. The crystal structure of kamchatkite $\text{KCu}_3\text{O}(\text{SO}_4)_2\text{Cl}$.

C6. The $\{uB, 2^1_\infty\}[\text{O}_2\text{M}_5]$ double chain consists of two edge-linked C5 chains. A complex with this structure may be identified in stoiberite $\text{Cu}_5\text{O}_2(\text{VO}_4)_2$,^{54, 55} the structure of which was not previously considered in terms of this aspect.

C7. The $\{uB, 1_{\infty}^1\}[\text{OM}_2]$ fundamental chain (Fig. 6). A single oxocentred chain, consisting of secondary tetrahedra edge-linked in succession, was first identified by Sahl²² in the crystal structure

Figure 6. The types of oxocentred chain complexes (C7–C11). A, B, C, D, E — tetrahedra belonging to different topological types.

of lanarkite $\text{Pb}_2\text{O}(\text{SO}_4)$. This one-dimensional structural unit based on $[\text{OM}_4]$ tetrahedra is one of the commonest in oxocentred complexes. Thus it has been detected in three new minerals of exhalation origin in the Tolbachick volcano: klyuchevskite,^{189, 190} aluminoklyuchevskite,¹⁹¹ and piypite.^{192, 193}

C8. The $\{uB, 2_{\infty}^1\}[\text{O}_2\text{M}_3]$ double chain. The edge-linking of two C7 chains leads to the formation of the C8 double chain.

C9. The $\{uB, 3_{\infty}^1\}[\text{O}_3\text{M}_4]$ triple chain is formed by the linking of three C7 chains. A similar complex with the formula $[\text{O}_3\text{La}_4]$ has been identified by Carre *et al.*²⁰ in the crystal structure of $\text{La}_4\text{O}_3\text{As}_3\text{S}_9$.²¹¹

The C7, C8, and C9 chains form a family with the general formula $\{uB, n_{\infty}^1\}[\text{O}_n\text{M}_{n+1}]$, where n is the multiplicity of the chain. It may be postulated that a chain belonging to the same family with $n = 4$ occurs in the crystal structure of $\text{Pb}_5\text{O}_4[\text{SO}_4]$, which could not be fully solved. This hypothesis is based on the existence of oxocentred chains of type C7 ($n = 1$) and C8 ($n = 2$) in the compounds $\text{Pb}_2\text{O}(\text{SO}_4)$ ²² and $\text{Pb}_3\text{O}_2(\text{SO}_4)$ ^{57–60} respectively, which have similar compositions.

C10, C11. The six-fold chains having the general formula $\{uB, 6_{\infty}^1\}[\text{O}_6\text{M}_7]$ consist of six type C7 chains linked in different ways. The possibility of identifying the C10 polyion in the $\text{Bi}_{14}\text{O}_{16}(\text{SO}_4)_5$ structure and of representing it by a block cut out of a type PbO layer was pointed out by Aurivillius.²¹² The C11 chain may be identified in the structure of the high-temperature modification of bismuth oxomolybdate $\gamma\text{-Bi}_2\text{MoO}_6$ tentatively determined on the basis of high-resolution electron microscopy data.²¹³ The difference between the C10 and C11 chains is reflected in the configurational and topological properties of the tetrahedra constituting

them. There are three configurational types of tetrahedra in the C10 polyion, each of which constitutes a topological equivalence class. The C11 chain consists of tetrahedra with five different configurations, two of which are of the same topological type. The example of these chains shows that the use of the configurational and topological properties of the tetrahedra is important for the classification of structural units.

C12. The $\{uB, 1_{\infty}^1\}[O_2M_5]$ single chain (Fig. 7). In this chain, links *via* corners and edges alternate. An example of a compound with such a chain is provided by georgbokiite $Cu_5O_2(SeO_3)_2Cl_2$ (in the original study,⁴² the coordination of the additional oxygen atom was not considered).

Figure 7. The types of oxocentred chain complexes (C12–C16). A, B, C — tetrahedra belonging to different topological types.

C13. The $\{uB, 2_{\infty}^1\}[OM_2]$ double chain, consisting of two type C12 chains, was first identified by Bergerhoff and Paeslack¹⁹ in kyanite $Al_2O(SiO_4)$.²¹⁸

C14. The oxocentred $\{uB, 1_{\infty}^1\}[O_2M_5]$ chain, which may be found in compounds of the aenigmatite structural type, is a topological analogue of the C12 chain but with a periodicity of 4.^{221–228}

C15. The $\{uB, 1_{\infty}^1\}[O_6M_{16}]$ single chain with a periodicity of 6 is an interesting example of the alternation of two bonds *via* neighbouring corners with a single bond *via* the edge. This remarkable polyion, with the formula $[O_3Pb_8]$, may be identified in the structure of freedite $Pb_8Cu(AsO_3)_2O_3Cl_5$, solved by Pertlik,⁶⁷ who did not, however, consider it within the framework of the approach which we are employing.

C16. The $\{lB, 1_{\infty}^1\}[OM_2]$ loop-branched chain has been detected in the structure of copper titanium oxoborate $Cu_9Ti(B_2O_5)_2(BO_3)_2O_6$. This consists of two types of C1 chains linked by two additional tetrahedra adjoining them *via* two edges each. It is essential to note that this compound contains also ‘additional’ oxygen atoms involved in nontetrahedral (ternary) coordination and copper atoms which do not enter into the complex under consideration. The C16 chain is the only example of a branched complex involving oxocentred chains.

4. Layered oxocentred complexes

A series of layers may be described as derivative of the type PbO tetrahedral layer. Carre *et al.*²⁰ suggested that certain chains based on the [OLa₄] tetrahedron be also considered in terms of this aspect. However, the above principle is subject to limitations, since there are many structural units which cannot be detected among derivatives of the PbO layer regardless of the way in which

it is ‘sliced’. We therefore use this approach only for certain layered structures. Tables 7 and 8 present the characteristics of the types of layered oxocentred complexes based on [OM₄] tetrahedra and the chemical compounds in the structures of which these complexes have been detected.

Table 7. Classification of the types of oxocentred layered complexes based on the [OM₄] tetrahedron.

L1. The $\{uB, 1_{\infty}^2\}[O_2M_5]$ layer (Fig. 8) can be regarded as made up of C5 single chains. In terms of its structure, it resembles the [Si₂O₅] tetrahedral networks constituting (together with octahedral networks) the structures of layered silicates.⁷⁶ However, the topological structures of the layer considered and the silicate layer differ, since the unshared corners of neighbouring tetrahedra in the L1 layer are turned in opposite directions relative to the plane of the layer. The difference between the silicate tetrahedral network and the L1 layer is analogous to the difference between the pyroxene chain and the C5 chain. The structural unit [O₂Cu₅] of the L1 type has been detected in the crystal structure of averievite $[Cu_5O_2](VO_4)_2 \cdot MCl$ (M = K, Rb, Cs) (Fig. 9).^{232, 233} In this structure, the oxocentred layers are located exactly one under the other, the [VO₄] groups are ‘glued’ to the

bases of the [OCu₄] tetrahedra and together with the layers form the fundamental electrically neutral Cu₅O₂(VO₄)₂ framework. As a consequence of the disposition of the layers one under the other, broad cavities with a radius in excess of 3.0 Å, which incorporate the alkali metal ions K⁺, Rb⁺, and Cs⁺ as well as the chloride ions Cl[−], are formed in the structure.

L2. A layer of this type is a ‘corrugated’ analogue of the L1 layer. It is distorted in such a way that the periodicity of the fundamental chain of the layer changes from 2 to 3. This layer has been detected by Shuvalov *et al.*²³⁴ in the crystal structure of NaCu₅O₂(SeO₃)₂Cl₃.

L3. The oxocentred {*uB*, 2_∞²}[OM] layer with the chemical formula [OLa] was identified by Bergerhoff and Paeslack¹⁹ in the La₂O₂S structure solved by Zachariasen.²³⁵ The multiplicity of this layer is 2, although it can be regarded as consisting of two corner-linked layers with a periodicity of 1.

L4. The [O₄M₃] structural unit of this type consists of two L3 layers ‘glued’ to one another or of four simple corner-linked single-period layers. As a result of the ‘glueing’, the O:M ratio becomes 1.333, *i.e.* greater than 1.

L5, L6, L7. The layers of these types can be regarded as a result of the successive linking of C7 chains. The C7 chains are initially linked *via* their edges into multiple chains similar to C8 and C9,

Figure 8. The types of oxocentred layered complexes *L1* and *L2*.

Figure 9. The crystal structure of averievite $\text{Cu}_5\text{O}_2(\text{VO}_4) \cdot \text{MCl}$.

after which these multiple chains are linked *via* lateral corners into infinite layers. Thus the *L5* and *L6* layers can be regarded as consisting of *C8* and *C9* chains respectively. The *L7* layer is formed from a *C7* four-fold chain, the individual fragments of which have not so far been detected in chemical compounds. The possibility of identifying the *L7* layer in the $\text{Bi}_{26}\text{O}_{27}(\text{SO}_4)_{12}$ crystal structure has been pointed out.²¹² The *L5* and *L6* layers were not considered in the original studies. It is of interest that the last two layers in compounds have similar chemical compositions — $[\text{O}_4\text{Cu}_3\text{Bi}_2]$ and $[\text{O}_6\text{Cu}_3\text{Bi}_4]$ respectively. In these complexes, the Bi atoms participate only in the edge-linking of the *C7* chains into multiple chains, whereas the Cu atoms are involved in corner-linking into a layer of the multiple fragments formed. Thus the functions of the cations in the topological structures of the *L5* and *L6* layers are different.

L8. The $\{uB, 1_\infty^2\}[\text{OM}_2]$ layer may be regarded as consisting of finite *I4* complexes.

L9. A type *L9* layer was first described by Keller and Langer²⁴³ in the structure of $\text{HgPb}_2\text{O}_2\text{Cl}_2$. The layer is made up of *C3* chains by the linking of the latter *via* the corners of the tetrahedra not involved in edge-linking.

L10. A $\{uB, 1_\infty^2\}[\text{OM}_2]$ layer has been noted by Bergerhoff and Paeslack¹⁹ in the crystal structure of dolerophanite $\text{Cu}_2\text{O}(\text{SO}_4)$. This layer can also be identified in the structure of francisite²⁴⁴ (Pring *et al.*²⁴⁴ did not consider the structure of the oxocentred layer).

L11. A type *L11* layer may be found in the crystal structure of pinakioleite $(\text{Mg}, \text{Mn})_2\text{Mn}^{3+}(\text{BO}_3)_2$. Together with the tetrahedrally coordinated ‘additional’ oxygen atoms, pinakioleite contains ‘additional’ oxygen atoms with the $[4 + 1]$ coordination — a ‘tetragonal pyramid’ — as well as metal atoms not involved in the oxocentred groups. On the other hand, all the ‘additional’ oxygen atoms in the structures of a series of diorthosilicates belonging to the mosandrite–rosenbuschite group^{246–251} are involved in tetrahedral coordination, while all the cations (with the exception of innelite and goetzenite) participate in the formation of the oxocentred tetrahedra. As in the case of the

structures of the cuspidine series (with a *C3* chain), the central oxygen atom in the $[\text{OM}_4]$ tetrahedra is partly substituted by fluorine, which does not disturb the overall structure of the complex.

L12. The $[\text{OM}]$ layer. The $[\text{OM}]$ layer is one of the commonest layers with edge-linking of tetrahedral complexes. For example, in the case of lead monoxide [tetragonal and one of the orthorhombic (*Cmma*) modifications], the $[\text{OPb}]$ layer is made up of $[\text{OPb}_4]$ tetrahedra.²⁵² An oxocentred layer of this type has been detected in the structures of a multiplicity of chemical compounds (see a review²⁷⁷ as well as Table 8).

L13. The layer in the orthorhombic (*Pbcm*) PbO ²⁷¹ differs structurally from *L12* by the marked ‘corrugations’ of the PbO layers. The topological structures of these layers are also different, although their constituent $[\text{OPb}_4]$ tetrahedra are topologically equivalent.

L14, L15 (Fig. 10), **L16.** These layers can be readily obtained by ‘cutting out’ different blocks of OPb_4 tetrahedra from the tetragonal PbO layer. In $\text{AgPb}_4\text{O}_4\text{Cl}$,²⁷² one tetrahedron is ‘cut out’ in each case, whereas in $\text{Pb}_5\text{O}_3(\text{GeO}_4)$ ⁶¹ blocks of six tetrahedra (three by two in size) are ‘cut out’. In the kombatite^{62,63} and sahlinite²⁷³ structures, ‘butterflies’ consisting of seven $[\text{OPb}_4]$ tetrahedra are ‘cut out’. In the layers formed after ‘cutting out’, the symmetry of the $[\text{OPb}_4]$ is distorted as a consequence of the removal of neighbouring tetrahedra.

Figure 10. The oxocentred layered complexes *L14* and *L15*.

L17. The $[\text{O}_7\text{Pb}_8]$ layer of this type is a highly ‘corrugated’ version of the *L12* and *L13* layers, where individual $[\text{OPb}_4]$ tetrahedra have been ‘cut out’. The O : M ratio in such a layer is 7 : 8.

L18. The oxofluorocentred $[\text{O}_8\text{F}_3(\text{Ca}, \text{Na})_8(\text{Ti}, \text{Nb})_4]$ layer, made up of a defective (with one-tetrahedron ‘cut out’) *L12* layer to which single type *C1* chains have been added from above and from below, may be identified in the crystal structure of the mineral fersmanite.²⁷⁵ The addition takes place in such a way that the direction of the *C1* chain from the upper side of the layer is perpendicular to the direction of the same chain from the lower side. Each second tetrahedron of the chain is then located above or below the ‘cut out’ in the main layer. The $[\text{Si}_2\text{O}_7]$ diorthosilicate groups are located between the layers having this structure in fersmanite. In the original study,²⁷⁵ the oxocentred complexes were not identified.

L19. A layer of this type is made up of three-period chains with alternation: two linkages *via* the edges and one linkage *via* a corner. Such chains are loop-branched, since they are connected by two additional tetrahedra.

L20. The $[\text{O}_4\text{M}_3]$ double layer is made up of two $L12$ layers edge-linked to one another.

5. Oxocentred framework complexes

The classification of three-dimensional polyhedral structures is one of the important problems in the crystal chemistry of inorganic compounds. Tables 9 and 10 present the types of oxocentred framework complexes based on $[\text{OM}_4]$ tetrahedra and the chemical compounds containing them.

Table 9. Statistics of oxocentred framework complexes based on $[\text{OM}_4]$ tetrahedra.

F1 (Fig. 11). The oxocentred type $F1$ framework is a reverse analogue of the cristobalite framework, which has been frequently noted by many investigators (see, for example, Belov⁷⁷). The crystal structure of cuprite Cu_2O ^{277, 278} consists of two interpenetrating electrically neutral anticristobalite $[\text{OCu}_2]$ frameworks (Fig. 11a). When univalent copper is replaced by divalent copper, the $[\text{OCu}_2]$ framework (Fig. 11b) acquires a 2+ charge per tetrahedron. The introduction of additional anions into this framework in order to compensate for the charge leads to the

crystal structures of melanothallite Cu₂OCl₂²⁷⁹ and Cu₂O(SeO₃)₂ (two modifications⁵¹). Similar frameworks with additional anions occur also in the Pd₂OCl₂²⁸² and Pb₂OF₂²⁸¹ structures. The latter structure was examined by Bergerhoff and Paeslack¹⁹ as an oxocentred framework. Pannetier and Lucas²⁸⁶ suggested that the A₂B₂O₆O' pyrochlore structural type, in particular, be considered as one containing the cuprite-like A₂O' (A = Sc, Y, Ln, Bi, Cd, Hg, Pb, *etc.*) framework. The following considerations were adduced in support of this model: firstly, the model makes it possible to consider the characteristic features of the disposition of the O' atom (position 8b), the orbitals of which are sp³-hybridised and the coordination is represented by a regular tetrahedron; secondly, the distortion of the cubic pyrochlore structure may be compared with the observed distortions of the polymorphic modifications of silica SiO₂; thirdly, if position A is occupied by a d¹⁰ atom of type Hg²⁺, Cd²⁺, or Ag⁺, the A–O' bond becomes stronger than the A–O bond and the O' oxygen becomes less mobile. The possibility of describing the pyrochlore structure taking into account the tetrahedral coordination of the O' oxygen has also been pointed out by Belov *et al.*²⁸⁷

F2. The oxocentred [O₂MgAl₃] framework, made up of L1 layers linked *via* corners not participating in the formation of the layer, may be identified in the crystal structure of grandierite.²⁸⁸

F3. The F3 framework is the oxocentred version of the wurtzite structure. Four [OZn₄] tetrahedra converge at each corner of this framework.

F4. The oxocentred [O₆M₁₁] framework has been found in the Bi₄Ag₁₈O₁₂ structure.²⁹² This framework consists of two types of fundamental chains — two-period C5 chain and a four-period chain formed as a result of the corner-linking of tetrahedra. In the structure of this compound, the chains are parallel to the *y* axis. This structure shows that the topological equivalence of all the tetrahedra in the polyion does not as yet ensure their configurational equivalence. In this structure, there are two configurational types of tetrahedra belonging to one topological class.

F5. The oxocentred framework of this type is made up of C7 lanarkite chains linked by the corners of the tetrahedra so that four tetrahedra converge at a single corner.

F6. The F6 framework is made up of L8 layers linked by non-shared corners of the tetrahedra.

F7. The delafossite CuFeO₂ structural type consists of a framework made up of continuous hexagonal layers of [OCuFe₃] tetrahedra linked *via* corners at which the copper atoms are located; within the layer, the linking is *via* the iron atoms.^{295, 296}

F8. The [O₂M₃] framework may be represented as consisting of single type C12 chains.

F9. The type F9 framework is made up of C1 chains linked in the following way: six C1 chains fitted together edgewise form a six-fold chain belonging to the O_nM_{n+2} family. The complex chains linked in this way are linked *via* the corners of the tetrahedra to form a framework dividing space into a series of broad parallel channels with a square cross-section. In the crystal structure of the compound Pb₁₂Ta₉O₂₀F₂₉, infinite columns of [TaO₆] octahedra are accommodated in these channels.³⁰²

F10, F11, F12. The frameworks of these types may be regarded as derivatives of the fluorite CaF₂ structure, which can be represented in its turn as one consisting of [FCa₄] tetrahedra. CeO₂,³⁰³ the structure of which is made up of [OCe₄] tetrahedra, is an analogue of fluorite. The structural type of bixbyite^{304, 305} corresponds to a defective fluorite framework, like the [OIn] framework in the crystal structure of In₆O₆(WO₆).³⁰⁶

F13 (Fig. 12a). The F13 type framework is made up of finite groups J6 linked by nonshared corners. The La₃Ir₃O₁₁ structure³⁰⁷ includes two interpenetrating [O₂La₃] frameworks.

F14 (Fig. 12b). The three-dimensional [O₂M₃] structure, characteristic of the crystal structures of aluminoborates M₂AlBO₅ (M = Co, Cu, Ni), has one-dimensional distorted hexagonal cavities in which the (BO₃) anions are accommodated.³¹⁰

Figure 12. The oxocentred frameworks F13 (a) and F14 (b).

F15. The type F15 framework describes the crystal structure of corundum Al₂O₃ when it is considered taking into account the tetrahedral coordination of the oxygen atoms.³¹¹ It is possible to describe the structure as hexagonal close packing of the oxygen atoms in which octahedral cavities are filled by aluminium atoms. However, the latter are appreciably displaced from the centres of the octahedral cavities, which is due to the tendency of oxygen to acquire the ideal tetrahedral coordination. The structure of corundum is also remarkable because three [OAl₄] tetrahedra are linked together in it *via* a single [Al–Al] edge.

F16. The [O₂M₃] framework consists of C12 single chains linked *via* corners participating in edge-linking within the chain.

F17. Analysis of the Ag₃BiO₄ structure showed that it contains a complex oxocentred framework made up of [OAg₃Bi] tetrahedra of three configurational types.³¹⁵

F18. In the crystal structure of Ag₅BiO₄, there is a complex framework with the ratio O : M = 2 : 3.³¹⁵ This framework is formed as a result of the intertwining of C5 single chains, so that five-petal 'flowers' made up of oxocentred tetrahedra converging at one corner are produced.

F19. The C12 chains in the Ag₅Pb₂O₆ structure are joined together in threes to form columns with a trigonal symmetry and are linked into a framework *via* the corners of the tetrahedra not participating in the linking process.³¹²

F20. In the study of the crystal structure of Ag₂₅Bi₃O₁₈³¹⁶ within the framework of the approach employed, a single common edge [Bi–Ag] between three [OAg₃Bi] tetrahedra was noted. This framework consists of [OAg₃Bi] tetrahedra of two topological types. The type A tetrahedra, linked to form triple edge 'knots', consist of vertical columns with symmetry 3. The type B tetrahedra form groups made up of six tetrahedra converging at one corner. These groups link the vertical 'knotted' columns into a three-dimensional framework.

F21. The F21 framework was identified by Riebe and Keller³¹⁷ in the crystal structure of Pb₁₃O₁₀Br₆. It consists of infinite chains of corner-linked [OPb₄] tetrahedra. These complex chains, arranged crosswise in the structure, are linked *via* the corners of the tetrahedra into a three-dimensional framework.

6. Structures with different oxocentred complexes

In conclusion of the description of the topological types of oxocentred complexes, it is essential to note the existence of the structural type with two different complexes based on [OM₄] tetrahedra. In the crystal structures of the compounds Pb₁₁Si₃O₁₇¹⁵⁵ (Fig. 13), and Pb₁₁Ge₃O₁₇,¹⁵⁶ there are two oxocentred polyions of different dimensionality — the C3 chain and the L19 layer. The [OPb₂] C3 chains are arranged in the (001) plane in the form of a layer (without mutual linking), while the [O₄Pb₇] L19 layer is parallel to this plane. These layers alternate, the orthosilicate and diorthosilicate groups [SiO₄]^{4–} and [Si₂O₇]^{6–} being located in the space between them. The crystal-

Figure 13. The crystal structure of $\text{Pb}_{11}\text{Si}_3\text{O}_{17}$.

chemical formula of the $\text{Pb}_{11}\text{Si}_3\text{O}_{17}$ structure should be written thus:

The presence in this structure of different polycations and poly-anions can be accounted for by their mutual stabilisation. The presence of silicate anions of two types and of different oxocentred structural units weakens the stresses generated.

V. Statistics of the corner and edge-linking $[\text{OM}_4]$ tetrahedra

The ability of oxocentred tetrahedra to be linked together in two different ways (*via* corners and edges) has led to the statistical analysis of different types of linking among the 63 polyions described.

We shall define the sharing index of an element of the tetrahedral group (corner, edge) as the number of tetrahedra between which the element is shared regardless of the method of sharing. The average sharing index of the corners of the tetrahedron $\bar{v}$ will be defined as the average of the sharing indices of its corners. Thus, if v_1, v_2, v_3 , and v_4 are the indices of the corners of the tetrahedron, it follows that

$$\bar{v} = \frac{\sum v_i}{4}, \quad i = 1-4.$$

By analogy with $\bar{v}$, we shall define the average sharing index of the edges of the tetrahedron $\bar{e}$:

$$\bar{e} = \frac{\sum e_i}{6}, \quad i = 1-6,$$

where e_i is the sharing index of the i th edge in the tetrahedron.

The average sharing index of an element [a corner ($\bar{v}$) or an edge ($\bar{e}$)] in the complex will be defined as the arithmetical mean of the sharing indices of the elements of topologically different tetrahedra. Account is taken of the number of tetrahedra of the given topological type in the complex. Thus, if there are two topological types of tetrahedra, A and B , in the complex in proportions of 2 : 1, then the average sharing index of the corners in the polyion is calculated by the formula

$$\bar{v} = \frac{2v_A + v_B}{3},$$

where v_A and v_B are the average sharing indices of the corners in the tetrahedra A and B .

The average sharing indices of the corners and edges in oxocentred complexes are presented in Table 11. For each dimensionality, the values have been averaged with respect to the

	2.437 ^a	1.278 ^a						

^a Average value.

number of polyions. It was found that the values of $\bar{v}$ naturally increase on passing from finite to framework complexes: 1.604 for *I*, 2.437 for *C*, 3.376 for *L*, and 3.886 for *F* (Fig. 14). As regards edge-linking, the values of $\bar{e}$ increase from 1.153 to 1.427 (1.278 for chains) on passing from finite layered complexes, but in the case of frameworks $\bar{e}$ diminishes to 1.328. This shows that edge-linking is most favourable for the linking of the $[\text{OM}_4]$ tetrahedra into a layer, *i.e.* into a two-dimensional structure. For framework complexes, this type of linking is less common apparently because the involvement of a large number of edges in a tetrahedral structure leads to an unduly high concentration of oxygen atoms and a decrease in the stability of the complex. The frameworks are formed preferentially by the corner-linking of the tetrahedra.

The average sharing indices of the corners and edges for oxocentred complexes as a whole, calculated from the data

Figure 14. Dependence of the average sharing indices of the corners (1) and edges (2) on the dimensionality of the oxocentred complexes.

presented in Table 11, proved to be 3.139 and 1.330 respectively. Thus each corner in the oxocentred complexes based on the [OM₄] tetrahedra belongs on average to three tetrahedra and each edge belongs to $1\frac{1}{3}$ tetrahedra.

We may note that the edge-linking of tetrahedra inevitably increases the sharing index of their corners. Thus one (out of six) shared edge of the tetrahedra increases the average sharing index $\bar{v}$ by $1/6$ and, by creating two (out of four) common corners, it increases $\bar{v}$ by 0.5. If the fraction due to edge-linking is subtracted from $\bar{v}$, we obtain the following values of $\bar{v}$ for pure corner-linking: 1.145 for *I*, 1.603 for *C*, 2.098 for *L*, and 2.902 for *F*. This demonstrates yet again the importance of corner-linking in the organisation of oxocentred frameworks.

VI. Rules governing the linking of oxocentred [OM₄] tetrahedra

The description of the established types of cationic complexes based on oxocentred [OM₄] tetrahedra can be usefully completed by the rules according to which individual tetrahedra are linked together into a structural fragment.

1. The [OM₄] tetrahedra can be linked together *via* corners (M) and/or edges (MM).
2. One corner may be shared by more than two oxocentred tetrahedra but as a rule by not more than eight tetrahedra.
3. One edge is usually shared by not more than two oxocentred tetrahedra and in exceptional cases by three tetrahedra.
4. The corner-linking of the [OM₄] tetrahedra is characteristic of polyions of any dimensionality, while edge-linking is primarily characteristic of finite chain and layered structural units. The frameworks are formed mainly as a result of the corner-linking of tetrahedra.

The elucidation of the maximum number of tetrahedra converging at one corner constitutes an interesting problem. If the set of tetrahedra ('petals') converging at one corner is called a 'flower', then the maximum number of 'petals' (8) has been noted in topologically identical 'flowers' produced from the four-fold layer *L*4, the double layer *L*20, and the fluorite-like framework *F*10. The central atoms in these 'petals' are Bi, Ba, and Ce respectively. It was found that, among the oxocentred complexes known to us, there are eleven topologically different 'flowers' in which the number of 'petals' ranges from 5 upwards. Evidently the 'flower' with eight 'petals' constitutes the limit, the addition of yet another tetrahedron to the latter being impossible without the formation of a face-linkage.

The instance where three tetrahedra are edge-linked has not apparently been encountered in the crystal structures of anionic complexes with tetrahedral structural units, but does occur in the oxocentred corundum frameworks [O₃Al₂] and [O₁₈Ag₂₅Bi₃]. In the latter case, the steric interactions of the M corners not involved in the three-fold edge-linking of two neighbouring tetrahedra are weakened as a result of the inclination of the M–M edge relative to the horizontal. If one edge in the tetrahedral complexes may be shared by not more than three tetrahedra, then the distance *R* between nonshared M corners of neighbouring tetrahedra corresponds exactly to the length of the M–M edge. If four tetrahedra are linked *via* a single edge, (without a face-linkage), the distance *R* cannot be greater than or equal to the length of the M–M edge without complete loss of tetrahedral geometry by the linked complexes.

Sn₂O(SO₄), Pb₂O(SO₄) (lanarkite), and Cu₂O(SO₄) (dolerophanite) may serve as examples of compounds in which the chemical composition of the cations influences the topology of the oxocentred polyion. In the first compound, there are finite groups *I*6 having the composition [O₄Sn₈], in lanarkite there are *C*7 [OPb₂] chains, whilst in dolerophanite there are *L*10 [OCu₂] layers.

Analysis of the incidence of various structural units based on [OM₄] tetrahedra shows that complexes made up of configura-

tionally and topologically equivalent tetrahedra are commonest. This is fully consistent with Pauling's rule.

VII. Statistics of the M–O bond lengths and M–O–M bond angles in [OM₄] complexes

It was stated above that, as a consequence of the edge-linking of two tetrahedra, the value of the opposite bond angle diminishes. The average values of the M–O–M bond angles based on the M–M edge shared by two [OM₄] tetrahedra are listed in Table 12 for M = Cu, Sn, Pb, and La.[‡] Evidently the M–O–M angle depends on the size of the atom M. The greater the M–O bond length, the smaller the diminution of the M–O–M angle. It is of interest that the average value <M–O–M> for all the atoms M considered is close to the 'ideal' value of 109.5°. The decrease in one or several M–O–M angles, induced by the presence of a common edge in the tetrahedron, is compensated by the increase in the bond angles based on the nonshared edges.

Table 12. The average M–O–M bond angles in [OM₄] complexes.

Bond	M–O / Å	M–O–M / deg ^a		M–O–M / deg ^b	
		I	II	I	II
Cu–O	1.94	93.5 (91.4–95.9)	12	109.6	72
Sn–O	2.26	101.8 (98.1–104.4)	3	109.0	6
Pb–O	2.33	103.1 (94.4, 98.2–109.2)	83	109.5	120
La–O	2.36	104.4 (101.6–107.6) average value	32	109.4	48
				109.5	246

Note. The following designations have been adopted: I — average values of the angles, the limits of the variation of the angle in the structure being indicated in brackets; II — number of values taken into account.

^a Values for the angle based on the common edge. ^b Values for all the angles in the tetrahedron.

Another fundamental feature of [OM₄] complexes is the possibility of the linking at one atom M of several [OM₄] tetrahedra. Table 13 presents the average M–O bond lengths for M corners of different connectedness in complexes with M = Cu or Pb. The M–O bond lengths for a nonshared M corner and for a M corner linking two [OM₄] tetrahedra do not actually differ. When the M–M edge is shared and the number of tetrahedra converging at an atom M increases, the M–O bond length also increases. When a corner is shared by three tetrahedra so that one tetrahedron is edge-linked to a second tetrahedron and corner-linked to a third tetrahedron (Table 13), the M–O bond length for M = Pb increases sharply (2.35 Å). When four [OPb₄] tetrahedra are linked *via* a single edge so that a tetrahedron is edge-linked to two others and corner-linked to the fourth, the bond length also increases (2.40 Å). We may note that in the last case we did not take into account in the calculation of the M–O bond length the type *L*12 layered [OPb] complexes in which all the corners of the [OPb₄] tetrahedron are shared in this way. For these complexes, the M–O bond length is on average 2.34 Å (24 bonds were taken into account) (the limits of their variation were 2.31–2.36 Å), *i.e.* smaller by 0.06 Å than for the analogous corners in the remaining complexes. Overall, one may say that an increase in the number of [OM₄] tetrahedra converging at one M corner induces an increase in the M–O bond length.

[‡] Only data for [OM₄] complexes with a single cation M were used for the analysis.

Table 13. The M–O bond lengths for M corners with different connectedness in [OM₄] tetrahedra.

Corner of tetrahedron ^a	Number of tetrahedra converging at one M corner	Number of compounds taken into account	Number of bonds taken into account	(M–O) _{av} /Å	Limits of variation of M–O /Å
Cu–O					
	1	15	43	1.92	1.90–1.95
	2	13	38	1.92	1.86–2.00
	2	10	36	1.94	1.81–2.00
	4	2	8	1.96	1.91–2.02
Pb–O					
	1	5	11	2.26	2.18–2.32
	2	5	7	2.25	2.20–2.34
	2	11	38	2.27	2.23–2.32
	3	5	15	2.27	2.19–2.34
	3	3	19	2.35	2.34–2.37
	4	8	33	2.40	2.39–2.41

^a The filled circle designates the corner where two tetrahedra are linked and the numeral 2 at the filled circle indicates that a further two tetrahedra are attached to the given tetrahedron *via* a corner; the semibold edge signifies that yet another tetrahedron has been attached to the given tetrahedron *via* an edge.

VIII. Conclusion

The topological types of the structural units based on oxocentred [OM₄] tetrahedra have been described in the present review. In all, 63 different [OM₄] polyions have been identified; 6 finite, 16 chain, 20 layered, and 21 framework polyions. Since the aim of the present review was the discovery and systematic topological treatment of the oxocentred complexes, we have hardly touched upon the analysis of the geometrical and energetic characteristics of specific crystal structures and on their relation with the type of organisation of the [OM₄] tetrahedra to form a complex. Only the relation between the physical properties of the compounds containing [OM₄] groups and the characteristic features of the linking of these tetrahedra into a complex has been illustrated (for georgbokiite). The studies initiated will be continued by a detailed analysis of the lengths and angles in various types of oxocentred complexes, the study of the correlation of the structures of the compounds described from the standpoint of the crystal chemistry of oxocentred complexes with the properties of these compounds, the discovery of a relation between the traditional and proposed methods for the description of structures, and questions concerning the existence of oxocentred complexes in noncrystalline media, for example in gases.

In writing the review, the authors widely employed the structural data bank Inorganic Crystal Structure Database (ICSD) supplied free of charge to the Department of Crystallography of the St. Petersburg University by Prof. H Bradaczek of the Free University of Berlin. The authors are grateful to Prof. P M Zorkii for valuable advice in connection with the discussion of the review. The review has been written with the financial support of the Russian Foundation for Basic Research (Project

No. 96-05-65576) and also of the 'Central Europe' section of the Russian Academy of Natural Sciences.

VI. Conclusion	174

Abstract. The problems in the use of rhenium compounds and supported mono-, bi-, and poly-metallic rhenium-containing catalysts for carrying out reactions involving the metathesis of alkenes and unsaturated functional compounds, the hydrogenation and dehydrogenation of hydrocarbons, the conversion of hydrocarbons and their industrial mixtures, and the hydrogenation of fractions comprising carboxylic acids and the products of the hydroformylation of synthetic aliphatic acid esters are examined. The characteristic features of the behaviour of platinum–rhenium/alumina catalysts under reforming conditions are described. The specificity of the action of rhenium heptasulfide in the hydrogenation reactions of condensed N-containing aromatic compounds and in the reductive C-alkylation of indoloisoquinoline by alcohols is noted. The bibliography includes 251 references.

I. Introduction

Rhenium, discovered in 1925,^{1,2} occupies a special place in the family of rare elements. In its various compounds, rhenium can exhibit oxidation states ranging from -1 to $+7$. The commonest oxidation state of $+7$ is characteristic of compounds such as rhenic acid and its salts or rhenium heptoxide.

Supported metallic and metal oxide catalysts are of great importance in heterogeneous catalysis. One of the requirements which must be met by a supported metal is its resistance to recrystallisation during the catalytic process. It is therefore useful to introduce into a catalyst a metal with a high melting point, which promotes an increase in the resistance of the catalyst to ageing. Such a metal may be rhenium, the melting point of which is 3170°C . It is also noteworthy that the high solubility of ammonium perrhenate, rhenium heptoxide, and rhenium pentacarbonyl in water facilitates the preparation of rhenium catalysts by the impregnation method.

A series of patents, the authors of which described the ability of rhenium to catalyse a wide variety of chemical reactions,

appeared soon after the discovery of rhenium.³ The relevant data, published up to 1984, have been presented in a monograph.⁴

Reactions involving the hydrogenation of ethene to ethane and the preparation of methane from CO and hydrogen on rhenium-containing copper catalysts were investigated at the beginning of the 1930s.^{5,6} The introduction of rhenium greatly increased their activity.

It was shown in 1935 that rhenium catalysts exhibit a higher activity in the dehydrogenation of alcohols than platinum, nickel, zinc, and copper.⁷ An extensive investigation of the catalytic properties of rhenium and of its compounds with oxygen, sulfur, and selenium under the conditions of the liquid-phase hydrogenation of more than 100 organic compounds at an elevated pressure in a static system was carried out in the 1950s.^{8,9} In contrast to the usual catalysts, rhenium oxides are capable of reducing carboxylic acids to the corresponding alcohols (ranging from ethyl to undecyl alcohol) and carboxylic acid amides to amines. Rhenium sulfides have a superior activity to that of the familiar catalysts for the dehydrogenation of alcohols to aldehydes and ketones, such as platinum, nickel, zinc, or copper.

The hydrogenation of hydrocarbons on supported rhenium–carbon catalysts was achieved in 1958.^{10,11} The $\text{Re}/\text{Al}_2\text{O}_3$ catalysts showed a high activity in the conversion of C_5 – C_7 hydrocarbons in the reforming process at elevated temperatures and hydrogen pressures.¹² At the same time, at atmospheric pressure the $\text{Re}/\text{Al}_2\text{O}_3$ and $\text{Re}/\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ catalysts proved to be appreciably less active than platinum/alumina catalysts.¹³

The promoting effect of rhenium introduced into a palladium/alumina catalyst was observed in 1962.¹⁴ Bimetallic (1% Re, 1% Pd) catalyst supported on Al_2O_3 and $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ exhibited a high activity in the reactions of C_6 hydrocarbons and in the reforming of petrol fractions,^{14,15} ensuring an increase in their octane number as a result of the increase in the content of aromatic and paraffinic isohydrocarbons.

The disproportionation reaction of alkenes (metathesis), which makes it possible to convert an individual alkene into two others, one of which has a higher and the other a smaller molecular mass than the initial hydrocarbon, was discovered in 1964.¹⁶ Thus ethene and butenes were obtained from propene on $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ at 25 – 100°C . Rhenium behaves in this reaction similarly to transition metals such as tungsten and molybdenum. Since 1966, the disproportionation reaction has begun to be used in industry (the ‘triolefin’ process). Information about the development of this process has been reported.¹⁷

A catalyst containing 0.01% – 3.0% of Pt and 0.01% – 5.0% of Re on alumina, which is active in the dehydrogenation of

Uspekhi Khimii 67 (2) 175–196 (1998); translated by A K Grzybowski

cyclohexane to benzene and in the reforming of the petrol fraction, was patented in the USA in 1968.¹⁸ The first factory in which an effective and stable bimetallic catalyst R-16, containing platinum and rhenium supported on an oxide, began to operate in May, 1968.¹⁹ The R-16, R-19, R-22, E-500, and E-501 bimetallic catalysts were introduced into industry by the American Companies Universal Oil Products, Chevron Research Co., and Engelhard Minerals and Chemicals Co., while the process itself came to be called 'rheniforming'.

In our country, the Lenneftkhim Scientific-Industrial Conglomerate (SIC) developed polymetallic rhenium-catalysts of the KR series for the reforming process.^{20, 21} The first industrial batch of the KR-104 catalyst (containing 0.36% of Pt and 0.20% of Re) was prepared in 1976. The properties of improved compositions of the KR-108 and KR-110 catalysts were not inferior to the best world-class specimens.

About 75%–80% of the mined rhenium has been used for the production of various alloys, which are widely employed in electrical engineering and in electronics, aviation, rocket, and space technology. Petroleum-processing undertakings became major consumers of rhenium in 1969. They began to use it in combination with platinum as the catalyst for the reforming process.⁴ As early as 1978, 92% of rhenium was consumed in the USA for the production of bimetallic Pt–Re catalysts for the conversion of petrol fractions into high-octane petrols. The importance of the employment of rhenium as the reforming catalyst has been noted at the plenary session of the International Symposium on Rhenium and Rhenium Alloys in Orlando (USA),²² which was devoted to the 70th anniversary of the discovery of this element.

The development of studies on rhenium-containing catalysts used in petroleum processing and in basic and fine chemical synthesis during recent years is analysed in the present review.

II. Catalytic properties of rhenium oxide/alumina systems

The metathesis of alkenes reduces to the exchange of alkylidene fragments between alkene molecules:

Valuable compounds, which may be used in perfumery, agriculture, and other fields, are formed in the metathesis of alkenes with functional groups.^{23–26}

Catalysts containing rhenium, molybdenum, and tungsten ($\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$, $\text{MoO}_3/\text{Al}_2\text{O}_3$, and $\text{WO}_3/\text{Al}_2\text{O}_3$) are the most active in the metathesis of alkenes. The rhenium/alumina catalyst merits special attention because it exhibits a high activity and selectivity even at room temperature and atmospheric pressure. The metathesis of propene in the presence of $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ occurs at 50 °C, whereas on $\text{MoO}_3/\text{Al}_2\text{O}_3$ and $\text{WO}_3/\text{Al}_2\text{O}_3$ the corresponding temperatures are 207 and 402 °C respectively.²⁷ Catalysts containing rhenium with a lower valence, for example $\text{Re}_2(\text{CO})_{10}/\text{Al}_2\text{O}_3$, are also active in this reaction.

Nowadays investigators have concentrated attention on the improvement of rhenium/alumina catalysts. Their activity in the metathesis of functional alkenes can be increased by introducing small amounts of promoting additives, for example allyltin,^{25, 26, 28} which is known as the cocatalyst in homogeneous catalytic systems. Such additives increase the effectiveness also of heterogeneous systems, initiating the formation of a metallocarbene in accordance with the scheme

One of the stages of the widely known carbene chain mechanism of metathesis²⁹ involves the formation of a metallocyclobutane:

Rhenium/alumina catalysts containing < 5% of Re_2O_7 exhibit a slight activity in the metathesis of alkenes.^{30, 31} A necessary reaction stage on these catalysts is the reduction of the carbene formed. Propene and higher alkenes are capable of reducing Re_2O_7 on aluminium oxide even at room temperature.³²

1. The metathesis of olefins and unsaturated functional compounds

The properties of the $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$ catalyst containing 3 mass % of Re_2O_7 have been investigated at room temperature in relation to the model reaction involving the disproportionation of propene to ethene and but-2-ene in a microcatalytic flow system.³³ Its activity, exceeding that of $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$, was further increased on introduction of tetramethyl- and tetraethyl-tin as a result of the participation of the Brønsted acid centres of the support in the process. The removal of surface OH groups reduced the activity of the catalyst. SnR_4 probably stabilises the active complex, which is especially important in the metathesis of functional alkenes.³⁴ SnR_4 -promoted $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$, which is more active than the catalyst containing the oxides of other metals, for example MoO_3 , WO_3 , or V_2O_5 , is used as the catalyst in this process.³⁵

The new catalytic system $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3 \cdot \text{B}_2\text{O}_3$ has been tested in relation to the model reaction involving the metathesis of methyl oleate — a typical functional alkene:³⁶

The catalysts were prepared by impregnation and partial drying at 110 °C. The amount of B_2O_3 introduced was 5%, 10%, 15%, and 20%. The catalyst containing 3 mass % of Re_2O_7 deposited on Al_2O_3 to which 15 mass % of B_2O_3 had been added exhibited the highest activity. The optimum catalyst activation temperature was 477 °C. For a reaction time longer than 1.5 h, a higher degree of conversion was achieved on this catalyst than on 18% $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$. The added B_2O_3 interacts with the acid centres of Al_2O_3 and weakens the linkages between rhenium particles and aluminium oxide. When the content of deposited B_2O_3 is in excess of the optimum value, the amount of rhenium reduced on the surface diminishes, which lowers the activity of the catalyst. The high activity and selectivity of the low-percentage $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3 \cdot \text{B}_2\text{O}_3$ catalyst at room temperature has been explained by the presence on the surface of strong Brønsted acid centres.

The catalytic activity may be altered by employing various cocatalysts. The promoting effect diminishes in the series³⁶

The most active metathesis catalysts — $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$, $\text{Re}_2\text{O}_7/\text{SiO}_2 \cdot \text{Al}_2\text{O}_3$, $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3 \cdot \text{B}_2\text{O}_3$, and $\text{M}_x\text{O}_y/\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ ($\text{M}_x\text{O}_y = \text{MoO}_3$, WO_3 , or V_2O_5) — were investigated by the temperature-programmed reduction method and thermal analysis.³⁷ The rhenium particles in the $\text{Re}_2\text{O}_7/\text{SiO}_2 \cdot \text{Al}_2\text{O}_3$ and $\text{M}_x\text{O}_y/\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ specimens exhibit redox properties. The presence of V_2O_5 , WO_3 , or MoO_3 diminishes the thermal stability of the rhenium particles in the $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ catalysts in the following sequence:

The unequal activities of these catalysts in the metathesis of alkenes and functional alkenes cannot be accounted for either by the different capacities of the rhenium particles for reduction, or

by possible steric hindrance in the formation of the rhenium–cyclobutane complex, or by a change in the thermal stability of the rhenium particles.³⁶

The activity of the $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ catalysts of the metathesis of propene increases on raising the heat treatment temperature during their preparation.³⁸ The optimum heat treatment temperature depends on the Re_2O_7 content and is in the range 827–927 °C. For a low Re_2O_7 content, the maximum heat treatment temperature is required. The much higher activity of the catalyst containing 3 mass % of Re_2O_7 has been attributed to the redistribution of the ReO_4 groups on the Al_2O_3 surface, which has been confirmed by spectroscopic data. The catalyst heat-treated at a high temperature can be regenerated after deactivation by heat treatment at the usual temperature of 550 °C without appreciable loss of the initial activity.

The strength of the Brønsted and Lewis acid centres increases with increase in the amount of Re_2O_7 supported on Al_2O_3 .³⁹ The impregnation of a catalyst having a low rhenium content (6 mass % of Re_2O_7) with hydrochloric acid promotes the manifestation of Brønsted acidity. With increase in the Re_2O_7 content, the Brønsted acidity of the aluminosilicate gradually increases, while the Lewis acidity passes through a maximum. The activity of the $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$, $\text{M}_x\text{O}_y/\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ ($\text{M}_x\text{O}_y = \text{V}_2\text{O}_5, \text{MoO}_3, \text{or WO}_3$), and $\text{Re}_2\text{O}_7/\text{SiO}_2 \cdot \text{Al}_2\text{O}_3$ catalysts of the metathesis of alkenes is directly correlated with their Brønsted acidity, in contrast to the Lewis acidity. Thus, in order to increase the activity of low-percentage rhenium catalysts in the metathesis of alkenes, it is necessary to increase their Brønsted acidity by introducing various modifying agents.³⁹

After heat treatment, a monolayer containing Re^{7+} ions is formed on the surfaces of the $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ catalysts.⁴⁰ For a low content of rhenium, the latter enters mainly into monomeric tetrahedrally coordinated ReO_4^+ ions, while in the presence of a high rhenium content $\text{Re}-\text{O}-\text{Re}$ linkages are formed. After interaction with the reactants, the rhenium is reduced and carbene complexes active in the metathesis are formed. The fraction of active rhenium ions is less than 1%. In the absence of cocatalysts, $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ altogether fails to exhibit an activity in the metathesis of alkenes with polar functional groups. The modification of the support, for example the introduction of SiO_2 into Al_2O_3 , increases the activity of the catalyst. The addition of a third metal oxide, for example MoO_3 , WO_3 , or V_2O_5 , increases the turnover number of the reaction for a low content of deposited rhenium. The addition of a tetraalkyltin not only increases the activity of the catalyst in the metathesis of alkenes but also makes it possible to achieve the metathesis of alkenes containing functional groups. The increase in the activity of low-percentage catalysts after their preliminary treatment with hydrogen at 500 °C and subsequent chemisorption of oxygen at 77 °C has been investigated by the temperature-programmed reduction, XPES, laser Raman spectroscopic, and EPR methods.⁴⁰ After such treatment, the signal due to adsorbed O_2^- ions was observed in the spectra. The active centres are formed in accordance with the scheme

It has been suggested that the carbene complex is formed during metathesis as a result of the generation of acid vacancies, which is followed by reactions of the type

Catalysts such as $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ are highly polar and therefore react with polar compounds, for example with alkenes, as well as water, which may be present in the reactants and is a catalytic poison. Molecules with polar groups are capable of blocking the free centres necessary for metathesis, for example

Other possible causes of deactivation have also been discussed.⁴⁰

The possibility of regenerating the 12% $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ catalysts, promoted by tetrabutyltin with the ratios $\text{Sn}:\text{Re} = 1:4, 2:4$, and $3:4$, and also of 3% $\text{Re}_2\text{O}_7/\text{SiO}_2 \cdot \text{Al}_2\text{O}_3$ promoted by tetraethyltin has been investigated. The metathesis of propene was carried out on these catalysts in a microcatalytic flow reactor at 20 and 80 °C and a pressure of 1.5 atm.⁴¹ The activity of the deactivated catalyst could be partially restored by increasing the content of the promoting agent and also by carrying out regeneration in a stream of oxygen with subsequent repeated addition of the promoting agent. Nevertheless, there was a partial loss of activity after each regeneration cycle. A study of the catalyst surface by scanning electron microscopy and X-ray diffraction after the temperature-programmed reduction showed that the loss of activity is associated with the formation on the surface of the oxide SnO_2 , which interacts with Re_2O_7 .

The study of the reactivity of alk-1-enes in metathesis under industrial conditions over the 12% $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ catalyst in the liquid phase⁴² showed that the rate of reaction diminishes with increase in the length of the hydrocarbon chain (from hex-1-ene to dec-1-ene). It has been suggested that this is associated with the fact that the rate of reaction is determined by the desorption of the product. Alkenes with a long chain and a symmetrical disposition of the inner double bond are formed in the metathesis of higher alkenes (oct-1-ene, dec-1-ene):

The reaction proceeds in accordance with the mechanism

Four products — ethene, tetradec-7-ene, hexadec-7-ene, and octadec-9-ene — are formed in the joint metathesis of oct-1-ene and dec-1-ene.⁴²

The kinetic description of the metathesis of oct-1-ene on $\text{Re}_2\text{O}_7/\gamma\text{-Al}_2\text{O}_3$ in the liquid phase was based on the metallocarbene mechanism.⁴³ The rate-limiting stage is either the internal conversion of the carbene complex or the desorption of the product. It was not possible to make a final choice on the basis of the experimental data. The proposed mathematical model makes it possible to describe the deactivation of the catalyst as a function of the duration and temperature of the reaction. The apparent activation energy for metathesis is 22.5 kJ mol⁻¹ and that for the deactivation of the catalyst is 12.0 kJ mol⁻¹. The constancy of the degree of conversion under the conditions of the deactivation of the catalyst can be maintained by gradually increasing the reaction temperature. Calculation within the framework of the mathematical model showed⁴³ that the temperature-programmed regime makes it possible to convert a much larger amount of oct-1-ene in each catalytic cycle.

The $\text{Re}_2\text{O}_7/\text{Al}_2\text{O}_3$ catalyst modified by the introduction of B_2O_3 into the support has been used for the metathesis of methyl oleate.⁴⁴ The concentration of Lewis and Brønsted acid centres

was determined spectroscopically during the reaction and also during the heat treatment of the support and the catalyst. When $\leq 5\%$ of B_2O_3 is introduced, the Al_2O_3 and B_2O_3 phases are present simultaneously in the specimen, each containing surface hydroxy-groups. For a higher B_2O_3 content, the hydroxy-groups of aluminium oxide are fully coated by boron oxide. The number of hydroxy-groups linked to boron diminishes with increase in the B_2O_3 content as a result of the formation of boron-containing linear polymers. When Re_2O_7 is supported on B_2O_3 -free Al_2O_3 , the ReO_4 groups react in the first place with the Lewis acid centres. If the B_2O_3 content exceeds 3%, then the surface hydroxy-groups are also substituted by the ReO_4 groups, which increases the catalytic activity. The ReO_4 groups which have reacted with the Lewis acid centres of the boronated support substitute the hydroxy-groups of the aluminium oxide during heat treatment. The hydroxy-groups of boron oxide are substituted only after heat treatment during ≥ 2 h at $550^\circ C$. For a B_2O_3 content greater than 10%, the reaction of the hydroxy-groups of boron with ReO_4 competes with the condensation reaction of two neighbouring hydroxy-groups. If it is supposed that the ReO_4 group substituted for the OH group of the support is a precursor of the active centre, then the increase in the activity of Re_2O_7 as a result of the introduction of B_2O_3 into Al_2O_3 can be explained either by the restoration of the linkages between the strong Lewis acid centres and ReO_4 or the formation of new surface hydroxy-groups, which serve as the acid centres.⁴⁴

The metathesis of cyclopropane hydrocarbons with different structures, namely n-butylcyclopropane, bicyclo[4.1.0]heptane (norcarane), and 1-methyl-1-phenylcyclopropane, at $20^\circ C$ has been investigated on a 20% $Re_2O_7/\gamma-Al_2O_3$ catalyst prepared by impregnating the support with a saturated NH_4ReO_4 solution containing tetrabutyltin.⁴⁵ The reactions were carried out under an argon atmosphere, using hexane or octane as the solvent. Ethene was present in the gas phase in all cases. The liquid phase contained $\sim 1\%$ of cyclohexene — the product of the elimination of carbene in the metathesis of norcarane:

When the reaction involved bicyclo[3.1.0]hexane, ethene was also present among the gaseous products, but the liquid product did not contain cyclopentene. This has been explained by the greater tendency of cyclopentene to polymerise. C_6 – C_{12} monoalkenes, including undec-5-ene (55 mass %), dodec-6-ene (35 mass %), dec-5-ene (5 mass %), nonene, octene, heptene, and hexene (~ 1 mass % each), were formed from n-butylcyclopropane. The degree of conversion of 1-methyl-1-phenylcyclopropane into ethene was 40%.

The scheme proposed for this process⁴⁶ combines the carbene chain mechanism of metathesis and the mechanism involving the formation of cyclopropane compounds:

where A and B are alkenes, C are cyclopropane compounds, X and X' are catalytic centres, and Y and Y' are intermediate complexes.

In the reaction involving 1-methyl-1-phenylcyclopropane, X probably represents a catalytic centre for metathesis, arising in the activation of the rhenium/alumina catalyst by tetrabutyltin.⁴⁵ The interaction with a substrate molecule, accompanied by the isomerisation of the initial hydrocarbon, is necessary for the transformation of X into the X' centre:

The isomerisation products may be *cis*- and *trans*-2-phenylbut-2-enes, which apparently polymerise. Carbene may also be eliminated from the initial molecule on the centre produced, while the elimination product (α -methylstyrene) also isomerises. Thus the cyclopropane hydrocarbons isomerise on the rhenium/alumina catalyst and eliminate carbene with evolution of ethene, while the compounds formed polymerise or undergo metathesis.⁴⁵

It has been established by the XPES method that the activity of the Re_2O_7/Al_2O_3 catalysts is determined by the reduction of Re^{7+} to give an intermediate oxidation state, which begins at 200 – $300^\circ C$. The reduction of rhenium in Re_2O_7/Al_2O_3 is known to be more difficult than in Re_2O_7/SiO_2 .^{47, 48} The state of rhenium in a fresh unpromoted 15% Re_2O_7/Al_2O_3 metathesis catalyst and in a specimen promoted with phenylcyclopropane has also been investigated by the XPES method.⁴⁹ The rhenium in the unpromoted catalyst exists in the form of ReO_4 tetrahedra linked to the support *via* one oxygen atom. The promotion of the catalyst with phenylcyclopropane has been explained⁴⁹ by the appearance on the surface of fragments with a rhenium–carbon bond in which the atomic ratio $Re:C = 1:1$. Such fragments may be carbene complexes containing the $Re=C$ double bond. The composition includes $> 90\%$ of the total number of rhenium atoms in the catalyst. The high concentration of these complexes on the surface of the specimen ensures its high catalytic activity in the metathesis of hex-1-ene, which has been confirmed experimentally.

2. Metathesis of functional alkenes

The metathesis of alkenes containing functional groups has been achieved on promoted and unpromoted rhenium/alumina catalysts.^{50–57} The experiments were performed at atmospheric pressure in a liquid-phase static system with stirring, ensuring that the reaction occurred in the kinetic region. The metathesis of allyl chloride, the allyl ether of allylcarbinol, allylbenzene, and diallyl ether⁵⁰ was achieved on catalysts supported on alumina and containing 0.5%–1.5% of Re with 5% or 10% of Mo or 1.5% of Re with 5% or 10% of V,⁵⁰ in which the molar ratios of the initial substances and Re_2O_7 were 560–3000 at temperatures of 22 and $55^\circ C$. Tetrabutyltin was used to promote the catalyst. The conversion of the initial substances into the corresponding bifunctional or cyclic unsaturated compounds (2,5-dihydrofuran and 2,3-dihydro- α -pyran) was 15%–20% (after 30 min) for a selectivity of 93%–95%. The catalyst containing 0.5 mass %–1.5 mass % of Re_2O_7 and 5 mass %–10 mass % of MoO_3 or V_2O_5 proved to be optimal.

The structure of the alkenyl fragment in an alkenyl allyl ether influences the selectivity and rate of its metathesis.⁵¹ The reactions of allyl-, methylallyl-, and phenylallyl-carbinols and the allyl ethers of allyl-, methyl-, dimethyl-, and phenyl-carbinols have been investigated on a rhenium/alumina catalyst promoted with tetrabutyltin (15 mass % of Re_2O_7 , 5 mass % of SnR_4 , and 80 mass % of $\gamma-Al_2O_3$) at temperatures ranging from 0 to $80^\circ C$ and for molar ratios of the initial substance and Re_2O_7 between 60 and 460. The reactivity of the ethers investigated depends on the structure of the alkenyl fragment. The presence of substituents at the carbon atom directly adjoining the oxygen atom retards the intramolecular metathesis. In the temperature range 20 – $80^\circ C$, the metathesis was characterised by a low activation energy (of the order of 10 – 13 kJ mol^{–1}).

The unsaturated cyclic ethers are formed in accordance with the scheme

$R^1, R^2 = H, CH_3, C_6H_5$.

The intramolecular reaction predominates in the metathesis of ethers with two double bonds.⁵¹

If the hydroxy-group of *o*-allylphenol is converted beforehand into an ether group, it is possible to achieve a high rate of metathesis of the corresponding compound. The metathesis of *o*-(allyl)propoxybenzene with formation of 1,4-bis(*o*-propoxyphenyl)but-2-ene has been carried out on a rhenium/alumina catalyst promoted with tetrabutyltin at 22 °C in solvents (hexane or benzene).⁵² The selectivity reached 94%–96%. It is suggested that the metathesis proceeds *via* the intermolecular mechanism.

Aromatic alkenyl compounds can be arranged in the following sequence in terms of their reactivity in the above reaction: allylbenzene > *o*-(allyl)propoxybenzene > styrene.

The influence of the preliminary treatment of the support on the activity of a catalyst containing Re₂O₇ (15 mass %), (C₄H₉)₄Sn (5 mass %), and γ-Al₂O₃ (80 mass %) has been investigated in relation to the metathesis of *n*-hex-1-ene, allyl chloride, and diallyl ether.⁵³ Treatment with water and a 0.1 N aqueous solution of hydrochloric acid increased the rate of metathesis of *n*-hex-1-ene and allyl chloride. This can be explained by the increase in the number of active centres of the catalyst and the increase in the acidity of the support, since an increase in acidity, especially Brønsted acidity, promotes the metathesis of unsaturated compounds with a functional group.³⁵ On the other hand, treatment of the support with ammonium hydroxide diminished the rate of metathesis.

When the support of the Re₂O₇/γ-Al₂O₃ catalyst was treated with trialkyl borate, which decomposes to boron trioxide, the rate of metathesis of *n*-hex-1-ene and diallyl ether decreased by a factor of 2.5–3 compared with the initial untreated specimen.⁵⁴ Thus the Re₂O₇ content can be increased from 10 mass %–15 mass % to 1 mass %–2.5 mass % without diminishing the activity of the catalyst. The maximum activity is attained for 2 mass %–4 mass % of Re₂O₇ and 1 mass %–5.0 mass % of triethyl borate. The structure of the substituent in the trialkyl borate does not affect the rate of metathesis. The degree of conversion of *n*-hex-1-ene on the catalyst containing 10% of (C₂H₅O)₃B, 5% of Re₂O₇, 1.5% of (C₄H₉)₄Sn, and 83.5% of Al₂O₃ reached 86.9% after 5 min, whereas the degree of conversion on the catalyst untreated with tetrabutyltin was 32.0% after 20 min. The rhenium/alumina–boron oxide catalyst can operate in the temperature range 0–48 °C.

The metathesis of allyl chloride and allylacetone on a similar rhenium/alumina–boron oxide catalyst, prepared using the ratio Re₂O₇:Sn(C₄H₉)₄ = 3 proceeds *via* an intermolecular mechanism in accordance with the equation⁵⁵

The metathesis products are dec-5-ene-2,9-dione and 1,4-dichlorobut-2-ene. As in the metathesis of *n*-hex-1-ene and diallyl ether, the Re₂O₇ content in the catalyst can be reduced from 15 mass % to 2.5 mass %–7.5 mass % as a result of the treatment without diminishing the activity and selectivity. However, these active and selective catalysts of the metathesis of unsaturated compounds with functional groups are not sufficiently stable.^{54,55} One of the causes of instability is the ability of the functional group to compete with the C=C bond for the active centres of the catalyst, *i.e.* the deactivation of the catalyst by the reactant.⁴⁰ The

introduction of variable-valence metals (Mo or V) into the rhenium/alumina catalyst makes it possible to activate it and reduce the rhenium oxide content.⁵⁶ In a modification of a rhenium/alumina catalyst, both untreated and treated with SnBu₄, with constant-valence metals (Na⁺, K⁺, Mg²⁺), its activity in the metathesis of *n*-hex-1-ene falls and the degree of conversion diminishes from 10.9% to 2.6%. The addition of Pd increases the activity of the catalyst containing 5 mass % of Re₂O₇, but its selectivity decreases from 93%–98% to 68%–76%. Preliminary treatment of the rhenium/alumina catalyst with triethyl borate^{54,55} increases its activity.

The stabilising effect of aluminium oxide on rhenium apparently weakens with increase in the degree of its coverage by boron, which agrees with the data of another publication.³⁶ Treatment of the support with hydrogen chloride and triethyl borate increases the activity of rhenium/alumina catalysts in the joint metathesis of 1,4-dichlorobut-2-ene and 2,3-dimethylbut-2-ene,⁵⁶ so that the Re₂O₇ content could be reduced by a factor of two — from 15% to 7.5%. The reaction, the product of which is 4-chloro-2-methylbut-2-ene, proceeds in accordance with the equation

The activity of rhenium/alumina metathesis catalysts depend on the conditions of their activation (duration and temperature of the heat treatment, the medium, *etc.*).⁵⁷

The highest activity of the catalyst containing 5 mass % of Re₂O₇ is reached after its treatment at 620–640 °C. The productivity of the catalyst in the metathesis of allyl chloride increases by a factor of 3. After the activation of the rhenium/alumina catalyst containing 15 mass % of Re₂O₇, the degree of conversion of both *n*-hex-1-ene and allyl chloride at 580 °C increases. The activity and productivity of the catalyst can also be increased by increasing the activation time to 13 h. The rate of metathesis of *n*-hex-1-ene then increases by a factor of ~1.5, while the productivity of the catalyst in the metathesis of allyl chloride increases by a factor of 2–3. A further increase in the activation time to 20 h does not alter the activity appreciably. Yet another way of increasing the activity is the deposition of ammonium perrhenate on aluminium oxide with an intermediate heat treatment at elevated temperatures.⁵⁷

III. Catalytic properties of other rhenium compounds

Metallic rhenium is known to be in most cases inferior in its hydrogenating activity to group VIII metals,⁴ but some of its compounds exhibit a high hydrogenating capacity.

1. Hydrogenation of organic compounds

Rhenocene hydride (η⁵-C₅H₅)₂ReH manifested a high activity in the hydrogenation reactions of cyclohexene, benzene, ethyl acetate, and 36% acetic acid.^{58,59}

At a temperature of 150 °C and a hydrogen pressure P_{H₂} = 100 atm, the degree of conversion of cyclohexene on a catalyst containing 0.8% of Re relative to the mass of the hydrocarbon attained 73% after 1 h in an autoclave. An increase in temperature to 180 °C made it possible to lower the amount of catalyst and the reaction time by a factor of 2 and to obtain cyclohexane in a quantitative yield. Rhenocene hydride was much more active than Re₂S₇ and even ReO₃.⁵⁹ When rhenium trioxide was used, the amount of rhenium had to be increased by a factor of 3, the reaction time had to be prolonged by a factor of 8, and the pressure had to be raised by a factor of 2 in order to attain the same activity.

Benzene was hydrogenated fully on rhenocene hydride at 180 °C and $P_{H_2} = 100$ atm for a reaction time $\tau = 30$ min and for a rhenium content of 1.0% relative to the mass of benzene. In this reaction too, the catalyst was much more active than ReO_3 .

The degree of conversion of ethyl acetate (EA) in the hydrogenation reaction at 200 °C, $P_{H_2} = 100$ atm, and $\tau = 3$ h reached 60%. Under these conditions, ~49% of EtOH accumulated in the catalytic reaction mixture. Under comparable conditions, the overall degree of conversion of ethyl acetate into EtOH on Re_2O_7 was lower by a factor of 2. It is noteworthy that platinum and palladium sulfides did not exhibit a hydrogenating activity. A high activity of Re_2O_7 in the ethyl acetate reduction reaction has been observed:⁶⁰ the yield of EtOH reached 82% at 175 °C, $P_{H_2} = 210$ atm, and $\tau = 5$ h. However, up to 6% of AcOH was formed under these conditions. The reaction proceeds in accordance with the equation

The appreciable activity of rhenocene hydride and a fairly high selectivity of the reaction have been noted in the hydrogenation of 36% acetic acid.⁵⁹ At 230 °C, $P_{H_2} = 120$ atm and $\tau = 3$ h for a Re content of 1% and for an overall degree of conversion of ~86%, the yield of EtOH was ~52%. Ethyl acetate was formed together with EtOH. Rhenocene hydride decomposed under the conditions indicated. The metallic phase formed exhibited an increased activity, since it was more highly disperse than bulk rhenium. The following activity series has been established for the rhenocene hydride-based heterometallic catalysts in the hydrogenation of acetic acid:

Rhenium pentacarbonyl $Re_2(CO)_{10}$ also exhibits a high hydrogenating activity.^{61–63} Cyclohexene was fully hydrogenated on this catalyst after 15 min at 230 °C and $P_{H_2} = 50$ atm and for a Re content of 1% relative to the mass of the substrate. The hydrogenation of benzene required a higher hydrogen pressure (100 atm). In terms of its activity in the cyclohexene and benzene hydrogenation reactions $Re_2(CO)_{10}$ is superior to rhenium oxides⁶⁰ and is slightly inferior to rhenocene hydride.⁵⁹ However, it decomposes under the conditions indicated above with formation of a metallic phase exhibiting a higher activity than bulk rhenium. The lower activity of rhenium pentacarbonyl compared with rhenocene hydride can be explained by the fact that part of

the metal remains bound in the form of the carbonyl. IR spectroscopic study showed that, under the conditions of the hydrogenation of both cyclohexene and benzene, rhenium carbonyl reacts with the components of the reaction mixture. One cannot apparently rule out the possibility that not rhenium carbonyl itself but its unstable complex is catalytically active. The complex differs from the four known rhenium carbonyl hydrides — the monomeric $HRe(CO)_5$ and the cluster compounds $H_3Re_3(CO)_{12}$, $H_4Re_4(CO)_{12}$ and $HRe_3(CO)_{14}$. It also follows from the analysis of the IR spectra that hydrogenation of benzene entails the formation of a metal carbonyl complex different from that in the hydrogenation of cyclohexene.⁶²

Rhenium oxides with the perovskite structure and having the general formula $Ba_2Bi^{III}_{1/3}\square_{2/3}Re^{VII}O_6$, where $B^{III} = Y$ or Sm , or $Ba_3LaZnRe^{VII}\square O_{12}$ (the symbol $\square$ denotes a vacancy in the cationic lattice) also possess hydrogenating properties.⁶⁴ The catalysts were synthesised under solid-phase reaction conditions using a known method^{65,66} and were identified by X-ray phase analysis. The hydrogenation of ethyl acetate on these catalysts was carried out in a static system (in an autoclave) at 280 °C and $P_{H_2} = 100$ atm and for $\tau = 3$ h. The $Ba_2Y_{1/3}\square_{2/3}ReO_6$ catalysts showed the highest activity: the overall degree of conversion of ethyl acetate was 35% for a selectivity in the formation of ethanol of 83.4%. After the catalyst worked for 3 h, the reaction products were removed and a fresh portion of ethyl acetate was introduced. After this, the degree of conversion of ethyl acetate into ethanol in the course of 3 h of the reaction increased from 29.2% to 43.2%. Yet another repetition of the same procedure led to a further increase in the degree of conversion from 43.2% to 47.9% (selectivity 86%). The increase in activity may be associated with the activation of the specimen in the course of the experiment by virtue of the reduction of $Re(VII)$. The transition of rhenium to lower oxidation states in the course of the reaction was indicated by a change in the colour of the specimen from yellow or yellow-green to black. Ethyl acetate is reduced on Re_2O_7 even at 230 °C, whereas on the oxides described this requires 280 °C, other conditions being equal. It may be that the hydrogenating activity is determined by the presence in the catalyst not only of rhenium but also of other cations. One may postulate that the hydrogenating activity can be partly accounted for also by the formation of reduced rhenium in a highly disperse state under the experimental conditions.

The hydrogenation of benzene and ethyl acetate has also been achieved on rhenium oxides with the perovskite structure having

Table 1. Hydrogenation of benzene^a and ethyl acetate^b on rhenium oxides with the perovskite structure⁶⁷ and certain other rhenium catalysts.

Catalyst	Yield of C_6H_{12} obtained from benzene (%) ^a	Hydrogenation of ethyl acetate ^b

Reaction conditions: ^a $T = 200$ °C, $P_{H_2} = 100$ atm, $\tau = 2$ h, 1% of Re; ^b $T = 280$ °C, $P_{H_2} = 100$ atm, $\tau = 3$ h, 2% of Re; ^c $T = 240$ °C, $P_{H_2} = 100$ atm, $\tau = 4$ h, 3% of Re (data of Broadbent and Bartley⁶⁰); ^d data of Ryashentseva *et al.*⁶⁴

the general formula $A_4BRe_2O_{12}$, where $A = Ba$ or Sr and $B = Co$ or Ni .⁶⁷ The results obtained are presented in Table 1.

For a rhenium content of 1% relative to benzene, the yield of cyclohexane increases from 18% to 78% as the barium content falls.⁶⁴ Evidently the presence of the large barium ions (ionic radius 1.36 Å) in the catalyst structure hinders the hydrogenation of benzene. Among barium-containing catalysts, the $Ba_{0.4}Sr_{3.6}CoRe_2O_{12}$ specimen had the highest activity under the reaction conditions (200 °C, $P_{H_2} = 90-100$ atm, Re content 1%) and the yield of cyclohexane, amounting to 78%, remained unchanged for 6 h. In the succeeding 16 h, the yield of cyclohexane fell to 35%. The $Sr_{4.0}CoRe_2O_{12}$ and $Sr_{4.0}NiRe_2O_{12}$ catalysts proved to be the most active in the hydrogenation of benzene. Benzene was virtually fully hydrogenated on these catalysts, containing 1% of rhenium, at $T = 200-300$ °C and $P_{H_2} = 100-120$ atm and for $\tau = 2-3$ h. The catalytic activity increased with increase in the ionisation potential of the cations A ($Ba < Sr$) and B ($Ca < Ni < Co$).

The state of the surfaces of the $Sr_4CoRe_2O_{12}$ and $Ba_4CaRe_2O_{12}$ specimens before and after catalysis has been investigated by the method of thermovacuum electrical conductivity curves (TVE). The specimens exhibited semiconducting properties. After the experiment on a strontium specimen, exhibiting a high hydrogenating activity, changes were observed in the surface possibly due to its reduction. However, the specimen remained a semiconductor, *i.e.* there was no reduction to the metallic or pseudometallic state. The low specific surface of the specimen ($1.5\text{ m}^2\text{ g}^{-1}$) and the presence on the surface of $\sim 12\%$ of reduced rhenium, relative to its overall content, after catalysis (according to XPS data) made it possible to suggest that metallic rhenium is largely located not on the surface but in the bulk of the catalyst and in a highly disperse form. In order to create active hydrogenation catalysts with the perovskite structure, it is apparently necessary to reduce the rhenium on the surface. It has been demonstrated by the XPS method that Re^{4+} and Re^{6+} ions are present in the $Sr_4CoRe_2O_{12}$ and $Sr_4NiRe_2O_{12}$ catalysts and may enter into the composition of the active centres.

The perovskites $Ba_2Sr_2CoRe_2O_{12}$, $Ba_{1.2}Sr_{2.8}CoRe_2O_{12}$, containing 2% of Re, and $Sr_4NiRe_2O_{12}$ proved to be less active and selective than Re_2S_7 and $Ba_2Y_{1/3}O_{2/3}ReO_6$ in the hydrogenation of ethyl acetate ($T = 280$ °C, $P_{H_2} = 100$ atm, $\tau = 3$ h) (Table 1). Consequently, rhenium oxides with the perovskite structure exhibit different activities in the reactions involving the hydrogenation of the benzene ring and the carbonyl group. The hydrogenation of the latter requires more severe conditions and is more sensitive to the cationic environment of the rhenium oxides.⁶⁴

2. Selective hydrogenation of N-containing condensed aromatic compounds

Rhenium heptasulfide exhibits a specific activity in the hydrogenation and reductive *N*-alkylation by C_1-C_4 alcohols of pyridine, picoline, and lutidines.⁶⁸⁻⁷¹ It is an effective catalyst of the selective hydrogenation of aryl-substituted pyridines, isoquinolines, indeno[2,1*a*]pyridines, benzo- and dibenzo-indolizines (the reaction does not involve the benzene ring), and dihydroxyanthracenes. In the presence of alcohols, *N*-alkylation takes place on Re_2S_7 simultaneously with hydrogenation. The results have been surveyed in a review.⁷²

New compounds, which are of interest from the standpoint of their biological activity, have been obtained by the hydrogenation of compounds of the indolizine series⁷³ on Re_2S_7 ($T = 250$ °C, $P_{H_2} = 140$ atm, $\tau = 4$ h). The following compounds were obtained: 2,8-diphenylperhydroindolizine from 2,8-diphenylindolizine, 1,2,3,4-tetrahydrobenzoindolizine and 1,2,3,4,4a,5-hexahydrobenzo[2,3]indolizine from benzo[2,3]indolizine, 5,6-dihydrobenzo[2,3;5,6]indolizine and 5,6,6a,7-tetrahydrodibenzo[2,3;5,6]indolizine from dibenzo[2,3;5,6]indolizine, 5,6-dihydrodi-

benzo[2,3;7,8]indolizine and 1-benzylidene-1,2-dihydroisoquinoline from dibenzo[2,3;7,8]indolizine, 4-(4-aminophenyl)-6-ethyl-2,3-dimethylpyridine and 4-(4-aminophenyl)-6-ethyl-2,3-dimethylpiperidine from 6-ethyl-2,3-dimethyl-4-(4-nitrophenyl)pyridine, and 1,2-dihydro-, 1,4-dihydro-, and 1,2,3,4-tetrahydroisoquinolines from 1-benzylisoquinoline.

The following reactions merit special attention:

The pyridine ring in benzoindolizines is hydrogenated more readily than the pyrrole ring. The presence of phenyl substituents in the indolizine does not prevent its complete reduction, while alkyl substituents hinder the hydrogenation reaction. The annelation of the pyrrole and pyridine rings of indolizine diminishes the degree of its hydrogenation. The nitro-group is reduced to the amino-group.

The hydrogenation of bromo-substituted 6- and 7-alkyl-2-(4'-bromophenyl)indolizines in the presence of Re_2S_7 has also been investigated.⁷⁴

$R^1 = Et, R^2 = H; R^1 = H, R^2 = Me; R^1 = H, R^2 = Et;$
 $R^1 = H, R^2 = Pr; R^1 = H, R^2 = C_5H_{11}.$

Under the conditions selected ($T = 260$ °C, $P_{H_2} = 140$ atm, $\tau = 4$ h), a mixture of *trans*- and *cis*-isomers, with respect to the fusion between the pyrrolidine and piperidine rings, of bromine-free 6- and 7-alkyl-2-phenylindolizines is formed. The 6- and 7-alkyl-2-phenylindolizines isolated are characterised by a *trans*-fusion involving the pyridine ring in the 'chair' conformation and

the pyrrolidine ring in the 'envelope' conformation. The nitrogen atom is located outside the plane passing through the four carbon atoms of the pyrrolidine ring. The ratio of the *cis*- and *trans*-isomers of the compounds obtained is 1 : 1.4.

The hydrogenation of indolo[2,1-*a*]isoquinoline **1** in protic solvents (alcohols) has been achieved in the presence of Re_2S_7 ($T = 250^\circ\text{C}$, $P_{\text{H}_2} = 140\text{ atm}$, $\tau = 4\text{ h}$).⁷⁵ The *N*-alkylation of the initial compound observed previously⁷² is ruled out owing to the presence in the molecule of a bridgehead nitrogen atom. Alkylation at the C_{11} atom takes place instead:⁷⁵

$\text{R} = \text{H}$ (**3**), CH_3 (**4**).

Methanol, ethanol, 1-butanol, and isopropyl alcohol were used as the alkylating agents. A mixture of compounds **2**, **3**, and **4** is formed in the first two instances in a high overall yield. The hydrogenation in 1-butanol leads to the formation of only the 11-butyl derivative **5** in 81% yield. If the dihydro-derivative **2** is subjected to reductive alkylation by 1-butanol, it is converted into 11-*n*-butyl-5,6-dihydroindoloisoquinoline **5** in a high yield. In the presence of Re_2S_7 , the isoquinoline **1** is initially hydrogenated under the conditions indicated above to dihydroisoquinoline **2**, which is subsequently alkylated with formation of the 11-alkyl derivatives of compound **5**. The alkylation proceeds *via* an electronic substitution mechanism, the yield of products increasing with decrease in the acidity of the alcohol.

5,5a,10a,11-Tetrahydro-10*H*-indeno[1,2-*b*]quinoline has been obtained by the hydrogenation of 10*H*-indeno[1,2-*b*]quinoline ($T = 250^\circ\text{C}$, $P_{\text{H}_2} = 140\text{ atm}$, $\tau = 4\text{ h}$) in benzene in the presence of Re_2S_7 . Its structure was confirmed by mass-spectrometric and IR spectroscopic data, electronic absorption spectra, and ^{13}C and ^1H NMR spectra:⁷⁶

The *cis*-fusion between the indane and tetrahydroquinoline fragments as well as the axial orientation of the proton at the C(5a) atom and the equatorial orientation of the proton at the C(10a) atom have been confirmed by molecular mechanical methods using the PC MODEL program.

The possibility of hydrogenating an exocyclic double bond of the fulvene type on Re_2S_7 has been investigated in relation to 9-(4-pyridylmethylene)fluorene, 9-(4-pyridylmethylene)-4-azafluorene, and 9-benzylidene-4-azafluorene.⁷⁷ The hydrogenation of 1-fulvene ($T = 250^\circ\text{C}$, $P_{\text{H}_2} = 130\text{ atm}$, $\tau = 4\text{ h}$) proceeds to the extent of 90%. Three compounds — 9-(4-pyridylmethyl)fluorene **6**, 9-(4-piperidylmethyl)fluorene **7**, and fluorene (the hydrogenolysis product) — were isolated from the products in 33%, 16%, and 10% yields respectively. The hydrogenation involves preferentially the exocyclic double bond of the fulvene fragment with formation of 9-azafluorenyl(pyridyl)methanes.

IV. Catalytic properties of rhenium and its compounds on supports

1. Hydrogenation of benzene and ethyl acetate

The dependence of the properties of supported rhenium-containing catalysts on the nature of the support (α -, θ -, and γ - Al_2O_3 , SiO_2 , $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, MgO), the concentration of the metal (0.3 mass %, 0.4 mass %, 2.0 mass %, and 3.7 mass %) and the nature of the initial rhenium compounds [HReO_4 , NH_4ReO_4 , KReO_4 , and $\text{Ba}(\text{ReO}_4)_2$] has been investigated.⁷⁸ The degree of dispersion of rhenium, measured by the hydrogen thermal desorption method, was compared with the activities of the supported catalyst in the hydrogenation of benzene (flow system, $T = 200^\circ\text{C}$, $P_{\text{H}_2} = 27.3\text{ atm}$, $P_{\text{C}_6\text{H}_6} = 2.7\text{ atm}$). Before the start of the experiments, the catalysts were reduced in a stream of purified hydrogen (500°C , space velocity $\nu_{\text{vol}} = 15\,000\text{ h}^{-1}$, $\tau = 4\text{ h}$). High-temperature reversible chemisorption of H_2 was observed on the fresh samples. Its overall extent depended on the nature of the support and the concentration and nature of the initial rhenium compounds taken for the preparation of the catalysts. The reversible chemisorption occurred only after the attainment of high degrees of reduction of rhenium. On the other hand, if rhenium was not fully converted into the metallic state, hydrogen was absorbed at temperatures corresponding to the additional reduction temperature. The degree of chemisorption was independent of the specific surface of the support: the maximum chemisorption was observed on Re/MgO ($S = 94\text{ m}^2\text{ g}^{-1}$) and the minimum chemisorption was noted on $\text{Re/Al}_2\text{O}_3 \cdot \text{SiO}_2$ ($S = 370\text{ m}^2\text{ g}^{-1}$). When the support was impregnated with perrhenic acid, the maximum chemisorption of H_2 was observed on silica gel and the minimum occurred on γ - Al_2O_3 . On γ - Al_2O_3 , the maximum chemisorption of hydrogen was attained when NH_4ReO_4 was employed, whereas on SiO_2 the minimum chemisorption was observed on the sample impregnated with KReO_4 . The chemisorption on the catalyst obtained by impregnating aluminium oxide with a solution of the salt NH_4ReO_4 appreciably increased with increase in the concentration of rhenium from 0.3 mass % – 0.4 mass % to 2.0 mass % – 3.7 mass %, while its further increase to 7% was accompanied by a less significant rise in chemisorption. The activity of the reduced rhenium depended on the strength of bonding of the chemisorbed hydrogen and was not correlated with the specific surface of the metal. Two regions of the thermal desorption of hydrogen were observed: at 70 – 400°C (form I) and at 500 – 800°C (form II). In order to estimate the degree of dispersion of rhenium, it is useful to employ the quantities characterising the desorption of form I.

The activities of the $\text{Re}/\gamma\text{-Al}_2\text{O}_3$ catalysts containing 10.4 mass % and 1.04 mass % of rhenium, subjected to a preliminary treatment with hydrogen at 550–800 °C (hydrogenation of benzene) or at 80–300 °C (hydrogenolysis of benzene) did not change or decrease with decrease in temperature.⁷⁹ A low concentration and high degree of dispersion of rhenium are unfavourable for both reactions, particularly for the hydrogenation of benzene. The activity of the low-percentage catalyst with an average rhenium particle size $l = 1.7\text{--}2.6$ nm was several times lower in both reactions than the activity of the high-percentage catalyst with $l = 3.4\text{--}4.4$ nm and rhenium powder with $l = 166$ nm.⁸⁰ The activity of the high-percentage catalysts in the hydrogenation reaction did not change when the average particle size was increased from 3.4 to 4.4 nm. The results obtained indicate a low activity of very small metallic particles and the presence of highly specific active centres for the hydrogenolysis of benzene. The negative influence of the decrease in the particle size of the metal on its activity in the hydrogenation of benzene has also been observed on palladium,⁸¹ ruthenium,⁸² rhodium,⁸³ and nickel.^{84,85} This may be associated with the enhancement of the role of the hydrogenolysis of the hydrocarbons.⁸⁶

The catalytic properties of the 5% $\text{Re}/\gamma\text{-Al}_2\text{O}_3$ system have been investigated in relation to the model ethyl acetate hydrogenation reaction.⁸⁷ The principal reaction product is ethanol, while diethyl ether, hydrocarbons, and water are formed as side products. A change in temperature from 190 to 250 °C, in the hydrogen pressure from 5 to 60 atm, and in the H_2 :EA molar ratio from 5 to 20 in the flow system after the catalyst had worked for 40 h did not affect its stationary activity. An increase in temperature from 250 to 270 °C did not entail an increase in the degree of conversion of ethyl acetate. The maximum degree of conversion of ethyl acetate into ethanol at 250 °C reached 40.9% for a diethyl ether content of 5.3%. It was shown that hydrocarbons are the products of the hydrogenolysis and not the dehydration of ethanol. Diethyl ether is formed from ethanol at a lower rate than from ethyl acetate. Under optimum conditions ($T = 230$ °C, $P_{\text{H}_2} = 60$ atm, H_2 :EA = 5, and $v_{\text{mass}} = 0.7$ h⁻¹), the degree of conversion of ethyl acetate into ethanol is 49%, while the selectivity is 83.5%.

The nature of the support (θ -, δ -, and α - Al_2O_3 or SiO_2) and the reduction conditions (reduction by the H_2 + EA mixture at 230 °C or by hydrogen at 500 °C) influence the hydrogenating properties of the supported rhenium catalyst in the conversion of ethyl acetate into ethanol⁸⁸ at 230 °C, $P_{\text{H}_2} = 30$ atm H_2 :EA = 5, and $v_{\text{mass}} = 0.7$ h⁻¹. The following activity series was obtained: $\text{Re}/\theta\text{-Al}_2\text{O}_3 > \text{Re}/\alpha\text{-Al}_2\text{O}_3 > \text{Re}/\delta\text{-Al}_2\text{O}_3 > \text{Re}/\text{SiO}_2 \approx \text{Re}/\gamma\text{-Al}_2\text{O}_3$. The first catalyst of this series was three times more active than the last. Regardless of the reduction procedure, the maximum selectivity in the hydrogenation of ethyl acetate to ethanol is attained on the $\text{Re}/\alpha\text{-Al}_2\text{O}_3$ sample. Diethyl ether is formed in measurable amounts only on the $\text{Re}/\gamma\text{-Al}_2\text{O}_3$ and $\text{Re}/\theta\text{-Al}_2\text{O}_3$ catalysts. Its formation is appreciably promoted by treatment with hydrogen. On $\text{Re}/\gamma\text{-Al}_2\text{O}_3$, the yield of diethyl ether is 1.5 times greater than that of ethanol. After preliminary treatment with the H_2 + EA mixture at 230 °C, $\text{C}_1\text{--C}_4$ hydrocarbons are formed on all the catalysts (the maximum and minimum yields are on $\text{Re}/\gamma\text{-Al}_2\text{O}_3$ and $\text{Re}/\alpha\text{-Al}_2\text{O}_3$ respectively). Preliminary treatment with hydrogen at 500 °C induces a sharp decrease in the degree of conversion of ethyl acetate into hydrocarbons on the $\text{Re}/\gamma\text{-Al}_2\text{O}_3$ and $\text{Re}/\theta\text{-Al}_2\text{O}_3$ catalysts. On the remaining samples, the yield of hydrocarbons as well as the selectivity in their formation change insignificantly. Rhenium(VII), supported on SiO_2 and $\theta\text{-Al}_2\text{O}_3$ (but not on $\gamma\text{-Al}_2\text{O}_3$), is fully reduced by hydrogen at 500 °C. The degree of dispersion of the metal diminishes in the sequence $\text{Re}/\gamma\text{-Al}_2\text{O}_3 > \text{Re}/\theta\text{-Al}_2\text{O}_3 > \text{Re}/\text{SiO}_2$. The temperature of the maximum desorption of hydrogen (200–300 °C), which can participate in the hydro-

genation process, diminishes in the same sequence.⁷⁸ The maximum activity of the $\text{Re}/\theta\text{-Al}_2\text{O}_3$ catalyst can be explained by the higher degree of dispersion of rhenium in it compared with Re/SiO_2 and the higher oxidation state of the metal compared with $\text{Re}/\gamma\text{-Al}_2\text{O}_3$. The activity of the catalyst after preliminary treatment with the reaction mixture is as a rule higher than after treatment with hydrogen. This is manifested particularly strikingly in the case of the $\text{Re}/\gamma\text{-Al}_2\text{O}_3$ catalyst, in which rhenium interacts strongly with the support. Hence it is reduced with greater difficulty.⁴⁷ The H_2 + EA mixture probably reduces the supported Re(VII) more effectively at 230 °C than pure hydrogen at 500 °C.⁸⁷ The kinetic data obtained suggest the possibility of the formation of diethyl ether directly from ethyl acetate.

Diethyl ether is formed with participation of the acid centres on the $\text{Re}/\gamma\text{-Al}_2\text{O}_3$ surface, on which C_2 hydrocarbons may also be formed to some extent. The absence of acid centres from the surfaces of the supports in the Re/SiO_2 and $\text{Re}/\alpha\text{-Al}_2\text{O}_3$ catalysts promotes the manifestation of a higher selectivity by the latter but a lower hydrogenating activity than in the case of $\text{Re}/\theta\text{-Al}_2\text{O}_3$.^{88,89}

In order to discover the relation between the catalytic properties and the state of rhenium in the specimens containing 0.5% of Re on γ -, θ -, and α - Al_2O_3 , the kinetic data for the hydrogenation of ethyl acetate ($T = 230$ °C, $P_{\text{H}_2} = 30$ atm, H_2 :EA = 5) were compared with the results of an IR spectroscopic study of the chemisorption of carbon monoxide.⁹⁰ Comparison of data obtained before and after the reaction made it possible to postulate the existence of metallic rhenium in two main states on the catalyst surface — Re_x^0 and Re_y^0 , differing in the degree of dispersion, the nature of the interaction with the support, and susceptibility to saturation by coke. On Re_x^0 , ethyl acetate is converted into ethanol and hydrocarbons, whilst on Re_y^0 it is converted into ethanol and diethyl ether. On the $\gamma\text{-Al}_2\text{O}_3$ -based samples, the ionic form Re^{n+} is also present and on it ethyl acetate is hydrogenated solely to diethyl ether. The ratio of the different states of rhenium determines their activity and selectivity in the ethyl acetate conversion reactions. The ideas described concerning the nature of the activity of rhenium/alumina catalysts for the hydrogenation of ethyl acetate are to some extent simplified. However, the observed features may prove useful for the development of more selective rhenium catalysts for the hydrogenation of carboxylic acid esters.

The addition of basic oxides — lithium or lanthanide oxides — affects the properties of the 2% $\text{Re}/\gamma\text{-Al}_2\text{O}_3$ catalyst in the hydrogenation of ethyl acetate.⁹¹ Such additives are known to diminish the acid functions of the support in the $\text{Pt}/\gamma\text{-Al}_2\text{O}_3$ and $\text{Pd}/\gamma\text{-Al}_2\text{O}_3$ catalysts for the dehydrogenation of alkanes and cycloalkanes.^{92,93} The addition of 1% of lithium to the rhenium/alumina catalyst suppresses the Lewis centres of the $\gamma\text{-Al}_2\text{O}_3$ support, as a result of which the selectivity in the hydrogenation of ethyl acetate increases to 78%–81% and diethyl ether is hardly formed. However, the hydrogenating activity of the catalyst and its stability diminish simultaneously (Table 2).

The introduction of between 5% and 7% of the lanthanide oxide is accompanied by an appreciable decrease in the hydrogenating activity of the rhenium/alumina catalyst, while the yield of diethyl ether falls from 10.4% to 1.7% and 0.6% respectively. The selectivity in the formation of ethanol diminishes under these conditions. The maximum hydrogenating activity and selectivity was shown by the catalyst containing 2 mass % of Re, 7 mass % of a lanthanide oxide, and 91 mass % of $\gamma\text{-Al}_2\text{O}_3$; for an overall degree of conversion of 31.2%, the activity was 81.4% in the formation of ethanol, 0.6% in the formation of diethyl ether, and 16% in the formation of hydrocarbons. The formation of hydrocarbons is apparently unrelated to the acid centres of $\gamma\text{-Al}_2\text{O}_3$.

Table 2. The influence of lithium and lanthanide oxide additives on the properties of the 2% Re/ γ -Al₂O₃ catalysts in the hydrogenation of ethyl acetate ($T = 230^\circ\text{C}$, $P_{\text{H}_2} = 30\text{ atm}$, $v_{\text{mass}} = 0.72\text{ h}^{-1}$, $\text{H}_2:\text{EA} = 5$, $\tau = 4\text{ h}$).⁹¹

2. Hydrogenation of halogen-containing compounds

Rhenium catalysts have come to be used recently for the hydrogenation of halogen-containing compounds. A large number of various elements have been mentioned in the patent literature as catalysts for these processes: platinum group noble metals, Group VII and VIII elements, including rhenium, and certain Group II, IV, and V elements deposited on carbon. CHCl₃ and CH₂Cl₂ may be obtained from carbon tetrachloride in a flow system, the overall degree of conversion of CCl₄ amounting to 80%.^{94,95} A catalyst containing $\geq 15\%$ of Cr on TiO₂ and impregnated with $\geq 1\%$ of Pt, Pd, Rh, Ru and Os, Re, or Ir has been used for the hydrogenation of halogen-containing hydrocarbons.⁹⁶ In the presence of metallic catalysts (Re, Co, Ni, Ru, Pd, Os, Ir, or Pt on carbon), fluoro-hydrocarbons are hydrogenated.⁹⁷ In particular, CF₃CHClF and CF₃CH₂F have been obtained from CF₃CCl₂F with selectivities of 11% and 87% respectively for an overall degree of conversion of 52.9%. There are data concerning the use of rhenium for the synthesis of 4-alkyl-2-fluorocyclohexanols.⁹⁸

3. Hydrogenation of mixtures of oxygen-containing compounds

Higher alcohols are widely used in the manufacture of lubricating oils, high-quality detergents, plasticisers, etc. The direct hydrogenation of the C₁₀–C₁₆ fraction of synthetic aliphatic acids to the corresponding alcohols at $T = 325\text{--}375^\circ\text{C}$ and $P_{\text{H}_2} = 300\text{--}500\text{ atm}$ on copper–chromium and zinc–chromium catalysts is therefore of special interest. However, the rhenium sulfide/alumina catalyst containing 1.5% of rhenium has a higher hydrogenating activity than industrial oxide catalysts.⁹⁹ At 250°C , $P_{\text{H}_2} = 250\text{ atm}$, and $v = 0.13\text{ h}^{-1}$, the degree of conversion of the C₁₀–C₁₆ fraction of synthetic aliphatic acids into the corresponding higher alcohols amounted to $\sim 80\%$ even after the rhenium catalysts had been operating for 750 h. The hydrogenating capacity of oxide catalysts falls to this level already after they have been used for 60 h. Rhenium sulfide/alumina catalysts containing 5%–8% of rhenium are not only more stable but also exhibit a higher productivity than the oxide catalysts.

The results obtained using supported rhenium catalysts in the hydrogenation reactions of the products of the hydroformylation of propene,^{63,100} mainly with formation of an aldehyde, merit attention. Depending on the reaction conditions, isobutyraldehyde as well as (in amounts ranging from 10% to 20%) ethers, esters, acetals, aldols, and other oxygen-containing compounds are formed as side products. The hydrogenation of butyraldehyde is usually carried out at $T = 120\text{--}320^\circ\text{C}$ and $P_{\text{H}_2} = 250\text{--}300\text{ atm}$ in the presence of catalysts containing Co, W, Ni, Zr, Mo, Cu, and other elements in the metallic, oxide, or sulfide forms. Supported nickel and cobalt catalysts developed by various foreign companies contain at least 30%–60% of the metal. The hydrogenation of the hydroformylation products does not consist merely in the reduction of the carbonyl group to a hydroxy-group but, since the reaction

plays the main role, effective catalysts and optimum conditions are selected primarily for this reaction. When it was carried out on the hydrogen sulfide-treated 7% Re/ γ -Al₂O₃ catalyst at $T = 120^\circ\text{C}$, $P_{\text{H}_2} = 300\text{ atm}$, and $v = 4\text{ h}^{-1}$, the content of butyraldehyde in the reaction mixture gradually fell from 37% to 2.3%, while the productivity of the process was fairly high.¹⁰⁰ An increase in temperature to $140\text{--}160^\circ\text{C}$ made it possible to attain a high degree of hydrogenation (98.7%) and high space velocities, up to 8.0 h^{-1} . The highest productivity ($3219\text{ g litre}^{-1}\text{ h}^{-1}$) was achieved at 180°C and $v = 10.5\text{ h}^{-1}$. The residual content of butyraldehyde was 0.5% and there were virtually no oxygen-containing compounds in the catalyst apart from butyl alcohol. The catalyst retained its high hydrogenating activity throughout five months. At $T = 120\text{--}160^\circ\text{C}$, $P_{\text{H}_2} = 300\text{ atm}$, and $v = 4\text{--}5\text{ h}^{-1}$, the degree of conversion of butyraldehyde into butyl alcohol remained at the level of 99%–100%.

The hydrogen sulfide-treated bimetallic catalyst (5% Ni, 1% Re)/Al₂O₃ also possesses a high activity. The introduction of rhenium into the known nickel hydrogenation catalysts makes it possible to reduce its content by a factor of 6–10.

In terms of the degree of hydrogenation of the butyl esters of synthetic C₇–C₉ aliphatic acids, the (2% Re, 7% Ln)/ γ -Al₂O₃ catalyst is superior to the industrial copper–chromium catalyst GIPKh-105 (flow-type apparatus, $T = 210\text{--}218^\circ\text{C}$, $v = 0.40\text{--}0.45\text{ h}^{-1}$, $P_{\text{H}_2} = 300\text{ atm}$, rate of consumption of hydrogen 900 litre h^{-1}).⁹¹ On the rhenium catalyst, the esters are quantitatively converted into alcohols and the degree of conversion hardly changes throughout 450 h of continuous operation. This catalyst also exhibits a higher productivity ($306\text{--}427\text{ g litre}^{-1}\text{ h}^{-1}$) than the GIPKh-105 industrial hydrogenation catalyst ($210\text{--}259\text{ g litre}^{-1}\text{ h}^{-1}$).

4. Hydrogenation of other organic compounds

The hydrogenation of compounds of the type RCOO(CH₂)_nCOOH to RCOO(CH₂)_nCH₂OH (R = alkyl, $n = 8\text{--}16$)¹⁰¹ and of carboxylic acids to aromatic alcohols is carried out in an autoclave in the presence of ruthenium or Re/Al₂O₃ catalysts.¹⁰² On catalysts containing Ru, Rh, Pd, Pt, or Re deposited on cobalt, it is possible to hydrogenate carboxylic acids or esters.¹⁰³ Lactones are obtained by hydrogenating dicarboxylic acids (saturated and unsaturated) and anhydrides in the presence of a Ni catalyst, supported on zirconium oxide or carbon, to which Group VIII noble metals and rhenium have been added.^{104–106} Thus γ -butyrolactone has been obtained in 84.9% yield in the hydrogenation of succinic anhydride in the presence of tetrahydrofuran on the (10% Ni, 0.9% Pd, 0.6% Re)/ZrO₂ catalyst (specific surface $98\text{ m}^2\text{ g}^{-1}$) in an autoclave at $P_{\text{H}_2} = 50\text{ atm}$ and $T = 200^\circ\text{C}$ for $\tau = 3\text{ h}$.^{104–106}

Vinyloxirane is hydrogenated to 1,2-epoxybutane in the presence of a catalyst containing Pd and Re on BaSO₄, ZrO₂, or TiO₂.¹⁰⁷

Supported Group VIII metals and various rhenium compounds [Bu₄ReO₄, Re₂(CO)₁₀, Bu₄NReO₄, etc.] are used to obtain butane-1,4-diol by hydrogenating γ -butyrolactone, maleic or succinic anhydride, or the corresponding acids.^{108–111} For example, butane-1,4-diol has been obtained in 66.0% yield from the lactone in an autoclave in the presence of zeolites of the alkaline type or water on Pd/C and Bu₄NReO₄ at $T = 180^\circ\text{C}$ and $P_{\text{H}_2} = 50$ atm for $\tau = 16$ h.¹⁰⁸ The reaction is carried out in a solution of NEt₃ in dimethoxyethane. In the absence of NEt₃, the yield is 43.2%. An even higher yield (72.5%) is attained in the presence of Pd/C and Re₂(CO)₁₀ in ethanol at $T = 180^\circ\text{C}$ and $P_{\text{H}_2} = 100$ atm for $\tau = 16$ h.¹⁰⁹ Butane-1,4-diol is formed in 70.0% yield from succinic anhydride or succinic acid in the presence of Ru/C, Re₂(CO)₁₀, and a 3 Å zeolite or water in dimethoxyethane ($T = 160^\circ\text{C}$ and $P_{\text{H}_2} = 100$ atm, $\tau = 16$ h). The reaction does not take place in the absence of the zeolite.¹¹⁰ Butane-1,4-diol has been obtained in 88.8% yield from succinic or maleic anhydride under similar conditions on Pt/C and Bu₄NReO₄ in Me₃COH at 180°C .¹¹¹

Tetrahydrofuran has been obtained with a selectivity of 90%–92% by hydrogenating maleic anhydride ($T = 250^\circ\text{C}$, $P_{\text{H}_2} = 140$ atm) on the (Co, Pd, Re)/C catalyst.¹¹² On a catalyst containing rhenium, Group VIII metals, and acid components (inorganic or organic acids), deposited on a metal oxide or a zeolite, tetrahydrofuran may be obtained by hydrogenating not only maleic anhydride but also succinic anhydride or γ -butyrolactone.¹¹³

The synthesis of γ -butyrolactone from water and 2,3- or 2,5-dihydrofurans in the presence or absence of hydrogen on hydrogenation catalysts, including a rhenium catalyst, at an elevated temperature has been described in a patent.¹¹⁴ In the hydrogenation of 2,5-dihydrofuran in the presence of water on the 6% Re/TiO₂ catalyst ($T = 154^\circ\text{C}$, $P_{\text{H}_2} = 120$ atm), a mixture containing 85% of butane-1,4-diol, 6% of tetrahydrofuran, 3% of γ -butyrolactone, 1% of 4-hydroxybutanol, and 5% of butanol is formed in one stage with a 100% degree of conversion.¹¹⁵

The reduction of oleic acid to octadec-9-en-1-ol (*cis*- and *trans*-isomers) has been achieved with an appreciable yield in an organic solvent on a catalyst containing Re and Sn as well as Al, Si, or Ti compounds.^{116,117} The reaction was carried out in an autoclave at $T = 250^\circ\text{C}$ and $P_{\text{H}_2} = 56$ atm.

A new bimetallic rhenium–tin catalyst for the reduction of oleic acid to octadec-9-en-1-ol in a satisfactory yield under mild conditions has been proposed.¹¹⁸ The catalyst was obtained by depositing NH₄ReO₄ and SnCl₂ on Al₂O₃. Its activity and selectivity depended on the type of support, the nature of the initial compound, the molar ratio of the metals, and the conditions in the activation and the reaction itself.

The hydrogenation of neocarboxylic acids leads to the formation of neoalcohols. For example, the corresponding alcohol has been obtained¹¹⁹ from a 30% solution of pivalic acid in dioxane in a flow system on a catalyst containing 4.8% of Re and 0.5% of Pd on carbon at $T = 230^\circ\text{C}$, $P_{\text{H}_2} = 300$ atm, and $v = 0.15$ h^{–1}. The selectivity of the reaction reached 97% for a degree of conversion of 100%.

The influence of metallic promoting agents (Sn, Ge, Re) and various basic additives on the properties of Pt/SiO₂ catalysts has been investigated in relation to the alkylation of sterically hindered anilines in the vapour phase with formation of mono-*N*-alkylanilines. The reaction took place with a high selectivity and activity.¹²⁰ Doubly promoted Pt/SiO₂ catalysts accelerate the reaction of *ortho*-substituted anilines with primary and secondary alcohols. This distinguishes them from the copper–chromium catalysts, which make it possible to achieve *N*-alkylation by primary alcohols alone. The catalyst should be capable of activating three stages: the dehydrogenation of the alcohol, the condensation of the aniline with formation of carbonyl compounds,

and the hydrogenation of the resulting imine to the final product — *N*-alkylaniline. When the reaction is carried out in the vapour phase, the hydrogenation stage is the most difficult.

3,5,5-Trialkyl-3-aminomethylcyclohexylamine, used to produce urethane elastomers, may be obtained in 78.5% yield by the catalytic hydrogenation of 3,5,5-trialkyl-5-cyanocyclohexanone in methanol on the Co, Re, Mo catalyst in the liquid phase in the presence of ammonia at 120°C and 80 atm.¹²¹ Diethylenetriamine and piperazine are formed in proportions of 15:62 by weight as a result of the hydrogenation of ethylenediamine on a catalyst having the following composition (mass %): 6.2 Ni, 4.4 Re, and 1.8 B.¹²² The reaction is carried out in the liquid phase at ethylenediamine and hydrogen flow rates of 10.64 and 9.82 g mol h^{–1} kg^{–1} respectively and $P_{\text{H}_2} = 36$ atm. The reaction time at 138.2°C is 705 h and the degree of conversion of ethylenediamine is 6.60%.

The influence of rhenium on the properties of the Pd/C catalyst in the hydrogenation reactions of *o*-, *m*-, and *p*-nitrobenzoic acids in an aqueous medium at 70°C has been investigated.^{123–125} Such catalysts are resistant to poisoning by S-containing impurities in the reaction solutions.¹²³

The reactivity of nitrobenzoic acid diminishes in the sequence *para* > *ortho* > *meta* on the (Pd, Re)/Al₂O₃ catalyst.¹²⁴ The presence of rhenium as well as the texture of Al₂O₃ affect the state of palladium and the activity of bimetallic catalysts containing 4.0%–4.5% of Pd and 0.9%–1.0% of Re in the hydrogenation of *m*-nitrobenzoic acid, which reacts with much greater difficulty than *o*- and *p*-nitrobenzoic acids.¹²⁵ The texture of γ -Al₂O₃ was altered by means of a hydrothermal treatment. The hydrogenation was carried out in aqueous solutions with an acid concentration of 2.4×10^{-2} – 1.3×10^{-1} M at $T = 70$ – 90°C , $P_{\text{H}_2} = 5$ – 10 atm, and a *m*-nitrobenzoic acid: Pd molar ratio of 2000. The addition of rhenium to the palladium/alumina catalyst increases the yield of *m*-aminobenzoic acid after 30 min of the reaction from 70% to 91%, while the process selectivity rises from 88% to 93%. *m*-Azoxybenzoic acid is formed as a side product. The introduction of rhenium prevents the sintering of the palladium particles, which increases the degree of dispersion of the metal.¹²⁶ The hydrothermal treatment of Al₂O₃ alters the macrostructure of the support, makes it possible to optimise the Pt/Re ratio on the surface, and increases the content of the palladium–rhenium groups, which, like the (Pd, Re)-clusters,¹²⁷ exhibit an appreciable catalytic activity. Thus the higher activity and selectivity of the bimetallic systems compared with the catalyst to which no rhenium has been added is due to the increase in the degree of dispersion and in the thermal stability of palladium. As a result of the alteration of the macrostructure of the support during the hydrothermal treatment, the Pd/Re ratio on the catalyst surface decreases from 4:1 to 1:1.

5. Dehydrogenation of hydrocarbons

The dehydrogenation of *n*-dodecane^{128–130} and cyclohexane¹³¹ has been achieved on supported rhenium-containing catalysts. Comparison of the activities of the 0.5% Re/Al₂O₃ and 0.5% Pt/Al₂O₃ catalysts in the dehydrogenation of *n*-dodecane ($T = 480^\circ\text{C}$, $P_{\text{H}_2} = 2.5$ atm, $v_{\text{vol}} = 50$ h^{–1}, C₁₂H₂₆:H₂ = 8) showed that the yield of monoalkenes is 18.6% on the former catalyst and 12.1% on the latter. The selectivities in the formation of *n*-monoalkenes for degrees of conversion of 23.2% and 24.8% were 80% and 49% respectively. However, as a result of contact with air after the reduction of the rhenium catalyst at 900°C and its cooling in hydrogen to 20°C , the yield of monoalkenes fell from 9.8% to 4.4%. It was observed that preliminary treatment with hydrogen at 700 – 900°C influences the activity of the rhenium/alumina catalyst.^{128,129}

A similar effect, induced by the preliminary high-temperature treatment with hydrogen (900°C , 3 h), was observed also when the 0.25% Re/Al₂O₃ catalyst was employed. After treatment at 600°C , the selectivity in the formation of monoalkenes fell from 91% to 84% and their yield decreased from ~16% to ~15%. A

decrease in the concentration of rhenium to 0.1% and preliminary treatment with hydrogen at temperatures ranging from 700 to 900 °C increased the dehydrogenating activity and diminished the isomerising and cracking activities and there was an increase in selectivity. The selectivity in the formation of monoalkenes on catalysts containing 0.2% and 0.5% of rhenium also increased after the preliminary heat treatment of the support (Al_2O_3) in air at 900 °C.¹²⁷

The preliminary treatment with hydrogen of the (0.2% Re, 0.2% Pb)/ Al_2O_3 bimetallic catalyst at 700–900 °C instead of the usual temperature of 500 °C also had a positive effect.¹²⁸ The yields of n-monoalkenes formed from n-dodecane were respectively 5.4% and 12.4% after treatment with hydrogen at 500 and 700–900 °C, while the productivity of the catalyst was 2.5 and 8.3 g of n-monoalkenes per gram of the catalyst per hour. The selectivity remained at a high level (93%) in both cases.

Iron has a positive effect on the dehydrogenating activity of the rhenium/alumina catalyst.¹³⁰ The catalyst obtained by depositing NH_4ReO_4 on the $\text{Fe}(\text{NO}_3)_3/\text{Al}_2\text{O}_3$ system heat-treated beforehand in air showed the highest activity in the dehydrogenation of n-decane and n-dodecane ($T = 480$ °C, $P_{\text{H}_2} = 2\text{--}2.5$ atm, $v_{\text{vol}} = 35\text{--}80$ h⁻¹, molar ratio hydrocarbon : hydrogen = 8). The degree of conversion of n-dodecane may be increased by a factor of 2.5–3 if the catalyst is subjected to a preliminary treatment with hydrogen at 500–800 °C. The activity of the resulting catalyst is higher than that of the (Pt, Re)/ Al_2O_3 specimen prepared similarly and reduced with hydrogen at the normally employed temperature of 500 °C. The dependence of the activity of the catalyst on the temperature of its preliminary treatment with hydrogen in the range from 500 to 900 °C passes through a minimum in the region of 600–700 °C.

The promoting effect of iron on rhenium is manifested for low iron contents. At an iron concentration of 3 at. %, the degree of conversion of n-dodecane increases by a factor of 1.7–2.0 if the preliminary activation of the sample with hydrogen is carried out at 900 °C and not 500 °C. However, for an iron content of 5 at. % and a reduction temperature in excess of 700 °C, the promoting effect vanishes. The highest degree of conversion is attained if the rhenium content is 0.25 mass %.

Modification with iron makes it possible to reduce by 150–200 °C the temperature at which the same effectiveness in the conversion of n-alkanes is reached as on the monometallic Re/ Al_2O_3 specimen. It has been suggested¹²⁸ that, in order to overcome the strong interaction between the metal, activating the C–H bond in alkanes, and the support, it is necessary to reduce the metal to the zerovalent state. The formation of the Re^0 active centres on the Al_2O_3 surface is favoured by reduction at a temperature above 700 °C and, in the case of bimetallic catalysts, by the deposition of a compound of the active metal (by impregnation with NH_4ReO_4) on the modified $\text{Fe}/\text{Al}_2\text{O}_3$ supports subjected to preliminary thermal oxidation.

The state of rhenium on the 0.25% Re/ Al_2O_3 catalyst reduced with hydrogen at 500–900 °C has been studied by analysing the diffuse reflection IR spectra of adsorbed CO.¹³¹ Together with ionic forms of rhenium (+1 and +4 oxidation states), a highly disperse (possibly two-dimensional) metallic phase, the electron-donating capacity of which is reduced as a result of a strong metal–support interaction, is present on the surface. The CO adsorbed in a linear form on such a metal is removed by evacuation even at 20 °C. The amount of the highly disperse metallic phase on the support surface increases monotonically with increase in the activation temperature. The activity of the catalyst in the n-dodecane dehydrogenation reaction varies in parallel with the concentration of the electron-deficient highly disperse metallic phase. On this basis, it has been concluded that the highly disperse Re^0 formed during the high-temperature treatment in a stream of hydrogen is a precursor of the catalytically active centres for the alkane dehydrogenation reaction.

The dehydrogenation of cyclohexane to benzene ($T = 350$ °C, $v = 0.5$ h⁻¹) on a rhenium catalyst in which sibunit [a granulated

pyrocarbon, bulk density 0.6 g cm⁻³, S_{sp} (with respect to N_2) = 680 m² g⁻¹, S_{sp} (with respect to phenol) = 230 m² g⁻¹] was used as the support, proceeds at a higher rate than on the catalyst obtained by depositing rhenium on γ - and θ - Al_2O_3 .¹³² On the catalysts containing 2% of Re supported on sibunit, γ - Al_2O_3 and θ - Al_2O_3 , the overall degrees of conversion of cyclohexane into benzene were 32.4 mass %, 15.2 mass %, and 9.7 mass % respectively. The selectivity of the catalysts at 350 °C diminished in the sequence $\text{Re}/\theta\text{-Al}_2\text{O}_3 > \text{Re}/\text{sibunit} > \text{Re}/\gamma\text{-Al}_2\text{O}_3$. With increase in the reaction temperature to 400 °C, the selectivities for the formation of benzene on the same three specimens were respectively 37.9%, 42.4%, and 16.8%. Evidently, the Re/sibunit catalyst is more sensitive to an increase in temperature than the catalysts on aluminium oxide. The dehydrogenating activity of the 2% Re/sibunit catalyst prepared using HReO_4 is higher by a factor of 1.3 than in the case where NH_4ReO_4 is employed. This has been attributed to the greater ease of the reduction of the $\text{Re}(\text{VII})$ formed from perrhenic acid. In contrast to the rhenium oxide catalyst, there is no strong interaction between the metal and the support in the rhenium–carbon system. The dehydrogenating activity of the catalyst is influenced by the oxidative treatment of the support with nitric and oxalic acids. After treatment with 13% nitric acid for 1 h, the selectivity of the 2% Re/sibunit catalyst ($T = 400$ °C, $v = 0.5$ h⁻¹) increased from 35.2% to 61.7%. This may be explained by a decrease in the particle size of the reduced rhenium. Preliminary addition of oxalic acid to the support has a stronger effect on the sibunit catalyst than on the θ -aluminium oxide catalyst. The selectivity in the conversion of cyclohexane into benzene on the 2% Re/sibunit catalyst for an overall degree of 40% rose from 42.2% to 51.1%, i.e. by a factor of 1.35, whereas on the 2% Re/ θ - Al_2O_3 catalyst the increase was from 50.5% to 61.2%, i.e. by a factor of 1.2.

6. Reactions with participation of CO, CO₂, and H₂O

Supported rhenium-containing catalysts have been used also in the hydrogenation of CO_2 to methanol,¹³³ which can proceed *via* the intermediate formation of CO. The rate of hydrogenation of CO on the Re/ ZrO_2 catalyst is higher than on Re/ CeO_2 . In order to elucidate the reaction mechanism, a study was made of the conversion of formic acid and formaldehyde in the presence of hydrogen using ¹³C as a tracer. It was shown that the surface formaldehyde participates in the methanol formation stage.

In contrast to the Co/ SiO_2 and Re/ SiO_2 catalysts the combined (Co, Re)/ SiO_2 catalyst is active in the hydrogenation of CO to ethanol and hydrocarbons.¹³⁴ The introduction of strontium into the bimetallic system diminishes the yield of the hydrocarbons and increases the selectivity in the formation of the alcohol from 10% to 25%. It has been demonstrated by physical methods that strontium controls the reduction of Co^{2+} to Co^0 and that the basic active centres of the catalyst contain highly disperse metallic cobalt. Rhenium promotes the reduction of Co^{2+} to Co^0 . The (Co, Re, Sr)/ SiO_2 catalyst was prepared by employing cobalt acetate. If $\text{Co}(\text{NO}_3)_2$ or CoCl_2 is used to prepare the sample, then rhenium has no modifying effect on the hydrogenation of CO to methanol.¹³⁵ The use of CoCl_2 has a particularly negative effect on the formation of methanol. Rhenium promotes the reduction of Co^{2+} to the metal, facilitating the hydrogen spill over.

The addition of promoting agents (Re, Ru, Ir, Rh, Pt or Os) to the Co/ SiO_2 catalyst obtained from $\text{Co}_2(\text{CO})_8$ did not alter its activity in the CO hydrogenation reaction.¹³⁶

An attempt has been made to use rhenium catalysts for the partial oxidation of methane by the oxygen in synthesis gas ($T = 1000$ °C, $v = 100\,000$ h⁻¹), but they were rapidly deactivated as a result of the volatilisation of the metal in the form of oxides.¹³⁷ Together with other metals (Ru, Rh, Ir), rhenium has been used as the catalyst of the reaction of methane with CO_2 .¹³⁸ At 777 °C, the degree of conversion of methane on the Re/ γ - Al_2O_3 system reached ~85%. However, at lower temperatures the activity of the rhenium catalyst diminished sharply. Thus at 500 °C the degree of conversion of methane was < 5%. The

authors explained this effect by the catalytic oxidation of the metal surface.

The characteristic features of the reduction of CO₂ under the conditions of the thermoprogrammed reaction have been investigated on the 3% Re/Al₂O₃ catalyst.¹³⁹ The rate of reaction increases sharply after the reduction of the catalyst and also as a result of the interaction of CO₂ with carbon fragments on addition of 1%–2% of hydrogen. It has been suggested that formate is formed as an intermediate in this process and that hydrogen has an initiating effect. At high hydrogen concentrations in the CO₂ + H₂ mixture, the conversion of carbon dioxide leads to the formation of CO and CH₄. The addition of formic acid to the reaction mixture increases the rate of formation of methane. It may be that the conversion of CO₂ proceeds *via* the formation of intermediate formate fragments, bypassing the CO₂ dissociation and CO hydrogenation stages. The reduction of CO₂ includes a stage in which surface carbonates are produced.

The acceleration of the Boudouard reaction ($\text{CO}_2 + \text{C} \rightleftharpoons 2\text{CO}$) has been observed on the 3% Re/Al₂O₃ catalyst in the presence of small amounts of hydrogen,¹⁴⁰ where it was less pronounced than on the 8% Fe/Al₂O₃ system. In the presence of the previously coke-saturated (in the isobutane conversion reaction) 3% Re/Al₂O₃ catalyst, the conversion of CO₂ under the conditions of thermoprogrammed heating occurred only at temperatures above 640 °C and the rate of formation of CO was low. The addition of 1%–3% of hydrogen to the stream of CO₂ induced a sharp acceleration of the reaction. The rate of conversion of CO₂ increased by a factor of 25, while the coke oxidation temperature fell by 200 °C. The activation energy for the formation of CO also decreased. The maximum rate of formation of CO was attained at 800 °C, while a further increase in temperature led to a decrease in rate. Under the conditions of thermoprogrammed cooling, the rate of conversion of CO₂ at temperatures below 800 °C was significantly higher than at the analogous temperatures under heating conditions. The authors explained this effect by a heterogeneous-chain mechanism of the reduction of CO₂ by rhenium or iron during the occurrence of the Boudouard reaction. The reaction

takes place at similar hydrogen and CO₂ concentrations.

It has been suggested that, when a heterogeneous-chain mechanism operates, ReHCOO is formed as an intermediate complex. Thus the higher reactivity of CO₂ compared with CO in hydrogenation reactions can be accounted for by the formation of intermediate active species in which the dissociation of the C–O bond is facilitated.¹³⁹

Together with other additives, rhenium improves the properties of Fischer–Tropsch catalysts containing 12%–20% of cobalt.¹⁴¹ Vada *et al.*¹⁴² added 1.0 mass % of Pt or Re to the catalyst containing 8.7% of Co and 91.3% of Al₂O₃ and carried out the hydrogenation of CO on it ($T = 200$ °C, $P_{\text{H}_2} = 5$ atm, and $\text{H}_2/\text{CO} = 2$ or $T = 220$ °C, $P_{\text{H}_2} = 1$ atm, and $\text{H}_2/\text{CO} = 7.3$). The introduction of Pt or Re appreciably increased the rate of reaction referred to unit mass of cobalt. The selectivity did not change under these conditions. The increase in the rate of reaction was induced by the fact that Pt and Re facilitate the reduction of Co atoms and increase their surface concentration.

The promoting effect of rhenium on the cobalt catalyst for the Fischer–Tropsch synthesis has been investigated by diffuse reflection IR spectroscopic methods.¹⁴³ Here it was also shown that rhenium promotes the reduction of cobalt. Rhenium is initially located in the surface layer and most probably forms the tricarbonyl.

Supported rhenium-containing catalysts are also used for the conversion of hydrocarbons by reaction with steam.

In terms of activity and selectivity in the conversion reactions of hydrocarbons with water vapour at temperatures above 600 °C, the 7% Re/ γ -Al₂O₃ catalyst is not inferior to the

industrial nickel-containing catalyst GIAP-3.¹⁴⁴ The following reactions take place under these conditions:

Later the same investigators studied the activity of the Re/ γ -Al₂O₃ catalyst containing 3% and 7.5% of rhenium in the conversion of isobutane by reaction with water vapour in the presence of the CS₂ catalytic poison.¹⁴⁵ The process was carried out in apparatus of the flow and flow-circulation types at atmospheric pressure. On the 3% Re/ γ -Al₂O₃ catalyst at $T = 700$ °C and $v_{\text{vol}} = 1500$ h^{–1} and for a steam/isobutane ratio of 12, the addition of CS₂ in amounts corresponding to sulfur contents of 4 and 30 mg per m³ of gas reduced the overall yield of the conversion product (H₂, CO, CO₂) from 95.7 vol.% (in the absence of sulfur) to 89.3 vol.% and 89.4 vol.% respectively. The introduction of 300 mg m^{–3} of sulfur not only reduced the content of H₂, CO, and CO₂ in the effluent gas but also led to the appearance of hydrocarbons with a lower molecular mass than that of the initial substance, including ethene and propene. The increase in the rhenium content from 3% to 7.5% did not improve the resistance of the catalyst to poisoning by sulfur.

The (Re, Co)/Al₂O₃ and (Re, Ni)/Al₂O₃ bimetallic catalysts have also been used for the conversion of isobutane.¹⁴⁶ The introduction of cobalt (3%) into the 1% Re/ γ -Al₂O₃ catalyst lowered and the introduction of nickel (3%) increased its activity and selectivity in the formation of H₂, CO, CO₂, and CH₄. In contrast to the 3% Ni/ γ -Al₂O₃ catalyst, the bimetallic catalysts containing 1% of Re and 3% of Ni on γ -Al₂O₃ ensured the full conversion of isobutane even at 500 °C. The gas formed had a nearly equilibrium composition, whereas in the presence of the industrial catalyst GIAP-3 as well as the nickel/alumina catalyst deviations from equilibrium towards the predominance of methane were observed. With increase in temperature, the compositions of the gas obtained on all three catalysts approached one another.

7. Oxidative dehydrogenation and acetoxylation reactions

The oxidative dehydrogenation of cyclohexane and ethylbenzene on rhenium-containing oxide systems has been investigated.¹⁴⁷ In the absence of air and water, the 2% Re₂O₇/ γ -Al₂O₃ and 2% Re₂O₇/ θ -Al₂O₃ catalysts exhibited a low activity: the degree of conversion of cyclohexane at 420 °C was only 0.5% and that of ethylbenzene was 4% at 500 °C. In the presence of oxygen, the effectiveness of the dehydrogenation of cyclohexane was higher by a factor of 10–30. In the oxidative dehydrogenation of ethylbenzene without the addition of water vapour, the activity of the catalysts increased by an order of magnitude. In the course of half an hour, the degree of conversion of ethylbenzene into styrene reached 52% for a selectivity of 90% and then remained constant.

The modification of binary magnesium-containing oxide systems by the addition of Re₂O₇ increases the activity of the catalyst. The optimum catalyst for the oxidative dehydrogenation of ethylbenzene proved to be the system incorporating V₂O₅ (11.2%), Re₂O₇ (1.2%), and MgO (87.6%). The degree of conversion of ethylbenzene into styrene on this sample was higher than on the binary system and some suppression of the extensive oxidation processes was achieved. In the presence of an excess of atmospheric oxygen (molar ratio styrene:oxygen = 1:1.5–2), the yield of styrene at 500 °C was 70% for a selectivity of 87%–88%. An increase in temperature to 540 °C led to an appreciable rise in the degree of extensive oxidation. The addition of Re₂O₇ to the V–Mg binary oxide system apparently intensifies the dehydrogenating function of the catalyst.

The gas-phase oxidative acetoxylation of propene to allyl acetate has been achieved on supported Pd and Pd, Re catalysts.^{148, 149} The reaction was carried out at atmospheric pressure, 180 °C, and a rate of supply of the acid of 2 h^{–1} using the ratios C₃H₆:AcOH:O₂ = 2:1:0.5. The high-silica zeolite TsVM

($\text{SiO}_2:\text{Al}_2\text{O}_3 = 29.6$).¹⁴⁸ $\gamma\text{-Al}_2\text{O}_3$, and $\text{Al}_2\text{O}_3\cdot\text{SiO}_2$ were used as supports.¹⁴⁹ The activities of the 1.5% Pd/TsVM and (1.5% Pd, 1.5% Re)/TsVM catalysts were 5.89×10^{-3} and $9.06 \times 10^{-3} \text{ mol g}^{-1} \text{ h}^{-1}$ for selectivities of 81% and 83% respectively. The introduction of rhenium increased the activity by a factor of 1.5. The activity of the (Pd, Re)/zeolite catalyst was influenced by the concentration of rhenium, the order in which it was introduced, and the composition of the initial perhenate [NH_4ReO_4 , KReO_4 , $\text{Ba}(\text{ReO}_4)_2$, or HReO_4]. The bimetallic catalyst with the ratio Pd:Re = 1, prepared from ammonium perhenate, had the highest activity. The introduction of 0.5%–0.7% of Re into the 0.7% Pd/ $\text{Al}_2\text{O}_3\cdot\text{SiO}_2$ catalyst increased its activity without altering the selectivity ($\sim 80\%$). A further increase in the rhenium concentration to 1%–1.5% diminished the activity and selectivity of the catalyst. The higher activity of the bimetallic catalysts, obtained as a result of the introduction of rhenium after the reduction of palladium, compared with the monometallic palladium sample, may be due to the interaction of rhenium oxides with the support surface, which depends on the degree of dehydroxylation of the surface.¹⁵⁰

V. Mixed rhenium-containing catalysts

1. Reactions of hydrocarbons

The principal reactions of the reforming process are dehydrogenation, aromatisation, isomerisation, and hydrogenolysis. The properties of many rhenium-containing catalysts have been investigated in relation to these reactions.

The (Pt, Re)/ Al_2O_3 bimetallic catalysts, prepared by precipitation, were investigated in the propane dehydrogenation reaction.¹⁵¹ The (Pt, Re)/ Al_2O_3 sample proved to be less active and selective in relation to the formation of propene than (Pt, Sn)/ Al_2O_3 . The hydrogenolysis of n-butane on Pt/ Al_2O_3 catalysts involves the formation of adsorbed carbon particles, which influence the proportions of the products obtained.¹⁵² The centres responsible for the dissociation of the central C–C bond are poisoned preferentially. Such species are not adsorbed on the (Pt, Re)/ Al_2O_3 catalysts.

The (Pt, Re)/ Al_2O_3 catalyst proved to be less active under n-heptane reforming conditions than (Pt, Ir)/ Al_2O_3 owing to cracking, which intensifies if the reduction takes place in the presence of water.¹⁵³ In order to facilitate the aromatisation of C_6 and C_7 alkanes on the Pt, Re reforming catalyst and to increase the selectivity of this reaction, it has been recommended that platinum deposited on the L-zeolite be introduced into the catalyst.¹⁵⁴ The catalyst is obtained by the mechanical mixing of the standard reforming catalyst with Pt/L-zeolite.

The aromatisation of n-hexane under reforming conditions using rhenium- and platinum-containing catalysts in proportions of 1:1 and 2:1 has been investigated.¹⁵⁵ Hydrogen has only a weak influence on the dehydrocyclisation of hexane to benzene. With increase in pressure, the selectivity of the reaction diminishes, which intensifies the isomerisation of n-hexane. However, this has little effect on the activity of the catalyst. The deposition of coke on both catalysts diminishes with increase in pressure and the $\text{H}_2:\text{C}_6\text{H}_{14}$ molar ratio. On the catalyst with Re:Pt = 2:1, the extent of the deposition of coke was much smaller than on the catalyst with the 1:1 composition.

The activity of (Pt, Re)/ Al_2O_3 catalysts depends on the method used for their preparation (joint or successive impregnation) and on the reduction procedure (direct reduction after the deposition of the metal, heat treatment with subsequent reduction).¹⁵⁶ Heat treatment appreciably diminishes the metal–metal interaction, which is indicated by the results obtained in the study of the hydrogenolysis of cyclopentane. Sulfiding of the catalysts increases their activity in the n-heptane dehydrocyclisation reaction.

The dehydrocyclising capacity of the Pt/ Al_2O_3 and (Pt, Re)/ Al_2O_3 metal cluster catalysts has been investigated in relation to the conversion of n-heptane into toluene under conditions close to

those in reforming ($T = 500^\circ\text{C}$, $P_{\text{H}_2} = 12 \text{ atm}$).¹⁵⁷ Platinum–rhenium metal cluster catalysts exhibited a higher selectivity and stability than the samples obtained by impregnating aluminium oxide with an aqueous solution of the initial platinum and rhenium compounds. The carbonyl complexes were decarbonised with formation of carbon particles and CO_2 . The increased activity of the catalyst was associated with the formation on their surface of highly disperse carbon particles. The metal cluster Pt, Re catalysts were more stable than the analogous Pt catalysts and the standard (Pt, Re)/ Al_2O_3 reforming catalysts.

The addition of boron and tin to the Pt/ Al_2O_3 and (Pt, Re)/ Al_2O_3 catalysts influences the activity of the latter in the dehydrogenation of cyclohexane, the dehydroisomerisation of methylcyclopentane, and the hydrocracking of 2,3-dimethylbutane.¹⁵⁸

In order to eliminate alkenes from the reforming products, they are subjected to selective hydrogenation on a catalyst containing (mass %) 0.05–0.15 Pt, 0.001–0.05 Cd and/or 0.01–0.1 Re, and 0.01–0.1 Sb on $\gamma\text{-Al}_2\text{O}_3$.¹⁵⁹

Group VIII metals (Pt, Rh, and Ru) supported on $\text{Al}_2\text{O}_3\cdot\text{TiO}_2$ exhibit a high activity in the benzene, naphthalene, and biphenyl hydrogenation reactions at 300°C and $P_{\text{H}_2} = 65 \text{ atm}$.^{160, 161} The activity of these catalysts increases after the addition of a second metal (Ir, Re, Pd). The bimetallic catalyst exhibits an enhanced resistance to poisoning by sulfur, the source of which may be thiophene. The activity of bimetallic catalysts on the TiO_2 support increases as a result of dispersion in combination with the addition of high-valence cations, for example W^{6+} . The bimetallic catalysts have a hydrogenating activity an order of magnitude higher than the usual hydrogenation catalyst (Co, Mo)/ Al_2O_3 .

In the study of the selective hydrogenation of *o*-xylene on metals deposited on SiO_2 (Pd, Ir, Pt, Ru, Os, Ni) in combination with rhenium, a correlation was observed between the electronic conductivity of the metal and the selectivity of the catalyst in relation to the formation of the *cis*-product.¹⁶² The influence of heat treatment on the reactivity and selectivity of the bimetallic catalysts was noted.

2. The influence of chlorine, sulfur, and coke on the properties of the bimetallic catalysts

Chlorine and sulfur are known to be active modifying agents for supported Pt, Re catalysts for the conversion of hydrocarbons and the reforming of petrol fractions. The promotion of the (0.3% Pt, 0.3% Re)/ Al_2O_3 catalyst was investigated by temperature-programmed reduction methods (TPR), analysis of the fine structure of X-ray absorption spectra (EXAFS), X-ray absorption near-edge structure spectroscopy (XANES), the oxygen adsorption method, and IR spectroscopy of adsorbed CO.^{163, 164} It was found that the presence of chlorine promotes the formation of a Re^{4+} -containing phase in the course of the preliminary treatment of the catalyst at 450°C . This phase interacts strongly with the surface layer of Al_2O_3 , which prevents the formation of the Pt–Re alloy on reduction of the species, the specific role of chlorine in the interaction of the metal with the Al_2O_3 support has also been confirmed by other results.¹⁶⁵ In the absence of chlorine, such interaction may be fairly intense, but, when a solution of chloroplatinic acid is deposited, the surface hydroxy-groups are replaced by chloride ions and a stable metal-supported complex is formed.

It has been confirmed by the TPR and XANES methods that the chloride present on the Al_2O_3 surface plays the main role in the formation of an alloy between Pt and Re during the reduction process.¹⁶⁶ The rhenium on the Al_2O_3 surface (tentatively in the form of an oxide) is mobile. In the presence of sulfur, the activity of the Pt, Re catalyst in the hydrogenation–dehydrogenation reactions falls. The irreversibly adsorbed sulfur binds the entire rhenium in the form of Re_2S and $\sim 10\%$ of platinum in the form of Pt_2S . With increase in the fraction of rhenium, the undesirable sensitivity of the catalyst to sulfur increases.

Rhenium, particularly in the form of the alloy with platinum, is a very active hydrogenolysis catalyst.¹⁶⁷ Sulfidation may decrease the activity of this catalyst to zero, since sulfur covers the rhenium surface. The sulfur compounds of rhenium themselves are incapable of accelerating the hydrogenolysis of hydrocarbons and act merely as diluents of the platinum. The addition of sulfur increases the resistance of the platinum catalyst to deactivation, but the adsorbed sulfur is rapidly lost. The introduction of rhenium influences the selectivity of the catalytic system, because it induces modification of the active centres of platinum and promotes the retention of sulfur on the surface. The probability of effecting reactions in which large ensembles of platinum atoms participate (hydrogenolysis, dehydrocyclisation, isomerisation, and cyclisation) diminishes as the latter are reduced. However, the alloying of platinum with rhenium does not influence the initial rate of hydrogenolysis.

Small ensembles of platinum atoms, formed on dilution of platinum by sulfur compounds of rhenium, are resistant to poisoning by carbon deposits, since there is no space on the catalyst surface for a large polymeric carbon structure to grow. Such a catalyst is very stable until the adjacent Pt, Re, S moieties lose their sulfur.

The reactions of cyclohexane and n-hexane have been investigated at 297–467 °C on platinum catalysts in which the support was a rhenium foil with an overall surface area of 0.5–1.0 cm².¹⁶⁸ The surface was sulfided before the reaction and under the reaction conditions by adding thiophene to the hydrocarbon. The ReS formed is catalytically inactive and only the dehydrogenation and hydrogenation reactions occur in the system, but the catalyst becomes more resistant to deactivation.

The problems of the deactivation of the (Pt, Re)/Al₂O₃ reforming catalysts by coke and sulfur have attracted the attention of investigators, since stability is one of the most important requirements which must be met by industrial catalysts. The content of residual coke, deposited on the (Pt, Re)/Al₂O₃ catalyst during the reforming of petroleum in the temperature range 350–650 °C has been determined.¹⁶⁹ The residual coke was investigated by the temperature-programmed oxidation method, X-ray diffraction, IR spectroscopy, chromatograph-linked mass spectroscopy, NMR, electronic spectroscopy, EPR, and chemical analysis. After the coke had been burnt away at 400 °C, the residual deposits were characterised by a minimal H : C ratio and a maximal concentration of C=O groups. At low temperatures, the most hydrogenated and amorphous carbon particles are the first to burn. At a high temperature, the combustion is nonselective and all the deposits burn simultaneously. In the course of combustion, coke is partly oxidised and intermediate species containing the C=O and C–OH groups are formed.

The effects of coating with rhenium and sulfidation of the surface of the platinum reforming catalyst have been investigated in relation to the reactions of n-hexane and cyclohexane on platinum without a support under the conditions of ultrahigh vacuum.¹⁷⁰ In the absence of sulfur, the degree of cyclisation of n-hexane diminished with increase in the rhenium content. The introduction of sulfur decreased the hydrogenolysis and increased the cyclising activity. The maximum cyclising activity of the sulfided catalyst was observed when the surface was coated by a monolayer of rhenium. Similar results have also been obtained under the conditions of the reactions of cyclohexane on the surface of the bimetallic Pt, Re catalyst: after sulfidation, the contribution of hydrogenolysis diminished, while that of dehydrogenation increased. The maximum rate of hydrogenation was attained on the sulfided catalyst with the platinum coated by 0.5 of a rhenium monolayer.

A multiflow reactor, which makes it possible to determine the composition of the gas phase along the catalyst bed and the coke deposition profile, has been used to investigate the deactivation of the Pt/Al₂O₃ and (Pt, Re)/Al₂O₃ catalysts in the reforming of n-heptane.¹⁷¹ At a low pressure (1.05 atm), the coke content on the Pt catalyst increased, while at a high pressure (12.25 atm) it

fell. The maximum deposition of coke was observed at an intermediate pressure. Correlations were noted between the coating of the surface by coke and the formation of C₅ naphthenes and also between the changes as a function of time in the supply of the starting material, pressure, and the location of the section on which coke is deposited. The C₅ naphthenes are apparently the main source for the formation of coke deactivating the catalyst. The addition of rhenium influences the deposition of coke and the formation of C₅ naphthenes. The form of the temperature-programmed oxidation (TPO) spectrum depends on the pressure at which the coke is deposited. An increase in the overall pressure leads to identical changes in the TPO spectra on the Pt and Pt, Re catalysts. The results confirm that rhenium increases the surface concentration of hydrogen on the Pt, Re catalyst and hence diminishes its dehydrocyclising and increases its hydrocyclising capacity. A smaller amount of dialkenes with a five-membered ring is formed on the Pt, Re catalyst than on Pt/Al₂O₃ and the (Pt, Re)/Al₂O₃ catalysts are therefore less coke-saturated and are more stable.

The sensitivity of the Pt/Al₂O₃, (Pt, Re)/Al₂O₃, (Pt, Ir)Al₂O₃, (Pt, Ge)Al₂O₃, and (Pt, Sn)/Al₂O₃ reforming catalysts to poisoning by sulfur has been investigated in relation to the model cyclohexane dehydrogenation reaction.¹⁷² The permissible sulfur content in the starting material when the reaction was carried out on the above catalyst diminished in the sequence (Pt, Ge) > (Pt, Ir) ≈ Pt ≈ (Pt, Sn) > (Pt, Re). The resistance of the catalyst to sulfur decreased in the sequence (Pt, Ge) > (Pt, Ir) ≈ (Pt, Re) > (Pt, Sn). The (Pt, Ge)Al₂O₃ bimetallic catalyst thus proved to be the most resistant to sulfur and also permitted the highest sulfur content in the starting material.

The influence of the rhenium content on the activity, stability, and the resistance to poisoning by sulfur of the (Pt, Re)/Al₂O₃ reforming catalyst has also been investigated.¹⁷³ An increase in the rhenium content in the catalysts subjected to preliminary sulfidation suppressed the dehydrocyclisation of n-heptane to toluene but facilitated the conversion of methylcyclopentane into benzene without appreciable ring opening. Another result of the increase in the rhenium content was a gradual diminution of the deactivation of the catalyst and of the accumulation of coke on the surface. However, in the presence of a high rhenium content, the catalyst became more sensitive to poisoning by sulfur. The dehydrocyclisation of n-hexane was suppressed to a greater extent compared with other hydrocarbons. The different behaviour of the catalysts with high and low rhenium contents has been explained by the synergistic activity of rhenium and sulfur.

A comparative study of the noncoke-saturated and partially coke-saturated sulfided (Pt, Re)/Al₂O₃ reforming catalysts in the isomerisation and dehydrocyclisation of hexane, heptane, and methylcyclopentane showed that sulfur promotes the removal of coke from the metal surface.¹⁷⁴ The amount of irreversibly chemisorbed sulfur increases in the series of catalysts Pt/Al₂O₃ < (Pt, Re)/Al₂O₃ < Re/Al₂O₃. The ensembles of platinum atoms in the (Pt, Re, S)/Al₂O₃ bimetallic catalysts are larger and have a less distorted structure than in (Pt, S)/Al₂O₃.

3. Hydrogenation of hydrocarbon mixtures

In the 1970s, increased attention was devoted to the questions of the selection of effective catalysts for the hydrogenation of aromatic hydrocarbons in kerosene fractions. The 'Unisar' process was effected on platinum catalysts.¹⁷⁵ The modification of platinum catalysts with rhenium makes it possible to achieve the selective hydrogenation of the most undesirable hydrocarbons present in the middle petroleum fractions, namely bicyclic aromatic hydrocarbons and polysubstituted alkylbenzenes. An advantage of the bimetallic catalyst over the platinum catalyst is also its inertness to hydrocarbons of other classes — alkanes and isoalkanes, particularly in relation to their hydrocracking.⁴

The effective hydrogen sulfide-treated (1% Pd, 1% Re)/Al₂O₃ catalyst has been developed for the two-stage hydrogenation of middle petroleum fractions.¹⁷⁶ The optimum conditions

($T = 250\text{ }^{\circ}\text{C}$, $P_{\text{H}_2} = 20\text{ atm}$, $v = 1.0\text{--}1.5\text{ h}^{-1}$, circulation of 800–1000 litres of hydrogen per litre of starting material), under which the degree of conversion of aromatic hydrocarbons is $\sim 90\%$ and the yield of the target product is $\sim 98\%$, were found. A similar degree of conversion of aromatic hydrocarbons on the platinum/alumina catalyst was not attained until $300\text{ }^{\circ}\text{C}$ and a hydrogen pressure of 40 atm.

4. Reforming

The greatest advance in the field of petroleum processing has been the achievement in 1968 of the rheniforming process using bimetallic Pt, Re catalysts on an oxide support, which are more active and stable than the platinum/alumina catalyst.¹⁹ The improvement of these catalytic systems is being continued at the present time. The application of a new method for the modification of aluminium hydroxide made it possible to deposit on the latter ultrasmall amounts of platinum (0.15%) and rhenium (0.3%).¹⁷⁷ This catalyst, with the ratio Re:Pt = 2:1 shows a satisfactory activity as well as a high selectivity, stability, and mechanical strength and is readily regenerated. Among all the known reforming catalysts, it contains the smallest amount of platinum.

The productivity of the reforming catalyst can be increased by adding a zeolite of the pentasil type.¹⁷⁸ The chlorinated (Pt, Re)/ Al_2O_3 catalyst mixed with HZSM-5 exhibits an increased activity and stability in the formation of aromatic compounds from *n*-heptane. A possible reaction mechanism involves the formation of intermediate carbonium and carbene ions.

The pressure dependence of the yield of hydrogen and of the octane number (o.n.) of the reformat has been investigated on the (Pt, Re)/ Al_2O_3 catalysts.¹⁷⁹ The yield of the processing products and hydrogen increased as the pressure increased from 12 to 25 atm. The octane numbers varied linearly with the concentration of the aromatic hydrocarbons. At a pressure of 12 atm, the hydrodealkylation of C_8 and higher aromatic hydrocarbons proceeded with formation of xylenes and higher aromatic compounds.

The conditions for the regeneration of the coke-saturated (Pt, Re)/ Al_2O_3 reforming catalyst by ozone–air and $\text{O}_2\text{--NO}_2$ mixtures were found.^{180,181} Coke was removed by ozone at low temperatures (since ozone decomposes at high temperatures) and then by oxygen. However, ozone removes coke nonselectively, whereas oxygen removes it selectively. In the first place, it was possible to eliminate coke deposited on metallic centres of the catalyst.

A special procedure for the ‘minimisation of the sulfided support’ is used in the regeneration of reforming catalysts containing chloride and sulfate ions.¹⁸² In the presence of an amount of sulfate to which a sulfur concentration in excess of 0.08%–0.1% corresponds, the rate of deactivation as a consequence of the formation of coke increases. The intensification of the coke formation process is a result, firstly, of the blocking of the Lewis acid centres of aluminium oxide by sulfate ions and, secondly, of the excessive sulfidation of the metal particles by the hydrogen sulfide formed on reduction of the sulfided catalyst by hydrogen.

The Pt, Re bimetallic reforming catalyst of type IIP-IPCL (India), exhibited a high activity, selectivity, stability, and capacity for regeneration in tests on a pilot apparatus designed to generate motor fuel.¹⁸³ The first cycle of tests was interrupted after 13 experiments owing to the deposition of sulfur. In the second cycle, the catalytic activity was lower while the deactivation was very rapid owing to the sulfurisation of the catalyst in the course of the first regeneration. A special technology, involving the removal of sulfates by hydrogen at $490\text{--}510\text{ }^{\circ}\text{C}$ and a pressure of 5–7 atm in the presence of ethylene chloride, was therefore used for the second regeneration. After such regeneration, the catalyst recovered its initial activity and stability and retained them in the course of three cycles.

The influence of temperature and of oxygen content, steam, and hydrocarbons in the gas phase on the initial characteristics of the CB-6 and CB-8 reforming catalysts (China) with a low platinum and rhenium content has been investigated.^{184,185} A deficiency of oxygen in the liquid phase leads to the formation of coke in the partial drying and regeneration stages, which induces a decrease in catalytic activity or complete deactivation.

The study of the influence of process parameters on the hydrocracking and isomerisation of petrol fractions on (Pt, Re)/ Al_2O_3 catalysts (R-62 and R-16G)¹⁸⁶ in a flow system has been investigated at $T = 505\text{--}525\text{ }^{\circ}\text{C}$ and $v = 2.7\text{--}5.4\text{ h}^{-1}$. It was established that the yield of liquid products increases with increase in the space velocity. The R-16G catalyst exhibits a high activity in the formation of gaseous products, *i.e.* in the hydrocracking reaction. This is associated with the influence of the acid centres of aluminium oxide and the use in this case of a higher pressure (27 atm) than in the process on the R-62 catalyst (12 atm). On the other hand, the R-62 catalyst exhibits a higher activity than R-16G in the dehydrogenation of naphthenes to aromatic hydrocarbons. The reforming of mixed hydrorefined petroleum has been achieved on an industrial pilot apparatus on the same catalysts [$T = 490\text{--}525\text{ }^{\circ}\text{C}$, $v = 2.7\text{--}5.4\text{ h}^{-1}$, hydrogen:hydrocarbon starting material = (5–7):1, $P_{\text{H}_2} = 27\text{ atm}$ on the R-16G catalyst and 12 atm on the R-62 catalyst].^{187,188} An increase in temperature promotes an increase in the octane number of the processing product and the formation of high-quality petrol. The greater activity of the R-62 catalyst in the dehydrogenation of naphthenes to aromatic hydrocarbons noted above can be explained by the fact that the occurrence of this structure-insensitive reaction is promoted by a lower pressure. The catalyst was not deactivated by coke, since its residence in the reactor was brief ($\sim 23\text{ h}$). The dehydroisomerisation and dehydrocyclisation of alkenes to aromatic hydrocarbons occurred to a lesser extent. An increase in temperature and a decrease in space velocity from 0.8 to 0.37 h^{-1} intensified the deposition of coke. The repeated regeneration of the catalyst led to an increase in the pore volume and in the overall porosity.¹⁸⁹

The influence of the chlorine content on the properties of fresh, coke-saturated, and regenerated samples of the (0.3% Pt, 0.3% Re)/ Al_2O_3 reforming catalyst has been investigated.¹⁹⁰ The equilibrium chlorine content was attained by treating the catalyst with the vapour of the $\text{H}_2\text{O--HCl}$ mixture in a stream of air or hydrogen and was determined by the $\text{H}_2\text{O}:\text{HCl}$ molar ratio and also by the temperature of the treatment. The equilibrium chlorine content in the fresh sample was independent of the nature of the chlorine compound introduced. The amount of chlorine retained by the support, calculated per unit surface area, was the same on the fresh and regenerated specimens. The presence of coke did not alter the amount of chlorine on the surface.

(Pt, Re)/ Al_2O_3 catalysts have been tested on a pilot apparatus under the conditions of hydrocracking and isomerisation of *n*-heptane and also under the conditions of the reforming of the petrol fraction with $T_b = 77\text{--}155\text{ }^{\circ}\text{C}$.¹⁹¹ Problems arising in the use of chlorinated (Pt, Re)/ Al_2O_3 catalysts under industrial conditions, problems of the recovery of the $\text{H}_2\text{O}:\text{HCl}$ balance, problems in the monitoring of sulfur, *etc.* have been examined.¹⁹² (Pt, Re)/ Al_2O_3 catalysts prepared by the joint impregnation method and containing chlorine exhibit a high activity because of the decrease in the deposition of coke on their metallic centres.¹⁹³ The stronger interaction of the metals in such a catalyst, the smaller the degree of its deactivation by coke.

The presence of fluorine on the Al_2O_3 surface prevents the formation of the strongly bound hexachloroplatinic acid complex PtO_xCl_y .¹⁹⁴ Heating in an inert gas leads to the removal of chlorine and the formation of metallic platinum. Treatment with hydrogen limits the possibility of the formation of a homogeneous Pt–Re solid solution. An increase in the amount of free rhenium in the catalyst promotes the intensification of its hydrogenolysing and the weakening of its aromatising capacities.

The properties of the CB-6 catalyst (China) reduced by electrolytic hydrogen and hydrogen obtained in the reforming process have been compared.¹⁹⁵ Reduction by electrolytic hydrogen led to an increase in the octane number of the petrol formed as a result of reforming by a factor of 2.2 and to a slight increase in the yield. The catalyst reduced by electrolytic hydrogen also possessed a greater stability. However, reduction of (Pt, Re)/Al₂O₃ catalyst by the hydrogen, evolved in the course of the reforming of petroleum, is more economical than the reduction by electrolytic hydrogen.¹⁹⁶

Sixteen kinetic models were proposed,¹⁹⁷ which make it possible to describe the parameters of petroleum reforming processes in the presence of the (Pt, Sn)/Al₂O₃ and (Pt, Re)/Al₂O₃ catalysts.

Analysis of the patent literature of recent years^{198–228} shows that the selection of effective regenerable rhenium-containing catalysts for the reforming processes is being continued. Pt, Re, Ir catalysts deposited on Al₂O₃, SiO₂, Al₂O₃·SiO₂, or a zeolite have been proposed.^{198–200} Tin, cadmium, germanium,^{201–205} as well as titanium²⁰⁵ are used as promoting agents instead of iridium. Effective bimetallic platinum–rhenium supported catalysts, activated by chlorine or fluorine, have been developed.^{206–211} Low-octane petrol fractions are subjected to reforming (220–260 °C, atmospheric pressure) in the presence of 0.1 mass %–0.3 mass % of Ni, Re, Os, Rh, Ir, Ru, Co, and/or Fe deposited on an oxide support.²¹² W, V, Mo, Re, Ni, Co, Cr, Mn, and noble metals (Pt or Pd) can also serve as hydrogenating and dehydrogenating components.²¹³ The introduction of lanthanide oxides, for example Nd₂O₃, into an aluminosilicate support containing more than 50% of SiO₂ increases the activity of the platinum–rhenium catalyst in reforming and isomerisation processes.²¹⁴

The combination of processes makes it possible to increase the octane numbers of the reforming products. For example, the product of the conversion of the starting material on the (Pt, Re)/Al₂O₃ catalyst is passed for this purpose over the (Pt, Sn)/Al₂O₃ catalyst.^{215,216} Studies associated with the regeneration of the catalysts,^{217,218} an increase in their useful lifetime, the reforming technology, *etc.*^{219–228} are being continued.

Much attention has been devoted to the preparation and physicochemical methods for the analysis of monometallic Pt/Al₂O₃ catalysts^{229,230} and also the commonest bimetallic reforming catalysts based on Pt and Re, Pt and Sn, Pt and Ir, and Pt and Ge.²²⁹

The interaction of the metals in (Pt, Re)/ γ -Al₂O₃ bimetallic catalysts has been investigated by the EXAFS and other spectroscopic methods.²³¹ The likely usefulness of the employment of various Pt, Re clusters with a definite structure in heterogeneous catalysis has been demonstrated by comparing their properties with those of the usual (Pt, Re)/Al₂O₃ bimetallic reforming catalysts.²³²

The properties of the 0.3% Pt/Al₂O₃ (EUROPT-3) and (0.3% Pt, 0.3% Re)/Al₂O₃ (EUROPT-4) catalysts have been investigated in relation to the structure-sensitive hydrogenolysis reactions of alkanes (ethane, propane, n-butane, n-hexane, 2- and 3-methylpentanes, n-octane).²³³ The rate and selectivity of the hydrogenolysis depend on the conditions in the preliminary treatment of the catalyst and the residual coke content on the surface. The bimetallic catalyst is more sensitive to the preliminary treatment than Pt/Al₂O₃, since rhenium-enriched phases or pure rhenium may be formed on its surface, which entails a change in the surface ratio Pt : Re. Under the conditions of vigorous hydrogenolysis of alkenes (ethene, butadiene) at 0 and 127 °C in a flow system, the (Pt, Re)/Al₂O₃ catalyst is rapidly deactivated, in contrast to Pt/Al₂O₃.

The methods for the preparation of bimetallic reforming catalysts, the conditions in their heat treatment, the role of the support, the impregnation methods, the selection of the initial solutions, the stability of the catalysts, and other problems have been discussed.²³⁴ Methods for the extraction of rhenium and

platinum from spent reforming catalysts have been examined.^{235,236}

Polymetallic (Pt, Re, Cd)/Al₂O₃ catalysts of type K-104 have been tested under the conditions of reforming of petrol fractions.²³⁷ During the initial period, coke is formed on the metallic centres of the RG-482 catalyst.²³⁸ On regeneration, it is removed initially from the metallic and then from the acid centres.²³⁹

A new trimetallic reforming catalyst, which makes it possible to increase the yield of C₅ hydrocarbons and hydrogen compared with the usual (Pt, Re)/Al₂O₃ bimetallic catalyst, has been proposed in a patent.²⁴⁰ Its stability is not inferior to that of the standard industrial catalyst.

Pt/Al₂O₃ and (Pt, Re)/Al₂O₃ mono- and bi-metallic catalysts, prepared by the methods used for the synthesis of industrial reforming catalysts, have been investigated by the EXAFS method.^{241–243} Under the conditions in the reforming of n-heptane, the formation of Pt–C bonds was observed in both mono- and bi-metallic systems. The deposition of carbon was investigated.^{242,243} The Pt–C bond is formed at 460 °C on the monometallic catalyst, whereas on (Pt, Re)/Al₂O₃ it is formed only at low temperatures, the process being accompanied by an appreciable change in the structure of the metallic particles. Modification of platinum with rhenium increases the stability of the catalyst and prevents the deposition of well structured carbon residues.

The results indicate also the presence of a long Re–O bond (2.20 Å) in the reduced (Pt, Re)/Al₂O₃ catalysts, which does not conflict with the idea that a structure formed as a result of the insertion of Re into Al₂O₃ exists. Such a structure emerges partly onto the surface and is reduced by the carbon–hydrogen mixture.

(Pt, Re)/Al₂O₃ catalysts have also been investigated by transmission electron microscopy combined with energy dispersive X-ray analysis.^{244–246} Rhenium–platinum alloy is not formed in this catalyst and there is a wide size distribution of the rhenium crystals on the support surface.²⁴⁴ Two types of platinum particles have been observed: three-dimensional metallic particles and small formations containing a few atoms. Some aggregation of the platinum particles in the course of the process has been observed under the conditions of the reforming of n-octane. The interaction of rhenium with Al₂O₃ and preliminary modification of platinum influence significantly the stability and selectivity of the catalyst in reactions involving cycloalkanes and in aromatisation processes. The distribution of active elements in (Pt, Re)/Al₂O₃ catalysts has been examined.^{245,246}

The TAP method (Temporal Analysis of Products — analysis of reaction products as a function of time) has been used to investigate the conversion paths of C₆ hydrocarbons on the Pt/Mg(Al)O, Pt/KL (K is an ion-exchange zeolite), and Pd/Mg(Al)O catalysts, as well as (0.3% Pt, 0.3% Re)/Al₂O₃ industrial catalysts (sulfided and nonsulfided).²⁴⁷ The reactions were carried out under pulsed conditions at 477 and 510 °C, a pressure of 1 atm, and a H₂ flow rate of 0.25 ml min^{–1}. The reforming products were analysed mass-spectrometrically. It was found that only benzene is formed from cyclohexane, while hex-1-ene is either dehydrocyclised or is hydrogenated to n-hexane with subsequent dehydrogenation and ring closure. The possible dehydrogenation of hexane to hexadiene with subsequent cyclisation takes place at approximately the same rate as that of the dehydrogenation of cyclohexane to benzene. Under the chosen conditions, the sulfidation of the catalyst does not exert an appreciable influence on the course of the reaction.

Under industrial conditions at high pressures, the formation of benzene from alkanes on the (Pt, Re)/Al₂O₃ catalyst proceeds via a two-stage mechanism.²⁴⁸

The application of the oxygen–hydrogen titration method²⁴⁹ made it possible to determine the degree of dispersion of platinum with a reproducibility of $\pm 3\%$ and of rhenium with a reproducibility of $\pm 5\%$. Previously, the reproducibility was $\pm 5\%$ for platinum and $\pm 10\%$ for rhenium.⁴

IR spectroscopic study of the adsorption of NO and CO molecules showed that a Pt–Re alloy or metallic clusters are not formed on the surfaces of reduced (Pt, Re)/Al₂O₃ catalysts with a low concentration of the metal (0.22% of Pt and 0.43% of Re).²⁵⁰

The TPR and XANES methods have been used to estimate the influence of the content of the metal and of the Re : Pt ratio on the susceptibility of rhenium in (Pt, Re)/Al₂O₃ catalysts to reduction.²⁵¹ It was found that the final oxidation state of metallic rhenium depends on both these parameters. The catalysts were investigated with laboratory bench and pilot apparatus. The degree of reduction of rhenium determines the catalytic properties of bimetallic Pt–Re systems. With increase in the Re : Pt ratio, the lifetime of the catalyst increases and this trend is maintained so long as rhenium continues to be reduced. A second rhenium phase, the appearance of which increases the reduction temperature, arises when the Re : Pt ratio exceeds 2 : 1. In the presence of a controlled sulfur content in the starting material, the catalyst with the ratio Re : Pt = 2 : 1 works twice as long as the catalyst with the ratio Re : Pt = 1 : 1.

VI. Conclusion

The behaviour of rhenium-containing catalysts in a series of organic reactions is distinguished by specificity compared with the behaviour of other transition metals. The possibility of the modification, activation, and reduction of the concentration of rhenium in the Re₂O₇/γ-Al₂O₃ catalysts used for the metathesis of unsaturated compounds and functional alkenes has been demonstrated in recent years. Unsaturated organic compounds which are difficult to obtain, including chlorine- and oxygen-containing ones, may be synthesised by reactions involving higher alkenes. The use of rhenium-containing catalysts permits metathesis or joint metathesis under milder conditions than on other catalytic systems.

Rhenocene hydride, rhenium pentacarbonyl, rhenium oxides with the perovskite structure, and rhenium heptasulfide are effective catalysts of the hydrogenation of a series of organic compounds and condensed nitrogen-containing aromatic ones. Supported rhenium catalysts exhibit a higher activity than the known industrial oxide catalysts in the hydrogenation reactions of oxygen-containing compounds (carboxylic acids, aldehydes, synthetic aliphatic acid esters, etc.).

The studies on rhenium-containing catalysts, especially bi- and poly-metallic ones, in which rhenium is used in combination with noble and Group VIII transition metals for hydrogenation, dehydrogenation, isomerisation, disproportionation, etc. reactions are being continued: the methods for the preparation, activation, regeneration, modification, and analysis of the catalysts are being improved and the mechanism of their action is being investigated. The range of physicochemical research methods is being constantly expanded. However, many questions concerning the unique role of rhenium, for example in bimetallic platinum–rhenium supported catalysts, remain unelucidated or controversial.

Rhenium-containing catalysts are widely used in two industrial processes — metathesis and reforming. Nowadays more than 30% of the total number of reforming catalysts employed throughout the world consist of Pt, Re catalysts.²³⁶

The most promising fields of application of rhenium and its compounds as catalysts still comprise diverse organic reactions as well as reactions with participation of CO, CO₂, O₂, H₂O, and chlorine-containing compounds.

The catalytic properties of rhenium have been discovered not long ago, so the possibilities for its employment in catalysis are still far from being exhausted.

Abstract. Published data on the synthesis and properties of *N*-halohydroxylamine derivatives are described systematically and analysed. The bibliography includes 123 references.

I. Introduction

The development of the chemistry of *N*-halohydroxylamine derivatives started relatively recently, although the first representative of this class, *N*-chloro-*N*-methoxy-*p*-toluenesulfonamide, was described as early as 1953.¹ *N*-Halo-*N*,*O*-dialkylhydroxylamines are the nitrogen analogues of α -halo ethers, which are widely used in organic synthesis as highly reactive alkylating reagents.² It is this formal analogy that attracted our attention about 20 years ago. This analogy has worked perfectly, and this permitted the synthesis of new classes of organic compounds by simple nucleophilic substitution of chlorine in *N*-chlorohydroxylamine derivatives. In particular, *N*-alkoxy-*N*-*tert*-alkyl-*O*-alkylhydroxylamines (nitrosoacetals),^{3,4} *N*,*N*-dialkoxy-*O*-alkylhydroxylamines (trialkoxamines, orthonitrites),⁵ and *N*-alkoxy-*O*-alkylhydroxylamines (NH-dialkoxamines, orthoethers of nitrosyl hydride)⁶ have been synthesised in this way, and oxidation of the latter compounds gave stable dialkoxyaminyl radicals⁷ and their dimers (tetraalkoxyhydrazines).^{7,8} The vast synthetic potential of *N*-halohydroxylamine derivatives is also due to the possibility of converting them into highly reactive intermediates such as *N*-alkoxynitrenes,⁹ *N*-substituted *N*-alkoxyaminyl radicals,^{7,10} and *N*-alkoxynitrenium ions.^{5,11} Thus intramolecular cyclisation of *N*-chloro-*O*-alkylhydroxamates involving an aromatic substituent present in the acyl or alkoxyl fragment of their molecules, which occurs *via* intermediate *N*-acyl-*N*-alkoxynitrenium ions, is a general method for the synthesis of a large number of nitrogen-containing heterocycles.^{12–18}

N-Halohydroxylamine derivatives are also of interest from the stereochemical viewpoint, since the two σ -electron-withdrawing

substituents attached to the nitrogen atom markedly increase its configurational stability.^{4,19–26} This made it possible to prepare optically active derivatives of 2-chloro-1,2-oxazolidine^{19,20} and 2-chloroxaziridine^{24,25} with an asymmetric nitrogen atom. The non-symmetrically substituted *N*-alkoxy-*N*-*tert*-alkyl-*O*-alkylhydroxylamines synthesised from *N*-chloro-*N*-*tert*-alkyl-*O*-alkylhydroxylamines were partially resolved into optical antipodes, which were the first chiral compounds with asymmetric nitrogen atoms in an open chain.⁴

Some aspects of the chemical behaviour of O–N–Cl systems have been considered in a number of reviews.^{12,27–29} In the present review, we have attempted to survey all the currently available data on the synthesis, properties, and stereochemistry of *N*-halohydroxylamine derivatives.

The stereochemistry and chemical properties of geminal oxygen – nitrogen – halogen systems are mostly determined by the stabilising interaction between the non-bonding (n) orbital of the oxygen atom and the antibonding σ^* orbital of the N–Hal bond, which is described in terms of the concept of valence bonds as hyperconjugation.

According to the theory of molecular orbital perturbation, the energy of $n-\sigma^*$ stabilisation is approximately proportional to the overlap of the interacting orbitals and is inversely proportional to the difference between their energies.^{30,31} The $n-\sigma^*$ interaction results in kinetic destabilisation of the N–Hal bond, *i.e.* in an increase in its tendency to dissociate (kinetic anomeric effect³²)† yielding a nitrenium ion stabilised due to the π -overlap between the vacant $2p_z$ orbital of the N atom and the occupied $2p_z$ orbital of the neighbouring O atom (Fig. 1).^{4,13–15,33,34}

N-Alkoxynitrenium (nitrenium-oxonium ions) are ambident cations. They react with nucleophiles according to two competing pathways.^{5,10,35,36}

† The structural consequences of the $n-\sigma^*$ interaction are considered in Section VII.

Figure 1. Interaction of the $2p_z$ orbitals of nitrogen and oxygen in alkoxyxynitrenium ions.

The addition of nucleophiles to the nitrenium centre [pathway (a)] is a reversible orbitally controlled reaction, which occurs in the case of 'soft' nucleophiles with high-lying highest occupied molecular orbitals (HOMO). Conversely, dealkylation of the oxonium site [pathway (b)] is an irreversible charge-controlled reaction occurring in the case of 'hard' nucleophiles having low-lying HOMO.

The thermal stability and the reactivity of *N*-halohydroxylamine derivatives depend appreciably on the type of the halogen. The former decreases,^{13,37} whereas the latter increases with an increase in the electron-withdrawing ability of the N–Hal bond. The above-mentioned properties of *N*-halohydroxylamine derivatives also depend substantially on the type of the third substituent at the nitrogen atom. Electron-releasing substituents, which favour ionisation of the N–Hal bond to even a greater extent, diminish the thermal stability and increase the reactivity of these compounds. For instance, whereas *N*-chloro-*N*-*tert*-alkyl-*O*-alkylhydroxylamines⁴ are stable distillable liquids, *N*-chloro-*N*-alkoxy-*O*-alkylhydroxylamines⁵ cannot be detected by ¹H NMR spectroscopy even at -30°C . Conversely, electron-withdrawing substituents decrease the polarisation of the N–Hal bond, and in some cases, they even change the direction of polarisation; this, for example, occurs in the case of *N*-halo-*N*-alkoxy-substituted sulfonamides^{1,38} and phosphamides.³⁸

II. *N*-Halo-*O*-alkylhydroxylamines

N-Halo-*O*-alkylhydroxylamines are unstable and have not been isolated in a pure state. Nevertheless, *N*-chloro-*O*-methylhydroxylamine, generated by treatment of *O*-methylhydroxylamine with *N*-chlorosuccinimide, has been involved *in situ* in the addition to tetramethylethylene.³⁹

NCS is *N*-chlorosuccinimide.

Two routes of transformation of *N*-chloro-*O*-*tert*-alkylhydroxylamines have been discovered; in weakly alkaline solutions, they form N_2O , while in strongly alkaline media (6 N or 8 N NaOH), they are converted into nitrosoalkanes.⁴⁰ Dinitrogen monoxide was assumed to result from decomposition of nitrosyl hydride formed upon dealkylation of the intermediate nitrenium-oxonium ions. Nitroso-derivatives result from 1,2-rearrangement of the alkoxyxynitrenes,^{41,42} which can be generated from *N*-chloro-*O*-alkylhydroxylamines *via* 1,1-elimination⁴⁰ or deprotonation of *N*-alkoxyxynitrenium ions.³⁵

R = Bu^t, Me₂EtC.

It has been assumed that the products of monohalogenation of *O*-diphenylmethylhydroxylamine⁴³ and 1,2-bis(aminoxyl)-ethane⁴⁴ are mostly formed *via* decomposition of intermediate hyponitrites yielding N_2 and alkoxy radicals, which, in turn, disproportionate to give an aldehyde (or ketone) and an alcohol.

NBS is *N*-bromosuccinimide;

In some cases, hyponitrites are the final products of monohalogenation of *O*-alkylhydroxylamines.^{45,46}

R = Et, Bu^t; XHal = Br₂, NaOCl, chloramine T.

One of the possible pathways to hyponitrites in this reaction includes decomposition of *N*-halo-*O*-alkylhydroxylamines to alkoxyxynitrenes and their subsequent dimerisation.⁴³ The intermediate formation of benzyloxyxynitrene has also been assumed⁴ for the chlorination of *O*-benzylhydroxylamine.⁴⁷

The bromination of *O*-methylhydroxylamine in the presence of *C*-nitroso-derivatives affords diazene oxides in 5%–20% yields.⁹

XBr = Br₂, NBS;

R = Me₂(NO₂)C, MeO₂CCMe₂, Ph, 2,4-(NO₂)₂C₆H₃,

III. *N*-Halo-*N*,*O*-dialkylhydroxylamines

This type of compound has been studied most comprehensively. Methods for synthesis of acyclic and cyclic *N*-chloro-, *N*-bromo-, and *N*-fluoro-derivatives have been developed; chemical properties of these derivatives have been studied.

1. Synthesis

The simplest representative of acyclic *N*-chloro-*N,O*-dialkylhydroxylamines, namely *N*-chloro-*N,O*-dimethylhydroxylamine **1**, has been prepared by chlorination of *N,O*-dimethylhydroxylamine⁴⁸ and by cleavage of amina **2** upon treatment with *N*-chlorosuccinimide.⁴

Compound **1** withstands vacuum distillation (b.p. 35 °C at 200 mm Hg). It was characterised by spectroscopic methods.^{4, 48, 49} However, the attempts to synthesise other *N*-chloro-*N,O*-dialkylhydroxylamines containing an α -hydrogen atom in the *N*-substituent failed.^{50, 51} These compounds are thermally unstable and are readily dehydrochlorinated to *O*-ethers of oximes.

$\text{R}^1 = \text{Me, Et; R}^2 = \text{H, Et; R}^3 = \text{Et, Me}.$

$\text{R} = \text{H, Me}.$

Conversely, *N*-chloro-*O*-alkyl-*N-tert*-alkylhydroxylamines **3a–g** for which this dehydrochlorination is impossible are thermally stable under ambient conditions. They have been prepared by chlorination of the corresponding hydroxylamines^{4, 48, 52–57} and by cleavage of *N-tert*-alkyl-*N*-methoxy-*O*-methylhydroxylamine **4** upon treatment with acyl chlorides or chlorotrimethylsilane.^{58, 59}

$\text{R}^1 = \text{MeO}_2\text{CCMe}_2; \text{R}^2 = \text{Me} \text{ (a)}, \text{Pr}^i \text{ (b)};$

$\text{R}^1 = \text{MeO}_2\text{CCH}_2\text{CMe}_2; \text{R}^2 = \text{Me} \text{ (c)}, \text{Pr}^i \text{ (d)}, \text{PhCH}_2 \text{ (e)};$

$\text{R}^1 = \text{MeO}_2\text{CC}(\text{CF}_3)\text{Me}; \text{R}^2 = \text{Me} \text{ (f)};$

$\text{R}^1 = (\text{EtO}_2\text{C})_2\text{CHCMe}_2; \text{R}^2 = \text{Me} \text{ (g)}.$

$\text{XCl} = \text{AcCl, CF}_3\text{COCl, SOCl}_2, \text{Me}_3\text{SiCl}.$

The compound **3a** in a pure state decomposes over a period of 12 h at 20 °C,⁴ whereas **3c** can be distilled *in vacuo* and remains unchanged in solution (CCl_4) for at least a month.⁴

The only known acyclic *N*-bromo-*N,O*-dialkylhydroxylamine **6** was synthesised by bromination of the oxime *O*-ether **5** in the presence of CsF .⁶⁰

The attempt to prepare *N*-bromo-*N-tert*-alkyl-*O*-methylhydroxylamine **7** was unsuccessful; this compound is unstable and undergoes further transformations under the reaction conditions.⁵⁹

Acyclic fluorinated *N*-fluoro-*N,O*-dialkylhydroxylamines have been reported. These derivatives have been synthesised by fluorination of the corresponding NH-hydroxylamines,⁶¹ oxime *O*-ethers,⁶⁰ and trifluoronitrosomethane⁶² and by photochemical reaction of *N,N*-difluoroamines with trifluoromethyl peroxide.⁶³

$\text{R}_\text{F} = \text{CF}_3, \text{C}_3\text{F}_7.$

Apart from the acyclic *N*-halo-*N,O*-dialkylhydroxylamines described above, a number of cyclic analogues have also been described. 2-Haloxaziridines **8a–e** and **9a,d** have been obtained in two ways: by halogenation of the corresponding NH-oxaziridines and by oxidation of *N*-chlorimine **10**.^{24, 25, 64, 65}

$\text{R} = \text{R}' = \text{Me} \text{ (a)}; \text{R} = \text{Me, R}' = \text{Et} \text{ (b)}; \text{R} = \text{R}' = \text{Bu}^t \text{ (c)};$

$\text{R, R}' = (\text{CH}_2)_5 \text{ (d)}; \text{R, R}' = \text{CH}_2\text{CH}(\text{Me})(\text{CH}_2)_3 \text{ (e)};$

MCPBA is *m*-chloroperbenzoic acid;

MNPA is monoperphthalic acid.

The chloroxaziridines **8a–e** can be distilled *in vacuo* without decomposition; in a pure state, they can be kept unchanged for 1 month at 0 °C, while as solutions in CDCl_3 , they are stable for 1 h at 100 °C in sealed tubes. The 2-bromoxaziridines **9a,d** are stable for 1 week at 0 °C in inert solvents; neat compounds can be stored at –78 °C but vigorously decompose to give the corresponding ketone at temperatures above 0 °C.⁶⁵

Thermally stable 2-chloro- and 2-fluoro-perhalo-1,2-oxazetines **11** have been prepared by halogenation of the corresponding 1,2-oxazetines.^{23, 66}

$\text{Hal} = \text{Cl, F}.$

Dimethyl 2-chloro-1,2-oxazolidine-3,3-dicarboxylate **12** has been synthesised by the chlorination of 1,2-oxazolidine **13**²⁰ and by the reaction of the methoxy-derivative **14** with SOCl_2 .^{20, 58}

R = MeO₂CCMe₂.

Stable aziridine derivative **21** containing an *N*-methoxyhydrazine moiety was synthesised in 70% yield as the product of nucleophilic substitution of chlorine by reaction of **3c** with ethylene imine.⁷⁰

The instability of *N*-methoxyhydrazine derivatives⁷⁰ is due to the easy rupture of the N–O bond, caused by the vicinal $n_{\text{N}(1)}-\sigma^*_{\text{N}-\text{O}}$ orbital interaction. In the aziridine **21**, this interaction is weak, because the positive mesomeric effect of the ethylene imine nitrogen atom is low. This accounts for the stability of this compound.

Nevertheless, the reaction of the compound **3c** with 2,2-dimethylethylene imine under the same conditions affords the acyclic product **22**.⁷⁰

It was assumed that, due the fact that 2,2-dimethylethylene imine is more basic than ethylene imine, the aziridine ring in the chlorine substitution product **21a** formed initially is cleaved under the action of HCl according to an S_N2 mechanism.

The reactions of **3a,c** with pyridine also occur as nucleophilic substitution of chlorine.⁷⁰

R = MeO₂CCMe₂, MeO₂CCH₂CMe₂.

Based on kinetic studies, it was concluded that this reaction occurs by the S_N2 mechanism.²⁰

It was shown that methanolysis of optically active *N*-chloro-1,2-oxazolidine (+)-**12** (its synthesis is described in Section VIII) occurs with retention of the optical activity and affords *N*-methoxy-1,2-oxazolidine *R*-(–)-**14** with an optical purity of about 3%.^{19,20} However, since the optical purity and the absolute configuration of the starting (+)-**12** are unknown, no reliable conclusions about the mechanism of this reaction can be drawn.

b. Formation of *C*-nitroso-derivatives

C-Nitroso-derivatives **23a,b** have been prepared by hydrolysis of *N*-chloro-*N*-*tert*-alkyl-*O*-methylhydroxylamines **3a,c** in the presence of K₂CO₃^{10,71} or SbCl₅.⁷¹

R = MeO₂CCMe₂ [**23a** (88%)], MeO₂CCH₂CMe₂ [**23c** (91%)].

Hydrolysis of *N*-chloro-1,2-oxazolidine **12** also gives rise to a nitrosoalkane. However, this product is unstable and rearranges to oxime **24** as a result of migration of the methoxycarbonyl group from the C atom to the O atom.⁵⁷

These reactions proceed presumably *via* intermediate nitrenium-oxonium ions. Water is a hard nucleophile; therefore, in conformity with the general principles outlined in Section I, it reacts with these ions with dealkylation of the oxonium centre.¹⁰

c. Redox reactions

When *N*-chloro-*N*-*tert*-alkyl-*O*-methylhydroxylamines **3a,c** react with sterically hindered alcohols in the presence of Et₃N,⁴ sterically hindered amines (Et₃N, Et₂NH),¹⁰ Grignard reagents,¹⁰ triphenylphosphine,¹⁰ or sodium ethanethiolate,¹⁰ nucleophilic substitution of chlorine is suppressed completely or partially by the competing redox reaction. This reaction affords *N*-substituted-*N*-methoxyaminyl radicals, dimerisation of which results in the formation of unstable 1,2-dimethoxyhydrazine derivatives. Decomposition of these compounds yields the final products, diazene oxides **16a,c**.

R = MeO₂CCMe₂ (**a**), MeO₂CCH₂CMe₂ (**c**).

d. 1,2-Rearrangements

1,2-Rearrangement with migration of the phenyl group to the electron-deficient nitrogen atom is the predominant route of transformation of *N*-chloro-*O*-alkyl-*N*-triphenylmethylhydroxylamines under conditions of alcoholysis. This rearrangement occurs spontaneously even in the absence of an external nucleophile.¹¹

R = Me, MeO₂CCMe₂; R' = Me, Et.

A 1,2-rearrangement with migration of the alkyl or methoxycarbonyl group from the carbon atom to the nitrogen atom was found in the chlorination of the adducts of MeONH₂ with cyclohexanone or dimethyl mesoxalate. The rearrangement products were isolated after treatment with Et₃N.¹¹

The mechanism of these rearrangements has not been studied; however, they are believed to involve the formation of intermediate nitrenium ions.

2-Haloxaziridines **8** and **9**, unlike *N*-chloro-*N,O*-dialkylhydroxylamines, possess relatively low reactivity with respect to nucleophiles. In addition, the reactions of these compounds with some nucleophiles, for example, MeO[−], Me₂NH, morpholine, dimethyl sulfide, and diisopropyl sulfide, occur as substitution of oxygen rather than chlorine, *i.e.* when the nucleophile attacks the nitrogen atom, an oxygen-containing anion becomes the leaving group.⁶⁵

R¹ = R² = Me (**a**); R¹ = Me, R² = Et (**b**); R¹ = R² = Bu^t (**c**); R¹, R² = (CH₂)₅ (**d**); R₂³ = Me₂, (CH₂)₂O(CH₂)₂; R⁴ = Me, Prⁱ.

The intermediate **A** thus formed decomposes yielding the corresponding ketone and a substituted *N*-haloamine **B**. The latter reacts with amines giving rise to tetrazene **25** (apparently, *via* diazenium salt and *N*-aminonitrene) or reacts with dialkyl sulfides with formation of *N*-chlorosulfinimines **26**. The formation of sulfoxides **27** in the reactions of **8a,d** with dialkyl sulfides was explained by hydrolysis of *N*-chlorosulfinimines **26**.

3. Other reactions

N-chloro-*N*-*tert*-alkyl-*O*-methylhydroxylamine **3a**⁵⁹ and oxazolidine **12**²⁰ react with gaseous HCl to give the corresponding hydrochlorides **28** and **29**.

The reaction of the compound **3a** with CF₃COCl affords *N*-methoxytrifluoroacetamide **30**, the hydrochloride **28**, and methyl *N*-methoxycarbamate **31**.⁵⁹

Presumably, the trifluoroacetamide **30** is formed upon decomposition of the *N*-chloro-*N*-methoxy-*N*-trifluoroacetylammium salt formed intermediately. *N*-Methoxycarbamate **31** results from 1,2-rearrangement of the compound **3a**, accompanied by migration of the methoxycarbonyl group, and subsequent hydrolysis of the resulting intermediate **C** by traces of water. The HCl evolved during this process reacts with the initial compound **3a** according to the scheme described above to give the hydrochloride **28**.

Treatment of **3a** with reagents facilitating ionisation or heterolytic rupture of the N–Cl bond, for example, SO₂ or BF₃·Et₂O, also results in 1,2-rearrangement.⁵⁹

This is why SO₂ initiates the addition of *N*-chloro-*N,O*-dialkylhydroxylamines **3a,c** to isobutene.⁵⁵

R = MeO₂CCMe₂, MeO₂CCH₂CCMe₂.

The reactions of **3a** and **3c** with AgF·H₂O in MeCN can follow different pathways depending on the nature of the alkyl substituent at the nitrogen atom.¹⁰

In the case of **3c**, this reaction was assumed to occur *via* elimination of methoxynitrene from the intermediate nitrenium ion to give a *tert*-alkyl cation, which is stabilised through the Ritter reaction with acetonitrile or deprotonation.¹⁰

The same transformation of **3a** does not occur, because the corresponding *tert*-alkyl cation is less stable; therefore in this case, redox process predominates.¹⁰

N-Chloroxazolidine **12** is reduced by Na₂SO₃ to give 1,2-oxazolidine **13** in 67% yield.²⁰

It was found that the sterically hindered 2-chloroxaziridine **8c**, unlike non-hindered **8a,b,d**, rearranges to α -chloronitrosoalkane **35**. The rearrangement of pure **8c** at 0 °C proceeds slowly, whereas that in CDCl₃ at 60 °C occurs over 15–20 min.^{64, 65} It was assumed⁶⁵ that this rearrangement occurs as intramolecular attack by chlorine on the carbon atom of the oxaziridine ring.

During photolysis of 2-chloroxaziridine **8c**, the corresponding oxaziridinyl radical was detected by EPR spectroscopy.⁷²

IV. *N*-Halo-*N*-alkoxy-*O*-alkylhydroxylamines

The only fluorine-containing compound of this type was prepared in 3% yield by photochemical reaction of *N,N*-difluoro-*O*-trifluoromethylhydroxylamine with trifluoromethyl peroxide.⁶³

N-Bromo- and *N*-iodo-derivatives of *N*-alkoxy-*O*-hydroxylamines are unknown. *N*-chloro-derivatives are thermally unstable, due to the easy heterolysis of the N—Cl bond yielding dialkoxynitrenium ions stabilised by resonance; these ions undergo irreversible dealkylation through the action of the internal nucleophile, *i.e.* the chlorine atom. For instance, chlorination of *N*-benzyloxy-*O*-methylhydroxylamine by Bu^tOCl gives benzyl chloride and methyl nitrite resulting from decomposition of the intermediate *N*-chloro-*N*-benzyloxy-*O*-methylhydroxylamine, which could not be detected by ¹H NMR spectroscopy even at −30 °C.⁵

$$R = \text{PhCH}_2.$$

Nevertheless, *N*-chloro-*N*-methoxy-*O*-methylhydroxylamine was *in situ* involved in several reactions. It was found that in reactions with Me₃N and pyridine, this compound, unlike *N*-chloro-*N*,*O*-dialkylhydroxylamines (Section III), acts as a methylating rather than an aminating reagent.⁵

Nu = Me₃N, Py.

This difference between the behaviour of *N*-chloro-*N,O*-dialkylhydroxylamines and *N*-chloro-*N*-alkoxy-*O*-alkylhydroxylamines in the above reactions was explained⁵ by the fact that the nitrogen electrophilic centre in the latter is 'harder' and, hence, the orbitally controlled addition of nucleophiles to the nitrenium centre becomes possible only for very 'soft' nucleophiles containing high-lying HOMO. A similar difference in the properties has also been noted for monoalkoxy- and dialkoxycarbenium cations.⁷³

In accordance with the foregoing, nucleophilic substitution of chlorine in *N*-chloro-*N*-alkoxy-*O*-alkylhydroxylamines occurs under the action of sodium methoxide and yields trialkoxyamines **36a,b**.^{5, 74}

R = Me [**36a** (64%)], Et [**36b** (50%)]; DME is dimethoxyethane.

V. Derivatives of *N,N*-dihalohydroxylamines

The only known compounds of this type are *N,N*-difluorohydroxylamine derivatives. The data on the synthesis and properties of compounds of the general formula XONF_2 , where $\text{X} = \text{CF}_3$, C_2F_5 , $\text{Cl}(\text{CF}_2)_2$, FOCH_2 , F_2NOCH_2 , $(\text{CF}_3)_2\text{N}$, FCO_2 , FSO_2 , SF_5 , published before 1976 have been surveyed in reviews.^{27,28} Later, a method for the synthesis of *N,N*-difluoro-*O*-perfluoroalkylhydroxylamines by reaction of perfluoroalkyl hypofluorites with difluoroamine–alkali metal fluoride complexes has been developed.⁷⁵

$$R_F = CF_3, \text{ iso-}C_3F_7, FOCF_2; MF = KF, RbF, KF-NaF.$$

N,N-Difluorohydroxylamine derivatives have also been synthesised by reactions of trifluoroamine oxide with fluoroalkenes in the presence of Lewis acids (BF_3 , AsF_5 , SbF_5).^{76, 77}

R = F, Cl, Br, C₂F₅O, C₃F₇OCF(CF₃)CF₂O;

R = CF₃, C₅F₁₁, SF₅, FCO.

N,N-Difluorohydroxylamines **37** are cleaved by AsF₅ to give FNO, which is formed as a nitrosonium salt.⁷⁸

R = CF₃, SF₅.

In reaction with perfluorocyclobutene, *O*-fluorosulfonyl-*N,N*-difluorohydroxylamine **38** acts as a pseudohalogen.⁷⁹

The reactions of **38** with ethylnitramine, ethylenedinitramine, and salts of azoles (imidazoles, pyrazoles, triazoles) lead to *N*-fluorosulfonylation products.⁸⁰ The reaction of **38** with the sodium salt of pyrazole was reported to be an example.⁸⁰

The reaction of the sodium salt of 4-nitrotriazole with the compound **38** is accompanied by ring opening. Subsequent hydrolysis affords formylnitrodiazomethane in 36% yield.⁸⁰

VI. *N*-Halo-*N*-alkoxyamides

As noted above, a typical feature of systems containing the O–N–Hal triad is polarisation of the N–Hal bond towards the halogen, which accounts for its anionic mobility. When the nitrogen atom carries an electron-withdrawing substituent, polarisation of the N–Hal bond decreases or even changes its direction, which has a substantial influence on the properties of these systems.

1. *N*-Halo-*N*-alkoxyphosphamides

N-Halo-*N*-alkoxyphosphamides **39**,⁸¹ **40**,³⁸ and **41**⁸² have been prepared by halogenation of the corresponding NH amides.

R = Me (a), PhCH₂ (b), Bu (c), Et (d).

The compounds **39a–d** are stable in a benzene solution (withstand refluxing for several hours); however, in a pure state they decompose over a period of 2 days at 0–5 °C. They give the typical 'positive chlorine' reaction.⁸¹ The addition of **39c** to styrene occurs by a radical mechanism and is not regiospecific yielding adducts **42** and **43** and some other products.⁸¹

The attempts to carry out nucleophilic substitution of the chlorine atom in *N*-chloro-*N*-alkoxyphosphamides **39a** and **40a** failed. The reaction with MeONa in MeOH involves the phosphoryl group and is accompanied by elimination of the pseudo-halogen fragment N(Cl)OMe.³⁸ The compound **39a** reacts with MeOH in the presence of Et₃N giving rise to amide **44**.³⁸

Photolysis of a solution of *N*-bromo-*N*-tert-butoxyphosphamide **41** in cyclopropane at –100 °C gave radical **45**, which was detected by EPR spectroscopy.⁸²

2. *N*-Halo-*N*-alkoxysulfonamides

N-Halo-*N*-alkoxysulfonamides **46a–e**^{1,38,83} and **47**^{84,85} have been described.

R = Me, R' = Me (a), MeSO₂ (b);

R = 4-MeC₆H₄, R' = Me (c);

R = Me₂N, R' = PhCH₂ (d);

R = 2,6-Me₂-4-Bu^tC₆H₂, R' = Bu^t (e).

R = Me, Me₂N, 4-O₂NC₆H₄,

R' = Bu^t; R = 4-MeC₆H₄,

R' = Me, Et, Prⁱ, Bu^t, PhCH₂;

R = 2,6-Me₂-4-Bu^tC₆H₂,

R' = Me, Bu^t, PhCH₂.

The attempt to prepare the *N*-Br analogue of the compound **46a** resulted in the formation of 1,2-dimethoxyhydrazine derivative **48**.⁸³

Halogenation of compound **49** yields hyponitrite **50**, apparently *via* the intermediate thiadiaziridine dioxide.^{46,86}

XHal = NaOCl, NaOBr, chloramine T.

N-Halo-*N*-alkoxysulfonamides **46a,b,d** act as chlorinating reagents with respect to H₂O and MeOH, being thus converted into the corresponding NH amides.^{38,83} Thus compound **46c** chlorinates aniline into the aromatic ring.¹

Photolysis of solutions of *N*-bromo-*N*-alkoxysulfonamides **47** in CFCl₃ or in a mixture of CFCl₃ with CH₂Cl₂ at –30 to –60 °C is accompanied by the generation of the corresponding *N*-alkoxysulfonamidyl radicals, which have been detected by EPR spectroscopy.^{84,85}

3. *N*-Halo-*N*-alkoxycarbamates

The only known compound of this type, methyl *N*-chloro-*N*-methoxycarbamate **52**, was synthesised by chlorination of the *N*-methoxycarbamate **51**. It can be distilled *in vacuo* without decomposition; upon treatment with MeOH and Et₃N it is converted into the initial *N*-methoxycarbamate **51** and hydrazine derivative **53**.^{87, 88}

4. *N*-Chloro-*N*-alkoxyureas

N-Chloro-*N*-alkoxyureas **54**,^{89, 90} **55a–h**,^{38, 91, 92} **56**,^{8, 93, 94} and **57a–i**⁹⁵ have been prepared by chlorination of the corresponding NH ureas with Bu^tOCl.

n = 0, 2, 3.

Ar = Ph (a), 4-ClC₆H₄ (b), 4-O₂NC₆H₄ (c), 4-MeC₆H₄ (d), 4-CNC₆H₄ (e), 4-MeSO₂C₆H₄ (f), 3-F₃CC₆H₄ (g), 3,4-Cl₂C₆H₃ (h), 2,6-Me₂C₆H₃ (i).

The compound **55a** was also obtained by cleavage of *N,N*-dimethoxyurea **58** upon treatment with acetyl chloride.⁹⁶

N-Chloro-*N*-alkoxyureas **54**, **55a–h**, **56**, and **57a–i** are non-distillable liquids or crystalline solids stable under ambient conditions. At room temperature in a CCl₄ solution, **55a** completely decomposes over a period of 25 days to give methyl *N,N*-dimethylcarbamate **59** and *N,N*-dimethylcarbamoyl chloride **60** in 1 : 1 ratio.³⁸

The carbamoyl chloride **60** results presumably from a concerted rearrangement with migration of chlorine to the carbonyl group and ejection of methoxynitrene (HERON rearrangement).⁹⁷ The driving force of this migration is the orbital *n*_O–σ*_{N–Cl} interaction in the O–N–Cl structural fragment. The *N,N*-dimethylcarbamate **59** is formed in this process upon interaction of *N,N*-dimethylcarbamoyl chloride with the MeOH produced among the products of decomposition of the intermediate methoxynitrene;³⁸ this process is shown below:

Among *N*-chloro-*N*-methoxyureas **57a–i**, only those which contain electron-withdrawing substituents in the aryl group are thermally stable under ambient conditions. The compound **57a** isomerises at room temperature giving *N*-(4-chlorophenyl)-*N'*-methoxyurea.⁹⁵

N-Chloro-*N*-alkoxyureas readily undergo nucleophilic substitution of chlorine atoms, because the carbamoyl group does not have any significant effect on the polarisation of the N–Cl bond. This also accounts for the similarity of chemical properties of *N*-chloro-*N*-alkoxyureas and *N*-chloro-*N,O*-dialkylhydroxylamines (see Section III). Thus *N*-chloro-*N*-alkoxyureas **54–56** react with alcohols and glycols in the presence of bases affording *N,N*-dialkoxyureas.^{8, 38, 89–94} For instance, these reactions have been described for **55a–h**.³⁸

B = R'ONa, collidine, NaOAc;

R' = Me, Et, Bu^t, CH₂=CHCH₂, CF₃CH₂, HO(CH₂)₂.

Intramolecular cyclisation of *N*-chloro-*N*-alkoxyurea **55h** gives rise to 1,3,2-dioxazolidine **61**.⁹⁸

B is collidine.

Products of nucleophilic substitution of chlorine in *N*-chloro-*N*-methoxyureas **55a** and **57b** were also obtained with other nucleophilic reagents.^{95, 99}

Nu = Me₃N, Py; R = Me, Ph.

On treatment with bases, *N*-chloro-*N*-methoxyureas **57a–h** cyclise to give 1-methoxy-2-benzimidazolinones **62**.⁹⁵

B = Bu^tOK, NaH.

The formation of non-aromatic intermediate **D** during the cyclisation of **57i** was proved by isolation of its adduct with MeOH.⁹⁵

The reaction of *N*-chloro-*N*-methoxyurea **55a** with Me₂NH affords bis(dimethylamino)methane **63** and the urea **64**,⁹⁹ these products are formed *via* a scheme similar to that considered in Section III for the reaction of *N*-chloro-*N*-*tert*-alkyl-*O*-methylhydroxylamine **3c** with Me₂NH. Dimethylurea **64** results apparently from carbamoylation of Me₂NH by an intermediate product.

The reaction of *N*-chloro-*N*-methoxyurea **55a** with *N,O*-dimethylhydroxylamine affords diazene **65** in 38% yield.⁹⁹ This reaction proceeds presumably according to a similar scheme except that the intermediate aminal does not disproportionate, but instead, it eliminates MeOH yielding the product **65**.

In the reaction of *N*-chloro-*N*-methoxyurea **55a** with Et₃N, nucleophilic substitution of chlorine is hampered for steric reasons. Therefore, a redox reaction occurs, the final products of which are formed upon transformations of the *N*-methoxycarbamidyl radical and substituted 1,2-dimethoxyhydrazine formed as intermediates.⁹⁹

5. *N*-Halo-*O*-alkylhydroxamates

Among compounds of this type, only *N*-chloro-derivatives are known; they are synthesised by the chlorination of the corresponding NH hydroxamates with Bu^tOCl. The attempts to iodinate and brominate *N*-methoxyamide of biphenyl-2-carboxylic acid resulted in the formation of *N*-methoxy-phenanthridone **66**, hydrazine derivative **67**, and the product of its decomposition **68**.^{13, 37}

X = Br, I.

Conversely, *N*-chloro-*N*-methoxyamide **69** is stable under ordinary conditions; its photolysis is accompanied by rupture of the N–Cl bond and gives the hydrazine **67**, resulting from dimerisation of the intermediate *N*-methoxyamidyl radical, and compound **68**.^{13, 37}

N-Alkoxyamidyl radicals have been detected by EPR spectroscopy during the photolysis of *N*-chloro-*O*-alkylhydroxamates **70**,¹⁰⁰ **72**, and **73**.¹⁰¹

R = H, Ph; X = Et₂C, PhN, MeN.

Similarly to *N*-chloro-*N*-alkoxyureas, *N*-chloro-*O*-alkylhydroxamates are able to undergo nucleophilic substitution of chlorine. Thus reaction of the compound **70** with sodium salt **74** gives hydrazine derivative **71** in a quantitative yield.¹⁰⁰

Two other reactions of *N*-chloro-*N*-alkoxybenzamides **75** — alcoholysis^{102, 103} and transformation into *N*-acetoxy-*N*-alkoxybenzamides **76** on treatment with silver acetate in ether — also proceed smoothly.^{102, 104}

R = Et, Bu, C₈H₁₇, PhCH₂.

However, alcoholysis of *N*-chloro-*N*-alkoxyarylamides **77a–h** does not result in nucleophilic substitution of chlorine.¹⁰⁵ Depending on the nature of the substituent R, these reactions give mostly compounds **78–80**.

R = Ph, R' = Me (**a**), PhCH₂ (**b**), Bu¹ (**c**); R = 4-MeOC₆H₄, R' = Me (**d**); R = 2-naphthyl, R' = Me (**e**); R = 4-O₂NC₆H₄, R' = Me (**f**); R = PhCO, R' = PhCH₂ (**g**); R = PhCH₂, R' = Me (**h**).

An important characteristic feature of *N*-chloro-*O*-alkylhydroxamates is their ability to be converted on treatment with Lewis acids into highly reactive intermediates, *N*-acyl-*N*-alkoxy-nitrenium ions,^{12–18, 33} which tend to undergo inter- and intramolecular electrophilic aromatic substitution. As a rule, these reactions occur at room temperature in the presence of metal ions (Ag⁺, Zn²⁺, Pd²⁺, Fe²⁺, Hg²⁺). The best results were achieved by using AgBF₄–THF, Ag₂CO₃–CF₃COOH, and Zn(OAc)₂–MeNO₂ systems. For instance, cyclisation of *N*-chloro-*N*-methoxyarylamides **81** is an efficient method for the synthesis of 2-hydroxy-1-methoxyindoles **82**.^{12, 14, 16–18}

R¹ = R³ = R⁴ = H, R² = Cl, Br, Me, MeCONH, NO₂; R¹ = R² = MeO, R³ = R⁴ = H; R¹ = R³ = R⁴ = H, R² = NO₂; R¹ = R⁴ = H, R² = MeO, R³ = Me; R¹ = H, R² = MeO, R³ = R⁴ = Me.

In principle, the electrophilic attack by the intermediate nitrenium ion is directed at one of three positions in the aromatic ring, C(1), C(2), or C(6).¹⁸ When the aromatic ring contains an *ortho*-substituent, the nitrenium ions attack C(2) and C(6).

Cyclisation of *N*-chloro-*O*-alkylhydroxamates **83** can involve the aromatic ring of both arylacyl and arylalkoxyl substituents.

R = (CH₂)_nPh.

In the former case, the reaction yields γ, δ, and ε-*N*-alkoxy-lactams **84**, while in the latter case, it gives 2,1-benzoxazepines and 2,1-benzoxazines but not benzoxazoles. It was shown experimentally¹⁵ that benzoxazepines result from the *ipso*-attack of the intermediate nitrenium ion on the aromatic nucleus followed by 1,2-migration of the alkyl group, while benzoxazines are formed upon the *ortho*-attack.

The cyclisation of *N*-chloro-*O*-alkylhydroxamates containing an *ortho*- or *para*-methoxy-substituted aryl group occurs through the *ipso*-attack of the intermediate nitrenium ion on the aromatic ring and affords spirodienones.^{14, 18} For example, compounds **86** and **87** have been prepared in this way.¹⁸

Yield of **86** (%): 71 (*n* = 1), 83 (*n* = 2), 83 (*n* = 3);

Yield of **87** (%): 82 (*n* = 2), 39 (*n* = 3).

N-Chloro-*O*-alkylhydroxamates are able to accomplish electrophilic amination of aromatic compounds in the presence of silver salts to give *N*-alkoxy-*N*-arylamides in 20%–93% yields.^{12–14, 16, 18}

ArH = C₆H₆, PhMe, *p*-MeC₆H₄, PhOMe, C₁₀H₈, PhCOOMe.

VII. Structure and stereochemistry

The stereoisomerism of molecules with a tricoordinated nitrogen atom is due to its pyramidal configuration. However, usual

N-alkylamines possess low configuration stabilities; the barriers to their pyramidal inversion ($\Delta G^\ddagger$) amount to 20–30 kJ mol⁻¹.^{106–108} An electronegative substituent at the nitrogen atom increases the inversion barriers by inducing rehybridisation of the bonding orbitals of the N atom accompanied by an increase in the *p*-character of the N–X σ -bond and, correspondingly, by an increase in the *s*-character of the nitrogen lone pair orbital.^{106–108} In addition, the planar transition state of the inversion is destabilised by the four-electron interaction between the lone pairs of the two linked heteroatoms. Both effects act in the same direction increasing the pyramidal stability. Indeed, the barriers to inversion in *N,N,O*-trialkylhydroxylamines¹⁰⁹ and in *N*-chloro-^{110,111} and *N*-fluoroamines¹¹¹ are as high as 40–50, 38, and 63 kJ mol⁻¹, respectively. The presence of two heteroatoms at the nitrogen atom in the O–N–Hal system accounts for the substantially increased configurational stability of the corresponding derivatives. In this case, the orbital $n_O-\sigma^*_{N-Hal}$ interaction also contributes to the stabilisation of the pyramidal configuration of the N atom.^{29,34,112,113} The inversion barriers in the *N*-chloro-*N,O*-dialkylhydroxylamines **3a,c,g** are 79–83 kJ mol⁻¹.⁴ The inversion barrier predicted⁴ for *N*-fluoro-*N,O*-dialkylhydroxylamines is 113 kJ mol⁻¹.

When the N atom is incorporated in a ring, its pyramidal stability further increases, because in this situation, the change of the nitrogen hybridisation to *sp*² in the planar transition state to inversion increases ring strain. Naturally, this effect is more pronounced in rigid bicyclic systems and in small rings. For instance, the inversion barrier in 2-chloro-1,2-oxazolidine **12** ($\Delta G^\ddagger = 87$ kJ mol⁻¹)^{19,20} is, on the average, 7 kJ mol⁻¹ higher than that in its acyclic analogues **3**.⁴ The nitrogen inversion in 2-chloro- and 2-fluoro-substituted perhalo-1,2-oxazetidines **11** is also hindered under normal conditions,²² and the corresponding 4-monochloro-derivatives have been obtained as stable invertomers.²³ The record-holding height of the barrier to the pyramidal inversion of nitrogen *via* a planar transition state ($\Delta H^\ddagger = 184.8$ kJ mol⁻¹) was predicted for non-substituted 2-chloroxaziridine by *ab initio* calculations in the 3–21G basis set.²⁶ However, the barrier for 2-chloroxaziridine found experimentally based on the kinetics of racemisation was almost three times lower ($\Delta H^\ddagger = 63.9$ kJ mol⁻¹, $\Delta S^\ddagger = 43.5$ e.u., and $\Delta G^\ddagger = 132$ kJ mol⁻¹ at 100 °C in *n*-heptane), and, besides, the rate of inversion increased by an order of magnitude on going to a polar solvent (*n*-butanol).²⁶ This was explained by assuming that in this case, inversion occurs by a dissociative mechanism, because inversion *via* a planar transition state is characterised by low $\Delta S^\ddagger$ values and slows down in polar solvents due to the more efficient solvation of the ground state, which is more polar (the calculation for 2-chloroxaziridine in the same basis set predicts the values $\mu = 2.7$ and 3.6 D for the transition and ground states, respectively). The transition state to the dissociative inversion is represented by a contact ion pair, because ionic mobility of chlorine is not manifested in reactions of 2-chloroxaziridines **8a–d** and **9a**.⁶⁵ The driving force of ionisation is the orbital $n_O-\sigma^*_{N-Cl}$ interaction, which results, according to the 2-chloroxaziridine structure optimised in the 6–31G* basis set, in a substantially lengthened N–Cl bond.²⁵

The introduction of a π -electron-withdrawing substituent to the nitrogen atom sharply decreases the barrier to its inversion, because π -conjugation is most efficient in the planar transition state.^{106,107} In fact, the calculated inversion barrier for *N*-chloro-*N*-formyl-*O*-methylhydroxylamine is only 10.5 kJ mol⁻¹.³⁴ For this compound, two other hindered processes can be expected, namely, amide rotation and rotation around the N–O bond with the maximum barriers of 47 and 55 kJ mol⁻¹, respectively.³⁴ The latter is ~ 10 kJ mol⁻¹ higher than the barriers to rotation around the N–O bond in *N,N,O*-trialkylhydroxylamines.¹⁰⁹ This increase in the barrier to the rotation around the N–O bond in *N*-chloro-*N*-formyl-*O*-methylhydroxylamine is due to the orbital $n_O-\sigma^*_{N-Cl}$ interaction, which makes the N–O bond ‘more double’.³⁴ The height of this barrier is in good agreement with the experimental $\Delta G^\ddagger_{N-O}$ value, equal to 58 kJ mol⁻¹, which was

determined for *N*-chloro-*N*-alkoxyurea **55g** by dynamic NMR.¹¹⁴ In *N*-chloro-*N*-alkoxyureas **55a,e,g**, hindered rotation around the Me₂N–C amide bond is also observed, the corresponding barriers being 60–67 kJ mol⁻¹.¹¹⁴

There are no experimental data about the structures of *N*-halohydroxylamines. The results of semiempirical and non-empirical calculations for 2-chloroxaziridine,^{25,65,115} *N*-chlorohydroxylamine,³³ *N*-chloro-*N*-methylhydroxylamine,⁶⁵ *N*-chloro-*N*-formylhydroxylamine,³³ *N*-chloro-*N*-formyl-*O*-methylhydroxylamine,³⁴ *N*-fluorohydroxylamine,^{116–121} *N,N*-difluorohydroxylamine,^{119,121} *N,O*-difluorohydroxylamine,^{119–121} trifluorohydroxylamine,^{119,121} and *N,N*-difluoro-*O*-fluorosulfonylhydroxylamine¹²² demonstrate that their geometry is affected by the anomeric $n_O-\sigma^*_{N-Hal}$ interaction, which is manifested as elongation of the N–Hal bonds and shortening of the N–O bonds in these compounds. In addition, it was shown that the energetically preferred conformation for *N*-chloro-³³ and *N*-fluorohydroxylamines^{116–121} as well as for *N*-chloro-*N*-formylhydroxylamine³³ and *N*-chloro-*N*-formyl-*O*-methylhydroxylamine³⁴ is that in which the H–O (or C–O) and N–Hal bonds are nearly perpendicular to each other and, hence, the anomeric $n_O-\sigma^*_{N-Hal}$ interaction is the maximum (Fig. 2, conformation A).

In the case of di- and trifluorohydroxylamines, conformation

Figure 2. Newman projections along the O–N bond for *N*-halohydroxylamine derivatives XON(Y)Hal. **A:** X = Y = H, Hal = Cl, F; X = H, Y = HCO, Hal = Cl; X = Me, Y = HCO, Hal = Cl; **B:** X = H, Y = F; X = F, Y = H; X = Y = F.

B (Fig. 2) has been predicted to be more stable; this conformation is stabilised by the $n_N-\sigma^*_{O-F}$ interaction, which is the most efficient in *O*-fluorohydroxylamine.

VIII. Optically active cyclic *N*-chlorohydroxylamines

The first optically active compound of this type, (+)-2-chloro-1,2-oxazolidine (+)-**12**, in which only the nitrogen atom was chiral, was prepared in a quantitative yield by cleavage of amination (*S*)-(-)-**88** by chlorine at –78 °C.^{19,20}

R = MeO₂C.

However, the time needed for its half-racemisation at 13 °C is only 8 min. The high configurational stability of 2-chloroxaziridines, the half-racemisation time of which at 20 °C is 833 years, made it possible to synthesise them in optically active forms by asymmetric chlorination and kinetic resolution.^{24,25}

CCl is *N*-chlorocamphorimide;

1-Eph is 1-ephedrine.

The absolute configurations of **8d** and **8e** were determined by NMR and CD methods.²⁵ The compound (5*S*)-(+)-**8e** was prepared as a mixture of two diastereoisomers in a ratio of 1.5:1, the absolute configuration of the predominant isomer being (2*R*,3*S*,5*S*). The sign of the Cotton effect of the long-wave band in the CD spectrum of optically active 2-chloroxaziridines was shown to be mostly determined by the absolute configuration of the N atom and to depend only slightly on the configurations of the carbon chiral centres.²⁵

IX. Conclusion

Analysis of the published data demonstrates that during the four decades of studies on the chemistry of *N*-halohydroxylamine derivatives, substantial progress has been achieved in this field. All main types of these compounds have been synthesised, namely, acyclic and cyclic *N*-halo-*N*,*O*-dialkylhydroxylamines, *N*-fluoro-*N*-alkoxy-*O*-alkylhydroxylamines, derivatives of *N*,*N*-difluorohydroxylamine, and *N*-halo-*N*-alkoxyamides. It was found that *N*-halo-*O*-alkylhydroxylamines and *N*-chloro-*N*-alkoxy-*O*-alkylhydroxylamines are thermally unstable under ambient conditions; nevertheless, they can be involved *in situ* in various chemical reactions.

The halogen atom in most of the systems containing the O–N–Hal triad can be easily removed as the anion, which is due to the hyperconjugation $n_{\text{O}}-\sigma^*_{\text{N-Hal}}$. Hence, *N*-chloro-*N*-tert-alkyl- and *N*-chloro-*N*-alkoxy-*O*-alkylhydroxylamines are powerful alkoxyaminating reagents.

A fundamentally important result obtained along this line is the discovered possibility of nucleophilic substitution of chlorine in '*N*-chloramides': *N*-chloro-*N*-alkoxyureas and *N*-chloro-*O*-alkylhydroxamates the chlorine atom of which, unlike that in their *N*-alkyl analogues, possesses anionic mobility. Under the action of Lewis acids, *N*-chloro-*O*-alkylhydroxamates form highly reactive intermediates, *N*-acyl-*N*-alkoxynitrenium ions, capable of reacting with aromatic compounds in intermolecular and intramolecular processes of electrophilic aromatic substitution.

Compounds containing O–N–Hal fragments belong to one of the few types of derivatives characterised by high pyramidal stability of the nitrogen atom. As a result, 2-chloroxaziridines and 2-chloro-1,2-oxazolidine derivatives have been partially resolved into optical antipodes with an asymmetric N atom.

The orbital $n_{\text{O}}-\sigma^*_{\text{N-Hal}}$ interaction in O–N–Hal systems accounts for the predominant existence of the conformation with nearly *anti*-periplanar *p*-orbital of the oxygen atom in relation to the N–Hal bond.

N-Amino-substituted derivatives of *N*-halo-*O*-alkylhydroxylamines remained beyond the scope of this review, because, similarly to *N*-halohydrazines, they exist entirely as alkoxydiazonium salts $\text{R}_2\text{N}^+=\text{NOR Hal}^-$.¹²³ These compounds act as aminoaminating reagents and undergo *O*-dealkylation upon treatment with nucleophiles [see Scheme 1, pathways (a) and (b)].

The vicinal orbital interaction considered for the O–N–Hal system and related anomeric effects are typical properties of many other geminal systems, for example, N–E–Hal and O–E–Hal, where E = C, N, O, P, S.

The review was supported by the Russian Foundation for Basic Research (Project No. 97–03–33021) and the INTAS (Grant No. 94–2839).

Organic derivatives of monocoordinated tellurium

I D Sadekov, A A Maksimenko, V L Nivorozhkin

Contents

I. Introduction	193
II. Synthesis and reactions of compounds containing C=Te bonds	193
III. Synthesis, reactions, structures, and spectroscopic characteristics of phosphine tellurides $R_3P=Te$	200
IV. Conclusion	206

Abstract. Data on the methods of synthesis, structures, and reactivity of organic derivatives of monocoordinated tellurium, namely, compounds with C=Te bonds and phosphine tellurides $R_3P=Te$, are described systematically and generalised. The use of the latter compounds as synthetic equivalents of elemental tellurium for the preparation of metal tellurides is considered. The bibliography includes 139 references.

I. Introduction

Organic derivatives of monocoordinated tellurium, namely, compounds with C=Te bonds and phosphine tellurides $R_3P=Te$, constitute a relatively little studied class of organotellurium compounds. In fact, the first phosphine telluride, tributylphosphine telluride, was synthesised in 1963,¹ while the first and still the only one known stable telluroketone, 1,1,3,3-tetramethylindanetellone, which is stable only in solution, was synthesised only in 1993.² The synthesis, structure, and chemical properties of tellurocarbonyl compounds and phosphine tellurides have been considered most comprehensively in a monograph devoted to the chemistry of organic derivatives of selenium and tellurium.^{3,4} However, during more than a decade, which has passed after the publication of this monograph, the number of studies dealing with the derivatives of monocoordinated tellurium has approximately doubled. New fields of application of tellurocarbonyl compounds have been discovered, for example, as dienophiles in the syntheses of six- and seven-membered tellurium-containing heterocycles. Of special interest is the use of phosphine tellurides as synthetic analogues of elemental tellurium for the synthesis of some organotellurium compounds, which undergo thermal decomposition under relatively mild conditions to give metal tellurides⁵ possessing semiconductor and other valuable properties.

II. Synthesis and reactions of compounds containing C=Te bonds

Up to now, four types of tellurocarbonyl compounds have been described in the literature: telluroketones (telluroaldehydes) $R_2C=Te$ ($R = H, \text{Alk}, \text{or Ar}$), tellurocarboxylic acids

$RC(=Te)OH$, *O*-alkyl tellurocarboxylates $RC(=Te)OR^1$, and telluroamides $RC(=Te)NR^1R^2$ and their analogues (tellurohydrazides and telluroureas). These compounds sharply differ in stability. Only representatives of the two latter types have been isolated in a pure state. The formation of telluroketones (telluroaldehydes) and tellurocarboxylic acids is judged either from the NMR spectra of reaction mixtures or from the products of their chemical transformations. However, the stability of tellurocarbonyl compounds of all these types is substantially enhanced when the tellurocarbonyl carbon atom carries bulky organic substituents or relatively strong π -electron-donating groups ($OR, NR_2, NR^1NR_2^2$) or upon coordination to transition metal compounds. It should be noted that one of the most efficient methods used to increase the stability of other classes of organotellurium derivatives, such as tellurenyl halides, azides, acetates, and isothiocyanates, diorganyl tritellurides, *etc.*, has not been used so far in the chemistry of tellurocarbonyl compounds. This method consists in the introduction, into appropriate positions of aryl or alkenyl substituents of functional groups ($CHO, COR, CO_2R, NO_2, N=N, CH=N, CH_2NMe_2$, *etc.*) containing sp^2 (or, more rarely, sp^3) hybridised O or N atoms, which form strong intramolecular coordination bonds with Te atoms.⁶

1. Telluroaldehydes and telluroketones

Despite the apparent similarity of chalcogens (S, Se, Te),⁷ their properties are appreciably different; therefore, in some cases, methods that are used successfully for the synthesis of organic derivatives of sulfur and selenium cannot be used to prepare their tellurium analogues. For example, 'dialkyl telluroketones' have been described in a study,¹⁰ which is cited in monographs dealing with the chemistry of organotellurium compounds.^{8,9} They were synthesised by a method similar to a method used to prepare thioketones, namely, by the reaction of the corresponding ketones with H_2Te in a strongly acidic medium. However, in reality, the reactions of H_2Te , generated *in situ* from aluminium telluride and water, with aldehydes and ketones afford alcohols¹¹ or mixtures of dialkyl ditellurides with alcohols.¹² Alcohols are formed in 50%–100% yields when H_2Te is passed through solutions of carbonyl compounds in THF.¹¹ When solutions of aldehydes contain strong acids ($CF_3COOH, PhSO_3H, H_2SO_4$), dialkyl ditellurides **1** are formed as the main reaction products (yields 34%–56%); in this case, only traces of primary aliphatic alcohols are formed.¹² Ketones react in a similar way, but the yields of the corresponding dialkyl and di(cycloalkyl) ditellurides are lower.¹²

I D Sadekov, A A Maksimenko, V L Nivorozhkin Research Institute of Physical and Organic Chemistry of the Rostov State University, prosp. Stachki 194/2, 344090 Rostov-on-Don, Russian Federation. Fax (7-863) 228 56 67. Tel. (7-863) 228 08 94 (I D Sadekov)

Received 3 June 1997

Uspekhi Khimii 67 (3) 219–235 (1998); translated by Z P Bobkova

According to the scheme proposed by the researchers cited,¹² the ditellurides **1** result from the reduction of telluroaldehydes **2** with hydrogen telluride. The influence of pH on the outcome of these reactions is due to the fact that in strongly acidic media the acid–base equilibrium $3 \rightleftharpoons 4$ is almost entirely shifted to the right:

a. Stable telluroketones

As noted above, 1,1,3,3-tetramethylindanetellone **5** is the only stable, although only in solution, telluroketone that has been characterised by various spectroscopic methods.² This compound was obtained in an almost quantitative yield, together with alkenes **6a** and **6b**, upon thermolysis of 1,3,4-tellurodiazoline **7**; the compound **7** was synthesised in 26% yield by treating the hydrazone of 1,1,3,3-tetramethylindanone with tellurium dichloride in the presence of Et₃N.¹³

The telluroketone **5** is very sensitive to oxygen and light; on exposure to UV radiation, it is converted into a mixture of ditelluride **8** and 1,1,3,3-tetramethylindanone.² The ¹³C NMR signal for the C=Te-group carbon atom (δ 301 ppm) is substantially shifted downfield with respect to the signals for other C=X groups (C=O, δ 226.0 ppm; C=S, δ 282.1 ppm; C=Se, δ 294.0 ppm). The same is true for the ¹²⁵Te signal (δ 2858.3 ppm in relation to Me₂Te), which is the lowest-field signal in the series of organotellurium compounds known. The long-wave absorption band (λ = 825 nm) in the UV spectrum of the ketone **5** undergoes substantial bathochromic shift with

respect to the bands of the corresponding selenium (λ = 667 nm) and sulfur (λ = 527 nm) derivatives.

The compound **5** enters into 1,3-dipolar cycloaddition with mesitylnitrile oxide yielding a derivative of a new heterocyclic system, oxatellurazole **9**. Like other tellurocarbonyl compounds (see below), the ketone **5** enters into the Diels–Alder reaction with 2,3-dimethylbutadiene² to give compounds **11** and **8** in addition to 1-telluracyclohex-3-ene derivative **10**.

The complex **12** was synthesised in a yield of more than 70% by the reaction of the telluroketone **5** with the complex (CO)₅W·THF.¹⁴ Earlier, complexes of this type had been obtained only by insertion of a Te atom into C=M bonds in transition metal complexes.

The compound **12** was isolated as dark-violet crystals. Unlike the initial telluroketone, it is resistant to heating and exposure to light. The signals for the C=Te-group atoms in the ¹³C and ¹²⁵Te NMR spectra are shifted upfield with respect to the corresponding signals in the spectra of **5**; they are manifested at δ 285 and 1783 ppm, respectively. The C=Te bond length in the complex **12** found by X-ray diffraction analysis¹⁴ amounts to 1.987 Å, which is close to the length of the similar bond in S=C=Te (1.904 Å);¹⁵ this indicates that the order of the C=Te bond in **12** is closer to two. The telluroketone **5** is a relatively weak donor; in fact, when the complex **12** is heated in MeCN at 60 °C, the tellurium-containing ligand is quantitatively replaced by MeCN.

b. Methods for the generation of unstable telluroaldehydes and telluroketones. Dimerisation and the Diels–Alder reaction

All the telluroaldehydes and telluroketones, except for the ketone **5**, are unstable. Conclusions about the formation of these compounds are based on the structures of products of their subsequent chemical transformations, first of all, dimerisation (or trimerisation in the case of telluroformaldehyde) and the Diels–Alder reaction.

Telluroformaldehyde was the first telluroaldehyde reported in the literature. It was obtained by treatment of tellurium mirrors with the carbene generated by thermal decomposition of diazomethane^{16–18} or by photodissociation of ketene.¹⁷ On cooling, the gaseous monomeric telluroformaldehyde trimerises to yield 1,3,5-tritelluracyclohexane **13**.

The structure of the heterocyclic compound **13** was confirmed by IR spectroscopy and mass spectrometry.¹⁸ The reactions of the compound **13** with bromine or iodine give the corresponding dihalomethanes.¹⁷

Apart from the trimer **13**, telluroformaldehyde can also exist as a polymeric form, poly(methylene telluride) **14**. Disodium methaneditelluroate resulting from reduction of poly(methylene ditelluride) **15**¹⁹ with sodium tetrahydridoborate in ethanol disproportionates into sodium telluride and telluroformaldehyde, which then polymerises to give the polytelluride **14**.²⁰

It has been suggested²¹ that the synthesis of poly(methylene telluride) occurs according to a scheme which includes reduction of the polyditelluride **15** with sodium tetrahydridoborate in methanol and alkylation of sodium methyleneditelluroate with dibromo(or diiodo)methane. In our opinion, this mechanism is erroneous. We believe that the polymer **14** results from disproportionation of the dianion as described above rather than from the alkylation.

Although in recent years several methods for the generation of telluroaldehydes and telluroketones have been developed, it is fairly difficult to judge their synthetic potential, because their chemical properties have not been extensively studied. The most efficient method for the preparation of telluroaldehydes **2** and telluroketones **16** is the reaction of bis(dimethylaluminium) telluride with aldehydes or ketones in boiling dioxane.^{22,23} The driving force of these reactions is the formation of thermodynamically favourable Al–O bonds.

$\text{R}^1 = \text{H}; \text{R}^2 = \text{Ph}$ (**2a**), Pr (**2b**), Bu^t (**2c**);²²

$\text{R}^1, \text{R}^2 =$  (**16a**),  (**16b**);²² $\text{R}^1 = \text{R}^2 = \text{C}_5\text{H}_5\text{FeC}_5\text{H}_4$ (**16c**).²³

The tellurocarbonyl compounds **2** and **16** formed initially can be trapped by 2,3-dimethylbutadiene or cyclopentadiene; this gives Diels–Alder adducts **17–19** in 44%–62% yields.²² These reactions are the only methods known to date for the synthesis of 1-telluracyclohex-3-enes²⁴ and 2-tellurabicyclo[2.2.1]hept-5-enes. The formation of the telluroketone **16c** is indicated by the blue colouration of the solution. Owing to the low stability of this compound, it was impossible to determine its spectral characteristics. Unlike the sulfur and selenium analogues which form complexes with pentacarbonylchromium and -tungsten, the reaction of the ketone **16c** with $(\text{CO})_5\text{M} \cdot \text{THF}$ ($\text{M} = \text{Cr}, \text{Mo}, \text{W}$) occurs as detelluration and affords tetraferrocenylethylene in a quantitative yield.²³

$\text{R} = \text{Ph}$ [**17a**, (49%)]; Pr [**17b**, (44%)]; Bu^t [**17c**, (62%)].

In the absence of dienes, the ketone **16a** dimerises to give 1,3-ditellurethane derivative **20** (yield 28%);²² reactions of this type for other ketones have not been reported.

It is noteworthy that the first ditelluretanes, *cis*- (**21a**) and *trans*- (**21b**) 2,4-dibenzylidene-1,3-ditelluretanes (the structure of the *trans*-isomer was confirmed by X-ray diffraction analysis²⁵), were obtained in low yields upon protonation of sodium phenylethynyltelluroate with a solution of HCl in ether.^{25,26} It has been reported²⁷ that ditellurethane **21a** and *cis*-3,5-dibenzylidene-1,2,4-tritellurole **22** are the main products of this reaction; the structure of the latter was determined by X-ray diffraction analysis.²⁷ The protonation of sodium phenylethynyltelluroate with CF_3COOH affords a mixture consisting of **21a** and *cis*- and *trans*-2,6-diphenyl-1,4-ditellurafulvalene, **23a** and **23b**, respectively.²⁸ Apparently, these reactions involve intermediate formation of a telluroketone, which either dimerises yielding the compounds **21** or **23**, or reacts with phenylethynyltelluroate anion being thus converted into the tritellurole **22**.²⁷

Tellurium-containing heterocycles have also been synthesised from tellurocarbonyl compounds generated by other methods. One of these methods, which has been used previously in the chemistry of selenoaldehydes,²⁹ is based on the reaction of benzylidenetriphenylphosphorane with powdered tellurium in boiling toluene.³⁰ The resulting tellurobenzaldehyde **2a** is trapped by 2,3-dimethylbutadiene to give the heterocyclic derivative **17a** in a yield of only 11%. This way of generation of telluroaldehydes is much less efficient than the method described above in which bis(dimethylaluminium) telluride acts as the tellurating reagent.

In view of the fact that phosphine tellurides (see below) are efficient synthetic analogues of elemental Te, it would be of interest to check whether these compounds could be used in this reaction instead of elemental Te.

The reaction of the phosphorane with an equimolar or catalytic amount of tellurium in the absence of a diene affords only *trans*-stilbene in a yield of more than 60%.³⁰

Yet another way of generating telluroketones, which has also been borrowed from the chemistry of organoselenium derivatives,³¹ consists in the elimination of HCN from tellurocyanate **24**.³² Hydrolysis of this compound under anaerobic conditions gives rise to a mixture of the *anti*- and *syn*-isomers of 1,3-ditelluretane **26a** and **26b** (yields 45% and 6%, respectively) resulting from dimerisation of the intermediate telluroketone **25**.

One more approach to the generation of tellurocarbonyl compounds reported in the literature, which is not associated with their formation from transition metal complexes, has been studied in relation to tellurocarbonyl difluoride **27**.^{33,34} This compound is formed in a fairly low yield upon treatment of bis(trifluoromethyltelluro)mercury with diethylaluminium iodide and rapidly dimerises to give 2,2,4,4-tetrafluoro-1,3-ditelluretane **28a**.^{33,34} The telluretane **28a** was obtained in higher yields (50%–60%) by pyrolysis of trifluoromethyltellurotrimethylstannane.³⁴ Co-condensation of the compound **27** with selenocarbonyl difluoride results in the formation of 2,2,4,4-tetrafluoro-1-selena-3-telluretane **29**.³⁴ The reaction of the compound **27** with 2,3-dimethylbutadiene gives 6,6-difluoro-3,4-dimethyl-1-telluracyclohex-3-ene **30**. This heterocyclic derivative was prepared in 48% yield by heating trifluoromethyltellurotrimethylstannane with 2,3-dimethylbutadiene in a sealed tube. The synthesis of dichloro- and dibromotelluretanes **28b,c** by treatment of the tetrafluoride **28a** with boron halides also deserves attention.³⁴

c. Telluration of transition metal complexes

Yet another method for stabilisation of telluroaldehydes and telluroketones is the formation of complexes with transition metal compounds. These complexes, unlike the complex of telluroketone with pentacarbonyltungsten (**12**) described above,¹⁴ are formed upon interaction of metal complexes of various structures with tellurium-containing nucleophiles or elemental tellurium, TeCN[−] and HTe[−] being usually employed as the tellurium-containing nucleophiles. For example, complexes **32a**³⁵ and **32b**³⁶ have been obtained in 18% and 12% yields, respectively, by the reaction of complexes **31** with TeCN[−]. The complex **32a** is thermally fairly unstable and is readily converted into binuclear complex **33** (the yield given above refers to **33**).

R = H (**a**), Ph (**b**).

The complexes **32** enter into reactions typical of tellurocarbonyl derivatives, in particular, into the Diels–Alder reaction, *i.e.* they behave similarly to ‘free’ tellurocarbonyl compounds. Their reaction with 2,3-dimethylbutadiene leads to pentacarbonyltungsten complexes of 1-tellura-3,4-dimethylcyclohex-3-enes **34a,b** in 12%³⁷ and 8%³⁶ yields, respectively. It has been reported³⁷ that the reactivity of complexes of the (CO)₅W–X=CPh₂ type, where X = S, Se, and Te, sharply increases in the series S < Se < Te. In fact, whereas the reaction of **32b** with 2,3-dimethylbutadiene at −25 °C is completed over a period of 45 min, the reaction of the selenium analogue with the same diene requires 10 hours at room temperature. Finally, pentacarbonyl(diphenylthione)tungsten does not react with this diene at all under these conditions.

R = H (**a**), Ph (**b**).

The complex **34a** exists in solution as an equilibrium mixture of two conformers in which the Ph group occupies an equatorial position.³⁶

The reactions of the complexes **32** with cyclopentadiene occur faster than with 2,3-dimethylbutadiene and afford tungsten complexes of 2-tellurabicyclo[2.2.1]hept-5-enes **35a,b**^{36,37} in 31% and 24% yields, respectively. The formation of the complex **35a** is highly stereoselective: the ratio of the *exo*- and *endo*-isomers is 11:1.³⁶ The structure of the major isomer, *exo*-**35a**, was established by X-ray diffraction analysis.³⁶

R = H (a); Ph (b).

Reactions of the complex **32b** with 1-diethylaminoprop-1-yne and bis(diethylamino)acetylene have also been studied.³⁸ They occur as [2 + 2]-cycloaddition followed by electrocyclic ring opening and give rise to telluroacrylamide complexes **36a,b**.³⁸ The complex **36b** decomposes on prolonged heating in an ethereal solution under a CO atmosphere to give $\text{W}(\text{CO})_6$, Te, and $\text{Et}_2\text{NCH}=\text{C}(\text{NEt}_2)\text{CHPh}_2$.

R = Me (**36a**), NEt_2 (**36b**).

Metal complexes have also been used to stabilise chalcogenokenes including telluroketenes.³⁹ Complexes **38** as well as their sulfur and selenium analogues have been synthesised in relatively high yields (68%–87%) by the reaction of vinylidene rhodium complexes **37** with chalcogens in benzene. Methylation of **38** (R = H) with methyl triflate and subsequent treatment with NH_4PF_6 results in the formation of an ionic complex **39**.³⁹

R = H, Me, Ph.

Finally, we would like to mention the synthesis of tellurocarbonyl complex **41a** (X = Te) in which the $\text{C}=\text{Te}$ group acts as a carbonyl ligand.⁴⁰ The complex **41a** as well as its sulfur (**41b**) and selenium (**41c**) analogues were obtained as crystals, stable in air, on treatment of osmium dichlorocarbene complex **40** with HX^- anions (X = S, Se, Te).

X = Te (a), S (b), Se (c).

The $\nu(\text{C}=\text{X})$ absorption frequencies in the IR spectra of the complexes **41a-c** regularly decrease in the order S (1315 cm^{-1}) > Se (1156 cm^{-1}) > Te (1056 cm^{-1}).⁴⁰

The tellurium-containing groups in the complexes **32** and **38** are bound to metal atoms either through the Te atom or by the $\text{C}=\text{Te}$ double bond, i.e. these compounds are η^1 -complexes. At

the same time, a number of heterobinuclear μ -alkylidene complexes of the dimetallacyclopropane type containing C and M in three-membered rings have also been described. Complexes of this type, for example, **43** and **45**, have been prepared as blue crystalline compounds by treatment of the manganese complexes **42**⁴¹ or **44**⁴² with diazoalkanes.^{41, 43}

R = H, Me; Cp^* is C_5Me_5 .

Cp is C_5H_5 .

The reactions of osmium complexes **46**⁴⁴ and **47**⁴⁵ with hydrogentelluride anions⁴⁴ or elemental tellurium⁴⁵ resulted in the formation of telluroformaldehyde complexes **48a,b**.

$\text{L}^1 = \text{L}^2 = \text{CO}$ (**46**, **48a**);

$\text{L}^1 = \text{NO}$, $\text{L}^2 = \text{Cl}$ (**47**, **48b**).

The reaction of the complex **48a** with HCl involves the $\text{Os}-\text{CH}_2$ bond and gives rise to complex **49**.⁴³ In the reaction with methyl iodide, the attack is directed at the tellurium atom; the cationic complex **50** thus formed is easily reduced by sodium tetrahydridoborate with opening of the three-membered ring to give complex **51**.⁴⁴

Rhodium complexes **53** containing rigid three-membered rings have been synthesised in relatively low yields by reaction of rhodium complexes **52** with sodium hydrogentelluride.^{46, 47}

L = Me_3P ,^{46, 47} Pr_3P ,⁴⁷ CO.⁴⁷

2. Telluronic acids

The synthesis and some reactions of tellurocarboxylic acids have been described only quite recently. These acids were prepared by acidolysis of the corresponding cesium tellurocarboxylates **54** with an ethereal solution of HCl.⁴⁸ At low temperatures in a polar solvent like THF, they exist mostly as the telluoroxo form **55** (telluronic acids).⁴⁸

R = 4-MeOC₆H₄ (a), 4-MeC₆H₄ (b), Me₃C (c).

The structure of the acids **55** has been confirmed by their spectral characteristics. The ¹H and ¹³C NMR spectra of these compounds recorded at -90 °C contain no signals corresponding to the TeH and C=O groups present in the isomeric tellurolic acids **56**. The singlets observed at δ 16.02, 16.48 and at δ 222.9, 223.1 ppm were attributed to the OH and C=Te fragments of the acids **55a** and **55b**, respectively. When the temperature was raised to -70 °C, the signals mentioned above were markedly broadened; this was attributed⁴⁸ to a dynamic exchange process involving the formation and rupture of hydrogen bonds (Te-H...O, O-H...O) in the above equilibrium. The telluoroxo structure of these compounds is also supported by the magnitudes of ¹²⁵Te chemical shifts (δ 952 ppm for **55a** and δ 1024 ppm for **55b**). The acids of the aromatic series are coloured dark-green (λ_{max} = 652 and 673 nm for **55a** and **55b**, respectively), whereas tellurotrimethylacetic acid **55c** is blue-violet (λ_{max} = 594 nm).

The isomeric tellurobenzoic Te-acid **56a** was prepared by treatment of the salt **54a** with liquid hydrogen chloride at -195 °C followed by raising the temperature to -90 °C. At -110 °C, the dark-brown salt **54a** was converted into the solid yellow acid **56a**, which is soluble in toluene at -90 °C. The signal observed in the ¹²⁵Te NMR spectrum of this compound at δ 535 ppm was assigned to the TeH group. When THF was added to the resulting solution, the acid **56a** was converted into the isomeric acid **55a**.⁴⁸

Tellurocarboxylic acids of both types are unstable at ambient temperature and are very sensitive to oxygen; on exposure to air even at -90 °C, they immediately decompose with liberation of elemental Te. The tellurolic acids **56** are appreciably less stable than telluronic acids **55**.⁴⁸

Tellurocarboxylic acids **55a,b** react with aryl isocyanates in THF or CH₂Cl₂ at -70 °C to give stable acyl carbamoyl tellurides **57a-c**, their yields exceeding 80%.⁴⁸

R = 4-MeOC₆H₄; R¹ = Ph (**57a**), 4-MeC₆H₄ (**57b**);
R = 4-MeC₆H₄; R¹ = Ph (**57c**).

The synthesis of free acids from their salts proved to be possible only for cesium salts.⁴⁹ These salts, which are relatively stable (for R = Ar) under an inert atmosphere, as well as their rubidium analogues, have been prepared in 40%–60% yields by the reactions of *O*-trimethylsilyl tellurocarboxylates **58** (see Section II.3) with cesium and rubidium fluorides.⁴⁹

M = Cs, Rb; R = Me, Bu^t, Ph, 2-MeC₆H₄, 4-MeC₆H₄, 2-MeOC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄.

The presence of a carbonyl group in the compounds **54** was confirmed by an X-ray diffraction study of Te-cesium 2-methoxytellurobenzoate **54a**.⁴⁹

It should be noted that salts of type **54** containing lighter alkali metal cations, that is, lithium,⁵⁰ sodium^{51,52} and potassium,⁵³ have been synthesised earlier using one of the reactions presented below:

M = Li, Na.

M = Na, K.

However, it was impossible to carry out X-ray diffraction analyses of these salts, because they were sensitive to oxygen and thermally unstable and, hence, it was difficult to purify them. The same features precluded preparation of the corresponding acids from these salts.

3. *O*-Alkyl and *O*-trimethylsilyl tellurocarboxylates

O-Alkyl tellurocarboxylates **59** were the first representatives of organotellurium compounds with the C=Te bond to be isolated in a pure state. These compounds were prepared by Barton *et al.*^{54,55} by the reaction of (1-chloro-2,2-dimethylpropylidene)dimethylammonium chloride **60** with alcohols and sodium hydrogentelluride, synthesised from NaBH₄ and Te in ethanol in the absence of air and light.

R = CH₂Bu^t (a), (–)-menthyl (b), adamantylmethyl (c),
5α-cholestan-3β-yl (d), Δ⁹-tigogenyl-3 (e).

The yields of the compounds **59** varied over wide limits, namely, from 6% in the case of **59b** to 91% for **59c**. Evidently, the higher stability of the compound **59a** is due to the presence of bulky *tert*-butyl groups in their molecules. In fact, when the analogous phenyl derivative is used instead of the chloride **60**, the reactions with alcohols and sodium hydrogentelluride afford the corresponding benzyl ethers as the final products. Tellurobenzoates **61** were postulated as intermediate compounds.^{56,57}

Since these reactions occur under relatively mild conditions, it was proposed^{56,57} to use them for protecting hydroxy groups in carbohydrates and other compounds, labile in alkaline media.

The compounds **59** are coloured violet, which is due to absorption of the tellurocarbonyl chromophore with $\lambda_{\max} = 584\text{--}596\text{ nm}$; the ^{13}C NMR signals for the carbon nuclei of the $\text{C}=\text{Te}$ group occur at $\delta\ 229\text{ ppm}$.^{54,55}

The esters **59** are quite stable to atmospheric oxygen in the dark. However, they are readily oxidised by phenylseleninic anhydride; in the case of **59d**, the ester of the corresponding carboxylic acid is formed in an almost quantitative yield.^{54,55}

The reaction of the telluroesters **59** with excess sodium hydrogentelluride initially yields a mixture of oligotellurides **62** and finally gives esters **63** and **64**. The formation of these compounds was explained in terms of the scheme given below.⁵⁵

The silyl esters **58** represent yet another type of telluroesters with $\text{C}=\text{Te}$ bonds. They have been synthesised by reactions of bis(acyl) tellurides **65** with bis(trialkylsilyl) tellurides **66** [pathway (a)], of acyl chlorides with equimolar amounts of bis(trimethylsilyl) tellurides [pathway (b)],^{58–61} and of sodium tellurocarboxylates with trialkylchlorosilanes [pathway (c)].⁵²

Compound	R	R'	Pathway
a	Me	Me ₃	a, b
b	Bu ^t	Me ₃	a, b
c	Me	Pr ⁱ Me ₂	a
d	2-MeC ₆ H ₄	Me ₃	c
e	2-MeC ₆ H ₄	Bu ^t Me ₂	c
f	Ph	Bu ^t Me ₂	a

The compounds **58** gradually decompose in solutions with liberation of tellurium giving mixtures of *E*- and *Z*-isomers of alkenes **68**^{58–61} (when $\text{R} = \text{R}' = \text{Me}$, the *E*:*Z* ratio amounts to 55:45⁵⁷). The stability of the esters **58** increases with increase in the size of the substituents R and R'. For example, in the reaction of bis(acetyl) telluride with bis(trimethylsilyl) telluride, the mixture of alkenes **68a** is formed in almost quantitative yield over a period of 30 min, whereas the reaction of bis(acetyl) telluride with

bis[(dimethyl)isopropylsilyl] telluride giving rise to a mixture of the alkenes **68c** is completed only over a period of 12 h.^{58,61}

Te-Silylated derivatives **67** are the precursors of the esters **58**; they either completely isomerise into *O*-silylated esters **58** (for $\text{R} = \text{Ar}$ ⁵²) or exist as equilibrium mixtures with them. Thus the reaction of pivaloyl chloride with silyl telluride **66** ($\text{R}^1 = \text{Me}$) affords an equilibrium mixture of the compounds **67b** (35%) and **58b** (65%),⁶⁰ as indicated by the spectral parameters of the blue liquid formed in this reaction ($\lambda_{\max} = 624\text{ nm}$ ^{58,60}). The ^{13}C NMR spectrum exhibits signals at $\delta\ 207.5$ ($\text{C}=\text{O}$) and $\delta\ 251.2$ ppm ($\text{C}=\text{Te}$); the ^{125}Te NMR signal corresponding to the compound **58b** is manifested at $\delta\ 1418\text{ ppm}$.⁶⁰

Similarly to telluroaldehydes and telluroketones (see Section II.1), the esters **58** enter into [2 + 4]-cycloaddition to 2,3-dimethylbutadiene and cyclopentadiene giving the corresponding tellurium-containing heterocycles.⁶⁰

4. Telluroamides and their analogues

The first telluroamides and tellurohydrazides **71** were synthesised at about the same time as telluroesters, in 1979.⁶² They have been prepared similarly to selenium analogues,⁶³ namely, by treating the salts **70** with the hydrogentelluride anion **69** generated from Et_3N and H_2Te in CH_2Cl_2 .⁶² The yields of the compounds **71** were low (5%–19%).

$\text{R}^1 = \text{Ph}$; $\text{R}^2 = \text{R}^3 = \text{Me}$ (a); $\text{R}^2 = \text{Me}$, $\text{R}^3 = \text{NMe}_2$ (b).

Telluroamides have also been synthesised from bis(dimethylaluminium) telluride, which had been used previously to prepare telluroaldehydes and telluroketones.^{22,23} (see Section II.1). Treatment of *N*-methylformanilide with this telluring reagent resulted in the synthesis of telluroformanilide **71d** in a yield of about 90%.⁶⁴

However, other telluroformanilides could not be isolated because they decomposed during purification.

The compounds **71** are stable at room temperature in the absence of water. They are rapidly hydrolysed in moist air or in wet solvents to give the corresponding amides and elemental tellurium resulting from fast oxidation of H_2Te .⁶² The hydrolysis is catalysed by alumina and silica gel; this apparently accounts for the fact that other telluroformanilides could not be isolated. The relatively high stability of telluroamides (hydrazides) **71a–c** is caused by the presence of strong electron-donating substituents

(NR₂, NR¹NR₂²) at the tellurocarbonyl carbon atom. Evidently, the stability of telluroamides, like that of telluroesters **59**, could be increased by introducing bulky substituents into their molecules. However, compounds of this type have not yet been synthesised.

The long-wave absorption bands associated with the $n \rightarrow \pi^*$ transition in the C=Te fragment in the UV spectra of the telluroamides **71a,d** shift bathochromically with respect to those in the spectra of the analogous selenium derivatives by more than 100 nm and are located at 540 nm.^{62, 64}

The ¹H NMR data imply that the barriers (ΔG) to rotation of the NMe₂ groups in the amides PhC(X)NMe₂ vary in the following sequence:

The deviation of the ΔG value for the telluroamide **71a** from the general tendency was attributed⁶⁵ to the increase in the steric strain in the ground state caused by the repulsion between the bulky Te atom and the (Z)-N-methyl group.

The stability of telluroureas **73** and **75** is also associated with the presence of electron-donating substituents at the tellurocarbonyl group. These compounds have been synthesised by the oxidation of alkenes **72**⁶⁶ or 1,3-dimethylbenzimidazoline with elemental Te. The compounds **73** were formed in 42%–45% yields, and the tellurourea **75** was obtained in ~9% yield.

R = Me (**a**), Et (**b**); M = Cr (**74a**), Mo (**74b**), W (**74c**).

The properties of the tellurourea **75** have scarcely been studied. It has been reported⁶⁷ that the long-wave absorption bands in the UV spectra of 1,3-dimethylbenzimidazolinechalcogenones shift bathochromically in the series: thione ($\lambda = 310$ nm), selenone ($\lambda = 318$ nm), tellurone ($\lambda = 372$ nm).

The properties of the telluroureas of type **73** have been studied somewhat more extensively.⁶⁶ These compounds are sensitive to air and decompose with the liberation of tellurium both in solutions and in the solid state. Complexes **74**, which are formed in 50%–75% yields in the reaction of the tellurourea **73b** with Cr, Mo, and W carbonyls, are more stable to air. The length of the C–Te bond in the complex **74a** corresponds to the length of a single C–Te bond and is equal to 2.12 Å; this is much longer than a similar bond in the complex **12** formed from the telluroketone **5** and tungstenpentacarbonyl (1.987 Å¹⁴). This was explained⁶⁶ by the assumption that the resonance-stabilised zwitter-ionic structures **76** make the predominant contributions to the ground state of the complexes.

III. Synthesis, reactions, structures, and spectroscopic characteristics of phosphine tellurides R₃P=Te

1. Synthesis of phosphine tellurides

The first compound with the P–Te bond was synthesised by Foss about 50 years ago.⁶⁸ The reaction of elemental Te with an ethanolic solution of potassium diethyl phosphite has resulted in the synthesis of (EtO)₂P(O)TeK. Later, the corresponding sodium derivative was used as an efficient dehalogenating reagent for α -chloro- and α -bromoketones,⁶⁹ and also for deoxygenation of epoxides.⁷⁰

As mentioned above, the first phosphine telluride, tributyl phosphine telluride, was synthesised by Zingaro in 1963.¹ This compound and similar compounds **77** have been prepared by the interaction of triorganylphosphines with elemental tellurium in anhydrous toluene.^{1, 71, 72} The yields of the compounds **77** varied from 5% to 45%. However, the reaction of tris(*tert*-butyl)-phosphine with tellurium carried out under the same conditions gave the corresponding phosphine telluride in an almost quantitative yield.⁷³ Phosphine tellurides have been synthesised in substantially higher yields (75%–80%) by heating trialkyl(cycloalkyl)phosphines with tellurium without a solvent.⁷⁴

R = Me (**a**),⁷² Et (**b**),⁷¹ Pr (**c**),^{71,74} Bu (**d**),^{1,71,74} Bu^t (**e**),⁷³ C₅H₁₁ (**f**),⁷⁴ cyclo-C₆H₁₁ (**g**),⁷⁴ C₈H₁₇ (**h**),⁷⁴ R₃ = PhBu₂ (**i**).⁷¹

It should be noted that there is no direct correlation between the solubility of tellurium in phosphines and the capability of the latter of being converted into phosphine tellurides. In fact, the solubility of tellurium in dimethyl(phenyl)phosphine (defined as the ratio of the number of moles of dissolved Te to the number of phosphine moles multiplied by 100)⁷¹ is 16.7, and that for dibutyl(phenyl)phosphine is 9.1; however, only the latter compound yields phosphine telluride upon interaction with tellurium. No triorganylphosphine tellurides containing more than one phenyl group have been obtained so far. For example, all attempts to prepare triphenylphosphine telluride failed. However, this compound has been obtained as a complex with triphenylphosphine in acetonitrile in the presence of lithium perchlorate.⁷⁵

The structure of the adduct **78** was determined by X-ray diffraction analysis.⁷⁵ It contains a linear P–Te–P fragment with non-equivalent P–Te bonds. The length of one of these bonds is 2.27–2.42 Å; this falls into the range of typical P=Te bonds in phosphine tellurides (2.31–2.37 Å^{76–80}); the other bond, which is 3.41–3.95 Å long, corresponds to a ‘secondary interaction’⁸¹ between the Te atom and the phosphorus atom in triphenylphosphine.

The reversible reaction between triorganylphosphines and NCTe[–] anions was used to estimate quantitatively the ‘tellurophilicity’ of phosphines;⁷⁸ for this purpose, the equilibrium constants (*K*) for the reaction

were measured. The following results were obtained:

R			Me ₂ N	Et ₂ N	Bu	
<i>K</i>	8.000	0.600	0.540	0.270	0.170	0.009

R	Pr ⁱ ₃ N	EtO	MeO	BuO	Ph
<i>K</i>	0.048	~ 0.003	~ 0.001	~ 0.003	0

The *K* values are in fairly good agreement with other findings. Thus the fact that Ph₃P does not form phosphine tellurides is consistent with the *K* value found (0.000). At the same time, various triaminophosphines characterised by relatively large *K* readily react with elemental tellurium giving tris(dialkylamino-phosphine) tellurides **79** in high yields.^{78, 82–85}

Amidophosphine tellurides of type **80**^{83, 86–88} and **81**⁸⁸ have been obtained in a similar way.

$n = 1$: $R^1 = R^2 = \text{Me}$;^{83, 87} $R^1 = \text{Me}$, $R^2 = R^3 = \text{Et}$;⁸⁸ $R^1 = \text{Ph}$, Et ;
 $R^2 = R^3 = \text{Me}$;⁸²

$n = 2$: $R^1 = \text{Bu}^t$; $R^2 = \text{H}$, $R^3 = \text{Pr}^i$, cyclo-C₆H₁₁.⁸⁶

Cyclic phosphine tellurides, which are relatively resistant against water and air compared to other phosphine tellurides, have been synthesised by the reactions of the corresponding diazadiphosphetidines with tellurium.^{89–91} Depending on the ratio of the reactants, these reactions gave diazadiphosphetidine monotellurides **82**^{89–91} and ditellurides **83**.⁸⁹

82a: $R^1 = \text{Me}$, $R^2 = \text{Bu}^t$, $R^3 = \text{Cl}$;⁸⁹

82b: $R^1 = R^3 = \text{NMe}_2$, $R^2 = \text{Bu}^t$;⁹⁰

82c: $R^1 = R^3 = \text{Bu}^t$, $R^2 = \text{Me}$.⁹¹

Dichloro(methyl)phosphine does not react with tellurium,⁹² although the chloro-substituted diazadiphosphetidine forms the corresponding telluride **82a** in 17% yield.⁸⁹

The fairly low tellurophilicity of trialkyl phosphites accounts for the fact that no trialkyl phosphotelluroates (RO)₃P=Te have been synthesised so far. However, phosphonites RP(OR')₂ are able to form compounds **84** with a P=Te bond. The stability of these compounds is largely determined by the nature of the hydrocarbon substituents attached directly to the phosphorus atom. For example, **84a** resulting from reaction of diethyl ethylphosphonite with Te decomposes during distillation,⁹³ whereas phosphotelluroate **84b** formed from diethyl allylphosphonite is relatively stable under an inert atmosphere.⁹⁴

$R = R' = \text{Et}$ (**a**); $R = \text{CH}_2\text{CH}=\text{CH}_2$, $R' = \text{Et}$ (**b**).

Phosphonotelluroate **85** was obtained in 44% yield by the reaction of bis(trimethylsilyl) hydrogenphosphonite with Te in dioxane.⁹⁵

Finally, it should be noted that *N*-diphenyltellurophosphinoyl(triphenyl)phosphazene **86** is formed in a yield of 87% when the corresponding phosphazene is heated with elemental tellurium in benzene.⁹⁶

Thus, synthesis of all types of compounds containing P=Te bonds is based on the reactions of P(III) derivatives with elemental tellurium. Other sources of tellurium do not afford phosphine tellurides, although their sulfur and selenium analogues are used to prepare the corresponding phosphine chalcogenides. For example, unlike diorganyl disulfides and diselenides, which react with triorganylphosphines to give triorganylphosphine sulfides or selenides,⁹⁷ diorganyl ditellurides subjected to photolysis in the presence of tertiary phosphines yield only mixtures of organyl tellurides and elemental tellurium.⁹⁸

2. Reactions of phosphine tellurides

Triorganylphosphine tellurides $R_3P=Te$ are golden-yellow crystalline compounds, which partially decompose in air or during recrystallisation. Therefore, they are normally recrystallised in the presence of the corresponding phosphines. In many cases, heating of solutions of phosphine tellurides in hydrocarbon solvents results in the formation of tellurium mirrors.⁷¹ Only tris(*tert*-butyl)phosphine telluride is thermally stable both in the solid state and in solutions.⁷³ Tris(dialkylaminophosphine) tellurides are also quite sensitive to air and decompose with liberation of elemental Te.⁸² Phosphine tellurides containing residues of cyclic nitrogen-containing compounds at the phosphorus atom are more stable.⁷⁸ Diazadiphosphetidine tellurides **82** and **83** are very stable both in the crystalline state and in solutions.^{88–90}

a. Exchange reactions

The ¹H, ³¹P and ¹²⁵Te spectra of mixtures of phosphine tellurides with phosphines recorded at room temperatures indicate that the Te atom migrates rapidly, on the NMR time scale, between the

phosphine molecules.^{73, 98–101} Apparently, this reaction occurs *via* a transition state like **87**.⁹⁹

$\text{R}^1 = \text{R}^2 = \text{Bu}^t$,^{73, 99, 100} Me_2N ,⁹⁹ Bu ,¹⁰⁰
 $\text{R}^1 = \text{Bu}^t$, $\text{R}^2 = \text{Me}_2\text{N}$.^{73, 99}

However, in the $\text{Bu}_3\text{P}=\text{Te}/\text{Bu}_2\text{PSiMe}_3$ system, the Te atom is rapidly and irreversibly transferred to the silylphosphine; the intermediate phosphine telluride **88** immediately rearranges into compound **89** containing a Te–Si bond.¹⁰¹ However, this compound and also similar derivatives with Te–Ge and Te–Sn bonds have not been isolated in an analytically pure state due to disproportionation, which is described by the following scheme:¹⁰¹

Fast, on the NMR time scale, transfer of a tellurium atom between phosphorus atoms has been observed for cyclic phosphine tellurides **82b,c**.^{90, 91}

$\text{R}^1 = \text{Me}_2\text{N}$, $\text{R}^2 = \text{Bu}^t$ (**b**);⁹⁰ $\text{R}^1 = \text{Bu}^t$, $\text{R}^2 = \text{Me}$ (**c**).⁹¹

The concentration dependence of the coalescence temperature indicates that this process can occur not only as intramolecular exchange, which is facilitated by the non-planarity of the diazadi-phosphetidine ring,⁷⁶ but also intermolecularly.

b. Protonation and alkylation

The protonation of phosphine tellurides with strong acids affords cations $[\text{R}_3\text{PTeH}]^+$.¹⁰² However, no salts with these cations have been isolated in a pure state; their formation in solutions has been judged only by NMR spectra.

Under mild conditions (benzene, room temperature), phosphine tellurides are alkylated with methyl iodide to give methyl-telluorophosphonium salts **90**, their yields being about 90%.¹⁰³ The salts **90** are soluble in nitromethane but decompose soon after dissolution.

$\text{R} = \text{Me}$, Pr^i , Bu , Bu^t , Me_2N .

It is of interest that not only phosphine tellurides but also their complexes with metal carbonyls can be methylated.¹⁰⁴ Thus the reaction of the complex **91** with methyl iodide gave cationic complex **92**.⁴

The P–Te bonds in the salts **90** tend to be cleaved by strong nucleophiles. For instance, treatment of these salts with methyl-lithium affords dimethyl telluride and triorganylphosphines.¹⁰³

c. Oxidation

The phosphine tellurides **77c,d** are oxidised with the ferrocenium salts $\text{Cp}_2\text{Fe}^+\text{X}^-$ ($\text{X} = \text{BF}_4$, PF_6 , SbF_6) at low temperatures to give dications **93**, the yields of which are about 30%, and ferrocene.¹⁰⁵

$\text{R} = \text{Pr}^i$ (**c**), Bu^t (**d**); $\text{X} = \text{BF}_4$, PF_6 , SbF_6 .

The salt **93** ($\text{R} = \text{Bu}^t$, $\text{X} = \text{SbF}_6$) was studied by X-ray diffraction analysis.¹⁰⁵ Based on the bond lengths Te–Te (2.71 Å) and P–Te (2.50 Å), which corresponds to a single bond between Te and P atoms) and on the Te–Te–Te (109°) and Te–Te–P (108.6°) bond angles, this compound was described¹⁰⁵ as a Te_3^{2+} dication stabilised by complex formation with Bu_3P .

In a more recent study,¹⁰⁶ tributylphosphine telluride has been used to stabilise the tellurenyl cations RTe^+ . These species were generated by oxidation of diorganyl ditellurides with the nitrosonium salts NO^+X^- ($\text{X} = \text{BF}_4$, ClO_4) and isolated as stable complexes $[\text{Bu}_3\text{P} \rightarrow \text{TeP}]^+\text{X}^-$.

d. Complex formation

Phosphine tellurides form complexes with some metal salts. Like their sulfur and selenium analogues, phosphine tellurides act as donors in complex formation. Moreover, since in this case the bipolar character of the $(\text{P}=\text{Te} \leftrightarrow \text{P}^+-\text{Te}^-)$ bond is more pronounced, phosphine tellurides are stronger donors than phosphine sulfides or phosphine selenides.

Thus tributylphosphine telluride reacts with mercury(II) bromide to give a complex of the composition $(\text{HgBr}_2)_4(\text{TePBu}_3)_3$, which is fairly sensitive to oxygen and heating.¹⁰⁷ According to X-ray diffraction data, this complex consists of dimeric $[(\text{HgTePBu}_3)_3\text{Br}_3]^{2+}$ cations and binuclear $[\text{Hg}_2\text{Br}_6]^{2-}$ anions. The reactions of trimethylphosphine telluride with nickel and cobalt salts follow a different pathway, which includes decomposition of phosphine telluride and liberation of elemental tellurium even at -30°C .⁷²

The first phosphine telluride complexes **91a–c** were prepared in almost quantitative yields on irradiation of mixtures of Cr, Mo, and W carbonyls with tris(*tert*-butyl)phosphine telluride in THF.¹⁰⁴ They appear as dark-red crystals fairly stable in air and at elevated temperatures.

$\text{M} = \text{Cr}$ (**a**), Mo (**b**), W (**c**).

The relatively high donor ability of the phosphine telluride ligands is indicated by the substantial upfield shift of the signals of the CO groups in the ^{13}C NMR spectra of the complexes **91**. This is also confirmed by the fact that the phosphine telluride ligands in the complexes **91**, unlike those in similar complexes derived from phosphine sulfides $(\text{CO})_5\text{M}-\text{S}=\text{PR}_3$,¹⁰⁸ are not replaced by Ph_3P or CO on heating in solutions at 80°C .¹⁰⁴ The length of the P–Te bond in the complex **91c** is 2.439 Å, which corresponds to a single P–Te bond.¹⁰⁴

The results of NMR studies of complexes **94** also indicate that phosphine tellurides are stronger donors than other phosphine

chalcogenides. These compounds have been synthesised¹⁰⁹ by a reaction similar to that used earlier¹¹⁰ to prepare the corresponding sulfur and selenium derivatives. The dark-brown complexes **94** were formed in almost quantitative yields on the interaction of salts **95** with phosphine tellurides in dichloromethane at room temperature.

R = Me (**a**), Prⁱ (**b**), Bu^t (**c**), Me₂N (**d**),  (**e**).

The compounds **94** are stable in air in the solid state but slowly decompose in solutions with liberation of tellurium to give complexes **96**.¹⁰⁹ The complex **94e**, which is the least stable in this series, decomposes yielding [CpFe(CO)₃]⁺BF₄[−] and the corresponding phosphine telluride. The attempts to replace one of the CO groups in the cation **94** by a second R₃P=Te molecule, which would have resulted in the formation of the cations [CpFe(CO)(TePR₃)₂]⁺, failed; heating or irradiation of mixtures of **94** with R₃P=Te was accompanied by intense decomposition. Meanwhile, treatment of the cations **94** with iodine resulted in the rupture of the Fe–Te bonds and in the formation of [CpFe(CO)₂I]₂.¹⁰⁹

It should be noted that the reaction of the uranium cyclopentadienyl complex **97** with tributylphosphine telluride, unlike the reactions of the salts **95**, is accompanied by elimination of tributylphosphine giving rise to compound **98**.¹¹¹

Triphenylphosphine sulfide and selenide react with the complex **97** yielding compounds with similar structures. In the case of triphenylphosphine oxide, this gives the complex (MeC₅H₄)₃U · OPPh₃.¹¹¹

e. Phosphine tellurides as synthetic equivalents of elemental tellurium. Preparation of metal tellurides

The use of phosphine tellurides as synthetic equivalents of elemental tellurium to introduce tellurium into molecules of organic and organoelement compounds is based on the fact that phosphine tellurides readily dissociate on heating. In some cases, phosphine tellurides are preferred over elemental tellurium, since the reactions can be carried out at lower temperatures and the products can be obtained in higher yields. Moreover, some telluration reactions can occur only with phosphine tellurides. Low-temperature synthesis of metal tellurides is among the most significant synthetic applications of phosphine tellurides. Thus triethylphosphine telluride reacts with metallic mercury in toluene at room temperature to give mercury telluride in an almost quantitative yield.¹¹²

Phosphine tellurides eliminate metallic tellurium at lower temperatures than the majority of widely used sources of tellurium such as Me₂Te and Et₂Te, which generate tellurium at temperatures above 200 °C.^{5, 113}

The easy thermal dissociation of phosphine tellurides has served as the basis for the recently developed synthesis of semiconductor nanosized crystals¹¹⁴ by pyrolysis of a mixture of organometallic substrates upon their injection into a hot coordinating solvent. Thus cadmium telluride with a size of crystals

ranging from 12 to 115 Å was obtained by the introduction of (C₈H₁₇)₃P=Te and Me₂Cd into (C₈H₁₇)₃P=O at 240 °C followed by keeping the reaction mixture at 190–220 °C to grow the crystals.¹¹⁴

The reactions of phosphine tellurides with some organoelement compounds result in insertion of tellurium into C–element bonds. For example, the formation of mercury telluride in the reaction of Et₃P=Te with diorganylmercury derivatives occurs according to the following scheme:¹¹²

R = Et, Ph.

It should be noted that various Ar₂Hg react with elemental tellurium only under fairly drastic conditions (> 200 °C) to give diaryl tellurides.^{8,9}

Insertion of Te atoms into Sc–C(sp³) or Sc–C(sp²) bonds occurs relatively easily when permethylscandoceno-alkyls or -aryls are made to react with tributylphosphine telluride or elemental tellurium.^{115–118} The reactions of scandocenes with phosphine telluride occur faster than the reactions with elemental tellurium, and compounds **99** are formed in higher yields (31%–71%).

R = Me₃SiCH₂, PhCH₂, *erythro*-CHDCHDBu^t, CH₂CHDCH₂CH₂CH=CMe₂, Ph, cyclo-C₅H₉CH₂.

The dimeric scandium μ-telluride **100** has been prepared in a similar way;^{115, 117} its structure was determined by X-ray diffraction analysis.

The advantages of Bu₃P=Te over elemental tellurium are illustrated by the synthesis of the scandocene derivative **101**.¹¹⁸ When elemental tellurium is used, the reaction is completed over 4–5 h, whereas in the case of Bu₃P=Te, this reaction occurs immediately after mixing the reactants.

Yet another example of the insertion of a Te atom into a C–element bond is the reaction of complexes **102** with trialkylphosphine tellurides yielding alkyltelluride manganese complexes **103**.^{119, 120} Pyrolysis of one of these products (**103b**) gives rise to manganese telluride.

R = CH₂Ph: R' = Me (**103a**), Et (**103b**);

A series of metal tellurides including manganese telluride have been prepared using complexes of metals in low oxidation states. Depending on the reaction conditions, the reactions involving these compounds either directly afford metal tellurides or initially

afford clusters the pyrolysis of which under relatively mild conditions leads to tellurides. Manganese¹²¹ and cobalt^{122, 123} tellurides have been obtained using carbonyls of the corresponding metals **104** the reactions of which with triethylphosphine telluride in toluene give rise to binuclear complexes **105**; these products result from the insertion of two tellurium atoms into metal–metal bonds in the initial complexes.

M = Mn, $n = 5$ (**a**); M = Co, $n = 4$ (**b**).

The dimeric molecules of **105** are built like diorganyl ditellurides R–Te–Te–R, but contain $(\text{Et}_3\text{P})_2(\text{CO})_{n-2}\text{M}$ groups instead of the organic radicals. The Te–Te bond lengths (2.763 Å in **105a**¹²¹ and 2.765 Å in **105b**¹²²) are somewhat larger than that in diphenyl ditelluride (2.712 Å¹²⁴). The pyrolysis of the complex **105a** giving crystalline manganese telluride occurs under substantially milder conditions (300 °C, 16 h) than does the synthesis of this telluride from the elements (heating to 800 °C followed by keeping the reaction mixture at 500 °C¹²¹).

When the $\text{Co}_2(\text{CO})_8 : (\text{Et}_3\text{P}=\text{Te}) : \text{Et}_3\text{P}$ ratio was varied, clusters **106**¹²² and **107a**^{122, 123} were isolated in addition to the compound **105b**. The former of these clusters can also be obtained from **105b**, $\text{Co}_2(\text{CO})_8$, and Et_3P ;¹²² treatment of the complex **105b** with $\text{Et}_3\text{P}=\text{Te}$ and Et_3P affords the cluster **107a**.¹²²

The chromium-containing cluster **107b**, similar to the cobalt derivative **107a**, was prepared by treatment of bis(triethylphosphinediallyl)chromium or bis(2,4-dimethylpentadienyl)chromium with triethylphosphine telluride.¹²⁵

According to X-ray diffraction data, the clusters **107a,b** are built of octahedra consisting of six cobalt (the Co–Co bond length is 3.23 Å¹²²) or chromium (the Cr–Cr bond length is 2.94 Å¹²⁵) atoms; the octahedra are incorporated into a cube combining 8 tellurium atoms; the triethylphosphine groups are bound only to metal atoms.

Pyrolysis of the clusters **107a** (300 °C, 45 min^{122, 123}) and **107b** (315 °C, 19 h¹²⁵) gives rise to polycrystalline β -CoTe and Cr_3Te_4 , respectively. In a relatively recent study,¹²⁶ the cluster $(\text{Ph}_2\text{PPr})_6\text{Co}_6\text{Te}_8$ the composition of which is close to that of **97a** was synthesised by the reaction of CoCl_2 with Ph_2PPr and trimethyl(phenyltelluro)silane.

The complexes bis(cyclooctadiene)nickel **108a**¹²⁷ and (cyclooctatetraene)iron **108b**¹²⁸ served as the starting compounds for the preparation of the tellurides of these metals. Thus heating of bis(cyclooctadiene)nickel **108a** in boiling toluene, which normally results in its dissociation to Ni and cyclooctadiene, affords polycrystalline nickel telluride when carried out in the presence of $\text{Et}_3\text{P}=\text{Te}$.¹²⁷ The synthesis of this telluride from the elements is possible only upon prolonged heating at 400–600 °C.

L = cyclooctadiene.

Nickel telluride¹²⁷ as well as a mixture of β - and γ -FeTe¹²⁸ have been synthesised by pyrolysis of clusters **109–111** formed initially. These clusters, like those considered above, are intermediate compounds on the way from organic substrates to inorganic solid materials. The nickel clusters **109** and **110** contain $\text{Et}_3\text{P} - \text{Ni} - \text{Te}$ fragments with tetracoordinated nickel and tellurium atoms;¹²⁷ in the cluster **111**, the tellurium atoms are tricoordinated, and the iron atoms are tetracoordinated.¹²⁸

M = Ni, L = cyclooctadiene (**108a**);

M = Fe, L₂ = cyclooctatetraene (**108b**).

Like nickel telluride, palladium telluride was synthesised using two procedures: by heating of an equimolar mixture of $\text{Pd}(\text{PPh}_3)_4$ and $\text{Et}_3\text{P}=\text{Te}$ in toluene¹²⁹ and *via* the clusters **112** and **113**; however, the clusters were isolated in fairly low yields (10% and 2%, respectively).

To complete the discussion of the methods for synthesis of metal tellurides, we shall mention a new approach developed recently,¹³⁰ which is based on the use of phosphine tellurides other than $\text{R}_3\text{P}=\text{Te}$. Complexes **114**, which have been obtained in almost quantitative yields by the reaction of phosphine tellurides **80** with zinc and cadmium bis[*N*-di(trimethylsilyl)amides], provide an example.^{130, 131}

M = Zn: R = Prⁱ (**114a**), cyclo-C₆H₁₁ (**114b**);

M = Cd: R = Prⁱ (**114c**), cyclo-C₆H₁₁ (**114d**).

The complexes **114** are crystalline compounds readily soluble in toluene. Based on the results of X-ray diffraction analysis of the selenium analogue of **114a**,¹³¹ a distorted tetrahedral structure has been ascribed to these complexes. Pyrolysis of the complexes **114a,b** at 300 °C and **114d** at 320 °C gives rise to cubic zinc telluride with an admixture of elemental tellurium and to cubic cadmium telluride, respectively.¹³⁰

Phosphine tellurides have also been used to synthesise compounds containing M–Te–M fragments. For example, the reaction of tributyltinhydride with tributylphosphine telluride in the presence of catalytic amounts of (C₅Me₅)₂TiH resulted in the formation of bis(tributylstannyl) telluride **115**.¹³² We shall not discuss the mechanism of the catalytic action of (C₅Me₅)₂TiH;¹³² however, it should be noted that without this compound, the formation of the telluride **115** proceeds very slowly.

Compounds **116** containing the M–Te–M' fragment (M and M' are atoms of different elements) were prepared by the reactions of dimetal derivatives **117** with tributylphosphine telluride.¹³² However, unlike **116a**, which rapidly disproportionates to give symmetrical tellurides **118a** and **119a**, its phenyl analogue disproportionates quite slowly.

R = Bu (a), Ph (b).

The reaction of the telluride **118** with tributylphosphine telluride giving rise to compound **120** is the only example of transformation of a telluride into a ditelluride known at present.^{132, 133} It is of interest to verify whether diorganyl tellurides R₂Te would be converted into diorganyl ditellurides R₂Te₂ upon treatment with tributylphosphine telluride. The compound **120** can be regarded as a synthetic equivalent of Te₂^{2–}, because its interaction with benzyl chloride affords dibenzyl ditelluride.¹³³

3. X-Ray diffraction analysis and spectroscopic characteristics of phosphine tellurides.

a. X-Ray diffraction analysis of phosphine tellurides

The data considered in this Section are mostly concerned with the lengths of P–Te bonds. Detailed information about the fine structure of phosphoryl groups R₃P can be found in original publications. The molecular and crystal structures of six compounds with P=Te bonds have been studied by X-ray diffraction analysis. The corresponding bond lengths are listed in Table 1.

It can be seen from Table 1 that the P=Te bond lengths vary over a narrow range and are intermediate between the theoretically predicted lengths of single (2.48 Å¹³⁴) and double (2.27 Å¹³⁴) P=Te bonds. These lengths have been reported⁸⁰ to correspond to a bond order of 1.5; this implies a substantial contribution of the bipolar P⁺–Te[–] structure to the ground state of phosphine telluride molecules. Comparison of the P–chalcogen bond lengths in tris(morpholinophosphine) telluride **79e** and its selenium analogue⁷⁸ with the sums of the radii of double bonds formed by the corresponding elements indicates that the contribution of the bipolar structure to the resonance hybrid in compounds with the P=Te bonds is larger than that in compounds with the P=Se bonds. This is indirectly supported by the conclusion, based on measurements of the dipole moments of phosphine chalcogenides, that the polarity of compounds increases in the sequence oxide < sulfide < selenide.¹³⁵ However, the values of the bond dipole moments of P=X bonds (X = O, S, Se, Te) calculated from the dipole moments of (C₈H₁₇)₃P=X¹³⁶ do not confirm this conclusion.

Table 1. Lengths of the P=Te bonds in phosphine tellurides.

Compound	Bond length / Å	Ref.	Compound	Bond length / Å	Ref.
Bu ₃ P=Te	2.368	80		2.354	76
	2.355	79		2.305	77
	2.357	78		2.327	77

The diazadiphosphetidine rings in the compounds **82c**⁷⁶ and *cis*-**83**⁷⁷ are markedly non-planar, whereas *trans*-**83**⁷⁷ is planar.

Although tellurium atoms in other types of organotellurium compounds tend to form both intramolecular⁶ and intermolecular bonds with atoms of other elements,¹³⁷ none of the phosphine tellurides has been found to contain any intermolecular contacts between tellurium and phosphorus atoms that would be shorter than the sum of their van der Waals radii.

b. Spectroscopic characteristics of phosphine tellurides.

Ultraviolet spectra of phosphine tellurides have been relatively little studied, which is apparently due to the fact that these compounds readily decompose in solutions. Therefore, the UV spectra have been reported only for the most stable compounds **79** in which the phosphorus atom is bound to nitrogen atoms incorporated into heterocycles. The absorption maxima of these compounds are observed at 280 nm.⁷⁸ Although the nature of the electronic transition responsible for this absorption is not known exactly, presumably,⁷⁸ it is the *n*→*π** transition. Particular interest is aroused by comparison of the UV spectra of compounds of the Ph₃P=X type containing O, S, Se, and Te atoms. The data for these derivatives presented in Table 2 indicate that the absorption bands shift bathochromically in the series O, S, Se, and Te.

Table 2. Data of the UV spectra for compounds R₃P=X.⁷⁸

R	X	λ _{max} / nm	lg ε
	O	< 205	
	S	~ 210	~ 3.70
	Se	~ 225	~ 3.56
	Te	286	2.79
	Te	288	2.85
	Te	281	2.80

According to several publications,^{73, 74, 78, 84, 96} the P=Te stretching bands lie in the range of 445–526 cm⁻¹. However, Watari,¹³⁸ who studied the IR and Raman spectra of Me₃P=Te and (CD₃)₃P=Te, did not find any absorption bands between 400 and 450 cm⁻¹; the bands for the P=Te stretching vibrations were observed at 376 cm⁻¹. It should be noted that the order of variation of the force constants of the P=X bonds in the series of phosphine chalcogenides R₃P=X differs depending on R. For R = Me₂N, the force constants change in the order O > Te > Se > S,⁸⁴ whereas in the case of R = Me, this order is O > S > Se > Te.¹³⁸

Data on the ³¹P and ¹²⁵Te NMR spectra of phosphine chalcogenides of various types are listed in Table 3.

Table 3. Chemical shifts (δ, ppm) and spin-spin coupling constants (J/ Hz) in the ³¹P and ¹²⁵Te NMR spectra of phosphine tellurides.

Compound	δ (³¹ P) ^a	δ (¹²⁵ Te) ^b	J(³¹ P– ¹²⁵ Te)	Ref.
Me ₃ P=Te		–513.4		80
Et ₃ P=Te		–875.2	1743	80
Pr ₃ P=Te		–1000.3	1735	80
Bu ₃ P=Te	+11.0		1720	83
		–807.0	1730	80
		–803.2	1732	139
Bu ₃ ^t P=Te	+75.2			99
		–836.5	1663	139
	+77.5		1600	73
(Me ₂ N) ₃ P=Te	+54.5		2003	85
	+58.8			99
		–826.4	2105	80
		–821.7	2095	139

			2040	80
() ₃ P=Te		–812.6	2153	139
			1821	80
Me(Me ₂ N) ₂ P=Te	+51.8		1950	83, 87
	+16.7			90
	+119.5			91
Et ₂ (EtO)P=Te	+83.0		1964	83

^a In relation to 85% H₃PO₄; ^b in relation to Me₂Te.

The ¹²⁵Te NMR spectra (provided that the solution contains no free phosphine) are well resolved doublets arising due to ³¹P–¹²⁵Te spin-spin coupling.¹³⁹ In the case of triphenylphosphine telluride which exists, as shown above, as a complex with triphenyl phosphine, the ¹²⁵Te signal is exhibited as a broad singlet at δ –491.8 ppm, owing to rapid migration of the Te atom between the Ph₃P groups.¹³⁹

The ¹²⁵Te chemical shifts range from δ –513 to –1000 ppm (in relation to Me₂Te) indicating that the Te nuclei are appreciably shielded and that the bipolar structures R₃P⁺–Te[–] make substantial contributions to the ground states of phosphine telluride molecules.

The ³¹P–¹²⁵Te spin-spin coupling constants are 1660–2150 Hz, the values for tris(dialkylaminophosphine) tellurides

being approximately 300–400 Hz greater than those for phosphine tellurides R₃P=Te.

IV. Conclusion

The data presented in this review demonstrate certain progress in the chemistry of organic derivatives of monocoordinated tellurium achieved over the past decade. Efficient methods for the generation of telluroaldehydes and telluroketones have been developed and the first relatively stable telluroketone was synthesised. Dimerisation and Diels–Alder reactions of these compounds have led to the synthesis of ditelluretanes, 1-telluracyclohex-3-enes and 2-tellurabicyclo[2.2.1]hept-5-enes. New complexes of tellurocarbonyl derivatives with transition metal compounds have been prepared and their chemical transformations have been studied. It has been shown that at low temperatures in polar solvents like THF, tellurocarboxylic acids exist in the telluroxo-form. The chemistry of telluroesters and telluroamides has been developed to a lesser extent. Development of new methods for the synthesis of compounds with C=Te bonds, study of the possibility of using these derivatives in the preparation of tellurium-containing heterocycles, and attempts to synthesise stable telluroaldehydes and telluroketones by introducing substituents, able to form intramolecular coordination bonds with the C=Te groups, into their molecules appear to be promising lines of research in this field.

As regards phosphine tellurides, the main progress has been achieved in the investigation of their reactivity towards alkylation, complex formation, oxidation, and other types of transformation. However, the discovery and study of reactions in which phosphine tellurides act as synthetic substitutes of elemental tellurium is the most important achievement. This property of phosphine tellurides forms the basis for using them in low-temperature syntheses of metal tellurides and new types of tellurium-containing clusters. In addition to further development of these studies, it appears of interest to attempt using phosphine tellurides as tellurating reagents in the synthesis of some organotellurium derivatives (the transformation of diorganyl tellurides into diorganyl ditellurides, reactions with halogen-containing substrates, etc.)

The review was supported by the Russian Foundation for Basic Research (Project No. 96–03–32502a) and the INTAS (Grant No. 94–4675).

Abstract. The methods of synthesis, properties, and reactivities of azo-compounds based on rhodanine and thiopropiorhodanine are examined. The possibilities of the wide scale practical employment of this series of reagents, including their modified and immobilised forms, in the analytical chemistry of platinum and heavy metals are discussed. The bibliography includes 115 references.

I. Introduction

Azo-compounds based on rhodanine (2-thioxo-4-thiazolidinone), thiorhodanine (2,4-dithioxothiazolidine), and aromatic amines containing salt-forming groups were first synthesised in 1971; these azo-compounds were obtained at the same time as analytical reagents.^{1,2} A distinctive feature of these reagents is their ability to enter into highly sensitive, selective, and contrasting colour reactions with noble (NM) and heavy (HM) metals in solutions and in the solid phase.^{3–13} Systematic studies on azo-compounds synthesised from 3-substituted derivatives of rhodanine, thiohydantoin (2-thiazolidine), selenisorhodanine [4-thioxo-2-(1,3-selenazolidinone)], the six-membered analogue thiopropiorhodanine (2,4-dithioxo-1,3-thiazane), as well as bisazo-compounds based on rhodanine resulted in the creation of a whole series of promising analytical reagents.^{14–24} By virtue of their exceptionally valuable properties, azorhodanines and azothiopropiorhodanines have found extensive applications in analytical chemistry. For example, various methods for the determination of 17 elements (photometric, differential photometric, extraction-photometric, sorption-photometric, including those using sensitive photometric cells, *etc.*) have been developed using these compounds. The method may be applied in the analysis of objects of different composition and with different contents of the components. It may be that azorhodanines and azothiopropiorhodanines are some of the most promising analytical reagents proposed during the last 25 years.

Rhodanine is known as the analytical reagent for the precipitation and gravimetric determination of silver, mercury, and other platinum metals.^{25–30}

However, the low sensitivity of rhodanine (as well as the products of its interaction) and the low sensitivity of the reactions precluded the wide scale employment of this reagent for the requirements of analytical chemistry, especially photometry. Because of the enhanced reactivity of the 5-methylene group, rhodanine interacts with compounds of different classes — aldehydes, ketones, and diazo-compounds.^{31–42} This leads to the possibility of obtaining from it new reagents containing the chromophoric groups $=C=CH-$ and $-N=N-$. The sensitivity and contrasting properties of the reactions of rhodanine condensation products with metal ions are greatly superior to those of rhodanine. Thus *p*-dimethylaminobenzylidenerhodanine has found fairly extensive applications in the photometric determination of silver and gold.^{29, 30, 43–49}

In contrast to the 5-condensed derivatives, the azo-compounds based on rhodanine and aromatic amines containing salt-forming groups (OH, SO_3H , $COOH$, AsO_3H_2)^{1–3, 13, 14, 16, 21, 24} are of interest for the determination of not only gold and silver but also of platinum, palladium, rhodium, iridium, ruthenium, and heavy metals. Such compounds are more stable in solution, dissolve relatively easily, and their reactions with the elements are characterised by an unusually high sensitivity [the molar absorption coefficient (ϵ) reaches $(3–9) \times 10^5$ in certain cases], good contrasting properties, and high selectivity. The selectivity is based on the sharp differences between the conditions and kinetics of the colour reactions with the elements and the spectroscopic characteristics and stability of the complexes formed.^{50–58}

II. Synthesis of the reagents and methods for their identification

About forty 5-azo-compounds based on rhodanine (**1a–m**), thiorhodanine (**2a–c**), thiohydantoin (**3a, b**), pseudothiohydantoin (**4a–d**), 3-aminorhodanine (**5a–f**), N-substituted 3-aminorhodanine (**6a, b**), bisazo-compounds based on rhodanine (**7a–c**), selenisorhodanine (**8a–d**), a six-membered structural analogue

of rhodanine — thiopropiorhodanine (**9a–d**), as well as aromatic amines containing predominantly salt-forming groups have been synthesised as possible analytical reagents.^{1–3, 13, 14, 16, 21, 24} The structural formulae and names of reagents of each group are presented in Table 1.

The azo-compounds are synthesised in accordance with a general scheme: by treating the heterocyclic azo-component with the corresponding diazotised amine under conditions suitable for each reaction (nature of the solvent, pH, time during which the reaction mass is allowed to stand, and the temperature regime). This ensures the preparation of reagents in high yields and reduces to the maximum extent the possibility of the formation of side products. The heterocyclic azo-components are obtained as follows: rhodanine — by the condensation of monochloroacetic acid with ammonium thiocyanate on heating;²⁵ thiorhodanine — from rhodanine by replacing the carbonyl group by the thiocarbonyl group on treatment with P_2S_5 ;¹ thiohydantoin — by the reaction of potassium thiocyanate with the hydrochloride of the ethyl ester of glycine;⁵⁹ pseudothiohydantoin — by condensing urea with monochloroacetic acid on heating;²⁵ 3-aminorhodanine — by condensing sodium monochloroacetate with hydrazine dithiocarbazine;^{60, 61} 3-aminobenzylidenerhodanine — by condensing 3-aminorhodanine with aldehydes in acetic acid; thiopropiorhodanine — by treating propiorhodanine with P_2S_5 in dry dioxane;⁶² propiorhodanine — by condensing chromotropic acid with freshly prepared ammonium dithiocarbamate and subsequent heating of thiocarbamoyl- β -thiolactic acid with acetic anhydride;⁶³ selenisorhodanine — by the interaction of 1,3-selenazolidine-2,4-dione with P_2S_5 in dry dioxane;⁶⁴ 1,3-selenazolidine-2,4-dione — by condensing monochloroacetic acid with selenourea on heating.

In order to obtain purer products and higher yields of the main substances, the synthesis is carried out in the presence of metal (calcium, lead) salts, but the solubility of the reagents is then reduced. The azo-compounds based on aminophenols and selenisorhodanine could not be isolated.

The azo-compounds are identified by paper chromatography, column chromatography, electrophoresis using various buffer systems and also from the characteristic absorption spectra of the reagents themselves (concentrated H_2SO_4 , neutral and alkaline solutions) and their complexes. The purity of the preparations is established by the potentiometric titration of the reagents with alkali and by spectrophotometric titration with solutions of metal salts.^{3, 7, 16, 65}

The study of 5-azo-compounds based on propiorhodanine [2-thioxo-4-(1,3-thiazanone)] showed that, in contrast to rhodanine, propiorhodanine does not react with diazonium salts even in the presence of activators of the azo-coupling reactions (pyridine, alkoxides). The reduced reactivity of the methylene group in the 5-position is due to the fact that the activating effect of the carbonyl group in the 4-position extends to the 5-methylene group, while the thioxo-group activates the 6-methylene group. On the other hand, in rhodanine the activating effect of the two groups is directed to the 5-methylene group of propiorhodanine. At the same time, the azo-coupling of thiopropiorhodanine with diazonium salts becomes possible as a result of the increase in electron density on the carbon atom in the 5-position as a consequence of enolisation and the formation of a thioenolate anion.^{62, 63}

III. Properties of the reagents

The reagents are powdered substances the colour of which varies from yellow to dark-red depending on the nature of the diazo- and azo-components; they dissolve in dioxane, dimethylformamide, ethanol, acetic acid, solutions of alkalis, and concentrated acids. The reagents containing sulfo-groups are readily soluble in water. In a dry form, they retain their analytical properties for more than three years.

The state of the reagents in solution is one of the principal factors determining the reactivity, the mechanism of the complex formation reaction, and the nature of the colour reactions with the elements. Solutions of the reagents undergo a sharp colour change as the pH is altered, which is due to the dissociation of the acid groups and the protonation of the basic groups as well as tautomeric transformations. For the azo-substituted rhodanines **1a–m**, the diazo-component of which contains a OH group, it is possible to identify several coloured forms: red (conc. H_2SO_4), yellow (pH 1–4), orange (pH 4–8), red (pH 8–10), and violet (pH > 11). For reagents without OH groups, a colour change from lemon-yellow (acid and neutral media) to yellow-orange (pH 9–10) and red (pH 11–13) is observed. Only three coloured forms have been identified for the azothiorhodanines **2a–c**, which contain an OH group: dark-red (acid and neutral media), violet (weakly alkaline media), and blue (strongly alkaline media). The azothiorhodanines are unstable in strongly acid media.

The above pH values and the sequence in which the acid groups of the reagents ionise have been established on the basis of the results of potentiometric and high-frequency titrations as well as the analysis of the absorption spectra at the pH corresponding to the potential jumps.^{3, 7, 16, 22, 65} The nature of the heteroatom (O, S) influences appreciably the pK for the dissociation of the NH group of the heterocycle. In the azothiorhodanines **2a–c**, the NH group is titrated at lower pH; on the other hand, the nature of the substituents in the diazo-component influences the pK of the OH group in the benzene ring.

For the majority of azorhodanines, $pK_{NH} < pK_{OH}$. However, in the case of disulfophenolazorhodanine **1b**, the NH and OH groups are titrated simultaneously, whilst in picramineazorhodanine **1e**, containing two strong electron-accepting substituents, the dissociation of the OH group in the benzene ring precedes that of the NH group.

In concentrated H_2SO_4 , a shift of the long-wavelength absorption band ($\Delta\lambda = 70$ nm) is observed for all 5-azo-substituted rhodanines relative to their absorption band in neutral solutions. According to calculated data,⁶⁵ the bathochromic shift in strongly acid media is due to the protonation of the reagents: the heteroatoms of the rhodanine ring are protonated but not the hydroxy-group in the benzene ring or the nitrogen atom of the azo- or hydrazo-group, because the highest negative charge is present on the heteroatoms of the rhodanine ring.

Several types of tautomerism are possible for azo-substituted rhodanines:

If the reagent contains a OH group in the benzene ring, there is yet another form of tautomerism: hydroxyazoquinone – hydrazone.

Table 1. Structural formulae and names of the reagents.

Azo-compound	Number	Name according to IUPAC nomenclature	Trivial name
	1a	5-chloro-2-hydroxy-3-[(4-oxo-2-thioxo-5-thiazolidinyl)azo]benzenesulfonic acid	sulfochlorophenolazo-rhodanine (SCPAR), rhodazol KhS
	1b	3,5-disulfo-2-[(4-oxo-2-thioxo-5-thiazolidinyl)azo]phenol	disulfofphenolazo-rhodanine
	1c	2-hydroxy-5-nitro-3-[(4-oxo-2-thioxo-5-thiazolidinyl)azo]benzenesulfonic acid	sulfonitrophenolazo-rhodanine
	1d	3-carboxy-2-hydroxy-5-[(4-oxo-2-thioxo-5-thiazolidinyl)azo]benzenesulfonic acid	carboxysulfofphenol-azorhodanine
	1e	3,5-dinitro-2-[(4-oxo-2-thioxo-5-thiazolidinyl)azo]phenol	picramineazorhodanine
	1f	4-chloro-2-[(4-oxo-2-thioxo-5-thiazolidinyl)azo]phenol	rhodazol Kh

	9d	2-carboxy-[(tetrahydro-2,4-dithioxo-1,3-thiazin-5-yl)azo]benzene	carboxybenzeneazothiopropiorhodanine

The molecules of azo-substituted rhodanines exist in aqueous solutions predominantly in the azodiketo-form. On complex formation, the equilibrium shifts towards the enolic form. This is confirmed by data concerning the number of protons liberated on formation of the complex between copper ions and SCPAR **1a**. The formation of a 1 : 1 complex is accompanied by the liberation of two protons.³ The concentration of the azothiol tautomer is low. Picramineazorhodanine **1e**, for which the contents of the diketo- and thiol forms are approximately the same, is an exception. For the reagents containing a OH group, the first bathochromic shift (pH 6–10) is due to the transition from the azo-form of the reagent to the quinone hydrazone form. In strongly alkaline solutions, a shift of the thione–thiol equilibrium towards the thiol azo-tautomer is observed, this being accompanied by a bathochromic shift of the long-wavelength absorption band. The presence of electron-accepting substituents in the benzene ring, for example in compounds such as sulfonitrophenolazorhodanine **1c** and picramineazorhodanine **1e**, ‘shifts’ the pH of the thione–thiol transition towards lower values.⁶⁵

A series of azorhodanines have been investigated by ¹³C NMR. It was concluded that the reagents containing OH groups in the benzene ring exist in the form of two isomers in organic solvents (OS) such as CD₃OD, DMSO, and CD₃COOD.^{66, 67}

Analysis of IR spectroscopic data for azo-derivatives of rhodanine, 3-aminorhodanine, and thiopropiorhodanine showed that the transition from rhodanine to thiopropiorhodanine entails significant changes in the nature of the interaction of the individual fragments of the heterocycle and a displacement of the equilibrium towards the quinone hydrazone tautomer.⁶⁸

5-Azo-substituted thiohydantoins **3a, b** and pseudothiohydantoins **4a–d** represent the least investigated series of reagents. Their stability is inferior to that of the azorhodanines **1a–m** and azo-3-aminorhodanines **5a–f**. The ionisation sequence of the acid groups is retained.

In the case of 5-azo-compounds based on 3-aminorhodanine and *N*-substituted rhodanines **6a, b**, the same features of the influence of substituents in the diazo-component on the spectroscopic characteristics and acid–base properties of the reagents are observed as for azorhodanines. For the same sequence of the dissociation of the acid groups, a strengthening of the acid properties of the OH groups in the benzene ring is observed. For example, $pK_{OH} = 8.5$ for sulfochlorophenolazorhodanine **1a**, while $pK_{OH} = 7$ for sulfochlorophenolazo-3-aminorhodanine **5a**. The bathochromic effect in concentrated H₂SO₄ is weaker than in the case of azo-substituted rhodanines.¹⁶

The introduction of a second areneazo-group into the reagent molecule affects the state of the reagent in acid media. Whereas the protonation of azorhodanines, accompanied by a deepening of the colour † (from 420 to 500 nm), is observed in 10–15 M H₂SO₄, the bisazo-compounds based on rhodanines **7a–c** are protonated already in 1–2 M H₂SO₄ whereupon the colour becomes even deeper (from 420 to 580 nm). The influence of thermochromism — the change in colour on heating in acid media — has been observed for the bisazo-compounds. A sharp change in the colour

of benzeneazobenzeneazorhodanines as a function of pH is observed in the presence of surfactants (for example, cetylpyridinium chloride) and certain organic solvents (ethanol, propanol, acetone), provided that the content of the latter exceeds 85%. At least two new coloured forms of the reagents, undetected in aqueous solutions in the absence of organic additives, appear under these conditions. It has also been noted that, in the presence of surfactants, the reagents are protonated in more acid media. The deepening of the colour in alkaline and acid solutions is accompanied by an increase in optical density at the absorption maximum.^{21–23}

5-Azo-substituted selenisorhodanines **8a–d** are unstable in solutions. When the pH changes, the colour of solutions of the reagents is altered. The nature of the heteroatom (Se) intensifies the acid properties of azoselenisorhodanines. The protonation of reagents takes place in more dilute acid solutions and is accompanied by a more pronounced deepening of the colour compared with azorhodanines ($\lambda_{max} \approx 530$ and 490 nm respectively).

5-Azo-substituted derivatives of thiopropiorhodanine have a deeper colour in neutral and alkaline solutions than the corresponding rhodanines ($\lambda_{max} \approx 540$ and 430 nm respectively). A change in the dissociation sequence of the NH and OH groups has been noted for these reagents. The OH group in the benzene ring is the first to dissociate (at lower pH). This can be due both to the difference between the acid properties of the azo-components themselves ($pK_{NH} = 5.8$ for rhodanine and 8.1 for thiopropiorhodanine) and to the difference between the mechanisms of the tautomeric transformations. A deepening of the colour of the reagents, as in the case of azorhodanines and azo-3-aminorhodanines, is not observed for azothiopropiorhodanines in strongly acid media. The yellow colour of the reagents in weakly acid media, characteristic of the neutral form, is retained even in concentrated H₂SO₄. A strong influence of surfactants and organic solvents on the colour of the reagents over a wide pH range is observed both for azothiopropiorhodanines and for azorhodanines and rhodanine-based bisazo-compounds.^{22, 23}

IV. Reactions with metal ions and the properties of the complexes formed

The reagents based on aminophenols give rise to the most sensitive and contrasting colour reactions. In the case of 5-azorhodanines, it is possible to identify three complex-formation pH ranges.^{1, 5, 7, 9, 65} Pd, Ag, Cu, Fe, Co, Ni, Zn, Cd, Pb, and Be react in the pH range 6–10. The colour then changes from orange (480 nm) to violet (530–580 nm); $\epsilon = 2 \times 10^4$. Cu, Pd, Ag, and Hg interact at pH 1–6, the colour changing from yellow (430 nm) to red-orange (430–500 nm); $\epsilon = (1.5–3) \times 10^4$. In acid and strongly acid media, noble metals (Pt, Pd, Rh, Ir, Ru, Au, Ag) and Hg interact with the reagent; the reactions are contrasting (430 → 500–530 nm) and highly sensitive; $\epsilon = (2–12) \times 10^4$. The reactions in strongly acid media proceed as a rule over a period of time and in the presence of a 30–50-fold excess of the reagent. The sensitivity and rate of the reaction as well as the solubility of the reaction products depend on the nature and concentration of the acids (mixture of acids) in which the reaction is performed. Heating increases the rate of the reactions of noble metals with azorhodanines, but the yield of the complexes of certain metals diminishes under these conditions. For example, the chloride complexes between platinum(IV) and SCPAR give rise to a colour reaction in the presence of reductants both in HCl and in a mixture of HCl with H₂SO₄ or H₃PO₄; heating decreases the yield of the complex. The colour development time is 20 and 4 h, while $\epsilon = 3.3 \times 10^4$ and 1.0×10^5 in HCl and in the HCl–H₃PO₄ mixture respectively (Table 2).

Rhodium and iridium give rise to a colour reaction with azorhodanines in H₃PO₄ and H₂SO₄; in the presence of CH₃COOH, the sensitivity of the reactions increases; heating to 70 and 90 °C respectively increases the rate of the reaction.

† The bathochromic shift of the main absorption band.

Table 2. Analytical characteristics of the colour reactions of azorhodanines and tyrodine.

Initial form of the elements	Reaction conditions	$\lambda_{\max}$ /nm	$10^{-3} \epsilon$	Ref.
Sulfochlorophenolazorhodanine				
Pt(IV), chloride	3 M HCl, 4 h	500	32	1, 5, 50
	2 M HCl + 2 M H ₃ PO ₄ , 4 h ^b	500	100	1, 5, 50
Pt(III), sulfate	2 M H ₂ SO ₄ + 11 M H ₃ PO ₄ , 30 min, 50 °C	500	100	18, 51, 54, 74
Pt(III), phosphate	12–15 M H ₃ PO ₄ , 50 min, 50 °C	500	100	18, 54, 58

Benzeneazorhodanine				
Hg(I), Hg(II), nitrate	pH 7–9, surfactant	570	100	21–23
Cu(II), chloride	pH 7–9, surfactant	570	20	21–23
Au(III), chloride	pH 7–9, surfactant	570	100	21–23
Re(IV)	2 M NaOH + 0.1 M SnCl ₂	570	$c_{\min} = 0.052 - 0.005 \mu\text{g ml}^{-1}$	79–81
Sulfobenzeneazophenolazorhodanine				
Pd(II), chloride	pH 1–3, surfactant	540	300	21–23
Au(III), chloride	pH 1–3, surfactant	540	600	21–23
Rh(III), chloride	pH 1–3, surfactant	540	100	21–23
Ru(III), Ru(IV), chloride	pH 1–3, surfactant	540	40	21–23

^a For the same sensitivities of the reactions of Pd(II) in the form of chlorides and in the form of sulfates, phosphates, and nitrates, the rates of the last three reactions are higher. ^b The reaction is carried out in the presence of reductants. ^c The two reagents 'tyrodine–macrocylic compound' method.

Gold interacts with azorhodanines in HCl solutions at room temperature, the reaction being completed after 5–10 min. The presence of H₂SO₄ and H₃PO₄ does not affect the sensitivity and rate of the reaction, but the solubility of the complexes increases and the permissible acidity range expands in H₃PO₄. Thus the optical density of solutions of the gold complexes of SCPAR is constant in 2–10 M H₃PO₄ and 0.5–1.3 M HCl, whereas in the absence of H₃PO₄ the maximum development of colour is observed in 1 M HCl.

The silver complexes, like the palladium complexes, have different molar absorption coefficients at the absorption maximum ($\lambda_{\max}$), compositions (reactant : metal ratio in the complex), solubilities, and other characteristics depending on the reaction conditions. In neutral and weakly acid solutions, palladium and silver form readily 1 : 1 complexes with azorhodanines. Saturation is then attained in the presence of a 2–3-fold excess of the reagent.

Among the reagents of the azorhodanine series, those which exist predominantly in the form of the diketo-tautomers in acid and neutral media are best, for example SCPAR, carboxysulphophenolazorhodanine **1d**, and *o*-phenolazorhodanine **1g**. Reagents which contain comparable amounts of diketo- and thiol forms in weakly acid media, for example sulfonitrophenolazorhodanine **1c** and picramineazorhodanine **1e**, are less sensitive. According to quantum-chemical studies, the reactions of silver with benzeneazorhodanines containing electron-donating substituents in the benzene ring should be characterised by a high sensitivity. The presence of a hydroxy-group enhances the contrasting properties of the reaction as a result of the hydroxyazoquinone–hydrazone tautomeric transition. In strongly acid media, the reactions of Ag and Pd as well as those of Rh, Ir, Ru, and Pd proceed over a period of time and in the presence of a large excess of the reagent. The sensitivity of the reactions in strongly acid media is higher than in

neutral and weakly alkaline solutions (pH 7–9). In terms of selectivity, the colour reactions of silver and palladium supplement one another. In strongly acid media, the selectivity of the determination in relation to nonferrous metals is higher and in relation to platinum metals is lower than in weakly acid and neutral solutions (pH 1–6).

5-Azothiorhodanines enter into colour reactions with gold, platinum, and palladium in 1–6 M HCl. The colour changes from red to blue-violet; $\varepsilon = (2-5) \times 10^4$. Silver interacts with 5-azothiopropiorhodanines at pH 1.5, the sensitivity of the reactions being low.

5-Azothiopropiorhodanines and 5-azothiopropiorhodanines do not react with rhodium and iridium, whereas thiopropiorhodanine-based azo-compounds enter into highly sensitive colour reactions with Pt, Pd, Au, and Ag in acid and strongly acid media; the colour changes from yellow to red. The presence of HCl has a negative influence on the reactions of gold and platinum. For platinum and gold, the optimum acid mixture comprises H_3PO_4 (H_2SO_4) and CH_3COOH . For platinum, the rate of reaction and the yield of the complexes increase in the presence of reductants.^{16, 17}

For silver, it is possible to identify two regions of interaction with azothiopropiorhodanines: neutral (pH 5–9, $\Delta\lambda = 30$ nm, $\varepsilon = 2.0 \times 10^4$) and acid (CH_3COOH – H_3PO_4 mixture, $\Delta\lambda = 75$ nm, $\varepsilon = 5.3 \times 10^4$) media. The formation of a coloured silver compound in strongly acid media was first noted for azorhodanines. The interaction of silver with azothiopropiorhodanines has a series of characteristic features compared with azorhodanines. In the case of azothio propiorhodanines, the most sensitive colour reaction with silver takes place in a CH_3COOH – H_3PO_4 acid mixture, while in the case of azorhodanines the addition of even insignificant amounts of CH_3COOH masks the reaction with silver, which can be accounted for by the greater stability of the silver complexes of azothiopropiorhodanines. The reaction of silver with azothiopropiorhodanines takes place in the presence of a 2–5-fold excess of the reagent, while that with azorhodanines requires a 20–50-fold excess of the reagent for saturation. Among the characteristic features of the reactions of silver with azothiopropiorhodanines, one should include also their high selectivity in relation to copper and other nonferrous metals, which is of great practical interest.

Tyrodine **9a** proved to be a promising reagent for lead.^{20, 69–71} Lead(II) interacts with tyrodine, forming a violet complex. The colour reaction develops over a period of 20–30 min. An increase in the temperature of the reaction mixture and changes in pH and in the reagent concentration do not lead to an increase in the rate of reaction. The curve for the time dependence of the optical density $A = f(\tau)$ is characterised by an induction period of 15–20 min, after which the reaction goes to completion in 1–2 min. It has been noted that the presence of up to 2% of the lead complex of tyrodine accelerates the reaction so much that the induction period is eliminated. An autocatalytic mechanism of the colour reaction between lead and tyrodine has been proposed and can be described as follows in general terms.⁷⁰

The first stage — the formation of a simple lead salt PbR involving the sulfo-group which is ionised under these conditions — is not accompanied by a colour change. This reaction is rapid (pH 3–4), the salt formed is sparingly soluble under the reaction conditions, and a weak opalescence of the solutions is observed. The first stage involves the formation of a 1 : 1 complex (PbR) with participation of the hydroxyazothioketone group of the reagent as a result of either an intramolecular rearrangement or interaction with a second molecule of the reagent (which is present in solution in an excess relative to lead). This stage is slow; 2–3 min after its onset, a change in the colour of the solution is observed and the opalescence vanishes. The third stage — the appearance of the final reaction product PbR_2 — is also slow, since both interacting species, PbR and R , are relatively unreactive: lead is partially hydrolysed and the hydroxy-group in the benzene ring of the reagent is undissociated;¹⁶ both species are to a considerable extent hydrated. It has been suggested that the final product PbR_2 actually possesses catalytic activity: in the fourth

stage, it dissociates, as a result of which compounds or radicals (PbR' and R') appear and are in the most active form at the instant of their formation (for example, as a result of minimal solvation). In the subsequent rapid reactions

and

the number of PbR_2 molecules increases, which is in fact the basis of the catalytic effect. Other mechanisms for the reaction of lead with tyrodine have also been proposed.⁷⁰

From the practical point of view, it is important that the development of the colour reaction between lead and tyrodine is not affected by large amounts of Ni, Co, Fe, Zn, Au, Pt, Rh, Be, Mn, Sn, and Ca; Ag, Hg, and Cu interfere. The high selectivity of the reaction permits the direct determination of lead in a series of systems (for example, in waste waters of the lead industries, anodic and cathodic copper, sulfuric acid) without preliminary separation from the accompanying elements.²⁰

A series of quantitative characteristics of the colour reaction of cadmium with tyrodine have been obtained.⁷² The colour reaction of cadmium is unaffected by 500–10 000-fold excess amounts of alkali and alkaline earth elements and 10–100-fold excess amounts of heavy metals; Pb, Hg, Ag, and Cu interfere. The influence of copper and mercury may be eliminated with the aid of thiourea. The colour reaction between cadmium and tyrodine has served as the basis of methods for the determination of cadmium in various types of water. Like lead, cadmium forms complexes with Cd : R = 1 : 2 under analytical conditions.⁷²

The colour reactions of azo-compounds based on 3-aminorhodanine **5a–f** and substituted 6-aminorhodanine **6a,b** with Pt, Pd, Au, and Ag are close to the corresponding reactions of azorhodanines as regards sensitivity, contrasting properties, and rate of development of the colour. On the other hand, like azothiorhodanines and azothiopropiorhodanine, these compounds do not react with rhodium and iridium, which is apparently associated with their instability in strongly acid media on heating, *i.e.* under conditions where the kinetically inert rhodium and iridium complexes react. The azo-compounds based on 3-aminorhodanine, for example *p*-phenolazo-3-aminorhodanine **5d**, are of considerable interest for the determination of monovalent and divalent mercury primarily by virtue of their high selectivity. Mercury interacts with the reagent in strongly acid media at room temperature with formation of a stable raspberry-red complex. Large amounts of Pb, Zn, Bi, Be, Ba, Ca, Mo, Ir, Ru, and Rh do not interfere with the determination; Ag, Au, and Pd do interfere. The reagent has been used in the analysis of biological objects and industrial waters without preliminary separation of mercury from the accompanying elements (in contrast to the widely familiar method for the determination of mercury with the aid of pyridyl-lazoresorcinol).¹⁹

Derivatives of benzeneazobenzeneazorhodanine **7a–c** enter into colour reactions with noble and heavy metals, but the sensitivity of the reactions is low. In terms of sensitivity, these reactions are inferior to the corresponding reactions with rhodanine-based monoazo-compounds. The colour reactions of azobenzeneazorhodanines proceed in less acid media. This can apparently be accounted for by the characteristic features of the structure of the reagents, namely by the presence of an extended π -electron system. This decreases the acidity required for the protonation of the reagents, which is accompanied by a pronounced deepening of the colour (λ_{max} for the neutral forms of benzeneazobenzeneazorhodanines is 440–480 nm, while that for the protonated forms is 580–620 nm). One of the important features of these reagents is that they enter into highly sensitive and contrasting colour reactions with noble and heavy metals in the presence of surfactants [$c_{\text{surf}} < \text{CMC}$ (CMC is critical micelle concentration)] and certain organic solvents when the content of the latter is more than 80%–85%.^{21–23} Two types of colour

reactions are characteristic of modified derivatives of benzene-azobenzeneazorhodanine. The first type of the interactions of these reagents includes those with Cu, Hg, Ag, Pd, and certain other elements in neutral and alkaline solutions, the reactions being characterised by effective contrasting properties ($\Delta\lambda = 250$ nm) and a higher sensitivity, the absorption coefficients ε increasing by a factor of 5–10. The interactions of the second type are those with Pt, Pd, Rh, and Ru (heavy metals and silver do not enter into reactions of this kind). The reactions proceed at pH 1–3 and are characterised by an even more pronounced increase in sensitivity with virtually unchanged contrasting properties. The reactions of Au and Pd with modified SBAPAR **7c** are the most sensitive, the absorption coefficients ε being 3×10^5 and 6×10^5 respectively. The sensitivity of reactions of the second type is greatly superior to that of the most sensitive reactions of noble metals with SCPAR and tyrodine. A high rate of development of the colour in these reactions should also be noted.

The ratio of the reagent to the metal in the complex (molar ratios method) is 2 : 1 in the presence of cetylpyridinium chloride in the case of reactions of the first type. Compounds even more 'saturated' with respect to the reagent are formed by reactions of the second type. The cause of such an increase may be associated both with the increase in the coordination capacity of the metal (for example, by virtue of dehydration on treatment with a surfactant or organic solvent) and with a change in the state of the reagent itself (for example, its aggregation, preceding the formation of the complexes).

Table 2 presents the characteristics of reactions of metal ions with the reagents (including their modified forms). The compounds examined apparently belong to the class of the most promising reagents of the azorhodanine and azo-thiopropiorhodanine series for the determination of noble and heavy metals both in solutions and in the solid phase.^{13, 73}

V. Characteristic features of the interaction with acido-complexes of platinum metals

The reactions of sulfate (Pt, Pd, Rh), phosphate (Pt, Pd, Rh, Ir), acetate (Rh), and hydroxynitrate (Pd) complexes have been investigated together with the traditional chloride complexes using sulfochlorophenolazorhodanine and tyrodine as the reagents^{1, 4, 8, 9, 53–56, 82} (see ‡).

The vast majority of methods for the determination of platinum elements are known to be applicable only to chloride systems. Analysis of other systems involves as a rule an additional stage in which the initial complexes are converted into chloride complexes. On the other hand, from the practical standpoint it is important to investigate the reactivities of acido-complexes of platinum metals based on various oxygen-containing acids (H_2SO_4 , HClO_4 , H_3PO_4 , CH_3COOH). These acids are in fact largely employed at various stages in the processing of natural and industrial materials and in refining. Studies of the reactivities of dimeric complexes of platinum elements with a metal–metal bond have acquired special importance. Such compounds have unusual thermodynamic and kinetic characteristics. They are readily aquated and enter into substitution reactions more vigorously than the chlorides. This leads to new possibilities in the analytical chemistry of the platinum elements. In the dimeric complexes, the

platinum elements can manifest unusual chemical properties. Many of the difficulties in the development of methods for the photometric determination of platinum metals, for example in the sulfate or phosphate form, are known to be associated with hydrolysis and the formation of unreactive polymeric forms in dilute acid solutions. A characteristic feature of azorhodanines and their analogues consists in their ability to enter into highly sensitive colour reactions with noble metals in strongly acid media, in which readily hydrolysable forms of the platinum elements may retain their reactivity. Simultaneously with the investigation of the colour reactions of acido-complexes of platinum metals, the behaviour of the initial forms of the complexes under the conditions of their colour reactions has been investigated spectrophotometrically. Taking into account the results of such studies, a hypothesis has been put forward concerning the nature of the active forms of the platinum elements and the factors determining their yield. Procedures have also been proposed for the stabilisation (standardisation) of the active forms and in certain cases procedures for the conversion of the initial forms into active ones.^{53, 56}

Dimeric platinum(III) phosphate and sulfate complexes as well as their chloride forms give rise to brightly coloured compounds with sulfochlorophenolazorhodanine and tyrodine.^{8, 53–56} Depending on the nature of the ligand and the oxidation state of the central atom in the initial complex, the conditions, kinetics, sensitivity, and selectivity of the colour reactions are different. Platinum phosphate and sulfate complexes interact with organic reagents in more acid media and a higher kinetic reactivity, compared with platinum(IV) chloride complexes, is characteristic of them. Markedly different effects of reductants on the colour reactions of acido-complexes of platinum have also been observed. Thus the reactions of platinum(IV) chloride complexes with organic reagents are strongly accelerated in the presence of reductants, whereas the influence of the latter on the colour reactions of the phosphates and sulfates is insignificant. The absorption spectra of platinum complexes with organic reagents are independent of the initial form of platinum.

The characteristics (reaction conditions, solubility of the products, behaviour in relation to reductants) of the colour reactions of dimeric platinum sulfate and phosphate complexes are similar. The coloured compounds of platinum sulfate and phosphate with organic reagents are more soluble and more stable on heating than the chloride forms of platinum. In the reactions of the chloride complexes, heating of the solutions even to 40–50 °C reduces the yield of the coloured compound, although the rate of reaction increases. Heating of the sulfate and phosphate complexes to 50–70 °C shortens the reaction time from 4 h to 30–60 min. Regardless of the nature of the ligand in the initial complex, the reaction with the organic reagent is apparently preceded by the stage involving the reduction of platinum(IV) to platinum(II). In the case of platinum(III) sulfate and phosphate complexes, the Pt–Pt bond is initially dissociated with formation of platinum(II) and platinum(IV), after which platinum(IV) is reduced to platinum(II). The reduction of platinum in the sulfate and phosphate complexes is faster than in the platinum(IV) chloride complexes and takes place at lower concentrations of the reductants in solution. One of the causes of the appreciable difference between the reactivities of the acido-complexes of platinum investigated in relation to organic reagents probably consists in the difference between the rates and conditions in the aquation and reduction of the initial forms. Evidently, the similarity of the behaviour of platinum sulfate and phosphate complexes and the characteristics of the colour reactions can be accounted for by the similar structures of such complexes.

The reactions of dimeric platinum sulfate and phosphate complexes are highly sensitive and selective. The complexes exhibit a high kinetic reactivity. All these features make it possible to classify the reactions considered as the most promising for the determination of platinum. Whilst showing equal resistances to the interfering effects of alkaline earth and alkali metals, the

‡ The sulfate complexes of platinum(III) $\{\text{K}_5\text{H}_3[\text{Pt}_2\text{SO}_4(\text{HSO}_4)_8\text{O}_5]\}$, tri- and tetra-valent ruthenium $\{\text{K}_2\text{H}[\text{Ru}_2(\text{O} \cdot \text{H}_2\text{O})_2(\text{SO}_4)_3]\}$, and rhodium(II) $[\text{Cs}_4\text{Rh}_2(\text{SO}_4)_4(\text{H}_2\text{O}) \cdot 2\text{H}_2\text{O}]$, the phosphate complexes of platinum(II, IV) $\{\text{K}_2(\text{H}_3\text{O})_3[\text{Pt}_2(\text{PO}_4)_3(\text{HPO}_4)\text{H}_2\text{O}]\}$, palladium(II) $\{\text{K}_3(\text{H}_3\text{O})_3[\text{Pd}(\text{P}_2\text{O}_7)_2] \cdot 2\text{H}_2\text{O}\}$, rhodium(III) $[\text{Na}_3(\text{H}_3\text{O})_6\text{Rh}(\text{P}_2\text{O}_7)_3]$, iridium(IV) $\{\text{K}_6\text{H}_2[\text{Ir}_4\text{O}_3(\text{H}_2\text{PO}_4)_{10}(\text{OH})_8]\}$, and tri- and tetra-valent ruthenium $[\text{K}_3\text{Ru}_2(\text{H}_2\text{P}_2\text{O}_7)_5 \cdot 7\text{H}_2\text{O}]$, the acetate complexes of rhodium(II) $[\text{Rh}_2(\text{CH}_3\text{COOH})_4 \cdot 2\text{H}_2\text{O}]$ and rhodium(III) $[\text{Rh}(\text{CH}_3\text{COO})_3]$, and the hydroxynitrate complex of palladium(II) $[\text{Pd}(\text{NO}_3)_2(\text{OH})_2]$ have been obtained by members of the Institute of General and Inorganic Chemistry of the Russian Academy of Sciences.^{83–91}

selectivity of the sulfate and phosphate complexes with respect to Cu, Fe, and other transition metals as well as Rh and Ir is markedly higher compared with the chloride forms. However, the selectivity with respect to silver and mercury is higher for the chloride forms. On the other hand, from the practical point of view, it is important that conditions have been found under which platinum sulfates and phosphates are stable and retain their reactivity for a long time. The possibility of converting kinetically inert platinum chloride complexes into more reactive ones, for example the phosphate complexes, has also been demonstrated; in this case, the reaction takes place in concentrated H_3PO_4 solutions at 200 °C in the presence of perchloric acid, which decomposes the chlorides, oxidising Cl^- to Cl_2 , the aquohydroxo-complexes formed react directly with H_3PO_4 .

Palladium(II) sulfate, phosphate, hydroxonitrate, and chloride complexes interact with SCPAR under similar conditions. The spectroscopic characteristics of these complexes are close, but the kinetic reactivity of the sulfates, phosphates, and hydroxonitrates is higher than that of the chlorides. The solubilities of the products of the interaction of the sulfates, phosphates, and hydroxonitrates are higher than those of the corresponding compounds derived from the chlorides.^{8,9,54,82}

Iridium sulfate and phosphate complexes are less active in reactions with organic reagents than the chloride complexes. On prolonged heating, iridium in the form of phosphates and sulfates reacts with sulfochlorophenolazorhodanine in strongly acid media. However, these reactions are less sensitive than those involving the chloride complexes.^{8,9}

Tri- and tetra-valent ruthenium sulfate, phosphate, and chloride complexes react with sulfochlorophenolazorhodanine to form coloured compounds with similar spectrophotometric characteristics. The reactions of ruthenium sulfate and phosphate with the reagent are preceded by a stage involving the conversion of the initial forms of ruthenium into the chloride form, which has been identified as $[\text{Ru}_2\text{OCl}_{10}]^{4-}$ on the basis of absorption spectra. Regardless of the nature of the ligand and the oxidation state of ruthenium in the initial complex, the aquochlororuthenium(III) complex apparently reacts with the organic reagent. The conditions of the colour reaction (a mixture of HCl with CH_3COOH) and the reducing properties of the reagent ensure the conversion of the initial forms of ruthenium into the active form.^{53,56}

In the presence of organic solvents, for example CH_3COOH , the formation of the chloride form from the initial phosphate and sulfate forms is possible in more dilute HCl solutions, for example in 0.5–2 M solutions instead of 5–7 M solutions. In the presence of organic solvents, the degree of hydrolysis of the chloride form apparently diminishes; under these conditions, the organic solvent is a stabilising additive. Furthermore, in the presence of organic solvents, the formation of the active form — the aquochlororuthenium(III) complex — and the substitution for the organic ligand take place more readily than in the case of large amounts of HCl, which entails an increase in the sensitivity of the reaction. Acido-complexes of ruthenium do not enter into colour reactions with sulfochlorophenolazorhodanine in sulfuric and phosphoric acid solutions, which is due to the formation of unreactive hydrolysed forms under these conditions. The interaction of ruthenium with sulfochlorophenolazorhodanine results in the formation of 1:2 complexes. Under the conditions of its interaction with ruthenium, the reagent is in a neutral form¹⁶ and apparently behaves as a monodentate ligand, ruthenium being coordinated to the reagent *via* the thioxo-group of rhodanine.

Regardless of the nature of the ligand and the oxidation state of the central atom in the initial rhodium complexes — rhodium(II) and rhodium(III) sulfates, phosphates, and acetates and rhodium(III) chlorides — coloured compounds with $\lambda_{\text{max}} = 510 \text{ nm}$ are formed in the reactions with SCPAR. Similar dependences of the yields of the reaction products on the nature and concentration of the acids and the reagent are observed for the above rhodium complexes. It has been suggested that the nature of the reactive form of rhodium in the reactions with SCPAR is the

same for all the initial forms of di- and tri-valent rhodium. There are significant differences in the kinetics and sensitivities of the reactions. The dimeric rhodium(II) acetate and sulfate complexes are more reactive in the ligand substitution reaction than, for example, rhodium(III) chlorides and acetates; the highest reactivity has been noted for the dimeric acetate complex.

The rate of formation of the coloured rhodium(II) acetate complex of SCPAR is unusually high. The reaction develops at room temperature over a period of 10–20 min and is characterised by a fairly high sensitivity. The high kinetic reactivity of the dimeric rhodium(II) complexes compared with the corresponding rhodium(III) complexes is due to their ability to form ‘more readily’ the labile aquo-complexes, with participation of which many processes, including ligand substitution reactions, take place faster.

In the case of the rhodium(III) sulfate, phosphate, and chloride complexes, one may postulate that one of the intermediate stages of the overall complex formation reaction between rhodium and SCPAR is the conversion of the initial forms into the more reactive (dimeric acetate or acetate-sulfate) rhodium(II) complexes. This is confirmed by the fact that the conditions of the colour reactions of acido-complexes of rhodium with SCPAR (mixture of 7 M H_2SO_4 and 6 M CH_3COOH , heating to 60–70 °C, excess of the reducing agent) are virtually identical with those in the preparative synthesis of these complexes.^{4,8,9}

The study of the state of solutions of rhodium acetate and sulfate complexes has shown that under certain conditions they retain their reactivity in relation to SCPAR for a fairly long time. The high kinetic reactivity of the dimeric rhodium complexes [in the first place, rhodium(II) acetate] as well as the high sensitivity of their reactions with SCPAR are properties which may serve as the basis for the creation of new high-speed methods for the determination of rhodium *via* reactions of its dimeric complexes.

VI. Applications

1. Photometry

One of the main fields in which azorhodanines and azothiopropiorhodanines are used is photometry. The distinctive features and advantages of azorhodanines as photometric reagents are as follows.

Firstly, the high sensitivity of the determination of the elements, primarily the platinum metals, and, secondly, the interaction with metal ions over a wide pH range. These properties are due to the presence of several functional-analytical groups in the reagent molecules. For example, there are three regions corresponding to the interaction of silver with SCPAR — pH 2–6 and 7–10 and 1–6 M H_2SO_4 , which makes it possible to employ in practice the ‘optimum’ region of the interaction, depending on the composition and the content of the object analysed. Thus, in the determination of silver with the aid of SCPAR, for example at pH 5–7, the presence of the remaining platinum group elements (except palladium) is permissible, whereas the determination of silver in strongly acid media (for example, in 6 M H_2SO_4) permits the presence of a much greater excess of nonferrous and heavy metals.

Thirdly, the reactivity of the reagents in relation to surfactants and certain organic solvents. Under certain conditions, this leads to the formation of modified forms of the reagents, the colour reactions of which with platinum and other metals are characterised by an unusually high sensitivity [$\varepsilon = (100–600) \times 10^3$].

Fourthly, the interaction with platinum metals in the form of various acido-complexes (chlorides, phosphates, sulfates, and acetates). Such interaction is due to the fact that azorhodanines and azothiopropiorhodanines react with platinum metals in strongly acid media, where the presence of stabilising additives (CH_3COOH , HCOOH , metal salts) is permissible. All these features hinder the hydrolysis of the platinum metals, *i.e.* hinder the formation of their unreactive forms.

Fifthly, the possibility of analysing solutions containing both individual forms of platinum metals and their sum. For example, ruthenium is determined in chloride and sulfate solutions, which are used for its preparation in the course of the complex processing of copper–nickel ores. The conditions in the colour reaction of ruthenium with SCPAR (mixture of HCl with CH₃COOH) (Table 2) and the reducing properties of the reagent ensure a fairly rapid conversion of the initial forms of ruthenium into the reactive form — ruthenium(III) chloride.

Sixthly, the high selectivity of the determination. Despite the fact that azorhodanines and azothiopropiorhodanines are group reagents, a high selectivity of the determination is attained by virtue of different spectroscopic characteristics of the colour reactions with the elements (sensitivity and contrasting properties of the reactions), reaction conditions (nature and concentration of the acids, pH), reaction kinetics, the stability of the complexes formed, and, in the case of noble metals, also the different reactivities of their initial forms.

Highly sensitive methods have been developed for the determination of Pt, Pd, Rh, Ir, Ru (in the form of various acido-complexes), Au, and Ag with sulfochlorophenolazorhodanine, Pt, Pd, Au, Ag, Pb, Cd, and Cu with tyrodine, Pd, Pt, Ru, Rh, and Cu with sulfobenzeneazorhodanine derivatives, and Hg and Cu with *p*-phenolazo-3-aminorhodanine, which have found applications in the analysis of various natural and industrial objects.^{1, 2, 4–11, 13–23, 50–56, 58, 69, 72, 74, 76, 77, 82, 92–100}

2. Differential photometry

The problem of creating direct differential-photometric (DP) methods for the determination of noble metals which are no less accurate than gravimetric or titrimetric methods (or approach them in accuracy) but are greatly superior to the latter in the speed of the determination has been successfully solved by virtue of the application of azorhodanines and tyrodine. The success has been due to the ready solubility of both the reagents themselves and of their complexes with noble metals, the possibility of the direct determination of the noble metals and a series of accompanying elements in natural and industrial objects, the possibility of using various acido-complexes as the initial form in reactions with the reagent, the fairly high kinetic reactivity of some of these complexes (phosphates, sulfates, acetates), and, in the case of Pt, Rh, and Ir chloride complexes, the possibility of activation, for example with ascorbic acid or copper salts. In the differential measuring procedure, the fundamental light absorption law holds over a wide range of concentrations of the noble metal. The DF methods developed are universal and, when combined with the photometric version, make it possible to determine 0.2–250 µg ml⁻¹ of the noble metal. High-speed DF methods are used in the analysis of alloys and composite materials for the direct determination of silver (Ag–Cu, 10%–90% Ag), platinum (Pt–Rh, Pt–Ir, 10%–20% Pt), and ruthenium [lead ruthenite, bismuth ruthenite, 30% Ru; residue remaining after the combustion of the waste from the manufacture of materials for the electronic industry containing Pb and Bi (ash), 50% Ru] and also in the analysis of other objects.^{24, 58, 74, 77}

3. Sorption-photometric methods

The methods in which azorhodanines are used both for determination and detection, on the one hand, and for the separation and concentration of reagents, on the other, merit special attention. Such are the electrophoretic and chromatographic (on paper and in a thin layer of sorbent) methods as well as methods based on the use of immobilised reagents. Their principal advantages are simplicity, clarity, and high speed of execution (primarily at the level of qualitative and semiquantitative visual determinations — test methods) and the possibility of combining separation (including the procedure based on the specific effect of the reagent) and concentration from large volumes under static or dynamic conditions.

a. Chromatographic and electrophoretic method

Conditions have been found and limits have been established for the detection of toxic heavy metals such as Cu, Pb, Zn, Fe, Ni, Cd, and Hg (the organic forms are methyl-, propyl-, and phenylmercury, while the inorganic forms are Hg⁺ and Hg²⁺) on a thin layer of sorbent (sorbfil, silufol) with the aid of azorhodanine derivatives — SCPAR and PATAR.

The sensitivity of the visual determination is 0.1–0.5 µg, and for Cu 0.01 µg, of the element in the zone. The possibility of the semiquantitative estimation of the content of both individual toxic elements and their sum has been demonstrated. The selectivity of the detection is achieved as a result of the specificity of the reagents, variation of the colour reaction conditions in a thin layer (nature of the acid, pH), and selection of the separation conditions on the chromatograph.

Conditions have been developed for the separation of various forms of mercury — organic (phenyl-, methyl-, and propylmercury) and inorganic (Hg⁺, Hg²⁺).

At the same time, when SCPAR is used in an ammoniacal medium as the mobile phase, it is possible to separate methylmercury (*R_f* = 0.9) and propylmercury (*R_f* = 0.45) from phenylmercury (*R_f* = 0.0) and inorganic mercury (*R_f* = 0.0) in the form of their coloured complexes with the reagent. The separation of organic and inorganic forms of mercury and their separation from other heavy metals with subsequent detection by means of SCPAR have also been achieved using other chromatographic systems. When chromatograms are sprayed with azorhodanines, red zones appear against the yellow background of the sorbent which is due to the formation of complexes of different forms of mercury with the reagent. The colour in the zones develops over a period of 1–5 min and is maintained for between 2 h and several days. The methods for the determination of toxic elements in a thin layer of sorbents have been tested on food products.¹²

Procedures have been devised for the development of chromatographic and electrophoretic zones of both individual noble metals (except osmium) and their sum in the form of various acido-complexes. The sensitivity of the visual detection is 0.5–0.01 µg of the element in the zone. Together with high sensitivity and stability (as a function of time) of the colour, the advantage of SCPAR as the developer over other reagents consists in the fact that SCPAR develops zones corresponding to different acido-forms of the noble metal. Methods have been proposed for the electrophoretic and paper and thin-layer chromatographic separation with subsequent detection of the noble metal (in the form of chloride complexes) by means of SCPAR in the Pd–Ir, Pd–Rh, Ir–Rh, Pt–Pd–Au, Pd–Pt–Ir, Pd–Pt–Rh, Pd–Au, and Pt–Rh systems. These methods have found applications in the analysis of alloys.^{101–102}

The electrophoretic mobilities of noble metals in the form of coloured compounds with azorhodanines in buffer solutions based on formic, acetic, and oxalic acids (pH 1.5–1.7), acetic and boric acids (pH 2), and pyridine and oxalic acid (pH 5.9) have been investigated. The electrophoretic characteristics have been determined. A clear-cut separation of the zones is observed in the case of Pd–Ag, Pt–Ag, and Pd–Au in the form of their complexes with SCPAR and other reagents.¹⁰³

b. Sorption-photometric methods based on the use of immobilised reagents

The prospects for the analytical application of the colour reactions of azorhodanines in the solid phase have been demonstrated.^{13, 73} Azorhodanines immobilised on a polymer matrix (for example, on a polyamide caprone membrane, a polyacrylonitrile fibre filled with finely disperse KU-2 cation exchanger, and a fabric with phosphate groups) retain their reactivity in relation to noble and heavy metals over a wide pH range (1–10), the reactions being fairly rapid. The similarity of the spectroscopic characteristics of the reactions of azorhodanines in solution and in the sorbent phase has been noted.

High-speed and sensitive methods for the determination of Pt, Pd, Au, Ag, Cu, and Hg with a $1-3 \mu\text{g ml}^{-1}$ detection limit have been developed with the aid of azorhodanines and azothiopropiorhodanines immobilised on polymer supports.^{22,23} A microporous polyamide material (a caprone membrane) or a polyacrylonitrile fibre filled with a finely-disperse cation exchanger (KU-2) have been used as supports. The supports are employed in the form of discs 0.8, 1, and 2 cm in diameter and with a mass of 2–10 mg. The reagents are immobilised by immersing the support disc in 10^{-5} – 10^{-6} M solutions of the reagents in a weakly acid medium (pH 2–5) for 15–30 min. Two versions of the determination have been proposed — static and dynamic. In the first case, the coloured discs (photometric elements) are lowered into a flask containing the sample (the preliminary preparation of the sample is carried out — acidification and introduction of additives activating the colour reaction and giving rise to a high rate of response) and are kept there for 5–60 min at 20–50 °C. In the second case, the coloured discs are placed in the cell of an optical sensor analyser or a vacuum pump is employed. The colour change on the discs is estimated visually (test methods) or from the change in the diffuse reflection coefficients. A high sensitivity of the determination is attained both as a result of the employment of qualitative reagents and the possibility of accumulating the element analysed from dilute solutions on the coloured support disc. The selectivity is ensured by the specificity of the immobilised forms of the reagents, the sorption conditions, and the kinetic differences between the colour reactions on the polymer matrix.

A sorption-photometric method for the determination of silver in natural waters with a detection limit of $5 \mu\text{g litre}^{-1}$ in accordance with the 'sorbent–metal–reagent' scheme has been developed. It involves the sorption of silver on discs made of polyacrylonitrile fibre filled with KU-2 cation exchanger and subsequent detection of silver in the sorbent phase with the aid of rhodazol Kh (compound **1f**) at 490 nm.²³

4. Extraction-photometric methods

The extraction-photometric method for the determination of silver (the 'two reagents' method) is based on the ability of silver to form mixed coloured compounds with azorhodanines or azothiopropiorhodanines and certain macrocyclic compounds (MCC) of the type

10

12,13-dibenzo-1,15-diaza-5,11-dioxacyclononadeca-1,14-diene

11

12,13-dibenzo-1,15-diaza-5,8,11-trioxacyclononadeca-1,14-diene

The MCC are used initially for the selective extraction of silver in the form of ionic associated species $[\text{Ag-MCC}]\text{Pi}$ (Pi = picrate). Then tyrodine, for example, is added to the organic layer. It interacts with the associated species to form mixed coloured compounds (reagent–Ag–MCC) characterised by an unusually high sensitivity; $\epsilon = (4-9) \times 10^5$. With the aid of the 'two reagents' method, it has been possible to reduce by more than an order of magnitude the detection limit for silver and also to increase the selectivity of the determination relative to Au, Pd, Pb, and Hg (Table 3).^{57,58} The method has been used in the determination of silver in drinking water. A somewhat greater complexity of this

Table 3. Photometric determination of silver with tyrodine by the direct method and by the 'two reagents' (MCC–tyrodine) method.

Characteristics of method	Direct determination with tyrodine ^a	'Two reagents' method, determination in extracts	
		see ^b	see ^c

method compared with the usual photometric version must be included among its disadvantages.

In order to increase the selectivity of the determination of silver with SCPAR in an inorganic raw material, silver was extracted (in the form of its complex with the reagent) with cyclohexanone (in the presence of tributyl phosphate) and photometric measurements on the coloured organic layer was subsequently carried out.⁵⁸

5. Automatic analytical schemes

A version of the flow-injection analysis (FIA) has been used with the aid of SCPAR for the spectrophotometric determination of noble metals.^{104,105} The difficulty of devising such methods arises from the kinetic inertness of noble metal complexes in reactions with the organic reagent.

In order to investigate the conditions under which the colour reactions of Au and Ag take place, a two-channel flow system was employed. Best results in the determination of silver were obtained with the following parameters of the FIA system: microvolume of solution containing the metal to be determined $V_0 = 200 \mu\text{l}$; length of thermostated reaction coil $l = 30 \text{ cm}$; flow rate of the support (dilute acid solution) with the metal to be determined $v_1 = 2.8 \text{ ml min}^{-1}$; flow rate of reagent solution $v_2 = 1.2 \text{ ml min}^{-1}$. The range of silver contents which can be determined is $0.3-4.5 \text{ mg litre}^{-1}$. The speed of the analysis is 180 determinations per hour. In the case of the slower reaction involving gold chloride complexes, the peak height is a maximum at $V_0 = 200-300 \mu\text{l}$, $v_1 = 1.2 \text{ ml min}^{-1}$, $v_2 = 0.8 \text{ ml min}^{-1}$, and $l = 60 \text{ cm}$. The range of gold contents which can be determined is $2-19 \text{ mg litre}^{-1}$. The speed of the analysis is 90 determinations per hour. Comparison of the conditions in the colour reactions of Au and Ag with SCPAR in the usual photometric version and in the FIA version demonstrates an appreciably lower optimum acid concentration in the latter case, which is necessary to ensure a higher rate of reaction and this is in its turn important for obtaining the narrowest and highest peaks and also attaining a higher number of determinations per unit time.

The flow-injection method for the determination of palladium with SCPAR at pH 5 is characterised by a speed of analysis of 120 determinations per hour.¹⁰⁵ The high speed of analysis in this case

is due primarily to the high rate of interaction of palladium with SCPAR in weakly acid media. The necessary selectivity of the method is achieved with the aid of masking substances. The range of concentration which can be determined is $0.045\text{--}30\text{ mg litre}^{-1}$. Thus a high number of determinations of noble metals per unit time is attained in FIA systems without loss of sensitivity and without narrowing the range of contents which can be determined compared with the static version employing the same reagent — SCPAR.

Continuous flow analysis (CFA) also belongs to the class of high-speed automatic analytical methods.¹⁰⁶ A photometric method has been proposed for the determination of silver with SCPAR in the presence of nonionic surfactants (Triton-100 X).¹⁰⁷ The introduction of the surfactant into the system stabilises the hydrodynamic flow parameters (ensures the stability of the rate and uniformity of the flow) and improves the solubility of the reagent, which has a positive effect on the reproducibility of the results. The selectivity of the determination of silver relative to Pb, Co, Ni, Cu, and Zn also increases under these conditions. The principal characteristics of the method are as follows: range of silver contents which can be determined $(0.4\text{--}0.5) \times 10^{-5}\text{ M}$; relative standard deviation 0.05; Triton-100 X content $0.3\% \text{--} 0.03\%$. The determination is carried out in 0.1 M HNO_3 .

6. Other methods

The kinetic determination of rhenium is based on the catalytic effect of tetravalent rhenium ions on the reduction of benzene-azobenzeneazorhodanine **7a** by tin(II) in an alkaline medium ($1.5\text{--}2.5\text{ M NaOH}$) and on the time variation of the optical density of the reagent solution. The calibration plot is linear in the range $0.01\text{--}0.1\text{ }\mu\text{g}$ of rhenium in 1 ml . The determination of $0.02\text{ }\mu\text{g}$ of rhenium in 1 ml is not interfered with by Mo, W, Ca, and Cu. The method has been used for the high-speed determination of the rhenium content in specimens of cupriferous sandstone.^{79–81}

In the concentration and separation of noble metals with chelating sorbents based on rhodanine, azorhodanine, and azothiopropiorhodanine, one uses, for example, cellulose, styrene–divinylbenzene copolymers, and sephadexes as the matrix. Polymeric compounds interact under approximately the same conditions as the monomers and the selectivity is also similar. The concentration and separation methods based on chelating sorbents have found extensive application in the analysis of ores, industrial solutions, and natural waters.^{108–115}

VII. Conclusion

Using azorhodanines and azothiopropiorhodanines as the reagents, it has been possible for the first time to approach the problem of the direct and high-speed determination of noble metals in a form other than the chlorides and to achieve a sensitivity of the determination which is unusually high for analytical reagents ($\varepsilon \approx 10^6$). There are diverse applications of azorhodanines and azothiopropiorhodanines, including their modified and immobilised forms, in inorganic analysis — in photometry, differential photometry, sorption photometry (primarily in methods where the reagent is used simultaneously for the concentration, extraction, separation, testing, and determination, including procedures employing sensitive photometric cells), in extraction photometry (including the 'two reagents' method), and in chromatographic and electrophoretic analytical methods. The likely usefulness of azorhodanines and azothiopropiorhodanines in automatic analytical schemes (FIA, CFA) has been demonstrated. Other applications of the reagents, including their use as intermediates in the synthesis of chelating sorbents for the concentration and separation of the elements and in kinetic analytical methods, have been noted. The methods developed using azorhodanines and azothiopropiorhodanines cover a wide range of noble and heavy metal concentrations which can be determined — $1 \times 10^{-3}\text{--}2 \times 10^2\text{ }\mu\text{g ml}^{-1}$. Reagents such as sulfo-

chlorophenolazorhodanine, tyrodine, *p*-aminophenol-3-amino-rhodanine, rhodazol Kh, and sulfo-derivatives of rhodanine and benzeneazobenzeneazorhodanine have found the greatest practical applications.

The unique properties of the reagents and, in the first place, the universality and effectiveness of their analytical activity are in many respects responsible for the interest of investigators in their further study and wider employment in inorganic chemical analysis.

Metal ions as enzyme effectors

E P Medyantseva, M G Vertlib, G K Budnikov

Contents

I. Introduction	225
II. The effect of metal ions on the catalytic activity of enzymes	226
III. Changes in the catalytic activity of enzymes in the presence of metal ions: an analytical aspect	230
IV. Conclusion	231

Abstract. The role of metal ions as enzyme effectors is considered. Data on inhibitory and activating effects of metal ions are summarised. The dual character of action of the effectors depending on their concentration and the nature of the enzyme is highlighted. The analytical applications of these effects are discussed. The bibliography includes 66 references.

I. Introduction

The role of metal ions in the mechanism of catalytic effects of enzymes is diverse.¹ One group of enzymes is characterised by the presence of one or several tightly bound metal ions involved in catalytic processes (metalloenzymes). Other enzymes do not contain directly bound metal ions but manifest catalytic activity only when the ions are present (metal-dependent or metal-activated enzymes). For enzymes of the third group, metals are not obligatory participants of the catalytic reaction; however, their presence in the system influences the enzyme activity (metal-independent enzymes).

Three types of metal–enzyme complexes are generally formed in enzymic catalysis:

(1) Complexes through the ligand L (substrate) as a bridge. Here, the metal ion binds only to the ligand and takes part in the catalysis not being directly bound to the enzyme (Fig. 1, pathway I). These complexes are typical of many enzymes, e.g., creatine kinase,^{2,3} and some other kinases and synthetases.^{4–6}

(2) Complexes in which the metal ion binds the ligand completely (Fig. 1, pathway IIa) or partly (Fig. 1, pathway IIb). The existence of enzyme–metal–ligand complexes has been demonstrated by NMR (pyruvate kinase),⁷ X-ray analysis (carboxypeptidase),⁸ and infrared spectroscopy (carbonic anhydrase).⁹

There exist at least two routes¹ for the formation of the enzyme–metal–ligand complexes with a bridge metal:¹

where L is the ligand.

A third route of enzyme–metal–ligand complex formation is also possible, where the metal ion non-bound to the enzyme manifests strong affinity for the ligand.

(3) Complexes with the enzyme as a bridge. Here, the metal ion and the ligand interact with different sites of the enzyme (Fig. 1, pathway III). This type of complex is characteristic of glutamine synthetase¹⁰ and some other synthetases.^{11, 12}

The catalytic activity of enzymes, which is their most distinctive feature, can vary widely depending on the mode of interaction of metal ions with enzymes. Therefore, the study of effects of metal ions on enzyme activity has both theoretical and practical significance.

Figure 1. The pathways of interaction of the enzyme (E) with the metal ion (Mⁿ⁺) and the ligand (L). For I–III, see text.

Uspekhi Khimii 67 (3) 252–260 (1998); translated by R L Birnova

This review will not consider metalloenzymes and metal-dependent enzymes. The role of metals in catalytic processes involving these enzymes is the subject of special studies and presents particular interest for biochemistry and medicine (see Refs 13–15). The review summarises the papers devoted mainly to the effect of metal ions on catalytic properties of metal-independent enzymes.

II. The effect of metal ions on the catalytic activity of enzymes

During the last 10–15 years interest in biochemical methods of determination of inorganic toxic agents based on the analysis of properties of native and immobilised enzymes in the presence of metal ions has increased. And the main contribution to the development of this field has been made by Russian scientists. The same conclusion can be made from the analysis of the Proceedings of the 5th International Symposium 'Kinetics in Analytical Chemistry' held in Moscow in 1995, which shows that the chemico-analytical aspect of the effect of metal ions on the catalytic activity of enzymes was mostly covered by reports of Russian investigators.

Most commonly, the catalytic activity of enzymes in the presence of metals is evaluated as changes in the rate of the enzymic reaction. This can be done by measuring the changes in the concentration of the substrate or reaction products with time. A physicochemical parameter (most often, optical density or an ionisation potential) related to the substance concentration is used as the analytical signal.

1. The inhibitory effect of metal ions

Far greater attention has been given to the study of the inhibitory effect of metal ions on the catalytic activity of enzymes than to the activating effect. In most studies, the effect of doubly charged metal cations was examined. In particular, doubly charged ions, like Hg^{2+} , Cu^{2+} , Co^{2+} , Cd^{2+} , Zn^{2+} , Pb^{2+} , Ni^{2+} , and some others were shown to inhibit bovine ribonuclease A,¹⁶ urease,^{17–19} cholinesterases,^{20–22} and some others. The I_{50} value (*i.e.*, the inhibitor concentration causing a 50% decrease in the enzyme catalytic activity) and the value of the inhibition constant, K_i , are commonly used for the quantitative estimation of the inhibitory effect.

Thus in order to estimate the inhibitory effect of metal ions (Ag^+ , Hg^{2+} , Cu^{2+} , Zn^{2+} , Pb^{2+} , Ni^{2+} , Cd^{2+} , Co^{2+}) on *St. saprophyticus* urease, the I_{50} values were determined for each of them.¹⁷ The smaller the I_{50} value the stronger the metal inhibits the enzyme. Ag^+ ions ($I_{50} = 8 \times 10^{-6}$ mol litre⁻¹) appeared to be the most effective inhibitor of *St. saprophyticus* urease. According to the strength of their inhibitory effect, these ions can be arranged in the following series: $\text{Ag}^+ > \text{Ni}^{2+} > \text{Cd}^{2+} > \text{Co}^{2+} > \text{Hg}^{2+} > \text{Cu}^{2+} > \text{Zn}^{2+} > \text{Pb}^{2+}$. The inhibitory action of these ions begins to manifest itself at concentrations from 1×10^{-7} to 2.5×10^{-6} mol litre⁻¹. The maximum inhibitory effect (100%) is observed at the concentrations 5×10^{-4} mol litre⁻¹ (Ag^+) and 1×10^{-3} mol litre⁻¹ (Hg^{2+} , Cu^{2+} , Zn^{2+} , Pb^{2+}). In the presence of Ni^{2+} , Cd^{2+} , and Co^{2+} ions (10^{-3} mol litre⁻¹) in the reaction medium, complete suppression of the enzyme activity does not occur: urease retains up to 10%–20% of its original activity. The inhibition of urease by the ions assayed is independent of the enzyme concentration and the time of incubation with the solution of a metal salt. The inhibitory effect of all these ions is reversible and is easily eliminated by dilution or desalting of the enzyme on a Sephadex G-25 column. However, when the concentration of Pb^{2+} , Hg^{2+} , Zn^{2+} , and Ag^+ ions in the reaction medium exceeds 10^{-3} mol litre⁻¹, irreversible denaturation of the enzyme takes place. The inhibition, which precluded reactivation of the enzyme, was not observed for Cu^{2+} , Ni^{2+} , Cd^{2+} , and Co^{2+} ions in the whole range of the concentrations studied (1×10^{-7} – 1×10^{-3} mol litre⁻¹). Although the authors do not draw such a

conclusion, it may be assumed that in this particular case reversible non-specific inhibition takes place.

The values of apparent inhibition constants, K_i , for Mg^{2+} , Co^{2+} , and Mn^{2+} ions, which competitively inhibit the activity of Ca^{2+} -ATPase of skeletal muscle plasma membranes, have been determined.²³ The smaller the K_i value the stronger the effect produced by the inhibitor. It was found that according to their affinity for Ca^{2+} -ATPase, these ions can be arranged in the following order: $\text{Mg}^{2+} > \text{Co}^{2+} > \text{Mn}^{2+}$. The inhibitory effect is a maximum at a Mg^{2+} concentration of 1×10^{-4} mol litre⁻¹. A linear dependence of the degree of inhibition of the enzymic activity on the magnesium concentration in the range of 1×10^{-5} – 5×10^{-5} mol litre⁻¹ was established. Further increase in the magnesium concentration influenced the inhibition to a lesser degree, *i.e.*, it disturbed the linear dependence.

Mn^{2+} and Co^{2+} ions used at concentrations 1×10^{-5} – 1×10^{-4} mol litre⁻¹ have no effect on Ca^{2+} -ATPase. Their inhibitory effect becomes apparent only at a concentration of *ca.* 2.5×10^{-4} mol litre⁻¹; a linear dependence of the decrease in the enzyme activity on the cation concentration is observed at concentrations from 2.5×10^{-5} to $(2–3) \times 10^{-3}$ mol litre⁻¹.

The study¹⁶ deserves special mention among other studies concerned with the inhibition of the catalytic activity of enzymes by metal ions. This not only quantitated the effect observed (*i.e.*, the experimental values of inhibition coefficients defined by the author as the ratio of initial rates of substrate cleavage in the presence and in the absence of M^{2+}), but also considered the influence of some other parameters (ionisation potentials, hydration energy, ionic radii of cations) on the magnitude of the inhibitory effect. In the work cited, the effect of Ca^{2+} , Mg^{2+} , Ba^{2+} , Sr^{2+} , Mn^{2+} , Fe^{2+} , Co^{2+} , Ni^{2+} , Pb^{2+} , Cd^{2+} , Zn^{2+} , Cu^{2+} , and Hg^{2+} on the catalytic activity of bovine RNase A was studied. The inhibitory effect of these cations was found to increase in the series: $\text{Ba}^{2+} \approx \text{Sr}^{2+} \approx \text{Ca}^{2+} < \text{Mg}^{2+} < \text{Mn}^{2+} < \text{Fe}^{2+} < \text{Co}^{2+} < \text{Ni}^{2+} < \text{Pb}^{2+} < \text{Cd}^{2+} < \text{Zn}^{2+} \ll \text{Cu}^{2+} < \text{Hg}^{2+}$. It is seen that Hg^{2+} , Cu^{2+} , and Zn^{2+} cations manifest the strongest inhibitory activity; the cations of the iron subgroup (Mn^{2+} , Fe^{2+} , Co^{2+} , and Ni^{2+}) are weak inhibitors, whereas the cations Ba^{2+} , Sr^{2+} , and Ca^{2+} do not produce any inhibitory effect at all.

In the author's opinion,¹⁶ the fact that the metal cations do not possess strict selectivity, *i.e.*, that they can interact with functional groups in the enzyme active centre differing in electronic effect, a complex dependence of the mode of enzyme inhibition by the metal cations on their concentration, and their ability to form complexes both with enzymes and the substrates preclude the estimation of the inhibitory activity of metal cations from the inhibition constants.

In order to evaluate the inhibitory strength of cations the author introduces a parameter W , which is equal to the sum of the electrostatic (Z^2/r) and the reduced covalent ($E - \Delta H$) characteristics:

$$W = \frac{Z^2}{r} + (E - \Delta H),$$

where Z is the ionic charge, r is the ionic radius, E is the sum of the ionisation potentials for the first and second electrons, and ΔH is the energy of cation hydration.

The higher inhibitory activity of Zn^{2+} , Cu^{2+} , and Hg^{2+} is largely determined by the reduced covalent characteristics. In the cations of the iron subgroup (Mn^{2+} , Fe^{2+} , Co^{2+} , and Ni^{2+}), the electrostatic characteristics are comparable with those of Zn^{2+} , Cu^{2+} , and Hg^{2+} , while the values of the reduced covalent characteristics are 2–3 times as low. These cations manifest only weak inhibitory activity. For Ba^{2+} , Ca^{2+} , Mg^{2+} , and Sr^{2+} cations, the values of electrostatic and, particularly, reduced covalent characteristics are smaller than those for Zn^{2+} , Cu^{2+} , and Hg^{2+} . It has been shown experimentally that these cations do not inhibit RNase at the concentrations from 1×10^{-4} to 1×10^{-2} mol litre⁻¹.

The effect of rare-earth elements (REE) (Pr, Nb, Sm, Eu, Tb, Er, Tu, Yb) on the catalytic activity of inorganic pyrophosphatases from bakers yeast and *E. coli* has been studied.²⁴ Analysis of the dependence of the rate of the indicator reaction on the concentration of REE over the range of 10^{-5} – 10^{-1} $\mu\text{g ml}^{-1}$ revealed that all these ions inhibited both enzymes; the inhibitory effect of different REE was manifested in different concentration ranges. Praseodymium (Pr^{3+}) appeared to be the most effective inhibitor of pyrophosphatases. The inhibitory effect decreased on going from praseodymium to ytterbium, *i.e.*, with a decrease in the ionic radius of REE. The mechanism of inorganic phosphatase inhibition by praseodymium is consistent with complete competitive inhibition. The value of the inhibition constant, which reflects the stability of the enzyme–inhibitor complex, demonstrates that Pr^{3+} ions form a catalytically inactive complex with pyrophosphatase, which is more stable than that with Eu^{3+} ions.

In other studies,^{24–32} only qualitative aspects of the effect of metal ions on the catalytic activity of enzymes have been considered with a mere statement of the existence of the corresponding effect and indicating the range of concentrations where it is manifested.

Cu^{2+} ions decrease the catalytic activity of glutamate dehydrogenase from bovine liver²⁵ ($I_{50} = 2 \times 10^{-6}$ mol litre⁻¹). At concentrations of Cu^{2+} equal to 1×10^{-5} mol litre⁻¹ and higher, the residual activity makes up 8%–10% of the original. This effect is a result of the direct interaction of the copper cations with glutamate dehydrogenase (the difference absorption spectrum of glutamate dehydrogenase in the presence of Cu^{2+} suggests the formation of an enzyme–metal complex). This inhibition is allosteric. Zn^{2+} ions also inhibit this enzyme. Spectral data point to identical conformational changes in the substrate-binding site induced by Cu^{2+} and Zn^{2+} cations.²⁵

Zn^{2+} cations also inhibit poly(ADP-ribose)polymerase from rat brain. At a Zn^{2+} concentration equal to 1.25×10^{-4} mol litre⁻¹, the enzyme is fully suppressed. The changes in the enzyme activity are due to the binding of Zn^{2+} ions with the sulfhydryl groups of polymerase. The inhibitory effect is reversible, since dithiothreitol neutralises the effect of this cation on the polymerase activity.²⁶

Pb^{2+} and Cd^{2+} ions (10^{-3} – 10^{-2} $\mu\text{g ml}^{-1}$) inhibit alkaline phosphatase from chicken intestine in the hydrolysis of *p*-nitrophenyl phosphate.^{23,27} The decrease in the activity is a maximum at Cd^{2+} concentrations of 1–10 $\mu\text{g ml}^{-1}$ (Ref. 23). Cd^{2+} ions (1×10^{-4} $\mu\text{g ml}^{-1}$) also inhibit horseradish peroxidase.²⁷ The catalytic activity of peroxidase is also inhibited by Hg^{2+} cations (5×10^{-13} – 5×10^{-8} mol litre⁻¹).^{28–30} A drop in peroxidase activity is also observed in the presence of Bi^{3+} [$(2\text{--}10) \times 10^{-4}$ $\mu\text{g ml}^{-1}$]. At higher Bi^{3+} concentrations, the rate of this reaction remains virtually unchanged.³¹

Protein disulfide reductase from bovine liver catalyses the thiol–disulfide exchange between glutathione and insulin and reactivates randomly oxidised ribonuclease. The activity of this enzyme is inhibited by Cu^{2+} and Hg^{2+} ions.²⁹

The effects of Zn^{2+} , Cu^{2+} , Mn^{2+} , Fe^{2+} , Co^{2+} , and Ni^{2+} ions on the activity of acetylcholinesterase (AChE) of human erythrocytes have been studied over a broad range of salt concentrations.^{20,33} It was found that all the salts in question (with the exception of MnCl_2 , which has no effect on the AChE activity) are reversible competitive inhibitors of AChE. To a first approximation, the inhibitory effect is directly proportional to the concentration of the corresponding metal. From the pH dependence of the AChE inhibition by the salts it was concluded that the AChE activity is inhibited by hydroxo complexes of the MOH^+ type.

Cu^{2+} and Cd^{2+} ions suppress the catalytic activity of cholinesterase (ChE) isolated from pea sprouts.²² Co^{2+} and Al^{3+} ions also manifest inhibitory activity. According to another report,²¹ Ca^{2+} and Mn^{2+} used at concentrations of 1×10^{-3} – 1×10^{-2} mol litre⁻¹ inhibit ChE from kidney bean roots, whereas Mg^{2+} has no effect on the enzyme.

Calcium occupies a special position among metals, since it manifests an activating rather than inhibitory effect.³⁴ However, it can also inhibit certain enzymes, *e.g.*, yeast hexokinase³⁰ and alkaline phosphatase.²⁷

It has been established that calcium ions taken at a 10–100-fold excess over praseodymium enhance the inhibitory effect of the latter. The inhibitory action of calcium²⁴ is ascribed to the fact that its ionic radius is similar to those of REE and thus it can exert a similar effect on the enzyme.

Ca^{2+} cations markedly decrease the activity of hexokinase.³⁵ The catalytic activity of alkaline phosphatase from chicken intestine is also decreased in the presence of calcium ions (10^{-3} – 1 $\mu\text{g ml}^{-1}$). It should be noted that the inhibitory effect of calcium on the enzyme decreases with an increase in the ion concentration.²⁷

Recently, some papers have been published, which deal with the study of the catalytic activity and properties of immobilised enzymes.^{18,19,36–38} Naturally, metal cations also change the catalytic activity of immobilised enzymes.

Urease immobilised on a solid carrier (a microporous styrene–divinylbenzene copolymer) is inhibited by ions of toxic metals. The inhibitory effect of Fe^{2+} manifests itself even at a concentration of 10^{-10} – 10^{-9} mol litre⁻¹, whereas that of most ions, at 10^{-8} mol litre⁻¹. With respect to the strength of their inhibitory action, the metal ions can be arranged in the following series:^{18,19} $\text{Ag}^+ > \text{Hg}^{2+} > \text{Fe}^{2+} > \text{Cu}^{2+} > \text{Ni}^{2+} > \text{Co}^{2+} > \text{Al}^{3+} > \text{Mg}^{2+} > \text{Cd}^{2+} > \text{Pb}^{2+}$. As noted above, Ag^+ is the strongest and Pb^{2+} is the weakest inhibitor of native urease.¹⁷ At the same time, the series of other metals for the native urease (see above) differs from that for the immobilised enzyme due to the changes caused by enzyme immobilisation.

A number of papers have been devoted to the effects of Zn^{2+} , Fe^{2+} , Ni^{2+} , Hg^{2+} , Pb^{2+} , Ti^+ , Bi^{3+} , Cd^{2+} , Cu^{2+} , Cr^{3+} , Hf^{4+} , Ti^{4+} , and Zr^{4+} ions on the catalytic activity of cholinesterase immobilised by incorporation into cellulose nitrate films.^{36–38} All these metals inhibit the immobilised enzyme. The greatest inactivating effect is produced by Cu^{2+} . The minimum Cu^{2+} concentration (c_{min}), which causes a statistically significant decrease in the catalytic activity of immobilised ChE, is 4×10^{-10} mol litre⁻¹. A similar change in the catalytic activity in the presence of other ions is observed at the following concentrations:^{36–38}

Ion	Zr (IV)	Ti (IV)	Nb (V)	Hf (V)	Ta (V)
c /mol litre ⁻¹	5×10^{-10}	8×10^{-10}	2×10^{-9}	3×10^{-9}	5×10^{-9}
Ion	Cr (III)	Pb (II)	Fe (III)	Cd (II)	
c /mol litre ⁻¹	5×10^{-8}	5×10^{-7}	1×10^{-6}	1×10^{-5}	

The inhibitory effect also depends on the catalytic activity of the enzyme itself. Thus, for ChE immobilised in a cellulose nitrate matrix with a specific activity of 1.12 ± 0.04 $\mu\text{mol min}^{-1} \text{cm}^{-2}$, c_{min} for Cu^{2+} is 4×10^{-10} mol litre⁻¹, whereas for the samples with a threefold lower specific activity (0.33 ± 0.02 $\mu\text{mol min}^{-1} \text{cm}^{-2}$), it is equal to 1×10^{-9} mol litre⁻¹ (Ref. 38).

Solutions of cysteine and EDTA restore completely the catalytic activity of immobilised ChE after the action of heavy metal ions. However, only 70% of totally inhibited ChE is observed in the case of Pb^{2+} . This is probably due to the interaction of Pb^{2+} with the histidine residue of the active centre of ChE, especially in the presence of high ($\sim 10^{-4}$ mol litre⁻¹) concentrations of Pb^{2+} (Ref. 36).

The mechanism of the inhibitory effect of metal ions on the catalytic activity of enzymes is rather difficult to establish. The metal can compete with the substrate for the binding sites in the active centre, it can also interact with different groups in the protein molecule outside the active centre but influencing the catalytic functions of the enzyme,³⁹ *i.e.*, it can bind to the allosteric centre of the enzyme.

It is believed that the effect of metal ions on the enzyme molecule can be due to the formation of thiolates with both

cysteine, which is a constituent of the enzyme, and products of cleavage of disulfide bridges.⁴⁰ If the cysteine residue is incorporated into the active centre of the enzyme or is responsible for the maintenance of the appropriate conformation of the protein molecule, the modification of its thiol group inactivates the enzyme. In addition, heavy metal ions can catalyse the oxidation of thiols to disulfides:⁴¹

Most commonly, the inhibitory effect of metal ions is ascribed to their ability to form coordinate bonds.⁴¹ As is known,⁴² the nucleophilic residues of some amino acids incorporated into the active centres of enzymes, can form coordinate bonds with heavy metal ions. For example, histidine, which is a constituent of the esterase region of the active centre of ChE, can interact with metal ions.³⁶ Some authors explain the difference in the inhibitory action of various metal ions by the difference in the ionic radii of cations.^{16, 29, 36}

2. The activating effect of metal cations

Metals can not only inhibit but also enhance the catalytic activity of enzymes. Most often, the activating effect is produced by ions of rare-earth metals. It should be noted that the processes related to the activation of enzymes with metal ions have been documented in far fewer publications than those on the inhibition processes. Unfortunately, in the case of studies of the inhibitory effect, most authors give only a qualitative outline of the activation process,^{43–56} without quantitative estimates, which makes it difficult to compare the published data.

The activating effect of Ca^{2+} cations on mitochondrial glycerol-3-phosphate dehydrogenase has been studied.⁴³ Ca^{2+} cations are not selective activators. They interact with both electron-donor amino acid residues and those nitrogen atoms of the peptide bonds that are not necessarily incorporated into the enzyme active centre. It thus follows that not all Ca^{2+} cations that interact with the enzyme play the same role in the maintenance of its activity. Some of them that interact with the amino acid residues remote from the enzyme active centre not only are devoid of the activation effect, but, conversely, produce an inhibitory effect.

Analysis of literature data reveals that the simultaneous presence of several metal cations, even of the same nature (Ca, Mg), has an ambiguous effect on the activity of the enzyme under study: one of the ions can either enhance the effect of the other ion (synergism) or attenuate it.

Most often, the synergistic effect is produced by Ca^{2+} and Mg^{2+} ions.³⁴ For example, even a short-term preincubation of phosphorylase kinase with these ions caused a sevenfold increase in the catalytic activity. It is believed that the simultaneous presence of Ca^{2+} and Mg^{2+} favours the interaction of phosphorylase kinase with glycogen.³⁴

Ca^{2+} and Mg^{2+} ions also activate myofibrillar creatine kinase from rat skeletal and cardiac muscles. Calcium activates the enzyme to a lesser degree than magnesium. In the presence of Mg^{2+} ions, calcium inhibits creatine kinase. Presumably, creatine kinase has different binding sites for Ca^{2+} and Mg^{2+} ions, since the latter does not eliminate the inhibitory effect of calcium even when used in a 100-fold excess.⁴⁴

Ca^{2+} and Mg^{2+} ions activate myometrium actomyosin ATPase. As the Ca^{2+} concentration is increased ($0.01–5 \times 10^{-3}$ mol litre⁻¹ in a Mg^{2+} -free medium or after addition of Mg^{2+} (1×10^{-3} mol litre⁻¹), the ATPase activity is noticeably increased and then reaches a plateau.³⁹

A change in the Mg^{2+} concentration from 1×10^{-5} to 5×10^{-3} mol litre⁻¹ in a Ca^{2+} -free medium increases the activity of ATPase in the region of low concentrations after which it reaches a plateau. Significant induction of the ATP-hydrolase reaction is observed after addition of the physiological concentration of Ca^{2+} (1×10^{-3} mol litre⁻¹) to the incubation medium. Ca^{2+} ions are more effective activators of the reaction of ATP hydrolysis.⁴⁶

The effect of cations of alkaline and alkaline-earth metals on the activity of native ChE^{21, 46} and immobilised butyrylcholinesterase³⁶ has been studied. Na^+ , K^+ , and Mg^{2+} ions stimulate the cholinesterase activity in pea sprouts by 30%–60%.^{21, 22} The catalytic activity of immobilised ChE increases in the presence of Na^+ , Mg^{2+} , and Mn^{2+} ions in the concentration range of $8 \times 10^{-4}–2 \times 10^{-2}$ mol litre⁻¹.³⁶ Presumably, this is due to the presence of an anionic group near the active centre of ChE, which prevents the interaction of the enzyme with the substrate. Introduction of these metal salts results in binding of this group by ions of ChE-activator metals, which creates the most favourable conditions for the formation of the Michaelis complex. It was found that the larger the radius and the charge on the activator metal the lower the concentration of this metal ion needed to block the anionic group of ChE.

Ca^{2+} cations activate butyrylcholinesterase.^{47–49} The maximum rate of the reaction is increased in the presence of Ca^{2+} , whereas the Michaelis constant remains practically unchanged. Apparently, Ca^{2+} ions do not compete with the substrate for the binding sites, since the activation cannot be eliminated by an excess of acetylcholine. It is believed that Ca^{2+} exerts an allosteric effect as it binds with specific sites.^{50, 51} Co^{2+} , Ni^{2+} , and Mn^{2+} ions do not influence the acetylcholine hydrolysis.⁴⁷

Immobilised ChE is activated by microquantities of heavy metals, such as Pb, Hg, Cd, and Tl used generally at concentrations below $10^{-7}–10^{-6}$ mol litre⁻¹.^{52, 53} Some platinum metals (Pt^{2+} , Rh^{3+}) also activate the immobilised ChE.^{54, 55}

It should be noted that the inhibitory effect correlates linearly with the concentration of the effector.^{27–31, 37, 38} As to the activation, this process demonstrates a more complex dependence on the concentration of metal ions.^{35, 36} First of all, an increase in the catalytic activity is observed over a small range of concentrations that differ usually by not more than a factor of 10–15 (Fig. 2). The maximum catalytic activity is manifested sometimes only at a definite concentration of the effector (Fig. 2b). In some cases, a small plateau is observed (Fig. 2a). A deviation from the optimum concentration results in a decrease of the enzyme catalytic activity towards the control level.

Among studies concerned with enzyme activation, that dealing with the mechanism of the activating effects of Mg^{2+} and Co^{2+} ions on glucose isomerase of *Actinomyces olivocinereus* 154 stands separately.⁵⁷ In this study, the main kinetic constants have been calculated and quantitative estimates of the activating capacity of these cations (the activation constants) have been given. It was found that the activating effect of Mg^{2+} ions is much stronger than that of Co^{2+} . The maximum activating effect of Mg^{2+} ions is observed at a concentration $(2.0–2.5) \times 10^{-2}$ mol litre⁻¹, that of Co^{2+} ions, at $(2.5–5) \times 10^{-4}$ mol litre⁻¹. Further increase in the concentrations of Mg^{2+} and Co^{2+} ions leads to the inhibition of glucose isomerase; for Co^{2+} ions, this phenomenon is more strongly pronounced and manifests itself even at a concentration of 1.25×10^{-3} mol litre⁻¹.

Studies of the activating effect of Mg^{2+} and Co^{2+} ions added to the reaction mixture simultaneously revealed a complex dependence of the enzyme activation on both the absolute concentrations of these metal ions and their ratio. The maximum activity was observed at a Mg^{2+} ion concentration of 2×10^{-5} mol litre⁻¹ and that of Co^{2+} at 5×10^{-3} mol litre⁻¹. It should be noted that for Mg^{2+} the optimum concentrations of this activator ion used in a mixture were slightly lower than when it was added separately, whereas for Co^{2+} ions, they were tenfold higher.

Mg^{2+} and Co^{2+} ions bind to different sites on glucose isomerase and influence its activity differently.⁵⁷ Therefore, the mechanism of activation of the glucose isomerisation reaction by these ions is also different. The activation with Mg^{2+} ions is non-competitive, while that with Co^{2+} ions is synergistic; when Mg^{2+} and Co^{2+} ions are used simultaneously, the activation is of a mixed type. In the non-competitive activation, glucose and Mg^{2+} ions bind to the enzyme independently of each other to form an

Figure 2. Dependence of the analytical signal (electric current at a potential of -0.55 V) on the concentration of metal ions (pH 9.05; the concentration of butyrylthiocholine iodide, 0.6 mg ml^{-1}). Specific activity of immobilised ChE is $0.35 \mu\text{mol min}^{-1} \text{ cm}^{-2}$ (a) and $1.17 \mu\text{mol min}^{-1} \text{ cm}^{-2}$ (b).

(a): (1) — Mn (II), (2) — Mg, (3) — Na; (b): (1) — Ca, (2) — Sr, (3) — Ba.

active bridge-like ternary complex (Fig. 1, pathway II). The value of the activation constant is very low (0.002), which points to a high stability of an active ternary complex ($\text{Mg}^{2+} - \text{E} - \text{S}$) and the activated enzyme ($\text{Mg}^{2+} - \text{E}$) and to a small rate constant for their dissociation into the original enzyme and the enzyme–substrate complex (ES). Thus, in the activation of glucose isomerase with Mg^{2+} , the major part of the enzyme is bound into the ternary complex $\text{Mg}^{2+} - \text{E} - \text{S}$. As has been mentioned above, the activation with Co^{2+} ions is synergistic. Co^{2+} ions bind to the glucose isomerase molecule and increase the enzyme affinity for glucose. In addition, the ES complex interacts with Co^{2+} ions much faster than the free enzyme. The authors suggest that the main role of Co^{2+} ions consists in conferring a conformation that is resistant to thermal inactivation on the enzyme quaternary structure rather than in the activation of the enzyme. Moreover, this conformation facilitates the attachment of glucose even in the absence of Mg^{2+} ions and accelerates the formation of a bridge-like ternary complex in their presence, as a result of which the rate of isomerisation increases. This is corroborated by experiments with simultaneous addition of Mg^{2+} and Co^{2+} ions to the reaction mixture.⁵⁷

Attempts have been undertaken^{56,58} to characterise quantitatively the processes of activation of immobilised ChE in the presence of alkaline-earth metal ions on the basis of voltammetric measurements. The results of these studies indicate that the activation is controlled by many factors, such as substrate concentration, pH, activity of the immobilised enzyme (*i.e.*, the type of immobilisation), activator concentration, incubation time, and the order in which the substrate and the effector act on

immobilised ChE. The maximum activating effect was observed at pH 8.95–9.05. The lower the catalytic activity of immobilised ChE the higher the concentration of metal ions needed for the manifestation of their activating effect. Thus immobilisation according to Nikolskaya³³ in which incorporation of the enzyme into a cellulose nitrate matrix was performed together with treatment with a bifunctional reagent (glutaraldehyde) gave immobilised ChE with a catalytic activity about 3–4 times lower than that obtained by immobilisation of the enzyme followed by treatment with a bifunctional reagent. In order to increase the catalytic activity of these samples, it is necessary to use high concentrations of the activators (6×10^{-3} – $6 \times 10^{-4} \text{ mol litre}^{-1} \text{ Ca}^{2+}$).³⁷ To verify these effects, the authors carried out a radiochemical analysis with ^{85}Sr . The results of this study suggest that under optimum conditions (pH 9.05, $5 \times 10^{-6} \text{ mol litre}^{-1} \text{ Sr}^{2+}$, substrate concentration, $2 \times 10^{-3} \text{ mol litre}^{-1}$) alkaline-earth metal ions change the catalytic activity of immobilised ChE in the order: $\text{Ca}^{2+} > \text{Sr}^{2+} > \text{Ba}^{2+}$, which is consistent with their ionic radii. Similar correlation between the ion radii and their activating effect was observed earlier for alkali metal ions.³⁶ As the substrate concentration is increased from 2×10^{-3} to $4 \times 10^{-3} \text{ mol litre}^{-1}$, the type of activation changed from associative to pseudo- and then to two-parametrically disbalanced activation. The activation constants for Ca^{2+} ions are $(3.7 \pm 0.3) \times 10^{-6} \text{ mol litre}^{-1}$ at low $[(1.5\text{--}3) \times 10^{-3} \text{ mol litre}^{-1}]$ and $(1.8 \pm 0.2) \times 10^{-8} \text{ mol litre}^{-1}$ at higher ($4 \times 10^{-3} \text{ mol litre}^{-1}$) substrate concentrations; that for Ba^{2+} ions is $(8.40 \pm 0.3) \times 10^{-6} \text{ mol litre}^{-1}$. The experimental values of the activation constants correlate with a stronger activating effect of Ca^{2+} ions (the catalytic activity of immobilised ChE is increased more strongly in the presence of Ca^{2+}).

3. The dependence of the mode of action of metal ions on their concentration

It is well known that the same metals can increase or decrease the catalytic activity of enzymes depending on their concentration.

Thus Cu^{2+} ions used in low concentrations stimulate the activity of purified poly(ADP-ribose)polymerase. At a Cu^{2+} concentration of $5 \times 10^{-6} \text{ mol litre}^{-1}$, the polymerase activity is increased 1.4-fold. Further increase in the Cu^{2+} concentration inhibits the enzyme activity and with $5 \times 10^{-5} \text{ mol litre}^{-1} \text{ Cu}^{2+}$ the polymerase activity drops down to zero. Poly(ADP-ribose)-polymerase contains sites with different affinity for Cu^{2+} cations. At low Cu^{2+} concentrations, the binding of these ions to the high-affinity sites of the enzyme increases the polymerase activity, whereas at high Cu^{2+} concentrations, the binding may also occur to sites with a lower affinity for the metal, which results in the inhibition of the enzyme activity.²⁶

Mg^{2+} ions (10^{-3} – $1 \mu\text{g ml}^{-1}$) inhibit alkaline phosphatase from chicken intestine. They strongly activate the enzyme over the concentration range 1 – $100 \mu\text{g ml}^{-1}$. Aluminium ions slightly inhibit the enzyme when used at the concentrations of 10^{-3} – $1 \mu\text{g ml}^{-1}$ but strongly activate it at the concentrations of 1 – $10 \mu\text{g ml}^{-1}$ (Ref. 27).

Low concentrations of Mn^{2+} , Ni^{2+} , and Co^{2+} ions activate muscle pyruvate kinase, whereas higher concentrations inhibit the enzyme. Ca^{2+} ions (4×10^{-4} – $2 \times 10^{-4} \text{ mol litre}^{-1}$) inhibit liver glutamate dehydrogenase and activate it at concentrations above $4 \times 10^{-4} \text{ mol litre}^{-1}$. At the same time, Mg^{2+} ions inhibit glutamate dehydrogenase only in the concentration range of $(2\text{--}4) \times 10^{-4} \text{ mol litre}^{-1}$. Higher and lower concentrations of Mg^{2+} activate this enzyme. Some phosphatases are activated by low concentrations of Mg^{2+} (up to $5 \times 10^{-3} \text{ mol litre}^{-1}$), whereas higher concentrations of this ion cause their inhibition.³⁴

The changes in the properties of enzymes in the presence of some metal ions are summarised in Table 1.

Almost all investigators emphasise that the effect of metal ions on the activity of ChE is of dual character: activation at small concentrations and inhibition at high concentrations.⁴⁷ Even such cations as Na^+ , Mg^{2+} , Ca^{2+} , Sr^{2+} , and Ba^{2+} do not increase the catalytic activity of ChE when used at high concentrations.⁵⁶

Table 1. The effect of some metal ions on the catalytic activity of enzymes.

Enzyme	Metal ion	Effect	c_{eff}^a /mol litre ⁻¹	Ref.
Ca ²⁺ -ATPase EC 3.6.1.3.	Mg ²⁺ , Co ²⁺	inhibitor	$1 \times 10^{-5} - 1 \times 10^{-3}$	23

	Mg ²⁺	activator	$4 \times 10^{-5} - 4 \times 10^{-3}$	27

^a c_{eff} is the concentration range where the effect is observed.

Pb²⁺, Hg²⁺, Cd²⁺, and Tl⁺ ions activate ChE at concentrations below $10^{-7} - 10^{-6}$ mol litre⁻¹ and inhibit the enzyme at higher concentrations.^{36, 37, 52, 53} Most authors attribute the activating

effect of cations to the possible formation of the ternary complex E–M–S (Fig. 1, pathway II),^{1, 58} which provides conformationally more favourable conditions for the enzymic reaction. The inhibitory effect of high concentrations of metal ions is assigned to the competitive reaction between metal and substrate cations (if the substrate bears a positive charge) for the active centre of the enzyme. At high salt concentrations, the active centre of the molecule can be occupied by metal ions, thus being inaccessible to the substrate cations. As a result, the catalytic activity of both native and immobilised ChE may decrease.^{36, 59} According to other authors,⁶⁰ the effect of metal ions on the enzyme activity is due to changes in the substrate solubility at high salt concentrations.

Obviously, the effect of metal ions on enzymes depends on many factors. It is therefore difficult and usually impossible to identify the determining factor. In particular, the effect of metals on the catalytic activity of enzymes depends on the nature of the metal, its size, charge, ionisation potential, the nature of the enzyme, its state (native or immobilised), conditions of the enzymic reaction, *etc.* Most commonly, the effect of metal ions on the enzyme activity is associated with their ability to form enzyme–substrate complexes, which may participate in the catalytic process by facilitating the transfer of electrons, to stabilise the active conformation of the enzyme or association of its subunits, and to act as an ‘anchor’ group without being directly involved in the catalytic act. These and other effects may also occur in combination. Unfortunately, the majority of authors give only qualitative characteristics of changes in the enzymic activity, which naturally hampers comparative analysis of the experimental data, and only very few try to estimate these effects quantitatively and get an insight into the mechanism of action of metal ions. These studies have received the greatest attention in the present review.

III. Changes in the catalytic activity of enzymes in the presence of metal ions: an analytical aspect

Over a long period of time, investigators have merely noted the effects of metal ions on the catalytic activity of enzymes, but these effects did not find practical application. As the bulk of experimental data have been accumulated, the analytical application of these effects became possible. The studies on this subject covering the period of 1949–1979 have been summarised in a review.⁶¹

One of the first studies by Russian authors on the application of the effects of metals on enzymes for analytical purposes was that by Dolmanova *et al.*²⁸ in which the authors offered a highly selective procedure for the quantitation of mercury, which was based on the inhibitory effect of mercury on horseradish peroxidase [the detection limit is $(1.0 \pm 0.5) \times 10^{-5}$ µg ml⁻¹]. Further investigations²⁹ in this field were directed to the use of various substrates and the optimisation of conditions for enzymic reactions, which made it possible to lower the detection limit to 3.0×10^{-7} µg ml⁻¹. Bismuth and cadmium ions interfere with the determination. A procedure for quantitation of mercury was proposed³⁰ (in which the lower limit of concentrations is 1×10^{-5} µg ml⁻¹), which differed from the standard ones by being time-saving (the analysis lasted for 30 minutes instead of 4 hours) and which permitted determination of mercury in the presence of relatively high (≥ 1 µg ml⁻¹) concentrations of Fe³⁺. Iron is masked by tartaric acid, which has no effect on the catalytic activity of peroxidase under the given experimental conditions and at selected concentrations. Quantitation of mercury in natural water is carried out using the method of additives, which makes it possible to estimate the effect of other components of the matrix (particularly that of Fe³⁺) without masking.

The inhibitory effect of Bi³⁺ on the catalytic activity of horseradish peroxidase was used as the basis for the kinetic method used for its quantitation. The lower limit of concentrations that can be determined is 2×10^{-4} µg ml⁻¹. This assay is not hampered by a 1000-fold excess of Ca, Mg, Zn, Ni, and Al, by

100-fold excess of Pb and Ag, and by a 10-fold excess of Cd. The presence of comparable amounts of Hg^{2+} interferes with the analysis.^{31, 62}

A highly sensitive ($c_{\min} = 8 \times 10^{-6} - 4 \times 10^{-4} \mu\text{g ml}^{-1}$), selective enzymic method²⁴ for the quantitation of REE is based on their inhibitory effect on the catalytic activity of bakers yeast and *E. coli* pyrophosphatases. The interference of Co^{2+} , Ni^{2+} , and Mn^{2+} ions was neutralised by introducing an excess of magnesium into the indicator reaction. The addition of $5 \times 10^{-3} \text{ mol litre}^{-1}$ of magnesium in the presence of $5 \times 10^{-5} \mu\text{g ml}^{-1}$ of praseodymium and of $5 \times 10^{-5} - 5 \times 10^{-3} \mu\text{g ml}^{-1}$ of manganese, cobalt, and nickel to the system eliminates their interference; this magnesium concentration has no effect on the inhibitory effect of praseodymium. The interference of calcium ions was eliminated by masking it with tartrate.

The high sensitivity of enzymic methods makes it possible to determine many components of various waters in small samples and without preliminary concentration at the maximum permissible concentration (MPC) level. For example, metal ions like Cu, Co, Ni, Fe, Mn, Cr, Hg, Cd, Bi, Pb, and Zn can be detected at concentrations of $1 - 100 \text{ pg ml}^{-1}$ on the basis of their inhibitory effect on horseradish peroxidase and alkaline phosphatase.⁶³

It was proposed to use enzymic methods in the study of formation of hydroxo complexes. The stability constants of hydroxo complexes, K_{MOH^+} , have been calculated for zinc, copper, iron, cobalt, and nickel.²⁰ Analytical methods based on the use of enzymes also permit measurement of the equilibrium concentrations of hydroxide ions and of ions of some *d*-block elements in complex heterogeneous systems and the study of salt hydrolysis with a high degree of sensitivity and selectivity unattainable by the majority of other methods.³⁴

The use of native enzymes for some specific assays has a number of disadvantages, such as the instability of enzymes on storage and under the influence of various factors (*e.g.*, heat treatment) and the impossibility to separate enzymes from the reagents and the reaction products. A contemporary approach to the solution of this task consists in the wide use of immobilised enzymes. Immobilisation favours the stabilisation of enzymes on long-term storage and increases their resistance to external factors. The possibility of multiple use of enzymes reduces considerably the cost of analysis.

The use of immobilised enzymes in metal ion assays has been reviewed.⁶⁴ Immobilisation of enzymes for determination of metal ions entails their incorporation into various membranes or binding to glass beads. Polymeric films with immobilised enzymes incorporated in them are now often used as membranes for biochemical sensors.

Thus an amperometric biochemical sensor for determination of metal ions has been constructed on the basis of ChE immobilised by incorporation into cellulose nitrate films.³⁶⁻³⁸ A method for assaying Cr^{3+} , Ti^{4+} , Zr^{4+} , and Hf^{4+} ($1 \times 10^{-10} - 1 \times 10^{-5} \text{ mol litre}^{-1}$) has been developed, which is based on the inhibitory effect of heavy metal ions on the catalytic activity of immobilised cholinesterase.³⁸

It was suggested⁶⁵ that Cu^{2+} be determined using an enzymic electrode containing glucose oxidase; it is based on the inhibitory effect of these cations on the enzyme in the concentration range of $2.5 \times 10^{-4} - 5 \times 10^{-3} \text{ mol litre}^{-1}$.

Recently, much attention has been paid to semiquantitative test-methods, which allow rapid, simple, and reliable determination of concentrations of toxic substances at the MPC level. The use of immobilised enzymes for the elaboration of these methods is also very promising.

A test-method for the determination of Hg^{2+} using peroxidase immobilised as a solid solution in chitosan has been described.⁶⁶ The assay is based on the inhibitory effect of mercury on the oxidation of *o*-dianisidine, *o*-phenylenediamine, and 3,3',5,5'-tetramethylbenzidine with hydrogen peroxide in the presence of thiourea catalysed by immobilised peroxidase. The change in the colour of the reaction solution due to the formation of red or

orange products of enzymic oxidation allows visual monitoring of the reaction rate. The lower limits of mercury concentrations that can be determined in these reactions are 1×10^{-5} , 5×10^{-5} , and $1 \times 10^{-7} \mu\text{g ml}^{-1}$, respectively. This method is noted for selectivity (the assays are hampered only by a 10^5 -fold excess of cadmium and bismuth), rapidity (the analysis is completed within 15 minutes), simplicity, and low cost.

Enzymic methods for assaying metal ions are characterised by high sensitivity and in some cases, high selectivity.²⁷ However, most of these assays are not sufficiently selective. A combination of high sensitivity of biochemical sensors based on immobilised enzymes with traditional methods of masking makes it possible to solve complex analytical problems. Thus, enzymes act as a new generation of analytical reagents. The use of biosensors for quantitation of metal ions is also a promising approach because it exploits the conditions modelling individual functions of a living organism. The elaboration of novel measuring tools including biosensors, especially those based on highly sensitive methods of registration, considerably extends the possibilities of evaluation of the effects of metal ions on the catalytic activity of enzymes. It may be assumed that in many cases the concentration range of inhibition or activation for a definite 'metal-enzyme' pair could not be determined because of the limited potentialities of the recording systems. In addition, in the case of specific assays, allowance should be made for the ionic composition of the medium and the composition of the buffer solutions used for each assay. Buffer solutions must be selected in such a way that their ionic composition ensures the maximum catalytic activity of the enzyme. This provides the conditions for the generation of a maximum analytical signal, which in turn extends the analytical capabilities of enzymic assays of various effectors including metal ions.^{37, 57}

IV. Conclusion

The above analysis of literature data shows that the effect of metal ions on the catalytic activity of enzymes is still a timely problem. At the same time, special mention should be made of some recent specific features of these studies. Thus in the 1960-70's interest in these studies was mostly biological or medical, while in the last decade interest has been shifted towards the chemical aspects of the problem. This is primarily due to the pollution of the biosphere with various metals above the permissible level and secondly, due to the possibility of their estimation with the help of enzyme preparations possessing higher sensitivity and, in some cases, selectivity. Two main trends in these studies can be isolated: quantitative assay of inhibitors or activators from the magnitude of the induced effect and the use of the activating effect of metal ions for increasing the sensitivity of assays for a wide range of compounds of various natures.

An overview of current literature demonstrates that it is difficult to predict *a priori* how one or another metal will influence the enzyme. This depends not only on the nature of the metal and the enzyme, but also on other specific conditions. The most important of those are the ionic radius and the concentration of the metal. One should not consider the problem of interaction of metal ions with the enzyme separately from the pH of the solution and the presence or the absence of the substrate. The activating or inhibitory effect of metal ions must be considered only with allowance for these factors.

Unfortunately, the majority of authors restrict themselves currently to the qualitative description of effects of metal ions on the catalytic activity of enzymes, while very few papers deal with quantitative estimates and analysis of the mechanism of interaction between metals and enzymes. It may be supposed, however, that the number of such publications will be increasing with the development of highly sensitive methods of registration.

IV. Theoretical background of the phase separation of solutions exposed to mechanical fields	238
V. Conclusion	240

Abstract. The review summarises and analyses recent results of studies into phase transitions in polymer solutions induced by mechanical fields. Processes of dynamic structure formation preceding phase transitions in shearing and longitudinal fields are described. The effect of molecular weight, chain flexibility, and concentration of the polymer, shear stress (rate), and surface energies of components on the phase separation of polymer solutions in a mechanical field is considered. The theoretical concepts of phase transitions in polymer solutions under mechanical stress are analysed. The bibliography includes 186 references.

I. Introduction

The study of phase transitions in polymer systems is a task of current interest, since phase transitions largely govern the structure, and hence, the properties of systems.

Processes leading to the formation of new phases play an important role in polymerisation and polycondensation, microencapsulation, adsorption from solution, and in the production of fibres, films, and membranes. Studies of phase equilibria are necessary for the development of the solution theory and for experimental verification of the existing theoretical assumptions. It is therefore natural that phase equilibria draw much attention.^{1–8}

Polymeric systems are exposed to various mechanical effects (shearing, stretching, compressing, and other deformations) during exploitation and processing. Directed mechanical stress is the main method for the orientation of polymers aimed at enhancement of their mechanical properties. For example, molecular orientation implemented by deformation of melts or solutions and arrested by a phase transition (crystallisation) has opened the possibility of manufacturing high-module fibres.

A considerable number of publications on the effect of mechanical stress on the phase transitions in polymer systems have appeared over recent years; some have been reviewed.^{9,10} Undoubtedly, mechanical stress can play a role of an independent thermodynamic factor determining the positions of the boundary curves, viz., binodals and liquidus curves, on phase diagrams.

According to Frenkel,⁸ mechanical stress should lead to a shift of these boundary curves. However, the theory of phase transitions in polymeric systems induced by mechanical fields[†] is still under development.

The accumulated body of data on the effect of a mechanical field on the liquid and crystalline phase separation, as well as on the gel formation in polymer solutions are summarised and analysed in this work. Phase transitions in polymer mixtures are not considered.

II. Dynamic structure formation in polymer solutions

Changes in viscosity, optical, thermodynamic, and other properties are observed in polymer solutions well below phase separation temperatures (T_{ph}) (on approaching T_{ph}).^{7,11–15} This implies a continuous reorganisation of the solutions: concentration fluctuations increase abruptly, and the size of light-scattering particles, which are nuclei of the new phase, increases.

In addition to temperature, concentration, and chemical structure of the components, the structure of polymer solutions is much affected by the external mechanical field. Its action can cause uncoiling of macromolecules, their orientation resulting in the formation of supramolecular structures, and decomposition of the structures already present.

Polymer flow can be caused by both stretching and shearing deformations. The shearing field causes the rotation of macromolecules, and the direction of deformation is reversed before a high degree of stretching is attained. Under uniaxial stretching conditions, the component of rotational movement is absent, and molecule stretching is determined by the $\varepsilon\tau$ product, where ε is the deformation rate and τ is the maximum time of molecule relaxation in which it returns to the coil conformation. Since τ is proportional to the molecular weight ($M^{1.5–2.0}$), considerable stretching of a macromolecule with high M can be reached even at very low polymer concentrations ($c \approx 10^{-2}$ g dl⁻¹).¹⁶ A small fraction of molecules with molecular weight 15 times higher than the average are deformed 100 times more strongly.¹⁷ For this reason, at moderate stretching stress in a flux, the majority of short molecules only move, while long molecules present in small quantities stretch almost completely and can form nuclei of a new phase.

The transition from a coil to a stretched chain was considered theoretically in a series of papers.^{18–25} It was shown within the

[†] Mechanical field signifies a field of vectors of stresses (forces) that appear in a system when it is deformed.

scope of nonequilibrium thermodynamics¹⁹ that in a longitudinal hydrodynamic field (under uniaxial stretching), full uncoiling of macromolecules occurs, which is accompanied by an increase in energy dissipation by the flowing solution. It was shown¹⁹ that in the case of unpermeable macromolecular coils, the transition of chains to the stretched state on changing the velocity gradient occurs as a first-order phase transition and is accompanied by an abrupt change in the conformational entropy of the chain. When the molecular weight of a polymer decreases, the transition behaviour becomes uniform.

The theoretical conclusions are confirmed by the experimental data for dilute solutions of carboxymethylcellulose, methylcellulose, nitrocellulose and a number of other polymers.¹⁹ The fact that a transition of polystyrene molecules in xylene solutions from coiled to strongly stretched state does occur was confirmed experimentally.^{26, 27} The transition, detected by the appearance of strong birefringence, was observed at shear rates ($\dot{\gamma}$) above a certain critical value ($\dot{\gamma}_{cr}$). The correlation $\dot{\gamma}_{cr} \propto N^n$, where N is the degree of polymerisation and $n = 1.47 \pm 0.08$, has been established for the polystyrene–toluene system.²⁸ The phenomenon of chain uncoiling was also observed in polymer melts. It was found²⁹ that the mean stretching of polyethylene molecules under shear deformations can be as high as 50%.

A number of papers^{20–26} present a theoretical consideration of macromolecule uncoiling in a longitudinal hydrodynamic field and analyse the changes in the friction coefficient of macro-

molecules and in the chain conformational microstructure under stretching. These processes change the environment of macromolecules to anisotropic.³⁰ Such induced anisotropy is determined by the orientation of macromolecules and manifests itself as experimentally observed birefringence of solutions, Weissenberg effect, flow swelling, *etc.*^{16, 31}

The degree of macromolecule uncoiling in a shearing field is much smaller than that in a stretching field.³² For example, 100% uncoiling of polyethylene molecules requires a *ca.* 10^3 times higher deformation rate in the shearing field than in the stretching field. Uncoiling and orientation of macromolecules leading to their association have been observed for solutions of poly(ethylene oxide) and polyacrylamide (PAA),³³ polyacrylic acid,³⁴ and poly(octyl methacrylate).³⁵

The increase in concentration fluctuations in the course of flowing has been observed for polystyrene solutions.^{36–38} The formation of supramolecular particles in such processes was considered in Refs 39 and 40. It was shown that, depending on $\dot{\gamma}$, a sharp increase in concentration fluctuations can lead to the phase separation of the system. In solutions of polymer mixtures, the dependence of the magnitude of concentration fluctuations on the shearing rate passes through a maximum at medium $\dot{\gamma}$ values. The micellar structure formation in aqueous surfactant solutions depends on $\dot{\gamma}$ in a similar way.^{41, 42}

It was found for the poly(vinyl alcohol)–water,^{41–46} poly(ethylene oxide)–water,^{47, 48} polyethylene–xylene,^{49, 50} and poly-

ethylene–octadecane⁵¹ systems that structure formation resulting in phase separation occurs in the solutions exposed to mechanical stress (stirring, flowing). Analogous effects were observed for polyacrylamide–water,^{52–54} polystyrene (PS)–dioctyl phthalate,⁵⁵ poly(methyl methacrylate)–chlorinated biphenyl,⁵⁶ polystyrene–decalin⁵⁷ and polystyrene–cyclohexane⁵⁸ systems. It was found that dynamic structure formation is most pronounced in solutions of medium concentration.⁵⁹ Table 1 displays data on the effect of mechanical field on the properties of a number of polymeric systems.

Structure formation occurs in rheometer parts of various shapes: cone–plane, coaxial cylinders, capillary. The effect of deformation on solubility does not depend on the type of deformation. For example, similar results were obtained⁶⁹ in a study of changes in T_{ph} of solutions for a laminar Poiseuille-type flow through a capillary and for a torsion flow geometry in a gap between a cone and a plate. This is a common phenomenon for solutions of polar and nonpolar polymers with high molecular weight in a wide range of concentrations at any temperatures and in any solvents.

Thus, a study of the structure of polymer solutions showed that, first, uncoiling of macromolecules, their orientation and association leading to phase separation occur in a hydrodynamic field; second, depending on the shear rate and the polymer concentration, the effect of a mechanical field on the solution structure has a dependence passing through an extremum; third, as the molecular weight of a polymer and concentration increase, structure formation starts at lower shear rates; and fourth, a solid phase with new morphology, which is completely stable with respect to re-dissolution, is sometimes isolated from the solution.

III. Phase transitions in polymer solutions induced by mechanical fields

1. Systems with crystalline phase separation

The effect of mechanical field on crystallisation has been studied most thoroughly for polymer melts.^{84–98} The phenomenon of stress-induced crystallisation was discovered in 1805 by Gough.⁸⁷ Later, this problem was studied by Katz,⁸⁸ Flory,⁸⁹ Krigbaum and Roe,⁹⁰ Vinogradov and Malkin,⁹¹ Haas and Maxwell,⁹² Southern and Porter,⁹³ Fritzsche and Price,⁹⁴ Baranov,⁹⁵ Hoffman,⁹⁶ and Lindenmeyer.⁹⁷ This phenomenon has been covered in detail in a monograph⁹ and in a review.⁹⁸

Crystallisation of polymers from solutions and melts induced by mechanical stress has been observed in a number of studies.^{99–121} For example, crystallisation of *cis*-1,4-polyisoprene, *trans*-1,4-polybutadiene, poly(ethylene terephthalate), poly(vinylcarbazole), and poly(vinyl chloride) due to stretching has been observed by birefringence and small-angle light-scattering methods.⁹⁹ The formation of rod-shaped crystalline structures upon shearing and stretching has been found for melts^{100,101} and solutions¹⁰² of poly(ethylene terephthalate) in *m*-cresol and diphenyl ether. The crystallisation of isotactic polystyrene,¹¹⁹ polyethylene,^{95,122} and poly(ethylene oxide)^{96,114,123} melts in a shearing field has been studied.

It has been found for melts that mechanical stress (stretching or shearing deformation) increases the degree of orientation of macromolecular chains so that the induction period of crystallisation decreases, the crystallisation temperature increases (by tens of degrees), the rate of nuclei growth increases by two to four orders of magnitude, the nucleation rate increases by one to two orders of magnitude, and the critical size of the new phase nuclei decreases.

An increase in the crystallisation temperature has also been found for polymer solutions. It was shown¹⁰² that crystallisation of poly(ethylene terephthalate) under flowing conditions occurs at a temperature 10 K higher than that on cooling under static conditions. The polymer that formed consisted of elongated crystals, which were more thermally stable than the spherulites obtained upon phase separation of unperturbed solutions.

Pennings *et al.*^{78,108,116} have carried out systematic studies of polyethylene crystallisation from flowing solutions. They found that flowing causes a 15–20 K increase in the crystallisation temperature, while the crystallisation rate increases by a factor of several thousand. Similar dependences for polymer solutions were observed in other studies.^{103–107,111} It should be noted that experimental data are in good agreement with those calculated using the theory of polymer crystallisation from melts under deformation.^{103,108} Acceleration of crystallisation under flow conditions has been found in solutions of polypropylene, poly(ethylene oxide),¹⁰⁴ and poly(*p*-phenylene terephthalamide).¹⁰⁴

In a study of polycapramide crystallisation in caprolactam,^{123,124} it was found that an increase in shear rate to 50 s^{−1} decreases the induction period of crystallisation, but starting from 130 s^{−1}, the flow slows down the crystallisation, *i.e.* inversion occurs. It is assumed^{95,123,124} that this phenomenon is caused by the destruction of crystallisation nuclei at high shear rates.

Thus, it has been shown experimentally that uncoiling of macromolecules in the flow and orientation of chains favour the formation of nuclei of a new phase and phase separation. A detailed study of the effect of shear stress on the position of the boundary curve in the crystal separation of phases has been first carried out by Malkin and Kulichikhin.¹²⁴ They have shown that the mechanical field causes the boundary curve to shift to higher temperatures. This shift depends on the shear rate and is caused by a decrease in the entropy of the system due to processes of uncoiling and orientation of molecules in the flow.

Later, the T_{ph} of solutions and the melting points (m.p.) of polyethylene under static and dynamic conditions (Fig. 1) were determined by Vshivkov *et al.*^{48,125,126} It was found that application of a mechanical field results not only in an increase in T_{ph} and m.p., but also in a change in the boundary curve shape. It was only in the case of dilute solutions ($c < 1$ mass %) that no change in T_{ph} within the γ range studied was observed. In concentrated solutions, an increase in the shear rate results in a 10–30 K increase in T_{ph} . For solutions with $c = 30$ mass % and 40 mass %, the T_{ph} – γ function is a curve with a maximum; this indicates that the dependence of the crystallisation rate on the rate of the solution deformation has an extremal form. A similar correlation was observed by other authors.¹²³ These data and the data given below prove that this phenomenon is of general character and results from two oppositely directed processes, namely, uncoiling of macromolecules, their orientation in the flow, and destruction of nuclei of a new phase by the mechanical field at high γ values. The first process favours the crystallisation and the second one impedes phase separation.

Figure 1. Boundary curves for the PE ($\bar{M}_n = 2.3 \times 10^5$)–xylene system. γ / s^{−1}: (1) 0, (2) 47, (3) 246.

From analysis of data on crystallisation of polyethylene from flowing solutions it was assumed¹²⁷ that the formation of amorphous gel-like phases precedes the formation of polyethylene fibrils. It was concluded that the phase diagram of solutions of a polymer that undergoes crystallisation can be changed both quantitatively and qualitatively under flowing conditions. In

fact, a shearing field can cause a qualitative change in the boundary curve (see Fig. 1). A maximum appears, the position of which is shifted towards low concentrations of the polymer on increasing the shear rate. Such curves are typical of systems where both liquid and crystal phase separation occurs simultaneously. However, we did not observe liquid phase separation in this system; the shearing field caused only a decrease in the degree of crystallinity of polyethylene precipitated from solutions.

2. Systems with liquid–liquid phase separation

Winsor¹²⁸ was the first to mention the effect of mechanical stress on stratification of liquids. He found that turbid systems, such as water–cyclohexanol–alkyl ethers of poly(ethylene glycol), lauryl alcohol–sulfodiethyl succinate–benzene–ethylene glycol and others, become transparent on vigorous shaking and return to the original state after a few minutes of rest.

Silberberg and Kuhn^{129–131} studied a polystyrene–ethylcellulose–benzene ternary system, which became turbid on cooling. They showed that the solution was turbid under quiescent conditions but became transparent on flowing at a certain critical shear rate and stratified again at a lower temperature, *i.e.*, the solubility of the components increased on flowing. In this case, the difference in phase separation temperatures under dynamic and static conditions (ΔT) was defined by the equation $\Delta T = -(\gamma_{cr}/\alpha)$, where $\alpha = 3.6 \times 10^6 \text{ mol}^{-1} \text{ litre}$. As can be seen from this equation, significant changes in T_{ph} under flow should occur for polymers with high molecular weight (10^6 – 10^7).

The enhancement of miscibility in the flow has also been observed for other ternary systems, such as polystyrene–polypropylene–decalin,¹³² polystyrene–polypropylene–toluene,¹³³ legumin–sodium chloride–water¹³⁴ and polystyrene–polybutadiene–dioctyl phthalate.^{135, 136}

The observed phenomenon was explained^{129–131} by the fact that the mechanical field destroys drops of a new phase. This is possible if the interfacial surface energy is low ($\sigma \approx 10^{-6} \text{ J m}^{-2}$). In this case, the energy of the hydrodynamic field may be sufficient to compensate the free energy gain due to the destruction of drops. The drops are destroyed until their volume reaches V

$$V = \left(\frac{0.74\sigma}{\eta\gamma} \right)^3,$$

where η is the viscosity of the medium.¹³⁷

Homogenisation in the flow of a polystyrene–polybutadiene–dioctyl phthalate ternary system, which stratifies on cooling, was studied using small-angle light scattering.^{136–138} It was found that the decrease in T_{ph} depends on the shear rate within its 6–1300 s^{-1} range according to the equation

$$\frac{\Delta T_{cr}}{T_{cr}} = (2.6 \pm 0.6) \times 10^{-3} \gamma^{0.50 + 0.02}.$$

The enhancement of solubility of the components is explained by the fact that a mechanical field suppresses the concentration fluctuations and destroys the nuclei of a new phase. Similar results were obtained using low-angle scattering of neutrons.¹³⁷

In a study of the optical properties of a polystyrene–toluene system, a decrease in the miscibility of components in the flow was observed.¹³⁹ A beam of light was passed parallel to the capillary walls, and it was found that the layer of the solution which scatters light decreased on flowing.

The effect of changes in mutual solubility of components in the flow on the shape of the phase diagram was first studied by Ver Strate and Philippoff.⁶⁷ They showed that T_{ph} for solutions of polystyrene in dioctyl phthalate and decalin increases in the flow from 284 to 313 K and from 289 to 302 K, respectively.

Later, the shift of boundary curves in shearing field was observed for polystyrene–cyclohexane, poly(methyl methacrylate)–butanol and poly(ethylene oxide)–water⁴⁷ systems. The observed increase in the higher critical solution temperature (UCST) and decrease in the lower critical solution temperature

Figure 2. Boundary curves for PS–cyclohexane (a), PS–di(2-ethylhexyl) phthalate (b), PMMA–butanol (c), and PEO–water (d) systems under static (1) and dynamic (2) conditions.

(LCST) (Fig. 2) means a decrease in solubility of the components and formation of stable associates of polymer macromolecules in solution at temperatures at which none are formed under static conditions. The observed phenomenon is explained^{47, 67} by uncoiling of macromolecular coils in the mechanical field and by the orientation of chains along the flow, which increases the number of contacts between the macromolecules, *i.e.* increases the degree of association. This assumption has been confirmed experimentally.^{54, 58, 70, 84, 140, 141}

The decrease in the solubility of components, which manifests itself as changes in the T_{ph} of flowing solutions, has also been observed for poly(vinyl acetate)–ethanol,¹⁴² poly(methyl methacrylate)–dimethylformamide,¹⁴³ polystyrene–cyclohexanone–ethanol,¹⁴⁴ polybutadiene–toluene–ethanol,¹⁴⁴ and poly-(dimethylsiloxane)–ethyl methyl ketone¹⁴⁵ systems.

It was shown¹⁴⁵ for the poly(propylene glycol)–water, polyacrylic acid–dioxane, and poly-*p*-chlorostyrene–isobutyl acetate systems¹⁴⁵ that mechanical stress does not necessarily result in shifting of the boundary curves if uncoiling of macromolecular coils and the orientation of chains in the flow are hindered. In this case, insignificant uncoiling of macromolecules is explained by the low molecular weight of poly(propylene glycol) (1000) and by the high stability of polyacrylic acid globules near T_{ph} due to intramolecular hydrogen bonds.¹⁴⁶ The orientation of poly-*p*-chlorostyrene molecules is hindered by thermal motion (LCST = 423 K). Thus, the orientation effects in all the three systems are small and can be compensated by the destruction of nuclei of new phases in the mechanical field; as a result, the position of the boundary curves remains unchanged.¹⁴⁷

Wolf *et al.*^{148–154} have systematically studied the liquid phase separation of polymer solutions initiated by mechanical field. Using solutions of polystyrene in decalin, *tert*-butyl acetate, and dioctyl phthalate, they showed that both stratification and homogenisation of a system in the flow can be expected, depending on the concentration and the molecular weight of the polymer and the γ value. For example, for polystyrene with $M = 10^5$, mechanical field does not affect the T_{ph} of the solutions; for the sample with $M = 6 \times 10^5$, flowing results in an increase in miscibility, which manifests itself as a decrease in T_{ph} ; for the sample with $M = 2 \times 10^6$, flowing decreases the solubility. For solutions with $M = 1.2 \times 10^6$, $\Delta T = 0$ at low shear rates, T_{ph} becomes negative (the solubility increases) with an increase in γ , and $\Delta T > 0$ at high shear rates ($\gamma = 3000 \text{ s}^{-1}$).

Figure 3. Boundary curves for a PS–di(2-ethylhexyl) phthalate system. $\bar{M}_\eta = 5.7 \times 10^4$ (a), 1.6×10^5 (b), 2.5×10^5 (c); γ/s^{-1} : (1) 0, (2) 24, (3) 118.

A different dependence was found for a polystyrene–cyclohexanone–ethanol system.¹⁴⁴ For the polystyrene samples with $M < 10^4$, the mechanical field did not affect T_{ph} , whereas at $M \approx 10^6$, the ΔT – γ dependence was described by a curve with a maximum. This is explained by the effect of two opposite processes occurring in the system, *viz.*, the orientation of macromolecules due to flowing and the destruction of new phase nuclei by the mechanical field. The first process favours phase separation and the second one prevents it. It was shown that the decrease in miscibility in the flow in the case of solutions of polystyrene, poly(vinyl acetate), and polybutadiene can be described by one curve in the ΔT – τ coordinates (where τ is the shear stress). The enhancement of solubility of the components (decrease in ΔT) starts from different τ for each polymer.

A systematic study of the effect of the polymer molecular weight and concentration on liquid phase separation under the action of mechanical field has been carried out for a polystyrene–di(2-ethylhexyl) phthalate system (Figs 2–4).^{155, 156} An increase in γ leads to a shift of the boundary curve towards higher temperatures, *i.e.* to a decrease in the solubility of a high-molecular polystyrene sample. A more complicated effect of mechanical field was observed for solutions of polystyrene with lower molecular weight. An increase in the solubility of the components, which manifested itself in a decrease in T_{ph} , was observed for a sample with $\bar{M}_\eta = 5.7 \times 10^4$. These data indicate an inversion of the effect of the mechanical field on liquid phase separation: the mutual solubility of the components increases in the flow in dilute and moderately concentrated solutions ($\Delta T < 0$) and decreases in concentrated solutions ($\Delta T > 0$). The higher the molecular weight of the polymer and the higher γ , the lower the concentration of the inversion point (c_i). It should be noted that c_i is close to the concentration c^* at which macromolecular coils begin to overlap. According to Debye, it equals $c^* = [\eta]^{-1}$, where $[\eta]$ is the characteristic viscosity. One may assume that in solutions with $c < c^*$, the shear field can destroy associates of fluctuation origin that form macromolecular coils in solution upon decrease in the quality of the solvent. The dependences of ΔT on the molecular weight of polystyrene for equiconcentrated solutions are described by curves with minima. In this case, the critical

Figure 4. Dependence of ΔT on $\lg M$ for the PS–di(2-ethylhexyl) phthalate system. $c/\text{g dl}^{-1}$: (a) 1.51, (b) 3.06, (c) 4.26, (d) 5.00; γ/dl^{-1} : (1) 118, (2) 24.

molecular weight (M_{cr}), which marks the limit where ΔT becomes positive, decreases with an increase in the polymer concentration and shear rate. The mutual solubility of the components in the shear field increases for solutions of polystyrene with $M < M_{\text{cr}}$.

In the opinion of Barham and Keller,¹⁴³ flowing of solutions results in adsorption of macromolecules on the capillary walls. They classify the adsorption-entanglement layers according to their thickness: (1) layers several microns thick formed upon adsorption from solutions in good solvents at small γ (the existence of such layers has been discussed in a monograph¹⁵⁷); (2) layers formed in poor solvents at large γ that can be several millimetres thick and block the capillary, which increases τ . In these cases, the formation of gel-like particles is referred to. An attempt was made¹⁵⁸ to distinguish processes of liquid phase separation and the formation of adsorption-entanglement layers using oscillating flow. Periodic changes in the flow direction hinder the growth of adsorption layers but do not prevent liquid phase separation, which is determined by the magnitude of shear stress rather than by its direction. Four types of flow behaviour of solutions of poly(methyl methacrylate) in dimethyl phthalate were found: (1) usual flowing, which is not disturbed either by adsorption or by phase separation, at small rates of rotor oscillation (less than $2 \times 10^{-5} \text{ rad s}^{-1}$); (2) flowing where τ increases with time to a constant value (at $2 \times 10^{-5} - 10^{-2} \text{ rad s}^{-1}$), which is related to the formation of adsorption-entanglement layers of interpenetrating chains; (3) flowing where τ increases continuously (at $10^{-2} - 2 \text{ rad s}^{-1}$) due to the formation of adsorption-entanglement layers followed by liquid phase separation according to the nucleation and growth mechanism in which the role of nuclei is played by adsorption layers; (4) flowing characterised by large unstable τ oscillations. At rates above 3 rad s^{-1} , solutions become turbid due to liquid phase separation according to the spinodal mechanism. Thus, transition from behaviour type 3 to type 4 corresponds to crossing a spinodal, while transition from behaviour type 2 to type 3 corresponds to crossing a binodal. Using these rheological criteria, Barham and Keller¹⁵⁸ have determined the binodals and spinodals and showed that boundary curves and UCST shift to higher temperatures as τ increases. The results of the analysis performed by these and other authors are presented in Table 2.

The effect of mechanical field on phase transitions in solutions in which both liquid and crystal phase separation occurs was first studied for the polyethylene glycol (PEG)–poly(propylene glycol) (PPG) and PEG–glycerol–water systems.^{168–170} In the former system, a combination of liquid phase separation and crystal phase separation on cooling is observed; in the latter, liquid phase separation on heating and crystal phase separation on cooling occur. In the PEG–PPG system, the shearing field considerably increases the crystallisation temperatures ($\Delta T \simeq 10–16$ K) and almost does not affect liquid phase separation. The absence of a noticeable effect of the hydrodynamic field on the liquid phase separation of PEG solutions is caused by the low molecular weight of PEG. A similar dependence was found for the PEG–glycerol–water system: the change in crystallisation temperatures in the flow was an order of magnitude greater than the change in liquid phase separation temperatures. In both systems, the solubility of the components decreases under flowing conditions.

3. Gel-forming systems

It was found¹⁷¹ for a polymethacrylic acid–water system that gel formation leading to a sharp increase in viscosity is observed in the shearing field. The time dependence of viscosity (at $\gamma = \text{const}$) is described by a curve with a maximum the position of which shifts to smaller times with increasing γ . The decrease in viscosity is explained by macroscopic destruction of the gel that formed. It is assumed that the aggregation of polymethacrylic acid molecules

results from the deformation and orientation of the polymer chains.

It was shown¹⁶⁹ that the increase in viscosity upon shear can be described by the Avrami equation, which is generally used for the description of polymer crystallisation. Gel formation under flowing conditions has been found for aqueous solutions of poly(vinyl alcohol),¹⁷² gelatine,¹²⁶ hydroxypropylguar,¹⁷³ and for a poly(dimethylsiloxane)–ethyl methyl ketone system.¹⁷⁴

An opposite phenomenon has been observed for a cellulose diacetate–acetone–water system, which forms a gel on cooling;^{125,170} applying mechanical field results in a decrease in gelation temperatures, *i.e.* widening of the homogeneous region. This phenomenon is probably caused by the fact that cellulose diacetate has high kinetic rigidity, thus no considerable additional uncoiling of macromolecules should be observed in the flow. Hence, the role of the hydrodynamic field is reduced mainly to the destruction of nuclei of a new phase, which enhances the mutual solubility of the components. It was found that under deformation with $\gamma \simeq 10^2 \text{ s}^{-1}$, solutions containing a 1.4–2 times higher concentration of the polymer can exist than in the absence of flow.

IV. Theoretical background of the phase separation of solutions exposed to mechanical fields

1. Liquid separation

At present, several approaches to the description of the effect of mechanical field on the miscibility of components in polymeric systems are known. For example, Di Marcio and Guttman¹⁷⁵ assume that the polymolecular nature of polymers is the reason for the stratification of the flowing solutions. Since the distance between the mass centres of particles and the capillary walls cannot be smaller than the radii of the particles, larger molecules will be closer to the capillary centre and will thus move at a higher velocity, which results in phase separation. However, this concept has not been developed further, as it did not explain the shift of boundary curves for monomolecular polymer solutions and low-molecular-weight compounds.

Other scientists^{67, 126, 127, 149, 154} suggest that the free energy of solution mixing in mechanical field (ΔG_γ) should be represented by a sum of the free energies of solution mixing under static conditions (ΔG) and the energy the solution can store while it flows (G_s),

$$\Delta G_\gamma = \Delta G + G_s.$$

The free energy of solution mixing under static conditions is calculated according to the Flory–Huggins theory

$$\Delta G = RT(n_1 \ln \varphi_1 + n_2 \ln \varphi_2 + \chi n_1 \varphi_2),$$

where n and φ with indices 1 and 2 are the mole number and the volume fraction of the solvent (1) and the polymer (2), respectively, and χ is the parameter describing the interaction of the solvent (1) with the polymer (2). The free energy G_s accumulated by the flowing solution due to uncoiling and orientation of macromolecules can be determined according to the equation^{67, 148}

$$G_s = \tau^2 I,$$

where τ is the shear stress and I is the compliance caused by the first difference of normal stresses, which equals

$$I = 0.4 \frac{M_2}{c_2 RT} \left(1 - \frac{\eta_0}{\eta} \right)^2$$

for Newtonian solutions, where M_2 is the molecular weight of the polymer, c_2 is the polymer concentration, and η_0 and η are the solvent and solution viscosities, respectively.

The first calculations of the stored energy at temperatures near T_{ph} were performed by Ver Strate and Philippoff⁶⁷ for the polystyrene–decalin system. It was shown that at $\Delta T \approx 5$ K, $\tau = 3 \times 10^3$ dyn s⁻¹, $I \approx 10^{-3}$ cm³ dyn⁻¹, $\chi = 0.5$, and $\phi_2 = 0.03$, the stored energy G_s is 2×10^{-4} cal cm⁻³. The magnitude of G_s is of the same order as the change in the energy of mixing ($\Delta G'$) required for the given change in the solution T_{ph} ($\Delta G' \approx 5 \times 10^{-4}$ cal cm⁻³). The concentration dependences of G_s and $\Delta G'$ corresponding to the change in T_{ph} in a polystyrene–di(2-ethylhexyl) phthalate system in the flow were calculated.¹⁵⁵ The calculated values coincided. Hence, the change in the solubility of components in a mechanical field can actually be caused by the energy stored by solutions in the flow.

It was found for a polystyrene–dioctyl phthalate system⁶⁹ that the dependence of normal stress, which determines G_s , on the polymer concentration at a constant τ is described by a curve containing a maximum. The pure solvent behaves as a Newtonian liquid, hence the normal stresses are equal to zero. The addition of the polymer imparts elastic properties to the solution, leading to the development of normal strains upon shear deformations. At high polymer concentrations, the fluctuation entanglement network hinders the elastic deformation of chains in the shearing field, which results in a decrease in normal stresses. It is the extremal character of the G_s – c dependence that explains the extremum observed on the ΔT – c dependence.⁶⁹

Using the Marrucci and Sarti relationship¹⁷⁶ between the solution elasticity and G_s , an equation relating the system parameters for the critical point in a shearing field was found⁶⁹

$$-\frac{1}{(1-\phi_2)^2} + 2\chi - \frac{a\bar{V}_1}{RT} = 0,$$

where a is a coefficient relating G_s to the volume fraction of the polymer and $\bar{V}_1$ is the partial molar volume of the solvent.

By comparing this equation with the known equation for $\gamma = 0$

$$-\frac{1}{(1-\phi_2)^2} + 2\chi_0 = 0,$$

it is possible to find a parameter of interaction between the components in a flowing solution

$$\chi = \chi_0 + \frac{a\bar{V}_1}{2RT}.$$

Presumably, the polymer concentration in the critical point of a system is not changed in the flow,⁶⁹ but the interaction parameter is 'shifted' by $\Delta\chi = a\bar{V}_1/2RT$. Hence, boundary curves for a system under mechanical stress should be shifted along the χ (or T) axis and remain parallel to the boundary curves for the undisturbed system. The ΔT values determined experimentally for solutions of polystyrene in dioctyl phthalate at 3–28 K coincided with those predicted⁶⁹ to within ± 3 K. However, it should be noted that experimental boundary curves are shifted along the T axis with an increase in τ but are not parallel to those for the undisturbed system.

The concept of stored energy was used^{149,154} to calculate a series of boundary curves. It was shown that in the general case, both an increase and a decrease in the solubility of components can be expected in a mechanical field. The overall pattern is determined by the relative behaviour of the concentration dependences of ΔG_γ , ΔG , and G_s (Fig. 5). For solutions of polymers with low molecular weight, a concentration higher than the critical concentration ϕ_2^{cr} corresponds to the maximum G_s , and in this case the contribution of G_s to ΔG of the system can result in the system homogenisation in the flow and hence in a change in the shape of the ΔG – ϕ_2 curve. For solutions of polymers with high molecular weights, the concentration at the maximum G_s and ϕ_2^{cr} are comparable. In this case, a homogeneous system whose ΔG – ϕ_2 curve is concave (which corresponds to the thermodynamically stable state) separates into two phases in mechanical

Figure 5. Concentration dependences of the stored free energy (G_s) and the free energy of solution formation under dynamic (ΔG_γ) and static (ΔG) conditions.¹⁵²

(a) shear-dissolution; (b) shear-demixing; (1) G_s , $\gamma = \text{const}$; (2) ΔG_γ ; (3) ΔG ; c is the polymer concentration.

field, and extremums appear on the ΔG_γ – ϕ_2 curve. According to the calculations,^{149,154} polymer solutions can separate into three coexisting phases at certain τ values. An eulytic point was introduced, where two binodals, which appear upon deformation from one original binodal corresponding to the undisturbed system, intersect.

The change in the free energy of mixing due to flow is related^{127,177} to a decrease in chain flexibility on deformation. The Flory equation¹⁷⁸ for f , i.e. the fraction of flexible chains in a macromolecule, was supplemented by parameter A , which describes the work of an external mechanical field required for stretching a macromolecule,

$$f = \frac{(z-2) \exp(-\varepsilon/kT - A)}{1 + (z-2) \exp(-\varepsilon/kT - A)}, \quad (1)$$

where z is the coordination number in the quasi-lattice model, ε is the difference between the free energies of the flexible and rigid macromolecule conformations, and $A = Fl/kT$ (F is the stretching force applied to a segment of length l). It was shown¹⁷⁷ that an isotropic solution can become anisotropic on imposing a mechanical field. This approach does not take into account the enhancement of the miscibility of components in the flow observed experimentally.

The authors of Ref. 127 analysed the latter two approximations. They used Eqn (1) under the condition that Fl is an increase in the free energy due to the translation of macromolecular segments with characteristic length l . In this case, the free energy of a system of semi-flexible chains in a flowing solution containing n_2 polymeric molecules and n_1 solvent molecules was written as:

$$\begin{aligned} \Delta G = kTn_2 \left\{ (x-1) - \ln\left(\frac{xz}{2}\right) + (x-2)[f \ln f + \right. \\ \left. + (1-f) \ln(1-f) - f \ln(z-2)] \right\} + n_2 \{ f(x-2)(\varepsilon + Fl) \} + \\ + kT(n_1 \ln \phi_1 + n_2 \ln \phi_2 + \chi n_2 \phi_1), \end{aligned} \quad (2)$$

where x is the number of segments of length l in the macromolecule. From Eqns (1) and (2), an equation was obtained for the free energy of mixing, ΔG . Using this equation, the chemical potentials of the components and the change in the free energy per mol of the polymer under flowing conditions were calculated

$$\Delta G_f = RT(x-2) \ln[(1-f)(z-1)]. \quad (3)$$

It was shown¹²⁷ that Eqn (3) for the calculation of a binodal can be solved only if, after phase separation, the chains in the concentrated phase are straightened to a larger extent than in the dilute phase. The approximation for accumulated energy was

analysed and the following expression for the energy of mixing of a flowing solution was obtained:

$$\Delta G_{\gamma} = RT \left\{ N_1 \ln \varphi_1 + N_2 \ln \varphi_2 + \chi x N_2 \varphi_1 - N_2 \left[\ln \frac{x}{2} + \ln \frac{z}{z-1} + (x-1) \ln \left(\frac{z-1}{e} \right) \right] \right\} + N_2 G_s,$$

where N_1 and N_2 are the mole numbers of the solvent and the polymer, respectively, G_s describes the free energy change due to stretching of one mole of macromolecules, and 'e' is the base of natural logarithms. It should be noted that the expressions for G_s presented in Ref. 127 were derived with account of the properties of the solution rather than of separate macromolecules. At $G'_s = G_s$ (the prime mark corresponds to the more concentrated phase), no displacement of the binodal should occur. It follows from the equation obtained in the same work

$$G'_s - G_s = RT(x-2) \ln \left(\frac{1-f'}{1-f} \right),$$

that the approximation of chain flexibility decrease is identical with the approximation of accumulated energy if G_s is interpreted as the free energy of the coil–stretched chain transition. In this case, the two-phase region broadens as the rigidity of macromolecules in the concentrated phase increases, and the binodal is shifted to higher temperatures with an increase in $(1-f)/(1-f')$; the critical concentration decreases in the flow, which is in accord with the experimental data.

The liquid phase separation of polymer solutions in a mechanical field has also been analysed theoretically in other papers.^{143, 179–181}

2. Crystalline phase separation

One of the first studies dealing with crystallisation of polymers under deformation was carried out by Flory,⁸⁹ who derived the dependence between the melting point and the degree of stretching of a loosely cross-linked polymer

$$\frac{1}{T_m^0} - \frac{1}{T_m} = \frac{R}{\Delta H_m} \left[\left(\frac{6}{\pi m} \right)^{1/2} \lambda - \frac{\lambda^2}{2m} - \frac{1}{\lambda m} \right], \quad (4)$$

where T_m^0 is the equilibrium melting point of non-deformed polymer, ΔH_m is the heat of melting of one mole of statistical segments, m is the number of statistical segments between cross-linking points, and λ is the stretching ratio. At small λ , Eqn (4) gives overestimated melting point values, since it was derived with the assumption that crystals grow only along the direction of stretching.

Krigbaum and Roe⁹⁰ suggested the following relationship between the deformation and the melting point:

$$\frac{1}{T_m^0} - \frac{1}{T_m} = \left(\frac{R}{2\Delta H_m} \right) m \left[\lambda^2 + \frac{2}{\lambda} - 3 \right].$$

This equation makes it possible to obtain equilibrium melting points for non-deformed specimens as well. However, as the authors themselves admit,⁹⁰ Eqn (4) gives a better fit of the experimental data over a broad range of λ values.

Flory⁸⁹ explains the increase in the melting point on stretching by a decrease in the polymer entropy by a value of the orientation entropy S_{or} . According to Yeh *et al.*,^{85, 86} the increase in the rate and temperature of crystallisation in the flow occurs for the same reason. They compared the following equations:

(1) for the melting point

$$T_m = \frac{\Delta H_m}{\Delta S_m} \text{ (under static conditions); } T_m = \frac{\Delta H_m}{\Delta S_m - |\Delta S_{or}|}$$

(under shearing conditions), where ΔH_m and ΔS_m are the specific enthalpy and entropy of melting and ΔS_{or} is the change in entropy caused by molecular orientation.

(2) for the nucleation rate N

$$\frac{N_{\gamma>0}}{N_{\gamma=0}} = \exp \left[-\frac{B}{RT} \left(\frac{1}{\Delta g} - \frac{1}{\Delta g + T|\Delta S_{or}|} \right) \right],$$

where Δg the free energy of nucleation and B is a constant.

It follows from the equations that an increase in the shearing rate, and hence $|\Delta S_{or}|$, increases the nucleation rate and the melting point. The decrease in polymer entropy due to the orientation of macromolecules in the flow has been calculated¹²⁶ for the polyethylene–xylene system according to the equation

$$|\Delta S_{or}| = \frac{\Delta S_m}{1 + T_m/\Delta T}.$$

The values of ΔS_{or} obtained are of the same order of magnitude as those reported for the polycaproatamide–caprolactam system.¹²⁴ The dependence of S_{or} on the concentration has a maximum, which indicates that the dependence of the coefficient of molecular extension on the concentration, which depends on S_{or} according to the equation⁸⁴

$$\alpha = 1 + A|\Delta S_{or}|,$$

where A is a constant for a particular system, also has an extremum. In fact, polymeric chains in dilute solutions are isolated and can change their conformations in the flow almost without interacting with each other, hence one should not expect a considerable effect of mechanical field on the phase behaviour of the system. As the polymer concentration increases, a fluctuation entanglement network, which does not yet hinder the orientation processes, is formed in solution. In this case, the interaction between the macromolecules is strong, which results in an increase in viscosity, and hydrodynamic field affects considerably the phase transition temperature. As the concentration is increased further, the network density increases, thus hindering the orientation processes. This diminishes the effect of mechanical field on phase transitions. The decrease in the molecular orientation due to the formation of a spatial network has been reported⁹⁶ for a polyethylene melt. The higher the shear rate, the lower concentration is required for the formation of a fluctuation entanglement network. Therefore, the maximum ΔS_{or} is reached at lower polymer concentrations.

V. Conclusion

Mechanical deformations (shearing, stretching) of polymer solutions lead to changes of the macromolecule conformations, their aggregation, and eventually to the phase separation of the systems. In some cases, on the contrary, the hydrodynamic field enhances the mutual solubility of the components. This is observed as a shift of boundary curves and depends largely on the difference in the surface energies of the components, σ_{12} . At $\sigma_{12} > 10^{-2} \text{ J m}^{-2}$, the miscibility of the components decreased in the flow and increased at $\sigma_{12} < 10^{-4} \text{ J m}^{-2}$ (Table 3), because the energy of the mechanical field is sufficient for the destruction of the new phase nuclei at low σ_{12} .

For systems with crystalline phase separation, no enhancement of the solubility of the components under flowing conditions was observed. Mechanical stress leads only to an increase in the polymer melting point in melts and solutions. The increase in the melting point is caused by a decrease in the entropy of the system due to the uncoiling and orientation of the macromolecules. Systems with crystalline phase separation are more sensitive to mechanical stress than systems with liquid phase separation. Mechanical field even affects the crystallisation of low-molecular-weight compounds with molecular weights of *ca.* 10^2 , and this effect becomes stronger as the molecular weight of the solute

Table 3. Values of σ_{12} and effect of shearing deformation on the mutual solubility of components.

System	$10^3 \sigma_{12} / \text{J m}^{-2}$ (293 K)	Solubility in mechanical field
PS–dioctyl phthalate	12.6	decreases
PS–decalin	15.3	"
PS–cyclohexane	20.2	"
PMMA–butanol	30.5	"
PEO–water	32.0 (363 K)	"
DAC ^a –acetone–water	0.3	increases
PS–ethylcellulose– benzene	10^{-2}	"
PDMS ^b –ethyl methyl ketone	0.2	"

^a DAC is cellulose diacetate; ^b PDMS is polydimethylsiloxane.

increases. In systems with liquid phase separation, the shearing field manifests itself as a change in the T_{ph} of solutions of polymers with molecular weights above 10^5 .

The dependences of ΔT on shear rate (stress) contain maxima. This does not depend on the type of phase separation and is caused by the existence of two oppositely directed processes in the system: uncoiling of macromolecules and their orientation in the flow (which favours phase separation) and destruction of new phase nuclei by the mechanical field at high shear rates (which hinders phase separation). Fig. 6 gives examples of dependences of ΔT on γ for different systems.

**Figure 6.** Dependence of ΔT on γ for various systems.

(a) PEG ($\bar{M}_\eta = 800$)–PPG ($\bar{M}_\eta = 3100$): $c_{PEG}/\text{mass \%}$: 1.1 (1), 3.51 (2), 5.42 (3); (b) PE ($\bar{M}_\eta = 2.3 \times 10^5$)–xylene: $c_{PE}/\text{mass \%}$: 10.0 (1), 30.0 (2), 40.0 (3); (c) PS ($\bar{M}_\eta = 3.3 \times 10^6$)–di(2-ethylhexyl) phthalate: $c_{PS}/\text{g dl}^{-1}$: 7.01 (1), 4.60 (2), 2.83 (3), 1.00 (4).

The concentration dependence of the effect of hydrodynamic field on ΔT has an extremum (Fig. 7). The maximum effect is observed in moderately concentrated solutions. This is valid for liquid and crystalline phase separation as well as for gel formation and is a result of the extremal concentration dependence of normal stresses that appear in the flow.

An inversion of the effect of the mechanical field on the mutual solubility of the components as a function of the polymer concentration and molecular weight and the shearing rate has

**Figure 7.** Concentration dependences of ΔT for different systems.

(a) PE ($\bar{M}_\eta = 2.3 \times 10^5$)–xylene, $\gamma = 47$ (1) and 246 s^{-1} (2); (b) (1) PEO ($\bar{M}_\eta = 4.0 \times 10^4$)–water, $\gamma = 9.5 \times 10^3 \text{ s}^{-1}$; (2) PS ($\bar{M}_\eta = 3.3 \times 10^6$)–di(2-ethylhexyl) phthalate, $\gamma = 246 \text{ s}^{-1}$; (3) PMMA ($\bar{M}_\eta = 9.9 \times 10^4$)–butanol, $\gamma = 3 \times 10^4 \text{ s}^{-1}$; (4) PS ($\bar{M}_\eta = 3.3 \times 10^6$)–cyclohexane, $\gamma = 2.1 \times 10^4 \text{ s}^{-1}$; (5) cellulose acetate ($\bar{M}_\eta = 6.9 \times 10^4$)–acetone/water (1.6/1.0), $\gamma = 170 \text{ s}^{-1}$; (c) PEG ($\bar{M}_\eta = 800$)–PPG ($\bar{M}_\eta = 3100$), $\gamma = 248$ (1) and 47 s^{-1} (2); PEG ($\bar{M}_\eta = 3.3 \times 10^4$)–glycerol/water (80/20), $\gamma = 248 \text{ s}^{-1}$ (3); PEG ($\bar{M}_\eta = 1.8 \times 10^3$)–glycerol/water (90/10), $\gamma = 248 \text{ s}^{-1}$ (4).

been observed for a number of systems with liquid phase separation.

These data make it possible to suggest the following mechanism for the effect of shearing field on the phase separation of polymer solutions. In dilute solutions, polymeric chains are isolated and can change their conformations in the flow almost without interactions. When the thermodynamic quality of the solvent gets worse (due to temperature changes), macromolecules can form associates. However, these structures are unstable and are easily destroyed by a mechanical field, which leads to enhancement of the mutual solubility of the components in the flow, *i.e.* to the displacement of the binodal ($\Delta T < 0$ for systems with upper critical solution temperatures). As the polymer concentration is increased, a fluctuation entanglement network, which does not yet hinder orientation processes, is formed in solution. In this case, the interaction between the macromolecules is strong, the hydrodynamic field affects the temperature of phase separation, and $\Delta T > 0$. As the concentration is increased further, the network density increases, thus hindering the orientation processes. This diminishes the effect of mechanical field on phase transitions, hence ΔT decreases. An increase in the polymer molecular weight favours the formation of a fluctuation network, therefore the concentration at the inversion point c_i and the concentration at the maximum ΔT decrease as these parameters increase.

This review does not deal with the destruction of macromolecules that occurs in polymer solutions at very high deformation rate and stress, as this phenomenon has been analysed in sufficient detail elsewhere.^{182–186}

Abstract. Data on the methods employed for cross-linking of DNA strands and for the synthesis of oligonucleotide duplexes with cross-links between strands are summarised. Existing methods are systematised; their advantages and drawbacks are discussed. The examples of applications of DNA duplexes with covalently cross-linked chains for the study of protein–nucleic acid recognition and mechanisms of action of nucleic acid-binding proteins for gaining information about the spatial structure of nucleic acids, and for the solution of other problems of molecular biology are given. The bibliography includes 131 references.

I. Introduction

Studies of fine details of cellular processes related to the expression and processing of genetic information require that a new generation of modified oligonucleotide derivatives be created that can be used as tools in these studies.

Therefore, in recent years the chemical approach employing modified oligonucleotides for the study of mechanisms of interaction of proteins with nucleic acids has been widely used in combination with physicochemical methods, such as X-ray structural analysis and NMR spectroscopy. The direct modifications of the nucleic acid chemical structure in protein–nucleic acid complexes and the analysis of properties of such synthetic systems has made it possible to gain information about the spatial structure of these complexes and the nature of protein–nucleic acid contacts. Directed modification allows useful properties to be conferred on oligonucleotides, such as resistance against nuclease degradation, enhanced thermodynamic stability of the duplexes formed by them, low toxicity, and the ability to penetrate cellular membranes. It also favours selective recognition and site-specific (including covalent) binding of DNA with proteins.^{1–9}

Oligonucleotides and their reactive derivatives are important tools for the study of protein–nucleic acid interactions in transcription, translation, replication, repair, recombination, and modification of nucleic acids. Until fairly recently, it was mainly derivatives of single-stranded oligonucleotides that were used to this end. Meanwhile, a great variety of processes, such as repair, recombination, initiation of transcription by the corresponding factors, *etc.*, occur with the involvement of double-stranded nucleic acids. Consequently, it is the double-stranded structures that should be used as models and affinity reagents in studies of these processes.

Modified nucleic acid duplexes have found use in elucidating the mechanisms of action of enzymes that interact with nucleic acids and in establishing the features of protein–nucleic acid recognition. The method based on the use of cross-linked nucleic acid duplexes is one of the most promising and popular procedures for investigation of protein–nucleic acid interactions. DNA duplexes with covalently cross-linked strands can be used as models for the study of the majority of the aforementioned cell-mediated processes and for the construction of affinity reagents and ‘decoys’ for proteins binding double-stranded DNA.^{10–16}

For example, if the mechanism of action of an enzyme includes the unwinding of the double helix of DNA, covalent cross-links between the strands will prevent this process and thus strongly suppress the action of the enzyme. Duplexes stabilised by cross-linking can be potential inhibitors of nucleic acid-binding proteins.^{10, 13} Duplexes with covalently cross-linked chains are promising for the isolation of proteins by affinity chromatography. Covalent cross-links formed in specific positions can stabilise thermodynamically unstable DNA structures.^{15, 17}

Two main methods exist for the synthesis of this type of compound. Historically, the first of them consists in non-specific treatment of sufficiently long DNA molecules with bifunctional alkylating agents, such as derivatives of psoralen, pyrroles, and some other compounds.^{1–5, 18} The second method, which leads to the formation of DNA duplexes with covalently cross-linked chains, is based on the use of derivatives of modified oligonucleotides containing chemically reactive groups.

One of the first to begin the study of reactions between the strands of DNA duplexes more than 30 years ago was a group of Russian investigators from the Siberian Branch of the Russian Academy of Sciences directed by Academician D G Knorre.^{1–3, 19–23} These studies have ushered in the method

of 'targeted chemical modification' which has been used in the structural analysis of nucleic acids. Conceptually, this method is related to the construction of synthetic analogues of nucleases specific for a definite type of DNA base. Later, this method gave way to the method of 'complementarily targeted modification'.^{1–3, 24–31} The latter consists in the introduction of a reactive alkylating group into an oligonucleotide. After hybridisation, this group interacts site-specifically with the target DNA, *i.e.*, it alkylates the target at a predetermined position.

Thus, the majority of studies connected with the use of alkylating reagents aimed at the modification of nucleic acids dealt with the synthesis of highly reactive derivatives, which reacted with the target nucleic acid resulting in labilisation of the glycosidic bond in one of the nucleosides and, as a consequence, in the cleavage of the phosphodiester bonds of the oligonucleotide.^{1–3} Irrespective of the nature of the alkylating reagent, double-stranded complexes with covalently cross-linked chains formed were unstable and underwent spontaneous hydrolysis in aqueous solutions. These investigations gave information about the reactions between the chains of double-stranded nucleic acids; however, the synthesis of DNA duplexes with covalently cross-linked chains was not the aim of these studies, and for this reason they are not considered in detail in the present review.

This review encompasses studies devoted predominantly to the preparation of synthetic oligonucleotide duplexes with covalently cross-linked chains and to the methods of nonspecific cross-linking of DNA chains. It does not consider covalently closed structures of nucleic acids, such as cyclic oligonucleotides and dumbbell-like structures, since this is an independent trend of research, which is also being developed in recent years.

II. The main methods for the synthesis of cross-linked DNA duplexes

It is known that bifunctional alkylating reagents that can form cross-links between the chains (such as 2-chloroethylnitrosourea, *etc.*) can also inhibit nucleic acid biosynthesis. In many cases, such reagents are efficient antitumour drugs.^{5, 6, 32–34} This is due to the fact that nonspecific cross-linking of DNA chains is highly toxic for the cell,^{5, 34} since it prevents expression of the genetic material. The ability to form cross-links in double-stranded DNA is the reason for the cytotoxicity of many compounds employed in clinical practice.

A great number of compounds that can cross-link nucleic acid chains have been described. Psoralen^{7, 11, 12, 18, 35–64} and pyrrole^{34, 65–71} derivatives are the most popular to this end. Other compounds used for the formation of interchain cross-links in double-stranded nucleic acids include aziridinolbenzoquinones (2,5-bisaziridino-1,4-benzoquinone^{72, 73} or alkylaziridino-1,4-benzoquinones),⁷⁴ aziridinonitrobenzamides (5-aziridino-2-nitro-4-nitrosobenzamide and 5-aziridino-4-hydroxylamino-2-nitrobenzamide⁷⁵), anthracyclines (daunomycin,⁷⁶ adriamycin,⁷⁷ anthramycin,^{78, 79} mitomycin C^{80–83} and its analogues⁸⁴), melamine derivatives, *e.g.*, trishydroxymethyl(trimethyl)melamine,⁸⁵ acridine derivatives, *e.g.*, 1-nitro-9-(3-*N,N*-dimethylaminopropyl)aminoacridine,⁸⁶ chloroambucyl,^{87, 88} 4-hydroperoxycyclophosphamide,⁸⁹ tris(2-chloroethyl)amine,^{90, 91} 1,3-bis(2-chloro-ethyl)-1-nitrosourea,⁹² 2-aminomethylpyrrolidine(cyclo-butane-1,1-dicarboxy)platinum(II),⁹³ cisplatin,^{34, 80, 92, 94} and *cis*-diamminedichloroplatinum(II).⁹⁵

Synthetic cross-linked oligonucleotide duplexes are the most convenient tools for the study of gene structure and functions. Their application has a number of salient advantages over non-specific alkylation of nucleic acids. The presently known bifunctional electrophilic reagents usually recognise those sequences in nucleic acids the length of which does not exceed two nucleotide residues. As a rule, the reactions with the participation of these reagents yield mixtures of monoadducts and products of intra-strand cross-links. Heterogeneity of the reaction mixture resulting from the alkylation of DNA with non-specific bifunctional

reagents¹⁸ is often an obstacle in the studies of effects of individual interstrand cross-links on DNA processing.

At present, the synthesis of oligonucleotide duplexes cross-linked at the predetermined positions of the double helix is complicated because the cross-links between the chains are either unstable⁹⁶ or endow significant disturbances in the secondary structure of DNA.^{35, 36} New approaches to the synthesis of DNA duplexes with interstrand cross-links have recently appeared, which permit cross-links to be created at any predetermined site of the DNA duplex and to introduce several cross-links into the same duplex.

The main requirements for the methods of synthesis of modified oligonucleotides that are used in the preparation of duplexes with covalently cross-linked chains can be formulated as follows: (1) the possibility of targeted incorporation of modified units into any predetermined position of the oligonucleotide chain; (2) the applicability of standard procedures of oligonucleotide synthesis, and (3) the possibility of incorporation of several modified units into the same oligonucleotide for subsequent synthesis of an oligonucleotide duplex with several cross-links between the chains.

III. Methods for the synthesis of modified oligonucleotides

Generally, an oligonucleotide can be modified at heterocyclic bases, phosphate groups (internucleotide or terminal), or carbohydrate residues. The potentialities of modern chemical synthesis of nucleic acid fragments allow targeted incorporation of one or several modified units (identical or different) into the oligonucleotide.

Compounds carrying primary aliphatic amino groups as well as aldehyde, carboxy, sulfhydryl, and phosphate groups are used for the cross-linking of the duplex chains. The general requirement for the formation of a cross-link is the localisation of the reactive group at the end of a spacer (a cross-linking arm). The length of the spacer can vary widely depending on the mutual arrangement of the reactive groups within the duplex. Thus in the case of psoralens, a relatively short, two-carbon-atoms-long spacer is sufficient for the interaction with the opposite chain.^{37, 38}

A functional group can be incorporated into the oligonucleotide by the following methods:⁸

(a) using a modified nucleotide component carrying the corresponding functional group in the chemical oligonucleotide synthesis;

(b) incorporating a precursor compound into the oligomeric chain followed by treatment with the corresponding reagents that give the target-modified unit either in the course of the oligonucleotide synthesis or after its completion;

(c) post-synthetic modification of an oligonucleotide.

The potentialities of the latter approach are limited. It can be used only for preparing oligonucleotide analogues carrying numerous statistically modified units (*e.g.*, units with identical heterocyclic bases undergoing modification). In the former two methods, modification is envisaged in the very pattern of the chemical synthesis of oligonucleotides.

The first method is the most versatile. It consists in preliminary formation of modified units and their subsequent incorporation into the oligonucleotide in the process of synthesis. This method does not constrain either the number or the chemical nature of the units to be introduced into the oligonucleotide chain. Moreover, it significantly simplifies isolation of the target product. Side reactions in the process of oligonucleotide synthesis are minimised because all chemically reactive functional groups of the oligonucleotide have been preliminarily protected. The initial modification of the nucleoside to be inserted is usually carried out in non-aqueous media, which permits the use of a broad spectrum of modifying reagents, whereas post-synthetic modifications are usually performed in aqueous solutions.

IV. The use of psoralens for the synthesis of covalently linked DNA duplexes

Psoralens {7*H*-furo[3,2-*g*][1]benzopyran-7-ones}[†] are polycyclic aromatic compounds of the general formula **1**; they have a planar structure and are capable of intercalating between the base pairs of the double helix.^{36, 39–41}

$R^1, R^2, R^3 = \text{H, Alk.}$

These compounds are specific to the thymidine and uridine residues. On UV irradiation of DNA duplexes at λ 320–360 nm, psoralen incorporates into the double helix and binds covalently with the pyrimidine bases of DNA, preferentially with thymine, at positions 5 and 6 to form four-membered rings (Scheme 1).^{37, 42, 43}

$R^1 - R^4$ are fragments of oligonucleotide chains.

Psoralens can enter into photoaddition reactions with cytidine. However, this reaction occurs 15 times more slowly than with thymidine.⁴⁴ In DNA, psoralens predominantly bind with the 5'-d(TpA) sequence.^{40, 43, 45, 46} The efficiency of psoralen photoaddition to this sequence is at least one order of magnitude higher than that to thymidine in any another environment. The same regularities hold for the synthesis of cross-linked RNA duplexes.^{11, 12, 47, 48}

Since psoralen is a bifunctional reagent, the photo-induced reaction can lead either to the monoadduct of the type **2**, when the psoralen molecule is added to only one chain of nucleic acid, or to the bisadduct of the general formula **3**. In the latter case, a duplex with covalently cross-linked chains is formed. The formation of the bisadduct **3** requires the absorption of two photons⁴⁹ and

occurs in two steps (Scheme 1).^{7, 11, 45} If the pyrone ring of psoralen enters into the reaction at the first stage, the bisadduct is not formed, since the furan ring of the monoadduct becomes incapable of absorbing UV light.¹¹

Intercalation of psoralen into the double helix, which usually increases the thermodynamic stability of the duplex, is a prerequisite for the reaction between the chains. The formation of adducts can be accompanied by photoinactivation of psoralen, which consists in photochemical degradation of the pyrone ring.³⁸ The adducts of nucleic acids with psoralen are decomposed into the original components on irradiation with UV light with a wavelength that depends on the structure of the psoralen derivative,^{39, 40, 42, 45} as a rule, it is equal to 254 nm. Thus, the cross-linking of DNA chains with psoralen is reversible.

In the absence of UV irradiation, psoralens are non-toxic. The ability of these compounds to form cross-links between DNA chains makes possible their application in *in vitro* and *in vivo* studies of the DNA structure. Psoralens are used both in medicine for photochemotherapy of some diseases^{39, 40, 50, 51} and in investigations of some molecular-biological processes. Psoralen has been used for the analysis of the secondary structure of RNA^{35, 47, 48, 50–52} and the structure of the DNA–RNA-polymerase transcription complex.^{12, 53–55} Currently, psoralen derivatives are used for the study of the secondary and tertiary structure of nucleic acids as well as for the analysis of mechanisms of DNA repair.^{56–58}

Methods of targeted incorporation of psoralen into oligonucleotides (directly in oligonucleotide synthesis or after its completion and removal of protective groups) are of prime interest. The monoadduct of psoralen with the oligonucleotide can be produced post-synthetically using an activating reagent.^{12, 59, 60} Such a monoadduct was obtained in the reaction of a 5'-phosphorylated self-complementary oligonucleotide with 4'-aminoalkyl-4,5',8-trimethylpsoralen in the presence of 1-ethyl-3-(3-dimethylamino)propylcarbodiimide hydrochloride, EtN=C=N(CH₂)₃-NMe₂·HCl (water-soluble carbodiimide, CDI). Hybridisation and irradiation yield a DNA duplex, which is cross-linked at the both ends.

The second method consists normally in the addition of psoralen to the 5'-end of the oligonucleotide in the oligonucleotide synthesis. Phosphoramidite derivatives of psoralen are used at the last stage of the synthesis.^{37, 38} A typical synthetic scheme for the incorporation of psoralen into oligonucleotides is described in Ref. 38: 4,5',8-trimethylpsoralen (**4**) was converted into the phosphoramidite **6** (Scheme 2) and the latter was used for the oligonucleotide synthesis.

4,5',8-Trimethylpsoralen **4** was added to the 5'-end of an 18-membered oligonucleotide; the resulting oligonucleotide **7** was introduced into the cross-linking reaction of DNA duplex chains (Scheme 3). 4,5',8-Trimethylpsoralen **4** was shown³⁸ to be stable both under conditions of synthesis and post-synthetic treatments of the oligonucleotide. It is noteworthy that psoralen-containing oligonucleotides of the type **7** are characterised by higher hydrophobicity, which is manifested in the increased retention time (in comparison with non-modified analogues) on HPLC.³⁸

In this case, the nucleotide sequence of the oligonucleotides constituting the duplex was selected so that psoralen **4** intercalated into a double helix and reacted with thymidine in the 5'-d(TpA)/3'-d(ApT) sequence.⁶¹ It was found that the maximum yield of the DNA duplex **8** could be obtained when the CH₂-O-CH₂CH₂ group was used as the spacer for the addition of psoralen to the oligonucleotide (Scheme 3).

As a rule, the yield of the product **8** increases within the first 10–30 min after the beginning of irradiation (360 nm, 20 °C) and reaches 70%–80% after 60 min. A quantitative yield could not be attained even with a 100-fold excess of the modified oligonucleotide **7** with respect to the DNA matrix³⁸ due to partial inactivation of psoralen in the irradiation.

The 5'-d(TpA)/3'-d(ApT) motif is present in signal sequences of many genes. They represent potential targets for psoralen-

[†] Henceforth, the nomenclature accepted in the original publication is used.

Scheme 2

modified oligonucleotides of the type 7. Thus oligonucleotides of this type can serve as convenient probes for the study of gene expression.

A method for the synthesis of psoralen-containing oligonucleotides using a modified deoxyadenosine[‡] phosphoramidite **9** has been proposed.³⁷

DMTr = (4-MeOC₆H₄)₂PhC.

[‡] Hereinafter, the term 'deoxynucleosides' will refer to 2'-deoxyribonucleosides.

Scheme 3

4,5',8-Trimethylpsoralen **4** was attached to the C(8) atom of deoxyadenosine through the sulfur atom and the pentamethylene spacer. Subsequent phosphitylation afforded compound **9**. To achieve the maximum yield (90%) in the coupling of the phosphoramidite **9** with an oligonucleotide, 5-(4-nitrophenyl)-1*H*-tetrazole was used instead of tetrazide; the duration of condensation was 8 min.

The optimum length of the spacer was established by molecular modelling. In this particular case, the optimum length of the spacer needed for the psoralen intercalation into the 5'-d(TA)/3'-d(AT) site is five carbon atoms. An analogous derivative of deoxyadenosine of the type **9** but with a two-carbon-atoms-long spacer manifested a very weak cross-linking capacity. The efficiency of photoaddition to the complementary matrix chain exceeded 90% after 1-hr UV irradiation at λ 345 nm. This resulted in the formation of several products, which correspond to different possibilities of psoralen incorporation into the double helix. It was noted that psoralen was effectively incorporated both into the 5'-d(TA)/3'-d(AT) and the 5'-d(AT)/3'-d(TA) sequences, where it reacted both with the thymidine unit in the opposite chain and the adjacent one.

Owing to the fact that the ends of DNA duplexes of the type **8** with covalently cross-linked chains remain free, various labels (radioactive, fluorescent, or any other) can be easily attached to these ends. In addition, such duplexes can be incorporated into more extended DNA structures.³⁷

The reaction of oligonucleotide methylphosphonates (OMP) bearing the psoralen derivative, 4'-[*N*-(2-aminoethyl)amino-methyl]-4,5',8-trimethylpsoralen **10** (PS-OMP) attached to their 5'-ends with single- and double-stranded DNA, has been studied.

Compound **10** was coupled with the 5'-end of OMP carrying a phosphate group to give compound **11** (Scheme 4). Water-soluble CDI was used for the activation of the phosphate group. It was shown that the P–N bond is resistant to nucleases; however, it is cleaved in an acidic medium to give the original 5'-phosphorylated OMP.

On irradiation, PS-OMP specifically reacted with the template. The presence in the duplex of less stable nucleotide pairs (e.g., G·T or G·A) reduced the yields of the duplex with covalently cross-linked chains.¹² This is due to the decrease in thermal stability of the original duplex. The formation of by-products that result from the interaction between the chains in

Scheme 4

N denotes deoxynucleoside residues, $m \geq 6$, $k \geq 0$.

non-canonical duplexes depends on temperature: by-products are formed at 20 °C and are absent at 40 °C. This can be explained by dissociation of less stable non-canonical duplexes with an increase in temperature. In the case of a canonical duplex, the temperature dependence of the yield of the covalently cross-linked duplex is not observed below its melting point. At higher temperatures, the yield of the target product drops drastically. The efficiency of the reaction between the chains of a DNA duplex is also influenced by the ratio of the rate of this reaction to the rate of psoralen photoinactivation. The yield of the cross-linked DNA duplex increases with increasing PS-OMP concentration. However, if the PS-OMP concentration is twice as high as that of the matrix, the latter becomes saturated and the yield of the target product does not further increase.¹²

The efficiency of the interaction of various oligonucleotides with the target under identical conditions differs markedly,¹² although the differences in the nucleotide sequences should not be manifested at 4 °C. Molecular simulation has shown¹² that psoralen can be inserted between the nucleotides of the target in two modes: either between the terminal nucleosides $N_{(n+1)}$ and $N_{(n)}$ or between the nucleosides $N_{(n)}$ and $N_{(n-1)}$, where $N_{(n+1)}$ is the 3'-terminal nucleoside of the target and $N_{(n)}$ is the nucleoside that is complementary to the 5'-terminal nucleoside of PS-OMP (Scheme 4). In the former case, the spatial structure of the reaction centre is the most favourable for the photoaddition of psoralen. The reaction between the chains is the most effective, when thymidine occupies position $(n+1)$ of the template and position $(n-1)$ in OMP, which precedes the psoralen-modified unit, and adenosine is in the positions n . In this case, the reaction occurs with two possible sites and the yield of the duplex with covalently cross-linked chains reaches 95%.

Oligonucleotides of the type **11** were used for the analysis of the secondary structure of nucleic acids.¹² It was shown, in particular, that the cross-linking with the single-stranded region of DNA occurs 10–30 times more efficiently than with the double-stranded one. Since OMP are characterised by enhanced resistance in the cell, these oligonucleotide derivatives can be used in *in vivo* studies.¹²

A series of PS-OMP that are complementary to the template and non-template strands of a 57-membered DNA duplex containing a 17-membered T7 promotor of RNA-polymerase were synthesised.¹² The effects of PS-OMP on *in vitro* transcription were investigated. It was shown that PS-OMP, which is covalently cross-linked with the encoding region of DNA, effectively suppressed transcription, whereas the oligonucleotide cross-linked with the non-coding region had little inhibitory effect. Thus, the oligonucleotide that is covalently cross-linked to the template in the promotor region prevents binding of polymerase with the double helix of DNA either directly or by changing its conformation in the promotor region.

Being an agent that can directly react with DNA, psoralen can induce various mutations.¹¹ Study of mutagenesis is necessary for the understanding of regularities of the origin of cancer, hereditary diseases, and evolutionary processes.^{11, 56, 57} It remained

unclear which of the psoralen-induced mutations were generated by the monoadduct and which resulted from the presence of cross-links between the chains.

The use of a plasmid containing a single, definite damaged site has made it possible to relate the initial damage of DNA induced by psoralen to the origin of subsequent mutations.¹¹ The use of statistically modified DNA did not allow a correlation between the nature of mutations and the type of the adduct. The cyclic closed double-stranded plasmid containing the site-specifically incorporated psoralen as a mono- or bis-adduct (in the latter case, the cross-link is formed between the strands of the plasmid), has been synthesised *in vitro* and incorporated into the cells of *E. coli*. The recombinant DNA contained only one site with thymine in the form of a monoadduct with psoralen. Synthesis of the psoralen-containing plasmid was carried out using T4-DNA-polymerase and an oligonucleotide with psoralen at the 3'-end as the primer. In this case psoralen did not influence either the elongation of the chain or its subsequent ligation. The monoadduct was converted into the bisadduct by UV irradiation; the plasmid with covalently cross-linked chains was isolated taking advantage of its acquired ability to undergo reversible thermal denaturing. In contrast to the plasmid with cross-linked chains, denaturing of an ordinary plasmid is irreversible. The type and frequency of mutations was followed using two different DNA molecules. It was found that both types of psoralen-induced damages (the formation of the both monoadduct and the cross-links between the chains) can lead to severe genotoxic effects.¹¹ This finding is consistent with the results obtained by other authors.^{58, 62, 63}

The mutation induced by the formation of the monoadduct was eliminated by the repair mechanism of the cell. In the case of the bisadduct, a great number of secondary mutations (deletions, substitutions, inversions) evolved. The activity of DNA with cross-linked chains was 1.6% of the native one.¹¹

Thus, it was shown that it is by bisadducts that the toxicity of psoralen is determined, and their formation results in severe damage to DNA. Treatment of nucleic acids with psoralen was shown to prevent replication and transcription processes.¹¹

It was proposed⁶⁴ to couple psoralen with distamycin-like imidazole **12** and pyrrole **13** derivatives in order to promote the delivery of psoralen to specific sequences of DNA. Like the oligopeptide distamycin, these compounds bind with DNA in the region of the small groove.

The use of oligonucleotides for the delivery of psoralen to specific sequences of DNA has posed a number of problems. They are connected with the low ability of the oligonucleotides to penetrate through hydrophobic cellular membranes and their susceptibility to nuclease hydrolysis. This circumstance restricts the application of such compounds.

The derivatives **12** and **13** are devoid of these drawbacks and can deliver psoralen to both GC-rich (imidazole analogues of distamycin, **12**) and AT-rich (pyrrole analogues, **13**) regions of DNA. It was found that the derivatives **12** and **13** modify DNA 10 and 1000 times more efficiently than psoralen. Compound **13** is 100 times more efficient than compound **12**. Hence, psoralen, being attached to reagents that possess affinity with respect to DNA, manifests enhanced efficiency in the formation of multiple cross-links between the chains of extended DNA.

V. Cross-linked nucleic acid duplexes synthesised using pyrrole derivatives

Bifunctional pyrrole derivatives **14**, together with psoralen derivatives, are widely used for cross-linking of chains of double-stranded nucleic acids.^{34, 65–71} Only bifunctional pyrrole derivatives can cross-link the nucleic acid chains.

Cross-linking with pyrrole derivatives **14** involves exocyclic amino groups of heterocyclic bases of DNA (usually, deoxyguanosine) and those functional groups of pyrrole derivatives that can undergo nucleophilic attack. Hence, pyrrole derivatives are alkylating agents. A hypothetical mechanism of this reaction has been proposed (Scheme 5).⁶⁵

Nu is the exocyclic amino group of guanine.

Pyrrole derivatives as such are not specific reagents and can react with many reaction centres of DNA. Therefore, treatment of DNA with bifunctional pyrrole derivatives of the type **14** cannot be used to introduce cross-links at predetermined positions of DNA. The main drawback of pyrrole derivatives as antitumour agents is their low selectivity (*i.e.*, the affinity for sequences with the length of no more than two nucleotides). Such limited selectivity of pyrrole derivatives is due to the high probability of occurrence of certain short repeated nucleotide sequences in the genome.

Enhancement of selectivity of bifunctional pyrrole derivatives is an important problem, particularly as regards their application as therapeutic agents. This can be achieved through a more targeted delivery of pyrrole derivatives to a definite genome region, *i.e.*, to a more rare nucleotide sequence. However, the solution of this task demands that the affinity of such agents for nucleic acids be increased.^{2, 34, 65–71} As a rule, it is sufficient to achieve selective interaction of the cross-linking reagent with sequences more extended than four nucleotide pairs. The main route for attacking the selectivity problem is the addition of a bifunctional alkylating agent (which has little or no affinity for nucleic acids) to compounds manifesting high affinity for definite sequences of DNA, *e.g.*, to oligopeptides.^{34, 65–70}

Synthesis of a new irreversible reagent **15** has been described.⁶⁶ Compound **15** belongs to the group of pyrrolobenzodiazepine dimers (PBD dimers). It binds with DNA through the small groove and reacts with the amino group of guanine (Scheme 6). The preferential sequence for the binding of this compound is the Pu-G-Pu triplet, where Pu is the purine nucleotide (A or G). The yield of the interstrand reaction product is about 50%.

R^1, R^2 are fragments of oligonucleotide chains.

The synthesis of C(8)-linked PBD dimers of the type **16**, which are homologous to compound **15**, has been described by the same authors,⁶⁷ and their relatively high affinity for DNA has been demonstrated. The highest efficiency of the interchain reaction was achieved with compounds **15** and **16b** (three- and five-carbon-atoms-linking groups, respectively).

$n = 4(\mathbf{a}), 5(\mathbf{b})$.

Treatment of double-stranded DNA with any PBD dimers increases the melting point of the duplexes.⁶⁷ The presence of cross-links in the linear double-stranded DNA prepared from the ring plasmid accounts for its rapid renaturation into a double-stranded form as the temperature decreases following thermal denaturing.⁶⁷ The ability of extended DNA to undergo rapid renaturation is a sign of cross-linking between the chains. Thus, PBD dimers can stabilise double-stranded DNA.

The cytotoxicity data⁶⁷ correlate with the yields of duplexes with covalently cross-linked chains. The PBD dimer ($n = 3$), *i.e.*, compound **15**, possesses the highest toxicity. On the other hand, the monomer of the type **17** hardly exerts any noticeable effect on the stability of DNA duplexes and is non-toxic.

Thus a possibility exists for the application of these compounds for the treatment of tumours. Their main shortcoming is relatively low affinity for DNA.

The mechanism of cross-linking of the DNA chains by bifunctional pyrrole derivatives was investigated.⁶⁵ It was found that all the pyrrole derivatives including natural (*e.g.*, the antitumour antibiotic mitomycin C **18**), and synthetic pyrroles **19** and **20** react with DNA by the same mechanism, they are directed to a common binding site and an alkylation site. Mitomycin C is converted into a bifunctional alkylating agent following reduction with specific enzymes. A binding site in DNA molecules, which is common for all the pyrrole derivatives in question, has been identified.

The exocyclic amino group of deoxyguanosine in the 5'-d(CG)/3'-d(GC) sequence is the common target site in DNA for all the alkylating pyrrole derivatives.⁶⁵ The formation of a cross-linked duplex requires the reaction of exocyclic amino groups of both deoxyguanosines with pyrrole derivatives. The structure of the adduct **21**, the reaction product of two molecules of deoxyguanosine and mitomycin C, is given below.

DNA duplexes containing only adenine and thymidine residues have been studied by Wou *et al.*⁶⁵ These duplexes differed in the nature of nucleosides in several nucleotide pairs. To obtain evidence for the involvement of the exocyclic amino group of guanine in the reaction between the chains, deoxyguanosine was substituted by inosine. This gave the duplexes containing the 5'-d(ACGT)/3'-d(TICA) and 5'-d(ACIT)/3'-d(TICA) fragments. When even one deoxyguanosine was substituted by inosine, the interchain cross-linking product disappeared completely. It was also shown⁶⁵ that the reaction in the 5'-d(CG)/3'-d(GC) sequence occurs at least ten times more efficiently than in any other sequence.

The structure of compounds thus obtained was established by an analysis of the products of total enzymic hydrolysis of the cross-linked duplexes and by mass spectroscopy. It is by this method that the structure of compound **21** has been established.⁶⁵ The same method has been used for structural elucidation of the adducts of the synthetic pyrrole derivatives **19** and **20**. It should be emphasised that computer simulation of a cross-linked DNA duplex revealed a relatively significant distortion of the native B-form of the DNA helix irrespective of the nature of the pyrrole derivatives, which is associated with the torsional rearrangement of the DNA structure.

Unfortunately, the attempts to rationalise the reason for such specificity failed. The reaction between the chains is a multistage process, which includes the formation of a mono- and then of a bis-adduct. Each of these stages can be responsible for the specificity. Since both the synthetic pyrrole derivatives **19** and **20** and natural compounds having a more complicated structure manifest identical specificity, it was concluded⁶⁵ that the specificity of pyrrole derivatives is inherent in the common elements of their structure. On the other hand, the significant differences in the efficiency of pyrrole derivatives as the reagents that cross-link DNA chains point to the important role of individual structural features of pyrrole derivatives.

Recent developments in this area^{68,69} have been mainly focussed on the enhancement of the selectivity of pyrrole derivatives. In order to increase the efficiency of affinity binding of the alkylating reagent with the nucleic acid target, it was proposed^{68,69} to prepare its conjugate with an oligopeptide that can specifically recognise the small groove of the double helix. The affinity reagent **22** containing the oligopeptide distamycin, which recognises the 5'-d(AATT) sequence (through the small groove), and pyrrole derivative, which recognises the 5'-d(CG) sequence, was obtained.^{68,69}

$n = 2(\mathbf{22}), 3(\mathbf{23}), 4(\mathbf{24})$.

Thus, the affinity reagent **22** selectively recognises the nucleotide sequence 5'-d(CGAATT)/3'-d(GCTTAA) and produces a cross-link between the chains. The activity of this reagent was tested both with a synthetic duplex and a linearised plasmid. It was found that the derivative **22** is three orders of magnitude more efficient as a cross-linking reagent than a pyrrole derivative non-bound with the peptide. After thermal denaturation and cooling, the plasmid treated with this reagent underwent rapid renaturation into a double-stranded form, which can be explained by the presence of cross-links between the chains.

R is an oligopeptide.

The effect of compound **22** on DNA samples with different nucleotide sequences was studied. It was found that only the DNA containing the 5'-d(CGAATTCG)/3'-d(GCTTAAGC) sequence efficiently reacted with compound **22** (the yield of the cross-linked product is about 70% with respect to DNA). This sequence contains both 5'-d(AATT), the binding site for distamycin, and 5'-d(CG), the consensus binding site for pyrrole derivative. By-products were formed in all the cases studied as a result of the reaction of compound **22** with two deoxyguanosine residues of the same DNA chain.

The synthesis of a series of bifunctional reagents that are homologous to compound **22** has been described.⁶⁹ In these reagents (**23**, **24**), 2,3-bis(hydroxymethyl)pyrrole is also linked to the oligopeptide distamycin. They differ from compound **22** only in the length of the linker connecting pyrrole derivative with the oligopeptide. Compounds **22–24** are three orders of magnitude more efficient and more selective than ordinary pyrrole derivatives. They can form both intrachain and interchain cross-links in DNA depending on the nucleotide sequence in the cross-linking site of pyrrole derivatives. The interchain cross-link is formed in the duplex containing the 5'-d(CGAATT)/3'-d(GCTTAA) sequence, while the intrachain cross-link is formed in the case of the 5'-d(GGAATT)/3'-d(CCTTAA) sequence.

The structures of nucleosides linked through pyrrole derivatives and isolated following total enzymic hydrolysis of internucleotide bonds are identical for both the interchain and intrachain reaction products. Comparison of binding efficiency of various substrates with each of compounds **22–24** revealed that both binding sites [5'-d(CG)/3'-d(GC) (pyrrole derivative) and 5'-d(AATT)/3'-d(TTAA) (distamycin)] play an important role. Nucleotide substitution in any of these sites (CG for GC or A·T for G·C) sharply decreased the efficiency of the reaction. Thus, the 5'-d(CGAATTCG)/3'-d(GCTTAAGC) sequence was found to be the consensus sequence.⁶⁹

Compounds **22–24** were brought into reaction with a linearised plasmid containing twenty seven 5'-d(AATT)/3'-d(TTAA) sites conjugated with 5'-d(GC)/3'-d(CG).⁶⁹ The efficiency of the interchain reaction was estimated according to Hartley.^{5,70,71} This method is based on the ability of DNA with covalently cross-linked chains to undergo rapid renaturation into a double-stranded form after thermal denaturation. The efficiency of this reaction increased⁶⁹ with an increase in the reagent:DNA ratio up to 5:1 (these conditions favour saturation of the peptide-binding sites). The highest yield (80%) was observed on treatment of the oligonucleotide duplexes containing the 5'-d(CGAATTCG)/3'-d(GCTTAAGC) sequence with the compound **22**. For the 5'-d(CGAAAACG)/3'-d(GCTTTTGC) sequence, the yield of the cross-linked product was about 50%,

whereas that for the 5'-d(GC...)/3'-d(CG...) sequences was no more than 10%. In the case of compound **23**, the yield for the 5'-d(CGAATTCG)/3'-d(GCTTAAGC) sequence was 40%. Sigurdsson and Hopkins⁶⁹ could not rationalise the decreased efficiency of this reaction with an increase in the linker length. Probably, this is due to the geometrical disorientation of pyrrole derivative in the reaction centre.

The structures of compounds thus obtained were analysed by studying the composition of products of total enzymic hydrolysis of duplexes with covalently cross-linked chains. Even prolonged hydrolysis of DNA with covalently cross-linked chains by a mixture of snake venom phosphodiesterase and alkaline phosphatase did not result in its complete disintegration into nucleosides. Increased amounts of snake venom phosphodiesterase in combination with endonucleases (DNAase I and DNAase II) were used for complete hydrolysis of the phosphodiester bonds of the duplex. The cytotoxicity of the compounds in question was relatively low and comparable with that of natural pyrrole derivatives.

The use of compounds of the type **22–24** for cross-linking of DNA chains has a number of advantages over psoralen derivatives. Psoralen recognises the large groove of DNA and binds thymidine residues in 5'-d(TA)/3'-d(AT) sequences through intercalation into the double helix. In contrast, pyrrole derivatives coupled with peptides (compounds **22–24**) recognise the small groove. It is noteworthy that a more extended (six nucleotides) sequence is recognised in this case, and the reagent itself remains outside the double helix of DNA without causing its destabilisation. However, the use of such targeted-action agents is now limited due to the lack of the general concept of the design of oligopeptides that bind to a predetermined nucleic acid sequence.³⁴

Thus, a series of compounds capable of cross-linking nucleic acid chains has been described.^{11, 12, 18, 34–95} Each of them binds with the duplex at a definite site and produces covalent cross-links with two nucleotides from the opposite chains. However, the majority of compounds described in the literature have a number of disadvantages. They are devoid of high binding specificity with a unique site in nucleic acids. This results, as a rule, in the formation of multiple interchain and intrachain cross-links. These reagents are not versatile, because they cannot form cross-links at predetermined positions between nucleic acid chains, but interact only with definite heterocyclic bases. In some cases, they destabilise the double helix at the cross-linking region, which results in disturbances in the geometry of the canonical spatial structure of nucleic acids. Psoralens, pyrrole derivatives, and other compounds mentioned above have found use both in clinical practice (as antitumour agents) and in the study of mechanisms of functioning of some molecular-biological systems. Nevertheless, it is a new generation of chemically designed synthetic systems devoid of the above drawbacks that will be helpful for the study of peculiarities of structural organisation and mechanisms of functioning of intracellular structures at the molecular level.

VI. The main methods for the synthesis of nucleic acid duplexes with cross-links in predetermined positions of the double helix

The use of nucleic acid duplexes with cross-links at predetermined positions of the double helix is the most promising for the study of protein–nucleic acid recognition and mechanisms of action of enzymes. As a rule, synthesis of such duplexes requires the use of reactive oligonucleotide derivatives containing modified nucleosides. The use of these derivatives has a number of advantages over the above-described methods. In particular, they provide a full control over the localisation of cross-links to be incorporated between the chains and the completion of the synthetic process. Various types of reactive derivatives have been proposed.

The synthesis of a series of oligonucleotides **25** containing N^4,N^4 -ethano-5-methyldeoxycytidine dC^e has been described.^{97–99} These oligonucleotides interact with the complementary chain of DNA, and N^4,N^4 -ethano-5-methyldeoxycytidine reacts with the oppositely located nucleotide immediately after hybridisation with the complementary target oligonucleotide under mild conditions and without treatment with activating reagents.⁹⁷ This method was named ‘hybridisation-triggered alkylation’.

$R^1 - R^3$ are fragments of oligonucleotide chains.

A phosphoramidite derivative of 5-methyldeoxycytidine carrying a triazole residue at position 4 was used in the synthesis of oligonucleotides of the type **25**. Oligonucleotides **26** containing this residue are stable under the conditions of the phosphoramidite procedure of oligonucleotide synthesis.

Treatment of the oligonucleotide **26** with ethyleneimine converts it into the oligonucleotide **25** in quantitative yield.⁹⁷ This makes it possible to incorporate a reactive acid-labile group into the oligonucleotide following all acidic treatments needed for the removal of the dimethoxytrityl group in the process of oligonucleotide synthesis.

R^1 and R^2 are fragments of oligonucleotide chains.

N^4,N^4 -Ethano-5-methyldeoxycytidine is unstable under conditions of standard treatment of oligonucleotides with ammonia (5 h, 55 °C, concentrated NH_4OH). Therefore, the 9-fluorenylmethoxycarbonyl group⁹⁷ (Fmoc) was used to protect the exocyclic amino groups of the nucleosides; this protective group is removed faster and under milder conditions of β -elimination than the benzoyl group routinely used for this purpose. Fmoc-protected deoxyadenosine and deoxycytidine phosphoramidites were synthesised. Attempts to obtain a Fmoc-derivative of deoxyguanosine in satisfactory yield failed. Conditions have been selected for removal of the protective groups with retention of the ethyleneimine ring of compound **25**.

The reaction with the oligonucleotide template is carried out for several days (the semi-conversion period is about 30 h at 24 °C).⁹⁸ The efficiency of the reaction between the chains substantially depends on the nature of the nucleotide that reacts with the dC^e unit of compound **25**. The following order of the efficiency of this reaction was established: $A \approx T \gg C \approx G$. The reaction occurs with each of the four bases to a certain degree. In some cases, only one by-product is formed in the interchain reaction. It is assumed⁹⁸ that under these conditions the reaction involves not only the opposite base in the other chain, but also one of the neighbouring bases of the duplex. The melting point of

duplexes with cross-linked chains is increased, on the average, by 15 °C (from 22 °C to 37 °C for a 21-membered AT-enriched duplex consisting of fifteen A·T pairs and six G·C pairs).

The main disadvantage of this method is the necessity of substitution of standard nucleoside phosphoramidites on Fmoc-containing ones. The Fmoc-group is extremely labile, therefore the yields of Fmoc-protected nucleosides are low and deoxyinosine must be used instead of deoxyguanosine. Moreover, the rate of the interchain reaction is too low (semiconversion period is 30 h) and therefore these oligonucleotides cannot be used as inhibitors of mRNA expression *in vitro*. On the other hand, the proposed method of interchain cross-linking⁹⁷ is devoid of such shortcomings as the necessity of activation of the alkylating function and low level of specificity. The latter can be due to the excessive reactivity of the alkylating group.

The majority of the known methods for the preparation of duplexes with covalently cross-linked chains are based on the interaction of a single-stranded DNA with oligodeoxyribonucleotide containing a reactive group. Recent reports suggest an alternative variant, which consists in the cross-linking of an oligonucleotide to double-stranded DNA within a triple helix (triplex).^{7, 88, 100–109} Thus, a method has been proposed for specific cross-linking of dC^e oligonucleotides with units of the type **25** described above to double-stranded DNA within the triplex.¹⁰⁰ In this case, the oligonucleotide is recognised by Hugstee's pairs and intercalates into the large groove of the target DNA duplex. In the $dC^e \cdot G \cdot C$ triplex, the electrophilic methylene group of N^4,N^4 -ethano-5-methyldeoxycytidine comes close to the N(7)- and O(6)-nucleophilic centres of deoxyguanosine.

$R^1 - R^3$ are oligonucleotides.

The ethyleneimine ring interacts with one of the guanine bases of the double helix of the target DNA. The reaction between the chains occurs under physiological conditions in more than 95% yield and is completed within 16 h. This method can be promising for specific *in vivo* inhibition of DNA transcription and replication due to the formation of an untwistable triplex.^{100, 101}

As has been mentioned above, one of the main problems connected with the introduction of new functional groups into the oligonucleotide is that under conditions of automated synthesis the DNA chain that is elongated is exposed to the action of acids, bases, and electrophilic reagents. The functional group to be introduced must withstand these treatments either as such or after protection. Since N^4,N^4 -ethano-5-methyldeoxycytidine is sensitive to nucleophiles,¹⁰¹ it can be incorporated only into oligothymidylates but not into an oligonucleotide containing nucleosides of all the four types, because only the former do not require post-synthesis ammonia treatment to remove protective

groups. This restricts the possible application of such oligonucleotides as substrates that can covalently bind to the DNA target. An attempt to apply this synthetic scheme to deoxyadenosine was even less successful.¹¹⁰ It was found that N^6,N^6 -ethanodeoxyadenosine was a weaker electrophile than N^4,N^4 -ethano-5-methyldeoxycytidine.

In a recent study, devoted to the synthesis of oligonucleotide duplexes with covalently cross-linked chains Shabarova *et al.*¹³ also described modification of the heterocyclic bases of deoxycytidine. Two approaches to the design of DNA duplexes with cross-links between oligonucleotides in the predetermined positions of the double helix were proposed. The first one consisted in the formation of an amide bond between the amino and carboxy groups of modified bases localised in the opposite chains, while the second one entails the formation of a covalent 'bridge' as the Schiff's base between the two amino groups using dialdehydes of the aliphatic series. To this end, deoxycytidine in the self-complementary oligonucleotide 5'-d(TAATGCATTA) was replaced by a 5-methyldeoxycytidine derivative containing an aliphatic amino group (oligonucleotide 10'', **27**) or a carboxy group (oligonucleotide 10', **28**). These functional groups occupied terminal positions at the spacer linked to the exocyclic amino group of 5-methyldeoxycytidine. In the formation of the DNA duplex **29**, the carboxy and amino groups turned to be close to each other, which enabled the reaction resulting in the formation of an amide bond between the chains to occur.

R^1 and R^2 are fragments of oligonucleotide chains.
CDI is $\text{EtN}=\text{C}=\text{N}(\text{CH}_2)_3\text{NMe}_2 \cdot \text{HCl}$.

Synthesis of a self-complementary oligonucleotide precursor, which is common for compounds **27** and **28**, viz., 5'-d(TAATGC*ATTA) **29**, where C* is the cytidine residue containing triazole at position 4, was carried out by the phosphoramidite method, and the triazolyl derivative of thymidine **30** was introduced in the reaction.

30

After completion of the synthesis, the polymer with the immobilised oligonucleotide was divided into two equal parts. One of them was treated with ethylenediamine to give compound **27**, while the other one was treated with β -aminopropionic acid to give compound **28**. The reaction between the chains was carried out with water-soluble CDI as the condensation reagent at 0 °C, which facilitated the formation of a double-stranded complex.

It must be noted that this system favours the formation of three types of oligonucleotide duplexes: $(10''):(10')$, $(10''):(10'')$, and $(10'):(10')$, since the original oligonucleotide is self-complementary. It was found that the $(10''):(10'')$ complex was the most stable, presumably owing to the electrostatic contacts between the amino and phosphate groups of the opposite chains. The predominance of the $(10''):(10'')$ complex in solution is responsible for the low yield of the target product, which can be formed from the $(10''):(10')$ complex. The optimum pH value for this reaction lies in the range of 5.5–6.0. Any deviation from this interval increases the amount of by-products as a result of modification of heterocyclic bases with carbodiimide. In addition, the formation of an adduct of the oligonucleotide $(10')$ with carbodiimide involving the carboxy group took place as a side process.

In the alternative version, the reaction between the chains of the 5'-d(TAATGC*ATTA)/3'-d(ATTAC*GTAAT), $(10''):(10'')$, duplex was carried out with glutaraldehyde. The Schiff's base formed initially was reduced with sodium borohydride to give a stable secondary amine. The yield of the target, cross-coupled duplex was brought to 20%.

R^1 and R^2 are fragments of oligonucleotide chains.

The low yield can be explained by several reasons. First, besides the aliphatic amino groups that have been introduced, oligonucleotides contain other reaction centres capable of reacting with glutaraldehyde (e.g., exocyclic amino groups of heterocyclic bases). Second, it is difficult to select conditions where two aliphatic amino groups of the modified duplex will react with the same molecule of glutaraldehyde, since the reaction is carried out with an excess of the aldehyde. Third, most probably, the optimum mutual arrangement of reactive amino groups was not realised, since they were localised in adjacent base pairs. Preliminary molecular modelling of the optimum mutual arrangement of reactive groups in the reaction centre has now become a standard procedure.

At the same time, it was demonstrated that oligonucleotides containing an aliphatic amino and a carboxy group can be used for the synthesis of DNA duplexes with an amide bond between the chains.¹³ It must be noted that the system was designed in such a way as to enable polymerisation of the duplex with covalently

cross-linked chains under the action of DNA-ligase. This gives a DNA-like polymer containing a repeating consensus Pribnow sequence, which is the main binding site for RNA-polymerase in the initiation of transcription. This requires unwinding of the DNA double helix with the formation of an open complex. As the presence of cross-links between DNA chains prevents unwinding, these compounds can be used for the study of initiation of transcription and, apparently, for influencing this process.

Gottikh *et al.*¹¹¹ have synthesised an unusual oligonucleotide derivative **31** with covalently cross-linked chains. This compound has a 'snail-like' structure and represents a chimeric oligonucleotide comprising an α -nucleotide cluster. Unlike ordinary DNA, the α - and β -oligonucleotides form a parallel duplex, which allows the chimeric oligonucleotide to occur as an intramolecular duplex. The cross-link is formed between the amino group attached through a spacer to a thymidine analogue in a single-stranded region and the 3'-terminal phosphate of the α -fragment. As expected, no reaction occurred directly between these groups because of steric hindrances. Therefore, an amino acid $\text{NH}_2-(\text{CH}_2)_n-\text{COOH}$ ($n = 1, 2, 7$) was coupled with the terminal phosphate of the α -fragment activated in the form of *N*-hydroxybenzotriazole ester. Then the reaction was carried out between the incorporated carboxy and amino groups using water-soluble CDI as the coupling reagent.

Owing to the presence of an interchain cross-link in compound **31**, this is highly resistant to nuclease degradation. It has been shown that RNAase H cleaves an oligoribonucleotide in the chimeric duplex involving compound **31**. The study¹¹¹ illustrates the possibility of conferring useful properties to a compound by cross-linking of oligonucleotide chains. Presumably, the oligonucleotide derivative **31** can be effectively used for the regulation of RNA expression.¹¹¹

A method for the synthesis of DNA duplexes in which the chains are cross-linked through a substituted pyrophosphate group was developed (Scheme 7).⁹⁶ This involves the reaction between the activated terminal phosphate group linked to an oligonucleotide through a spacer and the spatially close internucleotide phosphate group of the complementary oligonucleotide. The activation of the terminal phosphate group was carried out with water-soluble CDI.

The DNA duplexes containing a trisubstituted pyrophosphate internucleotide group in one of the chains are stable in aqueous buffer solutions (pH 6.0–8.75) in the absence of strong nucleophiles. At the same time, they are readily and selectively cleaved at this group with nucleophilic reagents, such as *N*-methylimidazole, amines, and some amino acids. In this case, the nucleophilic substitution reaction involves both phosphate groups of the trisubstituted pyrophosphate group and is accompanied by a cleavage of the interchain bond and transfer of one of the duplex residues to the nucleophile.⁹⁶ In contrast with DNA duplexes containing a disubstituted pyrophosphate internucleotide group in one of the chains, the reaction of nucleophilic substitution at the phosphorus atom in the DNA duplexes containing a trisubstituted pyrophosphate interchain internucleotide group can occur with

R^1-R^3 are fragments of oligonucleotide chains; $n = 3, 4, 7, 12$.

the involvement of both di- and tri-substituted phosphate groups to yield a complex mixture of oligonucleotides. Obviously, such DNA duplexes will be unstable in cell cultures. The method considered allows the synthesis of DNA duplexes with a reactive group between the chains. The interest in the synthesis of such compounds is connected with the possibility of their application for binding with proteins.

A method of preparation of cross-linked duplexes involving deoxyadenosine residues was proposed.¹¹² *N*⁶-(2-Aminoethyl)-deoxyadenosine (**32**) is converted into the phosphoramidite derivative **33**, which can be incorporated at any predetermined position of an oligonucleotide. *N*⁶-(2-Aminoethyl)deoxyadenosine **32** was obtained by treatment of 6-iododeoxyadenosine with ethylenediamine, and the amino group was protected by subsequent treatment of the reaction product with *S*-ethyltrifluoroethioacetate. The trifluoroacetyl protection is ideally suited for the incorporated aliphatic amino group.

A dinucleoside monophosphate containing the *N*⁶-modified deoxyadenosine **32** with an aliphatic amino group was synthesised.¹¹² The synthesis was carried out by the phosphoramidite method in solution; the yield was 95%. Higher oligonucleotides were not synthesised; however, this method is a model study aimed at the incorporation into oligonucleotides of compound **33** as a potential tool for interchain cross-linking.

The oligonucleotide synthesis involving the phosphoramidite derivative **33** was free of side reactions.¹¹² However, the effectiveness of this modification for the synthesis of duplexes with covalently cross-linked chains is unclear. It was proposed¹¹² to perform the reaction between the chains in the following way:¹¹² after hybridisation with the template, the aliphatic amino group has to be localised in the vicinity of the pyrimidine base of the complementary chain. The reaction of this base with the bisulfite ion at positions 5 and 6 facilitates the subsequent nucleophilic attack at position 4. The aliphatic amino group of *N*⁶-(2-aminoethyl)deoxyadenosine **32** will act as the nucleophile. This method of interchain cross-linking must not bring significant disturbance to the structure of the double helix. A disadvantage of this method is its inapplicability to cross-linking of oligonucleotides to extended DNA, since in the presence of the bisulfite anion

deoxycytidine in single-stranded regions can undergo side conversions into 2'-deoxyuridine, which is undesirable.

VII. The use of sulphhydryl derivatives for the synthesis of cross-linked nucleic acid duplexes

Oligonucleotides containing SH-groups have received wide acceptance in recent years. They not only allow the synthesis of various types of oligonucleotide derivatives, but also of cross-linked DNA duplexes in the predetermined positions of the double helix. The so-called 'convertible nucleoside approach' of oligonucleotide synthesis has become widespread.¹¹³ It consists in the incorporation of a precursor of the modified nucleoside carrying an SH group into the oligonucleotide that is synthesised. This precursor carries a different group, which is usually more resistant to synthetic and post-synthetic treatments. Later (sometimes even after hybridisation with the template), the precursor is converted into the target nucleoside with a thio group, which becomes involved in the reaction between the chains.

This strategy has considerable promise for it permits an access to various types of modified oligonucleotides from the same precursor because the incorporation of a functionalised linker is performed after completion of the oligonucleotide synthesis. This approach does not envisage the synthesis of a new starting monomer or a new modified oligonucleotide in order to change the length of the linker or the nature of the functional group. Another advantage of this method is that it allows a post-synthetic addition to oligonucleotide derivatives of ligands (oligopeptides, *etc.*) unable to withstand the treatments used in the oligonucleotide synthesis.

A characteristic feature of this method is that the monomer used in the synthesis contains a leaving group, which undergoes nucleophilic substitution. When a bifunctional nucleophile is used, reactive oligonucleotide derivatives are formed. At the same time, the bifunctional nucleophile fulfils the function of a linker.

In order to attain the maximum efficiency, a number of conditions must be observed.¹¹³ The nucleoside in question must be stable under conditions of automated synthesis of DNA and be rapidly and completely converted into a reactive derivative by a nucleophile. Incorporation of a linker must cause minimum disturbance to the structure of the DNA double helix. As a rule, this process should not involve the terminal oligonucleotide units so as to retain the possibility of further enzymic reactions, such as radioactive labelling, elongation of the oligonucleotide, or its incorporation into a plasmid.

Ferentz and Verdine¹¹³ have 'converted' deoxyinosine into modified deoxyadenosine. Earlier, these authors had shown¹¹⁴ that *O*⁶-phenyldeoxyinosine **34** was quantitatively converted into *N*⁶-alkyldeoxyadenosine **35** on aminolysis with alkylamines.

dR is the 2'-deoxyribose residue.

*O*⁶-Phenyldeoxyinosine 3'-phosphoramidite was synthesised and introduced into automated synthesis to give the oligonucleotide 5'-d(GCGAI*TTTCGC) **36**, where I* is the residue of the nucleoside **34**. After completion of the synthesis, the oligonucleotide **36** was treated with bis(2-aminoethyl) disulfide or bis(3-aminopropyl) disulfide, resulting in compound **37**.

R¹ and R² are fragments of the oligonucleotide chain; *n* = 2, 3.

The oligonucleotide **37** obtained was self-complementary and formed a duplex in which the modified bases are localised in neighbouring units. Treatment of the duplex with dithiothreitol led to the conversion of the disulfide into thiol and then the disulfide bond between the chains was closed by oxidation with the atmospheric oxygen. This binding is reversible. Repeated treatment of the duplex with dithiothreitol results in the cleavage of the interchain cross-link. It was shown¹¹³ that the products of enzymic hydrolysis of the DNA duplex with covalently cross-linked chains contain the dinucleoside **38**; the shape of the helix of the DNA duplex corresponds to the B-form of DNA, while the modified bases form ordinary Watson-Crick pairs.

n = 2, 3.

Computer simulation has revealed that the linker is localised in the large groove of DNA and does not cause any significant distortions in the spatial structure of the duplex. The original duplex and the duplex with covalently cross-linked chains have similar melting curve profiles. This indicates that the cross-linking between the chains does not disturb the duplex structure itself. Under these conditions, the melting point of the duplex with covalently cross-linked chains (75 °C) was by 18 °C higher than that for the original duplex in 1 M NaCl, whereas in 0.1 M NaCl it was by 30 °C higher.

Thus, the formation of a disulfide bond between the chains has a number of advantages. First, it increases significantly the stability of the DNA duplex. Second, it does not result in noticeable distortions in the DNA structure. DNA duplexes with chains linked by disulfide bonds can be used for the study of processes involving the unwinding of DNA by enzymes, *e.g.*, transcription, replication, and recombination.

Yet another approach to the synthesis of a DNA duplex with covalently cross-linked chains by the 'convertible nucleoside approach' has been described.¹⁴ *O*⁶-[2-(*p*-Nitrophenyl)ethyl]-2-fluorodeoxyinosine^{115, 116} was introduced into a self-complementary 18-membered oligonucleotide in the process of oligonucleotide synthesis. Treatment of this oligonucleotide with bis(aminoalkyl) disulfides (Scheme 8) or *N*-(2-methylthioethyl)-amine **39** led to the substitution of the fluorine atom for *N*-(ω-aminodithioalkyl)amino group or the *N*-(2-methylthioethyl)amino group.¹⁴

Following treatment with dithiothreitol, the reaction between the chains was carried out in the presence of atmospheric oxygen. The presence of a cross-link was proved by an analysis of a correlation between the melting point of the duplex with covalently cross-linked chains and the ability of these cross-links to induce entropic stabilisation of DNA.¹¹⁷

R^1 and R^2 are fragments of the oligonucleotide chain; $n = 2, 3$.

The melting point of the duplex cross-linked by a bis(2-aminoethyl) disulfide linker ($n = 2$) was lower than that of the duplex cross-linked with a bis(3-aminopropyl) disulfide linker ($n = 3$). Presumably, a shorter linker causes greater torsional tension in the DNA structure. Comparison with an oligonucleotide duplex containing the (2-methylthioethyl)amino groups revealed that this modification as such has little effect on the melting point of the duplex.¹⁴

The DNA duplexes thus synthesised with covalently cross-linked chains were used for the study of DNA methylation. This process plays an important role in the development of mammals and in the resistance of bacteria to viral infections.¹⁴ DNA-5-cytosine-methyltransferase (CMTase) catalyses transfer of the methyl group from *S*-adenosyl-L-methionine to cytosine. The enzyme recognises the symmetrical site of DNA, *viz.* 5'-d(GGCC)/3'-d(CCGG), and transfers the methyl group to the internal deoxycytidine residue of each chain. It was assumed¹⁴ that if the methylation site contains an interchain cross-link, the unwinding of the DNA double helix as an element of the enzyme action mechanism will be hampered considerably during the transfer of the methyl group.

It turned out that the enzyme actually induces a distortion of the double helix. In order to establish a correlation between the effect of interchain cross-linking and the recognition of the methylation site by the enzyme, the equilibrium binding has been studied under non-catalytic conditions. It was found that the duplex with a dithiooctamethylene bridge between the chains binds to the enzyme with the same efficiency as does the non-modified duplex, whereas the duplex with a dithiahexamethylene bridge binds 43 times more weakly. Thus, the presence of a cross-link between the chains has no effect on the enzyme binding with DNA (at least, for a longer linker). Moreover, in the latter case cross-linking between the chains results in allosteric activation of the protein binding. Most probably, this is due to the fact that the presence of an interchain cross-link generates torsional tension, which decreases the thermodynamic barrier to DNA unwinding. However, in contrast to cross-linking, methylation occurs much more slowly in comparison with the natural duplex. Nevertheless, under conditions of substrate saturation both duplexes with covalently cross-linked chains serve as substrates for CMTase and the degree of methylation is 10% relative to that of the non-modified duplex. This study illustrates the applicability of DNA duplexes with covalently cross-linked chains for gaining insight into the mechanisms of action of DNA-recognising enzymes.

Erlanson *et al.*¹⁴ have carried out computer simulation of the spatial structure of DNA duplexes with covalently cross-linked chains. The data obtained were compared with the results of X-ray analysis.¹¹⁸ The molecular dynamics methods were used to study the effect of the interchain cross-linking on the secondary struc-

ture of DNA. This made it possible to estimate the extent of distortions induced by cross-linking in the duplex structure and to evaluate its effect on the dynamic behaviour of DNA. Spatial structures of the self-complementary decanucleotide 5'-d(GCGAATTCGC) in the form of a duplex and of two modified duplexes with the same primary structure and a cross-link between the amino groups of deoxyadenosine residues in the central A·T pair were studied. The lengths of the linkers were six (dithiahexamethylene) or eight dithiaoctamethylene atoms (the nitrogen atoms were not taken into account).

It was shown¹¹⁸ that the canonical B-form of DNA and the Watson-Crick type of base pairing are preserved by all DNA duplexes in question. The parameters of the duplex helices with covalently cross-linked chains, of the large and small grooves, and of the base pairs, as well as the torsional angles of the sugar-phosphate backbone are also mostly similar to the corresponding parameters for the crystalline structure of the non-modified duplex. Yet, the presence of cross-links between the chains endows certain disorder in the geometry of the double helix. The deviations observed are insignificant: no more than 1.2 Å from the canonical B-form of DNA and no more than 1.3 Å from the experimentally determined parameters for the crystal of a non-modified duplex. These changes are more substantial with the shorter interchain linker. The dynamic properties of the duplexes with covalently cross-linked chains are also similar to those of the non-modified duplex. Certain changes are observed in a region adjacent to the cross-linking site and are especially pronounced in the case of a shorter linker. Structural distortions of general character are manifested in decreased mobility at the cross-link site irrespective of the linker length.

Thus, the changes in structural parameters originate mostly from the modification of the amino groups of deoxyadenosines rather than from the presence of a cross-link between the chain. On the whole, the presence of a cross-link between the chains induces insignificant changes in the duplex structure;¹¹⁸ therefore, these duplexes may be used for the study of proteins that interact with nucleic acids.

Yet another original procedure for obtaining DNA duplexes with covalently cross-linked chains on the basis of thiols has been proposed.¹¹⁹ Two residues of *N*³-(2-mercaptoethyl)thymidine **40** were incorporated into an oligodeoxyribonucleotide and two residues of *N*³-(2-mercaptoethyl)uridine **41**, into an oligoribonucleotide.

The phosphoramidite derivative of compound **40** was attached to the 5'- and 3'-ends of an oligodeoxyribonucleotide in the automated synthesis. The disulfide bond between the ends of a hairpin was closed by oxidation of the thio groups with atmospheric oxygen. The structure of the interchain cross-link at the end of the hairpin formed by two residues of compound **40** is shown below:

The structures of a covalently closed hairpin and its natural analogue are shown in Scheme 9. Their conformational structure was studied by NMR spectroscopy. It was found that the 8-membered double-stranded region in both hairpins has a canonical B-form; structurally both hairpins are completely isomorphic.

Scheme 9

In this case, the presence of an interchain cross-link neither influences the spatial structure of the hairpin nor interferes with the native B-conformation of the double helix. It should be noted that although in this study the cross-link was formed at the end of the DNA duplex, the modified nucleoside could be incorporated into any predetermined position of an oligonucleotide. This method can thus be applied for obtaining a set of various cross-linked oligonucleotide duplexes.

Thus, the synthesis of duplexes with covalently cross-linked chains based on sulfhydryl derivatives has a number of advantages over the use of alkylating agents, which do not ensure sequence-specific cross-linking of chains. The latter circumstance restricts their application in the engineering of interchain cross-links.

The disulfide method was used to cross-link fragments of the ribozyme RNA chain.¹⁷ The reaction was carried out between spatially close (but not complementary) regions of the RNA chain. Hence, here we do not deal with the formation of cross-links between the RNA chains within the duplex; however, this method is so elegant that it deserves special mention. Eckstein *et al.*¹⁷ took advantage of modification of the 2'-positions of certain sugar residues. Oligoribonucleotides with incorporated 2'-amino-2'-deoxyribonucleotides were synthesised for this purpose. Synthesis of 2'-amino-2'-deoxyribonucleosides has been described earlier.^{120–126}

The sulfhydryl groups were introduced as follows. First, the oligoribonucleotides were treated with the bifunctional reagent **42** (Scheme 10) containing the isothiocyanate and a protected sulfhydryl group. It was shown that compound **42** selectively reacts with the 2'-amino groups of the modified ribonucleotides.¹⁷

The reaction between the fragments of the ribozyme chain was initiated by dithiothreitol, which deprotected the sulfhydryl groups. This enabled the reaction between the ribozyme chains under the action of atmospheric oxygen (Scheme 10). The presence of a cross-link between the chains was confirmed by limited alkaline hydrolysis. One cleavage of the ribozyme chain at the site between the modified residues gave a single product with the same molecular weight as that of the original ribozyme.

Ribozymes with covalently cross-linked chains obtained by the above-described procedure were used to study the tertiary structure of the ribozyme in relation to the catalytic mechanism of RNA cleavage. The parameters of the ribozyme tertiary structure obtained earlier by X-ray analysis (Scheme 11, **A**) and fluorescence resonance energy transfer (FRET) solution measurements (Scheme 11, **B**) were different. [Ribbon representation of the tertiary structures of the hammerhead ribozyme based on (**A**) X-ray crystallography and (**B**) FRET solution measurements. Ribozymes and substrates are coloured black and light gray, respectively. Residues that are close in space according to the X-ray structure and the FRET model (dark gray) are connected by solid lines and the broken lines represent the corresponding long distances in the other model.] At the same time, both putative structures had identical general geometry. The difference between them lay in the orientation of the two helical regions of RNA relative to each other (helices I and II, Scheme 11). In order to compare these two spatial models of the ribozyme and to choose

Scheme 10

the model corresponding to the genuine biologically active structure, synthetic ribozymes with covalently cross-linked chains were used.

Scheme 11

The authors¹⁷ have succeeded in stabilising the spatial structure of the ribozyme according to each of the putative models. After hybridisation of the modified ribozymes with a non-hydrolysable substrate analogue containing a deoxynucleoside in the reaction centre, the reaction mixtures were treated with oxygen for 30 h. This permitted a highly efficient reaction between the chains irrespective of the localisation of the modified units in the ribozymes (Scheme 12). Roman numerals indicate the number of the helices. An arrow indicates the site of cleavage. Residues contained a 2'-amino function and utilised for cross-linking are filled by dark gray colour. The yield of the ribozymes with covalently cross-linked chains after all purification procedures was 15%.

The cross-links between the chains stabilised the spatial structure of the ribozyme in accordance with the predetermined one, which made it possible to measure the catalytic activity of two synthetic ribozymes with different spatial structures. As expected, the catalytic activity of the ribozyme depends on the localisation of the cross-link between the chains. The cross-link between the adjacent regions of the helices corresponding to the X-ray model (Schemes 11, 12, **A**) had practically no effect on the catalytic

Scheme 12

activity of the ribozyme. On the other hand, the cross-link between the adjacent nucleotides according to the other model (Schemes 11, 12, **B**) decreased the rate of the ribozyme-induced cleavage of the corresponding substrate by three orders of magnitude. It was thus concluded that the X-ray model corresponds to the real structure and that the previous methods that have previously been used in the study of the tertiary structure of RNA are inadequate. The results obtained by Eckstein *et al.*¹⁷ have provided the basis for further studies on ribozymes.¹²⁷

VIII. Synthesis of cross-linked nucleic acid duplexes using sugar moieties of nucleosides

In contrast to studies devoted to the modification of heterocyclic bases and phosphate groups of oligonucleotides, reports on the reactions between chains involving sugar residues are scarce.

A method for the synthesis of a duplex was proposed,¹⁵ which entails the formation of a cross-link between the amino group attached through a spacer to position 2 of the sugar residue of adenosine, on the one hand, and the aldehyde group in a non-nucleoside insert of the complementary chain, on the other hand.

$R^1 - R^4$ are the fragments of oligonucleotide chains.

Synthesis of this type of compound has been patented.¹⁶ In this case, the aldehyde group results from enzymic elimination of uracyl by uracyl-DNA-glycosylase from 2'-deoxyuridine incorporated into the oligonucleotide. The elimination of the heterocyclic

base is accompanied by the sugar ring opening and the formation of the aldehyde group. Treatment of the latter with the primary amine gives a Schiff's base, which is reduced to give a stable secondary amine. However, enzymic treatment does not yet allow the preparative synthesis of these compounds, which restricts their application as therapeutic agents.

As mentioned above, the main drawback of many procedures employed in the synthesis of cross-linked DNA duplexes is their low specificity. It is the specific cross-linking of DNA chains that allows the development of the most convenient tools for the study of protein-nucleic acid interactions. Therefore, in recent years most studies have been aimed at the elaboration of methods of site-specific cross-linking of chains in synthetic DNA duplexes.

A series of publications¹²⁸⁻¹³¹ are devoted to elaboration of a new effective method for the synthesis of cross-linked DNA duplexes that involves sugar residues of nucleosides. This method required the use of oligonucleotides modified at the carbohydrate fragment and containing a primary aliphatic amino group or a carboxy group. The existing procedures for incorporation of modified units into oligonucleotides permit introducing them into any predetermined position of the oligonucleotide chain or incorporate several modified units into the same oligonucleotide by a standard protocol of solid-phase phosphoramidite oligonucleotide synthesis.

The reaction between the primary amino group and the carboxy groups selected for the cross-linking of the duplex chains is activated by water-soluble CDI and results in the formation of an amide bond between the chains.

In the early 90's, several methods for the synthesis of 2'-amino-2'-deoxynucleotides were developed.¹²⁰⁻¹²⁶ High reactivity of the 2'-amino groups of 2'-amino-2'-deoxynucleosides in acylation reactions¹²⁰⁻¹²² has led to an idea of formation of a cross-link between the 2'-amino group in one chain and the carboxy group derived upon acylation of the 2'-amino-2'-deoxynucleoside of the complementary chain by a dicarboxylic acid anhydride. However, preparation of purine 2'-amino-2'-deoxynucleosides by transglycosylation (substitution of a heterocyclic base) of preformed 2'-amino-2'-deoxyuridine^{123, 124} inevitably resulted in the formation of a complex mixture of products and extremely low yield of the target product.

Thus, a non-nucleoside insert was used instead of purine 2'-amino-2'-deoxynucleosides. On the one hand, this disturbs the hydrogen bonds in the pair in which one heterocyclic base is missing. On the other hand, the use of this nucleoside substitution has a number of benefits. Compound **43** can be synthesised by a combination of simple high-yielding chemical reactions.^{128, 129} The distance of three carbon atoms between the phosphate groups, which is characteristic of natural oligonucleotides, is preserved in the structure of the non-nucleoside insert. This compound is resistant to synthetic and post-synthetic treatments of the oligonucleotide.

Synthesis of specifically protected pyrimidine 2'-amino-2'-deoxynucleosides **44** and **45** has been described.^{120, 121} The reaction between the chains of a modified duplex is performed in the following steps. First, a carboxy group is introduced into one chain. This is achieved by acylating the amino group incorporated

Scheme 13

Het = U, C^{Bz}; R¹–R⁴ are fragments of oligonucleotide chains.

into the oligonucleotide with a dicarboxylic anhydride. Molecular simulation allowed one to select succinic anhydride as the acylating reagent. Then the reaction between the chains was conducted in a morpholinoethyl sulfonate buffer (pH 5.0–6.7) for 1–3 days at 0–20 °C using water-soluble CDI as a condensation reagent (Scheme 13).

Previously, it had been demonstrated^{128, 129} that the reaction between the strands of modified DNA duplexes with a primary aliphatic amino group in one of them and a carboxy group in the other proceeds much more efficiently with the free amino group of 2'-amino-2'-deoxycytidine. This is explained by the fact that the pK_a value for this amino group (6.2)¹²¹ is much lower than that for the amino group of aliphatic amines, so this group exists mainly in a deprotonated form under the reaction conditions.

The effects of some other factors, such as the mutual arrangement of modified units, their number, nucleotide environment, thermodynamic stability of the precursor duplex, *etc.*, on the efficiency of the reaction between the chains, were studied.^{130, 131} Under optimum conditions, the yield of the corresponding DNA duplexes with covalently cross-linked chains reached 85% for certain systems.

The yields of the target products differ considerably for a 20- and a 25-membered systems (26% and 85%, respectively). This is accounted for by the fact that the efficiency of the reaction increased with an increase in the melting point of the original modified duplex.

Depending on the nucleotide environment of the modified units, the yield of the target product varied from 50% to 85%.^{130, 131} Substitution of 2'-amino-2'-deoxyuridine for 2'-amino-2'-deoxy-*arabino*-adenosine does not affect significantly the yield of the DNA duplex with covalently cross-linked chains.

The thermodynamic stability of DNA duplexes with incorporated modified units was in all cases lower than that of non-modified duplexes of the same primary structure. The decrease in the melting point depends on the length and the composition of the DNA duplex. In contrast, for duplexes with covalently cross-linked chains the melting point was higher than that for the corresponding modified and non-modified duplexes. The increase in the melting point was 4–8 °C relative to natural analogues, while that for the corresponding modified duplexes was 15–33 °C.^{128, 129}

Duplexes with covalently cross-linked chains are much more resistant to the action of a mixture of snake venom phosphodiesterase and alkaline phosphatase than those devoid of interchain cross-links. Under conditions where natural and modified duplexes are completely hydrolysed to give nucleosides, duplexes with covalently cross-linked chains maintain their structure by no less than 70%. Such a low level of hydrolysis under these conditions is due to the presence of a cross-link between the chains.

Comparative kinetics of enzymic hydrolysis of a 25-membered duplex with covalently cross-linked chains and of a non-modified duplex of the same primary structure by snake venom phosphodiesterase was carried out.¹³² Under selected conditions, enzymic hydrolysis of single-stranded oligonucleotides and a non-modified duplex occurred at a high rate. Single-stranded oligonucleotides

were completely hydrolysed to give nucleotides in 5 min, whereas the duplex with covalently cross-linked chains was not completely hydrolysed under identical conditions even in 3 h. Relatively easy splitting of two or three units was observed together with accumulation of products of partial hydrolysis with chains shortened by no more than 3–8 units. After scission of eight units, the reaction is appreciably retarded. Thus, the presence of a cross-link between the chains causes strong inhibition of the effect of snake venom phosphodiesterase.

In order to prove the ability of compounds obtained to serve as substrates of enzymes binding with unique nucleotide sequences of DNA and to confirm their structure, DNA duplexes with covalently cross-linked chains were site-specifically cleaved with restriction endonuclease *Alu* I.^{130, 131} The primary structure of covalently cross-linked DNA duplexes corresponded to the 25-membered non-modified DNA duplex; its nucleotide sequence is shown in Scheme 14. The recognition site of restriction endonuclease *Alu* I is given in *italics*; the sites of incorporation of the corresponding modified units **43** and **44** are underlined.

The position of cross-links between the chains relative to the recognition site of restriction endonuclease *Alu* I in DNA duplexes determines the composition of the hydrolysate. The formation of oligonucleotides of different lengths resulting from hydrolysis of DNA duplexes with covalently cross-linked chains and the non-modified duplex is illustrated by Scheme 14.

Scheme 14

p* is ³²P-phosphate.

The composition of reaction mixtures for all DNA duplexes is in agreement with the theoretical Scheme 14. Thus, it has been shown that the presence of cross-links between the chains in synthetic DNA duplexes does not prevent their cleavage with restriction endonuclease *Alu* I. The formation of a series of products of a definite length confirms the presence and position of cross-links between the chains in the synthetic DNA duplexes.

The experimental results^{128–131} suggest that DNA duplexes with covalently cross-linked chains can be used as efficient 'traps' for proteins binding with nucleic acids.

IX. Conclusion

The data presented in this review testify to the existence of efficient methods for preparing DNA duplexes with covalently cross-linked chains. Cross-linking of DNA chains can be achieved either nonspecifically (statistically) or at predetermined positions of the double helix.

Owing to existing methods, the synthesis of these compounds is no longer a very complicated task. DNA duplexes with covalently cross-linked chains have become a convenient tool for the study of protein–nucleic acid interactions. Convincing evidence for the significant potential of this approach can be derived from the investigations cited in the review.

Abstract. Traditional and new procedures for epoxidation of substituted norbornenes are described. The stereochemistry of this reaction and the influence of substituents on the reactivity of the substrate are analysed. The molecular rearrangements and heterocyclisation reactions that can accompany epoxidation are considered; examples of selective attack of oxidants at one of the double bonds in norbornenes containing an unsaturated substituent and also at a multiple bond in some polycyclic di- and triene systems are given. The bibliography includes 252 references.

I. Introduction

A great number of studies have been devoted to norbornene **1**, epoxynorbornane **2**, and their derivatives. This is mostly due to the fact that processing of norbornene-based epoxides gives practically valuable products and also to the fact that these compounds are readily produced from cyclopentadiene, which is a large-scale side product of the coke and petroleum processing industries. Thus dicyclopentadiene diepoxide **3** found application for the industrial manufacture of various polymeric compositions as early as the 1970s.

The special position occupied by norbornene and its derivatives in the synthesis of epoxides is due to the high reactivity of the strained double bond, stereoselectivity of the attack by oxidants, high stability of the resulting epoxides in neutral and alkaline media, and their clear-cut susceptibility to skeletal rearrangements in the presence of acids. No reviews specially devoted to epoxidation of substituted norbornenes have been published;

some information on this point can be found in reviews dealing with more general topics.^{1–10} The interest in the use of various epoxidising agents for preparing compounds of this type becomes even greater because the known attempts to use the halohydrin method in the synthesis of some epoxynorbornanes have failed. In the case of stereoisomeric *exo*- and *endo*-bicyclo[2.2.1]hept-2-ene-5-carbonitriles, bromohydrination is accompanied by Wagner–Meerwein rearrangement and yields adducts with a non-vicinal arrangement of the bromine and the hydroxyl precluding their transformation into epoxides in the presence of bases.¹¹

II. Methods for synthesis of epoxynorbornanes

Epoxynorbornane (2,3-epoxybicyclo[2.1.1]heptane or 3-oxatricyclo[3.2.1.0^{2,4}]octane) was first synthesised in 1954 by two research groups working independently by treatment of norbornene with peroxy acids.^{12,13} Later, norbornene has become a convenient model for the investigation of the mechanism of epoxidation of alkenes.^{1,4,5,14–17} This is due to the fact that among cycloalkenes, norbornene is the most reactive towards oxidation, irrespective of the particular oxidant used. This high reactivity of norbornene is explained by its strained character, caused by the fact that, according to a number of theoretical and experimental studies,¹⁸ the double bond in this molecule is non-planar (the strained state of the norbornene molecule is also manifested in spectroscopic and chemical characteristics^{18–22}). Norbornene has been epoxidised by, for example, organic peroxy acids^{23–29} (including those supported on polymeric substrates³⁰), alkyl hydroperoxides,^{2,6,31–33} peroxyimide acids in two-phase systems,³⁴ α -hydroperoxydiazenes,³⁵ and α -azo-hydroperoxides.³⁶ Quite promising for this purpose are Caro's acid,³⁷ peroxysulfur intermediates based on the superoxide anion (O_2^-),³⁸ as well as the new large class of dioxiranes generated from salts of Caro's acid and acetone.³⁹ Murray and coworkers³⁹ demonstrated the possibility of obtaining the labile monoepoxide and (previously unknown) diepoxide of norbornadiene using dimethyldioxirane. This permits the above experimental procedure to be highly appreciated (some modifications of this method have been reported, in particular, epoxidation of norbornene and other alkenes *via* oxaziridinium salts⁴⁰). The use of sodium perborate as the oxidant also seems quite promising.⁴¹

Molecular oxygen is used both for spontaneous oxygenation of norbornene (which is due to the highly strained character of

alkenes of this series)⁴² and for sensitised oxidation.^{43–45} Study of the latter reaction demonstrated that it occurs as stereospecific *exo*-addition of the peroxy radical to the strained π -bond of the substrate:

The oxidation of norbornene by oxygen has been carried out in the presence of silver catalysts^{46,47} and also specially prepared titanium silicate.⁴⁸ Photooxidation of norbornene catalysed by various compounds,⁴⁹ in particular, sulfur dioxide⁵⁰ has also been studied. Epoxidation of norbornene and other cycloalkenes using the oxygen of water as the oxidant in the presence of platinum complexes has been reported.⁵¹

In a number of studies, oxidation of norbornene derivatives by singlet oxygen has been described.^{52,53} The reaction with singlet oxygen in the presence of phosphites was assumed to involve the *in situ* formation of phosphadioxirane intermediates.⁵⁴

A convenient method for epoxidation of norbornene and its derivatives by oxygen in the presence of nitropalladium complexes has been proposed.^{55–58} The strained double bond in norbornene, vinylnorbornene, and methylnorbornene ensures the formation of a stable five-membered transition state, the yield of epoxide reaching 50%.

This method has also been used to oxidise a number of terminal alkenes and substituted cyclohexenes: the former are converted into ketones, while the latter form mixtures of epoxides, ketones, enols, and other products or do not react at all.⁵⁵

The reactivity of the intermediate complex can be changed by adding copper(II) chloride; in the presence of this salt, the thermal destruction leading to the epoxide is completely suppressed, and rearrangement of the substrate occurs instead.⁵⁶

Takai *et al.*^{59,60} found that norbornene and its derivatives are easily transformed into epoxides upon treatment with oxygen (as oxidant) and secondary or primary alcohols (as reducing agents) in the presence of catalytic amounts of 1,3-diketonoxyvanadium(IV) complexes. Later, a similar transformation was accomplished using nickel⁶¹ or iron⁶² complexes as catalysts in the presence of aldehydes. The reactions were carried out under atmospheric pressure at a moderate temperature, and the epoxides were obtained in high (up to quantitative) yields.⁶³ Heteropoly compounds of the type $(\text{NH}_4)_5\text{H}_4\text{PV}_6\text{W}_6\text{O}_{40}$ were also proposed as catalysts for this process.⁶⁴

An important aspect of the chemistry of norbornene derivatives is investigation of the regularities of liquid-phase catalytic oxidation reactions in which peroxides of transition metals (copper, nickel, cobalt, chromium, molybdenum, vanadium, rhenium, and manganese) are formed as active intermediates.^{31,65–77} Nickel(II) complexes with tetraaza-macrocycles, Schiff bases, and bidentate phosphines have also been studied.^{31,68} Thus in the oxidation of norbornene with iodosylbenzene in the presence of a nickel complex, the complex is activated by reducing iodosylbenzene to iodobenzene. During the transfer of oxygen, the resulting oxo-nickel(IV) intermediate experiences the influence of various factors: the nature of the solvent, concentrations of the reactants, and the temperature. In

particular, when H_2O^{18} is used, the labelled oxygen atom proves to be incorporated in the epoxide (80%).

This method cannot be used to epoxidise cycloalkenes. For example, cyclohexene is converted under these conditions into a mixture of the epoxide, cyclohex-2-enol, and the corresponding ketone (the yields are 36%, 49%, and 15%, respectively).⁶⁸

The use of chromium(III) salicylaldehyde complexes (*salen*) Cr^{III} has several advantages over the method described above (the yield of epoxynorbornane increases to 85%, and the method becomes applicable to some cycloalkenes). The catalytically active species in this reaction are chromium(V) oxo complexes resulting from interaction of the initial complexes (*salen*) Cr^{III} with iodosylbenzene. When pyridine, triphenylphosphine, or trimethylphosphine oxides are used as the ligands L, the activity of the complex increases by several orders of magnitude.⁷¹

The use of cyanopyridinium chlorochromate as the oxidant for norbornene and other cycloalkenes leads to products of another type, namely, chloro ketones.⁷⁸

Agarwal *et al.* have studied oxidation of cycloalkanes catalysed by $\text{Fe}(\text{III})$,⁷⁹ $\text{Cr}(\text{III})$,⁸⁰ $\text{Mn}(\text{III})$,^{81,82} and $\text{Ru}(\text{III})$ ⁸³ complexes with Schiff bases. Later, manganese complexes with Mannich bases have also been tested as catalysts for this reaction.⁸⁴ Among the cycloalkenes studied, norbornene was found to be the most reactive, and, what is especially important, to undergo the most selective epoxidation.⁷⁹

The epoxidation of alkenes with aqueous solutions of hydrogen peroxide, is accomplished using heteropolytungsten complexes of transition metals (chromium, iron), because they are stable with respect to solvolysis,^{85,86} and also complexes based on $\text{Ru}(\text{III})$ and $\text{Ru}(\text{II})$.^{87–90}

Drago *et al.*⁹⁰ successfully epoxidised norbornene using oxygen and sterically hindered ruthenium complexes (the selectivity of epoxide formation was 94%). The homolytic mechanism of this reaction

was confirmed experimentally.

At present, considerable attention is paid to the use of metal porphyrins as catalysts for this reaction, because oxidation involving these compounds is quite similar to the enzymic epoxidation and hydroxylation catalysed by cytochrome P-450⁹¹ or P-420.⁹² Considerable progress has already been achieved along this line: methods for asymmetric epoxidation have been developed;⁹¹ biomimetic electrochemical systems for the oxidation of hydrocarbons, in particular norbornene, by molecular oxygen have been constructed;⁹³ (usually, iodosylbenzene, peroxy acids, or alkyl hydroperoxides are used for oxidation).⁹⁴ The hypothesis of formation of the chlorohydrin intermediate during the oxidation of norbornene by sodium hypochlorite have been rejected based on stereochemical considerations.⁹⁵

Photocatalytic oxygenation of norbornene by molecular oxygen in the presence of iron tetraarylporphyrinates has been studied.⁹² Whereas cyclohexene and cycloheptene are oxidised to give mixtures of products containing only 20%–35% of the epoxide, norbornene **1** is entirely converted into epoxynorbornane **2** under the same conditions.

Ando *et al.*⁹⁶ proposed a peculiar scheme for the preparation of the compound **2** by joint oxidation of norbornene **1** and adamantylideneadamantane in the presence of iron(III) porphyrins. The results of kinetic studies suggest that the first stage consists in oxidation of adamantylideneadamantane; after that, the oxygen atom from the perepoxy intermediate thus formed is transferred to the metal porphyrin, and then norbornene is oxidised:

Ad is adamantylidene, P* is the porphyrin ligand.

Interesting results have been obtained with ruthenium porphyrin complexes as the catalysts.^{97,98} Oxidation of ruthenium tetramesitylporphyrinate by *m*-chloroperbenzoic acid (MCPBA) yielded stable crystalline dihydroxoruthenium(IV) tetramesitylporphyrinate, which was used to carry out aerobic oxidation of norbornene.⁹⁸

III. Reaction mechanism

Norbornene is a convenient model to study the mechanism of epoxidation. This process is described most often in terms of the scheme proposed by Lynch and Pausacker,¹⁷ who rationalised epoxidation of alkenes with peroxy acids as a synchronous process including formation of a three-membered cyclic transition state.

Since the above simple scheme is suitable only for describing processes carried out in weakly polar solvents, Kwart *et al.*^{99,100} proposed a different mechanism according to which this reaction is rationalised as dipolar 1,3-cycloaddition; this was confirmed by calculations.¹⁷

The structure of the cyclic transition state (three- or five-membered) has been discussed on the basis of a study of epoxidation kinetics, norbornene being used as the model com-

pound. It was found that the ratio of the rate constants for epoxidation of norbornene and cyclohexene by peroxyauric acid, equal to 1.2, differs sharply from the corresponding ratios found for the reactions of the same substrates with phenyl azide (6.5×10^3) or picryl azide (8.0×10^3).¹⁰¹ This is evidence against the 5-membered transition state in epoxidation. In fact, the strain in the three-membered transition state should smooth out the differences between the epoxidation patterns observed for various types of alkenes. Later, similar kinetic calculations served as the key for elucidation of the mechanism of oxidation of alkenes with ozone,¹⁰² xenon trioxide,¹⁰³ osmium tetroxide,¹⁰² and chromic acid.¹⁰⁴

Epoxidation of norbornene and its derivatives by performic acid has been studied.¹⁰⁵ Two variants (A and B) for the primary orientation of norbornene in relation to the plane of the peroxy-carbonyl group atoms are possible.

According to calculations, both transition states are first-order saddle points; however, in the former case the activation enthalpy ($\Delta H^\ddagger$) is lower by 4.7 kJ mol⁻¹.

In the case of iron porphyrinates,¹⁰⁶ the mechanism of epoxidation includes the formation of a high-valence metal porphyrin radical cation, for example, (Fe^{IV}=O)⁺, which acts as the direct oxidising agent, different key steps of the reaction being possible.

This might be the direct transfer of the oxygen atom [path (a)], homolytic addition followed by fast closure of the epoxide ring [path (b)], electrophilic addition and subsequent cyclisation [path (d)], reversible formation of metal oxetane followed by recyclisation and epoxide formation [path (e)] and electron transfer [path (c)] followed by transformation into a radical cation [path (f)] or a carbocation [path (g)].¹⁰⁴

In this case, unlike the traditional scheme for epoxidation by peroxy acids, a mechanism involving the intermediate formation of a radical cation [path (f)] has also been proposed.¹⁰⁷ This is confirmed by the composition of the reaction products and by kinetic data obtained for epoxidation of various alkenes. The logarithms of the rate constants for the epoxidation were found to

obey a linear correlation with the ionisation potentials of the alkenes.

The reaction mechanism was developed with allowance for the stereochemical data obtained for epoxidation of norbornene.^{107, 108} Traylor *et al.*¹⁰⁹ showed that the *exo*-stereoselectivity of epoxidation, typical of norbornene, does not hold in the presence of metal porphyrins, and the ratio of the yields of *exo*- and *endo*-epoxynorbornanes depends appreciably on the type of metal incorporated in the porphyrin nucleus and the type of substituents in the benzene rings of a substituted tetraphenylporphyrin.¹⁰⁹ Thus the ratio of *exo*- to *endo*-epoxynorbornanes amounts to ~1000 for electropositive Cr complexes and ~6 for electronegative Fe(III) complexes, the amount of the rearranged products decreasing in parallel. When norbornene is oxidised by pentafluoriodobenzene in the presence of iron tetra(4-methylphenyl)- or tetra(2,6-dichlorophenyl)porphyrinates, the yield of the epoxide is 45% or 82%, and the ratio of *exo*- to *endo*-stereoisomers is 71 or 9, respectively (in the case of oxidation by peroxy acids, this ratio is 600–700). Moreover, it was found that the logarithm of the (*exo/endo*) ratio correlates with the σ -Hammett constants of the substituents in the porphyrin benzene rings.¹⁰⁹

This finding can be explained by assuming a change of the reaction mechanism: in place of the electron transfer [path (*f*)], electrophilic attack [path (*d*)] occurs, resulting in the formation of a transition state consisting of the alkene weakly bound to the attacking reagent.

The electron density on the central metal atom in metal porphyrins increases in the following sequence of metals: iron(III) < manganese(III) < chromium(III). In the same series, the bond between the alkene and the attacking reagent in the transition state becomes stronger and the C...O distance decreases; simultaneously, steric hindrance becomes more significant, and the *exo*-stereoselectivity is enhanced.¹⁰⁹

Traylor *et al.*¹⁰⁹ who studied oxidation of norbornene with hydrogen peroxide and *tert*-butyl hydroperoxide catalysed by iron porphyrinate with fluorinated benzene rings, obtained the same *exo* : *endo* ratio (22 : 1) as was found using pentafluoriodobenzene as the oxidant.¹⁰⁹ As has been shown previously, this oxidising agent reacts with the porphyrinates giving iron(IV) radical cation (oxene). Traylor *et al.*¹¹⁰ were able to demonstrate that in the presence of iron porphyrinates, including hemin (Hm^+), as the catalysts, hydrogen peroxide and *tert*-butyl hydroperoxide undergo heterolytic cleavage to give oxene:

The approach to the mechanism of norbornene oxidation outlined above has been confirmed by investigating this reaction in the presence of new porphyrin catalysts¹¹¹ and new oxidants.¹¹²

In a study of joint oxidation of α -methylstyrene and norbornene with MCPBA or *o*-chloroperbenzoic acid in the presence of iron(III) porphyrinates, it was found that the selectivity of epoxidation changes crucially depending on the solvent.¹¹³ It was found that the formation of oxoferryl porphyrin radical cation is not the preferential route.

In some cases, fine structural features of the ligand have a substantial influence on the stereochemistry of epoxidation of norbornene.¹¹⁴ In particular, the use of isomeric ligands incorporating 3- and 4-pyridyl fragments leads to different results: in the former case, a mixture of stereoisomeric epoxides is formed, while in the latter case, only the *exo*-isomer is produced. Agarwal *et al.*¹¹⁴ explained these differences by specific features of coordination of the nitrogen atoms of the pyridine ligands to the manganese atom.

When MCPBA was used as the oxidant, the reaction gave various polycyclic structures (for example, 4–8) incorporating epoxynorbornane or related fragments.^{115–120}

IV. Stereochemistry of epoxidation of substituted norbornenes with peroxy acids

The stereochemical outcome of the epoxidation of substituted norbornenes with peroxy acids, namely, the formation of an *exo*-epoxide ring, is a particular case of the known Alder rule.¹²¹ It has been discussed in detail in a number of studies.^{122–125} Earlier, the configuration of the epoxides has been studied by converting them into known norbornanols; thus, it was found that the epoxynorbornane formed contains only a slight amount of the *endo*-epoxide (6%,¹²⁶ 0.5%¹²⁷). Brown *et al.*¹²⁷ attributed the *exo*-attack to the predominant steric hindrance of the *endo*-area by the norbornene fragment. As model compounds, they chose norbornene (1), *cis*-bicyclo[3.3.0]octene, and *endo*-5,6-trimethylenenorbornene 10. The increase in the steric hindrance of the *endo*-area of the ring was judged by the increase in the *exo*-stereoselectivity.¹²⁷

Compound			
<i>exo</i> : <i>endo</i> ratio of epoxides	87 : 13	99.5 : 0.5	99.9 : 0.1

Later, the selectivity of the attack and the high reactivity of norbornene have been explained by the influence of hyperconjugation and out-of-plane deformation. Theoretical studies showed that the =C–H bonds in norbornene, unlike those in cyclohexene or bicyclo[2.2.2]octene, are bent by 2–5° to the *endo*-area. In the transition state, the *endo*-bending ensures both *exo*-stereoselectivity and a high rate of the attack by an electrophilic reagent. The presence of the *endo*-bending was attributed to the repulsion between the π -orbital and the occupied orbitals of the methylene bridge.

In fact, the vast majority of known epoxynorbornanes have *exo*-configuration in which the protons of the C(7)H₂ bridge are appreciably non-equivalent, one of them being arranged directly

above the plane of the epoxide fragment and experiencing substantial paramagnetic shielding.

The non-equivalence of the bridging protons in the ^1H NMR spectrum as well as the unusual shielding of the C(7) atom in the ^{13}C NMR spectrum are the two criteria, which can be used to determine the stereochemistry of an epoxynorbornane fragment.^{125, 128} The *exo*-configuration has been confirmed by X-ray diffraction analysis.^{129, 130} *exo*-Stereoselective epoxidation has also been observed for the 7-oxa analogue of norbornene¹³¹ and for polycyclic compounds, related to norbornene but much more complicated, such as *syn*-1,2,3,4,5,6,7,8-octahydro-1,4:5,8-dimethanonaphthalene **11** and its derivatives **12** and **13**.

In this case, the *endo*-shielding is even more significant: the distances between the internal hydrogen atoms H(9), H(10) and H(3), H(6) are 3.416 and 2.728 Å,¹³² respectively; since, the $sp^2 \rightarrow sp^3$ transition relieves strain, these alkenes and polyenes are readily epoxidised.^{133, 134} The presence of a fulvene group in the compound **13** does not change the stereoselectivity of the attack by oxidants (peroxy acids, oxygen) directed at the strained double bond.¹³⁵ The *exo*-attack is also characteristic of the strained system **14** with a cyclobutene fragment.¹³⁶

As the ring becomes less strained and/or shielding of the two directions of the attack becomes equal, this stereochemical course no longer predominates; thus bicyclo[2.2.2]octene **16**, unlike benzonorbornene **15**, undergoes non-stereospecific epoxidation giving rise to *exo*(β)- and *endo*(α)-epoxides.^{13, 137}

The stereochemistry of epoxidation of the anhydride or esters of *endo*-bicyclo[2.2.2]oct-5-ene-2,3-dicarboxylic acid with trifluoroperoxyacetic acid is also non-stereospecific; the reaction mixture contains both epoxides together with products of lactonisation, whereas in the case of unsaturated lactone **17**, only the β -attack is observed, due to steric interactions involving the internal hydrogen atom of the methylene group.¹³⁸

The through-space interaction between the double bond and the aromatic fragment in benzobicyclo[2.2.2]octadienes¹³⁹ and dibenzobicyclo[2.2.2]octatrienes¹⁴⁰ has been studied by quantum chemistry and photoelectron spectroscopy. The results of the influence of substituents in the benzene ring of dibenzobicyclo[2.2.2]octatrienes **18** on the stereoselectivity of epoxidation are shown in Table 1.¹⁴⁰

It was found that electron-withdrawing substituents (NO_2 , F) facilitate the *syn*-attack, whereas electron-donating substituents do not exert this type of influence.

Table 1. Ratio of the *syn*- and *anti*-isomers in the products of electrophilic oxidation of 2-substituted dibenzobicyclo[2.2.2]octatrienes **18**.

Oxidant	Substituent X	Yield (%)	Ratio <i>syn</i> : <i>anti</i>
MCPBA	H	88	50 : 50
	NO_2	46	77 : 23
	OMe	63	48 : 52
	F	86	58 : 42
OsO_4	H	90	50 : 50
	NO_2	67	85 : 15
	OMe	96	48 : 52
	F	96	68 : 32
KMnO_4	H	58	50 : 50
	NO_2	48	88 : 12

Gandolfi *et al.*¹⁴¹ have found that the 80%–96% *syn*-stereoselectivity of the attack by MCPBA on the double bond of *endo,exo*-5,6-disubstituted bicyclo[2.2.0]oct-2-enes (containing OAc, CN, *etc.* as substituents) is controlled by hyperconjugation of the σ^* -orbitals of the bonds being formed with antiperiplanar σ -bonds of the allylic fragments.

In studies of epoxidation of anhydrides, nitriles, and esters of the norbornene series,^{142–145} it has been found that these compounds undergo only the *exo*-attack by peroxy acids. The reported formation of *endo*-epoxides on treatment of 5-substituted norbornenes with *O*-benzylmonoperoxyacetic acid⁶ seems doubtful; apparently, in this case, too, *exo*-epoxidation occurs.¹⁴⁶

exo-Stereoselective epoxidation has also been observed for the 7-oxa analogues of substituted norbornenes,^{147–150} for bicyclic nitrogen-containing systems with a similar structure,¹⁵¹ and for a broad range of bis-adducts of cyclopentadiene with various dienophiles.¹⁵² The *exo*-stereoselectivity of the Prileschajew reaction is strictly observed for unsaturated propellanes related to norbornene. For complex polyenes (for example, for the com-

pound **19**), stereoselectivity is retained, together with the chemoselectivity of the attack at the double bond.¹⁵³

According to the known Bartlett, Lynch, and Pausacker scheme,¹⁷ it can be assumed that formation of the transition state in the epoxidation of substituted norbornenes faces difficulties if the *exo*-area of the norbornene fragment contains bulky groups belonging to any of the two reacting molecules. The influence of methyl groups in various positions of the norbornene fragment on the stereochemistry of epoxidation by MCPBA has been estimated quantitatively (Table 2).^{30, 154, 155} It can be seen from Table 2 that only the *syn*-Me group at the 7-position prevents the attack. These data are consistent with the results obtained earlier for epoxidation of bornylene. For example, the formation of a mixture of isoborneol, borneol, epiisoborneol, and epiborneol^{156, 157} upon the reduction of bornylene epoxide proves unambiguously the presence of a mixture of stereoisomers of the epoxide, the quantitative composition of the resulting mixture of alcohols being indicative of predominant *endo*-attack in epoxidation.

Table 2. Influence of the position of methyl groups on the stereochemistry of epoxidation of substituted norbornenes.

Compound	Epoxide yield (%)	Content of <i>exo</i> -isomer (%)
Norbornene	87	99.0
7,7-Dimethylnorbornene	87	6.0
1-Methylnorbornene	88	99.0
2-Methylnorbornene	100	99.5
1,7,7-Trimethylnorbornene	80	5.0

To estimate the influence of the size of various groups on the stereochemistry of epoxidation, epoxidation of *syn*-7-substituted norbornenes by MCPBA was carried out^{158, 159} (Table 3).

X = H, Cl, SnMe₃, Br, Me, Bu^t.

It can be seen from Table 3 that neither the van der Waals radius nor the length of the C–X bond are crucial for the efficiency of the *endo*-attack. The found *exo* : *endo* ratios vary in parallel with the size of the ‘open space’ between the double bond and the substituent, calculated by Davis *et al.*¹⁵⁹ by the procedure

Table 3. Influence of the character of substituents on the stereochemistry of epoxidation of substituted norbornenes **20**.

Substituent X	Content of <i>exo</i> -isomer (%)	<i>exo</i> : <i>endo</i>	C–X bond length /Å	Van der Waals radius of the substituent /Å
H	99.0–99.5	100	1.10	1.20
Cl	62.0	1.6	1.77	1.80
SnMe ₃	55.0	1.2	(2.18)	—
Br	45.0	0.8	1.94	1.95
Me	6.0–14.0	0.1	1.54	2.00
Bu ^t	0.0	0.0	(1.54)	—

proposed by Wilcox.¹⁶⁰ Any influence of the polar factor can be ruled out because the outcomes of the epoxidation and hydroboration reactions are identical.

Gassman *et al.*¹⁶¹ showed that methyl and nitrile groups have different effects on epoxidation of the double bond in substituted *anti*-bicyclo[2.2.1]hept-2-en-7-ols **21**.

X = Me (*exo* : *endo* = 22 : 78), CN (*exo* : *endo* = 45 : 55).

Epoxidation of 7,7-dibromomethylnorbornene yielded the isomers in approximately equal amounts.¹⁶²

The data presented above^{161, 162} disprove the results obtained in another study¹⁶³ in which the products **22a,b** obtained by epoxidation of substituted norbornenes with a *syn*-7-trimethylsilyl group were identified as containing an *exo*-epoxide ring.

In the light of the data available from the literature, the *exo*-attack by a peroxy acid seems relatively unlikely. Moreover, the ¹H NMR spectral parameters reported by Fleming and Michael¹⁶³ unambiguously point to the *endo*-configuration of the epoxide ring. In fact, the H(2) and H(3) protons are responsible for chemical shifts of 3.63 and 3.53 ppm (**22a**) and 3.62 ppm (**22b**). The chemical shifts of the corresponding protons in *syn*-7-bromo(chloro or trimethylstannyl)-*exo*-2,3-epoxybicyclo[2.2.1]heptanes are 3.24, 3.26, and 2.97 ppm, whereas those in the corresponding *endo*-epoxides are 3.67, 3.70, and 3.45 ppm.^{158, 159}

The influence of steric hindrance on the epoxidation of *syn*-7-bromobicyclo[2.2.1]hept-2-ene **23** by peroxyphthalic acid (PPA) has been studied.²⁵ The stereoisomeric bromoepoxides formed in this reaction [mostly, the *endo*-isomer, 1.8 : 1] were subsequently reduced by tributyltinhydride at 140 °C.

The resulting *endo*-2,3-epoxynorbornane **2** was studied by spectroscopy and by kinetic methods.

The *syn*-substituents at the 7-position, which are arranged in space close to the double bond, should certainly influence not only the direction but also the rate of epoxidation. The rates of the reactions of *anti*-7-*tert*-butylbicyclo[2.2.1]hept-2-ene, containing

the bulkiest *tert*-butyl group, with diimide, hydrogen, mercury acetate, and MCPBA are lower than the rates of the same reactions of norbornene by factors of 1.55, 3.77, 5.49, and 5.16, respectively.¹⁶⁴ Unfortunately, no data concerning epoxidation of the *tert*-butyl-substituted *syn*-isomer are presented in the study cited;¹⁶⁴ however, it does not enter into the complex-formation reaction with Ag^+ or reactions with diimide, mercury acetate, or benzenethiol even in the *endo*-direction. This might be due to the repulsion of the ethylene fragment from the *tert*-butyl group resulting in a distorted molecular geometry and hampered *endo*-attack.

However, in some cases, substituents in the bridge facilitate the *exo*-attack. This is possible when the polar factor proves to be more significant than steric strain, for example, for 7,7-dimethoxynorbornene **24**.¹⁶⁵

In the opinion of the researchers cited,¹⁶⁵ the *exo*-addition is a consequence of formation of a hydrogen bond between the attacking peroxy acid and the oxygen of the 7-methoxy group.

The involvement of a hydroxy group in epoxidation is apparently a general reaction route. For instance, it accounts for the chemo- and stereo-selectivity of the oxidation of the alcohol **25** in the presence of a molybdenum catalyst¹⁶⁶ and also of other reactions.¹⁶⁷

V. The influence of substituents in the bicyclic system of norbornene on the reactivity of the double bond towards peroxy acids

Only a few studies specially devoted to the kinetics of epoxidation of substituted norbornenes have been published. Thus Brown *et al.*¹⁶⁸ demonstrated that the steric effect of the 7,7-dimethyl substitution is manifested as the change in the orientation of the attack by the oxidant (MCPBA) and as a 100-fold decrease in the reaction rate compared with that observed for norbornene, *exo*-epoxidation being retarded by more than three orders of magnitude.

A kinetic study dealing with epoxidation of 5,6-disubstituted (Cl, Br, COOMe) norbornene derivatives by perbenzoic acid (PBA) has been published.¹⁶⁹ The rate constants for this reaction, which correlate with the Hammett constants increase slightly in the following series of isomers: 5,6-*exo-cis* < 5,6-*trans* < 5,6-*endo-cis*. The researchers believe that these substituents exert mainly a polar influence, the effect of *exo*-substituents being stronger.

The crucial role of the inductive effect has been found for epoxidation of stereoisomeric norborn-2-ene-5-carboxylic acids and their esters.^{1, 142, 144, 145} According to the kinetic studies of Berti *et al.*,¹⁴⁴ the possibility of an influence of the carboxyl group on the rate-determining step of this reaction can be ruled out, because the ratio of the reaction rates for the *endo*-acid and its ester proved to be similar to that found for *ortho*-stilbenecarboxylic acids and their esters. The situation changes dramatically in

those cases where the substituent assists the reaction, as has been observed for epoxidation of norbornene derivatives containing *endo*-5-hydroxymethyl and *endo*-carboxamide groups.^{1, 144, 145, 170, 171} In both cases, intramolecular rear attack by the nucleophilic group on the electrophilic centre in the intermediate 'alkene-peroxy acid' complex results in cyclisation. Epoxidation of the corresponding *exo*-stereoisomers follows the normal pathway.^{172–174} (see also Section VII).

The influence of solvation and specific interactions has been clearly demonstrated in relation to epoxidation by peracetic acid of a number of stereoisomeric nitriles, acids, esters, amides, and alcohols, and also *endo*-stereoisomeric nitro- and bromomethyl-derivatives of norbornene.¹⁵⁴ In the presence of functional groups possessing clear-cut proton-donor or proton-acceptor properties, the inductive influence of substituents is masked by solvation effects; this has an influence on the correlation of the rate constants with the Taft constants of substituents. The effects of carboxyl and carboxamide groups on the epoxidation depend substantially on their orientation; in *exo*-isomers these groups are 'open' to the formation of intermolecular hydrogen bonds, whereas in *endo*-isomers they are shielded by the carbon cage of the molecule.

Quantum-chemical PM3 calculations for a number of transition states formed during epoxidation of substituted norbornenes by performic acid and comparison of the calculated parameters with the results of kinetic studies made it possible to find a correlation between the logarithms of the rate constants ($\lg k$) and the calculated activation enthalpies ($\Delta H^\ddagger$).¹⁰⁵

Comparison of the results of correlation analyses of substituted norbornenes and propenes (the ρ constants for these reaction series at 40 °C are -0.446 and -1.31 , respectively) implies that epoxidation of bicyclic alkenes is less sensitive to the inductive effect of substituents, because the bicyclic system smoothes out its influence.¹⁷⁵

Kinetic data concerning the interaction of the π -bond with closely arranged groups in polycyclic systems related to norbornene can be found in several studies. The through-space interaction has been studied in relation to epoxidation of substituted propellanes **26a–f**.

These reactions are *exo*-stereoselective in all cases; the reactivity of the double bond decreases in the following sequence (the relative epoxidation rates are given in parentheses): **26e** (13.20) > **26a** (1.00) > **26f** (0.36) > **26c** (0.04).^{176, 177}

Analysis of the IR spectra recorded in weakly polar solutions proves that the compound **26d** contains a strong intramolecular hydrogen bond

which deactivates the double bond. In aprotic bipolar solvents, the OH group participates in the formation of an intermolecular H bond with a solvent molecule.

The through-space $n_1-\pi$ orbital interaction arising in the latter case increases the nucleophilic properties of the double bond. The same is true for the *syn*-methoxy group in **26e**. The reactivity of the ester **26e** is 340 times higher than the reactivity of the ketone **26c** in which this type of interaction does not occur.

Comparison of the relative rates of epoxidation by MCPBA of the double bonds in 1,4,5,8-dimethano-1,4,4a,5,6,7,8,8a-octahydronaphthalenes (**27–32**), incorporating an anhydride group, indicates that the *syn*-arrangement of this group largely passivates the double bond. Comparison of the rates of epoxidation of the compound **27** and its oxa-analogue **28** shows that in the presence of the oxygen bridge, the nucleophilicity of the double bond further decreases.¹³⁰

Compound		
Relative epoxidation rate	1.00	0.58
Compound		
Relative epoxidation rate	19.00	1.20(α), 9.00(β)
Compound		
Relative epoxidation rate	0.40	8.30

VI. Molecular rearrangements during epoxidation of norbornene

A peculiar feature of the epoxidation of norbornene derivatives is the formation of various isomeric products including those resulting from the Wagner–Meerwein rearrangement and hydride shifts.¹⁷⁸

Electron-withdrawing groups at the 5- and 6-positions of the norborn-2-ene molecule prevent the C(1)–C(6) and C(4)–C(5) σ -bonds from participation in the delocalisation of charge at the C(2) and C(3) atoms; this decreases the role of nucleophilic assistance and, hence, the amount of rearranged products formed falls. For example, treatment of *exo*-bicyclo[2.2.1]hept-2-ene-5,6-dicarboxylic acid¹⁷⁹ and its 7-oxa analogue¹⁸⁰ with performic acid gives rise to the corresponding *exo*-epoxy acids. Trifluoroperoxyacetic acid can also be used as the oxidant in this reaction. When the molecule contains only one *exo*-carboxyl group, the reaction with performic acid is accompanied *in situ* by the Wagner–Meerwein rearrangement.¹⁴⁴

Electron-donating groups at the 5- and 6-positions increase the probability of the rearrangement during epoxidation; the rearrangement occurs even in those cases where one might expect the 'normal' reaction pattern. Thus, unlike benzonorbornene, epoxidation of which by various peroxy acids follows the normal route, the corresponding dimethoxy-derivative **33** reacts with trifluoroperoxyacetic or peracetic acid giving rise to the rearranged product **34**.

The addition of sodium acetate to peracetic acid makes it possible to retain some of the epoxide, whereas epoxidation by PBA gives the epoxide as the only reaction product.^{181, 182} Problems arise in those cases where the substituents at the double bond are capable of stabilising the carbocationic centre. These groups facilitate molecular rearrangements. For example, the Wagner–Meerwein rearrangement accompanies epoxidation of 2-phenylnorbornene with MCPBA^{183, 184} and 2-(*p*-anisyl)norbornene with peracetic acid even when a buffer solution has been added. Treatment of 2-phenylnorbornene with performic acid affords carbonate, due to the formation of a phenonium ion; hydrolysis of the carbonate results in the formation of *cis*-1,2-diol **35**. The latter can also be obtained from the same alkene using the Wagner method.¹⁸⁵

Nevertheless, aryl-containing epoxides were successfully obtained by using peroxybenzimidic acid as the oxidant in a weakly alkaline medium.¹⁸⁶ It was also found that *exo*- and *endo*-2,3-epoxy-2-phenylbornanes can be synthesised from the corresponding *cis*-*exo*- and *cis*-*endo*-diols.¹⁸⁵

Stereoisomeric 2-methoxy-2,3-epoxynorbornanes have been prepared in a similar way.¹⁵⁸

Later, diaryl-substituted oxiranes of the norbornene series have been synthesised from the corresponding diols on treatment with triphenylphosphine or other reagents.¹⁸⁷

Chlorine atoms at the double bond of norbornene exert a similar influence. Epoxidation of 2-chloro- and 2,3-dichloronorborn-2-ene by MCPBA yields extremely unstable epoxides.^{188–190}

Thus epoxide **36** decomposes at room temperature with heat evolution giving rise to a mixture of nine bicyclic compounds, ketones **37** and **38** being formed as the major products.

Oxidation of optically active (–)-(R)-2-chloronorbornene provided evidence indicating that the rearrangement involves a chloride shift rather than a hydride shift and that isomerisation is intramolecular. Unlike the epoxide **36**, 2,3-epoxy-2-chlorobicyclo[2.2.2]octane isomerises only at 100 °C in a sealed tube giving 3-chlorobicyclo[2.2.2]octan-2-one and no Wagner–Meerwein rearrangement products.⁷³

Aliphatic and alicyclic α -chloroepoxides behave in a similar way.

VII. Intramolecular cyclisation in reactions of substituted norbornenes with peroxy acids

Electrophilic intramolecular cyclisation of alkenes is a well-known reaction.¹⁹¹ Whereas epoxidation of acyclic alkenes is rarely accompanied by cyclisation, for substituted norbornenes reactions of this type are quite common.⁴ Nucleophilic groups, for example, a hydroxy group, present in the rear *endo*-area are often involved in epoxidation giving rise to cyclisation products.^{145, 192, 193}

This is due to the favourable arrangement of the nucleophile in the area of antibonding π^* -molecular orbital of the epoxide ring being formed. In accordance with the Kerten–Hammett principle, the possibility of realisation of molecular conformations, convenient for the formation of activated complexes, is especially significant in this case.

It is noteworthy that alcohol **39** reacts with perbenzoic acid forty times faster than the corresponding acetate.¹⁴⁴ Oxidation of norbornenes **40–42** follows a similar pathway.^{194–197}

Bis-ether **43** is an intermediate in the synthesis of natural loganin **44**.¹⁹⁸

Epoxidation of *exo*-hydroxymethyl substituted stereoisomers proceeds in a traditional way.¹⁴⁵

The hydroxy group in *endo*-5-hydroxynorborn-2-enes **45a,b** does not participate in cyclisation.¹⁴⁵ Shibasaki *et al.*¹⁹⁹ and, later, Holton and Kennedy²⁰⁰ have converted the alcohols **45a,b** into stable epoxy alcohols, which have been subsequently converted into various cyclised and rearranged products by treatment with potassium *tert*-butoxide in tetrahydrofuran.

$\text{R} = \text{H}$ (**45**), OCH_2Ph (**46**).

Epoxidation of acids of the norbornene series differs from that of alcohols in that in this case, the resulting epoxide intermediates are relatively stable. Thus, according to the data of IR spectroscopy, oxidation of acid **47** by perbenzoic acid yields initially an epoxy acid, which rapidly isomerises into hydroxy lactone **48**.¹⁴⁴

The lactone **48** can also be obtained from methyl 5-norbornenecarboxylate by treating it with performic acid. Treatment with other peroxy acids results in the conventional transformation of this ester into the epoxide.^{1,6} The different reactivity of hydroxymethyl and carboxyl groups towards cleavage of the oxirane fragment is reflected in the pattern of hydrolysis of epoxy lactone **49**.²⁰¹

It has been shown^{142,202} that epoxidation of dicarboxylic acids of the norbornene series is accompanied by lactonisation, if at least one of the carboxyl groups occupies an *endo*-position. Unlike substituted norbornenes, *endo*-acids and esters of the bicyclo[2.2.2]octene series are converted under similar conditions into mixtures of *exo*- and *endo*-epoxides and lactones; judging from the results of a special study,¹³⁸ the latter are produced only from *exo*-epoxides **50**.

Comparison of the behaviour of the two related bicyclic systems reveals two substantial points distinguishing bicyclo[2.2.2]octenes from substituted norbornenes, namely, the absence of *exo*-stereospecificity in the attack by a peroxy acid and a decrease in the ability to form lactones. Apparently, this is due to different degrees of strain and to specific conformational features of these systems.

It has been reported that the amide group can also participate in cyclisation.^{170,171}

Lactonisation of *endo*-carboxamides **51** ($R = \text{Alk, Ar, H; } R' = \text{Me}_3\text{N}$) occurs apparently *via* intramolecular rear attack by the carbonyl oxygen on the electrophilic centre in the intermediate 'alkene-peroxy acid' complex or in the intermediate compound. The corresponding *exo*-stereoisomers are readily converted into epoxides.^{173,174}

The formation of similar heterocyclic derivatives containing other heteroatoms has been little studied. Formation of epoxide from unsaturated sulfone has been reported.²⁰³ The attempt to obtain nitrogen-containing products of cyclisation from norbornenedicarboxamides failed.²⁰⁴ In 1994, substituted 4-azatri-cyclo[4.2.1.0^{3,7}]nonanes **53** (azabrendanes) were prepared by treatment of *endo*-(*N*-arylsulfonyl)bicyclo[2.2.1]hept-2-en-5-ylmethylamines with peroxyphthalic acid.^{205,206} The structure of the polycyclic cage of azabrendanes was confirmed by X-ray diffraction analysis.

Later, it was shown that the decrease in the basicity of the nitrogen atom following the replacement of the arylsulfonamide

group by perfluoroalkylsulfonamide group prevents intramolecular cyclisation.²⁰⁷ However, in the case of similar reactions of *endo*-ureas, substituted azabrendanes were isolated.²⁰⁸

exo-Stereoisomeric derivatives readily form epoxides under similar conditions.²⁰⁵⁻²¹⁰

VIII. Epoxidation of diene systems incorporating norbornene or related fragments

In the case of a favourable arrangement of the double bonds in a molecule of bicyclic diene, π -bonds may be involved in epoxidation, instead of σ -bonds which normally participate in transformations of norbornene; this should increase the probability of the *endo*-attack by a peroxy acid. In fact, the products of epoxidation of norbornadiene by perbenzoic, monoperoxyphthalic, or peroxyacetimidic acid were found to contain 13% of *endo*-epoxynorbornene.²¹¹ The stereoisomeric *endo*-epoxides synthesised from 7-methylnorbornadiene are stable upon refluxing in benzene containing traces of toluene-*p*-sulfonic acid.²¹² The oxidation of 7-phenylnorbornadiene gives no *endo*-epoxide, which might be due to coordination of the peroxy acid to the electron-donating benzene ring.²¹²

However, the major product of the oxidation of norbornadiene is *exo*-2,3-epoxynorborn-5-ene; the participation of a π -bond in the transformations precludes the traditional rearrangements (Wagner-Meerwein rearrangement, hydride shifts) and results in the formation of *endo*-bicyclo[3.1.0]hex-3-ene-6-carbaldehyde **54** in equilibrium with cyclic ether **55**.^{213,214} The transformation thus discovered is referred to as the Meinwald rearrangement. The different behaviour of the stereoisomeric *exo*- and *endo*-epoxides demonstrates the importance of a favourable arrangement of the frontier orbitals for donor-acceptor interactions to occur. These $\pi-\pi^*$ interactions reflect the general type of behaviour of norbornadiene in electrophilic reactions.

It should be noted that oxidation of norbornadiene with dimethyldioxirane yields both mono- and diepoxide;²¹⁵ the starting norbornadiene was prepared *in situ* by isomerisation of quadricyclene.

The rearrangement to bicyclic aldehydes induced by peroxy acids is also typical of *exo*-epoxides formed from 7-methyl- and 7-phenyl-norbornadiene;²¹² in the latter case, the main reaction product **56** undergoes epoxidation followed by cleavage of the

epoxide ring with rearrangement and by cyclisation being thus converted into side product **57**.

This rearrangement was used to prepare an intermediate compound in the synthesis of prostaglandins. Thus *exo*-epoxide **58** resulting from oxidation of 7-alkenylnorbornadiene (80%) was used in subsequent transformations.²¹⁶

Apart from the labile epoxides with alkyl substituents described above, their quite stable analogues **59** with electron-withdrawing alkoxy-carbonyl groups at the double bond are also known.²¹⁷ However, acid esters prepared *in situ* by enzymic hydrolysis of symmetrical diesters immediately undergo the Meinwald rearrangement giving bicyclo[3.1.0]hex-2-ene derivatives **60** in nearly quantitative yields.²¹⁷

The stability of the epoxides can be increased by introducing additional electron-withdrawing fragments. In fact, the 7-oxa-analogue of the epoxide **59** was prepared in a quantitative yield and used successfully in the synthesis of the nucleoside antibiotic cordycepin.²¹⁸

As opposed to norbornadienes, the less strained bicyclo[2.2.2]octadiene, on treatment with perbenzoic acid, adds only one equivalent of the acid, the addition occurring from the less shielded *endo*-side, which is richer in electrons.²¹⁹ When an excess of the peroxy acid was used, stable diepoxide was obtained. Based on barrelene **61**, mono-, di-, and tri-epoxides have been obtained.²²⁰ They can be isolated but are easily transformed in acidic media. Thus monoepoxide **62** is easily converted into cycloheptatriene-7-carbaldehyde.²²⁰

Oxidation of 7-alkoxynorbornadienes **63** occurs through *exo*-attack by a peroxy acid. Even in the case of 7-*tert*-butoxy-substituted derivative, despite the obvious steric hindrance, the reaction involves the *syn*-double bond.¹²²

However, a study has been published, which casts doubt upon the amazing electronic influence of the *tert*-butoxy group.²²¹ In fact, it was found that in the case of 7,7-diethoxynorbornadiene **64**, both multiple bonds undergo epoxidation. The structure of diepoxide **65** was reliably confirmed by NMR spectroscopy; however, the order of introduction of the epoxide fragments has not been studied in this work.²²²

In recent years, considerable attention has been devoted to epoxidation of dienes of the norbornene series containing exocyclic double bonds. It was shown that treatment of 7-isopropylidenenorbornene **66** with an equimolar amount of MCPBA results in selective epoxidation of the exocyclic double bond, the ratio of products **67** and **68** being equal to 34:66, due to the preferential *anti*-attack.^{139, 223}

A similar picture has also been observed for 9-isopropylidenebenzonorbornenes; the introduction of chlorine or fluorine atoms into the aromatic ring facilitates formation of the *syn*-product. Epoxidation of stereoisomeric 7,7-diphenylmethylene-*N*-methylnorbornene-2,3-dicarboximides **69** and **70** demonstrated that the stereochemistry of the dicarboximide group has crucial influence on the direction of the process.²²⁴

Epoxidation of 5-chloromethylnorborn-2-ene to give diepoxide **71** is described in a patent.²²⁵

Later, the product **71** and its tetracyclic analogue **72** were obtained from the adducts of cyclopentadiene with allyl chloride (or bromide).²²⁶

In recent years, particular attention has been devoted to epoxidation of available vinyl- and ethylenenorbornenes and the dimer of cyclopentadiene. Vinyl- and ethylenenorbornenes have been oxidised by peracetic, peroxyphthalic, *m*-chloro- and *p*-nitro-peroxybenzoic, and peroxyimide acids. Earlier, it has been noted that vinylnorbornene can be oxidised to give the monoepoxide by oxygen in the presence of nitropalladium complexes.^{126, 227, 228} When ethylenenorbornene is epoxidised by peracetic acid, the ratio of the products of oxidation at the endo- and exo-cyclic double bonds, found by ¹H NMR spectroscopy, is equal to 1 : 6.²²⁸ When equimolar amounts of the reactants are used, the reaction yields monoepoxides **73** and **74** incorporating a norbornene fragment.²²⁷

The monoepoxide **73** obtained using peroxyphthalic acid isomerises to give *endo*-5-acetylbicyclo[2.2.1]hept-2-ene. The different behaviour of the isomers is indicated by the fact that reactions of the diene with the above peroxy acids result in different ratios of the monoepoxides. Further epoxidation of the monoepoxides **73** and **74** affords stereoisomeric diepoxides.²²⁷

As the double bond moves away from the norbornene fragment, their mutual influence becomes less significant and the double bond in the ring becomes more reactive. Voronenkov *et al.*²²⁹ found that the logarithms of the rate constants for epoxidation are correlated with the first vertical ionisation potentials for a broad range of dienes of this type.

Numerous studies have been devoted to epoxidation of the cyclopentadiene dimer (CPDD) containing double bonds in the norbornene fragment and in the five-membered ring. The interest aroused by this object is due both to its accessibility and to the valuable properties of various polymeric materials based on epoxide derivatives of CPDD.²³⁰ Oxidation is usually carried out by peracetic,^{231, 232} peroxyphthalic,^{230, 233–235} and monoperoxy-maleic^{236, 237} acids (both free peroxy acids and those obtained *in situ* from the corresponding anhydrides and hydrogen peroxide have been used).^{233, 236}

The high sensitivity of the norbornene system in the transition state to steric effects results in that, of the four possible stereoisomers, only one product **3**, characterised by the *exo*-arrangement of both epoxide fragments, is produced. When the oxidant is in deficit, a mixture of monoepoxides is formed, the substituted epoxynorbornane being the major product.^{238, 239} The ratio of the monoepoxides depends substantially on the oxidant used.⁶⁴

It is of interest that during epoxidation of *endo*-tricyclo[5.2.1.0^{2,6}]dec-3-ene **75**, the attack occurs from the side of the methylene bridge, whereas the *exo*-isomer is attacked from the opposite side.

An attack by a peroxy acid from the *endo*-area has also been observed for polycyclic systems with a cyclobutene fragment.²⁴⁰

The oxidation of the corresponding alcohol occurs chemoselectively only at the cyclobutene fragment and is accompanied by intramolecular cyclisation.

Mono- and di-epoxidation of the norbornadiene dimer **76** has been accomplished.¹²⁹

The double bonds can be epoxidised successively or selectively; in particular, this occurs for the adducts of cyclic dienes with benzoquinone and their analogues ($n = 1, 2$).²⁴¹

The first stage of interaction of the diene **77** with peroxy acids is complicated by side processes,²⁴² whereas electrophilic epoxidation of the diene **78** occurs smoothly.²⁴³ Consecutive oxidation of a triene system has been described.²⁴⁴

Electron-withdrawing substituents decrease the nucleophilicity of the double bond in the bicycloheptane fragment of the norbornene and cyclopentadiene dimers; this results in selective epoxidation of the double bonds in the diene fragment. The syntheses of dieldrin (**79**), endrin (**80**), and other epoxides can serve as typical examples.^{194, 245, 246} In the case of heptachloro-derivative **81**, the oxirane fragment is *endo*-oriented.²⁴⁷

Of special interest are non-chemoselective reactions in which other fragments of the molecule are oxidised in parallel with the double bond.^{248–250}

However, by choosing appropriate peroxy acids and reaction conditions, one can attain a high degree of selectivity of the oxidation.²⁵¹

It should be noted that the epoxide **82** prepared from hydroxynorbornene cannot be obtained by epoxidation of the corresponding unsaturated ketone, because the double bond is deactivated by the electron-withdrawing carbonyl group, and the latter is selectively attacked by the peroxy acid.²⁵²

When the carbonyl group is located far from the double bond, stable epoxy ketones can be prepared, in particular, ketone **83**, which is a precursor of alkaloids of the tropane series.¹⁵¹

In most cases, epoxidation of ketones and alcohols is carried out with protected carbonyl or hydroxy groups, because the

epoxide derivatives of substituted norbornenes are especially unstable in the presence of acids.^{218, 251}

IX. Conclusion

In this review, the known methods for epoxidation of substituted norbornenes and dienes incorporating a norbornene fragment are described and diverse transformations accompanying epoxidation, in particular, molecular rearrangements, which often end with the formation of new heterocyclic systems, are considered. The information presented here demonstrates that norbornene and its derivatives occupy a special place in the chemistry of epoxidation of cycloalkenes. This is due to special structural features and to the strained character of the carbon cage, which predetermines the possibility of chemo- and stereoselective transformations during the oxidation of these compounds.

VI. Conclusion	291

Abstract. Reactions of nitrogen nucleophiles with haloalkenes in which the halogen atom occupies α -position with respect to an electron-withdrawing group are considered. Primary attention is devoted to the elucidation of the dependence of the reaction path on the nature of the nucleophile and substrate and on the reaction conditions. Possible mechanisms of nucleophilic substitution of vinylic halogen atoms in alkenes with activating and leaving groups attached to the same carbon atom are discussed. The bibliography includes 169 references.

I. Introduction

Modern strategy of organic synthesis is based on the use of polyfunctional but relatively simple building blocks in chemo-, regio-, and stereo-selective syntheses of complex molecules. In recent years, the methodologies of tandem and domino transformations have been actively developed. This makes it possible to minimise the number of synthetic steps, the expense, and the amount of wastes and to accelerate as much as possible the advance to the target objects.^{1,2} In the design of diverse complicated molecules, it is useful to proceed from compounds with so-called 'compositional functional groups'.³ Thus 'symbiosis' of a carbonyl (or cryptocarbonyl) group and a halogen atom at the α -carbon atom in a substrate not only activates each functional group but also opens up new prospects for the use of such substrates in synthesis.^{4,5} This type of compound is represented, for example, by haloalkenes **1** containing a geminal electron-withdrawing group (EWG). These derivatives are often used as the initial compounds in the syntheses of amino acid derivatives, various biologically important nitrogen-containing heterocycles, and analogues of natural compounds.

EWG = CN, COOR, C(O)R.

Uspekhi Khimii **67** (4) 317–332 (1998); translated by Z P Bobkova

The studies on reactions of haloalkenes activated by a geminal group with nitrogen-containing nucleophiles (referred to below as N-nucleophiles) began apparently in 1904, when Watson⁶ discovered the ability of piperidine to react with bromo(benzyl-idene)acetophenone yielding mono- and di-amino-derivatives. Further progress in this field appears to be a series of trials and errors, findings and delusions as follows from subsequent critical analyses of the early publications.^{7–9}

In this review, we attempt to trace the general regularities of the reactions of the haloalkenes **1** activated by geminal substitution with N-nucleophiles, which were mainly reported during the last 15 years.

In most cases, interaction of the haloalkenes **1** with N-nucleophiles can be represented by the following simplified scheme:

Hal = Cl, Br; EWG = CN (a), COOR (b), C(O)R (c), CHO (d).

The reaction products include Michael adducts **2**, substituted aziridines **3**, aminoalkenes with a vicinal (**4**) or geminal (**6**) activating group, and α,β -diamino-derivatives **5**. Other routes of transformations involving the activating group or the functional groups in the substituent are also possible. Even slight changes in the structure of the initial substrate or in the nature of the nitrogen-containing nucleophile, variation of the temperature, the solvent, the molar ratio and the order of mixing of the

reactants, *etc.* often result in the formation of absolutely different reaction products. Despite certain difficulties of prediction, some general rules governing the reactivity of the haloalkenes **1** in reactions with N-nucleophiles have been discovered. Thus the nature of the activating EWG is a crucial factor in all the cases considered. Analysis of the published data makes it possible to claim that the reactivity of the haloalkenes **1** with geminal substitution increases with increase in the electron-withdrawing properties of the EWG. In terms of their activating capacity, these groups can be arranged in the sequence $\text{CN} \leq \text{COOR} < < \text{C(O)R} < \text{CHO}$,¹⁰ which shows a good correlation with the activity series of unsaturated compounds of the $\text{CH}_2 = \text{CH} - \text{EWG}$ type in the Michael reaction with amines.¹¹

II. Reactions of haloalkenes activated by geminal groups with N-nucleophiles

1. Haloalkenes activated by a cyano group

As should be expected, haloalkenes **1a** with a *gem*-cyano group enter into the Michael reaction with secondary amines yielding initially β -amino- α -halo-derivatives **2a**. The chloro-derivatives have been isolated in a pure state.¹² Secondary amines and phthalimide add to α -chloroacrylonitrile on refluxing in methanol.¹³ The addition of diphenylmethyldeneamine to the same substrate occurs under mild conditions and gives no side products.¹⁴

The replacement of chlorine in the initial nitrile by bromine decreases the stability of the Michael adducts to such an extent that the corresponding β -amino- α -bromo-derivative **2a** cannot be even detected. In this case, the addition of amine is accompanied either by substitution of the halogen atom giving α,β -diamino-derivative **5a** or by elimination of hydrogen bromide giving rise to substituted β -aminoacrylonitriles **4a**.¹⁵

The use of sterically hindered amines (benzimidazole, 1,2,4-triazole) or substrates containing bulky substituents at the β -position usually results in the formation of β -aminoacrylonitriles **4a** as the only^{16–18} or predominant^{19,20} products. However, there are some exceptions. For example, treatment of furylhaloacrylonitriles **7a,b** with secondary amines (piperidine, morpholine, diethylamine) yields mixtures of α -amino- (**8a,b**) and β -amino- (**9a,b**) derivatives,^{19,20} whereas treatment with azides affords α -substituted acrylonitriles **10a** as the only products.²¹

Reactions of the cyanoalkenes **1a** with primary amines generally occur according to the scheme given above. However, in this case, there is a possibility of intramolecular cyclisation of the products **2a** to the corresponding aziridines. In fact, primary aliphatic and aromatic amines and even ammonia readily react with α -haloacrylonitriles **1a** to give aziridines **3a** in high yields.^{22–26} The stereochemistry and the mechanism of the addition have been studied.^{22,26}

The fact that the aziridine derivatives **3a** are actually formed *via* the Michael adduct **2a** was proved by detecting the latter by spectroscopy²² and by isolating it as a salt.²⁷ However, some examples have been reported in which the expected aziridines were not formed, and the adduct **2a** either remained unchanged^{13,28} or was converted upon dehydrohalogenation into 3-aminoacrylonitrile of type **4a** with a secondary amino group. This rare situation is realised, for example, for the nitriles **7b,c**, which react with primary amines giving only β -aminoacrylonitriles **9b,c** in good yields.²⁹

2. Haloalkenes activated by an ester group

Similar transformations have been observed in the series of haloalkenes **1b** activated by a geminal ester group. A distinctive feature of this type of reaction is that in some cases, the activating group also reacts with amines. As in the series of α -haloacrylonitriles **1a**, the outcome of the reaction depends on the nature of the amine, the structure of the substrate (the presence of substituents, the nature of the halogen), and the experimental conditions.

The use of bulky or weakly basic nucleophiles as well as very active Michael acceptors leads to termination of the reaction at the initial stage, when the products of the addition at the double bond have been formed. For example, the reaction of purine bases with methyl α -chloroacrylate (**11a**) or α -bromoacrylate (**11b**) affords the corresponding Michael adduct in high yield.³⁰

Hal = Cl (**a**), Br (**b**); R¹ = NH₂, R² = H; R¹ = Cl, R² = H; R¹ = R² = Cl.

A similar situation is observed when haloacrylates containing weakly nucleofugal fluorine are used. The suggestion³¹ that the ester group in α -fluoroacrylates might undergo ammonolysis by secondary and primary amines and by ammonia proved to be faulty. The attack by the N-nucleophile is directed at the β -carbon atom of the double bond and results in the formation of esters of *N*-mono- or *N,N*-di-substituted α -fluoro- β -alanine.³² No amides have been found among the reaction products.

R¹, R² = (CH₂)₅, (CH₂)₂; R¹ = R² = Et; R¹ = cyclo-C₆H₁₁, R² = H.

A mixture of diastereomeric products of conjugated addition **13** was obtained upon the interaction between equimolar amounts of a secondary amine and 3-chloro(or bromo)-5-methoxy-5*H*-furan-2-one (**12a,b**). In this case, the attack by the nucleophile occurs mostly from the side opposite to the methoxy group.³³

R₂N = N, N, Et₂N.

Primary amines and ammonia readily react with α -haloacrylates **1b** normally yielding the corresponding aziridines of type **3b**.^{34–38} The formation of the addition products was detected by

NMR spectroscopy,³³ and in the case of α -haloacrylic acids, the adducts were isolated as salts.³⁹

It should be emphasised that the structures of the substrate and the nucleophile as well as experimental conditions influence the reaction pathway so strongly that even slight variations often have fundamentally significant consequences. Thus replacement of bromine by chlorine in bromofuranone **12b** changes the direction of the nucleophilic attack: the reaction of 3-chloro-5-methoxy-5*H*-furan-2-one **12a** with benzylamine yields unexpectedly pyrrolinone **15** rather than the Michael type adduct **14** as the major product.³³

Methyl α -bromoacrylate prepared from methyl α,β -dibromopropionate reacts with 1,1-disubstituted hydrazines to give hydrazones **16** or **17** depending on the basicity of the N-nucleophile.⁴⁰

The influence of the experimental conditions on the reaction of α -haloacrylates with N-nucleophiles is clearly illustrated by the reaction of methyl bromo(4-*tert*-butylcyclohexylidene)acetate **18a** with benzylamine. At room temperature and atmospheric pressure, isomeric spiroheterocyclic compounds **19a,b** are formed as the only reaction products (yield 83%–85%). High pressure markedly increases both the rate and stereoselectivity of the reaction: the ratio of diastereomers with equatorial (**19a**) and axial (**19b**) orientation of the nitrogen atom ranges from 1.7:1 under ordinary pressure to 10:1 at 11 kbar. Refluxing a methanolic solution of the ester **18a** with two equivalents of benzylamine gives rise to a mixture of α -amino ester **20a** and the corresponding amide **20b**.^{36–38}

(a) MeOH, Δ , 18 days; (b) MeOH, 11 kbar, 25 °C, 4 days.

Aziridine derivatives can be easily obtained by reaction of primary amines with α -halo α,β -unsaturated esters.^{41–43} The ratio of *cis*- and *trans*-aziridines depends substantially on the solvent used. For example, the reaction of methyl α -bromocinna-

mate **21a** with primary amines in methanol yields *cis*-**22a** as the main product, whereas in benzene, the proportion of the corresponding *trans*-isomer increases to 45%.^{41,42} In the case of substrates **21b** containing a fluoroalkyl group at the β -position, closure of the aziridine ring is accompanied by amidation giving rise to compounds **22b**. This result has been attributed⁴³ to the influence of the electron-withdrawing polyfluoroalkyl substituent, which considerably enhances the reactivity of the ester group.

$R^1 = \text{Ph}$, $R^2 = \text{Me}$ (**a**); $R^1 = \text{CF}_3$, CHF_2CF_2 ; $R^2 = \text{Et}$ (**b**);
 $R^3 = \text{Me}$, C_6H_{13} , Bn .

Interesting results along this line have been obtained by de Meijere *et al.*^{44–46} As models, these researchers chose 2-halo-cyclopropylideneacetates **23**, which are highly reactive Michael acceptors. The higher reactivity of these compounds compared to other 3,3-disubstituted acrylates has been rationalised^{3,45,47} by the fact that the formation of the Michael adduct relieves the overall strain of the system, because during this reaction the *sp* hybridised carbon atom in the ring goes into the *sp*² hybridisation state. In fact, esters **23** easily add one equivalent of an N-nucleophile giving rise to 1'-substituted 2-chloro(or bromo)-2-cyclopropylacetates usually in good yields and with no side products.^{14,47–50}

$n = 0–4$; $\text{Hal} = \text{Cl}$; $R^1 = \text{Me}$, Bn , Bu^t ; $\text{Hal} = \text{Br}$; $R^1 = \text{Me}$;
 $\text{HNu} = \text{NH}_2\text{R}^2$, HNR_2^2 , HNAC_2 , $\text{HN}=\text{CPh}_2$, $\text{HN}=\text{CAR}_2$,
 $\text{HN}=\text{C(R)Ar}$, phthalimide.

However, in the case of primary amines, smooth addition to the substrates **23** is often accompanied by secondary reactions involving the chloromethine or alkoxy-carbonyl group. Acetamide and phthalimide, which are less nucleophilic, either do not react at all or give Michael adducts in low yields.⁴⁷ The best results were obtained in the reactions of chloro-substituted esters **23** with highly basic secondary amines and with diphenylmethyldeneamine in methanol. Aprotic and less polar solvents (DMF, Et_2O , CH_2Cl_2) markedly decreased the rate of addition.¹⁴ The halogen atoms in the Michael adducts tend to be substituted by other nucleophiles including amines. Thus the reaction of methyl chloro(cyclopropylidene)acetates **23a–e** with a five- or seven-fold excess of secondary amines leads to addition–substitution products **25** in good isolated yields.⁵¹

$n = 0$ (**23a**), 1 (**23b**), 2 (**23c**), 3 (**23d**), 4 (**23e**);
 $\text{X} = \text{OMe}$ (**24**), NR_2 (**25**); $\text{NR}_2 = \text{NMe}_2$, NEt_2 , N (cyclohexyl).

The outcome of the reactions of the esters **23a–e** with diethylamine, which is the bulkiest among the nucleophiles used, depends on the number of substituents in the cyclopropane ring of the

substrate. Tetramethyl-substituted chloro(cyclopropylidene)-acetate **23e** does not react with diethylamine even on prolonged refluxing (24 h, 70 °C). The substrate **23d** with three methyl groups in the ring is converted into **24** ($R = \text{Et}$). The formation of this product was rationalised by assuming the initial addition of diethylamine followed by substitution of the chlorine atom by methanol. The reaction of the dimethyl derivative **23c** with diethylamine under the same conditions affords two products, **24** and **25**. Finally, methyl chloro(cyclopropylidene)acetate **23a** with a non-substituted ring reacts with diethylamine giving rise to the Michael adduct and diamino ester **25** ($n = 0$, $R = \text{Et}$).

Methyl chloro(cyclopropylidene)acetate **23a** readily adds diphenylmethyldeneamine to give the corresponding adduct in 98% yield. Under certain conditions, the latter undergoes intramolecular substitution of chlorine and subsequent rearrangement being thus converted into β -aminocyclobutenecarboxylate or an isoquinoline derivative.^{52–54}

B is base.

The addition of N-nucleophiles to the double bonds of the compounds **23** or their analogues containing substituents other than methyl is usually highly diastereoselective. The nucleophilic attack occurs at the *trans*-position in relation to the bulkiest substituent in the cyclopropane ring.^{51,55,56}

$R^1 = \text{Me}$, Bn ; $R^2 = \text{Me}$, Et , CH_2OMe , CH_2OBn , SMe .

On passing from the chloro(or bromo)(cyclopropylidene)acetates **23** to alkyl bromo(cyclohexylidene)acetates **18a,b**, the reaction route changes sharply. Thus prolonged (3–24 days) refluxing of methyl (**18a**) or ethyl (**18b**) bromo(4-*tert*-butylcyclohexylidene)acetate with acyclic or heterocyclic secondary amines affords either one product of bromine substitution or a mixture of two products, depending on the solvent used. When the reaction is carried out in the corresponding alcohol (methanol or ethanol), methyl or ethyl amino(4-*tert*-butylcyclohex-1-enyl)acetate **26a,b** is formed as the only product in a good yield. Conversely, the reaction in toluene always yields a mixture of the amino ester **26a,b** and its isomer **27a,b**.³⁸ No Michael adduct of type **2b** or product of halogen *ipso*-substitution like **6b** was detected. Sterically hindered secondary amines (for example, 2,2,6,6-tetramethylpiperidine) do not react with the esters **18a,b**.

The reaction of amines with the same substrate **18a** at elevated pressures leads to absolutely different results.^{37, 38} In this case, the solvent (methanol) acts as a reactant, and adduct **28** is formed in 60%–70% yield together with a small (up to 9%) amount of the amino ester **26a** ($\text{R}^2 = \text{Et}$) or compound **29** (for reactions in the presence of di- and triethylamine, respectively). It is noteworthy that, as in the case of benzylamine, the nucleophilic attack of methanol results in predominant (up to 90%) formation of the isomer of **28** in which the methoxy group is equatorial. In the absence of amines or when dichloromethane is used as the solvent, the initial substrate **18a** remains unchanged under the same conditions (11 kbar, 25 °C).

Finally, the reaction of lithium piperidide with **18a** involves unexpectedly only the ester group, which is converted into an amide group. The double bond and the halogen atom remain intact.

The reaction of piperidine with methyl 3-aryl-2-haloacrylates **30a,b** occurs according to the classical addition–substitution pattern and yields a mixture of isomeric 2,3-dipiperidino-derivatives **31a** and **31b**, the *threo*-isomers **31b** being the predominant products.⁵⁷

$\text{Hal} = \text{Cl (a), Br (b)}; \text{Ar} = \text{Ph, 4-MeC}_6\text{H}_4, \text{4-BrC}_6\text{H}_4, \text{4-ClC}_6\text{H}_4, \text{4-O}_2\text{NC}_6\text{H}_4.$

Kinetic studies showed⁵⁷ that the rate of this reaction depends on the nature of substituent in the benzene ring, configuration of the alkene, and the nature of the halogen. For example, methyl (*E*)-2-bromo-3-phenylacrylate **30b** ($\text{Ar} = \text{Ph}$) reacts at 40 °C with piperidine 1200 times faster than the corresponding *Z*-isomer. Replacement of bromine in the substrate **30b** ($\text{Ar} = \text{4-O}_2\text{NC}_6\text{H}_4$) by chlorine decreases the reaction rate constant by a factor of ~6. Based on the kinetic measurements, it was concluded⁵⁷ that the nucleophilic attack at the β -carbon atom of the alkenes **30a,b** is the rate-determining step of the process.

A large series of studies^{58–68} have been devoted to 3-halocoumarins **32a** and 3-halothiocoumarins **32b**, which can be regarded as cyclic esters. The discussion about the routes for their transformation induced by N-nucleophiles is still being continued. In principle, nucleophilic attack can be directed at any of the three electrophilic centres — at positions 2, 3, or 4.

In fact, the interaction of highly basic amines with 3-halocoumarins **32a** containing a hydrogen atom at the 4-position ($\text{R}^1 = \text{H}$) gives rise to complex mixtures of products (Scheme 1) in which the *ipso*- and *syn*-substitution products **33a** and **34a** are the major components.^{58, 59, 67} However, in some cases, the reaction is accompanied by pyrone ring contraction and yields benzofuran derivatives **36a**.^{60, 63} In the series of thio-derivatives **32b**, benzo-thiophene **36b** is, as a rule, the only reaction product.^{62, 63}

It is quite probable that the ring contraction reaction follows a domino transformation pattern. First, the ring is cleaved giving amides **35a,b**, which can be isolated in some cases.^{60, 64} The resulting hydroxy (or thiol) group participates in the substitution of bromine, and this gives furan (**36a**) or thiophene (**36b**) derivatives. The driving force of these transformations is the creation of an aromatic system. This pathway is realised more easily in the case of thio-derivatives **32b** owing to the higher nucleophilicity of the thiol group in the intermediate amide **35b**.^{62, 63}

The transformation of halo-coumarins **32a** and -thiocoumarins **32b** containing a methyl group at the 4-position includes initial 1,3-shift of the methyl proton. The subsequent substitution of the allylic halogen yields either the corresponding aminomethyl derivatives **37a,b**⁶⁵ or their mixtures with the products of nucleophilic vinylic substitution **38a**,^{66–68} depending on the nature of the amine.

Scheme 1

3. Haloalkenes activated by a carbonyl group

The haloalkenes **1c** and **1d** with a geminal acyl or formyl group are the most reactive towards N-nucleophiles. The possibility of condensation at the keto and especially formyl group extends the spectrum of the transformations observed.

Similarly to esters and nitriles, α -halo α,β -unsaturated aldehydes and ketones react with secondary amines giving rise to α -, β -, or γ -amino-derivatives of α,β -unsaturated carbonyl compounds.^{16, 69–83} Thus reaction of 4-bromocholest-4-en-3-one **39** with heterocyclic amines affords a mixture of 4- and 6-amino-substituted cholestenones, **40** and **41**, respectively, the isomer **41** being the major product in all cases.^{77, 78}

Impressive results have been obtained in a study of the temperature dependence of the regioselectivity of the amination of bromobenzotropone **42** with dimethylamine.⁸¹ An increase in the temperature is favourable for the formation of the *ipso*-substitution product **43**. At 0 °C, β -amino-derivative **44** is formed specifically, whereas the reaction at 120 °C yields amino ketone **43** as the only product.

The reactions of 3-haloalkenones **45b,c** with amines yield in all cases only 3-aminoalkenones **46b,c**. However, when **45a** is introduced in this reaction, both the *ipso*-substitution products **46a** and compounds **47** are formed. In some cases, the reaction is accompanied by the γ -pyrone ring contraction and gives derivatives **48**.^{70–74, 82, 83} This difference between the behaviours of these compounds has not yet received any plausible explanation.

Complex mixtures containing *syn*-substitution products **50**, bridged compounds **51**, and lactams **52** are formed under mild conditions when α -bromo ketone **49** is made to react with primary amines. Secondary amines react with the same substrate giving rise to the corresponding β -enamino ketones **50**.⁸⁰

Nevertheless, in most cases, the reaction of 2-haloalk-2-enones **53** with ammonia and primary amines, like the reactions in the series of nitriles and esters, proved to be a versatile and efficient method for the synthesis of aziridinyl ketones **54**.^{84, 85} including those containing polyfluoroalkyl substituents.^{86, 87}

Hal = Cl, Br; R¹ = Me, Ph, CF₃; R² = Me, Bn, cyclo-C₆H₁₁, C₆H₁₃;
Ar = Ph, 4-PhC₆H₄.

The main limitation in the synthesis of the aziridines **54** is the steric accessibility of the nitrogen atom. The carbon atom attached to the amino group should not be tertiary.⁸⁵ Thus *tert*-butylamine does not form the corresponding aziridines **54** with α -bromoaldehydes,⁸⁵ although some nitriles of type **1a** and some aldehydes of type **1d** can be converted into aziridine derivatives with a *tert*-butyl group.^{24, 88}

At the same time, the reaction often involves a carbonyl group. For instance, 2-bromo-3-phenylinden-1-one **55** reacts with N-nucleophiles containing a primary amino group to give ketimine derivatives of aziridines **56**⁷⁵ or of the initial bromo ketones **57**.⁸⁹

R = OH, NHPH.

A similar situation has been observed for 2-haloalk-2-enals **1d**.^{88, 90, 91} Thus 2-chloropropenal **58a** and 2-chlorobut-2-enal **58b** react with three equivalents of a primary amine giving rise to azomethine derivatives of aziridines **59a,b**.⁸⁸ Interestingly, the reaction of the aldehyde **58a** with a twofold excess of amine affords a small amount of aziridine derivative **60** together with the azomethine **59a**.⁸⁸

R¹ = H (a), Me (b); R² = Et, Pr^t, Bu^t.

The condensation of 3-alkyl-2-fluorobut-2-enals **61** with *tert*-butylamine involves only the aldehyde group and results in the formation of aldimines **62**.⁹¹ Neither the double bond nor the fluorine atom participate in the process.

R = Me, Et, Bu^t.

The reactions of secondary amines with 2-haloalk-2-enals **58a–i** follow an unusual pathway and give an array of polyfunctional unsaturated compounds.^{9, 92–95}

The predominant route of transformations is mostly determined by the structure of the initial substrate. Thus the interaction of 2-chloropropenal **58a** with secondary amines gives mostly 1,3-diamino-2-chloropropenes **64a** [Scheme 2, pathway (b)]. The same reaction route is observed for 2-fluorobut-2-enal **58c**. Conversely, the reactions of 3-alkyl(or aryl)-2-chloro(or bromo)alk-2-enals **58b,d–g** with highly basic secondary amines normally yield *ipso*-substitution products **63b,d–g** as the major products [pathway (a)]. This route competes with fragmentation [pathway (c)], which results in the formation of carbonyl compounds **65b–h** and unsaturated diamines **66**. When the initial substrate contains a second alkyl substituent at the β -position (aldehyde **58h**), the *N*-formyl derivative of the initial amine **67** [pathway (d)] is produced, in addition to the substitution product **63h**, in a comparable amount. The presence of two phenyl groups in the substrate (**58i**) makes it completely inert towards secondary amines.

Scheme 2

R¹ = R² = H, Hal = Cl (a); R¹ = Me, R² = H, Hal = Cl (b), F (c), Br (d); R¹ = Pr, R² = H, Hal = Cl (e); R¹ = Ph, R² = H, Hal = Cl (f), Br (g); R¹ = R² = Me, Hal = Cl (h); R¹ = R² = Ph, Hal = Cl (i);

NR³ = NEt₂, NBu₂, N-pyrrolidine, N-piperidine, N-morpholine.

The selectivity of the reaction does not correlate with the basicity of the nucleophile. Indeed, piperidine, pyrrolidine, and diethylamine in which the nitrogen atoms are close in basicity and steric accessibility react with the same substrate **58b** according to pathways (a), (b), and (c), respectively.⁹⁴ Aprotic solvents (benzene, THF, pyridine) facilitate the *ipso*-substitution reaction [pathway (a)], whereas in protic solvents, pathway (c) prevails.^{94, 95}

Considerable interest was aroused by the reaction of 2-haloalk-2-enals with alkylaminotrimethylsilanes **68** containing an N–H bond. These nucleophiles could behave like secondary amines being involved in, for example, *ipso*-substitution of halogen or like aminosilanes with a tertiary amino group, which would result in the formation of 1,2- or 1,4-addition products.⁹⁶ It turned out that the aldehydes **58b,f,g,i** readily react with one equivalent of the alkylaminotrimethylsilane **68** giving rise to the products of 1,2-addition (**69b,f,g,i**) and/or 1,4-addition (**70b**). The adducts **69b,f,g,i** are unstable; they eliminate siloxane to give aldimines **71b,f,g,i**. This is a facile and efficient method for preparing valuable azomethine derivatives of 2-haloalk-2-enals.⁹⁷

$\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$, $\text{Hal} = \text{Cl}$ (**b**); $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$, $\text{Hal} = \text{Cl}$ (**f**); $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$, $\text{Hal} = \text{Br}$ (**g**); $\text{R}^1 = \text{R}^2 = \text{Ph}$, $\text{Hal} = \text{Cl}$ (**i**); $\text{R}^3 = \text{cyclo-C}_6\text{H}_{11}$, Bn , Ph .

To summarise the foregoing, it should be emphasised that although most of these transformations are described by a common scheme, it is often difficult to predict the outcome of reactions of haloalkenes, activated by geminal substitution, with N-nucleophiles. Nevertheless, the regularities discovered promote the intense use of haloalkenes **1a–d** in the synthesis of various heterocyclic compounds.

III. Reactions of haloalkenes activated by geminal groups with binucleophiles

Reactions of haloalkenes **1** with bidentate nucleophiles of various types (from α,α to α,ω) have resulted in the synthesis of a wide range of N-, S-, or O-containing heterocyclic derivatives. It is significant that these reactions are usually highly chemo- and regio-selective.

A possible route for interaction of the alkenes **1a–d** with binucleophiles is conjugated addition at the double bond. Depending on the activity of the electron-withdrawing substituent, the process is either terminated at the stage of formation of the Michael adduct **2a–d** or proceeds further as subsequent transformations of the adduct; these include nucleophilic substitution of the halogen atom [Scheme 3, pathway (a)] or nucleophilic attack at the activating group giving rise to a halo-containing heterocyclic derivative, which often undergoes subsequent transformations [pathway (b)]. The process can be directed at one or another route by varying the type of the activating group, the nature of the nucleophile, or experimental conditions.

Scheme 3

$n = 0-6$; $\text{X} = \text{Y} = \text{NR}^3$; $\text{X} = \text{NR}^3$, $\text{Y} = \text{O}$; $\text{X} = \text{S}$, $\text{Y} = \text{NR}^3$; $\text{R}^3 = \text{H}$, Alk , Ar ; $\text{Z} = \text{O}$, NH .

Thus phenylhydrazine readily adds to the double bond of 2-chloroacrylonitrile to give 2-chloro-3-phenylhydrazinopropionitrile **72** in a high yield; this product cyclises to give 1,5-disubstituted pyrazole **73**. In the case of more basic ethylhydrazine, the addition at the double bond involves the secondary amino group of the hydrazine, and this results in the formation of 1,3-disubstituted pyrazole **74**.²⁸

Despite the fact that unimolecular reactions are favourable from the entropy viewpoint, reactions of haloalkenes **1a–d** with N,N-binucleophiles can give rise to both intra- and inter-molecular cyclisation products. For instance, reaction of α -bromo α,β -unsaturated ketone **75a** with ethylenediamine affords derivative **76**.⁹⁸ 2-Bromoacrylonitrile **75b** reacts with hexamethylenediamine in a similar way and gives bis-aziridine **77** in a high yield.²⁴ Conversely, the reaction of ethyl α -bromoacrylate **75c** with ethylenediamine initially proceeds by a usual pathway but then an amide ring is closed, and 5-oxo-7-phenyl-1,4-diazanorcan **78** is formed as the final product.⁹⁹

$\text{EWG} = \text{COPh}$, $\text{R} = \text{R}^F$ (**75a**); $\text{EWG} = \text{CN}$, $\text{R} = \text{H}$ (**75b**); $\text{EWG} = \text{COOEt}$, $\text{R} = \text{Ph}$ (**75c**).

The reaction of substituted 2-bromoacrylonitrile **7b** with S-methylisothiourea leads to pyrimidine **79**.¹⁰⁰

Pyrimidine derivatives have also been obtained in reactions of urea and thiourea with β -substituted α -haloacrylates.^{101–104}

The influence of the steric accessibility of the nitrogen atom in the nucleophile on the direction of the attack has been demon-

strated in a number of studies.^{103–105} Thus benzamidine **80** ($R^3 = H$) with a primary amino group converts haloalkenes **1b–d** into pyrimidinones **81**. Mono-*N*-substituted amidines react with the same substrates under the same conditions giving rise to 2-imidazoline derivatives **82** (Scheme 4).

$R^1 = Ph, 4-ClC_6H_4, 4-MeC_6H_4$; $R^2 = H, Me, Bu^t, Ph, OMe, OEt$;
 $R^3 = H, Me, Pr^i, Bn$.

Hydroxylamine reacts with α -bromo- β -glycosyl α,β -unsaturated nitriles **83a** and ketones **83b** as an N,O-binucleophile affording isoxazole derivatives **84a** and isoxazoline derivatives **85b**, respectively (Scheme 5).^{20, 106, 107} The positions of substituents in the N,O-heterocycle make it possible to draw conclusions about the direction of the primary nucleophilic attack. As a rule, the nitrogen atom in N,O-binucleophiles proves to be more nucleophilic. However, rare examples of formation of isoxazoles in which the β -carbon atom of an alkene is bound to the oxygen have also been reported.^{20, 108}

EWG = CN (**a**), Ac (**b**); $R = H, OMe, OBn, CF_3CONH$.

Conversely, in the case of N,S-binucleophiles, the sulfur atom is more nucleophilic and adds at the double bond. The resulting Michael adduct with a free amino group participates in cyclocondensation involving either the α -carbon atom or the activating group.^{52, 109–113} Thus the reaction of 4-sulfanylazetidinone **86** with benzyl 2-bromo(cyclopropylidene)acetate yields a mixture of epimeric cyclopropanespiro-2-bisnorpenicillanates **87**.¹¹³ The formation of the ester **88** from benzyl α -bromocrotonate and the same binucleophile **86** was interpreted¹¹² by assuming isomerisation of the intermediate product of S-addition of the nucleophile.

HMPT is hexamethylphosphotriamide.

A clear illustration of the influence of the nature of the base used on the direction of cyclisation has been reported by Wessjohann and de Meijere.⁵² Treatment of α -chloroacrylate **23a** with 2-aminoethanethiol in the presence of K_2CO_3 gives rise to 1,4-thiazine derivative **89**, whereas the use of KOH under the same conditions results in the formation of seven-membered heterocycle **90**.

Reactions of N,N-, N,C-, and N,S-binucleophiles with α -halo α,β -unsaturated ketones **1c** begin with halogen substitution, which is followed by intramolecular interaction of the free amino group with the carbonyl carbon atom leading to cyclisation.^{89, 114–118} This route is realised, for example, when *o*-amino-benzenethiol is made to react with 2-bromo-3-phenylindenone **55**; this reaction results in the formation of compound **91** with a 1,4-benzothiazine ring.^{89, 115}

As a rule, reactions of haloalkenes **1** with binucleophiles afford heterocyclic compounds. However, in some cases,^{18, 29, 80, 119} β -aminoalkenes of type **4** have been obtained as the reaction products. This cannot be always explained by steric hindrance at the electrophilic centre of the substrate or by steric inaccessibility of a particular heteroatom in the nucleophile.

IV. Reactions of polyhaloalkenes with N-nucleophiles

Di- and tri-haloalkenes **92** and **93** are even more reactive and are widely used in organic synthesis. The presence of a halogen atom at the β -carbon atom sharply changes the general pattern of interaction of haloalkenes **1a–d** with N-nucleophiles. It is known that a halogen atom located in the β -position in relation to an activating group can be readily substituted. Therefore, compounds of this type have served as the basis for the preparation of various β -functionally substituted α,β -unsaturated carbonyl compounds and their analogues.^{120, 121}

The difference between the reactivities of halogen atoms occupying different positions with respect to an activating group is so great that reactions of N-nucleophiles with α,β -di- (**92**) and α,β,β -tri-haloalkenes **93** involve almost in all cases the β -halogen atom, whereas α -halogen remains absolutely inert. Thus primary and secondary amines enter into a tandem addition–elimination reaction with chiral dihalo(menthyloxy)furanone **94** to replace the β -halogen atom with high enantioselectivity.^{122–124}

Hal = Cl, Br; $\text{R}^1\text{R}^2\text{N} = (\text{CH}_2)_4\text{N}$, $\text{O}(\text{CH}_2\text{CH}_2)_2\text{N}$, BnNH , $\text{PhCH}(\text{Me})\text{NH}$; $\text{R}^3 = 1\text{-menthyl}$.

Secondary amines replace only the β -halogen atom in tri-fluoroacrylonitrile under mild conditions.¹²⁵ Of all possible paths of interaction of unsaturated perfluoro ketones **95a,b** with amines or binucleophiles, only chemoselective substitution of the vicinal fluorine atom does occur. The reaction with piperidine results in the formation of product **96a**. In the case of binucleophiles, this is followed by Michael cyclisation yielding imidazolidines **97a**.^{126, 127} The reaction of ketone **95b** with *o*-aminobenzenethiol gives substituted benzothiazepine **98b**. The primary attack by the thiol group in this reaction was confirmed by NMR monitoring.¹²⁷

$\text{R} = \text{H}$, Me; $\text{Ar} = \text{Ph}$ (**a**), 4- FC_6H_4 (**b**).

At first glance, these data seem to be at variance with the results obtained by Nguyen *et al.*¹²⁸ The reaction of *N,N*-diethylperfluorocrotonamide **99** with lithium diethylamide under mild conditions gave a mixture of isomeric α - (**100**) and β - (**101**)

diethylamino-derivatives in $\sim 3:1$ ratio. It is clear that in this case, the regioselectivity of nucleophilic substitution is influenced by the highly electron-withdrawing trifluoromethyl group.

The reactions of primary and secondary amines and also *N,N*- and *N,O*-bidentate nucleophiles with α,β,β -trichloro-substituted unsaturated ketones **102a,b** involve exclusively the β -chlorine atoms and give polyfunctional compounds **103a,b** and **104**.^{129, 130} No trisubstituted products or products of reaction at the carbonyl group are formed even with excess nucleophile. When the nucleophile:substrate ratio is decreased to 1:2, some of the initial ketone is recovered unchanged, but no monosubstituted products arise.¹³⁰

$\text{Y} = \text{CHCl}_2$ (**a**), CF_3 (**b**); $\text{X} = \text{NH}$, O ; $\text{R}^1\text{R}^2\text{N} = \text{PhMeN}$, PhNH , Bu^tNH ,

When β -bromo- α,β -dichloroacrolein **105a** is treated with primary amines, the replacement of the β -halogen atoms is accompanied by condensation at the aldehyde group resulting in the formation of 1,1-diamino-2-chloro-3-iminoprop-1-enes **106**.¹³¹ Neither an increase in the excess of amine nor raising the temperature lead to substitution of the α -chlorine atom.

On treatment with secondary amines, trihaloacroleins **105b–e** are unexpectedly converted into dihaloacrylamides **107b–e**.^{132, 133} it was found¹³³ that halogen was eliminated from the β -carbon atom. Based on this conclusion, a possible reaction mechanism was proposed that included primary nucleophilic attack on the carbonyl group of the substrate.

$\text{X} = \text{Y} = \text{Cl}$, $\text{Z} = \text{Br}$ (**a**); $\text{X} = \text{Y} = \text{Z} = \text{Cl}$ (**b**); $\text{X} = \text{Br}$, $\text{Y} = \text{Z} = \text{Cl}$ (**c**); $\text{X} = \text{Cl}$, $\text{Y} = \text{Z} = \text{Br}$ (**d**); $\text{X} = \text{Y} = \text{Z} = \text{Br}$ (**e**); $\text{R}^1 = \text{Ph}$, Bn , 2,4- $\text{Me}_2\text{C}_6\text{H}_3$;

The α -halogen atom in α,β -dihaloalkenes of type **92** can be involved in the reaction only in rare cases. For instance, reaction of 4,5-dichloro-3(2*H*)-pyridazinones **108** with N-nucleophiles affords either the product of substitution of only the β -halogen

Table 1. Reactions of pyridazinones **108** with N-nucleophiles.

HNR ₂ ²	R ¹	Solvent	t/h	Yield (%)		Ref.
				109	110	
	H	EtOH, Et ₃ N	4	40	—	134
	Me			50	—	
	Ph			50	—	
	H	BuOH	4	60	0	135
	Me	EtOH	4	73	7	135
	BnOCH ₂	H ₂ O	11	41	4	136
		PhMe	11	21	13	136

atom **109**¹³⁴ or a mixture of isomeric α - and β -amino-derivatives **110** and **109**, the latter being formed in substantially (up to 10 : 1) larger amounts (Table 1).^{135, 136}

When 5,6-dihalopyrimidines are treated with N-nucleophiles as well as with N,N-, N,O-, and N,S-binucleophiles, both halogen atoms are substituted.^{137–139}

Halogen atoms at a double bond may also remain intact during the reaction of haloalkenes of type **1** with nucleophiles; this is the case when the molecule of the initial substrate contains other, more electrophilic, sites.^{140, 141} It is of interest to consider molecules that contain halogen atoms attached to an *sp*³ hybridised carbon atom in addition to halogen atoms at a double bond. As a rule, the former are replaced much more easily.^{142, 143} Substitution at the vinylic centre requires more drastic conditions. Hence, these two processes can be carried out separately, and different amine fragments can be introduced into the molecule.¹⁴⁴ In some cases, β -halogen atoms can be easily substituted, other centres remaining intact (see, for example, Refs 145–150). Thus the reaction of substituted 2,3,5-trichloro-2-cyclopentenones **111** with various amines occurs smoothly and regioselectively in accordance with the expected *N*-oxovinylolation scheme, the α -chlorine atom at the double bond being inert.

R¹ = R² = OMe; R¹ = OH, R² = Me; R³ = CH₂CH=CH₂, CH=CH=CH₂; R⁴ = Me, R⁵ = H; R⁴ = HO(CH₂)₂, R⁵ = H; R⁴ = R⁵ = Me, Et; R⁴, R⁵ = MeN(CH₂CH₂)₂; R⁴, R⁵ = O(CH₂CH₂)₂; R⁴, R⁵ = (CH₂)₅.

When polychloro-derivatives **112a,b** are made to react with heterocyclic amines (piperidine, morpholine), the chlorine atom at the double bond undergoes nucleophilic substitution.¹⁵¹ The reaction of **112b** with pyridine follows a similar route.¹⁵² Aniline and its derivatives do not form substitution products; instead, they unexpectedly add to the C = N bond.^{151, 153}

Y = O (**a**), NSO₂Ar (**b**); Ar = 4-MeC₆H₄, 4-ClC₆H₄;

X = H, 4-Me, 3-Me; NR₂ = , .

The reactions of 2,3-dibromo-4*H*-1-benzothiopyran-4-one 1,1-dioxide **113a** with alkylamines, dialkylamines, aniline, and its derivatives afford only products **114** resulting from substitution of bromine that occupies the β -position with respect to the carbonyl group.^{154, 155}

The substitution of bromine in the substrate **113b** results in the formation of compound **115** in a low yield.¹⁵⁶

R³ = Br (**a**), Ph (**b**); R¹ = R² = Me; R¹ = H, R² = Me; Ph, C₆H₄OMe-4.

V. The mechanism of nucleophilic substitution of halogen atoms in *gem*-activated haloalkanes

The mechanism of vinylic nucleophilic substitution (S_NVin) in alkenes in which the leaving group is in the β -position in relation to the activating group has been studied fairly comprehensively.¹⁵⁷ About 30 different variants of this reaction have been proposed. However, the mechanism of this reaction for the alkenes in which the leaving and activating groups are attached to the same carbon atom has been much less studied. The diversity of the products of reactions of the haloalkenes **1a–d** with amines indicates unambiguously that it is not a one-step process. The scheme now generally accepted, which permits interpretation of the overwhelming majority of the results obtained, is quite obvious. An amine adds to the double bond of the haloalkene **1a–d** to give the adduct **2a–d** the structure of which is responsible for the direction of subsequent transformations. When primary amines are used, the adducts usually undergo intramolecular substitution of the halogen atom giving rise to aziridines **3a–d**. In the case of secondary amines, the transformations in question occur either as halogen substitution yielding α,β -diamino-derivatives **5a–d** or as dehydrohalogenation to give β -aminoalkenes

4a–d. This scheme was first proposed by Cromwell⁷ as the most probable hypothesis. Subsequently, it was confirmed experimentally and further developed. Strong evidence supporting this scheme has been provided by detection and, in some cases, isolation of the main intermediates. The Michael adducts **2** were isolated for the nitriles **1a**, esters **1b**, and ketones **1c**.^{158–160} The attractive hypothesis of the intermediate formation of an aziridinium salt has been confirmed only after isolation and full spectroscopic identification of this intermediate.^{160, 161} The transformation of the diamino-derivative **5** into the corresponding unsaturated compound **6**, discovered in a number of studies,^{95, 162} has provided final evidence for the reaction mechanism consisting of three successive steps, Ad–S_N–E.

The general scheme of transformations has been recently extended to the most reactive series of substrates **1d**.¹⁶² These compounds differ from all the other haloalkenes activated by geminal substitution in that their activating group does not remain unchanged during the transformations.

The sequence of transformations of 2-chloroacrolein **58a** and 2-chlorobut-2-enal **58b** on treatment with piperidine has been monitored by NMR spectroscopy. At low temperatures, several main intermediates were detected; they accounted for the formation of all the reaction products. Although the nature of the product resulting from the addition of one equivalent of the amine was not elucidated, some findings as well as the electronic structures of the starting compounds¹⁶³ suggest that the process starts with the 1,4-addition of the nucleophile.

The first intermediate that could be detected in the reaction of the substrate **58b** with piperidine at 5 °C was hemiaminal **116b**. In the presence of excess amine, **116b** readily undergoes bimolecular nucleophilic substitution of the halogen atom being thus converted into triamino-derivative **117b**. When the temperature is increased to 25 °C, the latter participates in several competing reactions, the removal of the hemiaminal protection with regeneration of the aldehyde group being the predominant route. The resulting 2,3-diamino aldehyde **118b** undergoes β-elimination of an amine molecule and is thus converted into the final product **63b**. A similar sequence of transformations is observed when **58a** is used as the substrate in this reaction. However, in this case, the hemiaminal **116a** formed initially is mostly dehydrated yielding the alkene **64a**. The sequence of transformations **116a** → **117a** → **118a** → **63a** is not the prevailing route. In general, the proposed scheme accounts for the diversity of the products obtained from haloalkenes activated by a formyl group. It also explains why transformations of this type do not occur in the series of substrates **1a–c**.

Despite the fact that the multistep scheme of nucleophilic vinylic substitution in these systems is currently generally accepted, in some cases, the possibility of direct substitution also cannot be dismissed.^{164, 165} For example, it is believed that the substitution of bromine in the alkene **119a** by the azide ion occurs as the Ad–S_N–E sequence of steps [Scheme 6, pathway (a)]. However, introduction of a phenyl group into the β-position of the substrate (compound **119b**) enables stabilisation of the negative charge in the β-position of the adduct **121**. Therefore, apart from the multistep substitution [pathway (a)], direct α-addition of the azide ion to the double bond [pathway (b)] resulting in the formation of the same substitution product **120b** also becomes possible.

Scheme 6

The question arises as to whether nucleophilic substitution in *gem*-activated haloalkenes always includes the step of conjugated addition, or whether another reaction route is also possible in those cases where the β-carbon atom proves to be inaccessible for some reason (mostly steric). The first attempt to answer this question was undertaken as early as the middle 1950s by a group of French chemists.¹⁶⁶ They studied reactions of ethyl 2-bromo-3-methylcrotonate **122** with secondary amines and suggested that the first step of the process is prototropic transformation of the initial α,β-unsaturated carbonyl compound **122** into its β,γ-isomer **123**. The subsequent bimolecular substitution of the allylic halogen atom gives rise to the amino-derivative **124** isomerisation of which induced by a strong base affords the final product **125**.

However, thorough studies¹⁶⁷ made it possible to give preference to the classical Ad–S_N–E mechanism, which includes formation of the ethyleneimmonium intermediate. This is the only possibility that provides a plausible explanation of the migration of the amine fragment from the β-carbon atom, where it is detected initially, to the α-position.

The idea¹⁶⁶ that the reaction might start with the 1,3-shift has later been confirmed for other examples.^{38, 65–68} Thus the diversity of products formed upon interaction of the esters **18a,b** with primary and secondary amines, and also the fact that the spiroaziridine derivative **19a,b** is not transformed into the isomeric ester **20** have led Rulev *et al*³⁸ to the conclusion that the process can occur by different mechanisms, depending on the type of the nucleophile and experimental conditions. The reactions with primary amines carried out at room temperature under an elevated or atmospheric pressure follow the classical Ad–S_N–E

pattern [pathway (a)]. Conversely, for the reactions with secondary amines and also for those with primary amines carried out under reflux, the key stages are isomerisation of the initial ester **18a,b** giving ester **126a,b** with an endocyclic double bond and the subsequent easy substitution of the allylic halogen atom by the amine [pathway (b)]. Examples of such isomerisation in the series of α -halo α,β -unsaturated acids, induced by amines under very mild conditions, have been reported.¹⁶⁸

VI. Conclusion

The high and diverse reactivity of haloalkenes containing an electron-withdrawing group in the α -position is based on the phenomenon, which has been called by Louis Henry 'functional solidarity'.¹⁶⁹ The essence of this phenomenon is the following. When several functional groups are bound to the same carbon atom in a molecule, their mutual influence results in some cases in substantially changed chemical properties, not typical of the same functional groups occurring separately.

Easily accessible *gem*-activated haloalkenes, which are used as polyfunctional building blocks, occupy a prominent place in modern organic synthesis. Analysis of the available data indicates that nucleophilic vinylic substitution in haloalkenes activated by a geminal group differs substantially from related reactions in the series of alkenes with vicinal leaving and activating groups. These reactions have specific features, and it is not always possible to predict the outcome of a particular transformation.

Despite the fact that such polydentate systems are widely used in synthesis, their potential is far from being exhausted. We believe that the synthetic and theoretical aspects of the chemistry of *gem*-activated haloalkenes would remain the focus of the attention of researchers as a part of the chemistry of unsaturated heteroatomic derivatives with a geminal electron-withdrawing group.

Methods of synthesis of nitrogen-containing heterocycles using ureas and related compounds

A A Bakibaev, A Yu Yagovkin, S N Vostretsov

Contents

I. Introduction	295
II. Methods of synthesis of monocyclic azaheterocycles	295
III. Methods of synthesis of bicyclic azaheterocycles	307
IV. Methods of synthesis of phthalocyanines, diazepines, and diazocines	307
V. Synthesis of azaheterocycles containing other elements	308
VI. Conclusion	311

Abstract. The review surveys numerous experimental data on the application of ureas in the synthesis of mono- and bi-cyclic nitrogen-containing heterocycles with the exception of pyrimidines and hydantoin. The methods of synthesis of phthalocyanines, diazepines, and diazocines from urea and its derivatives are also examined. The bibliography includes 220 references.

I. Introduction

The procedures of organic chemistry include nowadays a wide range of synthetic methods for the construction of azaheterocycles. Ureas are frequently used as the starting materials for this purpose, but, with the exception of studies describing the methods of synthesis of hydantoin^{1–3} and pyrimidines,^{4–10} there are no reviews in the literature surveying the extensive factual data on the methods of synthesis of nitrogen-containing heterocycles involving ureas. The purpose of the present review is to fill this gap. It does not include the methods of synthesis of hydantoin and pyrimidines except certain compounds of these classes where a non traditional approach to their synthesis has been employed.

II. Methods of synthesis of monocyclic azaheterocycles

1. Synthesis of heterocycles containing one nitrogen atom

One of the convenient methods for the preparation of the cyclic imides **4** with a wide variety of structures is the pyrolysis of the dicarboxylic acids **1** or their anhydrides **2** in the presence of a slight excess of urea **3**.^{11–16}

The early studies devoted to the synthesis of the imide **4** have been described in a review.¹⁷ Although the pyrolysis of the anhydrides **2** proceeds in the vast majority of cases under milder conditions (140–185 °C) than the pyrolysis of the dicarboxylic acids **1** (185–235 °C), the yields of like imides are comparable. It is generally known that, when dicarboxylic acids are used in these reactions, the anhydrides **2** are formed initially. Under the influence of the products of the thermal decomposition of urea (NH₃ and HNCO), the latter are converted into the target imides **4** via recyclisation–cyclisation stages. In order to increase the effectiveness of the process, it is recommended that the pyrolysis of aromatic dicarboxylic acids **1** be carried out in ethylene glycol,¹⁸ while that of the anhydrides **2** should be performed in xylenes, which readily remove water in the form of an azeotropic mixture.¹⁶ The methods for the aminolysis of the anhydrides **2** by urea are suitable for the synthesis of diimides^{19,20} and 3-dichloromaleimides.²¹ We may note that in the latter case the reaction does not involve the fairly mobile chlorine atoms. (¹⁵N)Homophthalimide has been synthesised by the reaction of (¹⁵N)urea and homophthalic anhydride and was then converted into 1,3-dibromo- (2-¹⁵N)isoquinoline by treatment with PBr₃ and POBr₃ (180 °C, 2 h).²² According to patent data,²³ the interaction of phthalic anhydride **2** with urea in the presence of the (NH₄)₂MoO₄ catalyst at 210 °C leads to a 75% yield of 1,3-diiminoisoindoline **5** after 30 min.

The reductive amination of 2-benzoylbenzoic acids or their esters with urea in formic acid (a modified Leuckart reagent) is completed by the formation of the dihydroisoindolinones **6**, characterised by a broad spectrum of biological activity.²⁴

R = H, Cl; R' = H, Me, Et.

The decahydroacridine-1,8-diones **7–10** (Scheme 1) can be readily obtained from 5,5-dimethylcyclohexane-1,3-dione (dime-done) and ureas in formic acid,^{25–27} in acetic acid in the presence of aldehydes,²⁶ in dimethyl sulfoxide (DMSO) in the presence of azomethines,²⁸ with participation of dialkyl sulfoxides,²⁹ or by the reaction of dimedone with arylidenebisureas in glacial acetic acid.³⁰

Scheme 1

R = H, Alk, Ar.

R¹, R², R³ = Alk.

Depending on the structure of the substrates and the ureas, it is possible to obtain with the aid of these reactions the hydrogenated acridine-1,8-diones **7–10** with substituents either in the 9-position (compounds **7**, **9**, and **10**) or in the 9- and 10-positions in the acridine ring (compounds **8**). It had been established^{26, 28} that the reactions of acyclic 1,3-dicarbonyl compounds with urea afford, together with the pyrimidinones which are traditional for reactions of this kind, also 3,5-disubstituted 1,4-dihydropyridines. Under these conditions, dihydropyridines are formed in larger amounts in a neutral or weakly basic medium²⁸ than in an acid medium.²⁶

It has been observed comparatively recently that trisubstituted pyridines **11–13** are formed on liquid-phase condensation of aldehydes with urea in the presence of metal complex cata-

lysts.^{31, 32} Thus, 2,3,5-trisubstituted pyridines **11** have been synthesised on heating aliphatic aldehydes with urea in an autoclave up to 200 °C in the presence of triethylaluminium and cobalt di(2-ethylhexanoate) as the catalyst (see Scheme 1).³¹

The mixed condensation of benzaldehyde with butyraldehyde and urea under analogous conditions makes it possible to obtain 3,5-diethyl-2-phenylpyridine in ~83% yield and with a high selectivity.³¹

The liquid-phase condensation of aliphatic C₄–C₈ aldehydes with aromatic aldehydes and urea in the presence of metal complex catalysts, obtained by reducing cobalt 2-ethylhexanoate or Co, Al, Ni, V, Cu, Pd, Ti, Zr, *etc.* acetylacetonates with the aid of AlR₃, BR₃, or MgR₂ leads to the aryl- and heteroaryl-substituted pyridines **12** and **13**.³² The composition of the reaction mixture and the yield of the reaction products depend on the structure of the initial aldehydes and the catalyst.

R = Alk; Ar = Ph, 4-NO₂C₆H₄, , , 2-HOC₆H₄, 2-FC₆H₄, 2-MeOC₆H₄.

The reactions of 1,1-dimethoxyureas with ethylene glycol and propane-1,3-diol in the presence of toluene-*p*-sulfonic acid lead to 2,2-dimethylcarbamoyl-1,3,2-dioxazolidine **14** and 2,2-dimethylcarbamoylperhydro-1,3,2-dioxazine **15** respectively. On hydrolysis in the KOH-benzyltriethylammonium system, the latter afford 1,3,2-dioxazolidine **16** and perhydro-1,3,2-dioxazine **17**.³³

n = 2 (**14**, **16**), 3 (**15**, **17**); TEBAC = Et₃BnN⁺Cl[−].

The cyclisation of 4-ureidobutanoic acid either in the presence of phosphorus oxide chloride under an inert atmosphere^{34, 35} or on treatment with acetic anhydride³⁶ leads to the pyrrolidinone **18**.

The azacyclisation of β-arypropionic acids on treatment with urea makes it possible to obtain substituted 4-pyrrolidin-2-ones **19** in high yields.³⁷

R = Ph, 4-BrC₆H₄, tetralinyl.

High-temperature (160–230 °C) reactions of ureas with 1,2-bifunctional compounds, one of the functional groups of which is OH, constitute a fairly general method of synthesis of oxazolinones and oxazolidinones. Thus heating of the α-hydroxyesters **20**

with 1,3-disubstituted ureas **21** affords the oxazolidine-2,4-diones **22** in satisfactory yields.³⁸

$\text{R}^1, \text{R}^2 = \text{H}, \text{Alk} (\text{C}_1 - \text{C}_4); \text{R}^3 = \text{Alk} (\text{C}_1 - \text{C}_{10}); \text{R}^4 = \text{R}^5 = \text{H}, \text{Ar}.$

Fusion of 2-amino-5-methoxyphenol hydrochloride **23** with urea leads to 6-methoxybenzoxazolin-2-one **24**.³⁹

In contrast to other acyloins, 1,2-pyridoins afford predominantly substituted 4,5-bis(2-pyridyl)-4-oxazolin-2-ones **25** on heating with urea in glacial acetic acid.⁴⁰

Aryloxiranes undergo interesting reactions on heating with urea without a solvent or in dimethylformamide.⁴¹ The reaction is kinetically controlled: electron-donating substituents in the *ortho*- and *para*-positions of the phenyl group promote the preferential formation of the 5-aryloxazolin-2-ones **27** while electron-accepting substituents promote the formation of 4-aryloxazolin-2-ones **26**.

The reactions of vicinal diols with urea, leading to 5-R-oxazolidin-2-ones **28** have been investigated.^{42–44} Compounds **28** can also be readily obtained from the monoesters of glycerol,^{42,43} 3-aminopropane-1,2-diol,⁴² and 2,3-epoxypropane-1,2-diol.⁴³

The formation of the oxazolidinones **28** from diols and related compounds apparently proceed *via* a series of consecutive stages, presented in Scheme 2.⁴²

Scheme 2

$\text{R} = \text{ArO}, \text{NH}_2.$

Since these reactions take place above the melting point of urea (under these conditions, it begins to undergo thermal decomposition into NH_3 and isocyanic acid⁴⁵), the nature of the carbamoylating reagent in Scheme 2 is evident. As regards one of the key stages in the Scheme, namely the decarboxylation stage, it too is entirely unambiguous, since the tendency of carbamates to decarboxylate at elevated temperatures is generally known.

After treatment of 3-(2-hydroxyalkyl)-1-nitrosoalkylureas **29** with bases the oxazolidin-2-ones **30** were isolated in 73%–96% yields.⁴⁶

$\text{R}^1 = \text{Me}, \text{Et}; \text{R}^2 = \text{H}, \text{Me}.$

It has been postulated that the reaction begins with the intramolecular nucleophilic attack by the hydroxy-group on the electrophilic carbon atom of the carbonyl group. The intermediate hemiacetal decomposes into the oxazolidinone **30** and the intermediate $\text{R}^1\text{N}=\text{NO} - \text{K}^+$.

The high-temperature reaction of cyclohexanone with urea in triethylamine makes it possible to synthesise the spiro-compound **31**, whilst in the presence of toluene-*p*-sulfonic acid, decahydrophenanthridinone **32** is formed.^{47–49}

The condensation of urea with α,β -unsaturated ketones in acid (HCl , 60°C) or basic (NEt_3 , 150°C) media leads to substituted 2-oxatetrahydro-pyrimidines.^{50,51} It has been observed⁵² that, on heating of 2-cyclohexylidenecyclohexanone and 2-cyclopentylidenecyclopentanone to 150°C in triethylamine, the pyridinones **33** are formed only in trace amounts. They are the main products when the reaction is carried out at a higher temperature in the presence of NEt_3 or toluene-*p*-sulfonic acid.

The azaheterocycle **33** becomes the main product when the reaction is carried out at higher temperatures ($180-200^\circ\text{C}$) in the presence of triethylamine or toluene-*p*-sulfonic acid. The tetrahydropyrimidinone **34** is formed as a result of the nucleophilic Michael addition of urea to the double bond of the α,β -unsaturated ketone with subsequent dehydration of the alkylurea **35**. On the other hand, the pyridones **33** are apparently formed *via* the deamination of the intermediate **36**.

The regioselective opening of the epoxide ring in the epoxide **37**, containing the polyfluoroacetal group, by urea in a basic medium leads to the creation of the oxazolidine ring. Compounds **38**, formed under these conditions, are new functional fluorine-containing monomers.⁵³

$\text{R}_\text{F} = \text{H}(\text{CF}_2)_n$; $n = 2-8$.

A series of studies⁵⁴⁻⁵⁸ have been devoted to the intramolecular cyclisation of unsaturated ureas initiated by various catalysts. A method of synthesis of 4,5-dihydrooxazoles **39-44** from allylureas by intramolecular heterocyclisation, initiated by phenylselenenyl chloride and catalysed by silica gel under an inert atmosphere, has been described.⁵⁴

The formation of a mixture of diastereoisomers of the oxazolines **41** and **42** with a twofold excess of the *trans*-isomer **41** is the stereochemical outcome of the intramolecular cyclisation of the terminal alkenylurea **45** with participation of PhSeCl .⁵⁴

2-Aminooxazolines **46** and **47** are also formed stereospecifically from phenylselenenylurea **48** in the presence of bases. Under these conditions, the *trans*-oxazoline **46** is formed from the *erythro*-isomer, while the analogous treatment of the *threo*-isomer leads to the *cis*-oxazoline **47**.⁵⁴

Allylisourea **49** interacts with organic selenium compounds under an inert atmosphere. Depending on the reaction conditions, it cyclises with formation of either the dihydro-1,3-oxazine **50** or the imidazoline **51**.⁵⁵

N-Alkenylthiosemicarbazides **52** and the thioureas **53** readily undergo iodocyclisation to compounds **54** and **55** in methylene chloride. Their subsequent treatment with Ac_2O in triethylamine affords 2-*R*-1,3-thiazolines **56** and 2-(*N*-phenylacetamido)dihydro-1,3-thiazine **57** with an exocyclic methylene group.⁵⁹

R = H, Ph.

The cyclisation of 1-allyl-3,3-diethylthiourea to 2-diethyl-amino-5-iodomethyl-1,3-thiazoline on treatment with iodonium nitrate in the presence of pyridine proceeds without the retention of the exocyclic methylene group.⁵⁹

The intramolecular cyclisation of allenic acylureas on treatment with diethylamine, *via* a series of intermediate stages, opens a path to tetrahydro-1,3-oxazine-2,4-diones **58** which are difficult to obtain.⁶⁰

R = Me, Ph; Am = C₅H_{11-n}.

It has been established that the reactions of *N*-arenesulfonyl-*N'*-trifluoroacetylureas and oxalyl chloride under severe conditions in the presence of triethylamine are completed by the formation of 1,3-oxazolidine-4,5-diones **59**.⁶¹

The cyclisation of phosphorylated *N*-(2,2-dichlorovinyl)ureas **60** to phosphorylated mesomeric betaines **61** and oxazoles **62a,b** proceeds in an interesting manner.⁶²

$$R, R' = H, Alk.$$

On heating with urea, 2,3-dichlorotetrahydrofuran gives rise to 2-amino-5-(2-hydroxyethyl)oxazoline **63**.⁶³ The reaction proceeds *via* the opening of the furan ring with subsequent cyclisation of the intermediate substituted urea.

Ureides, which on refluxing in AcOH afford 2-aryl(cycloalkyl)amino-4-oxazolinones **64**, are obtained by the interaction of carboxylic α -halo-acids with ureas.⁶⁴

X = Cl, Br;
R = H, Ph; R' = H, Ar, cyclo-Alk.

The oxazines **65** have been obtained in satisfactory yields in the study of the reactions of 3-ethoxycarbonyl-5,6-benzocoumarin with monosubstituted ureas.⁶⁵

R = H, Alk, Ar.

The photocyclisation of acryloylureas (Hg lamp, 450 W, Pyrex, argon) leads to the formation of *N*-substituted azetidin-2-one derivatives.⁶⁶

2. Synthesis of heterocycles containing two nitrogen atoms

a. Reactions of ureas with 1,2-bifunctional compounds

The azaheterocycles containing two nitrogen atoms are represented mainly by imidazole derivatives. The reactions of ureas with 1,2-bifunctional compounds proceed as a rule in polar solvents at temperatures below the decomposition temperature of urea ($< 132.5\text{ }^{\circ}\text{C}$) and afford imidazolidinones (compounds with a carbamide fragment in the ring). Thus the interaction of equimolar amounts of urea and glyoxal in an alkaline or acid medium leads to 4,5-dihydroxyimidazolidin-2-ones **66**.^{67–69} The 4,5-dialkoxy-derivatives **67** are formed in the reactions of ureas with glyoxal in alcoholic solutions in the presence of cation exchangers.⁷⁰

The vicinal diols **66** and their ethers **67** are convenient starting materials for the synthesis of a wide variety of bicyclic hetero-systems and, what is especially important, for the synthesis of bicyclic compounds with an asymmetric structure.⁷¹ In the acid-catalysed reaction with an equimolar amount of ureas, aromatic 1,2-diketones afford 4,5-diaryl-4,5-dihydroxyimidazolidin-2-ones.^{72, 73}

It was later established that a mixture of the *cis*- and *trans*-isomers of 4,5-dihydroxyimidazolidinones **68** and **69** is formed in the reactions of 1,2-dicarbonyl compounds with ureas.⁷⁴

It has been shown on the basis of ¹³C and ¹⁵N NMR spectroscopic and chromatographic data that the interaction of benzil with urea leads to mixture of the *cis*-diols **68** and *trans*-diols **69** in proportions of 65 : 35. The formation of the cyclic boric acid esters **70** and **71** has been used successfully for the separation of the diastereoisomers of such diols.⁷⁵

When urea or thiourea is heated with oxalic acid esters, parabanic acid **72a** or its 2-thio-analogue **72b** are formed respectively.⁷⁶

X = O (**a**), S (**b**).

The reaction of benzil with urea in formic acid at a high temperature leads to a mixture of the imidazoles **73** and **74** and tetraphenylpyrazine **75**.⁷⁷

The arylidenebisureas **76**, known as the starting materials for the synthesis of pyrimidines, afford exclusively 2-aryl-4,5-diphenylimidazoles **78** and phenylenebisimidazolines **79** in their reactions with benzil in formic acid or with the tetraketone **77** in acetic acid respectively.^{77, 78}

The hydrate of diphenylpropanetrione reacts with ureas in an acid or neutral medium to form the hydantoin derivatives **80**,⁷⁹ although the latter are usually obtained under alkaline conditions.^{1–3}

R = H, Alk.

One of the common reactions for the synthesis of imidazolin-2-ones **81** is the cyclisation of acyloins with urea.^{40, 80}

R = Alk, Ar, ArAlk.

Arylenebishydroxyketones react with urea under an argon atmosphere to form arylenebisimidazolinones **82**.⁸¹

Certain alkylarylacyloins react with urea under the conditions of acid catalysis, affording the methylenebisimidazolinones **83**,⁸² which are formed with participation of the activated CH₃ groups.

Scheme 3

$\text{R}^1 = \text{R}^2 = \text{H, Me.}$

Polyacyloins also react with urea and thiourea, giving rise to polyimidazolinones (thiones) **84**, which are important ingredients of polymeric composite materials.⁸³

$\text{X} = \text{O, S}; n = 15-10000.$

The cyclocondensation of phenanthrene-9,10-diols with urea leads to the phenanthroimidazolinones **85**, the structure of which has been confirmed by specific synthesis — the photolysis of 4,5-diaryl-2-imidazolinones **86** in acetic acid.⁸⁴

$\text{R} = \text{H, Me, Cl, Ph.}$

Aliphatic and alicyclic α -bromo ketones proved to be convenient starting materials for the synthesis of the imidazolin-2-ones **87–90**^{85–90} (Scheme 3). Imidazolinones of type **88** have also been obtained from α -keto alcohols and urea at comparatively low temperatures (125 $^\circ\text{C}$) in the presence of phosphomolybdic acid.⁹¹ The imidazolinones **87** and **88** are intermediates in the synthesis of biotin.

The imidazolidin-2-ones **91** and **92** are obtained as a rule by the condensation of aliphatic 1,2-diols with urea. Thus the interaction of ethylene glycol with urea under fairly severe conditions affords imidazolidin-2-one **91**.⁹²

$\text{R}^1 = \text{H, Ph, Ac}; \text{R}^2 = \text{H}; \text{R}^3 = \text{C}_3\text{H}_{11}; \text{Ad} = \text{adamantyl.}$

The presence of a fluorine atom in the 1- and 2-positions in the initial ethylene glycol facilitates significantly the formation of 4,5-difluoroimidazolidin-2-one **92**.⁹³

The cyclisation reaction between tartaric acid and urea **3** in concentrated sulfuric acid proceeds with participation of only the hydroxy-groups and is completed by the formation of 2-oxoimidazoline-4-carboxylic acid **93**.⁹⁴

Alkoxyimidazolidin-2-ones **94** ($n = 1$) are obtained by the alkylation of alkoxyureas with dihaloalkanes in DMF. The hydrogenolysis of compounds **94** (HCOONH_4 -Pd/C) leads to the corresponding *N*-hydroxyimidazolidin-2-ones **95** ($n = 1$).⁹⁵

$\text{R}^1 = \text{COOEt, H, CN}; \text{R}^2 = \text{H, Alk}; n = 1, 2.$

The commonest method of synthesis of benzimidazolin-2-ones **96** is perhaps the cyclocondensation of *o*-phenylenediamines with urea **3**.^{96–101}

$\text{R} = \text{H, Alk, Ar, Hal, OAlk, COOH, CN.}$

Heterocyclic 1,2-diamines react similarly with urea.¹⁰² It has been shown that the interaction of *N*-(4-fluorobenzyl)-*o*-phenylenediamine with [¹⁴C]urea results in the formation of 2-[¹⁴C]-1-(4-fluorophenyl)-2,3-dihydrobenzimidazolin-2-one.¹⁰³

It has been reported¹⁰⁴ that, on refluxing with urea in pentyl alcohol, 2,2'-diaminobiphenyl readily affords dibenzodihydrodi-1,3-azepin-2-one **97**.

Aliphatic 1,2-diamines condense with urea at 200–260 °C in polar solvents.^{105–107} At a temperature above 180 °C, urea forms cyclic products also with diamines of the type RNH(CH₂)_{*n*}NHR (*n* = 3, 4).¹⁰⁸

b. Intramolecular cyclisation of ureas

Anthraquinonoimidazolinone **98** has been synthesised by intramolecular substitution of the chlorine atom in a superbasic medium.¹⁰⁹

The intramolecular cyclisation of 2-substituted ureidoanthraquinones in a superbasic medium leads to angular condensed heterosystems — derivatives of naphthoquinazoline **99**.¹¹⁰

R = C≡CPh, COOH; R' = Z-CHPh (14.5%), E-CHPh (51%), O (27%).

The cyclisation of *N*-acyl-*N'*-(3-methoxyaryl)ureas in the presence of polyphosphoric acid (PPA) affords the dihydroquinazolinones **100** and their hydrolysis products **101**.¹¹¹

R = Me, Het.

On treatment with sodium nitrite in water in the presence of acetic acid, the cyanoacetylureas **102** are initially converted into the uracil derivatives **103**. However, the latter undergo an unexpected transformation of the pyrimidine heterocycle, whereupon derivatives of parabanic acid are formed.¹¹² The available literature data on the ways in which heterocycles are transformed¹¹³ do not provide a satisfactory mechanism of this reaction.

R = H, Me; R' = H, Hal, Me.

The cyclisation of the aroylureas **104**, obtained from the amino alcohols **105** and aroyl isocyanates, leads to a mixture of heterocyclic compounds — the *O*- and *N*-alkylation products **106** and **107**. An important feature is that the configuration of the asymmetric carbon atom is retained.¹¹⁴

R = Et, Buⁱ; R' = Ph, 4-ClC₆H₄, 2,4-Cl₂C₆H₃, 2-Cl-4-NO₂C₆H₃.

It has been proposed¹¹⁵ that the intramolecular cyclisation of the acetals of aldehydoureas in an acid medium be employed in the synthesis of 1-alkyl-4-imidazolin-2-ones **108**.¹¹⁵

On carbonylation in the presence of PdCl₂/CuCl₂ in methanol at room temperature and atmospheric CO pressure, the unsaturated urea **109** (R = CH₂Ph, R' = Me) gives rise to a mixture of perhydrogenated pyrimidinones **110** and **111** (yields 82% and 14% respectively). Only compound **110** is formed at 0 °C. Compounds **112**–**115** have been obtained under similar conditions.¹¹⁶

R = CH₂Ph; R' = Me [**110**, (82%)]; Prⁱ, Prⁱ [**112**, (84%)];
Prⁱ, Me [**113**, (82%)]; Bu^t, Me [**114**, (47%)]; Ph, Me [**115**, (58%)].

The pentylureas **116** afford mixtures of the hydrogenated imidazolidinones **117** and **118** under similar conditions.¹¹⁶ 1,3-Diazabicyclo[4.3.0]nonane-2,4-diones **120a** and 1,3-diazabicyclo[4.4.0]decane-2,4-diones **120b** are formed under the same conditions from *N*-penten-4-yl- and *N*-hexen-5-yl-ureas (compounds **119a** and **119b**) respectively.¹¹⁶

R = Me, Prⁱ; R' = Me, Prⁱ, CH₂Ph.

R = Me, Prⁱ, CH₂Ph; *n* = 1(**a**); 2(**b**).

The bromocyclisation of allylbenzoylurea on treatment with *N*-bromosuccinimide proceeds with formation of the substituted oxazoline **121**.⁵⁶

In contrast to this, the halocyclisation of the allylureas **122**, initiated by *N*-bromosuccinimide in CCl₄, leads to the bromomethylimidazolidinones **123**.⁵⁸

R = Ar, 2-Cl-C₆H₄CO, EtO₂CCH₂.

Preliminary silylation with trimethylsilyl trifluorosulfonate in the presence of NEt₃ in CH₂Cl₂ is necessary for the conversion of the allylureas **124** into the iodoethylimidazolines **125**.⁵⁷

R = Me (83%), PhCH₂ (71%).

Imidazoline derivatives **126** or tetrahydropyrimidine derivatives **127** are formed on iodocyclisation of unsaturated isothio-ureas. After treatment with diazabicycloundecane, they are converted into compounds **128** and **129** respectively.⁵⁷

R = Ph [**126a**, (89%)], Ac [**126b**, (77%)].

DBU = diazabicycloundecene.

After prolonged storage in the light in the absence of contact with air, intramolecular cyclocondensation of substituted 2-trimethylsilyloxy ethylureas takes place and leads to the imidazolidinones **130**. Their subsequent hydrolysis affords the imidazolidin-2-ones **131**.¹¹⁷

R¹ = Alk, R² = Me₃Si, Me₃SiOCH₂CH₂, R³ = H, CH₂CH₂OH.

The heterocyclisation of *N*-acyl-*N'*-arylureas **132** on treatment with polyphosphoric acid leads to 4-substituted quinazolin-2-ones **133**, which are believed to be formed as a result of a reaction of the Bischler–Napieralski type.¹¹⁸

R = Alk, Ph.

According to patent data,¹¹⁹ the refluxing of the iminoester of ureidoacetic acid with alkali in aqueous alcohol leads to 4-amino-Δ³-imidazolin-2-one **134** in a high yield.

134 (95%)

It has been established¹²⁰ that, on exposure to ultrasound in the presence of baker's yeast, *ortho*-substituted carbamide derivatives of benzonitrile **135** cyclise to the 4-iminoquinazolinones **136** in 82%–93% yields.

The cyclisation reaction between β -hydroxyethyl(propyl)-ureas **137** and carbonic acid esters, catalysed by Group I–IV metal halides, is completed by the formation of substituted imidazolidin-2-ones **138** in yields up to 60%. They are of interest as monomers and comonomers for the manufacture of plastics, coatings, varnishes, and ion-exchange resins.¹²¹

$\text{R}^1 = \text{R}^2 = \text{Cl, Br, NO}_2, \text{CF}_3, \text{Alk}(\text{C}_1\text{--C}_4)\text{O, Ar; R}^3 = \text{H, Me; R}^4, \text{R}^5 = \text{Alk}(\text{C}_1\text{--C}_4);$

c. Other methods of synthesis

An erroneous structure was initially attributed to the compound obtained by the condensation of cyclohexanone with urea on refluxing in *o*-xylene.¹²² It was later established that⁴⁷ it is 5,6,7,8-tetrahydrospiro[cyclohexane-1,2'-(1*H*)-quinazoline]-4'-(3'*H*)-one. In contrast to cyclohexanone, the high-temperature condensation of cyclododecanone **139** with urea at 280 °C¹²³ or on refluxing in *o*-xylene in the presence of *p*-TsOH (150 °C, 8 h)¹²³ leads to the condensed pyrimidine (1*H*,3*H*)-2,4-dione **140**.

Compound **140** has also been obtained by an independent synthesis from methyl 2-oxocyclododecanecarboxylate **141** and urea in the presence of sodium ethoxide.¹²³

The spiro-compounds **143** have been synthesised in satisfactory yields by the cyclocondensation of the dialkyl esters of 2,6-diaryl-4-oxocyclohexane-1,1-dicarboxylic acids **142** with urea in the presence of sodium alkoxides.¹²⁴

$\text{R} = \text{R}' = \text{Me, Et.}$

A remarkable example of the intramolecular rearrangement of the uracil derivatives **144** to the pyrazolones **145** has been described.¹²⁵ Thus the refluxing of the ureides **144** in EtOH or MeOH in the presence of sodium alkoxides affords the pyrazolones **145** and the symmetrical dimethylurea as a result of the intramolecular rearrangement of the ureides **144** and the attack by the alkoxy-group on the carbonyl C(6) atom.¹²⁵

$\text{R} = \text{H, Me; R}' = \text{Me, Et.}$

2-Aminobenzophenones are key compounds for the synthesis of tranquilisers of the 1,4-benzodiazepine series. The heterocyclisation reaction between 2-aminobenzophenones and urea **3** leads to quinazoline derivatives.^{126–129}

The cyclisation in the presence of ZnCl_2 affords 1- R' -6- R -4-phenylquinazolin-2-ones,^{128–130} while 6- R -4-phenylquinazolines are formed in the presence of formic acid.^{131, 132}

$\text{R} = \text{H, Cl; R}' = \text{H, Me.}$

It has been shown that *N*-allyl-*N*-nitroso-urea is converted into pyrazole in 18% yield *via* the intermediate vinyldiazomethane.¹²⁵

6-Chloro-2-quinazoline-4-carboxylic acid **146** has been synthesised by condensing 5-chloroisatin with urea in 1-pentanol in the presence of aqueous KOH.¹³¹

It has been established that, on heating in a sealed tube with ammonia, hydrazine, or hydroxylamine, *N*-ethoxycarbonylisatin **147** and urea afford spiro[imidazolidine-4,4'-(1*H*)-quinazoline]-2,2',5(3*H*) triones **148** after 4 h at 120 °C.¹³²

R [yield (%): H(59), NH_2 (57), OH(15).

On interaction with methylurea in boiling THF, *N*-methylcarbamoylisatin **149** recycles to the ureidoquinazolin-2-one derivative **150** in 29% yield after 5 h in the presence of diazabicycloundecene. On refluxing in 1,2-dichlorobenzene, compound **150** is converted into the spiro-compound **151** in 97% yield.¹³²

According to the data of Yamagishi *et al.*,¹³³ the ureidoquinazolinone **150** is formed from *N*-methylcarbamoylisatin **149** and methylurea *via* the acyclic intermediate **152**.

3. Syntheses of heterocycles containing three nitrogen atoms

Cyanuric acid — 1,3,5-triazine-2,4,6-trione **153** — is perhaps the main representative of azaheterocycles containing three nitrogen atoms. As a consequence of its unique properties, it has found application in various branches of industry.¹³⁴ Cyanuric acid is obtained mainly by the pyrolysis of urea in organic solvents in a fluidised bed on the surface of metals.¹³⁴ However, the pyrolysis affords, together with cyanuric acid, also related triazines — ammelide **154**, ammeline **155**, and melamine **156** — the products of the amination of cyanuric acid which are of independent practical interest.^{134, 135}

All these heterocycles are products of the cyclotrimerisation of isocyanic acid and/or cyanamide.

The recyclisation–cyclisation of 1,3-dimethyl-1,3,5-triazine-2,4-dione **157** on treatment with urea or guanidine in DMF in the presence of bases has been observed recently.¹³⁶

The interaction of 1,3,5-trimethylbiuret with 1,3-dimethylurea in chloroform at 200 °C leads to a mixture of the triazinones **158**–**160**.¹³⁷

Substituted amidrazones **161** react with urea to form 4,5-disubstituted 3-hydroxy-1,2,4-triazoles **162** in 54%–78% yields.¹³⁸

3-Hydroxy-*sym*-triazolo[4,3-*a*]pyridine and 3-hydroxy-*sym*-triazolo[4,3-*a*]phthalazine are formed on interaction with 2-hydrazinopyridine¹³⁹ or 1-hydrazino-phthalazine¹⁴⁰ respectively with urea.

The reaction of isatin **163** with urea is rapid and leads to the formation of 2-oxoindolinyl-3-spiro-2'-(6'-hydroxy-4'-oxo-2',3',4',5'-tetrahydro-*sym*-triazine) **164** in 34% yield.¹⁴¹

The presence of a mobile hydrogen atom in *N*-acyl-*N'*-arenesulfonylureas **165** and their tendency to undergo tautomeric transformations in reactions with acyl isocyanates **166** promotes the formation of the *sym*-triazine (compounds **167**)^{58–61} or triazole (compounds **168**) rings.¹⁴²

Urea or its mono- and *sym*-di-substituted derivatives react with 2 equivalents of formaldehyde and 1 equivalent of a primary amine to form 5-alkyl-2-oxotetrahydro-1,3,5-triazines **169**.¹⁴³ Glycylglycine enters into a similar reaction.¹⁴⁴

$\text{R} = \text{H}, \text{Alk}; \text{R}' = \text{Alk}$.

Perhydro-4-aryl-1,3,5-triazine-2,4-diones **170** can be synthesised either by the direct condensation of the corresponding substituted benzaldehydes with urea^{145, 146} or by the intermolecular cyclisation of benzyldienebisurea **76** in DMSO.¹⁴⁷

2-Ary(heteroaryl)-1,2,3-triazoles, which have the properties of optical bleaching agents, are synthesised by the interaction of compounds of the type $\text{A}[\text{NHN}=\text{C}(\text{Alk}, \text{Ar})\text{C}=\text{NOH}]_n$ (where A = aromatic or heterocyclic residue) with an excess of urea in water.¹⁴⁸ According to patent data,¹⁴⁹ the hydroxyalkyl derivatives of 1,3,5-triazacycloheptane-2,4-dione **172** have been obtained by the reaction of the diamines **171** with urea **3** or biuret at 100–150 °C in DMSO or DMF.

R = CH₂CH₂OH; R' = H, Alk.

4-Diazopyrazoles **173**, obtained by the diazotisation of *N*-alkyl-*N'*-(4-amino-5-pyrazolyl)ureas **174**, proved to be convenient synthons for the construction of various heterocyclic compounds of types **175–177**¹⁵⁰ (Scheme 4).

Scheme 4

R = Me, CH₂Ph.

The interaction of 1-chloroisocyanates **178** with 1,3-dimethylurea involves *N*-acylation with formation of the corresponding *N*-alkylideneaminocarbonylurea **179**.¹⁵¹

R = H, CF₃; R' = Ar, P(O)(OEt)₂.

Analysis of NMR spectroscopic data in polar solvents led to the observation that *N*-alkylideneureas **179** contain up to 13% of compounds **180** and **181**, formed as a result of intramolecular cyclisation.

The high-temperature reaction of ureas **3** or benzyldienebisurea **76** with DMSO constitutes a single-stage method of synthesis of 1,3,5-tris(methylthiomethyl)-1,3,5-triazine-2,4,6-trione **182**.¹⁵² The reaction of cyanuric acid **153** with DMSO also leads to compound **182**. On this basis, it has been concluded that cyanuric acid is an intermediate in the synthesis of the triazine **182** from ureas.

The interaction of the anion **183**, obtained from urea **3** by treatment with NaH in DMSO, with aromatic nitriles¹²³ leads to 4,6-diaryl-2-hydroxy-*sym*-triazines **184**. It has been suggested that the reaction is a two-stage process.

As a result of its reaction with trichloroacetonitrile in benzene in a sealed tube and subsequent treatment of the reaction product **186** with methanol, the arylideneurea derivative **185** affords the *sym*-triazinone **187**.¹⁵⁴

III. Methods of synthesis of bicyclic azaheterocycles

Bicyclic bisureas (BBU) have been known since the end of the past century. The principal methods of their synthesis, described in the literature up to 1972, have been surveyed.¹⁵⁵ By virtue of the valuable properties of the BBU, the methods of their synthesis using ureas are being constantly improved.

The most successful classification of the BBU, represented by structures of the type **188–191** which differ in the size of the rings and the ways in which they are joined together, has been proposed in Ref. 156.

X = O, S.

Since fundamentally new approaches to the synthesis of the BBU have not been developed in recent years, we shall confine ourselves to reactions by means of which the BBU are obtained. Furthermore, we shall present data which appeared in the literature after the publication of the review in Ref. 155.

The BBU of the bicyclooctane series **188** are synthesised by the reactions of 1,2-diketones,^{77, 78, 157–163} α -hydroxy ketone,^{81, 82} α -ketomonooximes, and α -isonitroso ketones¹⁶⁴ with ureas, predominantly under the conditions of acid catalysis. The type **188** BBU can be obtained stepwise. 4,5-Dihydroxyimidazolidin-2-ones are synthesised initially from the corresponding 1,2-bifunctional compounds and ureas and are then cyclocondensed with ureas and thioureas to compounds **188**.⁷¹ An advantage of the stepwise synthesis of the BBU is that this approach makes it possible to obtain BBU with an asymmetric structure. The BBU of the bicyclononane series **189** are synthesised by the reactions of 1,3-dicarbonyl compounds or their analogues with ureas.^{155, 165–167} The BBU of the bicyclodecane series **190** and compounds of type **191** are as a rule synthesised from ureidopyrimidines prepared beforehand^{155, 168} or by the interaction of the latter with aldehydes.

The kinetics of the reactions of carbonyl compounds with ureas have been investigated and the mechanisms of the formation of the BBU have been proposed in a series of studies.^{77, 78, 158, 159, 161–163, 167} The main requirement for the successful synthesis of the BBU **188–191** is the creation of conditions under which urea would not decompose.

IV. Methods of synthesis of phthalocyanines, diazepines, and diazocines

The decomposition of urea with elimination of ammonia at high temperatures has been used successfully in the amination of various organic substrates. One of the main synthetic applications of urea as an aminating agent is the preparation of phthalo- and naphthalo-cyanines. Phthalocyanines **192** are obtained from phthalic acids.¹⁶⁸ However, the main synthesis is from their anhydrides and imides^{168–172} or from phthalodinitrile¹⁷³ on interaction with urea **3** in the melt in the presence of transition metal (Cu,^{168–171, 174} Ni or Co^{172, 173}) compounds and a catalyst. The synthesis is sometimes carried out in high-boiling solvents.

R = H, NO₂, Alk, Ar, NH₂;

X = NH, O; M²⁺ = Cu, Ni, Co.

Molybdenum compounds and more rarely titanium or zirconium salts are used as catalysts for the synthesis of phthalocyanines.¹⁶⁸

Substituted phthalocyanines and their complexes with vanadium oxide are obtained in high yields by the high-temperature reaction of 4,5-dichloro-3,6-di(phenylthio)phthalic anhydride with urea in the presence of ammonium molybdate and VOCl in trichlorobenzene on heating.¹⁷⁵ Naphthalocyanines are synthesised similarly from derivatives of naphthalene-2,3-dicarboxylic acids and urea. The latter is used as the aminating agent.^{172, 176–178} Macrocyclic phthalocyanines and naphthalocyanines have found wide applications as optical, recording, and photosensitive materials.

The polymeric platinum-phthalocyanine is obtained by the reaction of pyromellitonitrile, PtCl₂, and urea and is used as the catalyst in the formation of indole from *N*-ethylaniline.¹⁷⁹

Tetrafluorinated¹⁸⁰ or tetrasulfonated¹⁸¹ phthalocyanines have been obtained by the reaction of the corresponding anhydrides or ammonium salts with urea in the presence of suitable metal salts.

It has been shown in a number of studies^{182–184} that urea can be used in the synthesis of benzodiazepine derivatives, which are of independent interest for pharmacology. Thus the interaction of 3-(2-oxocycloalkylidene)indolin-2-ones **193** with urea or thiourea in an alcoholic KOH solution leads to a mixture of reaction products: a tetracyclic system comprising indolodiazepinones (thiones) **194** and spiro-2-indolinones **195**. The yields of the reaction products were 30%–35% for **194** and 40%–50% for **195** respectively.¹⁸²

$R^1 = \text{H, Ar; } R^2 = \text{H, Me, Ac; } R^3 = \text{H, F, CF}_3$;
 $X = \text{O, S; } n = 1, 2$.

Cyclic ureas of the indolo[3,2-*d*]benzo[1,3]diazepin-2-one **196** and indolo[2,3-*d*]benzo[1,3]diazepin-2-one **197** series are formed when 2-phenylindolyl-3-semicarbazides or 3-phenylindolyl-2-semicarbazides are treated with sodium nitrite in acetic acid.¹⁸³

$R = 5\text{-Me, 5-Cl, H, 6,7-CH=CHCH=CH}$.

Examples of the formation of the diazepine and diazocine rings from ureas and 1,4- or 1,5-diamines respectively have been published.¹⁸⁴ For example, 1,3,4,5-tetrahydro-2*H*-benzo-1,3-diazepine-2-thione **198** and 1,2,3,4,5,6-hexahydrobenzo-1,3-diazocine-2-thione **199** have been synthesised from the corresponding diamines and thiourea.

Benzo-1,3-diazocin-2-one **201** is synthesised from 1,4- and 1,5-diamines *via* a series of intermediate stages leading to the *N*-substituted urea **200**.¹⁸⁴

On treatment with nucleophiles, 4-chloromethyltetrahydropyrimidin-2-ones undergo ring expansion, which leads to the 1,3-diazepinone derivatives **202**.¹⁸⁵

$R = \text{Me, Et; } X = \text{CN, SH, OEt, OMe, SO}_2\text{H, H, NR}_2$.

The interaction of 4-phenylbut-3-en-2-one **203** with urea in ethanol in the presence of an acid leads to the pyrimido[4,5-*d*]-1,3-diazocinedione **204** after 24 h at 50 °C.¹⁸⁶

It has been suggested that the quinazolinone **205** is an intermediate in the synthesis of the diazocinedione **204**. Its formation may be represented as a synchronous reaction of two molecules of the phenylbutenone **203** with urea.

V. Synthesis of azaheterocycles containing other elements

1. Phosphorus-containing heterocycles

The presence of a series of nucleophilic reaction centres in the carbamide fragment of *N*-acylureas promotes the heterocyclisation of the latter on treatment with phosphorylating agents. Thus the interaction of *N,N'*-dimethylacylureas with PCl_5 in proportions of 1:5 results in the formation of diazaphosphorinones, which are converted *in situ*, on treatment with SO_2 , into 4,6-dichloro-1,3-dimethyl-5-*R*-2,4-dioxo-1,3,4-diazaphosphorines **206**.¹⁸⁷

$R = \text{H, Me}$.

In contrast to dimethylacylureas, the reaction of monomethylacylureas with phosphorus pentachloride is completed mainly by the formation of a compound of the type $[\text{Cl}_3\text{P}=\text{NC}(\text{Cl})=\text{CHPCl}_3]^+\text{PCl}_6^-$ and a small amount (8.5%) of 2,2,4,6-tetrachloro-1-methyl-1,2-dihydro-1,5,2-diazaphosphorinonium hexachlorophosphate. On treatment with SO_2 , the latter is readily converted into 2,4,6-trichloro-3-methyl-4-oxo-3,4-dihydro-1,3,4-diazaphosphorine **207**.¹⁸⁸

R = H, Me.

It has been shown^{189–191} that the phosphorylation of *N*-acetylurea with a fivefold excess of PCl_5 proceeds with participation of the acetyl and free amino-groups with formation of 2,4,4,6-tetrachloro-1,3,4-diazaphosphorine **208** in a satisfactory yield.

Treatment of *N*-chloroacetyl-*N*'-methylurea with phosphorus pentachloride results in the formation of the substituted 1,3,2-diazaphosphetidin-4-one **209**.^{192, 193}

On the other hand, heating of chloroacetylurea with PCl_5 leads to 2,4,4,5,6-pentachloro-1,3,4-diazaphosphorine **210**.¹⁹⁴

1,3-Dialkyl(alkylaryl)-2,2,2-trichloro-1,3,2-diazaphosphetidin-4-ones **211** are obtained by the reaction of equimolar amounts of PCl_5 and *N,N'*-dialkyl-(alkylaryl)ureas.¹⁹⁵ When an excess of PCl_5 is employed, the carbonyl group is chlorinated.¹⁹⁶

R = Alk ($\text{C}_1\text{--C}_4$).

The 1,3,5,2-triazaphosphorines **212** and **213** are obtained by the interaction of PCl_5 with *sym*-dimethylurea.¹⁹⁷

The phosphorus analogues of barbituric acid **214** are formed on condensation of phosphonoacetic acid esters with urea **3** in the presence of sodium alkoxide.¹⁹⁸

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{Alk.}$

The condensation of 4-chloro-2-dialkoxyphosphorylbutyric acid esters with urea in the presence of sodium alkoxides (1 : 2) leads to spirocyclopropanediazaphosphorinones **215** via intermediate cyclopropane derivatives.¹⁹⁹

$\text{R}^1, \text{R}^2, \text{R}^3 = \text{Alk.}$

Aryl- and *sym*-diaryl-ureas and -thioureas readily afford the spiro-compounds **217** and **218** after 30 min on interaction with hexachlorodiazaphosphetidine **216** in acetonitrile.¹⁹⁹

X = O, S.

It has been shown²⁰⁰ that the chlorine atom in compounds of this type is substituted by pentacarbonylmanganese. The reaction is carried out under an inert atmosphere.

R = Alk, Ar.

Treatment of symmetrical dimethylsilylureas **219** with alkyl or aryl-fluorophosphanes results in cyclisation with the cleavage of the Si–C bond and the formation of the fluorophosphadiazetines **220**.²⁰¹

R = Alk, Ar.

The condensation of *o*-amino- or *o*-hydroxy-diphenylureas with tris(dialkylamino)phosphine afforded a series of the corresponding substituted 1,3,2-oxaza- or diaza-benzophospholenes **221**.²⁰²

R = NH₂, OH; X = O, NP(NAlk₂)₂.

2. Boron-containing heterocycles

On heating with N-substituted ureas, haloorganylboranes give rise to heterocycles of the type **222** and **223**.^{203–205}

R¹, R², R³ = Alk.

The reaction of the borazines **224** with dimethylurea results in the formation of 1,3,5-triaza-2,4-diboracyclohexan-6-ones **225**.²⁰⁶

R, R' = Alk.

The interaction of dimethylurea with borazine yields triaza-boracyclohexane-4,6-dione **226** after 10 min.²⁰⁶ It has been shown that the reaction proceeds *via* the intermediate formation of *N,N',N''*-trimethylbiuret.

Refluxing of dimethylurea with the borazines **227** in toluene leads to the bicyclic borazinones **228** after 9–10 h.²⁰⁶

R = Alk, Ph.

The interaction of compound **229** with dimethylurea is used to synthesise the corresponding 1,3,5-triaza-2-boracyclohexane-4,6-diones **230** and a mixture of the ammonium salts of the spirane borates **231**.²⁰⁷

X = Me₂NH₂, MeNH.

3. Sulfur-containing heterocycles

Aroylthiobiurets **232**, which readily undergo oxidative cyclisation to 5-arylamino-2-methyl-(2*H*)-1,2,4-thiadiazol-3-ones **233** (yield 31%–85%), have been obtained by the interaction of aroyl isothiocyanates with *N*-methylurea.²⁰⁸

Preparative methods of synthesis have been developed²⁰⁹ for thiadiazolodiones **234** on the basis of the reaction of chlorocarbonylsulfenyl chloride with ureas.

R = Me, MeOCH₂, cyclo-C₆H₁₁, Ar.

It has been established²¹⁰ that, on treatment with a 1:1 mixture of HgO and the disodium salt of ethylenediaminetetraacetic acid, aryl-substituted benzenesulfonylureas **235** cyclise to the sulfonylamidines **236** *via* a stage involving the formation of the sulfonylaminals **237**.

n = 1–3.

On treatment with catalytic amounts of HCl or CF₃COOH, the thiadiazinediones **238** are capable of undergoing reversible ring cleavage to ethynylthiocarbonylureas **239**. Subsequent treatment of the resulting solutions with an organic base is accompanied by complete displacement of the equilibrium towards the cyclic form **238**.²¹¹

According to Vovk,²¹¹ the transformation **238** $\rightleftharpoons$ **239** is an example of a new type of ring–chain enamidine tautomerism.

The interaction of chlorosulfonylureas **240** with sulfur trioxide and cyanamides entails the formation of 1,4,3,5-oxathiadiazine 4,4-dioxides **241**.^{212, 213}

R = H, Alk.

4. Oxygen-containing heterocycles

We examined the methods of synthesis of oxazole derivatives using ureas in the previous Sections of this review. The methods of synthesis of compounds with a larger ring size are described here. Thus a series of 1,5,3-benzodioxazepinones **242** have been synthesised in 64%–82% yields by refluxing *N*-alkylidene-*N'*-acylureas **243** with catechol and its derivatives.²¹⁴

R = Ar; R' = H, Cl, Br.

The vinyl ethers of the aminoalcohols **244** give rise to the cyclic carbamides **245** on treatment with *N,N'*-dialkylcarbamoyl chlorides in the presence of potassium carbonate and in the absence of steric hindrance to cyclisation.²¹⁵

R¹, R² = H, Me, Bu, CH₂Ph, cyclo-C₆H₁₁;
R³ = Me, Et, Bu, C₁₂H₂₅, C₁₈H₃₇;
n = 0, 1.

The substituted 1,2-oxazines **246** have been obtained by a three-component reaction of nitroalkenes **247** with 1,3-dicarbonyl compounds and urea **3**.²¹⁶

The interaction of unsubstituted urea and of its 1,3-disubstituted derivatives with aldehydes in the presence of acid catalysts results in the formation of 4-oxotetrahydro-1,3,5-oxadiazines **248**.^{217, 218}

R = H, Alk; R' = Alk, Ar.

The stable tetrahydro-1,3,5-oxadiazines **249** have been obtained by condensing ureas (thioureas) with polyfluoro ketones in acetic anhydride.²¹⁹

R = F, NO₂; X = O, S.

4,6-Dichloro-2-(*N*-methylimino)-3-methyl-4-oxo-1,3,4-oxazaphosphorine **250** has been synthesised by acetylating dimethylureas and subsequent treatment of the intermediate with PCl₅ and SO₂.²²⁰

VI. Conclusion

The data presented demonstrate the extensive possibilities for the employment of ureas and related compounds in the synthesis of azaheterocycles with a wide variety of structures — oxazoles, imidazoles, pyridines, phthalocyanines, triazines, and many others. The advances in the practical application of the compounds obtained using ureas, particularly in medicine and biochemistry, are so numerous that they require an independent survey.

Abstract. Results of studies on the radiation-chemical transformations of cellulose, its ethers, and some other polysaccharides (xylan, starch, dextran, chitin, chitosan, and heparin) are discussed. Ionising radiation causes the degradation of these compounds accompanied by decomposition of the pyranose ring and formation of compounds with carbonyl and carboxy groups, as well as formation of hydrogen, carbon dioxide, and carbon monoxide. The efficiency of degradation increases considerably with temperature and depends on the structure of the polysaccharide and the nature of its substituents. A mechanism of the radiation-chemical transformations of cellulose and other polysaccharides is suggested. The prospects of using radiation-chemical methods for processing of cellulose and other polysaccharides in industry and agriculture are considered. The bibliography includes 213 references.

I. Introduction

Cellulose is the most widespread natural polymer, the main component of plants. Products based on cellulose are widely used in everyday life. In many technological processes, cellulose undergoes radiation treatment. They include: sterilisation of cellulose-based dressings; degradation of plant raw materials aimed at the intensification of industrial hydrolysis of raw materials and production of foodstuff, forage, and technical products (alcohols, furfural, *etc.*); preliminary treatment of cellulose for subsequent production of its various derivatives (nitrates, xanthates, *etc.*), and a number of other processes.

The prospects for the successful adoption of radiation technology for preliminary cellulose treatment stem from the possibility of replacing ecologically hazardous chemical steps by pure

treatment with ionising radiation, reduction of the number of technological stages, and decrease in energy consumption. These factors encourage the studies in the field of radiation chemistry of cellulose and related compounds, in particular, on the elucidation of the detailed mechanism of radiation-induced chemical transformations. Furthermore, depending on the area of cellulose application, opposite problems are targeted: on the one hand, increase in the radiation stability of cellulose, and on the other hand, intensification of its degradation.

Preliminary destructive treatment of cellulose by ionising radiation may turn out to be particularly important for the industrial production of viscose and nitrate esters. The manufacture of these compounds generally includes a preliminary stage of cellulose treatment in order to decrease its molecular mass. Radiation treatment can eliminate this stage or simplify it considerably. In addition, radiation-induced degradation of cellulose-containing plant materials favours their subsequent acid hydrolysis, which is particularly important for the intensification of industry based on hydrolysis. It has also to be taken into consideration that cellulose and a number of other polysaccharides (chitin, starch, *etc.*) are the constituents of biological structures. Therefore, systems based on these polysaccharides are rather convenient models for studying the effect of radiation on biological structures.

We discussed the problems of the radiation chemistry of cellulose in a previous review¹ in which the results published before 1984 were systematised. Since that time, new experimental results on the mechanism of cellulose radiation-induced degradation have been obtained. This mechanism has the form of a local explosion of the pyranose ring in the polymeric chain, which results in its scission with formation of diverse products. To date, quantitative relationships for the radiation-chemical yields of degradation and major products[†] have been determined and ways for intensifying the degradation of cellulose and plant

[†] The radiation-chemical yields refer to 100 eV of energy absorbed. For example, the yield of degradation is the number of bonds cleaved per 100 eV of energy absorbed, the yield of gaseous products is the number of gas molecules per 100 eV of energy absorbed, the yield of the oxidised groups is the number of these groups per 100 eV of energy absorbed, *etc.*

materials by combined ionising radiation and thermal treatment as well as by mechanical treatment (grinding) have been established. The present review includes data on the radiation-induced degradation and chemical transformations of other polysaccharides (starch, xylan, chitin, *etc.*), which make it possible to reveal general regularities of the interaction of ionising radiation with this important class of natural compounds.

II. Random degradation of polymers

The main result of the action of ionising radiation on cellulose (as well as on other polysaccharides) is scission of the polymeric chain, *i.e.* the degradation changing the physicochemical properties of the polymer (structural state, mechanical strength, solubility in different media, reactivity, *etc.*).¹

Let us consider degradation in which a macromolecule undergoes random scission without cross-linking.^{2–5} It will be shown below that this process predominates on irradiation of cellulose and other polysaccharides.

The degradation of polymers is described using the statistical method. If the initial molecular-mass distribution (MMD) of the polymer is the most probable one and the chain scission occurs randomly, the MMD will be maintained with a decrease in the average molecular mass of the fragments. The following equation relating the number of scissions (S) per initial polymeric molecule to the number-average (P_n) and weight-average (P_w) degrees of polymerisation is valid

$$S = \frac{P_n^0 - P_n}{P_n} = \frac{P_w^0 - P_w}{P_w}, \quad (1)$$

where P_n^0 and P_w^0 are the starting number-average and weight-average degrees of polymerisation, respectively. For the most probable distribution, $P_w = 2P_n$.

The number of scissions can also be calculated from the radiation-chemical yield of degradation according to the following equation:

$$S = \frac{DP_n^0 m G^0}{10^2 N_A}, \quad (2)$$

where D is the absorbed dose, eV; m is the molecular mass of a polymer monomeric unit (which equals 162 for cellulose); and N_A is the Avogadro number.

Combining Eqns (1) and (2) we obtain the dependence of the number-average (or weight-average) degree of polymerisation on the absorbed dose of ionising radiation

$$\frac{1}{P_n} - \frac{1}{P_n^0} = \frac{G^0 m D}{10^2 N_A}. \quad (3)$$

Thus, the quantitative determination of the efficiency of radiation-chemical degradation of cellulose expressed through the yield G^0 is reduced to finding the dependence of P_n or P_w on the absorbed dose according to Eqn (3).

Experimental determination of the number-average degree of polymerisation P_n of cellulose is carried out rarely. This is usually performed using osmometry, which gives a considerable error. In practice, the degree of polymerisation of cellulose is most commonly determined by measuring the viscosity of its dilute solutions. The empirical Mark–Kuhn–Houwink equation, which relates the characteristic viscosity of a solution $[\eta]$ to the viscosity-average degree of polymerisation P_v , is valid in this case:

$$[\eta] = K P_v^\alpha. \quad (4)$$

For a given polymer, the K and α coefficients are constants provided the measurement conditions and solvents are the same. The dependence of P_v on P_n is given by the equation³

$$P_v = P_n[(\alpha + 1)\Gamma(\alpha + 1)]^{1/\alpha} = P_n^0 k, \quad (5)$$

where $\Gamma(\alpha + 1)$ is the gamma-function of α and k is a coefficient. Depending on the shape of the polymer macromolecule in solution and the character of the solvent effect, the value of $1/\alpha$ varies from 0.6 to 1.0, which corresponds to a variation of the term in brackets in Eqn (5) just from 1.82 to 2.0.³ Thus, one can determine the yield of polymer degradation G^0 from the experimental values of P_v using the equation

$$\frac{1}{P_v} - \frac{1}{P_v^0} = \frac{G^0 m D}{10^2 N_A k}, \quad (6)$$

where the k coefficient takes account of the actual ratio of P_v and P_n determined from Eqn (5).

In determination of the radiation-chemical yield of cellulose degradation, one makes certain assumptions on the character of its molecular-mass distribution and the random chain scission; also, one takes into consideration the use of different experimental methods for the measurement of its molecular mass with different inherent errors. The degradation of cellulose has been dealt with in a number of studies.^{6–24} The yields of degradation have a considerable scatter from 1.8–2.0 (see Refs 6 and 7) to 25 (see Ref. 8). Let us consider in more detail the effect of the main factors on the determination of the radiation-chemical yield of cellulose degradation.

Molecular-mass distribution factor. Equations (3) and (6) were obtained for the most probable molecular-mass distribution. However, this is generally not the case for the MMD of the original celluloses. One cannot state *a priori* that radiation-induced degradation results in the most probable distribution. Therefore, it is necessary to follow the changes of cellulose MMD during irradiation and to find the relationship between P_n and P_v . If the MMD differs from the most probable one, the k coefficient in Eqn (6) should differ from the value corresponding to the most probable distribution (~ 2). However, it was assumed groundlessly that $P_n = P_v$.^{6, 7, 9–14, 17–19} The radiation-chemical yield was generally close to 3.

This approach is based on the assumption on the monodisperse MMD and its retention during the irradiation, *i.e.* it is assumed that the radiation-induced cleavage of polymer chain bonds is not random. Then it should follow that the yield of degradation is underestimated considerably. If this process is random and the cellulose MMD is nonuniform before the irradiation, it will tend to reach uniformity during the irradiation. It will be shown below that the ratio $P_v \simeq 2P_n$ is established in the case of uniform MMD. Therefore, the yield of degradation should be twice as high as that measured under the assumption that $P_n = P_v$.

Assuming a random character of cellulose degradation, it is easy to show that with virtually any initial MMD, the most probable distribution is reached during the irradiation. The dose required for this may vary from 30 to 80 kGy depending on the initial MMD. For the first time, this conclusion seems to have been confirmed experimentally by Kusama *et al.*²⁰ It was shown that during γ -irradiation of cotton cellulose whose initial MMD was close to the monodisperse one ($P_v/P_n = 1.26$), the most probable distribution was reached at an absorbed dose of 30–50 kGy ($P_v/P_n = 2.0 \pm 0.1$). Hence, when the molecular mass of cellulose is determined by viscosimetry, the use of Eqn (6) for the description of degradation is justified at doses exceeding the above value.

Chemical stability of irradiated cellulose in different solvents. In early studies, the viscosity of cellulose was measured mostly in aqueous solutions of copper complexes with ammonia or ethylenediamine.^{6, 7, 9–12, 14, 16, 21–24} In some cases, the radiation-chemical yields of degradation differed considerably. As to the yield of carbonyl groups, it was unreasonably high (*e.g.*, 58 in Ref. 22). This fact may be regarded as an indication of the chain character of degradation. However, it became clear later that cellulose in the presence of bivalent copper underwent spontaneous oxidative alkaline degradation. This process was initiated

by the existing terminal carbonyl groups,²⁵ whose concentration in cellulose increases significantly after irradiation. Therefore, one has to consider critically the results obtained without taking account of the possible spontaneous alkaline degradation of cellulose in the solvents specified above.

A quantitative estimate of possible errors resulting from the use of alkaline solutions of copper complexes with ammonia or ethylenediamine for the analysis of cellulose was made in by Sakurada *et al.*¹³ As shown in later studies, the optimum solvent for cellulose is cadoxen, *i.e.* an aqueous solution containing cadmium oxide and ethylenediamine.^{26–28} In this solvent, cellulose undergoes no noticeable spontaneous degradation. It was extensively used in studies of the radiation-induced degradation of cellulose. In some cases, cellulose was nitrated first, and the viscosity of the resulting nitrates was then measured in acetone.^{13, 15, 20} All these methods made it possible to avoid the errors caused by the chemical degradation of irradiated cellulose during the preparation of its dilute solutions.

III. Radiation-chemical degradation of cellulose

The radiation-chemical degradation of cellulose of different origins in different solvents has been studied.^{16, 20, 29, 30} Changes in the degree of polymerisation of cotton cellulose upon γ -irradiation as measured by viscosimetry in cadoxen were shown to be a function of the absorbed dose.²⁹

Dose /kGy	0	5	10	32	170	480	680	800	1680
P_v	2537	827	723	314	138	32	30	28	14

It is seen that the degree of polymerisation decreases with an increase in the dose, *i.e.* cellulose undergoes degradation. It was noted²⁹ that the crystallinity index remains virtually unchanged at all absorbed doses and equals 73%. The amount of the fraction soluble in ethanol increases from 10.3% in non-irradiated cellulose to 43.7% at an absorbed dose of 1680 kGy. Figure 1 presents the dependence of $1/P_v - 1/P_v^0$ on the absorbed dose. Unless specified otherwise, it was dry cellulose that was subject to γ -irradiation *in vacuo* or in an inert gas. The cellulose was dried at 105 °C over P_2O_5 .

The characteristic viscosity of cotton cellulose has been measured in a solution of copper–ethylenediamine complex.¹⁶ Freshly prepared solutions were used, and the possible spontaneous alkaline degradation of cellulose was taken into account. In another study,³⁰ the sulfite cellulose with an initial degree of polymerisation of 920 was used; the characteristic viscosity was measured in cadoxen solutions. Finally, Kusama *et al.*²⁰ studied Mexican cotton with an initial degree of polymerisation of 3265,

whose characteristic viscosity was measured in acetone following nitration of the irradiated material.

At doses above ~ 50 kGy, all experimental data from these works^{16, 20, 29, 30} fit on a linear plot, which passes through the origin. Hence, Eqn (6) actually gives a good quantitative description of the dependence of the degree of polymerisation on the absorbed dose for celluloses from various sources. It turned out to be insignificant in practice what solvent was used for the determination of the characteristic viscosity of dilute cellulose solutions and what kind of cellulose was used. A detailed analysis of data for doses below 50 kGy showed some deviations of the $(1/P_v - 1/P_v^0) - D$ dependence from linearity, which is due to nonuniform MMD of the starting celluloses and to the fact that the most probable distribution is reached at doses above 50 kGy.

Thus, the validity of Eqn (6) confirms the random character of degradation and the attainment of the most probable molecular-mass distribution. When determining the radiation-chemical yield of degradation, one has to take into account the relationship between the viscosity-average and number-average degrees of polymerisation as a function of the α factor involved in Eqn (5). For cadoxen, the α factor is 0.94 (see Refs 26–28), and the corresponding relationship is $P_v = 1.96P_n$. For a copper–ethylenediamine complex solution, the α factor is considered to be 0.9 (see Ref. 16), and $P_v = 1.9P_n$. Finally, for solutions of nitrocellulose in acetone, the α factor is considered to be 1 (see Ref. 20), and $P_v = 2P_n$. Taking the errors inherent in the viscosimetric method into account, one has grounds to assume that the following relationships are valid for all of the solvents mentioned: $P_v = 2P_n$ and $P_v = P_w$. Hence, the k coefficient in Eqn (6) may be considered to be ~ 2 . Given the slope of the linear plot in Fig. 1, one can find the yield of cellulose degradation from Eqn (6); it equals 6.0 ± 1.0 . In Refs 16, 20, and 30, whose experimental data we used for the determination of the degradation yield, it was assumed that $P_v = P_n$. The yield determined under this assumption was about two times smaller than that determined by us.

It was noted¹² that the yield of degradation of various kinds of cellulose materials changed from 7.6 to 3.1 with an increase in the absorbed dose from 12 to 120 kGy. The yields were calculated assuming that $P_n = P_v$. This dependence of the yield on the dose can be explained as follows. At small doses, uniform MMD is not established yet, hence it is improper to use Eqn (6) for calculation of the yield. At large doses, uniform MMD is reached, so it is necessary to bear in mind that $P_v = 2P_n$. In this case, we find that the yield of degradation is 6.2, *i.e.* it agrees with the value determined above.

The viscosimetric method in copper–ammonia solutions was used to measure the degradation yields, which were found to be 4.5 (Ref. 24) and 5.0 (Refs 3 and 21), account being taken of the partial degradation of cellulose. The actual dependences of P_n and P_v on the characteristic viscosity according to Eqns (4) and (5) were used in these calculations. The P_n values of nitrocelluloses were determined by the osmometric method, and the degradation yields were calculated to be 3.3 (Ref. 13) and 2.9 (Ref. 15). These low yields might be due to the low accuracy of the method used and the small absorbed doses at which the uniform MMD was not achieved.

The discrepancies between the literature data for the radiation-chemical yields of cellulose degradation are explained by different interpretations of viscosimetric data for the molecular mass determination and by differences in the absorbed doses. Given a random pattern of radiation-induced degradation, it is only at a certain absorbed dose that the most probable distribution is reached, where $P_v = 2P_n$. In this case, Eqn (6) can be used for the yield determination. Analysis of experimental data from numerous works shows that, taking account of the factors specified above, the yields are very similar and are equal to 6.0 ± 1.0 .

Cellulose materials differ markedly in their initial molecular masses and in the MMD.^{31–34} For instance, the weight-average degree of polymerisation (P_w) changes from several thousand for

Figure 1. Dependence of $1/P_v - 1/P_v^0$ in cellulose on the absorbed dose; (1–4) data from Refs 29, 16, 30, and 20, respectively.

cotton linter to ~ 400 for viscose fibres.³⁴ As a rule, the MMD differs noticeably from the most probable distribution, and the non-uniformity factor $U = P_w/P_n$ for the majority of natural and industrial celluloses varies over the range 1.2–3.0.³³

Let us evaluate the effect of the MMD non-uniformity factor of the starting cellulose on the dependence of $1/P_v$ on the absorbed dose assuming a random degradation pattern. At absorbed doses D_c where the most probable distribution is reached, the following equation is valid:

$$\frac{1}{P_v} = \frac{G^0 m D_c}{10^2 N_A k} + \frac{U^0}{2P_v^0},$$

where $U^0 = P_w^0/P_n^0$.

According to this equation, the radiation-chemical yield of degradation can be calculated from the slope of the plot of $1/P_v$ versus the absorbed dose, while the intercept with the y-axis allows one to determine U^0 . This approach was used in a study of the radiation-induced degradation of wood and cotton cellulose.³⁵ The yield of degradation was 5.6 for both celluloses. The calculated U^0 value was in good agreement with the measured one.

Fractionation was used^{35,36} to determine the MMDs of various types of intact and irradiated celluloses, and the values of P_w and P_n were calculated. The integral MMD curves prior to and after irradiation are shown in Fig. 2. After irradiation, the integral MMD curve becomes considerably narrower and is shifted toward smaller P_w . For example, the major part of macromolecules in non-irradiated cellulose has P_w values in the region from 600 to 1500, whereas after irradiation to the absorbed dose of 40 kGy, more than 90% of the macromolecules have P_w from 250 to 400. The percentage of the α -fraction measured by the solubility of cellulose in a 17.5% alkali solution decreases as the absorbed dose increases, hence the content of a low-molecular-weight fraction having enhanced solubility increases. The results of mathematical treatment of the integral MMD curves are presented in Table 1. It is seen that both the number-average and weight-average degrees of polymerisation decrease as the dose increases, while the non-uniformity factor increases after irradiation to reach the value of ~ 2 , which corresponds to the most probable distribution. The pattern of U variation is similar to that found by Kusama *et al.*²⁰ who used gel permeation chromatography. The most probable MMD was observed²⁰ at somewhat smaller doses. This difference is probably due to the fact that the fractionation of irradiated celluloses results in a loss of some portion of the low-molecular-weight fraction, which in turn affects the P_w/P_n ratio.

Figure 2. Integral MMD curves for cotton cellulose.^{35,36} (1) before irradiation, (2) after irradiation; the absorbed dose was 40 kGy.

Thus, the experimental data from many studies on cellulose degradation are described satisfactorily by equations derived assuming a random cleavage of the polymeric chain. As a result of irradiation, the most probable MMD is attained. The average

Table 1. Molecular-weight characteristics of celluloses exposed to γ -irradiation.^{35,36}

Dose / kGy	P_v	P_w	P_n	P_w/P_n
Wood cellulose				
0	974	987	700	1.41
50	302	300	195	1.55
100	196	197	96	2.05
150	150	185	87	2.13
Cotton cellulose				
0	1220	1160	1060	1.1
40	330	340	240	1.4
100	190	182	124	2.0

radiation-chemical yield of degradation is generally 6.0 ± 1.0 . This yield is virtually independent of the dose rate of γ -irradiation or accelerated electrons, on the initial degree of polymerisation, and on whether the irradiation was carried out in a vacuum, in an inert gas, or in air. The absence of a noticeable effect of air on the degradation efficiency is most probably due to the dense crystalline packing of cellulose, which hinders the diffusion of oxygen to the reaction centres. Oxygen has only a slight effect on the formation of carbonyl and carboxy groups, which should be due to the partial radiation-induced oxidation of the surface layer of the material. Special studies showed that the presence of moisture has a slight inhibiting effect on the cellulose degradation.²⁰

The degradation of cellulose is well described by Eqn (6) up to an absorbed dose of ~ 200 kGy. At higher doses, $1/P_v - 1/P_v^0$ tends to a steady value. Since

$$\frac{1}{P_v} - \frac{1}{P_v^0} = \frac{1}{P_v^0} \left(\frac{P_v^0}{P_v} - 1 \right) = \frac{S}{P_v^0},$$

where S is the number of bonds cleaved in one macromolecule, the rate of accumulation of cleaved bonds decreases, *i.e.* the efficiency of degradation decreases. This phenomenon, which is rather common for radiation-chemical processes, results from the accumulation of radiolysis products with an increase in the absorbed dose; these products then accept the energy of the ionising radiation. For cellulose, this phenomenon may be due to the fact that the cleavage of bonds in macromolecules is accompanied by the formation and accumulation of radicals stable at room temperature and new functional groups. Compounds with carbonyl and carboxy groups are, along with radicals, efficient acceptors of electrons and excited species formed upon irradiation. Therefore, the accumulation of these compounds during radiolysis hinders subsequent degradation of cellulose. In fact, the degradation of cellulose-based materials containing carboxy groups (monocarboxylcellulose) is much slower.³⁷ It should be noted that up to very large absorbed doses (> 1000 kGy), the degradation of cellulose can be described by an empirical equation similar to Eqn (6) in which the value of D has an exponent q equal to 0.83 (see Refs 16 and 19) or 0.73 (see Ref. 12).

IV. Products of radiation-chemical transformations of cellulose

The action of ionising radiation on cellulose results in profound chemical transformations and produces carbonyl and carboxy groups at the sites of bond cleavage and gases, namely, H_2 , CO_2 , and CO .^{38–42} The dependences presented in Fig. 3 demonstrate the change in the content of $>C=O$ and $-COOH$ groups in the γ -irradiation of cotton cellulose at room temperature. The yields of formation of these groups are 6.5 ± 0.5 and 1.8 ± 0.2 , respectively. Hence, the process of cellulose degradation is accompanied by preferential formation of compounds with carbonyl groups. The yields presented here are in good agreement with the values found by Imamura *et al.*¹⁶ The yields of formation of the carboxy

Figure 3. Dependence of the accumulation of carbonyl (a) and carboxy (b) groups in cellulose on the absorbed dose.⁴²

group^{10, 12, 22, 23, 43–46} range from 0.9 to 1.4. Commercial brands of cellulose differ in the content of carbonyl and carboxy groups. However, this does not affect markedly the yields of these groups under γ -irradiation. Irradiation of cellulose increases their content in comparison with the initial concentrations (Table 2). To decrease the degree of polymerisation of commercial celluloses to ~ 300 – 400 , which is an optimum value for their conversion into viscose, nitrate esters, and other products, an irradiation dose of ~ 50 kGy is required. Such an absorbed dose produces ~ 3 mmol of carbonyl groups and 1 mmol of carboxy groups per 100 g of cellulose.

Table 2. Initial concentrations and radiation-chemical yields of oxidised groups upon γ -irradiation of cellulose.^{35, 36}

Cellulose	Concentration /mmol per 100 g		Yield /mmol per 100 eV	
	–CHO	–COOH	–CHO	–COOH
Sulfite wood	0.13	0.24	6.0	2.0
Sulfite wood, high viscosity	0.53	3.16	5.4	1.8
Cotton	0.10	0.45	5.9	2.5

In the initial stage of γ -irradiation, the dependence of the accumulation of carbonyl and carboxy groups in cellulose on the absorbed dose is linear (see Fig. 3). At greater doses, the concentration (c) of these groups increases with the absorbed dose according to the equation

$$c = BD^q,$$

i.e. it obeys the same law as the degradation of cellulose at similar doses. The B coefficient is 6.8×10^{-7} and 1.8×10^{-7} mol (g kGy) $^{-1}$ for carbonyl and carboxy groups, respectively.¹⁶ The q exponent was found to be ~ 0.5 for both groups. In a discussion of data by Blouin and Arthur¹⁰ for the accumulation of carboxy groups,¹² the q exponent was determined to be 0.69. Obviously, as in the case of degradation, the existence of a limiting concentration of functional groups in cellulose is explained by their involvement in radiation-chemical transformations.

The gaseous products of cellulose radiolysis were studied by several authors.^{22, 23, 47–50} The yields of hydrogen, carbon dioxide, and carbon monoxide measured in a vacuum in the γ -irradiation of cellulose were 1.3, 1.6, and 0.8, respectively.^{22, 23} Carbon dioxide predominates in the products of radiation-chemical transformations of cellulose. A systematic study of gas formation in the irradiation of cellulose in vacuum has been carried out.^{40, 42} Linear dependences of the H_2 , CO_2 , and CO accumulation on the absorbed dose were found up to doses of ~ 300 kGy. The yields determined from these linear plots were 3.2 (H_2), 6.0 (CO_2), and

0.9 (CO). In addition to the gases mentioned, a trace amount of methane was also detected. The reported yields and ratio of the gases formed agree with other data.⁴⁹

Because of the high molecular mass of macromolecules of cellulose and other polysaccharides, the use of traditional analytical methods such as chromatography and mass spectrometry for the determination of the final products of their radiation-chemical transformations is virtually impossible. It was noted^{48, 51, 52} that irradiated cellulose contains water-soluble and water-insoluble fractions. Components that dissolve well in ethanol can be isolated from the water-soluble fraction. They include cellobiose, glucose, arabinose, glyoxal, 2-oxogluconic acid, and a number of other acids.⁴⁸ Hydrolysis of the water-soluble fraction results in xylose, arabinose, glucuronic and formic acids, and malondialdehyde.^{43–45, 53} The following radiation-chemical yields were determined for some of these compounds: 48.7 ± 2.4 for glucose, 10.1 ± 2.0 for xylose, 2.3 ± 0.2 for formic acid, and 0.016 for malondialdehyde.⁴⁴ The formation of pentosans upon irradiation of cellulose was also reported.¹⁶

V. The nature of radical products in cellulose

There are plenty of data on free radicals formed under the action of ionising radiation on cellulose.^{54–64} However, the generally accepted concept of their nature has been settled only after a series of publications.^{65–69} Figure 4 shows the ESR spectra of several types of cellulose (absolutely dry, moistened with H_2O , and moistened with D_2O) γ -irradiated at 77 K. All of the irradiated samples are blue (the dry cellulose is weakly coloured, while the colour of moist samples is rather intense) and decolourise upon illumination. This is accompanied by disappearance of narrow singlet signals of ~ 1.0 – 1.2 mT (in the case of H_2O) or 0.3–0.5 mT (D_2O) widths in the central part of ESR spectra of moistened celluloses. In the spectrum of dry cellulose, the signal intensity is much lower, and photobleaching does not change noticeably the ESR spectrum. These singlets are due to captured electrons.^{66, 70}

Figure 4. ESR spectra of cellulose γ -irradiated at 77 K;⁷⁰ (a) absolutely dry cellulose; (b) moistened with H_2O (40%); (c) moistened with D_2O (40%).

After photoannealing of the captured electrons by visible light, the ESR spectra of dry and moistened celluloses become identical with the spectrum shown in Fig. 4a. The latter is a superposition of a triplet signal, in which the intensity ratio of the components is 1 : 2 : 1 and the splitting is 3.0 ± 0.2 mT, with a doublet signal with 2.6 ± 0.1 mT splitting (Fig. 4a shows the hyperfine structure of ESR signals of the radicals). The triplet and doublet signals are due to radicals in which the unpaired electron interacts with β -protons, viz. with one proton to form a doublet

and with two protons to form a triplet. The doublet signal can belong only to the radical formed upon abstraction of a hydrogen atom from the C(1) atom of the glucopyranose ring, while the triplet signal can be identified with any radical containing an unpaired electron at positions C(2), C(3), or C(4). Such interpretation of ESR spectra of irradiated cellulose has been suggested in a series of publications.^{65–69}

Subsequent analysis of the radical centre conformations made it possible to draw a fundamental conclusion that the radicals with doublet and triplet hyperfine structures (HFS) are terminal and appear due to the cleavage of the glucosidic bond in the polymeric chain of cellulose.⁷⁰

Let us discuss this approach in more detail. The monomer units of cellulose consist of pyranose rings in the chair conformation with axial hydrogen atoms.

The polymer and its fragments are characterised by high rigidity, which restricts considerably the conformational transitions.

In valence-saturated organic compounds, the carbon atom has four sp^3 -hybrid orbitals. Cleavage of one C–H bond results in sp^2 -hybridisation, while the unpaired electron in the radical centre occupies a $2p_z$ orbital perpendicular to the plane of the three sp^2 -orbitals. In this arrangement, it interacts efficiently with the β -protons. It is obvious that such radical centres at positions C(1) and C(4) of the pyranose ring cannot be obtained without cleavage of the polymeric chain of cellulose. The HFS coupling constants indicate that terminal radicals are formed. This conclusion is supported by calculations of HFS constants for “cellulose” radicals carried out with the assumption of complete sp^2 -hybridisation.⁷⁰ Figure 5 shows a projection of a radical fragment.

Figure 5. Frontal projection of the C_α – C_β radical fragment. X, Y, Z, and R are substituents. The angle θ between the axis of the $2p_z$ orbital of the unpaired electron and the projection of the C_α –H on the plane perpendicular to the C_α – C_β bond characterises the conformation of the radical centre.

The dependence of the HFS coupling constant for β -protons, a_H , on the angle of rotation around the C_α – C_β bond is expressed by the equation⁷¹

$$a_H = Q_\beta \rho_x \cos^2 \theta,$$

where Q_β is a constant equal to 5.86 mT for alkyl-substituted radicals,⁷² and ρ_x is a coefficient that takes into account the change in the spin density of the unpaired electron at the α -carbon atom caused by substituents. In radicals of the X–C–Y type, the value of ρ_x is calculated by the formula^{72, 73}

$$\rho_x = (1 - \Delta x)(1 - \Delta y)(1 - \Delta z).$$

The Δx , Δy , and Δz values show the fraction of spin density withdrawn by the X, Y, and Z substituents, respectively. The coupling constants of radical centres in cellulose were calculated with the use of data for substituents that best match the actual ones in the radicals in question. It was found that the calculated constants (2.72 mT for the triplet and 3.04 mT for the doublet) fit

those observed experimentally (2.6 and 3.0 mT, respectively) if one assumes that the θ angle for the axial β -hydrogen atoms with respect to the C(1) and C(4) atoms is 30° . This value agrees with that expected for the actual structure of the radical centres where they are localised at these positions of the pyranose ring at the ends of the polymeric chain.

Calculations for the radical centres at positions C(2) and C(3) with the expected triplet structures can be carried out less accurately due to the absence of data on the electronegativity of the closest substituents. Nevertheless, it is believed that the coupling constants for them (triplets) would also be close to the experimental value of 2.6 mT. Therefore, it cannot be ruled out that radicals with an unpaired electron at the C(2) or C(3) atoms also appear on irradiation of cellulose. However, the fact that the C(1)–H and C(4)–H bonds are the weakest makes them most susceptible to hydrogen abstraction.

The conclusion on the formation of radicals at these positions of the pyranose ring due to the polymeric chain cleavage is in good agreement with data on chain degradation and formation of products of radiation-chemical transformations. Moreover, considering the rigid structure of cellulose, sp^2 -hybridisation could be formed only due to the cleavage of the glucosidic bonds. Otherwise, due to the strong dependence of a_H on the angle θ , one could expect a considerable deviation of the HFS coupling constants from those found experimentally. Thus, the radical states in irradiated cellulose are localised in the terminal fragments of the polymeric chain.

An estimate⁷⁰ shows that the yields of radicals **1** and **2** are approximately the same, *i.e.* the radiation-induced cleavage of the C(1)–H and C(4)–H bonds occurs with about the same probability even at the liquid nitrogen temperature.

When a considerable amount of water (up to 50 mass%) was present in cellulose samples, an ESR signal was found in the temperature range corresponding to unfreezing of the vibrational-rotational mobility of the pyranose ring fragments. This signal is a triplet (2.5–2.7 mT splitting) of quadruplets (0.5–0.7 mT splitting).⁷⁴ It belongs to the radical **2**, whose ESR spectrum displays the hyperfine coupling on γ -protons at C(6) and C(2) due to the narrowing of the triplet signal components.

As mentioned above, γ -irradiation of cellulose at the liquid nitrogen temperature results in the formation of trapped electrons with low yield; which cause the blue colour of the samples.^{66, 67, 70} The colour intensity increases with the humidity of the samples. If heavy water is used, the ESR signal of trapped electrons becomes much narrower, and its intensity increases (Fig. 4*b,c*). The reason is that the stabilisation of electrons occurs in intermolecular traps in the field of oriented dipoles of water molecules.⁷⁵ The ESR signal of trapped electrons is an envelope of unresolved HFS due to the coupling of an unpaired electron with the closest protons (deuterons in the case of heavy water). The magnetic moment of the deuteron is *ca.* three times smaller than that of the proton, hence the HFS constant decreases, and narrowing of the ESR signal occurs.

The stabilisation of electrons occurs most efficiently in hydrated cellulose, which contains much more water than natural and industrial celluloses. Due to the transparency of the material, it was possible to record the optical spectrum of the trapped electrons. It is a single wide band with a maximum at 540 nm and a half-height width of ~ 1.3 eV,⁶⁶ which are close to the parameters of optical spectra of trapped electrons in glassy polyatomic alcohols^{76–78} and in concentrated aqueous solutions of carbohydrates.^{79, 80} However, even in hydrated cellulose, the yield of electrons was estimated to be only ~ 0.3 . In cotton and industrial

celluloses, this yield is even smaller, specifically only a few per cent of the overall yield of radicals. Thus, the stabilisation of electrons preferentially occurs in the water microphase. Efficient stabilisation takes place if a system has a glassy (amorphous) structure.^{74, 81} It may therefore be believed that the water present in cellulose exists in the glassy state when it is frozen.

The presence of moisture and ammonia in cellulose accelerates the thermal decay of radicals after γ -irradiation at 77 K.^{22, 55–58, 63, 68} Most probably, this is due to the plasticising effect of the admixtures that weaken the intermolecular bonds in the polymer.⁶⁸ It was noted⁷⁰ that radicals in which the unpaired electron is located at position C(1) (the doublet signal in the ESR spectrum) have the lowest thermal stability. In dry cellulose, such radicals gradually disappear at temperatures above 233 K. The disappearance of doublet and triplet signals occurs at 320–370 K, and a new doublet signal with a 1.4 ± 0.1 mT splitting becomes distinct in the ESR spectrum. Such a coupling constant is characteristic of allylic-type radicals in which the unpaired electron forms a conjugated structure with π -electrons of a double bond.⁸² Radicals of this type are formed in the dehydration of polyatomic alcohols,^{83, 84} mono- and poly-saccharides⁸⁵ according to the reaction

Obviously, dehydration of radicals in the irradiated cellulose (Scheme 1) is also the main process in thermal transformations.

Because of the distortion of the pyranose ring conformation and the decrease in the spin density ρ_z , hyperfine coupling with β -protons is not detected ($a_{\text{H}} < 0.8$ mT). Admixtures of lignin in the irradiated cellulose can cause a new signal to appear in the ESR spectrum (a symmetrical singlet with a width of ~ 1.0 mT).⁶⁷ No $\text{RO}^\bullet$ -type radicals have been detected in the irradiated cellulose.⁷⁴

The irradiation of cellulose at room temperature produces the same radicals as the irradiation at the liquid nitrogen temperature does. However, the concentration ratio of different radicals changes somewhat (the proportion of more thermally stable radicals with a triplet HFS increases). The yield of radicals is ~ 3.0 – 4.0 . The yield increases approximately twofold if the irradiation is carried out at room temperature.⁶³ The kinetics of the accumulation⁶³ and thermal decay⁶⁸ of radicals as a function of the accumulated dose were considered. The observed polychromatic kinetics of radical decay is caused by the physical non-

uniformity of the polymeric matrix. Therefore, the chemically identical processes occurring in the matrix have different rate constants of their limiting steps, *i.e.* a distribution of rate constants over the activation energy exists. The diffusion mobility of macroradicals increases by several orders when a polymer is plasticised with water. The elementary act of their diffusion apparently includes the migration of the pyranose unit, in which the radical is localised, relative to other polymer units. The presence of water weakens the bonds between the polymer chain segments.

VI. Mechanism of radiation-chemical transformations of cellulose

The first step of action of an ionising radiation on a material, *e.g.*, on cellulose (RH), is reduced to ionisation of its components

The Coulomb interaction of the electrons kicked out by irradiation and the parent positive ions after their thermalisation leads eventually to their recombination

This process is favoured considerably by a crystal-like and rigid structure of the polymer. The recombination of opposite charges formed in the physical step of the interaction of the irradiation with cellulose predominates, as follows from the extremely low yield of stabilised electrons, which does not exceed 5% of the overall yield of radicals after γ -irradiation at 77 K.⁷⁰ Recombination is probably preceded by charge migration, which is completed on defects of the crystal structure (mainly in amorphous regions). As a result, excited fragments of the polymer are formed. These fragments decompose with preferential cleavage of the C(1)–H and C(4)–H bonds of the glucopyranose ring

The hydrogen atoms formed abstract hydrogen from other carbon atoms at the corresponding positions

The resulting $\text{R}^\bullet$ radicals are unstable. Because their structures are strained, they decompose with the cleavage of the glucosidic bond to give radicals **1** and **2** and with scission of the glucopyranose ring (Scheme 2).

In our opinion, the available data do not make it possible to infer the detailed mechanism of intermediate reactions. Probably, a substantial role in the radiation-induced decomposition of cellulose belongs to the excited states. The scission of the glucopyranose ring results in CO_2 (or CO) and polymeric compounds containing terminal carbonyl or carboxy groups. Some possible ways for the chemical transformation of irradiated cellulose have been reviewed in detail.¹

According to the general scheme suggested for the radiation-chemical transformations of cellulose, the following ratio of yields of the main products should be expected:

$$2G_{\text{H}_2} = G_{\text{d}} \simeq G_{\text{RCHO}} \simeq G_{\text{CO}_2} + G_{\text{CO}},$$

where G_{d} is the degradation yield.

In fact, this ratio is fulfilled well in the γ -irradiation of celluloses at room temperature. This can be regarded as a confirmation of the general scheme suggested for the initial step of the radiation-induced degradation of cellulose. The yield of carbonyl groups is quite close to the degradation yield and the yield of carbon dioxide, *i.e.* each act of cleavage of the polymeric chain is accompanied by the formation of one CO_2 molecule and one carbonyl group.

It was found^{40, 42} that the degradation of cellulose in the γ -irradiation at the liquid nitrogen temperature is described by the same equations as at room temperature. However, the degradation yield decreases from 6.0 to 3.4. The yields of carbonyl and

Scheme 2

carboxy groups decrease from 6.5 and 1.8 to 3.3 and 1.3, respectively, while the yield of carbon dioxide decreases from 6.0 to 3.1. The yield of molecular hydrogen is about the same as that at room temperature.

Since the yield of hydrogen is used as a measure of the efficiency of radiation-induced cleavage of the C—H bonds in the polymer, it can be concluded that this process is not affected considerably by a decrease in temperature. The formation of CO₂ shows that deep radiation-chemical transformations of cellulose occur which lead to decomposition of the glucopyranose ring. The decrease in the CO₂ yield indicates that this process is hampered as the temperature is decreased. It should be emphasised that the gas analysis^{40, 42} has been carried out after the temperature was increased to 210 or 300 K. This was done in order to ascertain the role of radicals in the formation of CO₂ since the primary radicals partially disappear only at temperatures above 233 K.

The yields of gases were found to be independent of the temperature used for the determination of the gaseous products. Hence, the formation of CO₂ does not result from secondary reactions of radicals. Most likely, it is formed even at the liquid nitrogen temperature through decomposition of the glucopyranose ring in a single process, which involves the formation of radicals and cleavage of the glucosidic bond. This also occurs with the same ratio of yields of the main products ($G_d \approx G_{CO_2} \approx G_{RCHO}$) determined for the irradiation at room temperature and confirming that the acts of degradation and formation of carbon dioxide and carbonyl groups occur simultaneously. The decrease in the yields of cellulose degradation on passing from room temperature to liquid nitrogen temperature is probably due to the hindrance of intramolecular mobility at lower temperatures causing a decrease in the efficiency of degradation of the pyranose ring.

We have already mentioned the difficulties inherent in the determination of the yield of cellulose degradation by viscosimetry. This yield is calculated with a number of assumptions, such as the Gaussian distribution of molecular masses, the known dependence of viscosity on the degree of polymerisation, account of chemical reactions in the dissolution of cellulose, etc. Therefore, it is necessary to measure this most important characteristic of the efficiency of radiation-chemical transformation of the polymer by additional, independent methods. The formation of CO₂ and CO in the irradiated cellulose suggests that scission of the glucose fragment occurs. The overall yield of CO₂ and CO determines the yield of polymer degradation by this mechanism. Within the experimental error, the yield of gases coincides with the degradation yield found by viscosimetry. On the one hand, this confirms that the degradation of cellulose mainly involves the degradation of the glucose unit, and, on the other hand, this justifies the applicability of the viscosimetric method for characterisation of cellulose degradation.

The mechanism of formation and chemical transformations of radicals in cellulose can be determined more accurately by using the data available for similar processes in cellobiose.⁸⁶ Cellobiose

is a structural element of cellulose and is used in studies of model reactions of hydrogen atoms with carbohydrates and polysaccharides.^{87, 88} Analysis of these reactions indicates that degradation of polysaccharides can involve not only the glucosidic bond, but also the C—O bond in the pyranose ring. Pentoses (arabinose, xylose, etc.) were found among the hydrolysis products of radiation-chemical transformations of cellulose.^{44–46, 52} The suggested radiolysis scheme shows that they are formed through removal of one carbon atom as CO₂ and CO from the glucose fragment. Deeper degradation of the glucopyranose ring gives low-molecular-weight products (formaldehyde, formic acid, malondialdehyde, and others). Deoxy- and deoxyoxo-sugars (hexoses) are probably formed through disproportionation of the radicals **1** and **2**.

VII. Degradation of cellulose in plant tissues

Preliminary irradiation of plant raw materials (e.g., wood) changes its properties substantially: it increases the solubility in various media of the constituent cellulose, and, most importantly, enhances its ability to undergo acid hydrolysis.^{89–96} It is natural to relate the latter property to the degradation of cellulose in plant tissues, which contain 60%–80% of cellulose. Studies of the effect of irradiation on the physicochemical state of a lignin–carbohydrate complex from plant materials have confirmed this conclusion. They also demonstrated that the efficiency of cellulose degradation *in situ* is much lower than that in the pure state.^{97–99} This is due to the presence of lignin in plant tissues, which protects cellulose from the radiation-induced degradation.

Systematic studies of the degradation of cellulose within plant tissues have been carried out for aspen wood.^{100, 101} It was found that the yield of cellulose degradation *in situ* is actually about half that of cellulose isolated from this source and subjected to irradiation. However, this comparison is insufficient to draw a final conclusion on the effect of lignin on the efficiency of radiation-induced degradation of cellulose in plant tissues, because the approach used^{100, 101} for the yield determination did not take into account the possible additional hydrolytic degradation of cellulose during its isolation from the plant material. The degree of such degradation is the larger the higher the absorbed dose.

The hydrolytic degradation of cellulose in acidic media depends on the content of carbonyl and carboxy groups, which affect the hydrolysis rate. Therefore, cellulose degradation was studied in the course of its one-step delignification¹⁰² carried out according to Seifert.¹⁰³ The latter method involves treatment of a plant material with a solution containing acetylacetone, dioxane, and aqueous hydrochloric acid. It was shown that the dependence of $1/P_v$ on the duration of treatment with the delignifying solution is described by a first-order equation.^{104, 105} The rate constants of hydrolysis calculated from the slope of the $1/P_v - \tau$ plot increase with the absorbed dose (Table 3). Extrapolation of the kinetic straight line to the ordinate axis (*i.e.* to $\tau = 0$) makes it possible to

determine the degree of cellulose polymerisation in the plant tissue after irradiation, but before its isolation by the delignification process. As noted above, the latter process leads to additional hydrolysis of cellulose. The P_v values obtained are listed in Table 3. The dependence of $1/P_v$ on the absorbed dose is described well by Eqn (6). The degradation yield of aspen wood cellulose was calculated to be 1.8 ± 0.2 , *i.e.* one-third that for pure cellulose. The yield of CO_2 in the radiolysis of aspen wood, which can be related to the degradation of the constituent cellulose, is ~ 2.0 . Hence, like in the irradiation of pure cellulose, aspen wood decomposition also involves the degradation of glucopyranose rings.

Table 3. Change in viscosity-average degree of polymerisation of cellulose isolated from irradiated wood on the duration of delignification.¹⁰²

Dose /kGy	Degree of polymerisation at τ /min			
	30	40	50	60
0	360	350	340	330
50	200	180	165	150
100	160	150	140	120
150	135	120	110	100

Thus, cellulose irradiated *in situ* is decomposed to a much lesser extent than pure cellulose due to the protective effect of lignin. This effect is probably due to the transfer of the excitation energy from the cellulose complex to lignin. Lignin contains complex aromatic groups, which are known^{106,107} to act as protectors in the radiolysis in a mixture with other organic compounds.

The protective effect of lignin in the radiation-induced degradation of cellulose as a component of wood is detected when analysing the quantitative and qualitative composition of radicals at 77 and 300 K. It was shown that the same cellulose radicals **1** and **2** are formed as from pure cellulose, along with a lignin-type radical. The latter is observed in the ESR spectrum as a narrow symmetrical singlet with a g -factor 2.003 and a width 1.0 ± 0.1 mT.¹⁰¹ It was assumed that this is a phenoxyl radical formed upon cleavage of the ether lignin–carbohydrate bond. Analysis of the ESR spectrum of this radical in the 2-mm region confirmed the above assignment.⁷⁴ At absorbed doses < 60 kGy, the signal of the lignin radical predominates in the ESR spectrum, although the content of carbohydrates (cellulose and hemicellulose) is $\sim 70\%$ of the plant tissue weight. The yield of formation of cellulose radicals upon γ -irradiation of aspen wood at 77 K was found to be 0.8. In pure cellulose, this yield is 2.7. The yield of lignin radicals is 1.7.

Thus, the efficiency of *in situ* degradation of cellulose changes noticeably over a wide temperature range in which the plant tissue is irradiated; this can be explained by the protective effect of lignin present in it.

VIII. Radiation-thermal degradation of cellulose

Cellulose processing, primarily the manufacture of esters (viscose, nitrates, *etc.*), is preceded by a stage of its preliminary degradation in order to achieve the required average molecular mass and the optimum MMD. This is commonly done by hydrolysis or thermal treatment. Acidic or alkaline hydrolysis of cellulose makes it possible to achieve this goal. However, the disadvantages of this method (it is laborious, involves inevitable and considerable losses of material, and requires chemicals hazardous to the environment) necessitate the search for alternative ways for decreasing the molecular mass of cellulose. Thermolysis of the polymer also results in its degradation. The degree of polymerisation achievable by this method is limited to ~ 200 –250. Subsequent treatment leads only to pyrolysis with the formation of gaseous products,

levoglucosan, and resins.^{108, 109} Comparison of the above methods with radiation-induced degradation shows the attractiveness of the latter for industrial application. Such treatment of cellulose results in its deep and bulk-uniform degradation to the required and controlled molecular masses without using chemical reagents and without considerable decomposition. Combination of the radiation and thermal treatments makes it possible to decrease the energy consumption for cellulose degradation.

The radiation-induced degradation of cellulose is accelerated markedly with temperature.³⁸ The decrease in the degree of polymerisation in the γ -irradiation is more significant the higher the temperature. The dependence of P_v on the absorbed dose is well described in the coordinates of Eqn (6). Figure 6 demonstrates the dependence of the calculated yields of degradation on temperature in the Arrhenius equation coordinates; Table 4 lists the yields of degradation and the yields of the carbonyl and carboxy groups in the temperature range from 303 to 463 K. It is seen that two temperature ranges of the radiation-induced degradation of cellulose exist: < 380 K, where the yields do not change much, and > 380 K, where the yields increase markedly with temperature. It should be noted specially that the contribution of thermal degradation in the γ -irradiation was taken into account in the calculation of the yields, although it is insignificant.

Figure 6. Dependence of the yield of cellulose degradation (bonds per 100 eV of absorbed energy) on temperature in the Arrhenius equation coordinates.³⁸

The activation energy determined in the second temperature range is 23.4 ± 1.6 kJ mol⁻¹. It is most probable that the activation energy corresponds to the diffusion of radicals in the polymer. An increase in temperature initiates the transfer of the radical state to the nearest polymeric chain and causes its degradation. This explanation is based on the fact that the activation energy measured corresponds to the energy of conformational vibrations of the glucopyranose ring.¹⁰⁹ One can see from Table 4 that the degradation yield coincides with the yield of formation of carbonyl groups. It was also found³⁸ that the

Table 4. Yields of products upon radiation-thermal degradation of cellulose.³⁸

T/K	G_d	G_{CHO}	G_{COOH}
303	5.1	5.4	1.8
363	6.0	5.8	1.8
393	7.4	7.1	1.8
413	10.7	11.1	1.9
423	11.4	—	—
433	16.8	17.1	2.3
443	18.1	—	—
463	27.7	26.0	3.3

radiation-induced degradation at high temperatures is accompanied by the formation of hydrogen and carbon dioxide. The yield of the latter is about two times higher.

These facts indicate that the radiation-induced degradation of cellulose at temperatures above 380 K occurs by a chain mechanism, which is initiated by radicals formed upon irradiation. The ratio of the yields of the main products is the same as that in the irradiation under ordinary conditions. This indicates the similarity of processes of radiation-induced degradation occurring in different temperature ranges that are accompanied by degradation of glucopyranose rings with evolution of carbon dioxide and formation of compounds with carbonyl groups.

IX. Degradation of cellulose upon sequential irradiation and thermal treatment

Takeshi and Shosaki¹¹⁰ were the first to observe that degradation of cellulose exposed to γ -irradiation and thermal treatment depends considerably on the ordering of these processes. After irradiation or thermal treatment, the degree of polymerisation of cellulose decreases, while the amount of reducing sugar obtained on its acid hydrolysis increases (Table 5). In the heating–irradiation mode, the increase in the amount of reducing sugar is approximately the sum of the increments corresponding to each of the effects. When treatment is carried out in the irradiation–heating mode, a different picture is observed: the increase in the amount of reducing sugar is markedly greater than that expected for the additive degradation processes. A similar situation was observed when analysing the changes in the number of chain scissions (S). It was found that the total number of bond scissions ($S_{\gamma T}$) in a macromolecule upon consecutive γ -irradiation of cellulose (S_γ) and heating (S_T) can be represented as follows:^{40, 111–113}

$$S_{\gamma T} = S_\gamma + S_T + \beta D,$$

where β is a coefficient which takes account of the increase in the cellulose thermal degradation and D is the absorbed dose. It was also shown that the result of thermal treatment followed by irradiation is additive, *i.e.* the number of chain scissions observed ($S_{\gamma T}$) equals the sum of scissions obtained separately, *i.e.* S_γ and S_T .

Figure 7 shows plots of the number of bond scissions in wood cellulose as a function of the absorbed dose for different modes of irradiation and thermal treatment. In all cases, the dependence of $1/P_v$ on the absorbed dose is described by the simple Eqn (6). The slopes of straight lines 1 and 2 characterising the efficiency of degradation are the same, which confirms the above fact that preliminary thermal treatment does not affect the efficiency of subsequent radiation-induced degradation. On the other hand, the higher slope for consecutive radiation and thermal treatment corresponds to the more efficient polymer degradation. The β

Figure 7. Dependence of the number of bond scissions (S) in wood cellulose on the absorbed dose;¹¹² (1) radiation treatment; (2) successive thermal and radiation treatment; (3) successive radiation and thermal treatment. In all cases, the thermal treatment was carried out at 463 K for 3 h to reach a steady state.

factor is determined from the difference between the slopes of dependences of $1/P_v$ vs. the absorbed dose for each temperature. It is equal to 0.4×10^{-2} , 2.0×10^{-2} , and 3.8×10^{-2} scissions per 1 kGy at 423, 443, and 463 K, respectively.^{40, 112}

Hence, the efficiency of degradation of irradiated cellulose increases with temperature. Enhancement of degradation in the irradiation–heating mode probably results from the formation of defects such as weakened bonds, reactive groups, and radicals in cellulose upon irradiation. On heating, these defects activate scission of the polymeric chain. The Arrhenius-type dependence of the β factor on temperature made it possible to determine the activation energy, which is about 96 kJ mol^{−1}. This value corresponds to the activation energy of super-slow transmolecular motion of the cellulose macromolecule on its thermal treatment.⁶⁸

Thus, combination of irradiation and heating can lead to much deeper degradation of cellulose than that resulting from irradiation or thermal treatment separately. The most energetically favourable mode is the simultaneous action of irradiation and heat or successive irradiation and heating. It was shown^{114, 115} that electron accelerators can be used to implement successfully the destructive treatment of cellulose without the application of additional heating devices. Because of the very poor heat transfer properties of cellulose materials, their intense radiation-induced heating occurs on irradiation with accelerated electrons with dose intensity > 0.4 kGy s^{−1}. Under convective heat exchange conditions, the temperature increased nonuniformly across the depth and reached 430 K, thus providing an efficient degradation mode. Under these conditions, radiolysis products formed in cellulose impregnated with iron salts efficiently reduce the metal ions to produce pyrophoric compounds.^{116, 117}

Table 5. Viscosity-average degrees of polymerisation (P_v) and amount of reducing sugar in cellulose after different types of treatment.¹¹⁰

Treatment	P_v	$P_v/P_v^0 - 1$	Total sugar ^a	Increase in sugar content ^a
Without treatment	408	—	130	—
Irradiation (100 kGy)	71	4.7	167	37
Heating (473 K, 1 h)	190	1.1	155	25

X. Radiation-chemical transformations of polysaccharides

In addition to cellulose, plant materials include other polysaccharides, such as starch and xylan. A number of physicochemical properties and the biological role of cellulose and chitin are similar. Like cellulose, chitin is among the most abundant natural polymers. It constitutes the basis of the outside skeleton (cuticle) of insects, crustaceans, and other Arthropoda, and is a substitute of cellulose in lower plants (*e.g.*, in fungi). Deacetylation of chitin gives chitosan. In recent years, the radiation-chemical transformations of the above polysaccharides have been studied inten-

sively. Below, we discuss the results of the relevant studies and compare these with the data for cellulose.

1. Radiation-chemical transformations of xylans

The study of xylans has received much less attention than that of cellulose.^{118–123} It was reported^{118–120} that irradiation of xylan results in transformations that decrease the viscosity of its solutions and give products with carbonyl and carboxy groups. The degradation of xylans and the nature of the resultant radicals and final products have been studied systematically.^{121–123} 4-*O*-Methylglucuronoxylan isolated from beech holocellulose by extraction with 10% alkali was used. This compound contains 4-*O*-methyl-D-glucuronic acid residues glycosidically linked at position O(2) of about every eighth xylose unit.

The ESR spectra of xylan γ -irradiated at 77 K¹²¹ are shown in Fig. 8 for different absorbed doses. It is seen that the shape of the spectrum changes as the dose increases, which indicates that several types of radicals are formed, which accumulate at different rates. In the initial stage, a narrow singlet signal of trapped electrons predominates. At higher absorbed doses, two signals predominate in the spectrum: a triplet with 2.6 mT splitting and a doublet with 3.0 mT splitting, *i.e.* almost the same signals as those observed in irradiated cellulose. The doublet signal can belong only to the radical formed on abstraction of the hydrogen atom from position C(1) followed by cleavage of the glycosidic bond. The triplet signal can belong to any of the radicals formed upon abstraction of hydrogen from positions C(2), C(3), or C(4).

For positions C(2) and C(3), both β -protons are equivalent, which explains the observed structure of the ESR signal. When the radical state is localised at C(4), the two β -protons at C(5) are nonequivalent. The coupling constants with one of the β -protons at C(5) and with the β -proton at C(3) are approximately the same, while that with the other β -proton at C(5) is much smaller. In this case, a triplet ESR signal can be expected, and its components can be further sub-split into doublets due to the weaker coupling with one of the β -protons at C(5). However, considering that the C(1)–H and C(4)–H bonds are the weakest, it may be assumed that the formation of radicals in γ -irradiated xylan is due to the localisation of the unpaired electron at positions C(1) and C(4) and cleavage of the glycosidic bond. Hence, radicals of the same type as in the case of cellulose are formed.

Theoretical analysis of the ESR spectra¹²¹ agrees with this interpretation. The spin densities for radicals with localisation of

Figure 8. ESR spectra of xylan γ -irradiated at 77 K.¹²¹ Absorbed dose /kGy: (1) 10; (2) 30; (3) 240.

the unpaired electron at positions C(1) and C(4) are 0.696 and 0.619, and the coupling constants are 3.04 and 2.72 mT, respectively. The role of the glucuronic acid residue was found to be insignificant and not to affect significantly the nature of radicals formed. The radicals are accumulated linearly up to an absorbed dose of 300 kGy. The overall yield of radicals measured in this range is ~ 4.0 .

Figure 9. Gel-permeation chromatograms of xylan;¹²³ (1) original sample; absorbed dose /kGy: (2) 50; (3) 125.

The irradiation of xylan is accompanied by its intense degradation.^{122, 123} Figure 9 shows the gel-filtration curves of xylans γ -irradiated to different doses (the molecular-mass characteristics were monitored with a refractometer). It is seen that the peak height decreases, while the distribution curve broadens. Table 6 lists the experimental molecular masses M_v and the calculated number-average M_n and weight-average M_w molecular masses. The decrease in the molecular mass with an increase in the absorbed dose is the consequence of the radiation-induced degradation of the polysaccharide. This fact was pointed out by Beinart *et al.*,¹¹⁸ who also observed a noticeable decrease in the viscosity-average degree of polymerisation of glucuronoxylan after γ -irradiation and an increase in its solubility in water. In fact, the content of a water-soluble fraction in xylan increased from 35.7% to 54.5% at an absorbed dose 125 kGy (see Table 6). The degradation of xylan occurs in a random way, which follows from the change in the M_w/M_n ratio from 1.53 in the starting sample to 1.9 after irradiation to a 125 kGy dose. The latter ratio is close to 2.0, which corresponds to the most probable molecular-mass distribution of polymers. As indicated above, such MMD can result from random scissions of an infinite polymeric chain. This allows the use of Eqn (6) for the determination of the degradation yield. In fact, the dose dependence of $1/M_n$ (or $1/P_n$) predicted by this equation is linear in the high dose region, and the calculated degradation yield is 8 ± 1 .

It was also found that xylan, like cellulose, produces hydrogen and carbon dioxide, whose radiation-chemical yields are 2.8 and 4.4.^{122, 123} The presence of carbon dioxide indicates that the formation of radicals actually does not occur directly upon cleavage of the glycosidic bond but involves rupture of the

Table 6. Molecular-weight characteristics and solubility of irradiated xylan.¹²³

Dose /kGy	Extraction with water (%)	$10^{-3}M_w$	$10^{-3}M_n$	$10^{-3}M_v$	M_w/M_n
0	35.7	22.1	14.4	21.8	1.53
12.5	40.7	20.1	12.6	19.8	1.59

125	54.5	12.2	6.6	12.0	1.90

pyranose ring resulting in the formation of a carbon dioxide molecule. Hence, the mechanisms of radiation-induced degradation of xylan and cellulose are fairly similar.

2. Radiation-chemical transformations of chitin and chitosan

Chitin is a polysaccharide built of 1,4-linked 2-acetamido-2-deoxy- β -D-glucose moieties. It can be regarded as cellulose in which the OH groups at C(2) are replaced by acetamido groups. Deacetylation of chitin produces chitosan. The difficulty of studying the radiation-chemical transformations of chitin is due to its extraordinary chemical stability: γ -irradiation of chitin with even rather high doses does not cause a noticeable change in the IR spectra and is not accompanied by a decrease in the adsorption properties toward metal ions from aqueous solutions.^{124–127} The conclusion made as to the high radiation stability can hardly be considered proven because of the inadequacy of the methods used in the study. These methods are too insensitive to determine the destructive role of the ionising radiation. Moreover, the application of such methods to cellulose would lead to the same conclusions, since chemical changes are reflected in IR spectra at much higher doses where the number of new chemical bonds is comparable to that present in the material. In fact, the pattern and intensity of IR absorption spectra of cellulose is retained during its irradiation up to an absorbed dose of 1000 kGy, but the conclusion as to its high radiation stability cannot be made on this basis.²³

The difficulties of studying the degradation of chitin are associated primarily with the selection of an appropriate solvent for this compound and determination of the viscosimetric properties as a function of the absorbed dose. The molecular mass of chitin was determined from the characteristic viscosity in a solution in *N,N*-dimethylacetamide containing 5% lithium chloride¹²⁸ according to the procedure suggested by Terboevich *et al.*¹²⁹ Chitin samples from various sources were studied. During the irradiation, the molecular masses of chitins decreased, and the content of the amino and carboxy groups increased (Table 7). The dependence of $1/P_v$ on the absorbed dose predicted by Eqn (6) for random degradation was obeyed well (Fig. 10). The radiation-chemical yields of degradation of chitins obtained from crab and krill shells were almost the same (1.8 ± 0.2), while the yield for

Figure 10. Dependence of the $1/P_v - 1/P_v^0$ difference in chitin on the absorbed dose;¹²⁸ chitin source: (1) crab shells; (2) krill shells; (3) shrimp shells.

chitin from shrimp shells was 1.1 ± 0.1 . It is seen that the yields of degradation decrease markedly on going from cellulose to chitin. Up to high absorbed doses, degradation occurred without changes in the crystalline structure and without violation of the intermolecular packing, as was shown by X-ray diffraction analysis.¹²⁸ Similar dependences were reported for irradiated cellulose.^{29, 130, 131}

The irradiation of chitin leads to its deacetylation, which results in free primary amino groups and acetic acid; the degradation of the polymer produces compounds with carboxy groups. Table 7 presents the concentrations of the amino groups and the total concentrations of the carboxy groups. The radiation-chemical yields of these groups in chitins from various sources are 9 ± 2 . The yield of chitin degradation is rather low (1.1–1.8); this fact allows one to assume that the major part of carboxy groups determined by chemical analysis is due to acetic acid. This may be regarded as an indication that the free amino groups and the carboxy groups (acetic acid) are mainly formed as a result of deacetylation upon γ -irradiation. At high absorbed doses, the chitin shows the tendency to undergo deamination and decarboxylation. Hydrogen and carbon dioxide are the major gaseous products of chitin radiolysis. Their yields for chitin from crab shells at an absorbed dose of 150 kGy are $\sim 1.1 \pm 0.3$ and $\sim 1.4 \pm 0.4$, respectively (which are considerably smaller than those found for cellulose radiolysis, *viz.*, 3.2 and 6.0, respectively).

The radiation-chemical transformations of deacetylated chitin (chitosan), which is now widely used in various fields of industry, agriculture, and medicine, are perhaps of particular interest.¹³² Chitosan undergoes degradation under irradiation, both in aqueous solutions and in the dry state.^{133, 134} However, the quantitative estimation of the degradation efficiency has not been made. This problem has been studied for chitosan with degree of deacetylation 85%.¹³⁵ Viscosimetric analysis was carried out in aqueous 2% acetic acid containing 0.2 M AcONa according to the published procedure.¹³⁶ The radiation-chemical yield of chitosan degradation was found to be 4.2 ± 0.3 , which is markedly higher than that for chitin and lower than that for cellulose. The yields of hydrogen and carbon dioxide were 1.3 and 1.5, respectively. The irradiation of chitosan results in its partial deamination. For example, at an absorbed dose 600 kGy, the content of amino groups decreases by $\sim 4\%$, which corresponds to a radiation-chemical yield of deamination of ~ 3 .

The nature of radical products of low-temperature radiolysis of chitin and chitosan is the same as in the case of cellulose. Both in chitin¹²⁸ and in chitosan,¹³⁵ terminal radicals appear with localisation of the unpaired electron at C(1) and C(4). These radicals appear in the ESR spectra as a doublet with a ~ 3.0 mT splitting

Table 7. Changes in molecular mass and functional composition of chitin from various sources exposed to γ -irradiation.¹²⁸

and a triplet with 2.6 mT splitting. The ESR spectra of chitin have some specific features, namely, the doublet components have a slight additional splitting. This splitting can be caused by an anisotropy of the hyperfine structure due to the amino group adjacent to the C(1) position or by overlapping with another doublet signal with a higher HFS coupling constant (~ 2.9 mT). The latter may be due to the different positions of pyranose rings in the crystal structure of chitin (two nonequivalent positions) resulting in a slight nonequivalence of the two radical centres. The radiation-chemical yields of radicals in the γ -irradiation of chitin and chitosan at the liquid nitrogen temperature are 2.3 (see Ref. 128) and 3.0 (see Ref. 135), respectively.

Of interest are specific features of thermal transformations of radicals in chitin. It was found¹²⁸ that a decrease in their concentration starts from ~ 200 K. The radical at C(1) is more stable than that at C(4). Furthermore, as the primary radicals disappear (even at room temperature), an ESR signal appears as a quartet with a 1:3:3:1 intensity ratio of the components and a ~ 1.4 mT splitting between them. This signal can be assigned rather definitely to the $\text{GlcNHC}(\text{OH})\text{CH}_3$ radical, where Glc is the glucose residue. The quartet structure of the signal of this radical is due to splitting of the unpaired electron with three protons of the CH_3 group. The parameters of the ESR signal of the $\text{NH}_2\dot{\text{C}}(\text{OH})\text{CH}_3$ radical formed upon γ -irradiation of acetamide¹³⁷ are similar to those of the radical indicated above.

Calculations show that the presence of the amino group at C(2) in chitin and chitosan instead of the hydroxy group in cellulose scarcely affects the coupling constant of the doublet signal. For cellulose, the triplet ESR signal might be due to the localisation of the radical centre not only at C(4) but also at C(2), which is not the case for chitin and chitosan. If the radical were localised at C(2), the HFS of the signal would be different due to coupling of the unpaired electron with the nitrogen nucleus (nuclear spin 1). Thus, the conclusion that terminal radicals are preferentially formed at the C(1) and C(4) atoms in the irradiation of polysaccharides appears to be well substantiated.

The similarity of the nature of radicals formed upon γ -irradiation of chitin, chitosan, and cellulose indicates that the initial processes of their radiation-chemical transformations are similar. However, the yields of scission of the polymeric chain in chitin (1.1–1.8) and chitosan (4.2) are much lower than those in cellulose (~ 6.0). The yields of gaseous products are also much lower. The predominating process is the deacetylation of chitin leading to the formation of free primary amino groups and acetic acid, as well as the deamination in the case of chitosan. In a general form, the formation of acetic acid under γ -irradiation of chitin can be represented as hydrolytic deacetylation

In fact, agreement between the yields of the formation of amino and carboxy groups has been found.¹²⁸ In addition, ESR studies indicate that the deacetylation mechanism involves the following transformations of radicals at C(1):

These transformations may involve both intra- and inter-molecular hydrogen shift. Subsequent reactions of the $\text{GlcNHC}(\text{OH})\text{CH}_3$ radicals result in chitin deacetylation. The considerably higher yield of deacetylation products in comparison

with the yield of radicals and degradation yield can be explained by the chain character of the process (Scheme 3).

The reason why the origin of chitin affects the nature of the radicals formed and the degradation efficiency remains unclear. This may be due to the different structures of the materials themselves.

Thus, the replacement of the OH groups in cellulose with the NH_2 (chitosan) or $\text{NHC}(\text{O})\text{CH}_3$ groups (chitin) increases markedly the radiation stability of materials against degradation. Along with degradation, deamination (in the case of chitosan) and deacetylation (in the case of chitin) occur in these polysaccharides.

3. Radiation-chemical transformations of starch and dextran

Like cellulose, starch consists of d-glucose residues linked by 1,4- α - rather than β -glucosidic bonds. Cellulose is a cellobiose-type and starch is a maltose-type polysaccharide. The interest in the study of radiation-chemical transformations of starch is partially caused by the wide use of irradiation for sterilisation of food. It was found^{138–144} that the action of γ -irradiation on starch from different sources (from waxy and amilose corn, potatoes, manioc, rice, beans, wheat, and other plant products) results in the accumulation of carbonyl groups,¹³⁸ organic acids,¹³⁹ and hydrogen peroxide¹⁴⁰ and is accompanied by degradation.^{141–144} The accumulation of new functional groups depends on the source of the starch; this is explained by differences in its structure. The acidity increased during storage of the samples, whereas the content of hydrogen peroxide decreased. The content of water-soluble dextrans increased linearly with the absorbed dose. The moisture present in starch inhibited the formation of dextrans and reducing groups. Unfortunately, the authors of the works cited did not report quantitative data on the efficiency of radiation-chemical degradation of starch (*i.e.*, the yields).

According to the degradation mechanism common for polysaccharides, it may be believed that a degradation act is accompanied by the cleavage of a pyranose ring to produce one carbon dioxide molecule and a carbonyl-containing compound. Therefore, the yields of these products can also, to some degree, serve as an indication of the efficiency of the polysaccharide degradation. In fact, this rule was valid for all of the polysaccharides considered. It was found for potato starch¹⁴⁵ that, in addition to hydrogen, whose yield is 4.5 molecules per 100 eV of the energy adsorbed, CO_2 and CO are formed in 5.5 and 1.5 yields, respectively, while the yield of carbonyl groups is 6.5.¹⁴⁶ It is also worthy of note that the yields of reducing compounds upon the radiolysis of various starches also do not exceed 6–10.^{147,148} Therefore, taking into account the possible errors in the chemical analysis of products of the radiation-chemical transformations of starch, it can be assumed that the yield of its degradation is within 5–7. The yields of gaseous products that formed upon γ -irradiation of potato starch were also measured.¹⁴⁶ The resulting $G(\text{H}_2)/[G(\text{CO}_2) + G(\text{CO})]$ ratio was approximately the same as that found by Ershov and Isakova.¹⁴⁵ However, the absolute yields were by about an order of magnitude lower (0.5 for H_2 , 0.5 for CO_2 , and 0.2 for CO). They did not correlate with the yields of carbonyl and carboxy groups (6.5 and 5.0, respectively) measured in the same study, which also characterise the efficiency of the

radiation-chemical degradation of starch. It should be noted that this low yield of hydrogen is generally untypical for irradiation of saturated compounds.¹⁴⁹ An unusual (oscillating) dependence of the formation of products of radiolysis of potato starch and dextran on the absorbed dose was observed.¹⁴⁶ It was also found that the presence of moisture in starch resulted in an almost 30-fold increase in the hydrogen yield, while the yields of other gases remained the same. It is unlikely that this fact can be reduced only to the specific radiolytic behaviour of water structured by polysaccharides.

The radicals formed upon the action of radiation on starch at the liquid nitrogen temperature have the same nature as those in other polysaccharides: they are terminal with localisation of the unpaired electron at positions C(1) and C(4) of the pyranose ring.^{144, 145} Therefore, there is reason to assume that the nature of the linkage between the glucose residues (α -linkage in the case of starch and β -linkage in the case of cellulose) does not affect markedly the mechanism or the efficiency of bond cleavage.

A systematic analysis of the products of radiation-chemical degradation of corn starch in the presence of oxygen was carried out.¹⁵⁰ It was shown that the main products include oxo compounds and water; carboxy and aldehyde groups are also accumulated in about an order of magnitude smaller yields. The efficient radiation-chemical oxidation of starch is explained by the involvement of peroxide radicals in the reaction. The latter are formed due to trapping of oxygen molecules by radicals formed in the irradiation. Low-molecular-weight dicarboxylic acids are found among the products of starch radiolysis at high absorbed doses (up to 1000 kGy): tartaric (42.4%), citric (33.5%), malic (16.4%), succinic (4.6%), lactic (1.8%), and fumaric acids (1.3%). The formation of a dicarboxylic acid molecule implies the insertion of two additional oxygen atoms into a monomeric unit, which presumes the formation and subsequent transformation of two peroxide radicals. The possibility of a chain mechanism of the reaction is not ruled out.¹⁵⁰ The suggested schemes of the formation of dicarboxylic acids take into account that the isomerisation and dehydration of a polysaccharide occur at high rates and that the reaction of radicals with an oxygen molecule is by an order of magnitude faster than recombination.

The dextran chain comprises mainly α -1,6-glucosidic units. It also contains branches, [mainly at C(3)] built of mono- and disaccharides. Early studies^{151–157} of radiation-chemical transformations of dextrans were carried out for aqueous solutions. The possibility of decreasing the molecular mass of this polysaccharide was studied with the aim of using it as plasma extender.¹⁵¹ A stronger decrease in characteristic viscosity was noted for solutions than for the solid polymer. This indicated the degradation of dextran in which radical products of water radiolysis played the decisive role. Thus, irradiation turns out to be an efficient tool for directed decreasing the molecular masses, making it possible to lower them by a factor of tens and hundreds.

It was found that in the radiolysis of dry dextran^{152–155} the molecular mass and viscosity decrease, the rate of cleavage of molecular chains depending on the molecular mass. The degradation was accompanied by narrowing of MMD,^{156, 157} and radiation-chemical modification.

Different polysaccharides differ in the degree of crystallinity and in the content of bound water. These factors can affect markedly the direction and efficiency of their radiation-chemical degradation. These factors can be revealed with sufficient reliability only in rare cases. However, their important role is obvious. In this respect, a study by Petrov *et al.*¹⁵³ that dealt with the radiolysis of potato starch deserves special attention. Starch granules contain linear amylose molecules along with branched amylopectin. The crystallinity index of potato starch is only $\sim 20\%$. The adsorbed water in it is distributed nonuniformly among the units and is mainly located in structural channels and cavities of amorphous regions of amylopectin. A study of fractions of irradiated potato starch by gel-permeation chromatography showed that amylopectin is the component which is

destroyed preferentially. At a dose of 200 kGy, the content of amylopectin is 15% (as compared to 75% for the native starch), while that at a dose of 600 kGy is only 2%. The considerable increase in the reducing power of fractions along with the decrease in their molecular masses¹⁵⁷ confirm the formation of low-molecular-weight aldehydes and acids in the radiation-chemical transformations of amylopectin.

The effect of the structural factor on the radiation-chemical degradation and chemical transformations of native polysaccharides, which differed considerably in their degree of crystallinity and in the content of bound water, was studied under normal conditions and in a wide range of absorbed doses.¹⁵⁸ Cellulose, potato starch, amylopectin, and dextran were studied. Dextran macromolecules do not form a crystalline phase but exist as disordered coils with high density in the centre and low density at the periphery. The yields of reducing compounds and carboxy groups reach ~ 32 and ~ 14 , respectively, for dextran, as compared to 4–7 and 3–5 for other polysaccharides. The yields are determined by the density and type of distribution of amorphous regions, which provide free access of water and oxygen to the macroradicals and access of the H $\cdot$ and $\cdot$ OH radicals formed due to water decomposition to one or another carbon atom of the glucopyranose ring. The considerable yields of radiolysis products in dextran may indicate a chain mechanism of its radiation-oxidative decomposition.

The paper cited¹⁵⁸ also reports very low degradation yields of starch and dextran, namely, 0.3 and 1.0, respectively. These values disagree with the much higher yields of CO₂ and CO formation and the yields of reducing compounds and carboxy groups. Therefore, the conclusion is made about the possibility that these compounds are formed without the decomposition of the pyranose ring. However, this seeming contradiction is explained by the inapplicability of the approach used to describe degradation, which is valid only for linear polymers with the most probable MMD and random chain scission. This circumstance was noted even in early studies of the degradation of these polysaccharides in aqueous solutions. Native starch and dextran have very wide and nonuniform MMD, and the different nature of bonds in these branched polysaccharides does not presume *a priori* their equal proneness to radiation-induced degradation.

Numerous studies dealt with the action of radiation on aqueous solutions of such polysaccharides as agar-agar, alginic acids, pectins, glycogen, and some others. The results of these studies and the mechanism of the radiation-chemical transformations have been considered in sufficient detail by Bovey² and Kochetkov *et al.*¹⁵⁹ It was shown that degradation accompanied by a decrease in the molecular mass of the polymer is the dominating process.

4. Radiation-chemical transformations of heparin

Heparin is a natural acidic polysaccharide. It is a nonbranched heteropolysaccharide built mainly of two types of sulfated disaccharide residues linked through 1,4- α -glucosidic bonds. The structural formula of the repeating tetrameric unit of heparin can be written in the form:

Several studies were devoted to the radiolysis of heparin solutions.^{160–165} The degradation of macromolecular chains is the main radiolysis process. Specific features of the degradation of a dry polymer were studied by Kudryavtsev *et al.*¹⁶⁶ for the sodium salt of heparin in the form of a powder with a starting viscosity-average molecular weight (M_v) of 10,325 as an example. The reciprocal of M_v varied linearly with an increase in the absorbed dose according to Eqn (6); the calculated degradation

yield was 3.1 ± 0.4 . This is about half the degradation yields for cellulose, dextran, and starch. It can be concluded that the presence of sulfamino and sulfo groups in heparin, like the presence of acetamido groups in chitin, increases the resistance of the polysaccharide against radiation-induced degradation. Irradiation resulted in partial desulfation of heparin. Analysis of ESR spectra^{166–169} showed that radicals of the same types as those commonly observed in polysaccharides were present in irradiated heparin. These radicals appeared upon cleavage of glycosidic bonds, and their unpaired electrons are localised at positions C(1) and C(4). Chromatography of gaseous products did not detect carbon dioxide. It was concluded¹⁶⁶ that the radiolysis of heparin does not involve the degradation of the pyranose ring. However, it is hardly possible to agree with this conclusion. The observed formation of terminal radicals could not occur without rupture of the pyranose ring. Most likely, the sensitivity of the chromatographic method was insufficient to measure the concentration of CO_2 when using a small amount of the starting material. The yield of molecular hydrogen (~ 0.6 for dried heparin and 0.9 for non-dried heparin) was also low, which is difficult to explain.

It should be noted that the radiation-induced degradation of heparin is a convenient method for controlled variation of its molecular mass and for directed change of its properties.

XI. Radiation-chemical degradation of ethers and esters of cellulose and other polysaccharides

It is known²² that the presence of aromatic groups (benzyl, benzoyl, naphthoyl, *etc.*) in cotton cellulose increases considerably the tensile strength of fibres exposed to ionising radiation. Taking into consideration the decrease in the strength of cellulose materials upon degradation, it may be assumed that aromatic groups in cellulose favour a decrease in the degradation yield. It is also known^{106,107} that aromatic molecules are efficient energy acceptors.

Deactivation of excited states occurs with high probability without cleavage of chemical bonds.

The results of studies of the effect of irradiation on cellulose ethers and esters show that they also undergo degradation, although to a smaller extent.^{170–183} The efficiency of polymeric chain scission is determined by the nature of the substituent and the degree of substitution. The following cellulose derivatives have been studied:^{175,181} hydroxyethylcellulose (HEC), sodium salt of carboxymethylcellulose (Na-CMC), allyloxyethylcellulose (AOEC), allyloxycarbonylmethylcellulose (ACMC), and (methacryloyl)carboxymethylcellulose (MCMC). Samples with various degrees of substitution by allyl (j_a) and methacryloyl (j_m) groups (the number of groups per 100 anhydroglucose units) were used in the experiments. It was found that the solubilities of the ethers (ether-esters) before and after γ -irradiation differ greatly. For

Table 8. Change in the viscosity-average degree of polymerisation (P_v) of cellulose ethers (esters) as a function of the absorbed dose.¹⁷⁵

Cellulose derivative	Degree of polymerisation for absorbed dose /kGy						
	0	10	20	40	60	80	100
HEC	1995	—	1485	1187	908	617	565
Na-CMC	460	—	220	206	164	169	147
ACMC	359	213	185	196	—	157	140
($j_a = 5$)							
MCMC	348	219	224	219	—	160	—
($j_m = 4$)							

example, HEC, Na-CMC, ACMC ($j_a = 5$) and MCMC ($j_m = 4$) remain water-soluble at any absorbed dose (up to 120 kGy). However, AOEC ($j_a = 4$), AOEC ($j_a = 30$), and ACMC ($j_a = 40$) lose solubility even at a dose 10 kGy. This shows unambiguously that degradation processes dominate in derivatives of the first group, while cross-linking of polymeric chains resulting in the formation of a three-dimensional structure dominate in the second group. Table 8 demonstrates the dependence of the degree of polymerisation of various cellulose ethers and esters on the absorbed dose. It was found¹⁷⁵ that the dependence for Na-CMC is described well by Eqn (6). The degradation yield is almost the same within the experimental error and equals 2.5 ± 0.5 . This is consistent with the value of 2.8 calculated by us on the basis of other data.¹⁸² The yield for HEC is 1.5 ± 0.2 . Thus, the presence of functional groups in ethers determines their much lower degradation yield in comparison with cellulose.

Analysis for carboxy and peroxide groups and double bonds showed¹⁷⁵ that their content is primarily determined by the nature of substituent in the ether. For instance, no formation of double bonds or peroxide and carboxy groups is observed in HEC, unlike in the other ethers. According to IR spectroscopic data, only accumulation of carbonyl groups occurs with an increase in the absorbed dose. On the other hand, in AOEC with $j_a = 4$ and especially with $j_a = 30$, the number of double bonds decreases, while peroxide and carboxy groups are accumulated. These changes are probably caused by the addition of hydrogen atoms (formed due to radiation-induced cleavage of C—H bonds) to the allyl group followed by chemical transformations (Scheme 4).

The suggested scheme of radiation-chemical transformations makes it possible to explain the inverse character of changes in the concentrations of double bonds and peroxide groups observed for allylic derivatives of cellulose.

In Na-CMC, as well as in ACMC with $j_a = 5$ and 40, the number of carboxy groups decreases. In addition, a decrease in the number of double bonds and accumulation of peroxide groups is observed in the latter two samples. The process in MCMC with $j_m = 4$ occurs similarly, the differences being that peroxide groups

are detected only at a dose of 120 kGy and that the change in the number of double bonds is less distinct.

Cross-linking of allyl ethers and methacryloyl esters occurs through double bonds (Scheme 5).

This process depends on the concentration of double bonds in the macromolecule and on the mobility of groups containing these bonds, *i.e.* on various steric factors. The probability of cross-linking of macromolecules increases with an increase in concentration of double bonds in the starting ether and with an increase in the length of the substituent, which is characteristic of AOEC where the reactive double bond is located at the end of a grafted chain of ethylene oxide units. Therefore, AOEC forms a three-dimensional insoluble structure at a lower content of allyl groups than APMC.

The ESR spectra of γ -irradiated HEC and AOEC exhibit mainly superpositions of the spectra of cellulose-type radicals. The predominant signal in the spectra of Na-CMC, APMC, and MPMC is a triplet with 2.1 mT splitting, which overlaps with additional signals of cellulose radicals. The presence of a triplet signal indicates most likely that the radicals are localised on the carboxymethyl group, which protects cellulose from degradation.

Thus, the introduction of allyl groups in HEC and CMC affects substantially the chemical transformations that occur, on the one hand, and does not affect the nature of the radicals formed, on the other hand. This apparent contradiction may be explained by that the formation of radicals due to the addition of hydrogen atoms or other radicals to the allyl group is the reason for the chain cross-linking of polymers. However, the concentration of allyl radicals is either much lower than that of radicals formed in hydroxyethyl and carboxymethyl derivatives of cellulose (and allyl radicals are therefore not detected by ESR), or these radicals are transformed into more stable ones, which are observed in the ESR spectra.

In the case of cellulose nitrate, a decrease in molecular non-uniformity upon γ -irradiation is observed.^{176, 178} At a dose of 20 kGy, the polydispersity index (M_w/M_n) is 2.8 (*cf.* 8.3 for the original sample).¹⁷⁷ The polydispersity index approaches the value of 2, which corresponds to the most probable MMD, at high degrees of degradation. The calculated radiation-chemical degradation yield is 2.5, which is close to 1.8 found in another study.¹⁷¹ The decrease in molecular mass with simultaneous narrowing of the MMD of cellulose nitrate leads to the conclusion that no efficient cross-linking of macromolecules under γ -radiolysis occurs. An interesting feature of the radiolysis of cellulose nitrate is that a signal of the $\text{NO}_2^\bullet$ radical predominates in the ESR spectrum obtained after radiolysis at 77 K. It can be concluded on this basis that mobile electrons formed in the initial ionisation step are mostly trapped by electrophilic nitro groups in the reaction

Annealing of cellulose nitrate results in the appearance in the ESR spectrum of a triplet anisotropic signal stable up to 370 K when the $\text{NO}_2^\bullet$ radicals disappear completely. This signal was assigned¹⁷¹ to the terminal radical at C(1) of the pyranose ring. It was assumed that the unpaired electron interacted with one α - and one β -proton. The formation of a macroradical was explained by the polymeric chain scission. However, as was shown later,¹⁸⁴ this radical is formed due to the thermal degradation of cellulose nitrate even without preliminary irradiation due to $\text{RNO}_2^\bullet$ or $\text{RNO}_2\text{H}^\bullet$ radicals. These radicals are formed in the reaction

The role of oxygen in the radiation-induced degradation of cellulose nitrate macromolecules was found to be insignificant. It is manifested in a post-effect, which is observed as a reaction of macroradicals with an oxygen molecule to give peroxide radicals.

Cellulose acetate also undergoes degradation under γ -irradiation.^{172–174, 180, 183} The yield for diacetate¹⁷¹ was found to be unexpectedly low (0.8), which indicates the high protective effect of the acetyl groups against the polymeric chain scission. Benzyl groups also possess high protective ability.

Unfortunately, there are only scant data on the radiation-induced degradation of the ethers of other polysaccharides. Only studies on the radiation-chemical transformations of allylchitosan can be mentioned.^{181, 185} As in the case of analogous cellulose derivatives, the tendency of allylchitosan to cross-linking increases with an increase in the degree of substitution. However, this is also accompanied by polymeric chain degradation, which is evident from the increase in the content of carboxy groups as the absorbed dose increases.

Thus, cellulose ethers and esters, like cellulose itself, undergo degradation. However, this process is less distinct due to the protective action of substituents, which can serve as centres for localisation of the excitation energy or primary radical-ion radiolysis products.

XII. Conclusion

Analysis of data on radiation-chemical transformations of cellulose and some other polysaccharides shows a similarity of the mechanisms of the formation of the final radiolysis products. Radiation-induced degradation is the process which determines changes in the physicochemical properties of these compounds. By itself, this is not a new fact, which was already known in the 1950s. The achievements of recent years include accurate quantitative estimation of degradation yields, the finding that this mechanism is common for many other polysaccharides, and the elucidation of the nature of the primary radicals and of the mechanism of polymeric chain scission and formation of the main final products. Both in cellulose and in other polysaccharides, ionising radiation causes preferential abstraction of hydrogen atoms from the C(1) and C(4) atoms of the pyranose ring, rupture of the latter, and scission of the polymeric chain to produce a carbon dioxide molecule and a carbonyl compound.

This mechanism implies approximately equal yields of the main products ($G_d \approx G_{\text{CO}_2} \approx G_{\text{RCHO}}$), which is obeyed well for almost all linear polysaccharides. The unusual degradation mechanism involving pyranose ring opening is due to the fact that cellulose and other polysaccharides are polymers with chains rigidly fixed by a system of hydrogen bonds. Under these conditions, abstraction of hydrogen atoms from the C(1) and C(4) atoms leads to the formation of metastable radical states in which the stable conformation with sp^2 -hybridisation can be formed only through cleavage of a glycosidic bond and rupture of the adjacent pyranose ring. Thus, radiation-induced cleavage of one C—H bond initiates subsequent explosion of a pyranose ring and a cascade of splittings of other chemical bonds. This unusual degradation mechanism is probably characteristic of not only polysaccharides but also other polymers and compounds with

rigidly fixed conformations in which the formation of metastable radicals is initiated by some factor.

The degradation yields for cellulose, xylan, and starch are in the range from 5 to 7 bonds per 100 eV of absorbed energy of the ionising radiation. Taking the possible errors into account, it may be believed that the degradation yields for these polysaccharides are approximately equal. Starch, like cellulose, consists of D-glucose residues. However, they are linked by 1,4- α -glycosidic bonds in starch and by 1,4- β -glycosidic bonds in cellulose. This does not affect noticeably the efficiency of the radiation-induced degradation. On going to chitin, which, unlike cellulose, contains the CH₃CONH group at position C(2) instead of the OH group, the degradation yield decreases 4–5-fold, and deacetylation rather than degradation becomes the dominating process. The same effect is observed on replacing the OH group with an NH₂ group in the case of chitosan. However, this conclusion is not indisputable. It cannot be ruled out that the enhanced radiation stability of chitosan is also due to the presence of residual acetyl groups. The problem is that it is practically impossible to deacetylate chitin completely to prepare chitosan. The degree of deacetylation in chitosan used by Ershov *et al.*¹³⁵ for the study of its radiation-induced degradation was 85%. Probably, the presence of chitin admixture in chitosan increases the radiation resistance of the latter. The degradation efficiency of cellulose and chitosan ethers decreases the more strongly the higher the degree of substitution. In the case of unsaturated mixed ethers-esters, two competing processes occur, namely, cross-linking at unsaturated bonds and degradation; their ratio depends on the number of unsaturated groups in the ether and on their structure.

One has to admit that the mechanism of radiation-chemical transformations of cellulose and other polysaccharides has not yet been studied sufficiently. This is hindered by difficulties in chemical determination of the composition of the products (compounds with carbonyl and carboxy groups, sugar isomers, *etc.*) localised in the polymeric chain. Probably, studies of the transformations occurring in them may involve the data obtained in studies of the radiation-chemical transformations of simple saccharides that are the fragments of complex polysaccharides.

Radiolysis of monosaccharides has been studied much more thoroughly.¹⁵⁹ In particular, a number of interesting regularities found for these compounds, which can also hold for polysaccharides, deserve steady attention. For example, it has been shown that irradiation of frozen aqueous solutions of monosaccharides results in their epimerisation the nature of which is determined by the structure of the original saccharide. The formation of isomeric saccharides is attributed to reactions of electrons with radicals localised in the matrix. Undoubtedly, this process can also play an important role in the irradiation of polysaccharides in which the mobility of carbohydrate radicals is limited and they themselves act as acceptors of the electrons formed upon irradiation. It was also found that simple aminosaccharides have low stability against radiation.¹⁵⁹ For example, the radiation-chemical yield of decomposition of glucosamine (a fragment of chitosan) is certainly an evidence that chain processes occur. Acetylation of the amino group decreases considerably the degradation yield. On the other hand, methyl glycosides of both aminosaccharides, which do not have an open glycosidic centre, have degradation yields typical of usual monosaccharides without amino groups. Therefore, one can agree with the authors of the monograph cited¹⁵⁹ that on going to biopolymers much higher radiation stability of these compounds should be expected in comparison with the monosaccharide constituents. The results of studies of radiation-chemical transformations of chitin, chitosan, and heparin discussed in the present review confirm this important conclusion.

The ability of ionising radiation to cause cellulose degradation is extensively used for the development of original techniques for the isolation of cellulose from raw plant materials and for its preliminary treatment for subsequent manufacture of various products. It was shown^{186–190} that irradiation of wood chips in air to relatively small doses absorbed (5–20 kGy) increases their

stability in storage and increases the yield of cellulose in the sulfite pulping of wood. It is promising to use irradiation for the preparation of powdered cellulose and fillers from cotton linter.^{191,192} The possibility of producing microcrystalline cellulose by irradiating usual cellulose is being considered.¹⁹³

Radiation pretreatment of high-molecular-weight, highly viscous sulfite cellulose with very low reactivity to an absorbed dose of 5–10 kGy changes its physicochemical properties and enhances the reactivity to such an extent that it becomes possible to use this cellulose in the production of viscose fibres.¹⁹⁴ Irradiation makes it possible to decrease the amount of CS₂ required for xanthation from 30%–40% to 10%–15% and to elaborate a process for molding films from cellulose hydrate.¹⁹⁵ It was found that irradiation affects strongly the rate of cellulose nitration and the degree of substitution.^{36,196,197} The content of bound nitrogen increases from 12.9% to 13.5% as the absorbed dose increases from 0 to 40 kGy. Nitration of pre-irradiated cotton cellulose (10–40 kGy) results in esters with practically uniform MMD. This improves considerably their physicochemical parameters. Optimum conditions for the radiation pretreatment of cellulose from various sources using modern electron accelerators were developed for the manufacture of nitrates.

Irradiation of plant raw materials decreases the content of difficultly hydrolysable polysaccharides and increases the content of readily hydrolysable ones.^{90–100} The enhancement of hydrolysability occurs due to the radiation-induced degradation of polysaccharides. The rate constants for polysaccharide hydrolysis increase markedly with the dose. The adoption of radiation technology can simplify the existing manufacture of valuable technical compounds (ethanol, furfural, xylitol, and others) from plant raw materials. Radiation pre-treatment of cellulose-containing wood materials and agricultural waste (straw) facilitates their subsequent high-temperature acid or enzymic hydrolysis to give glucose.^{198–205}

A promising field of the use of radiation technology is the production of high-quality food additives from waste of plant origin (primarily, the waste of agricultural production, *i.e.* straw, corn cobs, *etc.*).²⁰⁶ It was found^{206–209} that an increase in the absorbed dose in these plant materials decreases the content of indigestible cellulose and increases the fraction of polysaccharides assimilable by ruminant animals. As a result of such a treatment, a plant material acquires the properties of a high-quality food additive (foraging sugar). Unfortunately, the radiation treatment is still rather expensive.^{210,211}

The radiation technology for the production of composite materials from polymers and wood or compressed waste of cellulose industry (see, *e.g.*, Refs 212 and 213), which is rather widespread, remains of current interest. The method involves impregnation of these materials with a monomer or oligomers (most commonly, methyl methacrylate is used) followed by ionising radiation-induced polymerisation. The resulting materials are used for the manufacture of high-quality parquet and other items.

The value of plant biomass, whose main components include cellulose and other polysaccharides, as a reproducible source of bound carbon for the industrial production of valuable technical, forage and food products will increase with time. It can also be believed that the role of radiation methods for the processing of plant biomass aimed at extraction of cellulose and other polysaccharides from it and for imparting to them the required properties will also increase.

IV. Models of non-heme monooxygenases	347
V. Conclusion	351

Abstract. The state-of-the-art of investigations in the field of catalysis of biological oxidation of saturated hydrocarbons by molecular oxygen and simulation of this process based on metal complexes is reviewed. The bibliography includes 296 references.

I. Introduction

Functionalisation of alkanes is of both theoretical and practical interest. Progress in homogeneous catalysis brought forth the problem of activation of C–H bonds as long as several decades ago. However, despite the considerable achievements in this area¹ practical requirements have stimulated the search for novel reactions and elaboration on their basis of more efficient procedures for alkane conversions. Currently, this is particularly urgent when the scantiness of natural resources of this valuable chemical raw material has become obvious. Petroleum and natural gas, the main sources of alkanes, are now mostly used as a fuel. Of nearly a billion tons of the petroleum extracted in the world, only 5% is chemically processed and direct functionalisation of alkanes is as low as fractions of a per cent. The inertness of alkanes is the main obstacle to the development of methods for their functionalisation; reactions with these compounds occur under drastic conditions and with low selectivity.

The main pathway of alkane functionalisation is their oxidation. In the living nature, this problem has been successfully solved in two ways: through aerobic oxidation, which involves molecular oxygen, and an anaerobic one. The corresponding natural enzymic systems still remain unsurpassed as regards the rate and the selectivity of alkane oxidation. Therefore, the biomimetic approach, *i.e.*, creation of chemical analogues of enzymes, seems to be especially promising in this respect. The current views about the aerobic biological oxidation of alkanes involving monooxygenases and its chemical simulation are discussed in this review.

II. Monooxygenases

The term ‘monooxygenases’ is generally applied to the enzymes that catalyse the oxidation of a substrate by molecular oxygen in the presence of a reducing agent according to the stoichiometric equation:

Thus, one atom of the oxygen molecule is incorporated into the substrate, whereas the other one forms water. Many monooxygenases contain metals as constituents, in the first place, iron and copper. Two equivalents of a reducing agent, which is needed for the monooxygenase cycle to be accomplished, come from an organic component that must be always present in the system. The role of this compound is to transfer electrons to the metal atom of the enzyme, which passes into the reduced state and thereby acquires the ability to react with molecular oxygen and activate it for further interactions with alkanes.

Hence, according to the current concepts,² activation of molecular oxygen resulting in the formation of metal peroxo- and oxo-complexes is the basic mechanism of the catalytic effect of monooxygenases. The chemistry of these complexes and their reactions with alkanes have attracted keen attention of investigators in the past decade.

1. Heme monooxygenases

a. Cytochrome P-450

Among monooxygenases, the suprafamily of cytochrome P-450 has been known for the longest time.^{3–5} Its active centre, like hemoglobin or myoglobin, contains heme, an iron-protoporphyrin complex. These enzymic systems can oxidise hundreds of thousands of low-molecular-weight compounds of both endogenous and exogenous origin.^{6–8} Cytochrome P-450 catalyses hydroxylation of alkanes, epoxidation of alkenes, *O*- and *N*-dealkylation, and other oxidation reactions. About 500 representatives of the cytochrome P-450 suprafamily are currently known.^{7,9} They differ from one another in the structure of their globular protein in the region of the active centre, but have identical prosthetic groups.

Cytochrome P-450 is the component of a multienzyme system, which also contains electron transfer enzymes. In mitochondria and most bacteria, electrons are transferred from NADH and NADPH to the enzyme by FAD-dependent reductase *via* iron–sulfur ferredoxin. In systems of the microsomal endoplasmic reticulum devoid of Fe₂S₂-ferredoxin, the electrons are transferred

from NADPH by cytochrome P-450 oxidoreductase, a flavoprotein that contains FAD and FMN.

The catalytic cycle of cytochrome P-450 varies depending on the electron source and the type of substrate being metabolised; however, its main stages are common for the whole cytochrome P-450 suprafamily (Fig. 1). The further the stage from the original state Fe^{III} in the catalytic cycle the less studied the structure of the intermediates and the mechanism of their formation. The reason is that the time of conversion of the corresponding intermediate may be too small for the latter to be registered by the modern technique.

Figure 1. The catalytic cycle of cytochrome P-450.

The kinetics of individual stages of the catalytic cycle has been studied for both bacterial¹⁰ and microsomal⁷ cytochrome P-450. The system of camphor monooxygenation from *Pseudomonas putida*, cytochrome P-450_{cam} (CYP101),¹¹ is being studied in more detail in comparison with microsomal cytochrome P-450 membrane-bound proteins the analysis of which in the isolated state faces certain difficulties. Interaction with the phospholipid bilayer can influence the generation of a catalytically active conformation of membrane-bound enzymes. However, kinetic regularities of these systems have much in common¹² (Table 1), which makes it possible to propose a unified mechanism for oxygen activation in liver and bacterial cytochrome P-450.

Table 1. The rate constants for various stages of the catalytic cycle of cytochrome P-450 in bacterial and microsomal systems.^{7, 12}

Stage ^a	Cytochrome P-450 _{cam} ^b		Microsomal cytochrome P-450 ^c
	<i>T</i> /°C	<i>k</i>	<i>k</i>
1	4	47 s ⁻¹	50 s ⁻¹
2	25	30–33 s ⁻¹	18 min ⁻¹ 11.5 min ⁻¹ (see ^d)
3	20	1.7 × 10 ⁶ M ⁻¹ s ⁻¹	> 10 ⁶ M ⁻¹ s ⁻¹ (see ^e)
4		1–4 s ⁻¹	2–7 s ⁻¹

^a See Fig. 1; ^b turnover number is 1900 min⁻¹; ^c turnover number is 24 min⁻¹ (benzphetamine, cytochrome P-450_{LM2}); ^d without substrate; ^e 25 °C.

Numerous spectral studies^{7, 12, 13} have established, with a sufficient degree of reliability, the nature of the intermediate complexes formed in the catalytic cycle of cytochrome P-450, starting from the original Fe^{III} to the $\text{Fe}^{\text{II}}\text{O}_2$ -complex. An equilibrium between the low-spin and the high-spin states of Fe^{III} in the original enzyme is shifted towards the former owing to the presence of a water molecule in a *trans*-position relative to the thiolate.¹⁴ Hydrophobic binding of a substrate results in the dissociation of the ligand from the 6th position and a shift of the equilibrium towards the high-spin state ($S = 5/2$). This is accom-

panied by a simultaneous increase in the redox potential of the iron complex, which facilitates electron transfer from the reductase to yield a high-spin Fe^{II} -heme ($S = 2$). Interaction of the latter with O_2 gives an oxygen complex similar to that of hemoglobin. At lower temperatures, this complex is relatively stable and can be identified by spectral methods for various isoforms of cytochrome P-450.^{15, 16}

Transfer of the second electron to oxycytochrome P-450 results in the formation of $\text{Fe}^{2+}\text{O}_2^{2-}$ or $\text{Fe}^{3+}\text{O}_2^{2-}$ species. In the absence of the substrate,¹² decomposition of these species yields a superoxide, the rate constant being 29 min⁻¹. Binding of a substrate with the enzyme inhibits this process; the rate constant for the formation of oxidation products is about 30 min⁻¹ and it changes slightly depending on the nature of the substrate and the enzyme.

The intermediate stages following the oxycytochrome reduction occur too fast for the intermediates to be detected by spectral methods. The mechanism of transformation of the substrate–reduced oxycytochrome complex is the least understood in the catalytic cycle of cytochrome P-450. It is usually assumed⁷ that the known oxidation products are formed through heterolytic or homolytic cleavage of the O–O bond in the iron peroxo-complex. Different versions of this mechanism agree only with certain parts of the experimental data available. Presumably, the operation of a particular mechanism depends on the nature of the substrate and the enzyme.

Most of investigators postulate the pentavalent iron oxene complex ($\text{P-450-Fe}^{\text{V}}=\text{O}$) as the direct oxidant of a substrate by analogy with the reactive intermediates of the catalytic cycle of peroxidase, which have the oxoferryl group ($\text{Fe}^{\text{IV}}=\text{O}$) in their active centre. However, the Mössbauer and Raman spectra of cytochrome P-450 recorded under catalytic conditions¹² suggest the presence of iron-superoxide structures similar to oxyhemoglobin HbO_2 , but different from the ferryl species of peroxidase. Probably, the superoxide complexes are formed as intermediate products in the activation of oxygen on cytochrome P-450. Unfortunately, the iron oxene species postulated for the catalytic cycle of cytochrome P-450 have not been identified yet by any of the existing physical methods. At the same time, the oxene species in peroxidase systems are relatively stable, well-characterised intermediates.^{17–19} The formation of reactive species in the conversion of hydrogen peroxide by peroxidase occurs under conditions of acid-alkaline catalysis in the imidazole fragment of histidine localised in the distal region of the enzyme heme.^{18, 20} In contrast to peroxidase, thiolate is the proximal ligand of the cytochrome P-450 heme.^{14, 21, 22} Presumably, the effect of the thiolate ligand and the presence of a substrate in close proximity to the reactive oxygen of cytochrome P-450 decrease the lifetime of the active species and prevent their registration.

Not only the lack of direct proofs of the existence of iron–oxene complexes of cytochrome P-450, but some other data raise doubt about the nature of the reactive species in the catalytic cycle of this enzyme. According to calculations, the $\text{P-450-Fe}=\text{O}$ complexes must be electrophilic.⁷ In practice, the reactions catalysed by this enzymic system suggest either the electrophilic or the nucleophilic character of the reactive species. The role of the nucleophile in the catalytic cycle of cytochrome P-450 can be played by iron peroxide, whereas iron oxene and iron hydroperoxide (or hydroxide) are the possible candidates for the electrophilic reactive intermediates. Electron density calculations demonstrate that the oxygen atom that is directly bound to the heme in peroxo-ferryl complexes with thiolate ligands, bears a partial positive charge, whereas the external oxygen atom bears a partial negative charge. It may thus be assumed that peroxo-complexes function as monooxygenating species. The catalytic activity of ferrocycytochrome P-450_{cam} with superoxide anion is additional evidence in favour of this hypothesis.^{7, 23} The peroxo intermediate is regarded as a direct oxidant in the oxidation of lauric acid²⁴ and in the oxidative deformylation of aldehydes by aromatase,^{25, 26} it is involved in reactions catalysed by NO-syn-

thase²⁷ and heme-oxygenase.²⁸ However, the formation of epoxides and *N*-oxides in these reactions is inconsistent with reactive peroxide or superoxide intermediates and attests to the involvement of oxene species.

Cytochrome P-450 catalyses substrate oxidation in the absence of molecular oxygen with iodosobenzene, peroxides, peroxy acids, and other oxygen donors as oxidants.⁷ In these so-called by-pass systems, cytochrome P-450 transfers the oxygen that is already activated from the oxidant to the substrate. In other words, it functions either as an oxene transferase or it oxidises substrates by detaching electrons as does peroxidase. A by-pass system with iodosobenzene is considered to be the best, because the composition of its monooxygenation products is the closest to that in the complete enzyme system. It should be noted, however, that the identity of the oxidation products does not always imply the identity of the reactive species in these systems.

There is evidence⁷ that the structure of reactive intermediates generated in the interaction of PhIO with cytochrome P-450 is closer to that of peroxo-species (Fe—O—O) than to that of the iron oxene (Fe=O). The oxygen atom of iodosobenzene in these intermediates is analogous to the external oxygen atom of iron peroxide. Moreover, the use of radiolabelled water has shown that the products of oxidation in this by-pass system contain an oxygen atom from the solvent. Therefore, some investigators suggest that iron peroxide or iron hydroperoxide are the most probable reactive intermediates of the by-pass systems.

Adrenal cortex cytochromes P-450 involved in the biosynthesis of steroid hormones are highly regioselective, apparently due to the rigid fixation of the substrate in a hydrophobic pocket near the active centre. Bacterial cytochrome P-450 involved in the hydroxylation of lauric acid catalyses alkane oxidation exclusively at the methyl group,^{29,30} thereby manifesting an ω -hydroxylase activity. This points definitely to very strong steric hindrances during the approximation of the alkane molecule to the active centre. However, in the case of liver cytochromes P-450 involved in detoxication of xenobiotics and capable of oxidising a wide variety of substrates, the observed regioselectivity is apparently determined mainly by the intrinsic reactivity of the active intermediate.³¹ In the ω -hydroxylation of racemic, (*R*)-, and (*S*)-1,1,1-trideuterio-2-phenylpropane by rat liver microsomes, the stereoselectivity depends on the type of cytochrome P-450 and the structure of the active centre. This suggests that in this case, too, regioselectivity is determined by the structure of the apoprotein rather than by the nature of the reactive intermediate.³² It thus follows that, depending on the apoprotein structure, identical reactive intermediates can have different selectivity in the formation of oxidation products, while different active intermediates can have similar selectivity.

Thus the nature of monooxygenating reactive species in the catalytic cycle of cytochrome P-450 is still open to discussion. In our opinion, oxoferryl complexes in cytochrome P-450-containing monooxygenases are the reactive species that oxidise the C—H bonds of alkanes.

Studies with targeted mutations³³ have shown that polar amino acid residues in the distal part of the cytochrome P-450 heme can be involved in proton transfer to the oxygen of the peroxo-complex, thus enabling the formation of an intermediate that hydroxylates the substrate. This is confirmed by the increase in the amount of peroxide and the decrease in the rate of substrate hydroxylation when the normal course of protonation is inhibited by targeted mutagenesis of threonine.³⁴ Simultaneous mutagenesis of aspartic acid (Asp251) and threonine (Thr252) in cytochrome P-450_{cam} has demonstrated³⁵ a cooperative effect of these amino acid residues that results in the cleavage of the O—O bond. Very probably, this reaction is the key stage of the mechanism of formation of the oxidation products (Fig. 2).

Figure 2. A schematic mechanism of the cleavage of the O—O bond in cytochrome P-450_{cam}.³⁵

b. *N*-Methylamine monooxygenase

It is necessary to mention another heme-containing monooxygenase from *Pseudomonas asinovorans*, which catalyses *N*-demethylation of secondary amines. Like peroxidase and unlike cytochrome P-450, it contains the imidazole moiety of histidine in the 5th axial (proximal) position of the heme; however, similarly to cytochrome P-450, it oxygenates the C—H bonds of methylamines. The intramolecular kinetic isotope effect (KIE) observed³⁶ for the methyl group of 1,1,1',1'-tetradeuterio-dimethylamine ($k_H/k_D = 1.76$) is close to the KIE for the analogous reactions of cytochrome P-450 and chloroperoxidase.

2. Non-heme monooxygenases

It has been established^{37–39} that non-heme iron-containing monooxygenases, such as methane monooxygenase and ω -hydroxylase, analogously to cytochrome P-450, can transfer the oxygen atom from a relatively weak oxidant, *viz.*, molecular oxygen (using two reducing equivalents) or from atomic oxygen donors, such as PhIO, ClO^- , H_2O_2 , RCOOOH , *etc.*, to the C—H bonds of alkanes.

a. ω -Hydroxylases

ω -Hydroxylases, which contain one iron atom in their active centre, are of considerable interest as the representatives of the family of non-heme monooxygenases. They mediate targeted hydroxylation of the methyl group of *n*-alkyl chains of various compounds including alkanes.

The non-heme monooxygenase system of *Pseudomonas oleovorans* comprises three components that are typical of any monooxygenase system: an iron-containing monooxygenase, a reducing agent, and a carrier. In this particular case, these are ω -hydroxylase, flavoprotein reductase, and rubredoxin.⁴⁰ Together with terminal hydroxylation of the methyl group in alkanes and fatty acids, this enzymic system can epoxidise terminal alkenes, convert sulfides into sulfoxides, and demethylate ethers.⁴¹ All these reactions are stereospecific⁴² with high KIE ($k_H/k_D = 6–8$).⁴³ The Fe=O species can serve as an active intermediate in the oxidation reactions catalysed by ω -hydroxylase.⁴⁴ The use of a 'radical clock' method with *trans*-1-methyl-2-phenyl-cyclopropane as the substrate has shown⁴³ that 1-phenyl-but-3-en-1-ol is the only oxidation product. The conclusion on the radical attack at the C—H bond can hardly be considered as unambiguous.

Non-heme ω -hydroxylase from *Pseudomonas aeruginosa*⁴⁵ oxidises *n*-alkanes ($\text{C}_5–\text{C}_{10}$) into the corresponding acids *via* the primary alcohols. The efficiency of oxidation is lower for branched alkanes. The methyl group in 1,4-dimethylcyclohexane

is oxidised only when it occupies the equatorial position, *i.e.*, the enzyme can oxidise compounds with a relatively planar conformation. Smooth oxidation was observed for alkylbenzenes. It was thus concluded that a hydrophobic cavity (5.8 Å) exists in the vicinity of the enzyme active centre. The presence of such a cavity in this particular enzymic system as well as in other monooxygenases may account for the unusual substrate specificity and regioselectivity observed in the oxidation of hydrocarbons.

b. Methane monooxygenase

Methane is the most widespread and the least reactive representative of the family of saturated hydrocarbons. Therefore, its catalytic oxidation under mild conditions is of the greatest interest. The examples of selective low-temperature oxidation of methane are rather scarce.^{37, 38, 46, 47} At the same time, the enzymic systems of various microorganisms, *viz.*, methane monooxygenases (MMO), catalyse efficient conversion of methane into methanol.^{48–51} Unlike heme monooxygenases and non-heme ω -hydroxylases, the iron at the active centre of MMO is a component of a binuclear centre, as in hemerythrin (HR), the protein, which is an oxygen carrier, like hemoglobin,^{52–54} and in ribonucleotide reductase (RR) where the binuclear iron complex performs one-electron oxidation of tyrosine. The latter is further involved in a complex oxidation–reduction cycle.^{55–58}

Several MMO from various bacterial sources, such as *Methylococcus capsulatus*,^{59, 60} *Methylosinus trichosporium*,⁶¹ and *Methylobacterium*⁶² have been studied. Depending on growth conditions, the enzyme can exist both in the membrane-bound and the cytoplasmic (soluble) form.⁶³

Water-soluble MMO from *M. capsulatus* has been studied in the most detail. This enzymic system oxidises the methyl group and the adjacent methylene group of *n*-alkanes [ω - and (ω -1)-hydroxylation]. In branched alkanes, it is the most remote from the branching part of the molecule that undergoes oxidation, which points to substantial steric hindrances in the vicinity of the active centre. Nevertheless, in the case of small molecules, *e.g.*, isobutane or *cis*-1,4-dimethylcyclohexane,⁶⁴ the oxidation affects predominantly the tertiary C–H bonds. These data suggest that the steric demands are determined not by the active centre itself, but rather by the protein environment, which forms a hydrophobic cavity of a definite size.

The MMO consist of three closely interrelated proteins, *viz.*, **A**, the monooxygenase (or hydroxylase) itself, which is a dimer and contains two to four iron atoms; **B**, a regulatory protein, and **C**, a reductase.^{65, 66} Protein **B** strongly affects the redox properties of the hydroxylase component of MMO.^{67, 68} In the case of *M. capsulatus*, the redox potentials of hydroxylase for the transfer of the first and the second electrons are equal to +48 and –135 mV (relative to the NHE) and are slightly shifted towards more negative potentials after the addition of a substrate. In the absence of the substrate, the hydroxylase cannot be reduced even at –200 mV. The transfer of the second electron occurs more easily than that of the first one, which makes it possible to avoid the formation of the unfavourable $\text{Fe}^{\text{III}}\text{Fe}^{\text{II}}$ state of the cluster. Similarly to cytochrome P-450, binding of a substrate facilitates the reduction of iron and initiates the catalytic cycle of MMO. Binding of protein **B** results in changes in the EPR spectrum of the $\text{Fe}^{\text{III}}\text{Fe}^{\text{III}}$ form of hydroxylase and strongly influences the rate and regioselectivity of alkane oxidation. Presumably, when protein **B** binds to hydroxylase, it induces conformational changes in the region of the active centre. This in turn changes the coordination environment of the iron and, as a consequence, the spectroscopic, redox, and catalytic properties.

It was reported^{69–72} that the active centre of MMO contains two iron atoms, which are linked by μ -oxo- μ -carboxylate bridges as in hemerythrin and ribonucleotide reductase.^{38, 54, 57, 58} As for the terminal ligands, some indirect data show that each iron atom in the active centre of MMO is coordinated to one imidazole moiety of histidine.^{73, 74}

An interesting comparison of MMO and RR can be made on the basis of X-ray data. The hydrophobic cavity in MMO is much larger than that in RR. This is consistent with the fact that MMO binds a hydrophobic substrate, *viz.*, methane. The position occupied by tyrosine in RR is occupied by cysteine in MMO. This allowed one to suggest an original hypothesis⁷⁵ about the catalytic mechanism of MMO with the involvement of the SH-group. Apart from cysteine, threonine (Thr213), which is apparently necessary for proton transport in the catalytic cycle, is the only amino acid containing a protonated group vicinal to the hydrophobic cavity; its effect is similar to that of Thr252 in cytochrome P-450.^{34, 35}

Thus, the spectral and X-ray data suggest that the iron in the active centre of MMO is the component of a binuclear μ -hydroxo-complex, which has much in common with the Fe–O–Fe centres of HR and RR for which X-ray data are also available (Fig. 3).⁷⁵

Figure 3. A schematic representation of binuclear active centres of hemerythrin, ribonucleotide reductase, and methane monooxygenase.

The catalytic cycle of MMO is very similar to that of cytochrome P-450. Alkane binding is followed by fast two-electron reduction of the μ -hydroxo- Fe_2^{III} to the μ -hydroxo- Fe_2^{II} state, which can rapidly react with O_2 .⁷⁶ One-electron reduction gives the μ -hydroxo- $\text{Fe}^{\text{III}}\text{Fe}^{\text{II}}$ intermediate, which slowly reacts with oxygen.^{48, 71}

The stepwise formation of three intermediates, *viz.*, **P**, **Q**, and **T**, from μ -hydroxo- Fe_2^{II} , has been established.⁵⁰ The intermediate **P** is formed immediately after mixing of O_2 with MMO subjected to two-electron reduction; it is then slowly converted into the intermediate **Q**. The rate of conversion of the intermediate **Q** depends on the nature and the concentration of the substrate, which suggests that the intermediate **Q** is the key oxidising agent. And finally, the intermediate **T** generated upon reaction of the intermediate **Q** with the substrate dissociates to give the oxygenated product. The dissociation of the intermediate **T** is the rate-limiting step of this reaction. According to Mössbauer spectroscopic data,^{49–51} the structure of the intermediate **Q** can be represented as a diferryl or a bis- μ -oxo-complex.

The binuclear structure of the active centre of MMO, the unusual substrate specificity and selectivity of alkane oxidation as well as the spectral characteristics of the reactive intermediates made it possible^{77–79} to develop new concepts of the catalytic mechanism of MMO:

According to these concepts, activation of O_2 occurs with the formation of $\mu\text{-}\eta^2\text{-}\eta^2$ -peroxide **1** as a result of lateral binding of the O_2 molecule. This intermediate is further converted into the bis- μ -oxo- Fe_2^{IV} intermediate **2**, which reacts with methane and is an alternative to ferryl. Unlike ferryl, the O atom in this intermediate occupies the bridging position between two iron atoms and thus ensures its more efficient stabilisation.

The interaction of the O atom of the intermediate **2** with the C—H bond of methane, which has the smallest length, allows an additional nucleophilic assistance of the second O-bridge, *e.g.*, due to the formation of a hydrogen bond with the H atom of methane. This speculation might rationalise the tunnelling effect of the proton in methane oxidation. Electronic and steric factors that control the interaction of the bis- μ -oxo- Fe_2^{IV} intermediate **2** with the C—H bond may account for the preferential oxidation of methane and lower alkanes and almost complete lack of selectivity in the oxidation of the bonds. Unexpectedly, the KIE for the interaction of the intermediate **Q** with CH_4 and CD_4 appeared to be very high (50–100).^{80, 81}

As has been noted above, mononuclear iron complexes at the active centres of various monooxygenases catalyse efficient oxidation of C—H bonds. The question of why Nature selected the binuclear iron complex as the active centre of MMO may be answered as follows: first, this allows simultaneous transfer of two electrons to the O_2 molecule thereby avoiding a thermodynamically and kinetically unfavourable stage of the formation of the oxygen radical anion en route to peroxide:

Second, both Fe^{III} ions can accept $\text{O}_2^{\cdot -}$ after heterolytic cleavage of the O—O bond without any preliminary protonation, which is extremely unfavourable in the strongly hydrophobic environment near the active centre.

Third, electron transfer from the neighbouring iron atom allows one to circumvent the superoxidised state of iron, which is unstable under the conditions of the non-heme environment.

In other words, the second iron atom plays the same role as the porphyrin ligand in compound **I** of peroxidase or in the active ferryl species of cytochrome P-450.

And finally, magnetic interaction between the iron ions of the complex enables coordination of the electron-orbital effects of both atoms in the attack at the C—H bond.

b. Toluene monooxygenases

Toluene monooxygenases T2MO, T3MO, and T4MO catalyse the formation of *o*-, *m*-, and *p*-cresols; they can also oxidise other hydrocarbons. The active centre of toluene monooxygenase comprises two iron atoms linked together by a hydroxyl bridge; its spectral characteristics are similar to those of MMO. Toluene monooxygenase catalyses the oxidation of substrates by either molecular oxygen in the presence of a reducing agent or hydrogen peroxide.^{82, 83}

Analysis of the data available on heme and non-heme monooxygenases demonstrates that the nature of the reactive intermediate formed in the monooxygenase-catalysed reactions is still controversial. Earlier, it was thought that the active complex of all iron-containing monooxygenases comprises the ferryl fragment —Fe=O with iron in the formal oxidation states IV and V. This concept could not be used to rationalise the experimental results

obtained for the non-heme enzyme, methane monooxygenase. This problem could be surmounted when it was assumed that oxygen can bind with two iron atoms to give $\text{Fe}^{\text{IV}}(\mu\text{-O})_2\text{Fe}^{\text{IV}}$, which can be regarded as a ferryl dimer. As far as heme systems are concerned, some investigators propose iron peroxide (or iron hydroperoxide) as the most probable reactive intermediate. Hence, a detailed structure of reactive intermediates of heme and non-heme monooxygenases has not been elucidated in full detail.

Another question of fundamental importance is the way whereby oxygen is transferred from the reactive oxidant to the hydrocarbon.

3. The mechanism of alkane monooxygenation

The nature of interactions of mono- and bi-nuclear ferryl intermediates in heme and non-heme monooxygenase systems with the C—H bonds of alkanes is still a widely debated topic.

The electronic structure of atomic oxygen is similar to that of the bivalent carbon compounds (carbenes) and by analogy it is termed oxene. Like carbenes, oxene in the triplet state reacts with alkanes as a free radical and detaches hydrogen. In the singlet state, it can also be inserted into the C—H bond to yield an alcohol.^{84, 85} Studies of the gas-phase reactions of singlet oxene with alkanes resulting in the generation of the OH radical showed⁸⁶ that this reaction can occur by two different routes, which are interpreted as the insertion of the O atom into the C—H bond and the detachment of the H atom. It should be noted that the insertion mechanism predominates if small molecules (CH_4 , C_2H_6) with strong C—H bonds are subject to attack, whereas hydrogen detachment takes place predominantly in the reaction with higher hydrocarbons [C_3H_8 , $\text{C}(\text{CH}_3)_4$] that are either sterically hindered and/or contain weaker C—H bonds. Thus the fraction of the route involving the detachment of H varies from 0.05 for CH_4 to 0.9 for $\text{C}(\text{CH}_3)_4$. It is concluded from these data⁸⁶ that the detachment can result from the intersection of two potential energy surfaces at the beginning of a single route that corresponds to insertion. The lifetime of the complex is 0.35×10^{-12} s for H_2 , 0.8×10^{-12} s for CH_4 , and 4.2×10^{-9} s for $\text{C}(\text{CH}_3)_4$.

The oxygen atom in the active centre of monooxygenase may be bound with the metal complex and its capacity to be inserted into the C—H bond or to detach the H atom is maintained. Such compounds (oxenoids) are related to the oxo-salts of transition metals. These compounds are also thought to be the intermediates possessing the superoxidative properties, *e.g.*, in the transfer of the oxygen atom from N_2O to metal ions.⁸⁷

Two possible mechanisms are usually considered: (a) synchronous insertion of the O atom detached from the metal ion into the C—H bond (the concerted, oxenoid mechanism)^{88–90} and (b) crypto-radical (the so-called oxygen rebound mechanism), which implies detachment of the hydrogen atom from the substrate molecule at the first stage with subsequent recombination of the alkyl radical formed with FeOH at the active centre of the enzyme.

The following data are in favour of the synchronous insertion mechanism. In the monooxygenase reaction, alkanes yield alcohols and retention of the original configuration of the asymmetric carbon atom where the oxidation involves the C—H bond is a characteristic feature in many cases.^{91, 92} It may therefore be assumed that this reaction proceeds without the intermediate formation of free radicals, which might lead to racemisation. Alkenes yield epoxides,⁹³ which retain the configuration of the original alkene.⁹⁴ Benzene and other aromatic hydrocarbons are converted into phenols and dihydrodiols.⁹⁵ Both types of compounds are formed *via* arene-1,2-oxides.⁹⁶ Migration of a group bound to the aromatic ring, which is characteristic of enzymic oxidation, from the position subject to hydroxylation to the neighbouring position (the NIH shift) is consistent with this conclusion.^{97, 98} Quantum-chemical grounds for the oxenoid mechanism have been published.⁹⁹

However, the oxygen rebound mechanism for heme and non-heme monooxygenases has recently received the most ample

recognition. This mechanism is usually supported by the following facts.

1. The large primary kinetic isotope effect in the cytochrome P-450-catalysed hydroxylation is attributed to the linear structure of the transition state ($\text{Fe}-\text{O}\cdots\text{H}-\text{R}$). It is assumed that the insertion of the O atom into the C—H bond must be characterised by a small isotope effect.¹⁰⁰

2. In some cases, partial or complete skeletal isomerisation of the original compound occurs en route to the reaction products. Presumably, this takes place in the intermediate alkyl radical.

3. The effect of radical traps. In the case of methane oxidation by methane monooxygenase, the use of radical traps allowed identification of the methyl radical.¹⁰¹

Evidence for a stepwise mechanism, which involves initial detachment of the hydrogen atom by a reactive oxidising species,^{102,103} follows from the high KIE (10–12) observed in hydroxylation by cytochrome P-450-containing monooxygenases^{104–107} and soluble MMO from *M. trichosporium*¹⁰⁸ as well as from the incomplete retention of the original configuration of the asymmetric carbon atom.

There are other facts in favour of the oxygen rebound mechanism. Thus allylic oxidation in a system with cytochrome P-450 resulted in the formation of isomeric allylic alcohols, which can be accounted for by the generation of the intermediate radical, $[\text{C}=\text{C}-\text{CH}^* \longleftrightarrow \text{C}^*-\text{C}=\text{CH}]$.¹⁰⁹ The rate constant for the recombination of the methylcyclopropyl and OH radicals was determined, $k_{\text{ox}} \approx 2 \times 10^{10} \text{ s}^{-1}$.¹¹⁰

Apparently, the ‘radical clock’ method¹¹⁰ not only confirms the intermediate formation of a radical, but also permits the quantitation of its kinetic behaviour. However, further applications of this method have shown that the increase in the isomerisation rate constant (due to the incorporation of the corresponding substituent into the cyclopropane ring) does not result in a parallel increase in the yield of the isomerised product. The ‘radical clock’ method yielded different k_{ox} values for different molecules [from $1.4 \times 10^{10} \text{ s}^{-1}$ to $(2-7) \times 10^{12} \text{ s}^{-1}$]^{111–113} with no obvious relation to the structure.^{111–113} Moreover, the use of a supersensitive probe¹¹⁴ gives an extremely high k_{ox} value of $1.4 \times 10^{13} \text{ s}^{-1}$ (based on the yield of the isomerisation product). The lifetime of a radical with such a great value of the recombination rate constant, which also includes diffusion, must correspond to the period of one vibration.

In the case of MMO from *M. capsulatus*,¹¹⁵ the rate constant for the recombination of the active oxo-species with a radical intermediate also exceeds 10^{13} s^{-1} . In this case, the reaction occurred with 100% retention of configuration,¹¹⁶ which obviously excludes the generation of an alkyl radical. The application of analogous tests to *M. trichosporium* has shown the formation of a small amount of rearranged products, which might attest to the presence of a radical intermediate. It was concluded from these data that the mechanism of this reaction can be different for different forms of MMO.

There are other data which are in conflict with the oxygen rebound mechanism. It was found¹¹⁷ that hydroxylation of the stereoisomers of deuterium-substituted camphor by cytochrome P-450_{cam} is accompanied by partial isomerisation and transfer of deuterium atoms from the *exo*- to the *endo*-position and *vice versa*. This phenomenon is considered as a proof of the radical mechanism. However, the camphor molecule at the active centre of the enzyme is fixed by a hydrogen bond and thus cannot rotate, which follows from the selectivity of this reaction: only 5-*exo*-hydroxycamphor is formed. This means that isomerisation owing to the rotation of the molecule is impossible. It was suggested¹¹⁷ that a certain radical exists, which can migrate freely and attack the camphor molecule at both the *exo*- and the *endo*-positions of the ring. It must be noted that the presence of this radical in the enzymic reaction is hardly probable.

Thus, neither of the two mechanisms mentioned above can explain the body of the experimental data for heme and non-heme monooxygenases altogether. Therefore, the hypothesis of the

mechanism of synchronous insertion of the oxygen atom into the C—H bond has been recently supplemented with one important detail, namely: the insertion of oxygen is preceded by the formation of an intermediate complex of the active oxygen with the hydrocarbon molecule. Thus, the oxygen atom plays the crucial role in the complex formation, whereas the metal acts as a ligand at the oxygen atom rather than the centre of complex formation. The complex with active oxygen comprises a strongly distorted substrate structure with pentacoordinated carbon. It is assumed that two hydrogen atoms or one hydrogen and one deuterium atom of this complex can interchange very easily.^{118,119}

If the lifetime of this intermediate is small, *e.g.*, if the O atom is rapidly inserted into the C—H bond, the isomerisation does not take place; if the rate of isomerisation is comparable to that of oxygen insertion, the isomerisation products are formed in appreciable amounts. Thus, the mechanism of this reaction is similar for various enzymes but the ratio of the rate constants for the intermediate isomerisation and the O atom insertion into the C—H bond changes, which results in different selectivities of this reaction. Within the framework of the pentacoordinated carbon mechanism, the unusual stereoselectivity of the hydroxylation of the isotopically substituted camphor in a system with cytochrome P-450_{cam} has received natural interpretation without any recourse to improbable speculations.¹²⁰

The existence of an intermediate with pentacoordinated carbon has also been postulated in Ref. 116. If this hypothesis is true, the dynamics of hydroxylation of alkanes is qualitatively analogous to the dynamics of hydroxylation of aromatic compounds and epoxidation of alkenes. The same mechanism can also explain the drastic differences in the isotope effects for closely related substrates, such as methane and ethane in the case of MMO. If the hydroxylation occurs in two steps, its rate can be limited by both the first (binding of the O atom to the C—H bond) and the second stage (insertion of the O atom leading to an alcohol) depending on the substrate. Presumably, the maximum isotope effect must be manifested at the second stage. It is believed that it is in the case of methane, the C—H bonds of which are among the strongest, that the rate is determined by the second stage and the isotope effect is a maximum.

A paradoxical situation has been observed earlier for *N*-dealkylation:³⁶ the isotope effect (8–10) was high for peroxidases the mechanism of which involved an electron transfer, but it was small (1–3) for various forms of cytochrome P-450, chloroperoxidase, and *N*-methylaminomonooxygenase, where the activated O atom directly reacts with the C—H bond.

This paradox can also be overcome by assuming a two-step mechanism involving intermediates with pentacoordinated carbon (**3a** and **3b**), for cytochrome P-450 and its analogues:

The first stage results in the formation of the intermediate **3a**, which is further converted into the intermediate **3b**. This is followed by the second stage, *viz.*, splitting of formaldehyde.

If the rate of this reaction is limited by the first stage, the isotope effect will be small.

The formation of an intermediate complex of the metal-bound oxygen atom with the carbon atom of an unsaturated molecule is beyond doubt for epoxidation of alkenes and hydroxylation of aromatic compounds. At the same time, the absence of saturation in the case of alkane hydroxylation apparently rules out the possibility of formation of an analogous intermediate complex. This new hypothesis is attractive in that it unifies the mechanisms

of atomic oxygen transfer to the C–H bonds of saturated compounds as well as to alkene and aromatic C=C bonds.

III. Models of heme monooxygenases

In addition to monooxygenases, the iron porphyrin complex (FeP) is present in the O₂ carriers (hemoglobin, myoglobin) and enzymes (catalase, peroxidase). One of the reasons for such wide occurrence of the porphyrin system in living nature is its stability. In addition, the porphyrin ring can play the role of an electron donor owing to its ability to generate the radical cation and thus to become an active participant of the catalytic process. Therefore, it was natural to employ metal porphyrins (MP) as catalysts in the simulation of heme monooxygenases. The first model system that involved iron porphyrin (hemin) was proposed in 1972 by Belova (Kulikova) *et al.*¹²¹ Over the past 25 years, studies in this area have continued at a fast pace. This illustrates the fruitfulness of a biomimetic approach in both the analysis of fundamental problems of enzymic catalysis and the design of novel catalysts.^{7, 122–124}

1. Models with active oxygen donors

The simulation of enzymic oxidation with the use of metal porphyrin complexes and active oxygen donors, such as iodosobenzene and its fluorinated analogues, sodium hypochlorite, hydrogen peroxide and alkylhydroperoxides, peroxy acids, potassium persulfate, amine *N*-oxides, and nitrous oxide, has turned out to be very successful.

Iodosobenzene as the active oxygen donor was used for the first time in a biological system.¹²⁵ Later, it was employed in a simple system based on iron tetraphenylporphyrinate (FeTPP)¹²⁶ responsible for the oxidation of a series of substrates, including alkanes, with a selectivity which is close to that of the enzymic one. A great number of systems initiating alkane oxidation in organic solvents or water–organic solvent mixtures in the presence of phase-transfer catalysts have been described. The most interesting of them are presented in Table 2.

In these systems, cycloalkanes are oxidised under mild conditions to give the corresponding alcohols and ketones (sometimes, alkyl halides) in yields up to 60% with respect to the oxidant consumed and up to 90% with respect to the substrate. The yield of the products, selectivity, and the rate of oxidation depend on the nature of the metalloporphyrin, the axial ligand, the oxygen source, and the substrate. Depending on the system, oxidation of cyclohexane (**4**) gives variable proportions of cyclohexanol (**5**) and cyclohexanone (**6**); the use of NaOCl as the oxidant also yields chlorocyclohexane (**7**). Oxidation of adamantane (**8**) gives adamantan-1-ol (**9**), adamantan-2-ol (**10**), adamantane-1,3-diol (**11**), and adamantanone (**12**) (Scheme 1). The efficiency of the catalyst

increases substantially upon introduction of substituents into the *ortho*-position of the phenyl rings of tetraphenylporphyrin. The greatest turnover number (14 600) was observed for halogenated ruthenium tetraphenylporphyrinate,¹³⁵ which catalysed alkane oxidation by 2,6-dichloropyridine *N*-oxide (DCPO) at a rate of 800 cycles per min. The virtually complete retention of configuration of the chiral carbon atom and high efficiency open up new opportunities for the application of this system in the stereoselective synthesis of tertiary alcohols.

Scheme 1

Thus, the systems with active oxygen donors are good functional models of heme monooxygenases owing to their ability to oxidise hydrocarbons under mild conditions with the selectivity and at rates which are close to those in enzymic reactions. Another problem of fundamental importance is the nature of the active species that interact with the substrate. As has been mentioned above, a ferryl ($P^{+}Fe^{IV}=O$) or a perferryl ($PFe^{V}=O$) complex has been usually assumed as an active intermediate in heme monooxygenase systems.

In the case of chemical models, the formation of the ($P^{+}Fe^{IV}=O$) intermediates was recorded by low-temperature spectroscopy in polar solvents (CH_2Cl_2 , CH_3CN), *viz.*, for the interaction of iron tetramesitylporphyrinate (FeTMP) with *m*-chloroperbenzoic acid¹⁰³ and for a $PFe^{III}-O_2^{-}-Ac_2O$ system.^{136, 137} The only stable $PMn^{V}=O$ complex known so far contains a macrocyclic tetraamide as the ligand.¹³⁸

The intermediates $TF_5PPRu^{II}CO(DCPO)$ and $TF_5PP^{+}Ru^{II}CO(DCPO)$ were identified in a $Ru^{II}TF_5PPCO$ [ruthenium tetrakis(pentafluorophenyl)porphyrinate]–DCPO system at low temperature.¹³⁵ The compound $TF_5PPRu^{III}(DCPO)_2$ was identified in the fast phase of alkane oxidation at 65 °C.

High-valent oxo-complexes of iron porphyrinates were detected in systems with NaOCl, PhIO, and $KHSO_5$; however,

Table 2. Alkane oxidation according to Scheme 1 in the presence of metalloporphyrins with active oxygen donors.

Substrate	Catalyst	Oxidant	Products (ratio)	Yield (%)	Ref.
Cyclohexane (4)	MnTFPPCl ^a	NaOCl	5 + 6 + 7 (1 : 1.3 : 3.8)	24 ^b	127
