V. The use of tetrazolium salts in dosimetry	677
VI. Conclusion	679

Abstract. Published data on radiolysis of liquid (mainly aqueous, water–alcohol and alcoholic) and solid [mainly in poly(vinyl alcohol)] solutions of tetrazolium salts are generalised. The mechanism of radiolytic transformations of these compounds is discussed. Their application in dosimetry of ionising radiation is considered in detail. The bibliography includes 60 references.

I. Introduction

Reduction of colourless or weakly coloured tetrazolium salts yields formazans, which are intensely coloured. This property of formazans has found application in various fields of science and engineering. They have been used in botany as colouring compounds sensitive to ultraviolet radiation,¹ as substances suitable for estimating the productivity of seeds of agricultural plants^{2,3} and the viability of stem and leaf tissues,^{4,5} for distinguishing between normal and malignant tissues,⁶ and for studying the histochemistry of oxidative enzymes.^{7,8} The use of formazans as analytical reagents for detection of O_2^- radical ions has also been reported.^{9–11} In addition, it is known (see, for example, Ref. 12) that liquid and solid solutions of formazans can be employed in the dosimetry of ionising radiation.

The properties, methods for the synthesis, and the mechanism of chemical reduction of tetrazolium salts have been considered in numerous publications (see, for example, Refs 13–17). The present review is mainly devoted to radiolytic transformations of these salts in various solvents (alcohols, water, aqueous alcohols, *etc.*). Solutions of 2,3,5-triphenyltetrazolium chloride (TPTC) have been studied most often; solutions of 2-(*p*-nitrophenyl)-3,5-diphenyltetrazolium chloride (NPTC), 5-(*p*-nitrophenyl)-2,3-diphenyltetrazolium bromide (NPTB), 3-(1-naphthyl)-2,5-diphenyltetrazolium bromide (DPTB), 3,3'-bianisylene-4,4'-bis(2,5-diphenyl-2*H*-tetrazolium) chloride (Tetrazolium Blue, TB), 2,2'-di(*p*-nitrophenyl)-5,5'-diphenyl-3,3'-(dimethoxy-4,4'-diphenylene)-2*H*-tetrazolium chloride (Nitrotetrazolium Blue, NTB) and

some other derivatives have been studied more rarely. Considerable attention is paid to the use of these systems in the dosimetry of ionising radiation.

II. Alcoholic solutions

Detailed data on the radiation yields of reduction of tetrazolium salts in alcoholic solutions and on the mechanism and kinetics of this process can be found in the literature.

1. Radiation yields of reduction

When colourless deaerated alcoholic solutions of tetrazolium (T^+) salts are exposed to radiation, the corresponding intensely coloured (pink, orange-red, or red) formazans are produced. For example, in the case of TPTC, this yields 1,3,5-triphenylformazan $PhNH-N=CPh-N=NPh$.

The radiation yields of formazans (F) in these solutions are listed in Table 1.

2. The mechanism of radiolytic reduction

Radiolytic reduction of tetrazolium salts is a two-electron process, *i.e.* the reduction of each tetrazolium salt molecule requires two reducing species. The yield of the formazan in this process is more than half the yield of solvated electrons (e_s^-) (for example, in isopropanol, the yield of e_s^- is 1.3²⁶). Based on this result, it was concluded that the salts are reduced by not only e_s^- but also by radicals of type $R\dot{C}HOH$ resulting from radiolysis of alcohols. When the doses are large enough, formazans undergo subsequent radiolytic transformations; the solutions become colourless, and hydrazidines are formed. The yields of decomposition of formazans have been determined for the radiolysis of solutions of 1,3,5-triphenylformazan,^{18,27} 3-(*p*-nitrophenyl)-1,5-diphenylformazan,²⁰ and 2,5-diphenyl-3-(1-naphthyl)formazan²⁰ in isopropanol (Table 2).

The conclusion about two-electron reduction of tetrazolium salts is confirmed by the data^{19,28,29} on pulse radiolysis of solutions of these compounds in ethanol and isopropanol. It was found that the interaction of the tetrazolium salt cation (T^+) with e_s^- or with an alcohol radical gives a short-lived species, namely tetrazolium radical ($T^\bullet$). In the case of TPTC, this radical has the following structure:

2,5-Diphenyl-3-(1-naphthyl)formazan	0.27	1.3	20
	0.77	2.4	20

A similar species is formed as an intermediate during the chemical reduction of these compounds (see, for example, Refs 3 and 17).

The structure of the tetrazolium radical has been confirmed by the results of EPR studies of irradiated frozen solutions of TPTC and 2,3,5-triphenyltetrazolium tetrafluoroborate.^{30,31} It was found that irradiation of these solutions at 77 K affords solvated electrons and alcohol radicals. During the subsequent fast warming up to room temperature, these species react with the tetrazolium salt yielding tetrazolium radicals. The EPR spectra of the radicals recorded after cooling the samples to 77 K are identical for these two salts and consist of eight lines with a splitting of $\sim 1.4 \text{ mT}$.

A similar EPR spectrum has been recorded at 77 K for the $T^{\bullet}$ radical resulting from reduction of TPTC with sodium ethoxide in isopropanol. The spectrum recorded at 300 K is somewhat different. Due to the anisotropy of the hyperfine coupling tensor, the spectrum of $T^{\bullet}$ in the liquid phase is characterised by smaller splitting ($\sim 0.7 \text{ mT}$).³¹

The data obtained in studies on pulse radiolysis of solutions of tetrazolium salts^{19,28,29} indicate that tetrazolium radicals arise in two processes, one of which is fast and the other is slow. For example, in the case of a triphenyltetrazolium salt (the TPT^+ cation) in isopropanol, this might occur as follows:

Table 3 contains the rate constants for reactions of this type for tetrazolium salts measured by the method of pulse radiolysis. Calculations using the Debye equation have shown that in the case of NPTC and NPTB, the rate of reaction (1) is controlled by diffusion, whereas for TPTC, the rate is lower than the diffusion limit.

The formazans are formed upon disproportionation of $T^{\bullet}$ radicals

Thus, the yield of the formazan (for example, in an isopropanol solution) should be equal to

$$G(F) = \frac{1}{2} \{ G(e_s^-) + G[(CH_3)_2\dot{C}OH] \}. \quad (4)$$

Since $G[(CH_3)_2\dot{C}OH]$ in isopropanol is ~ 5.5 molecule $(100 \text{ eV})^{-1}$,²⁶ the theoretical $G(F)$ value amounts to ~ 3.4 molecule $(100 \text{ eV})^{-1}$. Experimental yields are close to this value only for NPTB and DPTB (see Table 1). For TPTC and NPTC, the yields are substantially smaller. This is due to the fact that the tetrazolium radicals derived from these salts participate not only in reaction (3) but also in another reaction, which does not lead to formazan (for example, they can dimerise to give ditetrazolium salt TT).^{18,19}

According to our estimates,¹⁸ the k_3/k_4 ratio for a solution of TPTC in isopropanol is ~ 1.9 .

Tetrazolium salts dimerise relatively easily at the 4,4'-diphenyl bridge.³⁶ Nitrotetrazolium Blue is an example of this type of dimer. Ditetrazolium compounds have also been described in a review.¹⁷

Solutions of tetrazolium radicals in alcohols are characterised by intense optical absorption in the visible and ultraviolet spectral regions (Table 4). These radicals are relatively long-lived species, their lifetimes being of the order of milliseconds.

The reduction of formazan to hydrazidine (HH) is also a two-electron process.²⁶ It has been found by pulse radiolysis²⁷ that formazan reacts first with a solvated electron and an alcohol radical. The rate constants for these reactions in isopropanol are presented in Table 3. It was postulated²⁷ that the above reactions

Table 3. Rate constants [k / litre mol⁻¹ s⁻¹] for reactions of tetrazolium salts and formazans measured by pulse radiolysis.

yield formazan radical anions $\text{F}^{\bullet-}$, which are responsible for an intense optical absorption band with a maximum at 700 nm (the molar extinction coefficient is 3.8×10^3 m² mol⁻¹). The lifetime of these species is relatively long (more than 1–2 ms). By analogy with the behaviour of other radical cations in alcoholic solutions (see, for example, Ref. 37), it was suggested that $\text{F}^{\bullet-}$ are protonated in the following way (the reaction is written for isopropanol)

and disproportionation of the resulting $\text{FH}^\bullet$ gives HH

It should be noted that similar reactions occur during two-electron reduction of quinones to hydroquinones.³⁸

Obviously, the yield of formazan reduction in isopropanol should be determined by the equation

$$G(-\text{F}) = \frac{1}{2} \{G(\bar{\text{e}}_s) + G[(\text{CH}_3)_2\dot{\text{C}}\text{OH}]\}. \quad (8)$$

The calculated value of $G(-\text{F})$ is ~ 3.4 molecule (100 eV)⁻¹, which coincides with experimental results for 1,3,5-triphenylformazan²⁷ and 3-(*p*-nitrophenyl)-1,5-diphenylformazan²⁰ (see Table 2). However, in the case of 3-(1-naphthyl)-2,5-diphenylformazan,²⁰ the experimental yield is much lower than the theoretical yield. This is apparently due to the fact that the rate constant for

the reaction of this formazan with the alcohol radical is relatively low.

It has been found¹⁸ that the yield of formazan in the radiolysis of alcoholic solutions of tetrazolium salts decreases when the radiation doses are high. This effect is least pronounced for solutions of DPTB in isopropanol.²⁰ Evidently, the yield decreases due to reactions of F with e_s^- and $(CH_3)_2C^*OH$. 2-Isobutylantraquinone added to an isopropanol solution of TPTC largely 'protects' the formazan from decomposition.¹⁸ The dependences of the concentration of the formazan formed in isopropanol solutions of TPTC on the radiation dose in the presence and in the absence of 2-isobutylantraquinone are shown in Fig. 1.

Figure 1. Concentration of the formazan formed *versus* the dose in a deaerated 3×10^{-3} M solution of TPTC in the absence (1) and in the presence (2) of 5×10^{-3} mol litre $^{-1}$ of 2-isobutylantraquinone.

3. Radiolysis of aerated solutions

The yield of formazans in aerated alcoholic solutions is appreciably lower than in deaerated solutions; in some cases, formazans are not formed at all. For example, they are not formed upon irradiation of air-saturated 1×10^{-3} M solutions of DPTB with a dose of 200–300 Gy.²⁰ According to another study,³⁹ the $G(F)$ values for aerated 5×10^{-3} and 4.5×10^{-2} M ethanolic solutions of TPTC are 0.048 and 0.135 molecule $(100 \text{ eV})^{-1}$, respectively (at a dose of ~ 10 kGy). It was found²² that in the case of X-ray radiolysis of an aerated solution of TPTC in ethylene glycol (maximum energy 60 keV), $G(F)$ increases with an increase in the concentration and reaches 1.03 molecule $(100 \text{ eV})^{-1}$ in a 0.1 M solution at a dose of 9.2 kGy.

This type of behaviour can be explained as follows. Since the concentration of TPTC is high, a large portion of tetrazolium radicals, generated, for example, according to reaction (1), are converted again into TPT^+ .

A similar effect is also observed in the case of aqueous solutions of tetrazolium salts (see below). Yet another possible reason (although it is less significant) is that the alcohol radical might react with oxygen to give the peroxy radical $RCH(OH)O_2^*$, and the latter reacts with TPTC slowly or not at all.

In an ethylene glycol solution, $G(F)$ is close to $0.5 G(e_s^-)$. Apparently, due to the high viscosity of this alcohol, reaction (9) in this system is relatively slow, and the TPT^* radicals generated mostly disproportionate. The alcoholic radicals do not reduce TPTC, but instead, they react with oxygen to give the peroxy radicals.

III. Aqueous and water–alcohol solutions

Radiolysis of aqueous and water–alcohol solutions of tetrazolium salts has been studied in several publications.^{20–24, 32, 35} It was found that as in the case of alcoholic solutions, reduction to formazans is the prevailing process.

1. Characteristic features of radiolytic reduction in deaerated aqueous solutions

Irradiation of a deaerated aqueous solution of any of the tetrazolium salts studied results in the formation of a precipitate. The solution obtained by filtering this precipitate off and dissolving it in an alcohol, or by adding a sufficient amount of an appropriate organic solvent to the irradiated solution, or by extracting the product with a solvent exhibits an optical absorption spectrum typical of formazan. Upon irradiation of solutions in aqueous alcohols, when the alcohol concentration is high enough (for example, in a 1:1 water–isopropanol mixture²⁴), the precipitate does not appear, but solution acquires an intense red colour caused by the formation of formazan. It should be noted that in aqueous solutions, the concentration of formazan arising upon radiolysis depends on the γ -radiation dose only at high doses, because the product precipitates. In aqueous alcohols, this dependence is sharper.

The measured $G(F)$ values for radiolysis of deaerated solutions of some tetrazolium salts are listed in Table 1. It can be seen that without additives $G(F)$ increases from 0.4 to 1.4 molecule $(100 \text{ eV})^{-1}$ with an increase in the pH of the solution from 5.3 to 11.5. However, in the case of NPTB, this dependence is not observed. Upon the addition of some organic compounds (formates, EDTA, isopropanol) or in water–isopropanol mixtures, the formazan yield increases to 3.5 molecule $(100 \text{ eV})^{-1}$.

The radiolysis of water is described by the following general scheme:²⁶

Obviously, the first four products can participate in the radiolytic transformations of tetrazolium cations. Hydrated electrons e_{aq}^- reduce the T^+ cations to tetrazolium radicals T^* ; the latter disproportionate to give formazan. Hydrogen atoms do not participate in the reduction,³² but they add to benzene rings giving rise to H-adducts. The OH radical reacts with T^+ to give an OH-adduct. Hydrogen peroxide can oxidise T^* .

Subsequent transformations of the H- and OH-adducts give no formazans. Therefore, we can write

$$G(F) = \frac{1}{2} [G(e_{aq}^-) - G(H_2O_2)] \quad (12)$$

Calculation using this equation affords $G(F) = 1.1$ molecule $(100 \text{ eV})^{-1}$. The experimental $G(F)$ values obtained for alkaline media (except for those for DPTB) are close to this predicted value. In the case of NPTB, the yields measured both in alkaline and neutral media coincide with those calculated from Eqn (12).

The experimental $G(F)$ values found for acidic, neutral, and weakly alkaline solutions of TPTC and NPTC are smaller than the theoretical values. As an example, Fig. 2 shows the dependence of $G(F)$ on the pH for a deaerated 1×10^{-3} M solution of TPTC.³⁴ At $pH < 4$, the formazan yield is close to zero, which is due to the fast reaction

The H atoms react with T^+ giving H-adducts.

Apparently, the T^* radicals derived from TPTC and NPTC not only disproportionate giving rise to formazan but also participate in some other processes, which do not lead to this

Figure 2. Dependence of $G(F)$ in a deaerated 1×10^{-3} M aqueous solution of TPTC on the pH.

compound (for example, they can dimerise).^{32, 34} The tetrazolium radicals generated from NPTB do not tend to dimerise (apparently, due to steric hindrance). In alkaline media dimerisation does not occur either, probably due to the fact that the product formed upon the reaction of $T^{\bullet}$ with OH^- only disproportionates.³² It was found by pulse radiolysis³² that in TPTC solutions at $pH > 9$, when $G(F)$ increases (see Fig. 2), a new short-lived species appears in place of the $T^{\bullet}$ radicals consumed.

2. Radiolysis in the presence of organic compounds

Radiolysis of deaerated alkaline aqueous solutions containing organic compounds (formate, EDTA, alcohols) or solutions in water–alcohol mixtures results in $G(F)$ values reaching 3.5 molecule $(100 \text{ eV})^{-1}$ (see Table 1). Evidently,²¹ when the concentration of an organic compound is relatively high, it reacts with hydrogen atoms and $OH^{\bullet}$ radicals (and $O^{\bullet -}$) to give reducing radicals able to reduce an additional amount of T^{+} to $T^{\bullet}$. The corresponding reactions for $HCOO^-$ taken as an example can be written as follows:

The occurrence of reaction (16) is confirmed by high k_{16} values determined by pulse radiolysis (see Table 3). However, these reactions are not controlled by diffusion; therefore, the k_{16} values correlate with the potentials of the first reduction wave for the corresponding tetrazolium salts measured by polarography.²¹

Hydrogen peroxide reacts with $T^{\bullet}$ [reaction (11)], and the $OH^{\bullet}$ radical formed in this process participates in reaction (16). This yields radical anions $COO^{\bullet -}$, which then reduce T^+ . Thus, the yield of formazan can be calculated as follows:

$$G(F) = \frac{1}{2} [G(e_{aq}^-) + G(H) + G(OH)]. \quad (17)$$

The calculation by this expression using the yields of the water radiolysis products reported in our monograph²⁶ affords $G(F) = 3.2$ molecule $(100 \text{ eV})^{-1}$. The corresponding experimental results are close to this value (see Table 1).

3. Mechanism of radiolytic reduction. Intermediate products

The properties of tetrazolium radicals $T^{\bullet}$ and the H- and OH-adducts formed by tetrazolium salts in aqueous solutions have been studied by pulse radiolysis.^{21, 23, 32, 35} The optical characteristics of $T^{\bullet}$ (see Table 4) were measured in deaerated neutral or alkaline aqueous solutions of TPTC and NPTC containing *tert*-butyl alcohol.³² In these solutions, $OH^{\bullet}$ radicals react with the alcohol

The *tert*-butanol radical formed is inert towards tetrazolium salts. *tert*-Butyl alcohol can also react with hydrogen; however, the rate constant for this reaction is relatively low (1.2×10^5 litre $\text{mol}^{-1} \text{ s}^{-1}$).⁴⁰ Under the conditions employed in the study cited,³² small amounts of the H-adduct could be formed. The reaction of T^+ with e_{aq}^- in these solutions gives mainly $T^{\bullet}$ radicals. The optical characteristics of the $T^{\bullet}$ radicals were obtained after applying a correction for the absorption of the H-adduct.

The optical characteristics of the H-adducts $TH^{+\bullet}$ (see Table 4) were determined using deaerated acidic ($pH \ 2$) solutions of TPTC and NPTC containing *tert*-butyl alcohol.³² In these solutions, hydrated electrons react with H^+ [reaction (13)] being thus converted into hydrogen atoms, and the $OH^{\bullet}$ radicals react with the alcohol [reaction (18)] to give $\dot{C}H_2(CH_3)_2COH$ radicals, which are inert with respect to tetrazolium salts. The subsequent transformations afford only the H-adducts in which hydrogen is attached to the benzene ring of the molecule. This conclusion is based on the following observation.³² Tetrazolium salt molecules contain two types of sites, which could be reactive towards H atoms, namely, the tetrazole heterocycle and the benzene rings. If hydrogen were attached to the tetrazolium ring, the tetrazolium salt would be simultaneously reduced; however, this is not observed experimentally. Formazans are not formed in relatively acidic media (see Fig. 2).

The spectra of the OH-adducts of tetrazolium salts were recorded for deaerated neutral aqueous solutions of TPTC and NPTC saturated with nitrogen hemioxide.^{32, 35} In these solutions, e_{aq}^- reacts with N_2O and water giving rise to $OH^{\bullet}$ radicals.

When this solution is exposed to radiation, OH-adducts and, to a much lesser extent, H-adducts are formed. The optical characteristics of the OH-adducts listed in Table 4 were determined after applying a correction for the absorption of the H-adducts. The rate constants for the reactions of $OH^{\bullet}$ radicals with tetrazolium salts are close in the order of magnitude to the rate constants for the reactions of $OH^{\bullet}$ with benzene derivatives;⁴⁰ this confirms the assumption that the $OH^{\bullet}$ groups are attached to a benzene ring in the tetrazolium salt molecule.

The structure of the OH-adduct formed by TPTC has been determined by quantum-chemical calculations.⁴¹ It was found that the $OH^{\bullet}$ radical in the TPTC molecule is bound most likely to the benzene ring that is attached to the carbon atom of the tetrazolium ring. This structure is described by the formula

No formazan is formed in solutions saturated with nitrogen hemioxide;³² this means that the H- and OH-adducts are not formazan precursors. Stable products formed in these solutions are soluble in water and absorb light in the ultraviolet region of the spectrum (the maxima of the absorption bands are at 300 and ~ 320 nm for solutions of TPTC and NPTC, respectively).³²

The tetrazolium radicals and the H-adducts are consumed in second-order reactions (see Table 3). It has been noted above that both in aqueous and in alcoholic solutions, the $T^{\bullet}$ radicals derived from TPTC and NPTC disappear not only through disproportionation but also through dimerisation.

The ratios of the rate constants for disproportionation and dimerisation in neutral aqueous solutions of TPTC or NPTC are equal to 0.5 and 1, respectively (*i.e.* they are much smaller than the corresponding ratio for isopropanol solutions of TPTC; as noted above, the latter is ~ 1.9).²¹ The ratio of these rate constants depends on the pH; it is greater in alkaline solutions than in

neutral ones. This dependence might be due to a change in the structure of the tetrazolium radicals in alkaline media, which decreases the probability of dimerisation because of steric hindrance. When the pH values are sufficiently high, dimerisation does not occur at all.

The OH-adducts disappear in first-order reactions³² (see Table 3). This might be an intramolecular rearrangement of the OH-adducts or their decomposition with abstraction of a water molecule. Similar processes have been observed for the OH-adducts formed by phenol, aniline and toluene.²⁶

4. Radiolysis of aerated solutions

The $G(F)$ values for solutions of TPTC and NPTB saturated with air are substantially smaller than those for deaerated solutions (Table 5). A low yield of formazan [~ 0.16 molecule $(100 \text{ eV})^{-1}$] has also been found⁴² for X-ray radiolysis of an aerated 2% aqueous gel of agar-agar containing $0.09 \text{ mol litre}^{-1}$ of TPTC (the maximum energy of radiation was 60 keV).

Table 5. Formazan yields [$G(F)$ / molecule $(100 \text{ eV})^{-1}$] upon γ -radiolysis of deaerated and aerated aqueous and water–isopropyl alcohol (1 : 1 by volume) solutions of tetrazolium salts at various pH.^{23,24}

Tetra-zolium salts	Concentration/ mol litre^{-1}	Presence of alcohol	Gas saturating the solution	pH	$G(F)$
TPTC	8×10^{-4}	yes	argon	11.0	3.1
	8×10^{-4}	"	air	11.0	0.14
	1×10^{-3}	no	argon	6.9	0.45
	1×10^{-3}	"	air	10.3	1.2
	1×10^{-1} (see ^a)	"	"	7.0–7.5	0.22
NPTC	1×10^{-3}	"	argon	6.9	0.6
	1×10^{-3}	"	air	6.9	0.45
	1×10^{-3}	"	argon	11.3	1.3
	1×10^{-3}	"	air	11.3	1.5
	4×10^{-3}	yes	"	10.5	4.9
	1×10^{-2}	"	"	10.5	5.3
	5×10^{-4}	no	"	6.9	0.3
NPTB	5×10^{-4}	"	argon	6.9	1.2

^a Radiolysis under the action of X-rays (the maximum energy 60 keV). The solution contained the triethanolamine–HCl buffer.²²

However, in the case of aqueous solutions of NPTC, this difference in $G(F)$ is not manifested (see Table 5). This is due to the fact that the tetrazolium radical $\text{TPT}^{\bullet}$ generated from TPTC, as in alcoholic solutions, is able to react with oxygen to give the initial TPT^+ ion [see reaction (9)], whereas NPTC, on the contrary, can be reduced by the $\text{O}_2^{\bullet-}$ radical ions²⁴

Therefore, in aqueous and alcoholic solutions of NPTC, when the concentration of the tetrazolium salt is relatively high, atmospheric oxygen hardly influences the yield of formazan. In the case of solutions in aqueous alcohols, for the $\text{R}\dot{\text{C}}\text{HOH}$ radicals to be involved in the interaction with NPTC, the concentration of this salt needs to be high enough. Otherwise some of the alcohol radicals would react with oxygen to give peroxy radicals $\text{RCH(OH)O}_2^{\bullet}$, which are apparently unable to reduce NPTC.²⁴

The conclusions about the reasons for the low yields of formazan in aerated solutions of TPTC and NPTB have been confirmed by the results of a study carried out by the pulse radiolysis method.²³ It was found that the tetrazolium radicals $\text{T}^{\bullet}$ formed in these solutions in the presence of *tert*-butyl alcohol disappear much faster than in deaerated solutions. The constants

k_9 were determined by measuring the kinetics of consumption of $\text{T}^{\bullet}$ in the presence of oxygen (see Table 3).

The direction of electron transfer in reactions the rates of which are not controlled by diffusion may be determined, for instance, by the electron affinity of the reactants. Evidently, the electron affinity of the oxygen molecule should be higher than that of the TPTC and NPTB molecules but lower than that of the NPTC molecule.²³ This is confirmed by the results of determination of the half-wave potentials for the polarographic reduction of tetrazolium salts.²¹ The potentials for the single-electron reduction of tetrazolium salts and two-electron reduction of oxygen are -0.40 , -0.30 , -0.17 , and -0.30 V for TPTC, NPTB, NPTC, and O_2 , respectively.^{21,23}

The $G(F)$ values attained at high concentrations of NPTC are larger than the theoretical value (see Table 5) calculated from Eqn (17) using the known yields of the products of water radiolysis. It cannot be ruled out that in this system, due to the relatively high concentrations of conjugated acceptors (the alcohol, on the one hand, and TPTC and oxygen, on the other hand), the reactions in spurs are largely suppressed, and this results in increased yields of the primary radiolysis products, responsible for the formation of formazan.

5. Radiolytic reduction of Nitrotetrazolium Blue

Interesting results have been obtained in a pulse radiolysis study of the mechanism of reduction of Nitrotetrazolium Blue in aqueous solutions.^{10,33} The reduction of the two-charged cation, NTB^{2+} , contained in this molecule to give the corresponding diformazan is a four-electron process, which gives consecutively the monotetrazolium radical $\text{NTB}^{\bullet+}$, monoformazan MF^+ , monoformazan radical $\text{MF}^{\bullet}$ and finally diformazan DF.

Conditions were selected³³ under which exposure of a formate-containing aqueous solution of NTB^{2+} to an electron pulse affords $\text{NTB}^{\bullet+}$. The rate constant for the reduction of NTB^{2+} with the $\text{COO}^{\bullet-}$ radical anion was measured (see Table 3). Study of the kinetics of consumption of $\text{NTB}^{\bullet+}$ showed that the rate constant for this process depends crucially on the pH. The following reaction was postulated for a neutral medium:

The reaction in an alkaline medium yields the hydroxy-derivative $\text{NTB}^{\bullet+} \dots \text{OH}^-$, which disappears more rapidly than $\text{NTB}^{\bullet+}$. The corresponding reaction can be written as follows:

The k_{21} and k_{22} values found for these reactions are listed in Table 3. The higher rate of reaction (22) is apparently due to the fact that the positive charge of $\text{NTB}^{\bullet+}$ is shielded by the hydroxyl ion. Dimerisation of $\text{NTB}^{\bullet+}$ does not occur, probably for steric reasons.

The kinetics of the reaction

were studied by the stopped flow method.³³

The constant k_{23} found in this study is presented in Table 3. It was noted that the back reaction does not occur under the conditions employed. It was concluded that Nitrotetrazolium Blue can be used for qualitative but not quantitative determination of the $\text{O}_2^{\bullet-}$ radical anions. It should also be emphasised that H_2O does not react with NTB^{2+} .

IV. Solid matrices

Polymeric films with tetrazolium salts (mainly TPTC) introduced into them have been mostly studied as applied to the dosimetry of ionising radiation (see above). Radiolytic transformations of

TPTC and NPTC in poly(vinyl alcohol) films have been studied in detail.²⁵

The paramagnetic species formed in poly(vinyl alcohol) films irradiated under various conditions have been investigated.^{25, 43, 49} The yield of these species is ~ 4 molecule $(100 \text{ eV})^{-1}$. The EPR spectrum of an irradiated film recorded at 77 K points to the presence of three paramagnetic species: a captured electron and the $\sim \text{CH}_2\text{CH}[\text{OC}^+(\text{CH}_3)\text{O}^-\text{H}^+]\text{CH}_2\sim$ and $\sim \text{CH}_2\text{C}^+(\text{OH})\text{CH}_2\sim$ radicals. At room temperature, only the former radical is detected.

All the paramagnetic species mentioned above possess reducing properties. At relatively high temperatures, the species become mobile, and their interaction with TPTC and NPTC resulting in the formation of formazans becomes possible. This conclusion is confirmed experimentally. Table 1 presents the $G(\text{F})$ values obtained at room temperature for films containing various amounts of these salts.²⁵ It is noteworthy that the formazan concentration obeys a linear dependence on the radiation dose up to a dose of 25 kGy.

Evidently, the formation of formazan in films is also a two-electron process, T^+ ions being reduced in reactions with mobile electrons and with the radicals mentioned above. For example, the following reaction is possible²⁵

Thus, $G(\text{F})$ should be $0.5 G(\text{radical})$,[†] i.e. it should be equal to ~ 2 molecule $(100 \text{ eV})^{-1}$. However, only in a film containing $7.1 \times 10^{-3} \text{ mol litre}^{-1}$ of TPTC, $G(\text{F}) < 0.5 G(\text{radical})$; in all other cases, $G(\text{F})$ is greater than $0.5 G(\text{radical})$ (see Table 1), and for large concentrations of NPTC it is more than twice as great. It can be concluded that $G(\text{F})$ is determined both by the distance between tetrazolium salt molecules and by the electron-acceptor properties of these molecules.²⁵

A similar situation has been observed for poly(vinyl alcohol) films containing methylviologen MV^{2+} .^{47, 48} When these films are exposed to radiation, the colourless MV^{2+} dication is reduced via a single-electron process to give $\text{MV}^{+\cdot}$, which has an intense blue colour. According to several measurements,^{44, 45} the $G(\text{MV}^{+\cdot})$ values vary from 8.1 to 9.8 molecule $(100 \text{ eV})^{-1}$. This is much larger than the $G(\text{radical})$ value.

It was postulated²⁵ that the high $G(\text{F})$ values observed are due to the reactions of T^+ with radical pairs $\text{R}_1\cdots\text{R}_2$, which are formed in some polymers including poly(vinyl alcohol) films (see, for example, Ref. 50)

In the absence of tetrazolium salts, the radical pair undergoes recombination. The EPR spectrum of a poly(vinyl alcohol) film contains an unresolved signal with a g -factor of 4 corresponding to this radical pair;²⁵ the intensity of this signal is four orders of magnitude lower than that of the signal characterised by a g -factor of 2. Another possible reason is the transfer of the excitation energy along the chain of polymer bonds to a tetrazolium salt molecule.

Thus, in a solid matrix of a polymeric alcohol, tetrazolium salts are also reduced to formazans by electrons and 'alcohol' radicals.

V. The use of tetrazolium salts in dosimetry

The property of colourless or yellowish liquid or solid solutions of tetrazolium salts to turn pink, orange, or orange-red upon radiolytic reduction to formazans has been recommended for use in the dosimetry of ionising radiations.

1. Alcoholic, aqueous and water-alcohol solutions

Back in the late 1940s,¹² it was found that aqueous solutions and gelatine emulsions of TPTC change to a red colour on exposure to

UV light ($\lambda < 365 \text{ nm}$), α -particles, or X-rays. It was also found that the colour intensity did not depend on the pH in the range 5.5–6.6

In a number of publications (see, for example, Refs 22, 42, 51–53), it has been suggested to use TPTC in radiology and radiobiology in order to obtain three-dimensional images of dose distribution upon X-ray treatment. For example, a 2% aqueous gel of agar-agar containing TPTC (0.05%) has been used⁵² to model the three-dimensional dose distribution in fish and meat foodstuffs treated with X-rays (maximum energy 60 keV, dose $\sim 15 \text{ kGy}$). It has been reported⁴² that gels of this type are suitable for measurement of three-dimensional dose distribution for X-ray and electron radiations. It was also shown that the concentration of the formazan produced depends linearly on the radiation dose up to a dose of 12 MGy.

The influence of various parameters (the nature of the buffer solution, TPTC concentration, the presence of oxygen in the solution, and the dose rate) on the yield of formazan has been studied in detail.²² The precipitate of formazan formed upon irradiation with X-rays with a maximum energy of 60 keV was dissolved in an organic solvent (for example, in tetrahydrofuran) added to the solution. It was found that in aerated solutions, $G(\text{F})$ does not depend on the pH of the solution over the range 5–8. At higher pH values the yield increases, while at lower pH it decreases, and becomes equal to zero at pH 1.5. If the concentration of TPTC increases, the yield first increases and then remains constant in the concentration range from 3×10^{-3} to $1 \times 10^{-1} \text{ mol litre}^{-1}$. The $G(\text{F})$ values in deaerated solutions are approximately twice as large as those in aerated solutions. In systems saturated with oxygen, the $G(\text{F})$ values are 2.7 times lower than in aerated solutions. The addition of hydrogen peroxide decreases $G(\text{F})$. It was proposed to use aerated 2×10^{-2} – $1 \times 10^{-1} \text{ M}$ aqueous solutions of TPTC containing a triethanolamine–HCl buffer for the measurement of absorbed X-ray radiation doses ranging from 0.18 kGy to 0.18 MGy. Note that the dosimetric solution should be stored in the dark.

The possibility of using aerated ethanolic solutions of TPTC for determination of the absorbed doses of γ -radiation has been studied.³⁷ Solutions in ethanol containing 5% of methanol and 5% of isopropanol were used. It was found that a $4.5 \times 10^{-2} \text{ M}$ solution of TPTC can be used to measure radiation doses in the range 1–16 kGy. For lower concentrations of TPTC, the upper limit of the measurable doses decreases (at higher doses, the dependence of the formazan concentration on the dose becomes nonlinear, because the formazan starts to decompose).

Figure 3 presents the dependence of the optical absorption of aerated solutions of TPTC on the dose. It can be seen that the yield of formazan diminishes with a decrease in the TPTC concentration; the yield obtained in a $5 \times 10^{-3} \text{ M}$ solution is ~ 2.3 times

Figure 3. Optical density ($\lambda = 480 \text{ nm}$) of aerated 5×10^{-3} (1), 1×10^{-2} (2), 1.8×10^{-2} (3), and $4.5 \times 10^{-2} \text{ M}$ (4) ethanolic solutions of TPTC versus the radiation dose (optical path length 0.1 cm).

[†] $G(\text{radical})$ implies the yields of both radicals and electrons.

lower than that in a 4.5×10^{-2} M solution. The yields also depend on the temperature. The temperature coefficient in the range 0–30 °C is approximately +0.8% per 1 °C, but in the temperature range between 30 and 60 °C, it is substantially larger. Non-irradiated and radiated solutions are stable during storage in the dark in sealed tubes for at least 5 days. However, exposure to daylight and especially to bright sunlight leads to slow formation of formazan upon photolysis. If the solution is saturated with oxygen, the upper limit of determination of the dose increases to 36 kGy. Deaerated solutions are more 'sensitive' but the upper limit decreases to ~ 3 kGy. The optical characteristics of 1,3,5-triphenylformazan and other formazans are listed in Table 6.

Table 6. Optical characteristics of formazans.

Formazan	Matrix	$\lambda_{\max}/\text{nm}$	$10^{-3} \epsilon_{\max} / \text{m}^2 \text{mol}^{-1}$	Ref.

^a Ethanol contained 5% of methanol and 5% of isopropyl alcohol. ^b The shoulder at 540 nm belongs apparently to ditetrazolium salt. ^c The band at 550 nm might belong to ditetrazolium salt.

The formation of formazan in solutions of TPTC is inhibited by oxygen. Figure 4 shows the concentrations of the formazan formed in aerated 1×10^{-3} M aqueous solutions of TPTC versus the γ -radiation dose for two different pH values.²⁴ It can be seen that at low doses almost no formazan is formed. When the doses are larger than 0.8 kGy and oxygen in the solution is consumed almost entirely, the yield of formazan increases substantially.

A similar type of behaviour has been observed in the case of aerated solutions of Tetrazolium Blue in aqueous alcohols. These properties have been used to develop a threshold chemical dosimeter.⁵⁴ The threshold dose is detected by a sharp increase in the optical absorption of the solution in the maximum of the formazan band. This dose changes upon variation of the concentration of ethanol (the solubility of air in ethanol is approximately an order of magnitude higher than that in water) or tetrazolium

Figure 4. Dependence of the formazan concentration in an aerated 1×10^{-3} M aqueous solution of TPTC at pH 10.3 (1) and 8.5 (2) on the absorbed dose.

salt in the solution. The threshold doses measured by means of aerated solutions of TPTC or TB in aqueous ethanol amount to 1.6–3.4 kGy.

It follows from the foregoing that, due to the 'inhibiting' effect of oxygen, aerated aqueous and alcoholic solutions of TPTC can be used only for determination of relatively large radiation doses. It has been found²⁴ that this effect is not manifested in aqueous solutions of NPTC (see Table 5). An aerated $(0.4–1) \times 10^{-2}$ M solution of NPTC in a water–isopropyl alcohol mixture (1 : 1 by volume) containing $0.2 \text{ mol litre}^{-1}$ of formate (pH 9.5–11) can be used to determine absorbed γ -radiation doses in the range between 5 and 50 Gy (Fig. 5). Formate is needed to eliminate the short 'induction period'. The sensitivity of the spectrophotometric method for formazan analysis based on the use of a system with a 5×10^{-3} M solution of NPTC amounts to $6 \times 10^{-3} \text{ Gy}^{-1} \text{ cm}^{-1}$. When the NPTC concentration is equal to $1 \times 10^{-2} \text{ mol litre}^{-1}$, the sensitivity of the method increases to $1 \times 10^{-2} \text{ Gy}^{-1} \text{ cm}^{-1}$, and the threshold of the dose determination decreases to 1 Gy.

The optical absorption of irradiated solutions changes by not more than 3% over a period of 24 h. The solutions are sensitive to

Figure 5. Dependence of the optical density ($\lambda = 475 \text{ nm}$) of aerated water–alcohol (1 : 1 by volume) solutions of NPTC on the γ -radiation dose; (1) a 4×10^{-3} M water–isopropanol solution, pH 10.5; (2) the same solution containing $0.2 \text{ mol litre}^{-1}$ of formate; (3) a 1×10^{-3} M water–isopropanol solution containing $0.2 \text{ mol litre}^{-1}$ of formate, pH 10.5; (4) a 4×10^{-3} M water–ethanol solution containing $0.2 \text{ mol litre}^{-1}$ of formate, pH 9.5 (optical path length 1 cm).

light; therefore, they should be stored in the dark. The results are liable to a positive temperature effect, but if the measurements are carried out at $20 \pm 5^\circ\text{C}$, this effect can be neglected.

Similar results have been obtained with aerated weakly alkaline (pH 8.5–9) solutions of NTB (concentration 1.5×10^{-4} – 4.5×10^{-3} mol litre $^{-1}$) in aqueous alcohols (1 : 1 by volume).⁵⁴ Aqueous solutions of ethanol and isopropanol were used. This method permits determination of doses from 5 to 150 kGy.

2. Polymer films

Dosimetric systems based on tetrazolium salts in polymeric films have been described in the literature. The Kodak Pathe company (France) have developed a dosimetric gelatine film containing TPTC, suitable for measuring doses of about tens of kilogray.⁵⁷ Practical details of the application of these films in the dosimetry of ionising radiation can be found in the literature.^{55, 58, 59}

Other TPTC-containing polymeric films, for example, poly(vinyl acetate),³⁷ polyvinylpyrrolidone,⁵⁶ and poly(vinyl alcohol) films^{25, 35, 54, 60} have also been proposed for dosimetry.

Poly(vinyl alcohol) films have been studied most comprehensively. These films can be used to measure absorbed doses in the range from 0.5 to several tens of kilogray.²⁵ Another publication³⁵ presents a somewhat different range of measurable doses, from 1 to 100 kGy. For NPTC-containing films, the lower limit of determination of absorbed doses is 0.1 kGy.²⁵ In the case of films with TPTC, the readings do not depend on the dose rate, at least in the range from 0.96 to 3.2×10^7 Gy s $^{-1}$.^{35, 64} The optical absorption of irradiated films containing TPTC or NPTC changes by not more than 14% over a period of 27 days.⁵⁴ However, the readings are somewhat dependent on the temperature. The temperature coefficient for the readings for TPTC-containing poly(vinyl alcohol) films is about +0.46% per 1°C . This can be neglected if the measurements are performed at $20 \pm 5^\circ\text{C}$. The main drawback of films containing monotetrazolium salts is that they are sensitive to light. Therefore, they should be stored in the dark. This drawback can be largely eliminated if TB is used as the radiochromic additive.⁵⁴ During storage under ordinary conditions, the optical absorption of these films remains almost invariable over a period of 14 days. Transparent and matt films containing TB have been used for a long period as dose indicators for radiation sterilisation of medical wares.⁶⁰ The use of matt films is due to the need to distinguish more clearly the colours of nonirradiated and irradiated films.

It has been proposed³⁵ that TPTC-containing poly(vinyl acetate) films can serve for determination of doses between 5 and 50 kGy. In addition, they can be used to obtain radiographic images. It has been suggested⁵⁶ that polyvinylpyrrolidone films with TPTC may find application for determination of doses of up to 40 kGy, while NTB can be used as a radiochromic additive to polymeric matrices.

VI. Conclusion

The above discussion leads to the following conclusions.

1. The use of radiation-chemical methods (first of all, pulse radiolysis) made it possible to study the kinetics of reduction of tetrazolium salts to formazans in aqueous and alcoholic solutions and in solid matrices and to elucidate the nature of the intermediate species.

2. The investigation of radiolytic transformations of tetrazolium salts provided more precise data about some aspects of the action of ionising radiation on liquid alcohols and poly(vinyl alcohol) films. In particular, the nature of the free radicals formed in irradiated poly(vinyl alcohol) was determined, and the hypothesis of participation of radical pairs in radiation-induced chemical reactions with admixtures present in the polymer was confirmed.

3. Studies of the radiolytic transformations of tetrazolium salts led to new applications of these compounds in chemistry and biochemistry.

4. The development of dosimetric systems based on tetrazolium salts suitable for the measurement of different ranges of absorbed doses and their three-dimensional distribution in irradiated objects is fairly significant from the practical viewpoint.

The main drawback of these systems (their low resistance to light), which holds up their wide use, can be largely eliminated by using poly(vinyl alcohol) films containing Tetrazolium Blue as a radiochromic additive.

Abstract. Data on the structure and properties of highly cross-linked polymer networks in which the distance between cross-link points is several repeating units or even less than one unit, up to the networks consisting of nothing but cross-link points containing no linear fragments, are generalised. The dependences of a number of physical properties (the glass transition temperature, the modulus of elasticity, *etc.*) on the degree of cross-linking and the influence of various defects (branchings, dangled chains, *etc.*) on the properties of highly cross-linked networks are analysed. It is shown that the passage from sparse networks to highly cross-linked networks is accompanied by fundamental changes in their properties and that these properties can be described quantitatively taking into account the chemical structure of the network. The influence of the chemical structure of a cross-link point of the network on the properties is analysed; it is shown that the distances between the cross-link points in such networks can be estimated by nontraditional methods. Particular attention is paid to the cross-linked systems that are the basis for gradient-modulus materials in which the modulus of elasticity, the refractive index, and other properties vary over a wide range. The bibliography includes 93 references.

I. Introduction

The aim of this review is to analyse the influence of the structure of highly cross-linked polymer networks on their physical properties. The concept of the network structure includes the chemical structure of cross-link points and linear fragments between them, branchings, isolated loops, and other defects always present in the network. We will solve the above problem on the basis of an approach that is being developed by the author (in collaboration with Yu I Matveev) over many years and that makes it possible to take into account the influence of the energies of intermolecular interaction and chemical bonds on the properties of polymers. According to this approach, the repeating unit of a polymer or the

repeating fragment of a network is represented as a set of anharmonic oscillators interconnected by different types of intermolecular interactions (*e.g.*, dispersion, dipole-dipole, and hydrogen interaction) and chemical interactions. The temperature at which the set of oscillators loses its stability characterises the onset of such processes as glass transition or melting (energy changes on the level of intermolecular interaction), or the onset of intense thermal degradation (energy changes on the level of chemical bonds). Only the chemical structure of polymers needs to be known for calculating their properties. Any change in the topology of the network is related to changes in its chemical structure, which in turn affect its properties.^{1–4}

A purely empirical approach developed by Van Krevelen based on group contributions to a particular property is often used for calculating properties of polymers. Compared to the approach used in this study, it has a number of limitations and certain advantage. The limitations are the following: (1) if a group makes no contribution, then the properties of a polymer containing this group cannot be calculated; (2) the applicability of the approach only to linear polymers; there is no mention of polymer networks even in the third edition of the book by D W Van Krevelen *Properties of Polymers* Third Ed. (Amsterdam: Elsevier, 1990); and (3) group contributions to properties have no physical sense. The simplicity of calculations is an advantage of Van Krevelen's approach.

In this review, we have analysed the results obtained to date of studies of the influence of the above-mentioned structural network peculiarities on the properties of polymers. In the preparation of the review, the author not only compiled the published data, but also carried out numerous additional calculations of the properties of highly cross-linked polymer networks. This was associated with an attempt to answer the most frequently asked questions of specialists concerning the influence of the degree of cross-linking, the topology of the network, the chemical structure of the cross-linking agent (*i.e.*, the chemical structure of cross-link points), 'dangled' chains, branchings, loops, and other structural features on the properties.

Before considering peculiarities of the structure and properties of highly cross-linked polymer networks, it is necessary to define the concepts of a cross-link point, of a highly cross-linked network, and of a sparse network. *A cross-link point of the network is a group of atoms comprising an atom from which the chain branching occurs, neighbouring atoms chemically bonded to this*

Figure 1. Examples of dependences illustrating sharp changes in properties on the number of repeating units (m) between the neighbouring cross-link points of a network.

atom, and their nearest substituents.^{5, 6} A decrease in the number of repeating units between cross-link points (if it amounts to several tens) affects insignificantly the glass transition temperature, the molar volume, the refractive index, and some other characteristics. However, when the number of the repeating units between cross-link points is very small (several units), its decrease results in abrupt changes in the properties (Fig. 1). This is particularly noticeable when none of 'normal' polymer units remains between the cross-link points. Such systems are the most highly cross-linked polymer networks; cured epoxy resins, phenol-formaldehyde resins, graphite, diamond, and a number of other compounds can serve as examples.

A detailed study of the properties of highly cross-linked polymer networks was carried out for hypothetical tri- and tetrafunctional polyethylene-based networks, networks based on styrene-divinylbenzene copolymers, *etc.*¹ Abrupt changes in the properties of all polymers considered occurred when the number of repeating units in the linear fragments between cross-link points decreased down to 4–5. It is these networks that will be classified as highly cross-linked networks. Principal changes in both the structure and properties of highly cross-linked networks occur if the network virtually consists of nothing but cross-link points.

II. Density and the molar volume

The concept of 'a repeating fragment of a network' is illustrated in Fig. 2 in which tri- and tetrafunctional networks are represented schematically. The functionality of a network is characterised by the number of chains issuing out of one cross-link point. The molecular weight M_f of a repeating fragment of a trifunctional network (Fig. 2a) is calculated using the following formula

$$M_f = M_{c-1} + 1.5M_0m, \quad (1)$$

where M_{c-1} is the molecular weight of the cross-link point, M_0 is the molecular weight of the repeating unit of linear fragments connecting the cross-link points, and m is the average number of the repeating units in the linear fragments between the cross-link points.

Figure 2. Trifunctional (a) and tetrafunctional (b) networks with the same chemical structure of linear fragments.

The van der Waals volume of the repeating fragment of the network can be found from the relationship

$$\left(\sum_i \Delta V_i\right)_f = \left(\sum_i \Delta V_i\right)_{c-1} + 1.5\left(\sum_i \Delta V_i\right)_0 m, \quad (2)$$

where $\left(\sum_i \Delta V_i\right)_{c-1}$ and $\left(\sum_i \Delta V_i\right)_0$ are the van der Waals volumes of the cross-link point and of the repeating unit of the linear fragments between the cross-link points, respectively.

The formulae for calculating density (ρ_c) and molar volume (V_c) of a polymer network have the form

$$\rho_c = \frac{M_f k}{N_A \left(\sum_i \Delta V_i\right)_f} \quad \text{and} \quad V_c = \frac{N_A \left(\sum_i \Delta V_i\right)_f}{k},$$

where N_A is the Avogadro constant and k is the average value of the molecular packing coefficient.[†]

The van der Waals volumes of carbon, oxygen, sulfur, nitrogen, and other atoms chemically bonded to other atoms have been reported.^{3, 7} Using these data, the van der Waals volumes of repeating fragments of networks of different chemical nature (Table 1) can be calculated easily.

Studies of the bulk properties of polymer networks have shown that the average molecular packing coefficient at room temperature k_{25} is equal to ~ 0.7 , which is somewhat larger than that of linear polymers (0.681).

The relationships (1) and (2) are valid for rather sparse polymer networks in which the number of repeating units in the linear fragments between the cross-link points exceeds 10. The following relationships are valid for highly cross-linked polymer networks

$$M_f = M_{c-1} + 3M_0^* + 1.5(m-2)M_0$$

and

$$\left(\sum_i \Delta V_i\right)_f = \left(\sum_i \Delta V_i\right)_{c-1} + 3\left(\sum_i \Delta V_i\right)_0^* + 1.5(m-2)\left(\sum_i \Delta V_i\right)_0, \quad (3)$$

where M_0^* and $\left(\sum_i \Delta V_i\right)_0^*$ are respectively the molecular weight

and the van der Waals volume of the repeating units of linear chains immediately adjacent to the cross-link point (these units are of different chemical structure as compared to the 'normal' units).

For tetrafunctional sparse networks (see Fig. 2b) we have

$$M_f = M_{c-1} + 2M_0m \quad \text{and}$$

$$\left(\sum_i \Delta V_i\right)_f = \left(\sum_i \Delta V_i\right)_{c-1} + 2\left(\sum_i \Delta V_i\right)_0 m.$$

For highly cross-linked networks we get

$$M_f = M_{c-1} + 4M_0^* + 2(m-2)M_0$$

and

$$\left(\sum_i \Delta V_i\right)_f = \left(\sum_i \Delta V_i\right)_{c-1} + 4\left(\sum_i \Delta V_i\right)_0^* + 2(m-2)\left(\sum_i \Delta V_i\right)_0. \quad (4)$$

[†] It will be recalled that the molecular packing coefficient is the ratio of the van der Waals molar volume of a body to the molar volume of the body.²

Notes. All the components of the parameters are listed. For the structures of networks **1** – **13** and **15** – **20**, see text. The subscripts c-1, l, and f correspond to the cross-link point of the network, the linear fragment, and the repeating fragment, respectively.

It has been found^{7,8} that for all polymers irrespective of their chemical structure the molecular packing coefficient near absolute zero k_0 is nearly the same and is equal to ~ 0.731 .

At a glass transition temperature T_g , which is specific to each polymer, the molecular packing coefficient is also almost constant and is assessed as $k_g \approx 0.667$. For highly cross-linked polymer networks, $k_g \approx 0.681$ (see Ref. 4).

Since the molar volume of a polymer at the glass transition temperature is

$$V_g = V_0(1 + \alpha T_g),$$

where V_0 is the molar volume at absolute zero, α is the thermal coefficient of volume expansion, and

$$V_g = \frac{N_A \left(\sum_i \Delta V_i \right)}{k_g} \quad \text{and} \quad V_0 = \frac{N_A \left(\sum_i \Delta V_i \right)}{k_0},$$

then

$$\frac{k_0}{k_g} = 1 + \alpha T_g \quad \text{and} \quad \alpha = \frac{k_0/k_g - 1}{T_g}.$$

The coefficient of volume expansion in the rubbery state α_L can be approximately calculated using the φ_f constant from the Simkha–Boyer equation; the experimental constant for cured resins is equal to 0.106, i.e.,

$$\varphi_f = (\alpha_L - \alpha) T_g = 0.106.$$

Hence

$$\alpha_L = \frac{0.106 + \alpha T_g}{T_g}.$$

The molecular packing coefficient at 293 K and the density at the same temperature can be calculated using the following formulae

$$k_{293} = \frac{k_0}{1 + \alpha_{293}} \quad \text{and} \quad \rho_{293} = \frac{k_{293} M_f}{N_A \left(\sum_i \Delta V_i \right)_f} = \frac{1}{V_{u293}},$$

where $k_0 = 0.731$ and V_{u293} is the specific volume of the network at 293 K.

The calculated and experimental dependences of ρ_{293} on M_f for a number of epoxy resins based on bisphenol A and dicarbox-

Figure 3. Dependences of the density on the molecular weight of the repeating fragment obtained by the hydrostatic weighing method (1, 4), calculations (2, 4), and according to thermal dilatometric data (3, 5) for cured epoxy resins containing azelaic acid (1–3) and oleic acid (4, 5).

Figure 4. Temperature dependences of the molecular packing coefficient for epoxy resins containing azelaic acid (a) and oleic acid (b) cured with methyltetrahydrophthalic anhydride.

The content of azelaic acid, mole fraction: (1) 0.1; (2) 0.2; (3) 0.3; (4) 0.4; (5) 0.5; (6) 0.6; (7) 0.7; (8) 0.8; (9) 0.9; and (10) 1.0; the content of oleic acid, mole fraction: (1) 0.1; (2) 0.2; (3) 0.3; (4) 0.4; (5) 0.5; (6) 0.6; (7) 0.7; (8) 0.8; and (9) 0.9.

ylic azelaic acid (or monocarboxylic oleic acid) added to the compositions to lengthen the linear fragments or to introduce 'dangled' chains are shown in Fig. 3.

Temperature dependences of the molecular packing coefficient k for these networks are of interest (Fig. 4). These dependences were calculated using the specific volume measured at different temperatures

$$k(T) = \frac{N_A \left(\sum_i \Delta V_i \right)_f}{V_u(T) M_f}.$$

The empty volume ΔV_{ev} , which is the difference between the volume of the body at a given temperature and its van der Waals volume, is calculated as follows:

$$\Delta V_{ev}(T) = V(T) - N_A \left(\sum_i \Delta V_i \right)_f,$$

where $V(T)$ is the molar volume at temperature T .

At the glass transition temperature T_g , we have

$$\Delta V_{ev}(T_g) = V(T_g) - N_A \left(\sum_i \Delta V_i \right)_f,$$

and the fraction of the empty volume is

$$\frac{V_{ev}(T_g)}{V(T_g)} = 1 - k_g,$$

where k_g is the molecular packing coefficient at the glass transition temperature T_g . For highly cross-linked polymer networks, this parameter is constant in the first approximation and is equal to 0.322.

III. Analysis of the structure of highly cross-linked polymer networks

Analysis of the structure of highly cross-linked polymer networks is hampered by the fact that the initial oligomers (*e.g.*, epoxy oligomers) are, as a rule, polydisperse and contain various impurities. In addition, chemical processes occurring in the course of curing are complicated by side reactions. Therefore preference should be given to direct spectroscopic investigation techniques; however, indirect methods also can be useful.

The structure of polymer networks is analysed by both chemical and physical methods. Among purely chemical methods, mention may be made of a method based on a polymer chain fragmentation by unambiguous reactions.⁹ The network structure can be judged from the composition of the products formed. Another method consists in introducing stable nitroxyl radicals into the polymer matrix and estimating their molecular mobility from EPR spectra.¹⁰ IR spectroscopy is also used for analysing the structure of highly cross-linked networks.

The last method was used to study curing of bisphenol A diglycidyl ether with *m*-phenylenediamine.¹¹ The degree of curing with respect to epoxy groups was estimated from the decrease in the absorption band at 914 cm^{-1} . If the epoxy groups are in excess compared to the amino groups, they react mainly with hydroxyl groups at deep stages of curing. The network structure is also established by NMR spectroscopy and elemental analysis. These methods were used, *e.g.*, by Yu and Bell¹² who studied the reaction of bisphenol A diglycidyl ether with diphenyl carbonate in the presence of various catalysts. The epoxy resin reacts with polycarbonate to form polymer networks with a maximum glass transition temperature $T_g \approx 120^\circ \text{C}$. In studies of reactions of epoxy resins with aromatic polyesters,^{13–15} it has been found that the epoxy groups react with the ester groups to form networks possessing increased heat resistance.

NMR spectroscopy is used not only for analysing the chemical structure, but also for assessing the topology of the network structure. Using nuclear magnetic cross-relaxation data, a study was carried out of a number of epoxyamine polymers obtained with different ratios of the epoxy and the amino groups (diepoxide was partially replaced by monoepoxide so that the stoichiometric ratio was retained).¹⁶ The two-component spectrum of the cross-relaxation times and the values and the nature of temperature and concentration changes in the populations of selected groups of protons are due to the topology of the network structure.

Pulse NMR was used to study the relaxation properties of a number of model epoxy polymers based on resorcinol diglycidyl ether with different concentrations of cross-links, degrees of branching, and the nature of the cross-link point. On glass transition, the molecular motion in polymer networks occurs by at least two types of segments, *viz.*, by cross-link points with adjacent chain fragments and by linear fragments.

New results were obtained in pulse NMR studies of epoxy oligomers and networks based on them.^{17–20} This method was used to study the relaxation properties of epoxy oligomers.¹⁷ The kinetic inhomogeneity of these substances is associated either with phase separation or with a broad fractional composition. A comparison of the results obtained by pulse NMR with those of viscosimetric and dielectric studies has shown that the free volume of the system mainly affects the nature of the temperature dependence of relaxation parameters. NMR cross-relaxation, differential microcalorimetry, and IR spectroscopic studies of the process of structure formation of a polymer based on bisphenol A diglycidyl ether and 1,3-bis(aminomethyl)adamantane have shown¹⁸ that native specimens possess an ensemble of slowly relaxing protons with a glass transition temperature 20 K higher than that of a fully cured polymer. The temperature of freeing the mobility of the structural elements of native and fully cured polymers decreases as the temperature of isothermal curing increases. A model of large-scale motion in highly cross-linked polymer networks was pro-

posed,²⁰ which allowed one to rationalise the experimental results obtained in a pulse NMR study of epoxy networks.

Physical methods for the analysis of the structure of highly cross-linked networks are most widely used.^{21–23} They include swelling, mechanical measurements, osmometry, cryoscopy, measurements of ultrasound velocity, dielectric measurements, *etc.* Methods of determining hardness and penetration have been used widely to judge the degree of curing of thermosetting resins; the apparatus for such measurements was described by Ciecierski and Kohman.²⁴ Dynamic mechanical analysis is most widely used.^{25,26} The degree of conversion is judged from changes in the modulus of elasticity and in the loss factor $\tan \delta$.

A method for assessing the linear network fragment M_c based on measuring the depression of the solvent freezing temperature in the swollen network has been described.²⁷ The degree of curing can also be estimated from changes in the refractive index;²⁸ however, this method is only suitable at the initial curing stage. Another method consists in measuring linear expansion of a specimen and comparing this parameter with that of a standard specimen.²⁹ These studies are closely related to investigations of the kinetics of network curing.^{30–37} However, mechanical measurements (the equilibrium rubbery modulus) and sorption methods (the equilibrium degree of swelling or measurements of mechanical properties of swollen networks) remain most widely used methods for assessing the M_c value in polymer networks. Another method for assessing the structure of highly cross-linked polymer networks based on comparison of the calculated and experimental values of the glass transition temperature is also possible. As to the equilibrium rubbery modulus, the classical theory of rubber elasticity is, as a rule, inapplicable to highly cross-linked systems and another approach described in detail below is required in this case.

IV. Calculations of glass transition temperatures of polymer networks

Like many other properties of cross-linked systems, the glass transition temperature depends on the number (m) of repeating units between cross-link points (see Fig. 1). The glass transition temperature of a sparse network depends slightly on m ; however, a sharp increase in the glass transition temperature occurs to reach very high values as the number of repeating units of linear chains between adjacent cross-link points decreases substantially. The results of experiments and calculations show that the onset of sharp increase in the glass transition temperature is observed as the number of units in the linear fragments connecting cross-link points becomes less than 4 or 5. As was mentioned above, it is just the value m that suggests the passage from sparse networks to highly cross-linked networks.

Let us consider two limiting cases.

1. The network is too sparse, and $m \rightarrow \infty$. In this case, the network properties are virtually the same as those of a linear polymer of the same chemical structure. The glass transition temperature can be calculated using the following equation^{7,8}

$$T_g = \frac{\left(\sum_i \Delta V_i\right)_0}{\sum_i a_i \Delta V_i + \sum_j b_j}, \quad (5)$$

where a_i and b_j are parameters characterising the energy of a weak dispersion interaction averaged for each atom and the energy of strong intermolecular interaction (different kinds of the dipole-dipole interaction and hydrogen bonds), respectively.

2. The network is extremely highly cross-linked and consists of nothing but cross-link points. In this case, softening of the network upon heating can occur only because of its thermal degradation due to the cleavage of chemical bonds in the cross-link points. The softening temperature (more rigorously, the

temperature of the onset of intense thermal degradation) of this network can be calculated using the following equation³⁸

$$T_d = \frac{\left(\sum_i \Delta V_i\right)_{c-1}}{\sum_i K_i \Delta V_i}, \quad (5a)$$

where K_i is a parameter dependent on the energy of chemical bonds

$$K_i = \frac{63}{2} \frac{R}{(ad_0E)_i},$$

R is the universal gas constant, and a , d_0 , and E are parameters of the Morse potential

$$\phi(d) = E \{(\exp[-a(d-d_0)]-1)^2-1\},$$

where d is the distance between the chemically bonded atoms, d_0 is the equilibrium distance, and E is the bond dissociation energy.

Detailed calculations of glass transition temperatures of linear polymers and softening temperatures of highly cross-linked polymer networks can be found in the literature.^{3,7,8}

For the most part, actual networks correspond to an intermediate case since they contain rather long but finite-length linear fragments between cross-link points. Generalisation of Eqns (5) and (5a) taking into account the effects of both linear fragments and cross-link points of the network on the glass transition temperature resulted in the following relationship:^{5,6}

$$T_g = \frac{\left(\sum_i \Delta V_i\right)_f}{\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_l + \left(\sum_i K_i \Delta V_i\right)_{c-1}}, \quad (6)$$

where the denominator is the sum of the sets of the increments of the linear chains constituting the repeating fragment (the 'l' subscript) and of the cross-link point (the 'c-l' subscript).

This equation can be applied both to extremely sparse and to most highly cross-linked networks as well as to the networks of intermediate structure. In fact, if the network consists virtually of nothing but linear fragments, the effect of cross-link points can be neglected and Eqn (6) becomes Eqn (5). On the contrary, if the network consists of nothing but cross-link points, then Eqn (6) becomes Eqn (5a). For intermediate cases both terms in the denominator of Eqn (6) are taken into account.

Let us consider two important methodological problems. The first problem is associated with the assessment of the van der Waals volume of the repeating fragment of the network. For networks with tri- and tetrafunctional cross-link points considered above (see Fig. 2), the van der Waals volumes of repeating fragments are calculated using Eqns (3) and (4), respectively.

Yet another type of network is shown in Fig. 5. In such a network, linear chains and cross-linking bridges are of different chemical nature. The formula for calculating the van der Waals volume of the repeating network fragment has the form

$$\begin{aligned} \left(\sum_i \Delta V_i\right)_f = & \left(\sum_i \Delta V_i\right)_{l,1} (m_1 - 2) + 2 \left(\sum_i \Delta V_i\right)_{l,1}^* + \\ & + \left(\sum_i \Delta V_i\right)_{l,2} \frac{m_2 - 2}{2} + \left(\sum_i \Delta V_i\right)_{l,2}^* + \left(\sum_i \Delta V_i\right)_{c-1}, \end{aligned}$$

where $\left(\sum_i \Delta V_i\right)_{l,1}$ is the van der Waals volume of the repeating unit of linear fragments of chains that are being cross-linked, m_1 is

Figure 5. A network built of linear chains of the same chemical nature and cross-linking bridges of other chemical nature (a trifunctional cross-link point is shown).

the average number of such units between the cross-link points;

$\left(\sum_i \Delta V_i\right)_{1,1}^*$ is the van der Waals volume of the unit immediately adjacent to the cross-link point (this unit differs in its chemical structure from 'normal' units); $\left(\sum_i \Delta V_i\right)_{1,2}$ is the van der Waals volume of the repeating unit of linear fragment of cross-linking bridges, m_2 is the number of such units; and $\left(\sum_i \Delta V_i\right)_{1,2}^*$ is the van der Waals volume of the unit immediately adjacent to the cross-link point.

Let us dwell once again on the concept of 'a cross-link point of the network'. To formulate this concept, Eqn (6) was 'calibrated' using experimental glass transition temperatures of numerous well-characterised cross-linked systems.⁵ It turned out that the best agreement between the calculated and experimental results is achieved with the definition of the cross-link point given in the Introduction.

The molecular weight of averaged linear fragment can be estimated based on the chemical structure of the network and the experimental glass transition temperature. To this end, one must substitute the experimental T_g value into Eqn (6) and solve it with respect to m . Let us perform such an analysis in a general form for different types of networks.

First, we consider the network shown in Fig. 2b; four chains issue out of each cross-link point of this network and all the linear fragments have the repeating units of the same chemical structure. Using relationship (3) and Eqn (6), we can write for the repeating network fragment

$$T_g = \frac{2(m-2)\left(\sum_i \Delta V_i\right)_1 + 4\left(\sum_i \Delta V_i\right)_1^* + \left(\sum_i \Delta V_i\right)_{c-1}}{\left[2(m-2)\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_1 + 4\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_1^* + \left(\sum_i K_i \Delta V_i\right)_{c-1}\right]}, \quad (7)$$

where the first term in the denominator is the set of increments for the repeating unit of linear chains, the second term is the set of the increments for the outer units immediately adjacent to the cross-link points, and the third term is the set of increments for the cross-link point of the network.

The molecular weight M_c of linear chains between the cross-link points can be determined using the following formula

$$M_c = (m-2)M_0 + 2M_0^* + \frac{1}{2}M_{c-1}, \quad (8)$$

where M_0 is the molecular weight of a 'normal' unit, M_0^* is the molecular weight of the unit immediately adjacent to the cross-link point, and M_{c-1} is the molecular weight of the cross-link point.

Let us introduce the following designations:

$$\left(\sum_i \Delta V_i\right)_1 = A, \quad 2\left(\sum_i \Delta V_i\right)_1 + \frac{1}{2}\left(\sum_i \Delta V_i\right)_{c-1} = B,$$

$$\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_1 = C,$$

$$2\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_1^* + \frac{1}{2}\left(\sum_i K_i \Delta V_i\right)_{c-1} = D.$$

Then, after some transformations relationships (7) and (8) respectively take the form

$$m-2 = \frac{B - T_g D}{T_g C - A}, \quad M_c = \frac{B - T_g D}{T_g C - A} M_0 + 2M_0^* + \frac{1}{2}M_{c-1}.$$

Let us analyse a network with trifunctional cross-link points and chain fragments of the same chemical structure issuing out from the cross-link point (see Fig. 2a). We can write for the repeating fragment of such a network

$$T_g = \frac{\left[(m-2)\frac{3}{2}\left(\sum_i \Delta V_i\right)_1 + 3\left(\sum_i \Delta V_i\right)_1^* + \left(\sum_i \Delta V_i\right)_{c-1}\right]}{\left[(m-2)\frac{3}{2}\left(\sum_i a_i \Delta V_i + \sum_j b_j\right) + 3\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_1^* + \left(\sum_i K_i \Delta V_i\right)_{c-1}\right]}. \quad (9)$$

Taking into account the designations introduced we have

$$m-2 = \frac{2}{3} \frac{B_1 - T_g D_1}{T_g C - A},$$

where

$$B_1 = 3\left(\sum_i \Delta V_i\right)_1^* + \left(\sum_i \Delta V_i\right)_{c-1},$$

$$D_1 = 3\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_1^* + \left(\sum_i K_i \Delta V_i\right)_{c-1}.$$

Hence

$$M_c = (m-2)M_0 + 2M_0^* + \frac{2}{3}M_{c-1} = \frac{2}{3} \frac{B_1 - T_g D_1}{T_g C - A} M_0 + 2M_0^* + \frac{2}{3}M_{c-1}.$$

For the network shown in Fig. 5, the dependence of T_g on the composition has the form

$$T_g = \frac{\left\{(m-2)\left(\sum_i \Delta V_i\right)_{1,1} + 2\left(\sum_i \Delta V_i\right)_{1,1}^* + \frac{2}{3}\left(\sum_i \Delta V_i\right)_{c-1} + \frac{m_2-2}{2}\left(\sum_i \Delta V_i\right)_{1,2} + \left(\sum_i \Delta V_i\right)_{1,2}^* + \frac{1}{3}\left(\sum_i \Delta V_i\right)_{c-1}\right\}}{\left\{(m_1-2)\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{1,1} + 2\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{1,1}^* + \left(\sum_i K_i \Delta V_i\right)_{c-1} + \frac{m_2-2}{2}\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{1,2} + \left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{1,2}^*\right\}}, \quad (10)$$

where m_1 and m_2 are the numbers of 'normal' units in the linear chains and in the cross-linking bridges between adjacent cross-link points, respectively, and the asterisked parameters correspond to the units immediately adjacent to the cross-link points. The m_1/m_2 ratio is equal to the mole ratio of the components 1 and 2

$$\frac{m_1}{m_2} = \frac{q_1}{q_2},$$

where q_1 and q_2 are the numbers of moles of the components 1 and 2, respectively. Substituting this relationship into formula (10), we get

$$m_1 - 2 = \left[B_2 - 2A_1 - A_2 - T_g(D_2 - 2C_1 - C_2) - 2T_g \left(C_1 - \frac{q_1}{2q_2} C_2 \right) + 2 \left(A_1 - \frac{q_1}{2q_2} A_2 \right) \right] / \left[T_g \left(C_1 + \frac{q_1}{2q_2} C_2 \right) - \left(A_1 + \frac{q_1}{2q_2} A_2 \right) \right],$$

where

$$\begin{aligned} B_2 &= 2 \left(\sum_i \Delta V_i \right)_{1,1} + \frac{2}{3} \left(\sum_i \Delta V_i \right)_{c-1} + \left(\sum_i \Delta V_i \right)_{1,2} + \frac{1}{3} \left(\sum_i \Delta V_i \right)_{c-1}; \\ A_1 &= \left(\sum_i \Delta V_i \right)_{1,1}; \quad A_2 = \left(\sum_i \Delta V_i \right)_{1,2}, \\ D_2 &= 2 \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{1,1}^* + \left(\sum_i K_i \Delta V_i \right)_{c-1} + \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{1,2}^*; \\ C_1 &= \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{1,1}; \quad C_2 = \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{1,2}. \end{aligned}$$

Let us introduce the following designations:

$$B^* = B_2 - 2A_1 - A_2 + 2 \left(A_1 + \frac{q_1}{q_2} A_2 \right),$$

$$D^* = D_2 - C_2 + \frac{q_1}{q_2} C_2, \quad C^* = C_1 + \frac{q_1}{q_2} C_2; \quad A^* = C_1 + \frac{q_1}{q_2} A_2.$$

Taking into account these designations, we obtain

$$m_1 - 2 = \frac{B^* - T_g D^*}{T_g C^* - A^*}. \quad (11)$$

For a network consisting of the fragments of different nature, it is expedient to calculate two values of the molecular weight of the linear chains between cross-link points, viz., $M_{c,1}$, which is the molecular weight of the linear chain fragment between cross-link points for the chains that are being cross-linked, and $M_{c,2}$, which is the molecular weight of the linear chain fragment between cross-link points for the cross-linking bridges

$$M_{c,1} = (m_1 - 2)M_1 + 2M_1^* + M_{c-1,1}, \quad (12)$$

$$\begin{aligned} M_{c,2} &= (m_2 - 2)M_2 + 2M_2^* + M_{c-1,2} = \\ &= \left(\frac{q_1}{q_2} m_1 - 2 \right) + 2M_2^* + M_{c-1,2}, \end{aligned} \quad (13)$$

where $M_{c-1,1}$ is the molecular weight of a part of the cross-link point shared by the chains that are being cross-linked (see Fig. 5, filled segments of the circles) and $M_{c-1,2}$ is the molecular weight of

a part of the cross-link point shared by cross-linking bridges (see Fig. 5, open segments of the circles). The sum $M_{c-1,1} + M_{c-1,2}$ is equal to the molecular weight of the entire cross-link point M_{c-1} .

Taking into account formula (11), expressions (12) and (13) take the form

$$M_{c,1} = \frac{B^* - T_g D^*}{T_g C^* - A^*} M_1 + 2M_1^* + M_{c-1,1},$$

$$M_{c,2} = \frac{q_1}{q_2} M_2 \left(\frac{B^* - T_g D^*}{T_g C^* - A^*} + 1 \right) + 2(M_2^* - M_2) + M_{c-1,2}.$$

The average molecular weight M_a of the chain between cross-link points of the network can be calculated using the following formula

$$M_a = \alpha M_{c,1} + (1 - \alpha) M_{c,2},$$

where $\alpha = q_1/(q_1 + q_2)$.

Networks with tetrafunctional cross-link points. Let us consider calculations of T_g and M_c for three types of networks in more detail. We will analyse a hypothetical polyethylene-based network (structure 1) as the simplest example of a network with a tetrafunctional cross-link point and linear chains of the same chemical structure issuing out of the cross-link point.

For such a network, the van der Waals volume of the repeating fragment can be determined using the following relationship

$$\left(\sum_i \Delta V_i \right)_f = \left(\sum_i \Delta V_i \right)_{c-1} + 2 \left(\sum_i \Delta V_i \right)_0 (m - 2),$$

where the first term is the van der Waals volume of the cross-link point (enclosed by dashes), and the second term is the van der Waals volume of the CH₂ group. The values of all the parameters of the network are given in Table 1. By substituting them into Eqn (7), it is possible to calculate the glass transition temperature

$$T_g = \frac{34.2m + 5}{160.4m - 217.86} \times 10^3. \quad (14)$$

Relationship (14) is valid if $m \geq 2$. The dependence of T_g on m calculated using this formula is shown in Fig. 6a.

If $m = 1$, then the situation changes so that the network has the structure 2.

Such a network consists of nothing but cross-link points, each CH₂ group being shared by two adjacent cross-link points. For the calculated values of the above mentioned parameters of the network, see Table 1.

Figure 6. Dependences of T_g on m for a model polyethylene-based network with a trifunctional (1) and tetrafunctional (2) cross-link points (a), for cured epoxy resin (b), and for a network based on polystyrene and divinylbenzene (c).

This network contains no linear fragments; hence $\left(\sum_i a_i \Delta V_i + \sum_j b_j\right) = 0$ and softening of such a network occurs only because of thermal degradation (*i.e.*, decomposition through cleavage of chemical bonds). Substitution of all the parameters into Eqn (7) gives

$$T_g = T_d = \frac{39.2}{54.3} \times 10^3 = 721 \text{ K}.$$

The network with $m = 0$ has structure **3** (the ideal diamond structure). The parameters of such a network are also listed in Table 1.

After substituting the numerical values into Eqn (7) we obtain

$$T_g = T_d = \frac{5.0}{5.7} \times 10^3 = 870 \text{ K}.$$

Thus, the calculated temperature of the onset of thermal degradation of diamond is equal to $\sim 873 \text{ K}$; it is known that the complete combustion of diamond occurs on heating to 1273 K.

Networks with trifunctional cross-link points. Let us consider the behaviour of a network with a trifunctional cross-link point (marked by dashes).

Substitution of all parameters of the network (see Table 1) into Eqn (9) gives

$$T_g = \frac{11 + 25.65m}{119.9m - 151.9} \times 10^3. \quad (15)$$

The dependence of T_g on m is shown in Fig. 6a. It can be seen that T_g decreases sharply as m increases, *i.e.*, with increase in the size of linear fragments between cross-link points.

Formula (15) is valid if $m \geq 2$. If $m = 1$, we have the structure **5**.

Network **5** consists of nothing but cross-link points, which are the repeating network fragments (indicated by dashed lines in the scheme).

Substituting the parameters of this network (see Table 1) into Eqn (9), we get

$$T_g = T_d = \frac{34.65}{46.88} \times 10^3 = 740 \text{ K}.$$

If $m = 0$, we have the structure **6**, in which each carbon atom is a branching point.

Substitution of the network parameters (see Table 1) into Eqn (9) gives

$$T_g = T_d = \frac{11.0}{14.96} \times 10^3 = 735 \text{ K}.$$

Let us consider a network in which linear chains and cross-linking bridges are of different chemical structure. We will analyse an actual epoxy resin-based network **7** as an example.

The stoichiometric composition of the network was 2 moles of an epoxy oligomer per 1 mole of a curing agent (diamine). The cross-link point of the network is indicated by dashed lines.

Substituting the values of the network parameters (see Table 1) into Eqn (10), we get

$$T_g = \frac{300.6 + 152.3m}{519.3 + 490.6m + 175.6 + 66.1} \times 10^3. \quad (16)$$

If $m = 0$, we have the structure of cured epoxy resin based on diglycidyl ether of the corresponding bisphenol. For such a resin the calculated $T_g = 395 \text{ K}$, while the experimental $T_g = 396 \text{ K}$.

The dependence of T_g on m calculated using formula (16) is shown in Fig. 6b. The glass transition temperature increases as the

linear network fragment between cross-link points decreases, which is particularly noticeable if $m \rightarrow 0$.

1. The effect of the cross-link distribution in the network on the glass transition temperature

Let us analyse the effect of the cross-link distribution along the chains on the glass transition temperature of the network taking a well-studied network **8** based on polystyrene cross-linked with divinylbenzene as an example. This is a trifunctional network, *i.e.*, three chains issue out of each cross-link point (marked by dashed lines).

Substituting the values of the network parameters (see Table 1) into Eqn (10), we get

$$T_g = \frac{53.3 + 109.7m - 17.1 + 29.4}{72.9 + 294.0m - 80.2 + 67.6} \times 10^3 = \frac{64.6 + 109.7m}{60.3 + 294.0m} \times 10^3. \quad (17)$$

Formula (17) is valid if $m \geq 1$.[‡] The dependence of T_g on m calculated using formula (17) is presented in Fig. 6 *c*.

It can be seen that the glass transition temperature increases sharply as the number of polystyrene units between adjacent cross-link points decreases, particularly when the number of these units ($m - 1$) $\rightarrow 0$.

If $m = 0$, then the degree of cross-linking of the network is equal to 100%. In structure **9**, the cross-link point of such a network is outlined by dashes.

Substituting the values of the network parameters (see Table 1) into Eqn (10), we obtain

$$T_g = \frac{36.2 + 29.4}{48.6 + 67.6} \times 10^3 = 656 \text{ K}.$$

Let us consider the effect of the cross-link distribution along linear chains on the glass transition temperature using the concept of the degree of cross-linking α .

Let us calculate the values of all parameters of Eqn (10) for a fragment of network **10** (see Table 1).

Account must be taken of the fact that the CH₂ group in the polystyrene repeating unit immediately adjacent to the cross-link point of the network (marked by dashes) is a constituent of the cross-link point. The parameters for this unit are listed in Table 1. The parameters for the 'normal' polystyrene unit (**12**) are also given in Table 1. Having calculated all parameters of Eqn (10), let us consider three cases.

a. Uniform cross-link distribution

In the case of uniform cross-link distribution Eqn (10) takes the form

$$T_g = \left[\alpha \left(\sum_i \Delta V_i \right)_1 + (1 - \alpha) \left(\sum_i \Delta V_i \right)_{12} \right] / \left[\alpha \left(\sum_i a_i \Delta V_i + \sum_j b_j + \sum_i K_i \Delta V_i \right)_1 + \alpha \left(\sum_i a_i \Delta V_i + \sum_j b_j + \sum_i K_i \Delta V_i \right)_2^* + (1 - 2\alpha) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{12} \right], \quad (18)$$

where α is the degree of cross-linking, which characterises the portion of phenyl groups involved in cross-links and is equal to $1/m$. Substituting the values of all the network parameters into Eqn (18), we get

$$T_g = \frac{\alpha 65.6 + (1 - \alpha) 109.7}{\alpha 116.2 + \alpha 238.1 + (1 - 2\alpha) 294.0} \times 10^3. \quad (19)$$

Formula (19) is valid only if $0 < \alpha \leq 0.5$. If $\alpha \geq 0.5$, the network is free of polystyrene units and formula (19) takes the form

$$T_g = \frac{\alpha 65.6 + (1 - \alpha) 109.7}{\alpha 116.2 + (1 - \alpha) 238.1} \times 10^3. \quad (20)$$

Figure 7. Dependence of T_g on the degree of cross-linking α for the network based on polystyrene and divinylbenzene. The distribution of cross-link points: (1) uniform; (2) random; and (3) the most non-uniform. The points represent the experimental values.

[‡] It should be noted that if $m \rightarrow \infty$, we obtain the calculated T_g of linear polystyrene (373 K).

If $\alpha = 0$, we get the calculated glass transition temperature of linear polystyrene.

The dependence of T_g on the degree of cross-linking α calculated using Eqns (19) and (20) is shown in Fig. 7 (curve 1). Two portions, in which fast and slow increase in T_g are observed can be distinguished in the curve of this dependence. From the analysis performed above, it follows that this is due to a specific effect of cross-link points of the network on T_g .

b. Random cross-link distribution

The function of distribution in distances for a random field of points distributed along a straight line takes the form

$$\bar{f}(l) = 1 - e^{-l/l_a},$$

where l is the distance between neighbouring points (in our case it is the distance between cross-link points), and l_a is the average distance.

Going to the degree of polymerisation m , we get

$$\bar{f}(m) = 1 - e^{-m/m_a}.$$

In the case of neighbouring cross-link points, the number of the CH_2 groups belonging both to styrene units and to cross-link points (marked by dashed lines)

will be less than in the case when cross-link points are separated by linear fragments.

As a result, the $\alpha \left(\sum_i a_i \Delta V_i + \sum_j b_j + \sum_i K_i \Delta V_i \right)_2^*$ value decreases by an amount proportional to the number of adjacent cross-links. Simultaneously, the $(1 - \alpha) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{12}$ value increases by the same amount.

Since our interest is focused on neighbouring cross-link points, at $m = 1$ the function $\bar{f}(m)$ has the form $\bar{f}(m) = 1 - e^{-1/m}$, and taking into account that $m_1 = 1/\alpha$, we obtain

$$\bar{f}(1) = 1 - e^{-\alpha}.$$

Then we should substitute $\alpha - \alpha(1 - e^{-\alpha}) = \alpha/e^\alpha$ for α in the second term and $1 - 2\alpha + \alpha(1 - e^{-\alpha}) = 1 - \alpha - \alpha/e^\alpha$ for $(1 - 2\alpha)$ in the third term in the denominator of relationship (19).

On substitution, we obtain

$$T_g = \left[\alpha \left(\sum_i \Delta V_i \right)_1 + (1 - \alpha) \left(\sum_i \Delta V_i \right)_{12} \right] / \left[\alpha \left(\sum_i a_i \Delta V_i + \sum_j b_j + \sum_i K_i \Delta V_i \right)_1 + \right. \quad (21)$$

$$\left. + \frac{\alpha}{e^\alpha} \left(\sum_i a_i \Delta V_i + \sum_j b_j + \sum_i K_i \Delta V_i \right)_2^* + \left(1 - \alpha - \frac{\alpha}{e^\alpha} \right) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{12} \right].$$

Substituting the parameters of networks 8, 10–12 (see Table 1) into Eqn (21), we get

$$T_g = \frac{\alpha 65.6 + (1 - \alpha) 109.7}{\alpha 116.2 + (\alpha/e^\alpha) 238.1 + (1 - \alpha - \alpha/e^\alpha) 294.0} \times 10^3. \quad (22)$$

Formula (22) is valid if $(\alpha + \alpha/e^\alpha) \leq 1$, which corresponds to $\alpha \leq 0.66$.

If $(\alpha + \alpha/e^\alpha) \geq 1$, there are no uncross-linked polystyrene units and formula (22) goes over into relationship (20). The dependence of T_g on α obtained using Eqns (22) and (20) is shown in Fig. 7 (curve 2).

c. The most non-uniform cross-link distribution

The most non-uniform distribution corresponds to the case where a large number of cross-link points are adjacent and form long sequences connected by linear fragments of polystyrene chains (Fig. 8). For such a distribution of cross-link points, the number

Figure 8. The most non-uniform distribution of cross-link points.

of polystyrene units immediately adjacent to the point can be neglected and we can write

$$T_g = \left[\alpha \left(\sum_i \Delta V_i \right)_1 + (1 - \alpha) \left(\sum_i \Delta V_i \right)_{12} \right] / \left[\alpha \left(\sum_i a_i \Delta V_i + \sum_j b_j + \sum_i K_i \Delta V_i \right)_1 + \right. \quad (23)$$

$$\left. + (1 - \alpha) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{12} \right].$$

Substituting all values of the network parameters (see Table 1) into formula (23), we obtain

$$T_g = \frac{\alpha 65.6 + (1 - \alpha) 109.7}{\alpha 116.2 + (1 - \alpha) 294.0} \times 10^3. \quad (24)$$

The dependence of T_g on α calculated using relationship (24) is shown in Fig. 7 (curve 3). The experimental data obtained by Shefer and Gottlieb³⁹ are also shown in this figure. Curve 2 fits well the experimental points; this indicates a random distribution of cross-link points in the actual network.

2. The influence of the structure of the cross-link point on the glass transition temperature of the network

Let us consider the problem of the influence of the chemical structure of the network on its glass transition temperature taking networks with linear fragments between cross-link points of the same chemical structure and cross-link points of different chemical

structure as an example. Polydimethylsiloxane networks with the following chemical structure⁴⁰

are suitable for such an analysis.

The synthesis of highly cross-linked polymer networks with small n values is based on the use of individual compounds with a precisely set value of n ; therefore, if the degree of conversion is close to 100%, then the M_c value of such networks is given with sufficient accuracy.

The values of all increments entering into Eqn (6) are given in Table 1. Substituting them in Eqn (6), we get the following dependence of the glass transition temperature T_g of the network on the degree of polymerisation

$$T_g = \frac{239.8 + 108.1n}{428.3 + 721.5n} \times 10^3. \quad (25)$$

This dependence fits well the experimental points corresponding to glass transition temperatures; the plot is shown in Fig. 9. It can easily be shown for the networks with tetrafunctional cross-link points (**14**) that the calculated $T_g(n)$ dependence is described by the same formula (25), since each value in the numerator and in the denominator of this formula is multiplied by the same number (4/3). The experimental $T_g(n)$ dependence for network **13** is the same as that for network **14**.

Let us consider the influence of the structure of the cross-link point of polydimethylsiloxane networks on their glass transition temperature.

To calculate T_g values of the networks containing cross-link points of different structure, it is expedient to determine first the

$\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{\text{lf}}$ and $\left(\sum_i \Delta V_i\right)_{\text{lf}}$ values for one linear network fragment between two neighbouring cross-link points. The calculations lead to the following values of these parameters:

$$\left(\sum_i \Delta V_i\right)_{\text{lf}} = 72.1n - 0.5 \text{ \AA}^3,$$

Figure 9. Dependence of T_g on n for the structures **13** and **14**.

$$\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{\text{lf}} = (481n - 11.5) \times 10^{-3} \text{ \AA}^3 \text{ K}^{-1}.$$

The $\left(\sum_i \Delta V_i\right)_{\text{lf}}$ and $\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{\text{lf}}$ values found are the same for all the networks under consideration.

Using Eqn (21), the relationships were obtained that make it possible to calculate the T_g value depending on the number of repeating units n in the linear fragments connecting cross-link points of polydimethylsiloxane networks.

The $T_g(n)$ dependences for polydimethylsiloxane networks calculated using these relationships are shown in Fig. 10. It can be seen that the structure of the cross-link point affects considerably the T_g value only if n varies from 1 to 4 ($\alpha = 1 - 0.25$). The effect of cross-link points rapidly decreases as the distance between them increases, and glass transition temperatures of all networks approach that of polydimethylsiloxane (150 K) already at $n = 10$.

Figure 10. Dependences of T_g of polydimethylsiloxane networks on n for different types of cross-link points. For the designations of fragments (1–5), see text.

3. The influence of dangled chains and other defects of the network on the glass transition temperature of polymer networks

Among a wide variety of types of dangled chains we will dwell only on two types. The first type is a modification of network **1** with a portion of cross-linking bridges 'cut' in two.

In this case the cross-link point of the network is retained; however, it becomes trifunctional (as can be seen in the scheme, the chemical structure of the cross-link point is also retained).

The repeating fragment of this structure consists of the repeating fragment of a trifunctional network and a dangled chain. Then, we can write for the van der Waals volume

$$\left(\sum_i \Delta V_i\right)_f = \left(\sum_i \Delta V_i\right)_{c-1} + 1.5 \left(\sum_i \Delta V_i\right)_0 (m-2) + \left(\sum_i \Delta V_i\right)_{dc},$$

where the first, the second, and the third terms are the van der Waals volumes of the cross-link point of the network (outlined by dashes in the scheme), of the CH_2 group, and of the dangled chain, respectively. In this case

$$\left(\sum_i \Delta V_i\right)_{dc} = \left(\sum_i \Delta V_i\right)_0 \left(\frac{m}{2} - 2\right) + \left(\sum_i \Delta V_i\right)_{\text{CH}_3},$$

where the last term is the van der Waals volume of the end CH_3 group.

It should be noted that, in principle, it is impossible for a network free of dangled chains and for a network containing them to be of the same chemical structure. In other words, the appearance of dangled chains always leads to changes in the chemical structure of the network, which affects the glass transition temperature and other properties.

Substituting the values of the parameters of structure **15** (see Table 1) in Eqn (6), we obtain

$$T_g = \frac{\alpha(11.1 + 34.2m) + (1 - \alpha)(5.0 + 34.2)}{\alpha(160.4m - 336.2 + 102.9) + (1 - \alpha)(160.4m - 217.86)} \times 10^3$$

or

$$T_g = \frac{5.0 + 34.2m + 6.1\alpha}{160.4m - 15.44\alpha - 217.86} \times 10^3. \quad (26)$$

Relationship (26) is valid if $\alpha \leq 0.5$ since if $m \geq 2$, then two cross-link points, out of which dangled chains issue, appear as a result of 'breaking' each linear chain.

The $T_g(\alpha)$ dependence calculated using formula (26) is shown in Fig. 11a. It can be seen that T_g increases slightly as α increases and that the slope of this dependence decreases as the number of units (m) between cross-link points increases. At first glance, it may seem that the appearance of network defects such as dangled chains must result in a decrease in the glass transition temperature rather than in its increase. However, it should be kept in mind that in this case the appearance of dangled chains does not reduce the number of cross-link points; even their chemical structure is retained. In addition, the appearance of each branching requires introducing a b_f increment, which favours the increase in T_g .

If upon 'breaking' of the chains the cross-link point ceases to fulfil its initial function (*i.e.*, it is no longer a cross-link point of the network), it is natural that the glass transition temperature will decrease. An example of such a network is shown below.

Figure 11. The dependences of T_g on α (for different m) for a tetrafunctional polyethylene network with dangled chains with a constant (a) and variable (b) number of cross-link points and for a trifunctional polyethylene network with dangled chains (c). m : (1) 4; (2) 5; (3) 6.

Linear chains are formed upon 'breaking' of linear fragments of the network; therefore, calculations for the former cross-link point should be carried out using a_i and b_j increments instead of K_i increments, *i.e.*,

$$\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{c-1} = 320.9 \times 10^{-3} \text{ } \text{\AA}^3 \text{ K}^{-1}.$$

Taking account of this fact and using Eqn (6), we get

$$T_g = \frac{\alpha(17.2 + 34.2m) + (1 - \alpha)(5.0 + 34.2m)}{\alpha(80.2m + 160.4m) + (1 - \alpha)(160.4m - 217.86)} \times 10^3$$

or

$$T_g = \frac{5.0 + 12.2\alpha + 34.2m}{160.4m + 298.1\alpha - 217.86} \times 10^3, \quad (27)$$

where α is the proportion of former cross-link points out of which two 'broken' chains issue.

Relationship (27) is valid if $\alpha \leq 0.25$. The $T_g(\alpha)$ dependence calculated using formula (27) is shown in Fig. 11b. It can be seen that the glass transition temperature rapidly decreases with the increase in the proportion of cross-link points out of which two 'broken' chains issue. This is explained by the fact that the branching point ceases to play the role of the cross-link point and the linear fragment between neighbouring cross-link points becomes twice as long.

Let us consider a trifunctional network with dangled chains. The scheme of such a hypothetical polyethylene-based network is shown below.

In this case upon 'breaking' the cross-linked chains the point from which the dangled chain issues ceases to play its role and becomes a constituent of a linear fragment with branching.

Using Eqn (6), we obtain

$$T_g = \frac{\alpha(25.652m + 17.1) + (1 - \alpha)(25.65m + 11)}{\alpha(24.8 + 120.3m) + (1 - \alpha)(120.3m - 152.76)} \times 10^3$$

or

$$T_g = \frac{6.1\alpha + 25.65m + 11.0}{177.56\alpha + 120.3m - 152.76} \times 10^3,$$

where α is the proportion of structures with dangled chains.

The $T_g(\alpha)$ dependences for the network with dangled chains are shown in Fig. 11c. The glass transition temperature of the network rapidly decreases with an increase in the proportion of dangled chains (especially for small m).

We have already considered hypothetical polyethylene-based networks in which the fragments between cross-link points and dangled chains are of the same chemical structure. Let us consider now a system in which the chemical structure of dangled chains differs from that of chains forming the network. Such a system based on an epoxy resin has been synthesised and studied.⁴ The ED-20 epoxy resin was cured with methyltetrahydrophthalic anhydride. To obtain a network with dangled chains, methyltetrahydrophthalic anhydride was partially replaced by oleic acid. The results of calculations and experimental studies of such networks have been reported in detail.^{4,6}

In addition to dangled chains, a network can also contain such defects as isolated loops. Different types of defects are illustrated by Fig. 12. Only those branching sites out of which the chains

Figure 12. Schematic view of various network defects.

forming cross-links (*i.e.*, chains connecting neighbouring chains) issue are cross-link points. Such structures are marked by the 'plus' sign. The branching sites, out of which the chains issue representing either offshoots or isolated loops (formed through end attachment to the initial point or to some other point of the same chain) rather than cross-links, are not cross-link points (marked by the 'minus' sign).

Such defects must be taken into account when calculating the glass transition temperature using relationship (6). If the branching site is a cross-link point (in the sense mentioned above), K_i increments should be used. If the branching site does not play the role of a cross-link point, then a_i and b_j increments for the same atoms should be substituted in relationship (6).

It is possible to estimate the proportion of defects in an actual network by comparing the calculated and experimental T_g values. Let us perform such an analysis taking a network based on methyl methacrylate-1-methoxy-1-vinyl-1-sila-2,7-dioxa-4,5-(1,2-carborano)cycloheptane copolymer as an example. The chemical structure of this copolymer has the form⁴¹

When the copolymer is exposed to heat, ring opening occurs in the fragment **17** to form a network of the following chemical structure:

The cross-link point is marked by dashes.

The values of $\left(\sum_i \Delta V_i \right)$, $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)$ and $\left(\sum_i K_i \Delta V_i \right)$ for the fragments **16** and **17** of this network are given in Table 1.

Let us consider the dependence of the glass transition temperature on the chemical structure of the network in general form with taking account of the fact that the network has structural defects and branching (see Fig. 12). Then, relationship (6) can be written in the form

$$T_g = \left(\sum_i \Delta V_i \right) / \left[\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1 + y \left(\sum_i K_i \Delta V_i \right)_{c-1} + (1-y) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right) \right], \quad (28)$$

where y is the proportion of branching sites that function as cross-link points. Comparing the calculated and experimental glass transition temperature, one can find the y value from the transformed expression (28):

$$y = \left[T_g^{-1} \left(\sum_i \Delta V_i \right) - \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1 - \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{c-1} \right] / \left[\left(\sum_i K_i \Delta V_i \right)_{c-1} - \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1 \right],$$

where T_g is the experimental glass transition temperature.

When copolymers are used for the network formation, as in our case, the situation becomes more complicated. Let us assume that one of the copolymer components does not form a network. Then, in an ideal case (the degree of cross-linking is equal to 100%) we have

$$T_g = \left[(1-n) \left(\sum_i \Delta V_i \right)_{16} + n \left(\sum_i \Delta V_i \right)_{17} \right] / \left\{ (1-n) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{16} + n \left[\left(\sum_i a_i \Delta V_i + \sum_j b_j \right) + \left(\sum_i K_i \Delta V_i \right)_{17} \right] \right\}$$

(n is the proportion of the units of structure **17**).

If some of the branching sites do not act as cross-link points, then

$$T_g = \left[(1-n) \left(\sum_i \Delta V_i \right)_{16} + n \left(\sum_i \Delta V_i \right)_{17} \right] / \left\{ (1-n) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{16} + n \left[\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1 + y \left(\sum_i K_i \Delta V_i \right)_{c-1} + (1-y) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{17} \right] \right\}. \quad (29)$$

Let us use relationship (29) to calculate the proportions of active and inactive cross-link points [y and $(1-y)$, respectively]. According to our calculations,

$$\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{c-1,16} = 490.4 \times 10^{-3} \text{ Å}^3 \text{ K}^{-1}.$$

Substituting the $\left(\sum_i \Delta V_i \right)_{16}$, $\left(\sum_i \Delta V_i \right)_{17}$, $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_1$, $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{17}$, $\left(\sum_i K_i \Delta V_i \right)_{c-1}$, and $\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{c-1,17}$ values (see Table 1) in formula (29), we get

$$T_g = \frac{96.8 + 112.1n}{255.8 - 420.5ny + 635.6n} \times 10^3. \quad (30)$$

The experimental and calculated dependences of T_g on the content of the component **17** for different proportions of active cross-link points y are shown in Fig. 13. The calculations were performed using formula (30). It can be seen that, e.g., if a proportion of the component **17** is 20%, the proportions of active and inactive cross-link points are equal to 58% and 42%, respectively; if a content of this component is 10%, the proportion of active cross-link points is equal to ~55%, etc. Thus, these networks (Ref. 41), despite being highly cross-linked, possess considerable defectiveness. If a content of the structure **17** in the copolymer is 20%, the proportion of the sol fraction is equal to 18.5%. Therefore, some portion of inactive cross-link points is contained in the branched copolymer, which is 'washed out' of the system. The remaining part of inactive cross-link points ($42\% - 18.5\% = 23.5\%$) is incorporated into the network and form branchings or isolated loops.

Let us take yet another example of assessing the network structure on the basis of comparing the calculated and experimental glass transition temperatures.⁴² Let us consider ebonites, since different types of networks can be formed in them and also because a considerable body of contradictory experimental data on their structure and mechanical properties has been accumulated. Let us calculate the T_g value of a polyisoprene-based ebonite assuming that the amount of sulfur used in the reaction corresponds to one sulfur atom per one polyisoprene repeating unit. Let us consider several variants of the formation of a network that may comprise four types of structures.

Figure 13. Dependences of T_g on the proportion of 1-methoxy-1-vinyl-1-sila-2,7-dioxa-4,5-(1,2-carborane)cycloheptane (n) in the **16–17** copolymer. The proportion of active cross-link points: (1) 1; (2) 0.9; (3) 0.8; (4) 0.7; (5) 0.6; (6) 0.5; and (7) 0.4. The points represent experimental values.

The structures **18a–c** contain respectively mono-, di-, and polysulfide bridges, and structure **18d** is the initial polyisoprene repeating unit. In the structure **18a**, all the atoms constitute the

cross-link point of the network; hence, $\left(\sum_i a_i \Delta V_i + \sum_j b_j\right) = 0$ for this structure. The values of all parameters of structures **18a–d** are listed in Table 1.

The glass transition temperature of the structure **18a** calculated using Eqn (6) coincides with the temperature of the onset of intense thermal degradation T_d (since all the atoms constitute the cross-link point of the network)

$$T_g = T_d = 673 \text{ K}.$$

Hence, if all sulfur is consumed for curing of the polyisoprene so that only monosulfide bonds are formed, then T_g should coincide with the temperature of the onset of intense thermal degradation, which is equal to 673 K. In practice, the glass transition temperature of ebonites lies in the interval 333–493 K (see Ref. 43); therefore it is likely that di- and possibly polysulfide bridges are formed in addition to the monosulfide bonds. Let us calculate the T_g value of a cross-linked system with different types of bridges between the polyisoprene chains.

Let us find a relation connecting the T_g value of ebonite with the mole fractions of bridges containing mono-, di-, and polysulfide groups. Let $\beta_1, \beta_2, \dots, \beta_n$ be the mole fractions of cross-link points (bridges) containing mono-, di-, and n -sulfide groups, respectively. With a given stoichiometric ratio of sulfur and polyisoprene, the appearance of one disulfide bond leads to one uncross-linked polyisoprene unit; the appearance of a trisulfide bond leads to two uncross-linked polyisoprene units, *etc.* Hence, the proportion of uncross-linked polyisoprene units will be equal to

$$\beta_u = \beta_2 + 2\beta_3 + \dots + (n-1)\beta_n = \sum_{i=2}^n \beta_i(i-1).$$

Then, having regard to the foregoing and this relation, we obtain

$$T_g = \left[\beta_1 \left(\sum_i \Delta V_i \right)_1 + \beta_2 \left(\sum_i \Delta V_i \right)_2 + \dots + \beta_n \left(\sum_i \Delta V_i \right)_n + \left(\sum_i \Delta V_i \right)_4 \sum_{i=2}^n \beta_i(i-1) \right] / \left\{ \beta_1 \left(\sum_i K_i \Delta V_i \right)_1 + \beta_2 \left(\sum_i K_i \Delta V_i \right)_2 + \dots + \beta_n \left[\left(\sum_i K_i \Delta V_i \right)_3 + \left(\sum_i a_i \Delta V_i \right)_3 \right] + \left(\sum_i a_i \Delta V_i + \sum_j b_j \right) \sum_{i=2}^n \beta_i(i-1) \right\}. \quad (31)$$

Here account is taken of the fact that

$$\sum_{i=2}^n \beta_i(i-1) = 1 - \beta_1 - \beta_2 - \dots - \beta_n = 1 - \sum_{i=1}^n \beta_i.$$

Let us consider several particular cases. If the network is formed only by mono- and disulfide cross-linking bridges, then

$$T_g = \left[\beta_1 \left(\sum_i \Delta V_i \right)_1 + \beta_2 \left(\sum_i \Delta V_i \right)_2 + (1 - \beta_1 - \beta_2) \left(\sum_i \Delta V_i \right)_4 \right] / \left[\beta_1 \left(\sum_i K_i \Delta V_i \right)_1 + \beta_2 \left(\sum_i K_i \Delta V_i \right)_2 + (1 - \beta_1 - \beta_2) \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_4 \right].$$

Taking account of the fact that $\beta_2 = 1 - \beta_1 - \beta_2$, finally we obtain

$$T_g = \left[(1 - 2\beta_2) \left(\sum_i \Delta V_i \right)_1 + \beta_2 \left(\sum_i \Delta V_i \right)_2 + \beta_2 \left(\sum_i \Delta V_i \right)_4 \right] / \left[(1 - 2\beta_2) \left(\sum_i K_i \Delta V_i \right)_1 + \beta_2 \left(\sum_i K_i \Delta V_i \right)_2 + \beta_2 \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_4 \right]. \quad (32)$$

Relationship (32) relates the T_g value of the ebonite network to the mole fraction of disulfide cross-linking bridges β_2 . Substituting the numerical values of all the increments in this relationship, we obtain

$$T_g = \frac{92.2 + 8.2\beta_2}{136.9 + 299.7\beta_2} \times 10^3.$$

The dependence of T_g on β_2 is shown in Fig. 14. As the proportion of disulfide bonds increases, the glass transition temperature gradually decreases and becomes equal to ~ 330 K at $\beta_2 = 0.5$ (in the case of disulfide bridges only).

It has been reported that only bridges with a small number of sulfur atoms are formed (the average number is taken to be 2.6).⁴³ Taking account of this fact, let us evaluate the effect of the proportion of bridges with different length (up to three sulfur atoms) on T_g .

We shall designate the number of cross-linked units as

$$m_c = m_1 + m_2 + m_3,$$

where m_1, m_2 , and m_3 are the numbers of units connected by mono-, di-, and trisulfide bridges, respectively. The total number of units (both cross-linked and free) is equal to

$$m_a + m_2 + 2m_3 = m_1 + m_2 + m_3 + m_2 + 2m_3 = m_1 + 2m_2 + 3m_3.$$

Then

$$\beta_1 = \frac{m_1}{m_1 + 2m_2 + 3m_3}, \quad \beta_2 = \frac{m_2}{m_1 + 2m_2 + 3m_3},$$

$$\beta_3 = \frac{m_3}{m_1 + 2m_2 + 3m_3}, \quad \beta_4 = \frac{m_2 + 2m_3}{m_1 + 2m_2 + 3m_3}.$$

Dividing the numerators and the denominators of these expressions by m_3 and substituting the relations obtained in Eqn (31), we get

$$T_g = 10^3 \left[92.2 \frac{m_1}{m_3} + 111.1 \frac{m_2}{m_3} + 130.0 + 81.5 \left(\frac{m_2}{m_3} + 2 \right) \right] / \left[136.9 \frac{m_1}{m_3} + 172.8 \frac{m_2}{m_3} + 239.5 + 413.25 \left(\frac{m_2}{m_3} + 2 \right) \right].$$

Figure 14. The calculated dependence of T_g of ebonites containing only mono- and disulfide cross-linking bridges on the proportion of the disulfide bonds.

Figure 15. The triangle diagram characterising the effect of the composition of the ebonite network on T_g . The numbers at isolines are the T_g (K) values.

Let us consider a triangle similar to the Gibbs triangle; the proportions of bridges with different bonds are plotted on the sides of the triangle, while the isolines represent the lines of equal glass transitions temperatures (Fig. 15). It can be seen that the T_g values of ebonites can vary over a very wide range if mono-, di-, and trisulfide bridges are present. The maximum softening temperature corresponding to the presence of monosulfide bridges only and coinciding in this case with the temperature of intense degradation is equal to 673 K; the minimum T_g (263 K) is characteristic of a network containing only trisulfide bridges.

It is also possible to conceive the cases where the sulfide bridges can have variable lengths and there is certain distribution in bridge lengths in the actual system. Such a situation has been considered in the literature;⁴² the glass transition temperatures of ebonites were calculated taking into account the function of length distribution of sulfide bridges. It has been concluded that the bridges cannot contain large number of sulfur atoms and that the claims of other authors that the bridges are formed mainly by disulfide chains are correct.

It thus follows that the glass transition temperature of a polymer increases upon cross-linking in all cases. This is particularly noticeable when the number of repeating units in linear fragments between cross-link points is small. However, a slight increase in T_g upon cross-linking is also observed in the case of a large number of repeating units in linear fragments. The reasons for such a behaviour of T_g have been considered.^{6, 44, 45} According to Shefer and Gottlieb,³⁹ one of the reasons is the decrease in the concentration of end groups leading to a complete loss of chain mobility. Other reasons are associated with transformation of low-molecular-weight molecules resulting in the formation of offshoots and cross-links, with non-Gaussian chain statistics, and with cyclisation.^{46–53}

According to a theory proposed by Hale, Macosko, and Bair,⁴⁵ the glass transition temperature of a polymer network is determined using the following equation

$$T_g = \frac{T_{g,u}}{(1 - K_2 X_c)/(1 - Y X_c^2)},$$

where K_2 is the DiMarzio constant dependent on the chemical structure of the polymer network, X_c is the density of active cross-link points, and Y is the parameter accounting for the non-Gaussian 'behaviour'. The $T_{g,u}$ value is determined from the following equation

$$\frac{1}{T_{g,u}} = \frac{1}{T_{g,\infty}} + \frac{K_1}{M_n},$$

where $T_{g,\infty}$ is the glass transition temperature of a polymer with an infinite molecular weight, and M_n is the number-average molecular weight.

According to a theory proposed by Stutz, Illers, and Mertes, the T_g value is described by the following equation⁴⁴

$$T_g = T_{g,u} \left(1 + \frac{K_2 X_c}{1 - X_c} \right),$$

where X_c is the density of cross-links defined as the mole fraction of all cross-links in the system divided by the network functionality.

Changes in the glass transition temperature of end-linked networks in the case of some violation of the stoichiometric ratio have been studied.⁴³ The polymer network had the following chemical structure

The experimental results of measuring the relative changes in T_g upon complete conversion of end groups in the reaction with a cross-linking agent are shown in Fig. 16. The following compound was chosen as cross-linking agent:

The authors of the study cited have concluded that their data correspond to the Hale–Macosko–Bair theory according to which changes in T_g become noticeable after the gel point; this is due to the contribution of elastically effective cross-link points

Figure 16. Relative changes in the glass transition temperatures of polymer networks estimated by different methods (r is the stoichiometric ratio). (1) the Stutz–Illers–Mertes method; (2) the Hale–Macosko–Bair method; (3) the Hale–Macosko–Bair method modified by Shefer and Gottlieb; and (4) the Askadskii–Matveev method.

absent in the pre-gel period. It can be said that this result corresponds to the conclusion of the Gibbs–DiMarzio theory, *viz.*, not any branching points but the elastically effective cross-link points make major contribution to the T_g value.

The Hale–Macosko–Bair theory modified by Shefer and Gottlieb makes it possible to approximate the dependence of the glass transition temperature T_g on the stoichiometric ratio r .

Let us consider the possibilities of application of this approach to the analysis of the changes in T_g upon cross-linking. The experimental dependence of the $(T_g - T_{g0})/(T_{g1} - T_{g0})$ ratio on the stoichiometric ratio r (here T_g is the glass transition temperature of the polymer network, T_{g0} is the glass transition temperature of the initial linear polymer, and T_{g1} is the glass transition temperature of the network at $r = 1$) can be described by Eqn (6). In this case, the initial linear polymer was polydimethylsiloxane with vinyl end groups and a number-average molecular weight M_n of 3500.

Let us consider a case with $r = 1$, where a tetrafunctional cross-link point is formed. The calculated parameters of the network with these points are given in Table 1. Substituting these values in Eqn (6), we obtain the dependence of the glass transition temperature T_g on the number (m) of polydimethylsiloxane repeating units between the cross-link points

$$T_g = \frac{714.4 + 144.2m}{4289 + 962m} \times 10^3. \quad (33)$$

If $r < 1$ (a deficit of cross-linking agent), then ‘dangled’ chains are formed as a result of the reaction between one functional group of linear polydimethylsiloxane and the cross-linking agent. The structure of such a system is shown below:

The following parameters were found for a dangled chain marked by a dashed line:

$$\left(\sum_i \Delta V_i \right)_{dc} = 274 + 72.1m,$$

$$\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{dc} = (1634 + 481m) \times 10^{-3} \text{ Å}^3 \text{ K}^{-1}.$$

According to the principle of calculation of the glass transition temperature (see above), if a chain issuing out of the branching point does not reach another branching point and remains dangled (*i.e.*, no cross-link between two chains is formed), then such a branching point cannot be considered as a cross-link point. In this case a_i and b_j increments should be used in Eqn (6) instead of K_i increments for the atoms constituting the branching point and we obtain

$$\left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{c-1} = 319.8 \times 10^{-3} \text{ Å}^3 \text{ K}^{-1}.$$

In the presence of dangled chains Eqn (6) can be written in general form as follows:

$$T_g = \left\{ \left[\left(\sum_i \Delta V_i \right)_{c-1} + 2 \left(\sum_i \Delta V_i \right)_1 \right] r + \right. \quad (34)$$

$$\left. + 2 \left(\sum_i \Delta V_i \right)_{dc} (1-r) \right] / \left[\left(\sum_i K_i \Delta V_i \right)_{c-1} r + \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{c-1} (1-r) + 2 \left(\sum_i a_i \Delta V_i + \sum_j b_j \right) r + 2 \left(\sum_i a_i \Delta V_i + \sum_j b_j \right)_{dc} (1-r) \right] \}; \quad r \leq 1.$$

It is natural that if $r = 1$, then Eqn (34) becomes relationship (33). Substituting the values of all the parameters found preliminarily in Eqn (34) gives

$$T_g = \frac{583.0 + 131.4r + 144.2m}{3588 + 701r + 962m} \times 10^3. \quad (35)$$

It should be noted that end-group cross-linking of polydimethylsiloxane chains with a rather high molecular weight (M_n) of 3500 leads to a very small increase in the glass transition temperature.

Let us express the $(T_g - T_{g0})/(T_{g1} - T_{g0})$ ratio using relationships (33) and (35). According to Eqn (35), $T_{g0} = 150.88 \text{ K}$ at $r = 1$; taking account of this fact, we obtain for $r \leq 1$

$$\frac{T_g - T_{g0}}{T_{g1} - T_{g0}} = \frac{(41.6 + 25.63r - 0.95m)(4289 + 962m)}{(3588 + 701r + 962m)(67.3 - 0.95m)}. \quad (36)$$

The results of calculations using relationship (36) are shown in Fig. 16. The experimental data as well as three theoretical dependences found by the Stutz–Illers–Mertes method, by the Hale–Macosko–Bair method, and by the Hale–Macosko–Bair method modified by Shefer and Gottlieb are also plotted in this figure. As can be seen, experimental and calculated dependences are in fairly good agreement; however, it is noteworthy that Eqn (36) contains no fitting parameters and that all the parameters of this equation are determined based on the chemical structure of the network without using experimental parameters.

Let us consider a situation when the cross-linking agent is present in excess ($r > 1$). Here, (1) trifunctional cross-link points rather than tetrafunctional cross-link points, (2) long chains between cross-link points, and (3) a network with cross-link points whose functionality varies from 0 to 4 can be formed. Clearly, a portion of the cross-linking agent does not react with end groups and this substance acts as plasticiser.

Let us consider only one case where long chains between cross-link points are formed. Such a situation is possible for $r = 2$. The system has the following chemical structure

The following parameters for the fragment between the dashed lines were found for the portion of the cross-linking agent constituting the chain and forming this structure:

$$\left(\sum_i \Delta V_i \right)_{c-1} = 184.1 \text{ Å}^3;$$

$$\left(\sum_i a_i \Delta V_i + \sum_j b_j \right) = 1353.2 \times 10^{-3} \text{ Å}^3 \text{ K}^{-1}.$$

For polydimethylsiloxane (PDMS) chains with the $-(\text{CH}_2)_2-\text{Si}-(\text{CH}_3)_2$ fragments we have

$$\left(\sum_i \Delta V_i\right)_{\text{PDMS}} = 339.7 + 72.1m \text{ \AA}^3;$$

$$\left(\sum_i a_i \Delta V_i + \sum_j b_j\right)_{\text{PDMS}} = (2120.6 + 481m) \times 10^{-3} \text{ \AA}^3 \text{ K}^{-1}.$$

If $r = 2$, then the glass transition temperature is determined from the following relationship

$$T_g = \frac{523.8 + 72.1m}{3473.8 + 481m} \times 10^3. \quad (37)$$

If $m = 44$, which corresponds to a M_n of 3500, then the $(T_g - T_{g0})/(T_{g1} - T_{g0})$ ratio becomes negative. However, as can be seen in Fig. 16, the experimental value of this ratio is equal to 0.5 at $r = 2$; this means that the formation of entirely linear chains is impossible. In addition to linear chains, the system must also contain cross-links. Their proportion can be determined from relationships (35) for $r = 1$ and (37), and for this network ($m = 44$) we obtain

$$T_g = \frac{7059.2\alpha + 3696.2(1-\alpha)}{46617\alpha + 24637.8(1-\alpha)} \times 10^3. \quad (38)$$

Using the experimental value (0.5) of the $(T_g - T_{g0})/(T_{g1} - T_{g0})$ ratio and Eqn (38), we can find that $\alpha = 0.7$. Hence, this system contains a mixture of linear and cross-linked fragments. Thus, the approach described also makes it possible to solve the inverse problem, *viz.*, to determine the degree of cross-linking α from experimental data on changes in the glass transition temperature.

Thus, any changes in the network topology lead to changing the chemical structure of the entire system, which is of crucial importance in the case of highly cross-linked networks and considerably affects their properties. This approach takes into account all changes in the network structure, which makes possible to describe the properties with a good accuracy. The calculations do not require the use of the so-called fitting parameters, which are unknown beforehand and should be found from the experimental dependences. Alternative approaches for the description of the glass transition temperature of polymer networks have been analysed using a number of particular examples. Though they can be used to describe, *e.g.*, the dependence of the glass transition temperature on the degree of cross-linking with a good accuracy, they require introducing fitting parameters, *i.e.*, are devoid of predictive power.

V. The equilibrium rubbery modulus of polymer networks

1. Computational methods for estimating the equilibrium modulus

To estimate the equilibrium rubbery modulus E_∞ and the molecular weight of the network fragment M_c in the case of cross-linked elastomers with fairly sparse cross-links, the known equation of the classical theory of rubber elasticity is used

$$E_\infty = 3\rho \frac{RT}{M_c}, \quad (39)$$

where ρ is the density of the cross-linked elastomer, R is the universal gas constant, and T is the absolute temperature.

The application of Eqn (39) to highly cross-linked networks with linear fragments containing a very small number of repeating units (down to one or even less) leads to considerable discrepancies between the experimental and calculated E_∞ values.

Equation (39) can be used to describe the properties of highly cross-linked networks if the so-called front factor ϕ is introduced

$$E_\infty = \phi 3\rho \frac{RT}{M_c}.$$

However, the introduction of the front factor does not alter the situation for the better, since comparing the calculated and experimental E_∞ values allows one only to evaluate this front factor. Therefore, an attempt was made to obtain a generalised equation for estimating E and M_c that would be valid in the case of both sparse and highly cross-linked networks.⁵⁴

Let us perform a detailed analysis of the influence of a large number of cross-link points on the equilibrium rubbery modulus. It should be noted preliminarily that the van der Waals volume of cross-link points for sparse networks is incommensurably less than that of linear network fragments; therefore, it can be neglected when estimating the compressibility of a cross-linked system. This is impossible in the case of highly cross-linked networks, since the total van der Waals volumes of cross-link points and of linear fragments are nearly the same (the former may even be larger than the latter).

Considering the cross-linked elastomer as a system consisting of two subsystems (elastic and rotational-isomeric), let us analyse first the latter subsystem. It has been shown⁷ that the force constant of a rotational-isomeric subsystem can be determined if the difference in the energies of rotational isomers is known, which depends on the size of 'molecular defects' l_i^d in the polymer in the following way:

$$\Delta E_i = 4D_i a^2 (l_i^d)^2, \quad (40)$$

where D_i is the averaged energy of intermolecular interaction characteristic of the given type of atom, and a is the constant of the Morse potential

$$\varphi(R) = D[(e^{-a(R-r_0)} - 1)^2 - 1],$$

where D is the depth of the potential well, and r_0 is the equilibrium interatomic distance in the harmonic approximation.

To determine the size of the molecular defect l_i^d , let us consider the 'cylinder of interaction' between two hydrogen atoms bonded to carbon atoms (Fig. 17).⁵⁵ The volume of the cylinder is the sum of the volumes of interacting atoms ΔV_i and the defect volume itself. The volumes of the 'cylinders of interaction' for the crystalline (V_c^{cr}) and amorphous (V_c^{a}) polymers are respectively

$$V_c^{\text{cr}} = 2\Delta V_i + \delta_i^{\text{cr}} \Delta V_i, \quad V_c^{\text{a}} = 2\Delta V_i + \delta_i^{\text{a}} \Delta V_i,$$

where ΔV_i is the van der Waals volume of the i th atom, and the quantities δ_i^{cr} and δ_i^{a} enter into the relationships for the molecular packing coefficients for the crystalline and amorphous polymers.

$$k_c = \frac{\sum_i \Delta V_i}{\sum_i \Delta V_i + \sum_i \delta_i^{\text{cr}} \Delta V_i}, \quad k_a = \frac{\sum_i \Delta V_i}{\sum_i \Delta V_i + \sum_i \delta_i^{\text{a}} \Delta V_i}.$$

The δ_i^{cr} and δ_i^{a} values for each atom can be found in the literature.⁵⁴

The defect size is

$$l_i^d = \frac{V_c^{\text{a}} - V_c^{\text{cr}}}{2S_c} = \frac{\delta_i^{\text{a}} - \delta_i^{\text{cr}}}{2} \frac{\Delta V_i}{S_c},$$

where ΔV_i is the part of the van der Waals volume of the i th atom which is overlapped by the van der Waals volume of the atom chemically bonded to it; a factor of 2 appears in the denominator because the amplitude of the jump of the i th atom is equal to half the defect size, and S_c is the base area of the 'cylinder of interaction'.

To estimate l_i^d , let us consider the limiting case where the base radius of the 'cylinder of interaction' is equal to the van der Waals radius of the i th atom. In this case we have

$$l_i^d = \frac{1}{3} R_i (\delta_i^{\text{a}} - \delta_i^{\text{cr}}).$$

Figure 17. The ‘cylinder of interaction’ of two hydrogen atoms; d_i is the length of the chemical bond between the H and C atoms, and L_i and S_i are respectively the height and the base area of the ‘cylinder of interaction’.

For hydrocarbon polymers, $R_i = R_H$ (R_H is the van der Waals radius of the hydrogen atom equal to 1.17 Å) and the defect size l_i^d is a constant equal to 0.053 R_H . Substituting the l_i^d value obtained in expression (40), we can determine the contribution of the hydrogen atom to the energy difference of rotational isomers: $\Delta E_H = 4.56 \text{ kJ mol}^{-1}$. The value obtained corresponds in order of magnitude to spectroscopic data on the energy difference of rotational isomers.

For further analysis, we rewrite relationship (40) in the form

$$\Delta E_i = 4D_i a^2 R_i^2 \left(\frac{l_i^d}{R_i} \right)^2, \quad (41)$$

where R_i is the van der Waals radius of the i th atom, and l_i^d is the size of the defect formed by the given atom.

The aR_i value was estimated as ~ 6 (Ref. 7).

To evaluate the contribution of the rotational-isomeric subsystem to the temperature dependence of the modulus of elasticity of the polymer in the transition zone and in the rubber-like region, it is necessary to find l_i^d values for different atoms and types of the intermolecular interaction.

The calculations of melting points of polymers (T_m) showed⁷ that the energy of the intermolecular interaction D_i for a given type of atom depends on whether it is a constituent of the atomic group that forms a hydrogen bond or is involved in the dipole-dipole interaction. Therefore, the influence of specific interaction will manifest itself mainly through the energy of intermolecular interaction D_i of the given type of atom when ΔE_i is calculated using formula (41), while δ_i^a and δ_i^{cr} increments are not affected by the hydrogen bonds and dipole–dipole interactions.

If a repeating unit consists of a set of different types of atoms, it is necessary to introduce the concept of the effective energy difference ΔE_{ef} of rotational isomers, which can be found as follows. To estimate the modulus of elasticity of amorphous polymers, let us use the following relationship⁷

$$E = \left(\sum_i \Delta V_i \right) / \sum_i \frac{\Delta V_i S_i}{\alpha_i l_i}, \quad (42)$$

where ΔV_i is the van der Waals volume of the i th atom of the repeating unit; S_i is the van der Waals surface of the i th atom; through this surface the intermolecular interaction occurs (see Fig. 17); α_i is the force constant of the i th atom; and l_i is the characteristic bond length.

For the rubbery state, the α_i coefficient in the denominator of expression (42) should be replaced by the force constant of the rotational-isomeric subsystem α_{ri} (see Ref. 7),

$$\alpha_{ri} = \frac{RT}{q_i (l_i^d)^2}, \quad (43)$$

where $q_i = \exp(\Delta E_i/RT)$, and ΔE_i is the energy difference of rotational isomers. Taking into account relationship (43), the denominator of Eqn (42) takes the form $\sum_i \Delta V_i (l_i^d)^2 S_i q_i / RT l_i^d$.

Let us introduce the effective parameter q_{ef} in such a way that it be determined from the condition

$$\sum_i \frac{(l_i^d)^2 S_i q_i}{l_i} \Delta V_i = \frac{(l_{ef}^d)^2 q_{ef} S_{ef} \sum_i \Delta V_i}{l_{ef}}. \quad (44)$$

Taking into account relationship (40), we obtain the following formula for l_{ef}

$$(l_{ef}^d)^2 = \frac{\Delta E_{ef}}{4D_{ef} a^2},$$

where $D_{ef} = \alpha RT_m$, $S_{ef} = \langle S \rangle$, and $l_{ef}^d = \langle l \rangle$. The condition (44) can be written as follows:

$$\sum_i \frac{(l_i^d)^2 S_i q_i}{l_i} \Delta V_i \Big|_{T=T_m} = \frac{\Delta E_{ef} q_{ef} \langle S \rangle}{4\alpha RT_m a^2 \langle l \rangle} \sum_i \Delta V_i. \quad (45)$$

The left side of expression (45) and the quantities $\langle S \rangle$ and $\langle l \rangle$ in the right side are known. Therefore, the problem is reduced to the search for the solution of an equation of the type $b = xe^x$, where $x = \Delta E_{ef}/RT_m$, and b includes all the known terms of Eqn (45). This will make it possible to determine how different types of atoms affect ΔE_{ef} . If a hydrogen atom (and the corresponding ΔE_H value) is taken as the initial (the most typical) atom constituting polymers, then the appearance of other types of atoms with ΔE_i in the structure of the repeating unit will change ΔE_{ef} , the change being dependent on the statistical weight of these types of atoms in the repeating unit. The ΔE_{ef} value will either increase or decrease: $\Delta E_{ef} > \Delta E_H$ if $\Delta E_i > \Delta E_H$, and $\Delta E_{ef} < \Delta E_H$ if $\Delta E_i < \Delta E_H$.

Let us examine now the influence of the degree of cross-linking on the modulus of elasticity of a cross-linked polymer in the rubbery state. Considering a network polymer as a mixture of linear fragments and cross-link points, we write

$$\frac{1}{E_c} = \frac{\gamma}{E_l} + \frac{1-\gamma}{E_{c-1}} \quad \text{or} \quad E_c = \frac{E_l}{\gamma + (1-\gamma)E_l/E_{c-1}}, \quad (46)$$

where E_l and E_{c-1} are the moduli of elasticity for linear fragments and cross-link points, respectively, and γ is the concentration (fraction) of linear fragments.

Formula (46) was obtained by summing the compressibilities of linear fragments of the polymer chain and cross-link points, hence

$$\gamma = \left(\sum_i \Delta V_i \right)_l / \left(\sum_i \Delta V_i \right)_f.$$

The $\left(\sum_i \Delta V_i \right)_l / \left(\sum_i \Delta V_i \right)_f$ ratio can be written in the form

$$\frac{\left(\sum_i \Delta V_i \right)_l}{\left(\sum_i \Delta V_i \right)_f} = \frac{n \left(\sum_i \Delta V_i \right)_l^0}{n \left(\sum_i \Delta V_i \right)_l^0 + \left(\sum_i \Delta V_i \right)_{c-1}},$$

where n is the number of repeating units per cross-link point, and

$\left(\sum_i \Delta V_i \right)_l^0$ is the van der Waals volume of the repeating unit of the linear fragment.

Let us introduce the following designations: $\zeta = E_l/E_{c-1}$ and

$\beta = \left(\sum_i \Delta V_i \right)_{c-1} / \left(\sum_i \Delta V_i \right)_l^0$, where E_l is the modulus of

elasticity of a linear polymer and E_{c-1} is the modulus of elasticity of a cross-linked polymer consisting of nothing but cross-link points. Then we obtain the following relationship:

$$\gamma = \frac{n}{n + \beta}.$$

Expression (46) can be transformed to the form

$$\frac{E_l}{E_c} = \gamma + (1 - \gamma) \frac{E_l}{E_{c-1}} = \frac{n}{n + \beta} + \frac{\beta \zeta}{n + \beta}. \quad (47)$$

Since the polymer consisting of nothing but cross-link points has the modulus of elasticity many decimal orders of magnitude larger than that of the linear elastomer, then $\zeta \ll 1$ and for highly cross-linked networks $\zeta \ll \beta$. Hence the second term in expression (47) can be neglected, *i.e.*,

$$\frac{E_l}{E_c} = \frac{n}{n + \beta}. \quad (47a)$$

We revert now to the effective l_{ef} , q_{ef} , l_{ef}^d , and S_{ef} values. Taking into account the fact that the force constant of a rotational-isomeric subsystem is proportional to the mean-statistical number of the repeating units in the linear fragments between cross-link points (n), we can rewrite the relationship (42) in the form

$$E_l = \frac{l_{ef} RT}{(l_{ef}^d)^2 q_{ef} S_{ef} n},$$

and the modulus of elasticity of the rotational-isomeric subsystem of such a hypothetical polymer at $n_0 = 1$ and at temperature $T = T_0$ is

$$(E_l)_0 = \frac{l_{ef} RT_0}{(l_{ef}^d)^2 q_{ef}^0 S_{ef}}.$$

The ratio of these moduli is

$$\frac{E_l}{(E_l)_0} = \frac{T}{T_0} \frac{q_{ef}^0}{q_{ef} n}, \quad (48)$$

where $q_{ef} = \exp(\Delta E_{ef}/RT)$ and $q_{ef}^0 = \exp(\Delta E_{ef}/RT_0)$.

Substituting expression (48) in relationship (47a), we have

$$\frac{E_c}{(E_l)_0} = \frac{n + \beta}{n^2} \frac{T}{T_0} \frac{q_{ef}^0}{q_{ef}}. \quad (49)$$

For practical calculations account must be taken of the fact that the repeating network fragment consists of $n\Phi/2$ repeating units; therefore, with consideration of functionality Φ , expression (49) should be written as

$$\frac{E_c}{(E_l)_0} = \frac{2(n + \beta)}{\Phi n^2} \frac{T q_{ef}^0}{T_0 q_{ef}}. \quad (50)$$

Let us analyse Eqn (50) in more detail and compare it with the equation given by the classical theory of rubber elasticity (39). It can be seen that these equations are similar and Eqn (50) describes the modulus of elasticity for both sparse and highly cross-linked networks. In fact, if we write $n = M_c/M_0$, then from Eqn (50) we obtain

$$E_c = (E_l)_0 \frac{2}{\Phi} \frac{M_c/M_0 + \beta}{(M_c/M_0)^2} \frac{T}{T_0} \frac{q_{ef}^0}{q_{ef}},$$

where M_0 is the molecular weight of the repeating unit.

For sparse networks, $\beta \ll M_c/M_0$, then

$$E_c = (E_l)_0 \frac{2}{\Phi} \frac{M_0}{M_c} \frac{T}{T_0} \frac{q_{ef}^0}{q_{ef}}. \quad (51)$$

Comparing formulae (39) and (51), we get

$$(E_l)_0 = \frac{3\rho R \Phi T_0 q_{ef}^0}{2M_0 q_{ef}}. \quad (52)$$

If the modulus of elasticity is measured at $T = T_0$, then $q_{ef} = q_{ef}^0$, and Eqn (50) simplifies and takes the form

$$E_c = (E_l)_0 \frac{2(n + \beta)}{\Phi n^2}. \quad (53)$$

If chain fragments between cross-link points are long (sparse networks), the condition $\beta \ll n$ is fulfilled and Eqn (53) goes over into the following relationship

$$E_c = (E_l)_0 \frac{2}{\Phi n},$$

and, with consideration of relationships $T_0/T = q_{ef}^0/q_{ef}$ and $M_0 n = M_c$, we obtain

$$E_c = \frac{3\rho RT}{M_c}, \quad (54)$$

i.e., Eqns (54) and (39) coincide.

Relationship (53) is convenient for practical calculations of the modulus of elasticity of highly cross-linked networks; the $(E_l)_0$ value can be either calculated using Eqn (52) or determined from experimental data on the equilibrium modulus of elasticity of sparse networks where $n \gg 1$.

Let us perform several additional transformations. At $T = T_0$ and $q_{ef} = q_{ef}^0$, expression (52) takes the form

$$(E_l)_0 = \frac{3\rho R \Phi T}{2M_0}. \quad (55)$$

From relationships (53) and (55) we get

$$E_c = \frac{3\rho RT(n + \beta)}{M_0 n^2}, \quad (56)$$

and from formula (56), taking account that $M_c = M_0 n$, we obtain

$$E_c = \frac{3\rho RT(n + \beta)}{M_c n}. \quad (57)$$

Let us divide the numerator and the denominator of formula (57) by n ; then

$$E_c = \frac{3\rho RT(1 + \beta/n)}{M_c} \quad (58)$$

or

$$M_c = \frac{3\rho RT(1 + \beta/n)}{E_c}. \quad (59)$$

For a sparse network, $\beta \ll 1$ and $n \gg 1$; therefore, $\beta/n \rightarrow 0$ and the generalised equation (58) goes over into conventional Eqn (39).

In the case of highly cross-linked networks, the M_c value can be evaluated using formula (59). For the sake of convenience it can be transformed (considering that $n = M_c/M_0$) to the following form

$$E_c = \frac{3\rho RT(1 + \beta M_0/M_c)}{M_c}.$$

From this equation we get

$$M_c = \frac{3\rho RT + \sqrt{3\rho RT(3\rho RT + 4E_c M_0 \beta)}}{2E_c}. \quad (60)$$

For sparse networks, $\beta \rightarrow 0$ and formula (60) goes over into Eqn (39).

2. The equilibrium rubbery modulus of model networks

Let us consider a model polydimethylsiloxane-based network studied by Mark and Sullivan⁵⁶ as an example. The network structure is shown below

The cross-link point of the network is marked by dashed lines. For this network, we have

$$\left(\sum_i \Delta V_i\right)_{c-1} = 34.7 \text{ \AA}, \quad \left(\sum_i \Delta V_i\right)_1 = 72.1 \text{ \AA},$$

$$\beta = \frac{34.7}{72.1} = 0.481.$$

All details of the chemical structure of the network should be taken into account when calculating the equilibrium rubbery modulus of highly cross-linked networks using Eqn (53) and the glass transition temperature T_g using Eqn (6). The point is that at $m = 0$ this network has the following structure

In this case only a part of the unit **A** is a constituent of a linear chain fragment between neighbouring cross-link points of the network, since the oxygen atom of this unit is shared by the neighbouring cross-link point. For the quantity n defined as the

$\left(\sum_i \Delta V_i\right)_1^* / \left(\sum_i \Delta V_i\right)_1^0$ ratio in which the numerator is equal to the van der Waals volume of the group **B**, we get $n = 0.99$. If $m = 1$, then $n = 1.99$, etc. Taking account of this fact is of prime importance when calculating the glass transition temperature T_g using Eqn (6). In this case Eqn (6) goes over into the following formula

$$T_g = \frac{\left(\sum_i \Delta V_i\right)_{c-1}^* + m \left(\sum_i \Delta V_i\right)_1^0 + \left(\sum_i \Delta V_i\right)_1^*}{\left(\sum_i K_i \Delta V_i\right)_{c-1} + m \left(\sum_i a_i \Delta V_i\right)_1^0 + \left(\sum_i a_i \Delta V_i\right)_1^*},$$

where the second and the third terms in the denominator are the sets of increments for the units **A** and **B**, respectively (note that in the case of the network considered $\sum_j b_j = 0$).

To calculate the equilibrium rubbery modulus E_c using Eqn (53), it is necessary first to evaluate the $(E_l)_0$ value. It has been mentioned above that this can be done in two ways. The first way is to use formula (55), i.e., the $(E_l)_0$ value is determined entirely by computation. Substituting $\rho = 1.169 \text{ g cm}^{-3}$, $\Phi = 4$,

Table 2. Characteristics of polydimethylsiloxane networks.

m	n	β	E_c/MPa	T_g/K
0	0.99	0.482	148	183
1	1.99	0.241	61.5	166
2	2.99	0.160	38.2	161
3	3.99	0.120	27.6	158
4	4.99	0.096	21.6	156
6	6.99	0.069	15.0	154
9	9.99	0.048	10.3	153

$M_0 = 74.15$, and $T = 293 \text{ K}$ in this formula, we obtain $(E_l)_0 = 230 \text{ MPa}$.

The second way is to use formula (53) and the experimental E_c value for a sparse network. Using the experimental E_c value obtained by Mark and Sullivan⁵⁶ and Eqn (53), we get $(E_l)_0 = 197 \text{ MPa}$. The calculations of E_c using formula (53) and this $(E_l)_0$ value lead to the values of the equilibrium moduli listed in Table 2. It can be seen that the E_c value increases rapidly and for a very highly cross-linked network ($n = 1$) large E_c values are reached as the distance between adjacent cross-link points of the network decreases. It should be noted that the glass transition temperature remains below room temperature.

In the preceding section, we have considered the possibilities of evaluating the equilibrium rubbery modulus for highly cross-linked networks based on their chemical structure. However, the inverse problem, viz., the estimation of the composition of the microphase that forms effective cross-link points of the network, can also be solved.

In fact, if the chemical structure of the cross-linking agent differs essentially from that of chains subjected to cross-linking, microphase separation can occur. Let us analyse several systems. Considerable attention has been focused recently on the so-called bimodal networks.^{57–59} The mechanical behaviour of such networks was studied by Sharaf and Mark.⁶⁰ These networks can be prepared by different methods, e.g., by random ‘along-the-chain’ cross-linking of polydimethylsiloxane chains containing reactive methylvinylsiloxane units. If the cross-linking agent has the chemical structure shown below,

then the following bimodal networks are formed:^{61, 62}

Tetrakisdimethylsiloxysilane is also used as cross-linking agent.^{63–65} The mechanical properties of networks with this cross-linking agent have been studied^{61–65} and it has been

shown^{63–65} that the experimental data are in good agreement with the results obtained using the Flory–Erman theory.^{66–68} However, Gottlieb *et al.*^{61, 62} have found that the values of the moduli of elasticity are considerably larger (by 10%–15%) than those predicted by the Flory–Erman theory based on the density of cross-links. The discrepancy can be due to neglecting the contribution of active entanglements.⁶⁰ With this contribution taken into account, the values calculated using the Flory–Erman theory and the experimental ones coincide.^{61, 62}

Other approaches explaining the discrepancy between the calculated and experimental data are also possible. For instance, the following explanation of the discrepancy mentioned is proposed. It is based on assumptions made by Sharaf and Mark^{57–59} that short segments between cross-link points located along the molecule subjected to cross-linking can act as elastically effective chains by themselves. In accordance with this, it has been postulated that the length distribution of the network chains is bimodal.^{57–59} Several investigators interpret large values of the modulus of elasticity obtained in the case of small deformations as a consequence of the contributions of short chains formed by the cross-linking agent (Fig. 18a).⁶⁰

Another explanation of the experimental fact that the modulus of elasticity increases (all things being the same) due to the presence of short chains between cross-link points can be based on the approach described above. According to this approach, the equilibrium rubbery modulus is calculated using generalised Eqns (56) or (58). In this case, the definition of the cross-link point of the network given in the Introduction is used. However, when the chemical structure of linear chains and that of the cross-linking agent differ essentially, the concept of ‘a cross-link point of the network’ can become more complicated. According to the initial definition of ‘a cross-link point of the network’, which is valid when calculating glass transition temperatures, this cross-link point is marked by dashed lines. However, the possibility of microphase separation should be considered when analysing and calculating the equilibrium rubbery modulus. Here, one microphase is the polydimethylsiloxane microphase, while the other is that formed by the cross-linking agent. In this case (see Fig. 18b), the cross-link point of the network consists of the cross-linking agent with the adjacent CH₂ groups; this cross-link point is marked by double dashed lines.

In order that a microphase be able to act as a cross-link point, it must be rigid. Such a situation occurs in the case of block copolymers. For instance, in polystyrene–polybutadiene block copolymers the polystyrene domains act as cross-link points while the polybutadiene component plays the role of the rubber matrix. It is possible to calculate the possibility of microphase separation computationally from the difference of the surface energies of microphases. According to calculations of the surface energies for polydimethylsiloxane chains and for the complicated cross-link point (see Fig. 18b) using the method proposed in the literature,^{69, 70} the surface energy of polydimethylsiloxane chains is equal to 20.7 dyn cm^{−1} while that of the cross-linking agent is

equal to 30 dyn cm^{−1}. The difference between these energies is quite sufficient for microphase separation.

Assuming that rigid domains play the role of cross-link points, the van der Waals volume of such a cross-link point is equal to 315.8 Å³. The van der Waals volume of the polydimethylsiloxane repeating unit is equal to 108.15 Å³; therefore, the β value in Eqn (56) will be equal to 2.92. Now it is necessary to evaluate the $(E_i)_0$ value using Eqn (55). Substituting all the parameters required, we get that $(E_i)_0 = 149$ MPa at room temperature. Then, Eqn (56) can be written as follows:

$$E_c = 149 \frac{2(173 - a \cdot 2.92)}{3 \times 173^2},$$

where a is the number of the structures **1** in the complicated cross-link point.

Since the mole fraction of methylvinylsiloxane units was equal to 0.0057 (Ref. 56), a factor of 173 appears in the denominator of the last relationship. The fact that the experimental moduli are 15%–25% larger than those predicted by theory indicates that the complicated cross-link point contains 9–15 units of the cross-linking agent. This example shows that the approach described above also makes it possible to solve the inverse problem by comparing the calculated and experimental values of the equilibrium rubbery modulus, to assess the network structure, and to determine the structure of the cross-link point.

Thus, on going to highly cross-linked networks, when the linear fragment contains less than five repeating units, the account of the influence of the chemical structure of the cross-link point becomes necessary for a correct evaluation of the equilibrium rubbery modulus. Using this approach, one can eliminate the unpredictable front factor usually introduced into the classical equation of the rubber elasticity theory to obtain coincidence between the calculated and experimental values of the equilibrium rubbery modulus. The use of generalised Eqn (58) makes it possible to predict the equilibrium rubbery modulus value with a good accuracy, thus providing a way of designing the chemical structure of the network for the preparation of materials with unusual properties.

VI. Different-modulus and gradient-modulus polymers based on highly cross-linked networks

In this section we will consider the use of computational schemes that make it possible to evaluate the glass transition temperatures T_g and the equilibrium rubbery moduli E of highly cross-linked networks in designing polymeric materials with unusual properties. The case in point will be the design and preparation of two types of elastic different-modulus polymeric materials: (1) materials for which the modulus of elasticity is constant for each specimen but varies over a very wide range from one specimen to another, and (2) materials in which the modulus of elasticity changes gradually in a prescribed manner within the same specimen in which no layers and interfaces are present.

For example, gradual transition from rubber to plastic or *vice versa* is required within the same specimen. Such a transition will allow one to design complex different-modulus constructions without using traditional methods of joining, *viz.*, gluing, welding, *etc.* The problem of realisation of this idea is associated with two fundamental peculiarities of the behaviour of polymeric materials that require clarification.

The temperature dependence of the modulus of elasticity of a typical polymer is represented schematically in Fig. 19; unfortunately, in the glassy state region the modulus of elasticity depends slightly on the chemical structure of the polymer and varies within the limits $(2–3) \times 10^3$ MPa. Therein lies the first problem of preparing different-modulus and gradient-modulus materials. Within the temperature zone of transition from the glassy to the rubbery state, the modulus of elasticity decreases sharply in the narrow temperature interval ($\Delta T = 20–30^\circ$). In this connection, it may appear at first glance that the problem of obtaining polymers

Figure 18. A scheme of a topological structure of polydimethylsiloxane networks cross-linked by a short-chain cross-linking agent. (a) the formation of bimodal networks according to Sharaf and Mark;⁶⁰ (b) the topological structure of the same network in the case of microphase separation.

Figure 19. Temperature dependence of the modulus of elasticity.

with different moduli of elasticity varying, *e.g.*, in the interval from 3×10^3 to 3 MPa, is simple, *viz.*, it is merely necessary to obtain polymers with glass transition temperatures close to room temperature (if different-modulus materials must be used at room temperature). However, as is known, materials possess pronounced viscoelastic behaviour in the transition zone; in addition, their mechanical properties change sharply as the temperature either slightly decreases (transition to plastic) or increases (transition to rubber). Therein lies the second problem of obtaining different-modulus materials, which, in addition to the wide range of changes in the modulus of elasticity, must possess elastic rather than viscoelastic properties and retain the predetermined gradient of properties over a wide temperature range.

Theoretically, the materials free of plasticisers or fillers and possessing the moduli of elasticity varying over a wide range can be obtained by designing and preparing highly cross-linked network structures containing bulky rigid cross-link points connected by flexible linear chains of controlled lengths (Fig. 20). This follows from the generalised Eqn (58), which can be used for evaluating the equilibrium rubbery modulus E of cross-linked systems.

Figure 20. A scheme of a structure of a network containing bulky cross-link points and short and flexible linear chains.

According to Eqn (58), large E value can be achieved on going to highly cross-linked networks with bulky cross-link points where $n \rightarrow 1$ and $\beta > 1$. In this case, linear fragments between cross-link points should be very flexible to retain the low glass transition temperature.

Cross-linked polyisocyanurates of the following chemical structure were synthesised^{71–77} as structures containing rigid bulky cross-link points connected by flexible linear ($-R-$) chains:

The trifunctional isocyanurate ring plays the role of a cross-link point (outlined by dashes).

Short organosilicon chains with $n = 1-4$ were used as linear fragments.^{71,72}

In other studies, cross-linked copolymeric polyisocyanurates were obtained.^{73–76}

Oligomeric diols were used as one of the initial components in the synthesis of these materials. Reactions of these diols with a diisocyanate (in particular, with toluylene 2,4-diisocyanate) resulted in macrodiisocyanates with urethane backbone

Commercial oligomeric rubbers with hydroxyl end groups (*e.g.*, the PF-OP-15 polyether, an oligomeric tetrahydrofuran-propene oxide copolymer) can be used as diols.

Macrodiisocyanates obtained from oligomeric rubbers undergo polycyclotrimerisation *in situ* and copolymerisation with diisocyanates of any structure (aromatic, alicyclic, or aliphatic) that are capable of forming cross-linked polyisocyanurates at a sufficient rate to yield cross-linked polymers. Actually, copolymers of mixed structures are prepared. The polymer simultaneously contains a network built of the products of homopolycyclotrimerisation of both the oligomer and the diisocyanate and a network with linear chains randomly distributed in the structure as a result of reaction of the oligomer with the diisocyanate.

The content of rigid cyclic structures in the network formed increases with the increase in the excess of diisocyanate with respect to the oligomeric macrodiisocyanate in the initial reaction mixture. Thus, the ratio of flexible (polyether) and rigid (isocyanurate rings with adjacent cyclic diisocyanates) fragments can be arbitrarily changed, which permits controlling the mechanical properties over a wide range. To check the possibility of controlling the properties of polymer networks in this way, glass transition temperatures of these cross-linked systems with variable chemical composition were calculated preliminarily using Eqn (6). Gradual decrease in T_g with an increase in the proportion of flexible rubber fragment can be seen in Fig. 21.

Calculations of the equilibrium modulus of elasticity using Eqn (53) have shown⁷⁴ that if T_g is below room temperature, the equilibrium modulus E_∞ can reach high values, intermediate between those of rubber and plastic. Such kind of preliminary calculations was carried out for networks with organosilicon linear fragments.^{71,72} As a result, the following expression relating the T_g value of the network to the number of dimethyl-siloxane units (n) in the linear fragment was obtained for the structure in question

$$T_g = \frac{751 + 108.15n}{2450 + 721.5n} \times 10^3. \quad (61)$$

Figure 21. Dependence of the calculated glass transition temperature T_g of polyisocyanurate polymers based on diisocyanates of different structure on the mole fraction α of the PF-OP-15 rubber.

The results of calculations carried out using expression (61) are listed in Table 3. It can be seen that the T_g values are below room temperature and decrease as n increases approaching the glass transition temperature of polydimethylsiloxane.

The values of the equilibrium moduli which fall into the range from 3 to 886 MPa depending on the n value are also listed in Table 3.

Experimental studies of cross-linked polymers with the structure considered above confirmed the correctness of the assumptions made and calculations carried out.^{71, 72} Thus, the E_∞ values of the networks obtained with organosilicon linear fragments change over a range from 3 to 3×10^3 MPa (Fig. 22) depending on the length of the linear fragment.

Microphase separation due to considerably different surface energies of organosilicon chains ($\sim 21 \text{ dyn cm}^{-1}$) and isocyanurate cross-link points ($\sim 35 \text{ dyn cm}^{-1}$) is of great importance for such materials; its development was confirmed by X-ray photoelectron spectroscopy, electron microscopy, and dynamic mechanical analysis.^{71, 72}

The microphase separation can occur both in linear block copolymers (or polymer mixtures) and in polymer networks. Two clearly defined maxima are observed in these cases in the temperature dependence of the loss factor $\tan \delta$.

Table 3. Calculated and experimental characteristics of cured macrodiisocyanates.

n	T_g/K	E/MPa	
		Calculated	Experimental
0	310	—	—
1	271	884	886
2	268	249	283
3	232	123	149
6	206	40	43
9	193	22	24
19	174	8	7
43	161	3	3
∞	150	—	—

Figure 22. Dependence of the modulus of elasticity E on the number of dimethylsiloxane units n in linear fragments of polyisocyanurate networks.

The temperature dependence of the loss factor $\tan \delta$ for block specimens of the polyisocyanurates under consideration with different lengths of linear organosilicon fragments is shown in Fig. 23. The low-temperature peak is shifted towards low temperatures as the length of the linear fragment increases approaching the glass transition temperature of poly(dimethylsiloxane). The high-temperature maximum associated with the glass transition of the entire system is virtually independent of n starting from $n = 2$.

Thus, there are two rather clearly defined transition temperatures, which can be considered as the glass transition temperature of the polydimethylsiloxane microphase in the polymer network and the glass transition temperature of the microphase containing isocyanurate cross-link points with adjacent spacers. This suggests that the microphase separation caused by incompatibility of the polydimethylsiloxane fragments and isocyanurate cross-link points with adjacent spacers exists in the system.

Taking into account the fact that the transition temperatures in both microphases are shifted towards each other, one can calculate the compositions of the microphases provided that the transition temperature coincides with the glass transition temperatures of microphases of given compositions. Since the transition temperature of the microphase formed mainly of organosilicon fragments is higher than that of polydimethylsiloxane itself, it is obvious that the polydimethylsiloxane microphase contains neighbouring fragments.

What is the structure of these fragments? Glass transition temperatures of the following structures were calculated⁷² to answer this question

Figure 23. Temperature dependence of the loss factor $\tan \delta$ for block specimens of polyisocyanurate networks with different lengths of linear organosilicon fragments. n : (1) 1.2; (2) 2.1; (3) 3.2; (4) 5.4; (5) 9.2; (6) 22.

Glass transition temperatures of polydimethylsiloxane fragments with adjacent chain fragments indicated by dashed lines were calculated stepwise for different n using formula (6). These fragments were 'elongated' until the calculated glass transition temperature coincided with the experimentally determined temperature of the first transition. It turned out that the calculated and experimental transition temperatures coincide when the polydimethylsiloxane domains contain chain fragments marked by double dashed lines, the structure of these fragments being independent of n , i.e., of the length of the organosilicon chain. Such an approach to estimating the composition of microdomains can be extended to any objects characterised by microphase separation.

If microphase separation occurs in the system, then the concept of 'a cross-link point of the network' from the viewpoint of its chemical structure should be extended when calculating the equilibrium rubbery modulus. In fact, a rigid microphase (*e.g.*, consisting of isocyanurate cross-link points with adjacent spacers) plays the role of cross-link points provided that the glass transition temperature of this microphase is above room temperature. The presence of such a 'macro-cross-link point' leads to a considerable increase in the β value in Eqn (53), which favours the increase in the equilibrium rubbery modulus.

Such an analysis has been carried out for the system considered above⁷² and it was found that T_g of rigid domains is equal to 306 K and that their van der Waals volume is equal to 751 Å³.

Taking into account the van der Waals volume of the polydimethylsiloxane repeating unit ($180.15 \text{ \AA}^3$) we obtain $\beta = 751/180.15 \approx 4.2$.

The equilibrium rubbery moduli were determined experimentally⁷² from the stress relaxation curves approximated using physically well-founded memory functions.^{78–81}

The dependence of the modulus of elasticity of polyisocyanurate networks on the average number of repeating units in polydimethylsiloxane chains connecting the cross-link points is shown in Fig. 22. As was mentioned above, the range of numerical values of the modulus of elasticity for such networks exceeds the range characteristic of the zone of transition from the glassy to the rubbery state. However, despite this fact, these materials possess elastic mechanical behaviour characteristic of polymeric glasses rather than viscoelastic behaviour characteristic of all polymers in the transition zone. This is confirmed by the stress relaxation curves (Fig. 24). The first specimen was a

Figure 24. Stress relaxation curves for the ED-20 epoxy resin cured with methyltetrahydrophthalic anhydride (1) and a mixture of poly(sebacic anhydride) and azelaic acid (2), and for a polyisocyanurate network with linear organosilicon fragments with $n = 6.2$ (3).

conventional ED-20 epoxy resin cured with methyltetrahydrophthalic anhydride. This system has a glass transition temperature of 120 °C and is a glassy polymer at room temperature. Fast stress (σ) relaxation is observed in the initial period, then the drop in σ slows down, and the stress changes only slightly. The second specimen was an ED-20 epoxy resin cured with a mixture of poly(sebacic anhydride) and azelaic acid taken in such a proportion that the transition zone for this specimen was in the interval from -5 to 34 °C. The stress relaxation curve is characteristic of the transition zone, *i.e.*, fast stress relaxation virtually down to zero is observed.

The third specimen was a polysilycynurate network with linear organosilicon fragments ($n = 6.2$). With this size of linear chains, the initial stress σ_0 is nearly equal to that of the viscoelastic material (7.5 MPa). However, the mechanical behaviour is fundamentally different, *viz.*, fast but small stress relaxation is observed in the initial period and then the stress virtually ceases to drop, *i.e.*, the material behaves as an elastic glassy polymer.[§]

Let us consider the properties of gradient-modulus materials based on the oligomeric PF-OP-15 rubber and toluylene 2,4-diisocyanate.

To obtain gradient-modulus materials, the initial components are gradually measured out thus achieving the targeted control of the chemical composition of the network within the same specimen.

This allowed one to prepare specimens in which the modulus of elasticity changed from 4.5 MPa (which is characteristic of rubbers) to 2000 MPa (which is characteristic of plastics).^{75, 76} The change occurred smoothly within the same material (with no interfaces and intermediate layers).

The dependence of the modulus of elasticity on the content of toluylene 2,4-diisocyanate in the initial reaction mixture is shown in Fig. 25 as an example. It can be seen that the modulus of elasticity changes linearly along the length of the specimen so that a gradual transition from rubber to plastic occurs with no interfaces, as was mentioned above.

Figure 25. Dependence of the modulus of elasticity varying along the specimen length (l) on the content of toluylene 2,4-diisocyanate (G) in a mixture with oligomeric macrodiisocyanate.

To analyse the character of mechanical behaviour of the materials obtained, the stress relaxation curves were studied for

§ It is well to bear in mind that there are no absolutely elastic polymeric materials (except for ideal crystals). Therefore the terms 'elastic behaviour' and 'elastic material', as applied to the polymers, are conditional. The term 'elastic behaviour' is used in reference to such a behaviour where the stress relaxation occurs at a very slow rate.

Figure 26. Stress relaxation curves for polyisocyanurate networks obtained from oligoether diisocyanate, toluylene diisocyanate at a content of the latter compound of 6% (1), 46% (2), and 27% (3); for the ED-20 epoxy oligomer cured with methyltetrahydrophthalic anhydride (4); and for an ED-20-based epoxy viscoelastic polymer cured with a mixture of poly(sebacic anhydride) (27.3%) and azelaic acid (13.8%) (5).

microspecimens cut from the initial macrospecimen in regions with different gradients of the modulus of elasticity (Fig. 26). For comparison, a stress relaxation curve for the viscoelastic material [ED-20 epoxy resin cured with poly(sebacic acid anhydride) in the presence of azelaic acid] is also shown in this figure. The glass transition temperature of this network is close to room temperature (the same temperature is characteristic of the material whose relaxation behaviour is illustrated by Fig. 24 [specimen (2)]). The stress relaxation curves were plotted in 'relative stress–time' coordinates; the relative stress was calculated as σ/σ_0 , where σ is the current relaxing stress, and σ_0 is the initial stress developed at the instant of termination of 'instantaneous' initiation of the deformation.

Fast relaxation of the relative stress nearly down to zero is observed for the conventional viscoelastic material, while a slower drop in the stress characteristic of polymeric glasses or rubbers followed by a very slow rate of stress relaxation is observed for the cross-linked polymers synthesised.^{75,76}

Thus, despite the fact that a part of the material within the same specimen is characterised by the modulus of elasticity corresponding to the transition zone, this part possesses elastic mechanical behaviour similar to that of glasses or rubbers rather than viscoelastic behaviour characteristic of all polymers in the transition zone.

The dynamic mechanical analysis of the networks obtained shows that they have very small $\tan \delta$ values, like elastic materials, and that the value of the storage modulus E' is characteristic of the transition zone.

Films based on cross-linked polyisocyanurates with the gradient of the modulus of elasticity perpendicular to the film plane were obtained. These films formed by highly cross-linked polymer networks possess good mechanical properties (a strength of 50 MPa and a limiting elongation of 90%). Such gradient-modulus materials are devoid of brittleness, which is the major drawback of highly cross-linked polymer networks.

Thus, it is possible to obtain polymeric materials possessing new properties using the principles of the molecular design of polymer networks and performing targeted synthesis of the networks. The curves shown in Fig. 27 illustrate the mechanical behaviour of conventional and new polymeric materials over a wide temperature interval. As was mentioned above, irrespective of their chemical structure, conventional materials in the glassy state have approximately the same moduli of elasticity $[(2-3) \times 10^3 \text{ MPa}]$. On heating of these materials to their glass transition temperatures, the moduli of elasticity decrease sharply

Figure 27. Temperature dependence of the modulus of elasticity for conventional polymers (1) and networks with bulky cross-link points and short and flexible linear fragments (2).

in the narrow temperature interval $\Delta T \approx 20-30^\circ$ and the materials undergo transition to the rubbery state.

A fundamentally different picture is observed for new materials. At low temperatures, the new materials (like conventional ones) are also in the glassy state. However, on heating to the temperature of the first relaxation transition the modulus of elasticity decreases very slowly (up to the temperature of the second relaxation transition). Only after passing this temperature a sharp decrease in the modulus of elasticity occurs and the material undergoes transition to ordinary rubbery state. In this case the temperature interval, in which the slow drop in the modulus of elasticity is observed, is ~ 200 degrees. This interval is the major operating range for these materials. Despite the fact that within this interval the moduli of elasticity take the values characteristic of the zone of transition from the glassy to the rubbery state, the materials possess elastic rather than viscoelastic behaviour. It is possible that in this case a new physical state is observed different from the glassy and rubbery states. It is needless to say that this assumption is tentative, though the distinction in the mechanical behaviour of conventional materials and those under consideration is beyond doubt.

VII. Optical sensitivity of highly cross-linked networks

The stress-optical coefficient C_σ , *i.e.*, the coefficient of proportionality between birefringence Δn and the mechanical stress σ that induces birefringence, is one of the characteristics of the optical sensitivity of materials

$$\Delta n = C_\sigma \sigma.$$

The stress-optical coefficient C_σ is a fundamental characteristic of the materials used in the photoelasticity method of stress investigation. In this method, a model of an actual construction made of transparent, optically sensitive materials is loaded as required. As a result, birefringence appears in the material the model is made of and the stress-strain state of the construction can be judged from the birefringence pattern. In the case of three-dimensional models, the deformation freezing method is rather efficient. A model is heated to the temperature at which the constituent material undergoes transition to the rubbery state; it is then loaded and cooled under load to room temperature, which is about $80-100^\circ$ lower than the glass transition temperature for conventional optically sensitive materials. The deformations and optical anisotropy appearing upon loading the model are frozen. Then the model is sliced and these specimens are investigated thereafter.

Without dwelling on other modifications of the photoelasticity method of stress analysis, we should note that their progress is only possible as new polymeric materials with desired optico-mechanical properties have become available. Two types of materials (elastic and viscoelastic ones) are required to solve different problems. Different-modulus polymeric materials with the ratio of the moduli of elasticity from 2 to 10 and possessing elastic properties both under static and under dynamic loads are

required for studying the stress fields in laminated elastic media by the dynamic photoelasticity method. Such materials have come into use in dynamic photoelastic studies recently.⁷¹ The problem of their preparation is that all polymeric glasses irrespective of their chemical structure have nearly the same moduli of elasticity ($\sim 10^3$ MPa).

It might seem that different-modulus materials could be prepared if polymers were synthesised that possess the behaviour characteristic of the zone of transition from the glassy to the rubbery state at the test temperature (*e.g.*, at room temperature). Since the modulus of elasticity decreases sharply in this zone, it is always possible to choose a material with the desired modulus of elasticity. However, materials in the transition zone possess extremely high viscoelasticity, whereas elastic materials are required for solving this problem by the photoelasticity method of stress analysis. Polymer networks of specific chemical structure (highly cross-linked networks possessing extremely large rubbery moduli have low glass transition temperatures much below room temperature) fulfil these two incompatible requirements. The present state-of-the-art studies in the field of predicting the properties of such systems makes it possible to predict the structure of highly cross-linked networks that would meet these two contradictory requirements.^{72, 82}

Using the above approach, the glass transition temperatures and the moduli of elasticity of cross-linked carbosilicon organosilicon polyisocyanurates with short linear fragments of different lengths were predicted.^{71, 72} The structure of these networks is shown in page 705. The relaxation properties of these materials have already been compared to those of the viscoelastic material. Let us consider mechanical and optical properties of the networks under creep conditions.

The time dependences of mechanical and optical creep are shown in Fig. 28. It can be seen that a gradual increase in the compliance values is observed after loading the viscoelastic material, whereas fast creep relaxation is observed for silicon-containing cross-linked polyisocyanurates in contrast to typical viscoelastic polymer.

Thus, it can be pointed out that elastic behaviour, complicated only by weak indications of viscoelasticity, is characteristic of carbosilicon organosilicon polyisocyanurates.^{71, 72}

Table 4 lists the values of the equilibrium moduli of elasticity (E_∞) found by fitting the stress relaxation curves using new memory functions,⁷⁸ which make it possible not only to obtain high correlation coefficients but also to calculate such physical characteristics of a material as the number of microdefects, the initial entropy of the system, *etc.* The stress-related values of

Table 4. Optico-mechanical characteristics of cross-linked macrodiisocyanates.

n	Static load		Dynamic load		
	E_∞/MPa	$\sigma_0^{1.0}/\text{MPa}$ (295 K)	$\eta/\text{m s}^{-1}$	E_d/MPa	$\sigma_0^{1.0}/\text{MPa}$
1.2	866	1.26	1980	4822	2.6
2.5	283	1.14	1700	3454	2.3
3.8	149	1.08	1270	1897	2.1
5.4	—	0.80	1000	1140	1.8
6.2	43	0.69	800	727	1.6
9.2	24	0.41	570	357	1.0

material strip $\sigma_0^{1.0}$ are also given in this table. As can be seen from the table, the stress-optical sensitivity ($\sim 1/\sigma_0^{1.0}$) in the series of polyisocyanurates differing only in the number of dimethylsiloxane units between cross-link points of the network increases as the length of the linear fragment n increases. It seems most likely that the increase in optical sensitivity, despite the decrease in the concentration of the groups possessing high anisotropy of polarizability (isocyanurate ring, aromatic rings), is associated with an increase in the mobility of the macrochain, which depends both on the concentration of cross-link points in the network and on the number of dimethylsiloxane units with low potential energy barrier to rotation about the Si—O—Si bond.⁸³

Dynamic characteristics of optico-mechanical properties of the polymers can differ appreciably from the static ones because of the influence of the time factor. Thus, the duration of the processes that occur under the action of short-term impulse loads and are recorded in the optical birefringence pattern model are from several to hundreds of microseconds. In this case conventional quasi-static creep and stress relaxation tests cannot reproduce the essence of the phenomena occurring in the polymeric material upon dynamic action.

The photogram analysis shows that longitudinal and transverse waves propagate along the rods made of cross-linked polyisocyanurates at a constant velocity. The values of the velocity of propagation of longitudinal waves C_p and the dynamic moduli of elasticity E_d calculated using the following equation

$$E_d = \rho C_p^2,$$

where ρ is the density of the material, are listed in Table 4. As can be seen, the velocities of propagation of longitudinal waves C_p and

Figure 28. The mechanical $I(t)$ (a, c) and optical $D(t)$ (b, d) creep curves for polyisocyanurate networks with $n = 6.2$ and $\sigma = 1.4$ MPa (a, b) and for the viscoelastic polymer based on the ED-20 epoxy oligomer cured with a mixture of poly(sebacic anhydride) (27.3%) (c, d) and azelaic acid (13.8%).

Figure 29. Changes in impulse birefringence pattern $m(t)$ at different cross-sections l of the rods made of a cross-linked polyisocyanurate with $n = 2.5$ for $l = 50$ (1); 100 (2); and 150 (3) mm (a); those for an ED-20-based viscoelastic polymer cured with a mixture of poly(sebacic anhydride) (27.3%) and azelaic acid (13.8%) for $l = 60$ (1); 110 (2); and 160 (3) mm (b).

the dynamic moduli of elasticity E_d of the materials presented vary over a wide range.

Thus, optically sensitive materials based on the cross-linked polyisocyanurates with short chains between cross-link points differ substantially from the traditional ones. The latter have different static moduli of elasticity but virtually the same dynamic moduli of elasticity, which limits the field of their application when solving certain dynamic problems.

To evaluate the viscoelastic properties of cross-linked polyisocyanurates under conditions of dynamic action, let us consider the birefringence patterns under the impulse loading $m(t)$ at different cross-sections l of the rods.⁸² For comparison, the impulse values $m(t)$ are plotted on the same graph (Fig. 29) with the shift in time, which takes account of the velocity of wave propagation in the materials. In contrast to the typical viscoelastic polymer, slight changes in the shape of impulses and their durations observed with increasing distance covered in the rods are characteristic of specimens of cross-linked polyisocyanurates with $n = 1-9$; this indicates their weak viscoelasticity under impulse loading. Hence, optically sensitive cross-linked polyisocyanurates are suitable for studying the stress-strain state of laminated media by the dynamic photoelasticity method.

Previously, we have considered elastic polymeric materials. However, optically sensitive materials possessing viscoelasticity are required for solving a number of problems. It is natural that viscoelastic behaviour is mostly characteristic of the zone of transition from the glassy to the rubbery state.

The currently available methods of creep simulation by the photoelasticity method (the photocreep method) are based on a specific selection of materials possessing both high optical sensitivity and pronounced viscoelastic properties. To solve this problem, it is necessary to have polymer networks for which the test temperature falls into the zone of transition from the glassy to the rubbery state. Viscoelasticity of the materials will increase as the test temperature approaches the glass transition temperature. Therefore, it is necessary to have a set of polymeric materials with

preset glass transition temperatures not equidistant from the test temperature. The preparation of such materials has been reported in the literature.⁸⁴⁻⁸⁸

In addition to physical characteristics considered above [density (the molar volume), the glass transition temperature, and the equilibrium rubbery modulus], the molar (or specific) heat capacity, the coefficient of volume expansion in the glassy and in the rubbery states, the dielectric constant, the refractive index, the energy of intermolecular interaction, *etc.*, can also be calculated for highly cross-linked polymer networks. These properties are calculated using the same relationships as for linear polymers with account of the fact that in the case of networks their repeating fragments rather than the 'monomer' units of the polymers play the role of the repeating units.

The ability to calculate the characteristics mentioned above makes it possible to solve the inverse problem, *viz.*, to judge the structure of a network (especially of a complex network) from the experimental characteristics. Analysis of the structure of phenol-formaldehyde resins is an example of such an approach.⁸⁹

VIII. Analysis of the structure of cross-linked polymers (taking cured phenol-formaldehyde resins as an example)

Phenol-formaldehyde (PF) resins belong to the oldest representatives of highly cross-linked polymer networks; however, interest in their structure and properties has persisted up to the present.⁹⁰ Numerous studies have been dedicated to the analysis of the structure and properties of PF resins; however, there is no agreement concerning the chemical structure of the network formed by these resins as yet. This is probably due to the fact that the network may have different structures depending on the course of curing of PF resins. In addition, OH groups capable of forming hydrogen bonds are present in the network structure. Hydrogen bonds can be formed both due to intermolecular interaction of the OH groups in the neighbouring chains of PF resins and due to interaction between the OH groups within the same repeating unit.

It is convenient to clarify the sense of such concepts as the inter- and intramolecular interaction from the viewpoint of the approach presented using a simplified scheme (Fig. 30). Figure 30a illustrates the case of intermolecular interaction resulting in the formation of a network of physical (hydrogen) bonds between the chains. It is natural that the formation of this network favours an increase in the glass transition temperature. Figure 30b illustrates the case where two OH groups are within the same unit of a linear fragment of PF resin; the hydrogen bonding occurs within this unit while no formation of a network of physical bonds between the neighbouring chains occurs. Of course, different types of intermolecular interaction (hydrogen bonding) can actually co-exist and appreciably affect the properties of PF resins (see below).

Figure 30. A scheme of a network of hydrogen bonds; (a) hydrogen bonding between neighbouring chains; (b) hydrogen bonding within the same repeating unit.

The cured PF resin can contain the following structures (the cross-link point is shown near the structure **20a**):

The structure **20a** constitutes only the network, the repeating fragment of which is marked by dashed lines. The cross-link point is specified within the repeating fragment (in accordance with our definition of the chemical structure of the cross-link point).

Let us calculate the glass transition temperature of the network using Eqn (6). It is reasonable that the entire cross-link point contains three of these sets of atoms. The data for structure **20a** are given in Table 1.

Substituting the values of the parameters for the ideal structure **20a** in Eqn (6), we get

$$T_g = \frac{101.1}{21.5 \cdot 3 + 71.6} \times 10^3 = 743 \text{ K}.$$

The calculated T_g is much higher than the experimental T_g values. The experimental values of the parameters are listed below: $T_g = 343\text{--}433 \text{ K}$, $\rho = 1.24\text{--}1.33 \text{ g cm}^{-3}$, $n = 1.57\text{--}1.63$, $\alpha = (18.0\text{--}22.5) \times 10^{-5} \text{ K}^{-1}$, $C_p = 29\text{--}48 \text{ cal mol}^{-1} \text{ deg}^{-1}$.

Hence, the actual network differs in structure from the ideal one.

The possible structure **20b** of PF resins corresponds to a linear polymer (the repeating unit is marked by dashed lines). The data for this structure are listed in Table 1.

If both OH groups are involved in the formation of the hydrogen bonds between the chains (see Fig. 30), then

$$\begin{aligned} \sum_j b_j &= 2b_h + b_m; \\ \sum_j b_j &= (-139.6 \times 2 + 16.0) \times 10^{-3} = \\ &= -263.2 \times 2 \times 10^{-3} \text{ Å}^3 \text{ K}^{-1}. \end{aligned}$$

Substitution of the values of all parameters in Eqn (5) gives the following T_g value of the ideal linear structure **20b**:

$$T_g = \frac{123.05}{505.4 - 263.2} \times 10^3 = 508 \text{ K}.$$

As for the structure **20a**, this value is beyond the experimental temperature interval in which the α -transition for PF resins is observed.

The structure **20c** forms only linear chains; their repeating unit is enclosed by dashed lines. The following relationship is valid for such a structure

$$\begin{aligned} \sum_j b_j &= b_h + b_m = (-139.6 + 16.0) \times 10^{-3} = \\ &= -123.6 \times 10^{-3} \text{ Å}^3 \text{ K}^{-1}. \end{aligned}$$

By substituting the values of the parameters in Eqn (5) we can obtain T_g of the ideal structure **20c**.

$$T_g = \frac{99.05}{331.9 - 123.6} \times 10^3 = 476 \text{ K}.$$

This value is somewhat higher than the observed temperature interval of α -transition for PF resins.

The structure **20d** forms a network the repeating fragment of which is shown by dashed lines (the cross-link point of the network is enclosed by dashed lines). All parameters for the structure **20d** are given in Table 1. Substituting the values of the parameters in Eqn (6), we get the T_g value of an ideal network based on the structure **20d**

$$T_g = \frac{91.25}{56.5 + 120.7} \times 10^3 = 515 \text{ K}.$$

Thus, the glass transition temperature of such a highly cross-linked polymer network is rather high.

The structure **20e** has the same molecular formula as the structure **20b**; however, hydrogen bonding occurs within the same repeating unit. Such a structure was described by Nikolaev.⁹¹

If hydrogen bonds are formed between the neighbouring OH groups within the same repeating unit, then no formation of the physical network between the chains due to the hydrogen bonds occurs. Then the following should be taken into account when

determining the $\sum_j b_j$ value for calculating the glass transition

temperature: the fact that the structure **20e** is linear requires the introduction of the b_m increment to account for the m -substitution in the aromatic ring; in addition, there are two branchings from the aromatic ring, which requires introducing two b_d increments. Then

$$\begin{aligned} \sum_j b_j &= b_m + 2b_d = 16.0 - 2 \times 55.4 = \\ &= -94.8 \times 10^{-3} \text{ Å}^3 \text{ K}^{-1}. \end{aligned}$$

Substituting the values of all parameters of the structure **20e** in Eqn (6), we obtain

$$T_g = \frac{123.05}{505.4 - 94.8} \times 10^3 = 300 \text{ K}.$$

This T_g value is below the temperature interval of α -transition for cured PF resins.

None of the calculated glass transition temperatures of possible ideal structures of PF resins fall into the interval in which experimental values are observed. This suggests that the cured PF resin has a more complex structure than the ideal structures considered above, which has been noted by most investigators. It is most likely that the actual structure of PF resins consists of a set of the considered ideal structures.

To establish the most plausible actual structure of PF resins, let us calculate, in addition to T_g , such characteristics of cured PF resins as density ρ , the refractive index n , the coefficient of volume

Table 5. Calculated characteristics of ideal structures of cured PF resins.

PF structure	T_g / K	ρ / g cm ⁻³	n	$10^4 \alpha$ / K ⁻¹	C_p^s / kcal mol ⁻¹ deg ⁻¹
20a	743	1.253	1.621	1.30	31.9
20b	508	1.250	1.583	1.89	42.4
20c	476	1.205	1.604	2.02	31.4
20d	515	1.301	1.645	1.86	26.1
20e	300	1.250	1.583	3.20	42.4

expansion α_G , and the molar heat capacity C_p^s . These characteristics were chosen with account of their sensitivity to the changes in the structural formula of the substance and of the fact that both the increase and decrease in the values of other characteristics can be observed for different ideal structures of PF resins with the increase in the glass transition temperature. The latter is of importance for searching the most plausible structure of PF resins using the experimental design method.

The calculated densities of PF resins for structures **20a–20e** are listed in Table 5.

The refractive index n was calculated using the following equation⁷

$$\frac{n^2 - 1}{n^2 + 2} = \frac{k R_f}{N_A \left(\sum_i \Delta V_i \right)_f}, \quad (62)$$

in which the molar refraction of the repeating fragment R_f is the sum of the refractions R_i of particular atoms and increments for different types of bonds (double and triple bonds).

The n values for different structures found using Eqn (62) are listed in Table 5.

The calculations of the molar heat capacity C_p^s in the glassy state of the polymer were carried out using the following relationship⁹²

$$C_p^s = \sum_i C_{p,i}^s \Delta V_i - 0.77,$$

where $C_{p,i}^s$ are the partial heat capacities characteristic of each atom and ΔV_i are the van der Waals volumes of the atoms.

The coefficient of volume expansion α is related to the glass transition temperature by the following relationship⁷

$$\alpha = \frac{0.096}{T_g}.$$

Comparison of calculated and experimental values of the characteristics of possible ideal structures of PF resins (see Table 5) allows one to conclude that a cured PF resin represents a set of structures rather than an ideal network. The experimental design method of construction of simplex lattices and polynomial 'composition–property' models was applied to multicomponent systems to find such a set of structures.⁸⁹

It has been found⁸⁹ that one possible relation between the relative content of ideal structures corresponding to the permissible set of network structures has the form $\alpha_1 = \alpha_5 = 0.345$, $\alpha_3 = 0.2$, and $\alpha_4 = 0.11$, where α_1 , α_3 , α_4 , and α_5 are the mole fractions of the structures **20a**, **20c**, **20d**, and **20e**, respectively.

The following values have been found for the actual network, viz., $T_g = 429$ K, $\rho = 1.248$ g cm⁻³, $n = 1.6057$, $\alpha = 2.238 \times 10^{-4}$ K⁻¹, and $C_p^s = 34.8$ cal mol⁻¹ deg⁻¹. All these values fall into the range of experimental values (see Table 5).

Taking into account the narrow limits of the permissible set of ideal structures of cured PF resin, it is possible to conclude that the actual network structure considered is close to the most plausible one.

Thus, comparing the experimental and calculated characteristics of complex highly cross-linked network systems allows one to draw certain conclusions on their structure.

IX. Conclusion

The study of the influence of the chemical structure of highly cross-linked polymer networks on their properties shows that the passage from sparse networks to highly cross-linked networks occurs when the number of the repeating units between the cross-link points is reduced to 4–5. Changes in the properties become particularly noticeable as the number of repeating units is reduced to 1–2 or becomes less than 1. Changes in the chemical structure of a highly cross-linked network to an extent that it only vaguely resembles that of the initial network is the main reason for principal changes in the network properties.

Numerous studies of the structure and properties of highly cross-linked networks have shown that the classical theory of rubber elasticity becomes inapplicable to the description of the dependence of the equilibrium rubbery modulus on the distance between the cross-link points. The same is also valid when solving the inverse problem (estimation of the distance between the cross-link points from the experimentally measured equilibrium rubbery modulus). This required the development of altogether new approaches and methods for assessing the structure and properties of highly cross-linked polymer networks. An analysis of the potentialities of the equations and computational schemes proposed has shown that the distance between the cross-link points can be estimated with a good accuracy by comparing experimental and calculated glass transition temperatures. The proposed generalised equation for evaluating the equilibrium rubbery modulus makes it possible to perform calculations with a good accuracy for both highly cross-linked and sparse networks. All the relationships considered in this review require no fitting parameters and allow one to analyse the properties on the basis only of the chemical structure of the network. Mention should be made of yet another important circumstance, viz., any change in the network topology (the appearance of dangled chains, branchings, isolated loops, and cycles) results in changes in its chemical structure and, as a consequence, in changes in the physical properties.

This approach is of fundamental importance for designing cross-linked polymers with unusual properties. Primarily it concerns gradient-modulus polymeric materials in which the modulus of elasticity changes by a factor of 1000–10 000 within the same specimen in a prescribed manner. In this case it has been possible to eliminate the major drawback of the polymers in the zone of transition from the glassy to the rubbery state and possessing pronounced viscoelasticity. In addition to the moduli of elasticity characteristic of the transition zone, the new materials obtained possess elastic behaviour rather than viscoelastic behaviour.

Yet another example is the use of this approach for predicting the unusual properties of cross-linked polymers followed by the synthesis of these materials that have found application in the photoelasticity method.

IV. Pyrolytic methods	716
V. Radiation and photochemical dechlorination methods	717
VI. Biotechnological methods	718
VII. Oxidative methods	719
VIII. Hydrogenolysis of polychlorobiphenyls	721

Abstract. The principal sources of the pollution of the environment by polychlorobiphenyls are indicated and their ecological danger is estimated; the output in the manufacture and applications of polychlorobiphenyls are quoted. The known methods for the neutralisation of polychlorobiphenyls are examined. The methods considered are analysed and their practical significance for industry is estimated. The bibliography includes 277 references.

I. Introduction

Polychlorobiphenyls (PCB) possess a series of unique physical and chemical properties: exceptional thermophysical and electrical insulating characteristics, thermal stability, inertness to acids and bases, fire resistance, satisfactory solubility in fats, oils, and organic solvents, high compatibility with resins, plasticity, resistance to corrosion, and an excellent capacity for adhesion.^{1–9} All these features are responsible for their wide-scale employment as dielectrics in transformers and capacitors,^{1, 3, 7, 10–18} as hydraulic liquids,^{10, 13, 16–20} as heat exchangers and refrigerants,^{1, 3, 6, 9, 10, 12–14, 16–18, 20} as lubricating oils,^{3, 6, 16, 17, 20} as components of varnishes, paints, and adhesive compositions,^{6, 10, 14, 15–17, 20–24} as plasticisers and fillers in plastics and elastomers,^{1, 3, 6, 16, 17, 20, 24} as antipyrenes,^{1, 9, 15, 20, 25} and as solvents.^{1, 6, 16, 22}

The industrial synthesis of PCB is based on the substitutional chlorination of biphenyl in the presence of electrophilic substitution catalysts.^{7, 26}

Polychlorodibenzofurans (PCDF) are formed as side products:⁷

There are 209 individual PCB differing in the number and positions of chlorine atoms in the molecule. Depending on the content of chlorine atoms, PCB have different numbers of isomers (Table 1).

Table 1. The number of possible PCB isomers for different contents of chlorine atoms in the molecules.²⁷

Name of PCB	Molecular formula of PCB	No. of isomers
Monochlorobiphenyl	C ₁₂ H ₉ Cl	3
Dichlorobiphenyl	C ₁₂ H ₈ Cl ₂	12
Trichlorobiphenyl	C ₁₂ H ₇ Cl ₃	24
Tetrachlorobiphenyl	C ₁₂ H ₆ Cl ₄	42
Pentachlorobiphenyl	C ₁₂ H ₅ Cl ₅	46
Hexachlorobiphenyl	C ₁₂ H ₄ Cl ₆	42
Heptachlorobiphenyl	C ₁₂ H ₃ Cl ₇	24
Octachlorobiphenyl	C ₁₂ H ₂ Cl ₈	12
Nonachlorobiphenyl	C ₁₂ HCl ₉	3
Decachlorobiphenyl	C ₁₂ Cl ₁₀	1

Technical PCB mixtures produced by industry consist of 50–70 individual compounds. Most of them contain between 3 and 8 chlorine atoms, although there are small amounts of both more and less chlorinated PCB. These mixtures are known under different names: Arochlor (USA), Phenochlor (France), Chlophen (Federal Republic of Germany), Kanechlor (Japan), Fenchlor (Italy), and Sovol (Russia). The proportions of PCB in the Arochlors are presented in Table 2.

The world manufacture of PCB has increased successively from 1929 to 1970 when these compounds were recognised as

C ₁₂ H ₂ Cl ₈	66.0	—	—	—	8
C ₁₂ HCl ₉	68.8	—	—	—	1

pollutants of the environment.¹⁶ Towards the end of the 1980s, the total amount of PCB produced was estimated as 1 million tonnes.^{16,17} Analysis of the pattern of the consumption of PCB in various countries showed that about 40% of this amount, *i.e.* 400 000 tonnes enter the environment, while the remaining 600 000 tonnes, at the time when the estimate was made, was still being used or was stored in settling tanks.¹⁷ According to later estimates, even after the prohibition of the manufacture of these products in the USA, Japan, and a number of European countries, the content of PCB in the environment hardly changed.

The nature and dynamics of the distribution of PCB in the environment is in many respects determined by their physical properties such as persistence, chemical inertness, fairly high vapour pressure, and capacity for diffusion.^{1–9,26–33} The persistence of PCB makes it possible to include them among typical xenobiotics which are not very susceptible to the action of a wide variety of microorganisms and animal enzyme systems.³⁴ Persistence combined with lipophilicity promotes the bioaccumulation of PCB in the fatty tissues of man and animals in amounts dangerous for vital activity.^{9,10,16,17,35–37} Chemical inertness is responsible for the resistance of PCB to the action of environmental abiotic factors, the relatively high vapour pressure facilitates their spreading in the atmosphere, while their capacity for diffusion favours their migration in the soil and in subterranean and surface waters.

Despite the gradual reduction of the applications of PCB in the economy, they continue to pollute the environment^{4,10} and nowadays these toxic products, which have spread virtually throughout the entire terrestrial globe, are present in the organism of each of us.^{10,16} As PCB are incorporated in the biological chains, the weakly chlorinated components are progressively lost by virtue of their selective biotransformation.^{8,9,28,37,38} The most dangerous highly chlorinated PCB therefore accumulate in the human and animal organisms.

According to data of the World Health Organisation,²⁸ the principal ways in which PCB enter the environment are as follows: vaporisation from plasticisers; evolution on combustion of industrial and domestic waste and also when transformers, capacitors, and other industrial equipment in which PCB are used are switched on; leakage together with other industrial waste; the

removal of PCB to rubbish dumps and aeration fields; other unmonitored pathways.

The environment is polluted mainly *via* the first three pathways. The typical PCB concentrations in various objects in the environment²⁷ are as follows: in the air of agricultural regions 0.05 ng m⁻³, in the air of cities 1–5 ng m⁻³; on the surface of soil 2–50 µg kg⁻¹; in plants 10 µg kg⁻¹; in water 2 ng litre⁻¹; in fatty tissues 1 ng kg⁻¹; in human breast milk 10 µg kg⁻¹; in the organisms of marine animals 5–50 ng kg⁻¹; in the fat of the otter 5–200 ng kg⁻¹.

The potential danger of PCB is associated with their use in open systems, with possible spillage, with leakage and vaporisation from capacitors, transformers, and other elements of equipment in the course of their cleaning, emptying, and filling, with the breakdown of hermetic seals in equipment, and with the occurrence of fires in plant where PCB are employed as dielectric liquids or heat exchangers.^{7,8,16,17,36–42} An example of mass poisoning of people by PCB as a consequence of the breakdown of hermetic seals in heat-exchange apparatus in the course of the refining of rice oil is known. This incident, which has entered history as the 'Yusho incident', occurred in Japan in 1968. The symptoms of poisoning were an increase in the size and hypersecretion by mammary glands, nausea, vomiting, enlargement and porphyria of the liver, pathological changes in the peripheral nervous system and in the composition of blood, and disturbance of the functioning of adrenal glands.

Thermal overloading or fires in plant (transformers, capacitors) in which PCB-containing materials were employed as dielectrics or refrigerants constitutes a major hazard to the environment, because uncontrolled combustion of PCB results in the formation of the highly toxic polychlorodibenzodioxins (PCDD) and polychlorodibenzofurans (PCDF).^{7–9,39,40,42–45} According to certain ideas,^{7,46,47} such transformations may occur in accordance with processes (3).

The combination of persistence, chemical stability, and lipophilicity of PCB creates the possibility of their bioaccumulation in lipid-rich liver, kidney, adrenal gland, lung, and brain tissues of man and animals.^{1,4,8,15,28} The concentration of PCB in human blood and milk has been noted.^{1,7,16,28}

Until recently, the toxicity of PCB remained controversial. Some investigators denied the existence of a connection between various diseases and the presence of PCB in human and animal organisms, others attributed a number of serious toxicological effects, causing chronic illnesses, to the action of PCB.^{1,5,7,9,15,16,24,35,48,49}

More rigorous studies carried out recently made it possible to discover a whole spectrum of the toxic effects of PCB on man and laboratory animals, including lethal effects, harmful influence on reproduction and development, liver porphyria, weight loss, dermatological effects, suppression of the immune system, disturbance of the functioning of the kidneys, atrophy of the thymus, carcinogenesis, disorganisation of the homeostasis of the steroid hormones, and a mutagenic effect.^{37,45,50}

The massive effect of PCB on ecosystems as a whole and on man in particular is intensified by constantly operating factors such as the increase in the content of PCB in water and aqueous ecosystems as a result of the entry of surfactants into the latter,² the biotransformation of PCB in the environment into still more

toxic products,⁵¹ and the accumulation of PCB in human and animal organisms as a consequence of their accumulation in the food chains.³⁷ The increase in the level of PCB in living organisms and the destruction of animals induced by this, sometimes on a mass scale, noted in a number of regions of the planet (particularly in the aquatic systems of the Pacific Ocean), indicates the potential danger of the bioaccumulation of PCB to populations of living organisms and whole ecosystems.^{7, 18, 37} It has to be borne in mind that, by virtue of their chemical and thermal stability and exceptional operating properties, the PCB-containing materials produced earlier by industry will continue in use for a long time yet (more than 20 years) in active closed systems.⁵²

Thus the danger of the accumulation of PCB in living organisms and the threat of the destruction of populations and whole ecosystems, as well as the potential possibility of leakages or a series of discharges from settling tanks and active plant have raised the problem of the pollution of the environment by these compounds to the class of global environmental problems.

Bearing in mind the very serious level of environmental danger, Canada, the USA, Japan, the countries of the EEC, and other states have developed measures regulating the manufacture, use, processing, and destruction of PCB.^{8, 18, 35, 53–63} These measures include the following: complete prohibition of the manufacture of PCB, gradual replacement of PCB by alternative materials with less toxic properties, the monitoring of materials containing PCB in the course of their employment, storage, transport, and distribution, the development of effective ecologically safe technologies for the processing and neutralisation of PCB-containing materials, the monitoring of the neutralisation and processing of waste, and the development of new rules for the operation of plant in which PCB is employed taking into account more stringent requirements for the ecological safety of industries.

The possibility of the gradual removal of PCB-containing materials from the sphere of man's economic activity and of a universal ban on their manufacture depends on the solution of the problem of the replacement of PCB by new materials with similar operating characteristics but with a significantly lower toxicity. The question of the search for substitutes of PCB-based dielectric materials is most acute.

New compositions and individual compounds have been obtained and tested in recent years. They have been recommended as substitutes for PCB in transformers and capacitors. For example, these are mineral and silicone oils,^{9, 17, 64–66} high-molecular paraffins,^{9, 65} alkylated biphenyls and terphenyls,^{9, 17} esters of phosphoric, phthalic, and other carboxylic acids,^{9, 17} and esters of polyhydric alcohols.⁶⁵ While less toxic, these substances approach PCB as regards their dielectric properties but are inferior to them in chemical inertness and resistance to combustion.

Less toxic polychlorotoluenes⁶⁷ and chloromethylbenzenes⁶⁸ have been proposed for the replacement of PCB in hydraulic systems.⁶⁸ The report of the promising application of absolutely nontoxic and chemically stable perfluorinated organic compounds as components of lubricating oils merits attention.⁴¹

However, overall the search for new materials to be used as substitutes for PCB for various purposes has been fragmentary.

In the system of measures designed to lower the degree of pollution of the environment, the conservation of PCB removed from the sphere of economic activity in settling tanks or storage sites occupies a definite place.^{5, 35, 69–77} In practice, various storage methods are employed, but the safest is the method involving enclosure in glass.⁷¹ However, there is no information about the ecological risk when this operation is performed. Thus enclosure in glass may entail the formation of toxic PCDD and PCDF and their subsequent diffusion together with PCB into the environment. The hardening method is widely used in the storage of PCB, but it cannot guarantee their complete isolation from the environment.^{70, 76, 77} The main disadvantages of the method involving the storage of hardened PCB are as follows: as a consequence of the appreciable volatility and diffusibility as well

as the leaching of PCB, one cannot rule out the possibility of their entry into soil, underground and surface waters, and the atmosphere; the need to search for storage sites remote from populated areas, definite requirements for geological structures at the storage sites, and the continually rising cost of this operation;^{69, 72, 74} One should also take into account the negative attitude of the population to the possibility of storage of any waste on adjacent territories.

The storage of undecomposed PCB in settling tanks is a less reliable method of their conservation. The inevitability of the diffusion of PCB from the settling tanks is aggravated by the probability of accidents at the storage sites.

The most promising procedure for lowering the amount of PCB in the environment involves their conversion into environmentally safe products. One may identify the following methods for the processing of PCB: chemical and electrochemical dechlorination, thermal, photochemical, and radiation-chemical and biotechnological methods, oxidation, and hydrogenolysis. These methods may include operations involving the concentration of PCB before treatment. Such operations include extraction, adsorption, dialysis, vaporisation, distillation, and filtration.^{5, 18, 25, 63, 50, 77–88} Operations of this kind acquire particular importance when the removal of residual PCB from transformers and capacitors is required. By virtue of the application of extraction by liquids at the critical temperature and pressure, the effectiveness of the extraction of PCB from plant to be cleaned has increased in recent years.^{80, 85, 87}

II. Reagent-based neutralisation methods

Diverse reagents, reaction conditions, catalytic systems, and apparatus are used in the chemical methods for the neutralisation of PCB. The reagents are usually alkali metals (Na, K, Li),^{9, 52, 80, 89–97} with the aid of which a version of the Wurtz reaction takes place:⁹⁸

In this method, use is made of the dechlorinating effect of the alkali metal (in particular, sodium). The organic dechlorination products are high-molecular polynuclear compounds.

According to the ideas developed by Oku *et al.*,⁹⁹ the mechanism of reaction (4) includes the following stages:

In the presence of compounds containing relatively mobile hydrogen (hexane, cyclohexane, other hydrocarbons), the aryl radicals are involved in a chain of new reactions:

The main result is the substitution of the chlorine atoms in PCB by hydrogen *via* reaction (7). Thus hydrocarbons with fairly reactive C–H bonds regulate the average molecular mass of the dechlorination products, but are themselves decomposed in this process. The regulating function of hydrocarbons is important because it permits the retention of the possibility of further dechlorination of PCB at advanced stages of the reaction with respect to chlorine, whereupon contact between the sodium atoms and the chlorine atoms still present in the polynuclear chlorination products becomes sterically hindered.

In order to decompose PCB, the alkali metal is usually dispersed in the bulk of the material being treated or a hydrocarbon solvent is used as the reaction medium. A version of the process in a flow system using the alkali metal (Na or K) deposited on an inert material as the reagent has also been described.⁸⁹ This method is characterised by a high degree of decomposition of

PCB, but its application is held back by a series of limitations and deficiencies — the high cost of the neutralisation process, increased danger of the process, and conversion of the treated compounds into high-molecular products which lower the quality of the materials being purified. Furthermore, alkali metals may interact with valuable components of the materials being purified, exerting a negative effect on their operating characteristics.¹⁰⁰

There are data concerning the use of alkaline earth and other metals, such as Mg, Ca, Fe, Sb, Zn, and Pb^{101, 102} in a molten salt and in the vapour phase^{101, 103} for the dechlorination of PCB. As regards safety and dechlorination efficiency alkali metal naphthalides and anthracides have a definite advantage over alkali metals.^{18, 77, 104–107} The higher efficiency of the dechlorination by the naphthalides and anthracides is due to the possibility of increasing the degree of dispersion of the reagent down to the molecular level. On the other hand, the metals in the compounds specified are chemically bound and this makes them more inert to oxygen and water, which increases the safety of the process in its turn. Compounds between alkali metals and carbon are a variety of reagents of this type.¹⁰⁸ The main disadvantages of the dechlorinating agents listed is the difficulty of isolating them from the reaction mass and the fact that high-molecular products, exerting a negative influence on the quality of the neutralised material, are formed with participation of the given reagents.

Strong bases — alkali and alkaline earth metals and oxides and hydroxides,^{77, 80, 101, 102, 109–115} alkoxides, glycolates, and polyglycolates^{18, 77, 80, 85, 95, 116–123} — constitute a large group of reagents. Alkali metal carbonates or hydrogen carbonates make up yet another group.^{124, 125} Their dechlorinating activity is based on the nucleophilic substitution of the chlorine in PCB. Thus, when aqueous solutions of alkalis are used, the main reaction proceeds in accordance with the equation

Aqueous solutions of alkalis are insufficiently effective and are quite expensive. Furthermore, the presence of chlorine in the 2- and 2'-positions in the PCB being neutralised creates structural preconditions for the formation of PCDF:

Alkali metal glycolates, polyglycolates, carbonates, and hydrogen carbonates are more effective dechlorinating agents, since the polarisability of their anions is greater.^{110, 126}

In contrast to alkali metals, as well as compounds of alkali metals with naphthalene, anthracene, and carbon, these reagents do not require the use of special safety measures, the processes involving them can be readily controlled, and the products obtained after dechlorination can be readily separated from the purified material. In most cases, the methods for the employment of such reagents are universal in relation to the object being treated: they can be applied in the detoxification of soils, sludges, sewage, and simply PCB-containing materials. The disadvantages of these methods are as follows: the need to neutralise the excess alkaline agent with formation of salt waste, the possibility of the impairment of the operating quality of the materials being

neutralised as a consequence of the formation of hydrolysis and alcoholysis products, the rapid wear of the equipment working in corrosive media at high temperatures.

In view of the existence of the last problem, the process involving the detoxification of PCB-containing materials by alkaline agents, initiated with ultrasound under milder conditions, merits attention.¹¹⁵ The influence of alkaline reagents on the quality of the processed materials imposes certain limitations on their content of PCB: it should not exceed 1 mass %.¹⁰⁰

The oxidation–reduction processes with participation of a wide variety of oxidants and reductants constitute a separate group of methods for the chemical detoxification of PCB-containing materials. The oxidants include hydrogen peroxide, sodium iodate,^{125, 127} permanganates, persulfates and perborates,⁴⁹ and peracetic acid,¹²⁸ while the reductants comprise the hydrides of alkyl derivatives of alkaline metals,⁹⁵ alkali and alkaline earth metal hydroborates,^{49, 129} and alcohols.^{130, 131} When alcohols are used as the reducing agents, the attainment of the necessary rate of the process requires either more severe conditions (170–200 atm, 150–350 °C) or the radical reduction reaction must be carried out in the presence of alkali metal hydroxides and chemical initiators.

The methods indicated require the application of expensive reagents and can hardly be recommended for industrial application.

Methods for the processing of PCB involving their interaction with elemental sulfur in the vapour phase at high temperatures are of undoubted practical interest.^{59, 130, 132} An environmentally safe polymeric product is obtained and can be used as an additive to asphalt, a binder for concrete, a vulcanising agent for raw rubber, and as a material for the preparation of resistors. The products SCl_2 and CS_2 formed together with the polymer can be readily separated from the latter together with the unreacted elemental sulfur, which is returned to the process. This method is suitable exclusively for the treatment of concentrated PCB, but the possibilities for its wide-scale application are restricted by the available elemental sulfur resources.

III. Electrochemical methods

The majority of the known methods for the electrochemical oxidation and reduction of PCB are used within the framework of laboratory research.^{77, 133–141} Certain results are promising as regards energy expenditure¹³⁴ and apparent yields,¹⁴² but overall the prospects for the application of these methods in industry are at the present time small owing to the insufficiently high degree of conversion of PCB^{137, 141} and the high requirements which must be met by the purity of the initial PCB. However, the interest in the electrochemical methods has persisted for several reasons. Firstly, it is possible to organise the process under the conditions of cathodic reduction:

which imparts to it resource-saving qualities. Secondly, electrochemical devices are suitable for the creation of mobile systems for the processing of waste at the site of their formation and accumulation. Thirdly, such devices have an advantage in the conversion of dielectric liquids, lubricating oils, and other spent PCB-containing materials into a valuable hydrocarbon fuel.

IV. Pyrolytic methods

Among the pyrolytic methods for the decomposition of PCB, the process in which a hollow tube heated from the outside by electrodes or other electrically heated elements merits attention.^{16, 122, 142–144} Porous graphite may be used for the preparation of the tube. In order to avoid the breakdown of the material of the reactor, a stream of nitrogen or other inert gas is passed from the outside into the porous surface.

The PCB decomposition products are a solid carbon residue and gases, mainly HCl and Cl₂, as well as a certain amount of organochlorine compounds. The gases are trapped in series-connected absorbers irrigated with water and an alkaline solution and also in an adsorber with activated charcoal. In order to ensure the effective destruction of the PCB and a decrease in process temperature, it is recommended that a small amount of oxygen be added to the initial mixture.¹²²

In order to attain the quantitative decomposition of PCB, in certain cases the pyrolytic processes are carried out on solid catalysts, activated charcoal, metallic Zn, Ni, Cu, Fe, Al, Pb, Pt, Rh, and Cr or the oxides, carbonates, and silicates of these metals.^{145–147}

One of the difficulties in the application of pyrolytic methods is the difficulty of achieving an effective supply of heat to ensure the specified temperature. This problem can be solved successfully if the process is carried out in salt melts.^{87, 148} Nevertheless pyrolysis in melts has hardly come to be widely used, since equipment wears rapidly in a salt medium and the high temperatures needed to apply these methods render industries of this kind dangerous.

The plasma pyrolysis occurring at temperatures from 5000 to 25 000 °C involves the complete decomposition of PCB; H₂, CO, CO₂, HCl, CH₄, H₂O, and elemental carbon being formed as the products.^{87, 149–151} The presence of oxygen-containing compounds in the products is associated with the use of alcohols as solvents for the preparation of the initial mixtures.¹⁵¹

A novel method for the pyrolysis of PCB has been put forward in France.¹⁵² The process is carried out at 1500 °C in the presence of water vapour. The main reaction products are chlorine and C₁–C₂ hydrocarbons. The chlorine is absorbed by a solution of alkali while the hydrocarbons are used as a fuel.

In the communications quoted above, devoted to pyrolytic decomposition methods, the degree of decomposition of PCB is quoted as the sole criterion of the effectiveness of the processes and this parameter is in all cases close to 100%. The lack of any kind of data on the composition of the products with different degrees of conversion hinders even a preliminary interpretation of the process mechanisms. Certain conclusions about the initial period of the pyrolytic decomposition of PCB can be made on the basis of the results of a detailed study of the pyrolysis of chlorobenzenes in the region of relatively low temperatures.^{153, 154} The principal pyrolysis products under these conditions are chlorobiphenyl and dichlorobiphenyl and the reactions responsible for their formation are reversible. Adopting the principle of microreversibility as a guide,¹⁵⁵ the proposed mechanism of the pyrolysis of chlorobenzenes can be extended also to the pyrolysis of polychlorobiphenyls.

An important advantage of the pyrolytic methods compared with the widely used combustion is the absence of the highly toxic PCDF and PCDD from the products. However, the large energy consumption in these processes increases their cost and impairs their ecological parameters. Furthermore, the pyrolytic process is relatively unselective and is therefore unsuitable for the dechlorination of materials with a low PCB content. To a certain extent, these disadvantages are overcome by employing catalytic pyrolysis, but the formation of pyrolytic carbon leads to rapid deactivation of the catalyst.

V. Radiation and photochemical dechlorination methods

The radiation and photochemical dechlorination methods are being rigorously investigated.^{2, 77, 156–181} Their successful application does not require additional chemical reagents.^{77, 156–165} The processes can be described by the following stoichiometric equation in relation to the dechlorination of 2,2',4,4',6,6'-hexachlorobiphenyl:¹⁸²

Thermokinetic analysis^{155, 183} made it possible to put forward the following mechanism of the photochemical dechlorination:

Evidently in the dechlorination initiated by γ -quanta the reactions involving the homolysis of the C–Cl bond are accompanied by competing reactions in which the C–H and C–C bonds are homolysed.

An advantage of the radiation and photochemical methods compared with the reagent-based dechlorination methods is simpler composition of the products and the absence of salt waste. However, the very low quantum or radiation-chemical yields of these processes lead to large energy expenditures and hence an impairment of the economic parameters of the industrial processes. In this connection, the search for photocatalytic systems and methods whereby the reagent concentration fields can be altered in the initiation stage in order to achieve the selective absorption of energy quanta and their effective utilisation for the generation of the necessary intermediates are of definite interest.^{156, 157, 159, 160, 163–167, 173, 184} On the other hand, the possibility of economising on the energy by increasing the quantum and radiation-chemical yield is limited because the rate constants for reaction (17) are low at the low temperatures characteristic of these processes¹⁵³ and conditions for the occurrence of chain processes are not therefore realised.

Radiation and photochemical dechlorination may find a practical application for the neutralisation of industrial and domestic sewage, provided that more effective and selective methods are developed for the application of energy to PCB-containing materials. In this sense, the report on the detoxification of waste waters in the presence of titanium dioxide on treatment with ultrasound under normal conditions merits attention.¹⁸⁵

The nature of the products of the photochemical and radiation-chemical dechlorination changes in the presence of compounds containing comparatively mobile hydrogen (cyclohexane, other hydrocarbons, alcohols, water, sodium tetrahydroborate, etc.)^{169, 172, 173, 175, 176, 179–184, 186} Some of the reactions occurring are indicated schematically below in relation to 2,2',4,4',6,6'-hexachlorobiphenyl.¹⁸²

As can be seen, in the presence of hydrocarbons chlorine is replaced by hydrogen, which in fact gives rise to the neutralisation effect. On the other hand, when water and alcohols are used, there is a risk of the formation of the highly toxic PCDF. Evidently this risk exists also under the conditions of the photochemical and radiation-chemical dechlorination of PCB in an oxidising medium.^{46, 166} From the standpoint of the protection of nature, it is therefore useful to employ only hydrocarbons as the reagents. Nevertheless, despite the high reactivity of hydrocarbons in radical reactions, the quantum and radiation-chemical yields remain low and this prevents the introduction of such processes into industry.

When caustic alkali is added to the PCB–alcohol reaction system, the radiation or photochemical dechlorination of PCB by the alcohol proceeds *via* a radical-chain mechanism:^{170, 177–181, 186, 187}

Here the quantum yield increases by two–three orders of magnitude.¹⁷⁹ This effect can be accounted for by the operation of the following mechanism (in relation to the radiation-chemical dechlorination of PCB by the 2-propanol–NaOH system):

It is seen from the scheme presented that the function of alkali is associated with the production of the anion $(\text{CH}_3)_2\text{CO}^-$, which effectively dechlorinates the PCB molecule and regenerates the initial $\text{Ar}^\bullet$ radical by means of electron transfer *via* reaction (26). A significant economy in energy is achieved in this dechlorination method,^{188, 189} but the additional consumption of expensive reagents limits its application.

One should bear in mind that the use of visible and ultraviolet light to initiate the reactions is relatively ineffective owing to the lack of transparency of the majority of the reaction media to waves in this range, while the technique of radiation-chemical initiation is too expensive and the effect obtained does not compensate for the expenditure. When chemical reagents are used as initiators, the caustic alkali–alcohol system may be recommended for the detoxification of sewage and materials with a low PCB content.

In conclusion of the consideration of dechlorination processes initiated by photochemical reactions, we may mention the method for the decomposition of PCB in the plasma of a radiofrequency glow discharge developed in Japan.¹⁹⁰ The nature of the products formed under these conditions is determined by the nature of the dechlorinating agent. In an oxygen plasma, PCB decomposes to CO_2 , CO , ClO_2 , Cl_2 , and HCl , while in the presence of water vapour CO_2 and HCl are formed. The use of a hydrogen plasma leads to the formation of C_2 – C_7 hydrocarbons (alkanes, alkenes) and HCl . The application of these processes ensures the quantitative binding of PCB without risk of the formation of PCDD and PCDF. Dechlorination in a plasma is most attractive because the hydrocarbons obtained may be used as a fuel. The prospects for this method are associated exclusively with the processing of concentrated PCB. There are so far no data on its industrial tests, which is apparently due to the low productivity of the process and the large energy expenditures.

VI. Biotechnological methods

During the last two decades, investigators have shown a steady interest in the problem of the search for effective PCB biodecomposition methods. This can be accounted for, firstly, by the high resistance of PCB and, secondly, by the fact that biological purification is the concluding stage in many detoxification processes, including the purification of sewage. The object neutralised usually consists of complex mixtures of toxicants and the decomposition of the PCB present in them limits the entire process as a whole.

A series of investigations have been devoted to the problem of the biodegradation of PCB.^{3, 9, 37, 38, 51, 77, 85, 191–202} It has been shown that both pure cultures of micro organisms and their mixtures can be used for the detoxification of PCB-containing materials. The microflora from the bottom deposits in rivers, lakes, and soils and the active sludge from the purification equipment in the cellulose-paper industry and undertakings of the food industry are used as mixtures of microorganism cultures.^{77, 192–198, 200–202} None of the natural strains isolated is capable of fully decomposing PCB, the highly chlorinated PCB being the most resistant to biodegradation.^{100, 200}

The difficulty of the study of the biodegradation mechanism is associated with the complexity of the processes investigated, which constitute a chain of consecutive-parallel reactions, each of which is catalysed by its own enzyme. Nevertheless, many groups of investigators who have studied the aerobic decomposition of PCB by microorganisms maintain a single view on the sequence of reactions leading to the decomposition of these compounds.^{203–214} This sequence includes the following stages: the interaction of an oxygen molecule with one of the aromatic rings of PCB with formation of the corresponding dihydrodiol; the transformation of the dihydrodiol into a dihydric phenol; the cleavage of the aromatic ring and the formation of the chlorinated 2-hydroxy-6-oxo-6-phenylpenta-2,4-dienecarboxylic acid; the formation of chlorobenzoic acid:

The above scheme has been confirmed by mass-spectrometric studies of the intermediate and final biodecomposition products, as well as by chemical tests on the latter.²⁰³ At the same time, on the basis of this scheme one cannot answer the fundamental question concerning the possibility of the intensification of biodecomposition processes.

An increase in the effectiveness of the decomposition of PCB may be promoted by the application of substrates such as sodium acetate²⁰⁰ or inorganic nitrogen and phosphorus compounds²¹⁵ as nutrients for the microorganisms, as well as by the use of mixtures of different cultures^{200, 201} and by the combination of PCB biodegradation processes with other biotechnological processes, for example composting.²¹⁶

The biodegradation methods are very convenient for the dechlorination of PCB dispersed in the environment, for example in soils and water sources, and also for the detoxification of

subterranean waters, sewage, sludge, and domestic waste with a low PCB content.^{3, 9, 51, 77, 85, 192, 194, 195, 200, 216}

The rate of biotechnological purification of sewage can be increased by employing emulsifying agents, which increase the solubility of PCB and PCB-containing oils in water.⁷⁷ The creation of highly productive biotechnological PCB degradation methods is possible if more active strains of microorganisms are cultured. For the productivity achieved at the present time, the biotechnological method for the decomposition of PCB is most reasonably employed at the end of the dechlorination process in combination with other methods, for example chemical and photochemical.^{77, 123, 130, 202} This is favoured also by the high degree of decomposition of PCB molecules containing fewer chlorine atoms in the concluding stage.

Another problem arising when biodegradation methods are employed consists in the preservation of the vitality of the PCB-decomposing microorganisms in the soil, where they should compete effectively with soil microorganisms.

Finally, certain difficulties arise owing to the interaction of PCB molecules with compounds in the bottom deposits and the soil. Such interaction prevents the microbiological decomposition of PCB.

VII. Oxidative methods

Among the methods for the neutralisation of PCB-containing materials, the oxidative procedures predominate. They can be divided into combustion proper and special oxidation methods. The latter include catalytic oxidation, plasma methods, ozonisation, and oxidation under hypercritical conditions.

Combustion predominates not only among the oxidative methods but in general among the methods for the detoxification of PCB and PCB-containing materials. This is due to the universality of this procedure as regards the types of materials processed, the ease of controlling the process, and its suitability for various technological versions and conditions of the neutralisation process, which facilitates the creation of mobile apparatus and ensures the possibility of employing the heat of the combustion process, complete decomposition of the PCB in the cycle, *etc.*

The processes involving the combustion of PCB and polychlorobiphenyl-containing mixtures have been the object of numerous investigations^{5, 6, 9, 16, 18, 42, 48, 50, 55, 56, 74, 77, 85, 87, 143, 217–232} in the course of the last three decades, the aim of which consisted in the search for conditions ensuring the most complete oxidation. The requirements which must be met by the PCB combustion processes are fairly rigorous. Thus, according to the standards established by the Environmental Protection Agency in the USA the degree of destruction of PCB in these processes should not be less than 99.9999%.²³³ This is achieved by selecting the optimum ratios of PCB, the oxidants, and the additional fuel as well as the temperature and residence time of the mixture in the combustion chamber.²³⁴ We shall examine the principles governing this choice.

The ratios of the components of the initial mixture are determined primarily by stoichiometric considerations.²³⁴ Thus exhaustive oxidation of the $C_{12}H_xCl_{10-x}$ molecule to CO_2 , H_2O , and HCl should be described by the equation

This equation has a physical significance only for $x > 5$. When $x = 5$, water is not formed. For $x < 5$, the combustion process proceeds in the direction of the formation of molecular chlorine²³⁵ in accordance with the equation

The formation of molecular chlorine is undesirable for two reasons. Firstly, it has a highly corrosive effect on the material of the apparatus used in the combustion processes. Secondly, its quantitative extraction from effluent gases is a difficult problem and requires the use of expensive alkaline agents. Direct combustion of the majority of the commercial PCB mixtures should lead irreversibly to the formation of appreciable amounts of molecular chlorine. The virtually complete suppression of the formation of molecular chlorine in the combustion of highly chlorinated PCB can be achieved by introducing into the initial mixture of PCB and the oxidant an additional hydrocarbon fuel, which is an external source of the hydrogen atoms lacking in the PCB molecules.^{235, 236} If methane is used as such a fuel, the PCB combustion process can be described by the equation

The introduction of a fuel, the amount of which is expressed by the stoichiometric coefficient β , should not only make good the deficiency of the hydrogen in PCB but should also ensure the required temperature of the flame and its stability.

In its turn, the combustion temperature is determined from the condition for the complete suppression of the formation of PCDD and PCDF. The Environmental Protection Agency in the USA recommends that this requirement be satisfied by ensuring a temperature in excess of 1200 °C and a residence time in the combustion chamber longer than 2 s.^{46, 233, 237} A definite excess of the fuel relative to PCB and an excess of the oxidant relative to the fuel are necessary for this purpose.^{235, 236} There is no need to go far beyond the limit of 1200 °C, because this leads to an excess consumption of fuel and rapid wear of the equipment. A certain excess of the oxidant (oxygen, air) is needed for the exhaustive degradation of PCB and the suppression of soot formation.^{235, 236} However, this excess should not be enormous, because, in accordance with the Deacon equilibrium

the undesirable formation of chlorine is possible at a high oxygen concentration.

There have been few studies devoted to the quantitative aspects and mechanisms of the combustion processes of halohydrocarbons and they are concerned mainly with halomethanes.^{235, 236, 238–240} We suggest that the ideas developed in these investigations cannot be extended to haloarenes, because the chemical properties of the latter differ too much from those of halomethanes. On the other hand, two phenomena observed in the study of the combustion of halohydrocarbons may have a bearing also on the combustion of PCB.

The first concerns the inhibiting effect of halohydrocarbons. By extending the ideas developed in a series of investigations,^{236, 241–244} it is possible to put forward the following mechanism of the inhibition of the combustion of the PCB–fuel mixture,

Reactions (32) and (33) reflect the role of HCl (the product of the combustion of any chlorohydrocarbon) as a trapping agent for the $H \cdot$ and $OH \cdot$ free radical species responsible for the combustion process. Reactions (34) and (35) describe the involvement of chlorine atoms in chain termination and hence also in the inhibition of the combustion process.

The second observed phenomenon is the acceleration of the combustion of chlorohydrocarbons by water vapour:

Water vapour initiates the formation of the $\text{H}^\bullet$, $\text{O}^\bullet$, and $\text{OH}^\bullet$ radicals which are responsible for the oxidation process. The mechanism examined explains the suppression of the formation of chlorine in the chlorohydrocarbon combustion process.^{245, 246} Firstly, by virtue of the occurrence of reaction (36), the concentration of chlorine radicals falls and hence their recombination [reaction (34)] with formation of Cl_2 diminishes. Secondly, water vapour behaves as a donor of hydrogen atoms [reactions (36) and (37)] and hence it makes good the deficiency of hydrogen in PCB.

The technological formulation of the process depends in many respects on the state of aggregation of the material being neutralised. The simplest apparatus consists of a hollow combustion chamber fitted with a special burner with attachments for the supply of the PCB-containing material, the fuel (when this is necessary), and air (oxygen).^{217, 231} It is used to neutralise PCB-containing liquid waste and sewage. The joint combustion of concentrated sewage and liquid PCB-containing waste makes it possible to avoid the formation of PCDD and PCDF.²³¹ A two-chamber apparatus, consisting of a rotary furnace and a final combustion chamber,^{6, 18, 42, 77, 179, 183} in which a temperature higher by 200 °C than in the first chamber is maintained to ensure the completion of the process and the suppression of the PCDD and PCDF formation reactions, is used in certain cases. The two-chamber apparatus proved to be the most effective device for the combustion of liquid waste and its universal application has been recommended by the Environmental Protection Agency in the USA.¹⁸³

The most widely used procedure for the destruction of PCB-containing solid and liquid waste is combustion in cyclone and cement furnaces and incinerators. By virtue of the high temperature and a fairly long contact time, the complete decomposition of PCB and the intermediate PCDD and PCDF is achieved in rotating cement furnaces,^{54, 77, 174, 176} while the limestone present in the initial charge binds quantitatively the acid gases formed on combustion (Cl_2 , HCl , *etc.*). The addition of PCB-containing materials to the initial charge improves the quality of the cement obtained.⁷⁷ The materials combusted served as an additional source of heat and this makes it possible to economise on the main fuel.¹⁷⁴

An interesting method involving the combination of the combustion of PCB-containing materials with a blast furnace process has been proposed.¹⁷⁴ As in the cement furnaces, here the problem of the recovery of the heat is solved successfully and the acid gases formed are bound by the limestone used as the flux.

The highest efficiency of the combustion of solid PCB-containing waste is achieved in special furnaces consisting of three series-connected reaction units: a rotating furnace, a final combustion furnace, and a chamber for the combustion of gaseous products.^{18, 183} Such devices are suitable for the combustion of materials. In the version described, they are used for the combustion of domestic rubbish, whilst liquid PCB-containing waste can be supplied directly into the final combustion chamber. Gas, petroleum products, or coal can be used as the fuel for the combustion of any PCB-containing waste.¹⁸ In most cases, the effluent acid gases are absorbed in two series-connected scrubbers irrigated with water and an aqueous solution of alkali.^{184, 242} Limestone is sometimes added to the initial mixture to bind the acid gases.^{77, 171} A fluidised bed regime may be established to intensify the process in the combustion chamber,⁷⁷ but the melting point of the inert material used in this case imposes certain limitations on the combustion conditions. For example, the melting point of sand is 1100 °C.

The combustion furnaces can be combined into a single aggregate with any heat consuming unit. Thus examples of the

combustion of PCB-containing oils in boiler aggregates,²¹⁶ for heating aluminium furnaces,²²³ and for the generation of the additional heat in the lime preparation process⁷⁷ are known. The combustion methods are very convenient to use in devising mobile systems designed for the processing of local sources of pollution by PCB on trailers and in ocean-going vessels.^{77, 219}

The main deficiency of the combustion method is the risk of the formation of the highly toxic PCDD and PCDF during the oxidative degradation of PCB.^{18, 218, 235, 247} In a number of instances, the absence of PCDD and PCDF among the combustion products was noted^{54, 217, 221} and these data have been confirmed by kinetic and thermodynamic calculations, according to which these compounds should not be formed at temperatures above 1200 °C and for contact times longer than 2 s.²³⁷ Nevertheless, in the highly productive plant which actually exists it is difficult to ensure the ideal functioning of the combustion reactors, *i.e.* a uniform temperature throughout the volume of the chamber and an identical residence time in the reaction zone for all the particles in the reaction stream. For this reason, there is always a probability of the formation of the highly toxic PCDD and PCDF. A greater uniformity of the temperature field in the combustion chamber can apparently be ensured by employing a fluidised bed technique or by carrying out the process in the melt of an inert material, for example glass.⁷⁷

The complete suppression of the formation of PCDD and PCDF is achieved when PCB are combusted in an oxygen and water vapour atmosphere.²²⁰

One of the deficiencies of the combustion processes is a low selectivity, so that their use for the destruction of PCB is fully justified only for a fairly high content of the latter in the materials being neutralised.⁸⁷ The Environmental Protection Agency in the USA determined the lower limit of the PCB content in spent materials at the level of 500 mg of PCB per kilogram of the material.²²⁴

Among other deficiencies of the combustion processes, one may note the high cost, the additional consumption of fuel, the rapid wear of equipment in corrosive media (Cl_2 and HCl) and at high temperatures, and also the irreversible loss of the hydrocarbon component.^{68, 230} The last deficiency is of a fundamental character, because the aim of the overall strategy in the development of the world technology is the creation of resource-saving industries.

Only a few scattered studies have been devoted to the field of the catalytic oxidation of PCB.^{12, 232, 237, 248–252} The application of catalysts makes it possible to lower appreciably the process temperature and hence to reduce the capital and energy expenditure. It is remarkable that PCDD and PCDF are not formed under catalytic conditions, and the emission of nitrogen oxides is appreciably reduced. RuO_2 , $\text{Cr}_2\text{O}_3/\text{Al}_2\text{O}_3$, $\text{CuO}/\text{Al}_2\text{O}_3$, Co_3O_4 , the mixed catalysts CuCr_2O_4 , Pt-Pd , and metal chlorides on an inert porous support, which are capable of being converted into the corresponding oxides on heating in air, are used as catalysts. Despite promising results, systematic studies on the characteristic features of the catalytic PCB oxidation processes are lacking and this hinders an assessment of the prospects for their application.

The methods for the oxidative decomposition of PCB in plasma or electric arc discharges are of undoubted interest.^{11, 151, 252, 253} The complete conversion of PCB into gaseous products (CO , CO_2 , H_2O , HCl , Cl_2 , ClO_2) without risk of the formation of PCDD and PCDF is ensured under these conditions. However, such processes are characterised by low selectivity and high energy expenditures, so that their application is justified only if it is necessary to detoxify concentrated PCB-containing materials.

The neutralisation of PCB by the ozonisation method has been tested in relation to aqueous solutions of these toxicants.^{77, 254, 255} At the usual temperatures, the degree of decomposition of PCB reaches 97.0%–99.4%. The acceleration of this process is promoted by UV irradiation and by the addition of potassium hydroxide to the solution. This method is of interest for the detoxification of sewage, since simultaneous ozonisation ensures its disinfection.

PCB can also be oxidised by employing a mixture of oxygen (air) with water as the reagent under conditions ensuring the attainment of hypercritical parameters of the latter.⁷⁷ In this state, the hydrogen bonds are significantly weakened and the dielectric constant diminishes to 3–10. As a result, water becomes a good solvent for the organic mass and the oxygen supplied to such a system rapidly oxidises the substrate. The exothermicity of the process makes it possible to maintain the temperature at a level of $\sim 550^\circ\text{C}$. When this method is used, the formation of PCDD and PCDF is ruled out and the complete decomposition of PCB is ensured. However, additional studies are needed in order to analyse the material and energy balances and to elucidate the economic desirability of the development of the method.

VIII. Hydrogenolysis of polychlorobiphenyls

The interest in detoxification of organochlorine waste by the dechlorination method has increased in recent years.²⁵⁵ This has been induced by a series of evident advantages of this process compared with other procedures for the conversion of organochlorine compounds, including PCB. Firstly, hydrogenolysis proceeds fairly 'smoothly' under comparatively mild conditions up to the complete conversion of the initial organic reagent. Secondly, the reaction is selective in relation to the object processed, which makes it possible to achieve successfully the dechlorination of organochlorine compounds within any range of their concentrations. If other undesirable organoelement compounds are present in the reaction mixture, then they can be readily converted into the corresponding hydrocarbons by hydrogenolysis. Thus there is a possibility of the regeneration of the spent lubricating oils and other PCB-containing materials. Thirdly, in the hydrogenolysis the formation of PCDD and PCDF is ruled out. Fourthly, this method has an evident resource-saving character.

Processes involving the hydrogenolysis of organohalogen compounds have been the objects of numerous investigations. Nevertheless, the number of studies in which the chemical behaviour of PCB in these reactions has been considered is limited.^{49, 80, 129, 256–271} The aim of the majority of studies was to solve applied problems in the detoxification of PCB-containing materials.

The hydrogenolysis of PCB can be achieved by the thermal, catalytic, and the usual chemical methods. In the last case, expensive alkali and alkaline earth metal hydrides and hydroborates^{49, 100, 186, 267} as well as silanes and polymethylsiloxanes^{129, 268} are used as the dechlorinating agents. These methods are more in the nature of preparative procedures and cannot be considered as a basis for industrial application.

There have been several studies devoted to quantitative aspects of the thermal hydrogenolysis of chloroarenes, including chlorobiphenyls.^{259, 272–274} The results of the investigation of the pyrolytic decomposition of arenes and chloroarenes should be regarded as a component of these studies.^{152, 275} The gas-phase thermal hydrogenolysis of PCB by hydrogen at $700–925^\circ\text{C}$ leads to the formation of benzene and hydrogen chloride as the final products with insignificant soot formation.²⁵⁹

Analysis of the results obtained in the studies quoted above and of the thermal kinetic data presented in some of them makes it possible to postulate the following mechanism of the thermal hydrogenolysis (in relation to 4-chlorobiphenyl):

Detailed investigation of the behaviour of PCB at different hydrogen concentrations^{153, 259, 275} has shown that reactions (43)–(45) are reversible. The processes which are the reverse of the above reactions may be regarded as stages in the thermolysis of chlorobenzenes. The pyrolysis of chlorobenzenes should then be supplemented by stages involving initiation and the formation of HCl:

Under the pyrolysis conditions, the concentration of molecular hydrogen is extremely low and equilibrium (41) is significantly displaced to the left, which leads to high $[\text{Cl}\cdot]/[\text{H}\cdot]$ ratios. This induces in its turn the displacement of equilibrium (43)–(45) also to the left, *i.e.* in the direction of the products of the thermolysis of chlorobiphenyls.

The main difficulty in the occurrence of thermal hydrogenolysis is the supply of heat for the creation of the required temperature regime. However, at the current level of the technology of high-temperature processes, this difficulty has been overcome. There have been promising communications concerning the possibility of replacing hydrogen in the thermal hydrogenolysis of PCB by the cheaper methane and other alkanes.^{257, 263, 275} A tubular furnace, in the intertubular space of which it is possible to combust the methane employed, is entirely suitable for the organisation of such a process.

Numerous versions of the catalytic hydrogenolysis of organochlorine compounds have been described in the literature.^{256, 271} The processes are carried out both in the liquid and gas phases, usually on metals such as Pt, Pd, Rh, Ru, Ir, Os, Ni, Co, Fe, Re, Mn, Mo, W, Cr, V, Cu, Ag, and Au. The properties of the catalysts can be varied widely by fusing them with other metals, by adding promoting agents, and by selecting supports.

A detailed analysis of the characteristic features of the catalytic hydrogenolysis of various aromatic chloro-compounds, including PCB, has been carried out in mutually complementing reviews^{256, 271} and we shall therefore confine ourselves here to a brief description of the existing ideas.

The kinetics of the catalytic hydrogenolysis of a series of chloroalkanes, chloroalkenes, and chloroarenes indicate that the majority of the process proceed *via* the Langmuir–Hinshelwood mechanism with dissociative adsorption of hydrogen on the catalyst surface. The extensive experimental data accumulated provide guidelines in the search for more effective catalysts and for the extension of the ideas developed to new objects.

Many experimental data have been obtained in recent years on the catalytic hydrogenolysis of polychlorobiphenyls.^{258, 260–262, 264, 265, 270, 276} The reactions take place in the gas and liquid phases and in the latter case alkalis may be added to the reaction mass in

order to bind the hydrogen chloride formed. Supported Group VIB and Group VIII metals, Raney nickel, and the nickel--molybdenum alloy catalyst have been used successfully as catalysts. The hydrogenolysis of PCB on nickel, deposited on kieselguhr, in the gas and liquid phases has been studied in detail.²⁷⁶

The possibility of the quantitative dechlorination of certain PCB to biphenyl under mild conditions indicates major prospects for catalytic hydrogenolysis. The heat of reaction is sufficient to maintain the necessary, comparatively low, temperature in the reaction zone. In connection with the problem of increasing the useful life of the catalyst and of the restoration of its activity in the regeneration cycle, attention has been drawn to a study²⁷⁷ of the hydrogenolysis of PCB with the aid of a combined reagent comprising alkali and a hydrogen-transferring agent. The authors regard this process as an alternative to the usual catalytic hydrogenolysis. Hydrocarbons incorporating highly mobile hydrogen atoms (alkanes containing tertiary C—H bonds or alkylarenes with benzyl C—H bonds) are used as the hydrogen donor. The role of the hydrogen-transferring agent is performed by anthracene, phenanthrene, alkylnaphthalenes, and also graphite, soot, or transition metals (in the first place iron). The overall process can be described by the equation

where H* are active hydrogen atoms evolved by the hydrogenating form of the transferring agent, for example the dihydroanthracene formed on interaction with the hydrogen donor, *i.e.*

or the adsorbent (carbon, transition metals). In the latter case, the version proposed by the authors differs little from the usual heterogeneous-catalytic hydrogenolysis, because transition metals (the classical catalysts for these processes) promote the dissociative adsorption of H₂ and the formation of atomic hydrogen as the active surface intermediate. The idea of hydrogen transfer with the aid of polycyclic aromatic compounds is attractive, but the prospects for the technological application of this process are obscure, because problems arise associated with the application of expensive alkali and the difficulties in the separation of the reaction mass and the utilisation of the products of the conversion of the hydrogen donors.

* * *

The examination of the problem of the pollution of the environment by PCB and of the known methods for their neutralisation has shown that, in the practical solution of this ecological problem, it is possible to apply both individual methods for the processing of PCB and their various combinations. The use of two and more methods is most rational, for example, in the utilisation of articles containing high PCB concentrations. Such methods may be combustion and biological purification, dechlorination, oxidation, *etc.* A concrete technology for the neutralisation of PCB, determined by the state of aggregation of the material, the concentration of PCB in it, the specified degree of purification, and other technological and ecological factors, must be selected in each case.

Oxidative methods in the synthesis of vicinal di- and polycarbonyl compounds

V D Filimonov, M S Yusubov, Ki-Van Chi

Contents

I. Introduction	725
II. Oxidation of carbonyl compounds and their derivatives	725
III. Oxidation of 1,2-diols, epoxides and other vicinally substituted compounds	735
IV. Oxidation of alkanes, alkenes, alkynes and their derivatives	738
V. Conclusion	743

Abstract. The review systematises and summarises the oxidative methods for the synthesis of compounds with vicinal carbonyl functions. The oxidative reagents used for this purpose, their scope and limitations are discussed. The bibliography includes 307 references.

I. Introduction

Alicyclic and cyclic 1,2-dicarbonyl and vicinal polycarbonyl compounds have been known for over 150 years. The properties of many of them have been well studied, and some have found practical use as biologically active compounds, intermediates in the synthesis of various heterocyclic compounds, analytical reagents, photopolymerisation initiators *etc.* Bis-1,2-diketones find use as monomers for the preparation of thermostable polyphenylquinoxalines.

Some representatives of this class (*e.g.*, ‘oxocarbons’ and ‘pseudooxocarbons’) are rather exotic compounds but present considerable interest for theoretical organic chemistry.^{1–3} To date, vicinal polycarbonyl compounds with five carbonyls have been obtained. Activity in this field of research does not cease.

Methods for the synthesis of 1,2-, bis-1,2- and polycarbonyl compounds^{1,4} and cyclic oxocarbons and pseudooxocarbons² have been reviewed.

The present review systematises and summarises the literature data on the oxidative methods for the synthesis of di- and polycarbonyl compounds with preservation of the carbon skeleton of the starting substrates. The existing methods for the synthesis of these compounds are divided into the following main groups: (1) introduction of a carbonyl group at the α -position with respect to the existing one in aldehydes, ketones, carboxylic acids and their α -substituted (hydroxy-, halogeno-, *etc.*) derivatives; (2) oxidative transformations of epoxides and vicinal compounds containing the CHX-CHY moiety; (3) oxidation of the alkyl groups and compounds with multiple bonds. The reagents used for oxidation are described for each of the above substrate types. Generally, we refer to studies not included in the

reviews mentioned above.^{1,2,4} However, in some instances we mention them in order to give a full picture of the existing reagents and the most reliable methods.

One should bear in mind that vicinal di- and polycarbonyl compounds tend to undergo hydration, and their mono- or dihydrates, *i.e.*, *gem*-diols, are commonly obtained as the final products. It is also typical of vicinal di- and polycarbonyl compounds to exist as various types of enols; the ratio of the carbonyl and enol forms has not been always determined with certainty.

II. Oxidation of carbonyl compounds and their derivatives

Syntheses of vicinal di- and polycarbonyl compounds are most commonly based on substrates already containing at least one carbonyl group.

1. Oxidation of the α -methyl and α -methylene groups of aldehydes, ketones and carboxylic acids

The reagents known for the preparative oxidation of the α -methyl and α -methylene groups of aldehydes and ketones are listed in Table 1. Nitrogen oxides and aromatic nitrosamines were the first reagents used for the oxidation of ketones (more seldom, aldehydes). They had been used rather widely in the synthesis of 1,2-dicarbonyl compounds before such reagents as selenium dioxide and DMSO appeared.^{1,2,4,5}

Since the turn of the century, treatment of 1,3-diarylpropan-2-ones with ‘nitrous gas’, which is generated from nitric acid and arsenic oxide at -30°C , has been known to give ‘isonitrosodimers’. The latter decomposed on heating to give nitrogen and aromatic vicinal triketone hydrates.⁶ This reaction was used in the synthesis of diethyl oxomalonate from diethyl malonate and N_2O_3 (yield 75%).⁷ It was pointed out that the oxidation of diethyl malonate is more convenient if NO_2 is used.¹ Later, diaryl triketones were obtained in high yields using an equimolar mixture of NO and NO_2 .⁸

In 1901, the oxidising effect of *p*-nitrosodimethylaniline on the methylene group of certain β -diketones and/or β -oxo esters, which resulted in contiguous tricarbonyl derivatives, was discovered. Examples of such reactions have been presented in reviews.^{1,5} Despite the high toxicity of the reagent, the method is sometimes used even now. For example, the following scheme for the preparation of dioxo esters (**1a–c**) from esters has been implemented.⁹

Table 1. Reagents used for the oxidation of carbonyl compounds and their derivatives into vicinal di- and polycarbonyl compounds.

Substrate	Reagent	Product
RCOMe	AlkONO, NaNO ₂ –H ⁺ , HalNO, HSO ₄ NO, NH ₄ CrO ₃ Cl, nitrosonium salts, SeO ₂ , H ₂ SeO ₃ , PhSeSePh–(NH) ₄ S ₂ O ₈ –MeOH, HBr–DMSO	RCOCHO
RCOCH ₂ R and cyclic ketones	KMnO ₄ –Al ₂ O ₃ , NH ₄ CrO ₃ Cl, O ₂ –V ₂ O ₅ or V ₂ O ₅ , nitrosonium salts, SeO ₂ , H ₂ SeO ₃ , HBr–DMSO, NBS–DMSO	RCOCOR
β-Diketones	NO–NO ₂ , 4-Me ₂ NC ₆ H ₄ NO, ¹ O ₂ – <i>hν</i> –Bu ₄ NF, PhIO, SeO ₂ , H ₂ SeO ₃ , HBr–DMSO, NBS–DMSO	Vic. triketones
β-Oxo esters	NO–NO ₂ , 4-Me ₂ NC ₆ H ₄ NO, KMnO ₄ –Al ₂ O ₃ , Bu ^t OOH–V ₂ O ₅ –SiO ₂ , CrO ₃ , O ₂ –Co(OBz) ₂ , PhSeSePh–(NH) ₄ S ₂ O ₈ –MeOH	R ¹ COCOCOOR ²
R(Me ₃ SiO)C=CR(OSiMe ₃)	Br ₂ –CHCl ₃	RCOCOR

Note. NBS is *N*-bromosuccinimide.

R = 1-allyl-3-indolyl (**a**), 4-Me₂NC₆H₄ (**b**), 1-methyl-2-pyrrolyl (**c**);
(a) 4-Me₂NC₆H₄NO, KOH, EtOH; (b) HCl, CH₂Cl₂.

It was noted that compounds **1a–c** could not be obtained by the photooxidation of the phosphorylides of intermediate β-diketones.⁹

Certain ketones react with pentyl nitrite to give α-nitroso derivatives (oximes); this reaction with an excess of the reagent under mild conditions gives α-diketones.¹⁰ This procedure made it possible to synthesise 1-phenylpropane-1,2-dione from propiophenone and camphorquinone from camphor. Alkyl nitrites react with ketones as sources of the nitrosonium ion (NO⁺). Ketones are also successfully oxidised with other reagents that generate NO⁺ *in situ*, for example, inorganic nitrites in the presence of acids, nitrosyl halides and nitrososulfates. Some of aryl methyl ketones were oxidised with these reagents under mild conditions into arylglyoxals or their acetals.¹¹ Acetals are formed in 50%–70% yields in the reaction of acetophenones with MeONO in a mixture of MeOH with HCl at 0–5 °C in 4 h. Heating of aryl methyl ketones with NaNO₂ in HCl at 60 °C gives the corresponding arylglyoxals directly in yields higher than 60%.¹¹

The oxidative properties of organic nitrosonium salts are similar to those of nitrosodimethylaniline and alkyl nitrites. Their use as oxidants of alcohols, amines and ketones is covered in a review,¹² and we shall not dwell on this topic.

Such a popular oxidant as potassium permanganate generally cleaves ketones to carboxylic acids or (in basic media) transforms them to oxocarboxylic acids.⁵ However, KMnO₄ immobilised on alumina can selectively oxidise the α-methylene groups of ketones. Oxidation of cyclohexanone in dichloromethane at room temperature for 120 h results in cyclohexane-1,2-dione in 58% yield.¹³ The same reagent oxidises ethyl phenylacetate in 161 h to give ethyl phenylglyoxylate in an almost quantitative yield. However, phenylacetic acid undergoes decarboxylation under these conditions to give benzaldehyde.¹³

Ferrocenyl diketones (**2a–c**) were first obtained¹⁴ in 50%–65% yields upon the oxidation of the corresponding ferrocenyl ketones with MnO₂ in boiling dichloromethane.

Fc is ferrocenyl; R = Ph (**a**), 4-C₆H₄Ph (**b**), Fc (**c**).

Yet another example of a fundamental change in the properties of an oxidant after its immobilisation on a support was

demonstrated for V₂O₅ adsorbed on montmorillonite or SiO₂, which is an efficient catalyst for the oxidation of the methylene group of methyl phenylacetates with *tert*-butylhydroperoxide to give alkyl arylglyoxylates (**3a–j**).¹⁵

R = H(**a**), 2-MeO(**b**), 4-MeO(**c**), 4-Me(**d**), 4-NH₂(**e**), 4-NO₂(**f**), 2-Cl(**g**), 4-Cl(**h**), 2-PhCH₂(**i**), 4-PhCH₂(**j**).

Choudary *et al.*¹⁵ claimed that they were the first to oxidise the α-methylene group in arylacetic esters to the carbonyl group. However, as early as in 1957 phenylacetic acid was transformed to the acid **3a** in 86% yield upon treatment with air in the presence of cobalt benzoate at 110–115 °C.¹⁶ Diethyl malonate is oxidised with N₂O₃ as discussed above.

Butan-2-one is oxidised on V₂O₅ under aerobic and anaerobic conditions at 250–350 °C to butane-2,3-dione.^{17,18} Experiments involving ¹⁸O₂ showed that the resulting diketone did not contain this isotope. Acetic acid and acetaldehyde are the main side products, which are formed mainly due to the decomposition of butanedione. To a smaller extent, these products result from the oxidation of the original ketone in the enol form.

Copper acetate has been long used for the synthesis of 1,2-dicarbonyl compounds from α-hydroxy ketones (see Section III). An equimolar mixture of I₂ and Cu(OAc)₂ oxidises the α-methylene group in cyclohexanone and its derivatives on boiling in aqueous acetic acid for 15 h to give the corresponding cyclohexane-1,2-diones (**4a–h**) in up to 70% yields.¹⁹

R¹ = R² = R³ = H, R⁴ = (**a**), Me (**b**), Et (**c**), cyclo-C₆H₁₁ (**d**), Ph (**e**);
R¹ = R² = H, R³ = R⁴ = Me (**f**); R¹ = R⁴ = H, R² = R³ = Me (**g**);
R¹ = R² = R³ = Me, R⁴ = H (**h**).

The same procedure made it possible to obtain cholestane-2,3-dione (**5**) from cholestan-3-one in 40% yield.¹⁹

According to IR, ¹H and ¹³C NMR spectral data, compounds **4a–h** and **5** exist in the enol form.¹⁹

Oxidation of cyclic α -chloro β -diketones with hydrogen peroxide in the presence of MeReO_3 resulted in their decomposition to dicarboxylic acids *via* intermediate contiguous tricarbonyl compounds, which were detected in some instances by NMR spectroscopy.²⁰

The methylene group in barbituric acid can be oxidised with CrO_3 to give alloxan (**6**). The same result was obtained in the oxidation of benzylidenebarbituric acid (yield 75%–84%).^{21,22}

The other known reagent based on CrO_3 , namely, pyridinium chlorochromate introduced in practical organic synthesis in 1977 by Corey, oxidises successfully various benzyl ketones (but not aliphatic ketones) in boiling CH_2Cl_2 .²³

Compound	R ¹	R ²	Yield (%)
7a	H	Ph	80
7b	H	Me	85
7c	H	Et	80
7d	4-MeO	Me	60
7e	2-Me	Me	65

A similar reagent, ammonium chlorochromate ($\text{NH}_4\text{CrO}_3\text{Cl}$), transforms acetophenone to phenylglyoxal rather easily (DMF, 75 °C, 6 h) in 80% yield.²⁴ The same authors²⁵ used this reagent to oxidise butan-2-one to a mixture of ethylglyoxal and butane-2,3-dione and to oxidise 3-methylbutan-2-one to isopropylglyoxal.

A new method for the photooxidation of the methylene group of acyclic and cyclic β -diketones by singlet oxygen was suggested in 1985.^{26,27} The reaction occurs successfully only in the presence of tetrabutylammonium fluoride. Presumably, the fluoride anion enhances the nucleophilic properties of the enol forms, thus activating the electrophilic attack by singlet oxygen. This method gave high yields (60%–97%) of tricarboxyl compounds (**8**–**11**, **12a–c**).

$\text{R}^1 = \text{R}^2 = \text{Ph}$ (**12a**); $\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{Me}$ (**12b**); $\text{R}^1 = \text{R}^2 = \text{Me}$ (**12a**).

It should be noted that the similar photooxidation of five- and six-membered cyclic α -diketones results in ring opening to give aldehyde or oxo carboxylic acids, probably *via* intermediate *endo*-peroxides.^{26–29}

It is well known that the oxidation of acyclic ketones with oxygen in the presence of bases serves as a method for the synthesis of carboxylic acids. Oxidation of 3-methyl- and 3-ethylpentane-2,4-diones gives a mixture of acetic acid and the corresponding 3-hydroxy 2-ketones and 2,3-diketones.³⁰ This process is not a preparative method for the synthesis of diketones. However, it was found that cyclohexanone and cyclopentanone dissolved in dimethoxyethane undergo oxidation with atmospheric oxygen in the presence of Bu^tOK at -20°C to give the diketone **4a** and cyclopentane-1,2-dione, respectively.³¹ The yields of cyclopentanedione and especially diketone **4a** are low due to ring opening resulting in dicarboxylic acids. The similar reactions with cycloheptanone and cyclooctanone also give the corresponding diketones, but only as intermediates, which undergo subsequent aldol condensation. The stability of the diketone **4a** and cyclopentane-1,2-dione under these conditions is explained³¹ by the predominance of the enol forms.

1,2-Diketones and α -oxo esters (**13a–g**) are obtained in moderate to high yields (21%–83%) by the ozonolysis of Na-salts of β -diketones and β -oxo esters followed by treatment of the intermediate ozonides with hydrogen peroxide or dimethyl sulfide.³²

$\text{R}^1 = \text{OEt}$; $\text{R}^2 = \text{Bu}$ (**a**), PhCH_2 (**b**), 4-EtOCH₂C₆H₄CH₂ (**c**), $(\text{EtO})_2\text{P(O)CH}_2\text{CH}_2$ (**d**); $\text{R}^1 = \text{Me}$; $\text{R}^2 = \text{Bu}^t$ (**e**), PhCH_2 (**f**), 4-EtOCH₂C₆H₄CH₂ (**g**).

Compounds of hypervalent iodine are used very widely in organic synthesis, particularly as oxidising reagents for the α -hydroxylation of carbonyl compounds (see *e.g.*, the reviews^{33–36}). Much less is known about direct oxidation of ketones with these reagents to α -dicarbonyl compounds. The use of 1,1,1-triacetoxy-1- λ^5 -benzo-1,2-iodoxol-3-one ('periodinane' or the Dess–Martin reagent) in moist CH_2Cl_2 in the presence of pyridine for the oxidation of *tert*-butyl 2-hydroxy-2-phenylpropionate to the corresponding dioxo ester **14** was reported.³⁷

Diacetoxy- λ^3 -iodanylbenzene oxidises 1,3-indanedione in alcohols in the presence of H_2SO_4 to the corresponding 2,2-dialkoxyindanediones.³⁸

The kinetics and mechanism of the oxidation of cyclopentanone and cyclohexanone to the corresponding 1,2-diketones with bromoamine-T (4-MeC₆H₄SO₂NNaBr) in acidic media was studied.³⁹ Enolisation of the starting ketones was found to be the limiting step of the oxidation.

Selenium dioxide is a much more versatile reagent for the synthesis of vicinal polycarbonyl compounds. Its extensive use in practical organic synthesis started in the early 30's, and this reagent is still important today. Both SeO₂ and selenious acid (H₂SeO₃), which is prepared by concentrating aqueous solutions of selenium dioxide, are used in syntheses of dicarbonyl compounds. Both reagents selectively oxidise the α -methyl groups of aliphatic and aromatic ketones and acetaldehyde as well as the α -methylene groups of cyclic ketones. Oxidation can be carried out by heating the reagent and substrates in the absence of solvents. However, the reaction is more commonly performed in such solvents as water, ethanol, acetic acid and dioxane; sometimes, xylene, acetic anhydride and pyridine are used. A wide range of aryl methyl ketones with various donor and acceptor substituents in the ring are oxidised with SeO₂ to the corresponding arylglyoxals in yields usually exceeding 70%.^{4, 5, 40} However, *ortho*-acetylacetophenone, unlike the *para*-isomer,⁴ gives 2-hydroxy-1,4-naphthoquinone rather than bisglyoxal.⁴¹ It is reported in patent literature that the oxidation of acetophenone with SeO₂ in C_{1–9} aliphatic alcohols at 100 °C gives the corresponding phenylglyoxal acetals.⁴² Acetaldehyde is oxidised with H₂SeO₃ to glyoxal (isolated as a bisulfite derivative in 72%–74% yield⁴³). It can be noted that glyoxal is also formed from acetone by refluxing the latter with SeO₂ in xylene in the presence of water.⁴⁰ Selenious acid in aqueous dioxane readily oxidises cyclohexanone at room temperature to give cyclohexane-1,2-dione (yield 60%).⁴⁴ The use of SeO₂ in this reaction gives nearly the same yield but requires more drastic conditions (refluxing for 6–8 h).⁴⁵

Selenium dioxide has also been used to oxidise many β -diketones (acetylacetone, benzoylmesitoylmethane, dimesitoylmethane, 5-hydroxy-4-phenylcyclopent-4-ene-1,3-dione, *etc.*) to the corresponding 1,2,3-triones.¹ Bisglyoxals (**15a,b**) used in the synthesis of cyclic vicinal tetraketones were also obtained with this reagent.⁴⁶

The possible mechanisms of oxidation with selenium dioxide have been discussed in reviews.^{4, 40}

Despite the high efficiency and selectivity combined with mild conditions of the reaction, SeO₂ has a serious drawback noted in many works, namely, the difficulty of purification of the final products from selenium that is formed. Black selenium that is evolved can be filtered off, but a small amount of colloidal selenium ('red selenium') remains in solution and cannot be removed even by distillation. This necessitates an additional work-up of the products, *viz.*, shaking with mercury or inactive Raney nickel or treatment with potassium cyanide, SO₂, potassium hydrogensulfite in acidic media or thiourea.^{5, 40}

Yet another selenium-based oxidant, diphenyl diselenide, has been suggested recently.⁴⁷ It proved to be very efficient (in catalytic or stoichiometric quantities) for the preparation of α -oxo acetals **16** from the corresponding methyl ketones in the presence of ammonium peroxodisulfate (NH₄)₂S₂O₈.

The reaction is carried out in boiling methanol and is applicable to a broad range of aromatic and heterocyclic methyl

ketones (except for acetylpyridine) as well as to unsaturated, cycloaliphatic and, in certain cases, aliphatic methyl ketones. It is assumed that the process occurs through electrophilic attack of PhSe⁺ on the enol form of the ketone.⁴⁷

The same group of authors⁴⁸ expanded this oxidation method to β -diketones and β -oxo esters.

R¹ = Alk, Ph; R² = Alk, Ph, OAlk, OCH₂Ph.

In this case, only a catalytic amount of PhSeSePh was used, and the yields of oxo acetals **17** were considerably lower (10%–75%), especially for the diketones containing the acetyl fragment, which also undergoes partial oxidation. This reaction affords side products **18** and **19**.⁴⁸

Since the discovery of a very simple method for the oxidation of activated alkyl halides, including phenacetyl bromides, with DMSO in the presence of bases (the Kornblum reaction),⁴⁹ a large number of studies have appeared in which DMSO is used as a convenient oxidant (for the relevant reviews, see Refs 5, 50–52). No wonder that DMSO plays an important role in the synthesis of α -dicarbonyl compounds as well.

For example, DMSO in the presence of dry HBr oxidises the methylene groups in cyclic β -diketones to produce 1,2,3-triones **9** and **20** in 80% and 30% yields, respectively.^{53, 54}

It was found later that the oxidation of another cyclic diketone, dimedone (**21**), with DMSO in the presence of hydrogen bromide brings about not only oxidation of the methylene group but also ring bromination to give dibromotriketone **22**. In addition, a product of ring contraction, *viz.*, tribromocyclopentanedione **23**, is formed.⁵⁵

The DMSO–aqueous HBr system turned out to be very efficient in the transformation of acetylarenes to arylglyoxals **24a–e**.⁵⁶

R = 4-Ph (a), 4-MeO (b), 4-NO₂ (c), 4-Br (d), 2-Ph (e).

This is probably the most convenient reagent presently available for this transformation. The reaction is carried out at 55 °C for 1–24 h to give the corresponding arylglyoxals in high yields (42%–94%). Side processes have been noted in two cases only.

For example, the oxidation of 2-acetyl biphenyl results in oxidative cyclisation to give phenanthrenequinone in 47% yield. In the case of 4-acetyldiphenylamine, oxidation is accompanied by bromination of the unsubstituted phenyl ring to afford 4-(4-bromoanilino)phenylglyoxal (90%). Under the same conditions, 1,2-diphenylethanone affords quantitatively diphenylethanedione **7a** in 24 h, while 1,3-diphenylpropane-1,3-dione gives diphenyltriketone hydrate **12a**.⁵⁶

The following point related to the mechanism of this reaction is worthy of note. It is generally accepted that the Kornblum reaction occurs through the following pathway (without details of the decomposition step of the dimethylsulfoxonium intermediate **25**):^{50–52}

However, comparison of the results of oxidation of aryl methyl ketones in the DMSO–HBr–H₂O system and oxidation of α -bromoacetophenone in dry DMSO made it possible to suggest a different mechanism for oxidation with aqueous DMSO.⁵⁶ It was assumed that in this case the role of DMSO is reduced to the oxidative generation of a small amount of bromine followed by bromination and debromination of ketones with subsequent hydrolysis to arylglyoxal hydrates. Whatever the actual mechanism of this reaction, the DMSO–HBr–H₂O system is the most convenient for the preparative oxidation of acyclic ketones to α -dicarbonyl compounds and of acyclic β -diketones to triketones, provided that the substrates subject to oxidation are insensitive to bromine. A method has been patented for the synthesis of benzil **7a** using a concentrated HBr–DMSO system.⁵⁷ Other examples of smooth oxidation of methylene groups in bisdeoxybenzoins **26**, **27** to bis- α -diketones (**28**, **29**) are also known.^{58, 59}

The latter reaction, which serves as one of the steps in the synthesis of an aromatic tris- α -diketone⁵⁹ (see Section IV), demonstrates the high regioselectivity of the DMSO–HBr oxidising system with respect to the methyl groups in the acetylenic diketone **27**, since the triple bond remains unaffected. It is difficult or impossible to reach such a selectivity with other oxidants, e.g., SeO₂.

The methylene groups in 1,2-diphenylethanone and 1,3-diphenylpropane-1,3-dione are smoothly oxidised with a mixture of DMSO with concentrated H₂SO₄ in the presence of a catalytic amount of iodine.⁶⁰ However, the use of the same oxidative system for 1-phenylpropan-2-one and cyclohexanone gives very low yields of the diketones **7b** and **4a**. In this case, acetophenone gives a mixture of *Z*- and *E*-isomers of the enol form of 2-methylthio-1,4-diphenylbutane-1,4-dione, which are formed as products of phenylglyoxal transformation.⁶⁰

On prolonged action, *N*-bromosuccinimide in dry DMSO oxidises 1,2-diarylethanones at room temperature to give the corresponding diarylethanediones and oxidises indan-1-one, indan-2-one and indane-1,2-dione to indane-1,2,3-trione (**9**). The

reaction with 1,3-diphenylpropane-1,3-dione under the same conditions affords diphenyl triketone **12a**.^{61, 62} It is assumed⁶² that *N*-bromosuccinimide acts as a brominating agent to give the intermediate 3-bromoindan-1-one, which is then oxidised with DMSO according to the Kornblum reaction.

The methyl groups of aryl methyl ketones are oxidised on treatment with DMSO and benzoyl chloride at room temperature. However, instead of arylglyoxals, the reaction gives acetals of their fully hydrated forms with formaldehyde, i.e. 1-aryl-2,4,6,8-tetraoxabicyclo[3.3.0]octanes.⁶³

The vast variety of methods and reagents for the synthesis of α -hydroxycarbonyl compounds by hydroxylation of stable enol forms, e.g., of vinyl ethers/esters and thioethers/thioesters, enol silyl ethers and ketene silylacetals (for reviews, see Refs 5, 35, 64, 65) contrasts with the surprisingly small number of reagents known for their direct transformation to α -dicarbonyl derivatives. In fact, even the formation of α -dicarbonyl structures **30** and **31** in the oxidation of bisilyl ethers **32** and **33** with *m*-chloroperbenzoic acid (the Rubbotom method)^{46, 66, 67} actually occurs due to hydroxylation.

It is known that 1,2-bis(trimethylsilyloxy)alkenes, which are stable under non-hydrolytic conditions, can be oxidised with bromine in chloroform or CCl₄ to the corresponding cyclic diketones. This reaction occurs most successfully if it results in cyclobutanedione or non-enolizing diketones.^{68–71} In other cases, Me₃SiBr that is formed reacts with the enol forms of the resulting diketones, giving new silyl ethers of enols and, subsequently, various halogen-containing compounds.⁷⁰

A similar approach afforded 3,3,7,7-tetramethylcycloheptane-1,2-dione^{72, 73} and adamantylcyclobutanedione.⁷⁴ Likewise, the reaction of bromine with the bisilyl ether of bicyclo[4.2.0]octa-2,6-diene gives benzocyclobutanedione (**34**) through bromination and dehydrobromination.⁷³

2. Oxidation of α -hydroxycarbonyl compounds

Transformations of α -hydroxycarbonyl compounds to α -dicarbonyl compounds are well studied. Undoubtedly, the largest number of reagents for this kind of transformations have been

approved using the oxidation of benzoin as a very convenient model. Even 150 years ago, Laurent⁷⁵ and Zinin⁷⁶ showed that benzoin can be oxidised to benzil **7a** on treatment with chlorine or nitric acid. However, these reactions, unlike those developed later, did not become preparative methods.

Treatment of a solution of benzoin in pyridine with air in the presence of copper(II) sulfate at 100 °C for 2 h oxidises it to diketone **7a** in 86% yield.⁷⁷ Compound **7a** is obtained in quantitative yield by refluxing a solution of benzoin in acetic acid in the presence of a catalytic amount of copper acetate and ammonium nitrate.⁷⁸ Similar results are obtained if a catalytic amount of cobalt,^{78,79} iron or nickel salts⁷⁸ or complexes of Fe(II) with certain cysteine-containing peptides⁸⁰ are used. Complexes of Fe(II) with α,α' -xylenedithiolates catalyse the oxidation of benzoin to benzil **7a** in DMF at room temperature both by the atmospheric oxygen and *p*-benzoquinone; the latter oxidant was found to be more efficient in this reaction.⁸¹ It was suggested⁸² to prepare 4,4'-bis(carboxyphenyl)ethanedione ethers by oxidation of the appropriate benzoin with air in ethanol in the absence of catalysts at 60 °C for 13 h. 2-Hydroxy-1-phenyl-2-(2-quinolyl)ethanone (α -quinaldoin) is readily oxidised on passing air through its boiling solution in dioxane to give phenyl(2-quinolyl)ethanedione.⁵

The most commonly used oxidants are listed in Table 2 together with the relevant reaction conditions. These data make it possible to compare the reactivities of different reagents with respect to the oxidation of α -hydroxy ketones. Quinolinium fluorochromate, Bi(MnO₄)₂, AgBrO₃, AlCl₃, and *o*-iodylbenzoic acid can be regarded as the most efficient reagents.

In several studies,^{87–92} benzoin and other alcohols were oxidised with the same reagents under similar conditions. It turned out that such alcohols as benzyl alcohol, diphenylmethanol, and 1-phenylethanol were comparable with each other and

with benzoin with respect to the time required for their oxidation and the yields of the monoketones in the preparative experiments, *i.e.* the activity of these substrates is quite similar. However, oxidation of 4- and 4'-chloro-, bromo-, and methoxy-substituted benzoin with sodium or silver bromates in the presence of AlCl₃⁹⁰ or barium permanganate⁸⁸ is accompanied by an insignificant decrease in the yields of the corresponding diarylethanediones and an approximately twofold increase in the reaction time. The oxidation of 2-furoin with barium permanganate occurs much more slowly (4 h, yield 80%). These results of preparative experiments provide no more than a qualitative picture of the effect of the nature of α -hydroxy ketones and oxidants on the oxidation to 1,2-diketones. In order to reveal distinct regularities, one has to determine the rates of oxidation of different substrates under similar conditions. However, to our knowledge, there are no comparable kinetic experiments of this kind, although both the kinetics and the oxidation mechanism of α -hydroxy ketones have been studied rather thoroughly. For example, it follows from kinetic studies on the oxidation of benzoin with quinolinium dichromate to compound **7a** that the oxidation is 6 times slower than the substrate enolisation. Oxidation occurs through the initial coordination of the chromium atom with the carbonyl group of the substrate.⁹⁷

Many other reagents are known that oxidise benzoin to the diketone **7a**. For example, anhydrous Fe(NO₃)₃, which is normally unstable, is rather stable if impregnated in acidic montmorillonite. It affords benzil **7a** in a higher yield (85%–95%) than ytterbium nitrate.⁹⁸ On the other hand, K₂FeO₄ immobilised on the same support gives the diketone **7a** in only 36% yield, since this reagent cleaves the C–C bond of benzoin, producing benzaldehyde.⁹⁹ It was reported,¹⁰⁰ without specifying the conditions and yields of the reaction products, that catalytic amounts of tris(2,4-dibromophenyl)aminium hexachloroantimonate oxidise benzoin to the corresponding diarylethanediones. Benzoin can be oxidised with titanium isopropoxide,¹⁰¹ benzyltriethylammonium tribromide,¹⁰² triphenylstibine dibromide (Ph₃SbBr₂),¹⁰³ Ph₃PBr₂,¹⁰⁴ and PhMe₃N⁺Br₃[–]·NBS¹⁰⁵ to benzil **7a** in almost quantitative yield. Cobalt(III) acetate in acetic acid oxidises deoxybenzoins to benzoin and further to diphenylethanedione derivatives.¹⁰⁶

Copper sulfate and acetate have long been widely used for the oxidation of various benzoin structures. For instance, stoichiometric amounts of CuSO₄·5H₂O oxidise 1,2-difuryl-2-hydroxyethanone (2-furoin) and 2-phenyl-1-(2-pyrrolyl)-2-hydroxyethanone in aqueous pyridine at 100 °C in 2 h to give difurylethanedione (fural)¹⁰⁷ and phenyl(2-pyrrolyl)ethanedione¹⁰⁸ in 63% and 95% yields, respectively. Probably, copper acetate has an even higher oxidising activity. It oxidises 3-hydroxy-1,4-diphenylbutan-2-one to 1,4-diphenylbutane-2,3-dione in almost quantitative yield on refluxing for 7 min in 70% AcOH¹⁰⁹ and 2-hydroxycyclodecanone (sebacoine), also in aqueous AcOH,¹¹⁰ to cyclodecane-1,2-dione (sebacil) in 1 min. Copper acetate in AcOH was successfully used in the synthesis of cyclic diketones **35** and **36a,b**.^{46,65}

Table 2. Reagents and reaction conditions for the oxidation of 2-hydroxy-1,2-diphenylethanone (benzoin) to diphenylethanedione (benzil).

^a Benzylic acid is formed as a product of benzylic rearrangement of diphenylethanedione.

Sodium salts of enolic forms of hydroxy ketones that are formed in the acyloin condensation of esters (enedioxides **37**) are oxidised with thionyl chloride *in situ* at low temperature to symmetric α -diketones **39** via intermediate sulfites **38**.¹¹¹

$R = Me, Et, Bu^i, cyclo-C_3H_5, adamantyl, Ph$.

Reagents based on DMSO were successfully used for the oxidation of α -hydroxycarbonyl compounds. An aqueous solution of HBr in DMSO readily oxidises benzoin to benzil **7a** in high yield.⁵⁶ It is interesting that the same reagent also oxidises *o*-methylbenzoin to compound **7a**.¹¹² The reactivity of deoxybenzoin and its α -substituted derivatives in the oxidation to benzil **7a** was studied.¹¹³ The series of reactivities, benzoin > 2-bromo-1,2-diphenylethanone > 1,2-diphenylethanone, is a good confirmation of the suggested scheme of the oxidation of ketones with HBr in DMSO.⁵⁶ A combination of DMSO with P_2O_5 was used in the synthesis of azetidine-2,3-diones **40**, which were then oxidised to α -amino acid *N*-carboxyanhydrides according to Baeyer–Villiger.¹¹⁴

$R^1 = Me, Bu, Pr^i, Bu^i$; $R^2 = Ph, Ar, CH_2Ph$.

Such reagents as *N*-chlorosuccinimide with Me_2S and Et_3N , pyridinium chromate, pyridinium chlorochromate, the Jones reagent (CrO_3, H_2SO_4, H_2O), trifluoroacetic anhydride in DMSO, tetra-*n*-propylammonium perruthenate, RuO_4 , and $NaIO_4$ proved to be unsuitable for this purpose. The Corey reagent (Me_2SBr_2, Et_3N) was also inefficient,¹¹⁴ although it has been used successfully in the synthesis of various azetidine-2,3-diones from α -hydroxy- β -lactams.¹¹⁵ Treatment of hydroxy- β -lactams with sodium hypochlorite also leads to their oxidation according to Baeyer–Villiger.¹¹⁶

The Swern reagent ($DMSO-CICOCOCI$) oxidises dihydroxy[12]paracyclophanedione **31** to the tetraketone **41** under mild conditions ($-40^\circ C, 45\text{ min}$).⁶⁷

Oxidation of cyclotridecanedione **42** to the tetraketone **43** has been performed successfully by the same authors⁶⁸ with such a well-known reagent for the oxidation of alcohols as *N*-bromosuccinimide in CCl_4 .

However, bistetraketones **44** were obtained using nitric acid.⁴⁶

As a rule, aromatic derivatives of α -hydroxy ketones are readily oxidised with $DMSO-Ac_2O$, but the yields of α -diketones from aliphatic derivatives are low.¹¹⁷

α -Oxocarboxylic acids are important biologically active compounds and are of considerable interest for organic synthesis. It is not surprising that the development of methods for their synthesis draws much attention. Many reagents for the oxidation of alkyl α -hydroxycarboxylates to the corresponding oxo derivatives are known. These include $Pb(OAc)_4$, Ph_3SbBr_2 , tertiary amine oxides, sodium peroxodisulfate, 2-fluoro-1-methylpyridinium tosylate, DMSO with hexamethylenetetramine, $PhSOCl$, a complex of dimethyl selenide with *N*-chlorosuccinimide, sodium hypochlorite, diacetoxy- λ^3 -iodanylbenzene, $Co(II)$ compounds, bis(tetrabutylammonium) dichromate, $KMnO_4-CuSO_4$, ammonium vanadate, manganese pyrophosphate, immobilised chromic acid, chromyl chloride, vanadium(V) derivatives, periodinane (see *e.g.* Ref 118 and the references cited therein). A review published recently¹¹⁹ deals with the use of tetrapropylammonium perruthenate ($Pr_4N^+RuO_4^-$) as a mild catalytic reagent, particularly for the synthesis of α -keto acids. It was suggested to obtain esters of β, γ -unsaturated α -oxocarboxylic acids by the oxidation of the corresponding α -hydroxy derivatives according to the Swern procedure ($DMSO, CICOCOCI, CH_2Cl_2, -50^\circ C$).¹²⁰

In view of the abundance of studies in this field, the detailed discussion of oxidative methods for the synthesis of α -oxocarboxylic acids is beyond the scope of our review. Therefore, we shall discuss here only relatively new and, in our opinion, versatile reagents applicable for the synthesis of other α -dicarbonyl compounds as well.

For example, the importance of tetramethyl-1-piperidinyloxy (TEMPO) has increased in recent years.

In particular, it was shown that various linear and cyclic primary and secondary alcohols are oxidised in high yields to high-purity aldehydes or ketones under mild conditions on treatment with 4-acetylamino-TEMPO ($R = AcNH$) in dichloromethane in the presence of *p*-TsOH.¹²¹ The reagent is readily generated in the reaction mixture. Phenylglyoxylic acid is formed under these conditions in 91% yield from phenylglycolic acid.¹²¹

Oxaziridines, particularly various 2-sulfonyloxaziridines, are powerful oxidants due to the high electrophilicity of the ring oxygen atom. They are used most widely for the α -hydroxylation of carbonyl compounds.^{64, 122} It was found that perfluoro-*cis*-2,3-dialkyloxaziridines also oxidise secondary alcohols to ketones at room temperature. In particular, they oxidise ethyl lactate (**45**) to ethyl pyruvate (**46**).¹²³

Finally, let us note a recently observed example of the oxidation of alkyl hydroxycarboxylates to α -oxo esters **46** and **47** on treatment with *tert*-butyl hydroperoxide in the presence of copper(I) and (II) salts and even metallic copper under phase-transfer catalysis conditions.¹²⁴

R = Me (**46**), Ph (**47**).

Dibismuth trioxide oxidises 12-hydroxy-11-ketosteroids to 11,12-diketosteroids in up to 70% yields.¹²⁵ This reagent can also be used for the synthesis of vicinal vinyl diketones from the corresponding vinyl α -hydroxy ketones.¹²⁶ Iodine combined with AcOH and MeOH oxidises D-(–)-ascorbic acid to D-(–)-dehydroascorbic acid in low yield.¹²⁷ Aliphatic α -hydroxy ketones are transformed to the corresponding α -diketones on treatment with *N*-bromosuccinimide in dry CCl₄ or aqueous dioxane.¹²⁸ Basic copper(II) carbonate [CuCO₃·Cu(OH)₂] acts in a similar way.¹²⁹ Acyloins of dioxepane structure were successfully oxidised to the corresponding α -diketones upon boiling with SeO₂ in a mixture of toluene and acetic acid.¹³⁰ The action of a solution of ferric chloride in HCl on 2-hydroxycyclohexanone results in a high yield of cyclohexanedione **4a**.¹³¹

3. Oxidation of α -halocarbonyl compounds

Oxidation of α -halocarbonyl compounds is one of the most convenient and popular methods for the synthesis of diketones.¹³²

A very simple and convenient method is the oxidation of halo ketones according to Kornblum with DMSO in the presence of bases.^{49–52, 133} In this case, α -bromocarbonyl compounds are oxidised more readily than alkyl or even benzyl bromides. The oxidation of α -bromo ketones with DMSO is commonly carried out at room temperature. This is explained by easier elimination of the proton from the intermediate dimethylsulfoxonium salt **48** due to the adjacent carbonyl group (see also Section II.1).^{134, 135}

The method is particularly convenient for the oxidation of acyclic α -bromocarbonyl compounds. For example, phenylglyoxal (yield 71%) and diketone **7a** (yield 95%) were obtained by the oxidation of 2-bromo-1-phenylethanone and diphenylbromoethanone in dry DMSO at 25 and 45 °C, respectively.⁴⁹ The addition of sodium carbonate accelerates the process. However, the oxidation of *e.g.* ethyl bromoacetate with DMSO was also carried out without a base, using 2-phenoxyethyloxirane to bind the HBr evolved (the yield of ethyl glyoxylate was 70%).¹³⁶ However, it was noted¹³⁷ that *tert*-butyl bromoacetate could not be oxidised with DMSO. It was also shown that the addition of potassium iodide to a mixture of DMSO and Na₂CO₃ accelerates the oxidation of bromo ketones.¹³⁸

In the first studies by Kornblum and co-workers and in many subsequent studies, dry DMSO was used. Thorough dehydration of such a hygroscopic compound as DMSO is a difficult procedure. It was shown⁵⁶ that it is easier to oxidise aryl methyl ketones, α -hydroxy- and α -bromoacetophenone with aqueous HBr in DMSO. In this case, the oxidation mechanism differs considerably from that of the classical Kornblum reaction. The role of DMSO in an aqueous medium is reduced to the generation of Br₂ from HBr, while the dimethylsulfoxonium ion **48**, which is the key intermediate in the Kornblum reaction, is not formed in aqueous HBr (see Section II.1).

3-Bromocamphor is oxidised to camphoroquinone upon passing air through a solution of the substrate and NaI in DMSO.¹³⁹ However, despite the apparent similarity with the Kornblum reaction, its mechanism is different: DMSO serves as a solvent, while the process goes *via* free-radical intermediates.¹³⁹

Complications are observed in the oxidation of cyclic α -bromo ketones with DMSO. In this case, oxidation often competes with elimination of the DMSO molecule from the intermediate **48**. Instead of diketones, or along with them, this process produces α,β -unsaturated ketones and α -hydroxy ketones. This reaction pathway is particularly typical of steroid derivatives.¹⁴⁰ Heating of 2-bromocyclohexanone and 2-bromocyclopentanone in DMSO at 100 °C gives 3-bromocyclohexane-1,2-dione and 3-bromocyclopentane-1,2-dione rather than the corresponding diketones.^{141, 142} Under these conditions, the bromo ketone **49** gives the diketone **50**, which exists in the enol form, only in the presence of epichlorohydrin to bind the HBr that evolves. The reaction in the absence of epichlorohydrin results in the compound **51** as the main product.^{142, 143}

It was suggested^{142, 143} that this effect is due to the oxidation of the hydrogen bromide, which is formed in the primary oxidation act, with dimethyl sulfoxide to bromine, which brominates the intermediate diketone.

Nitrates formed in the reaction of α -bromo ketones and α -bromo acids with AgNO₃ undergo smooth transformations on treatment with a catalytic amount of sodium acetate in DMSO at room temperature to give high yields of α -dicarbonyl compounds or α -oxo acids.^{144–146}

The Kröhnke method (treatment of α -bromo ketones with pyridine and 4-nitrosodimethylaniline followed by hydrolysis) is of very limited use in the synthesis of 1,2-dicarbonyl compounds.¹³²

The oxidation of α -bromo acids and their esters with pyridine *N*-oxide is an efficient method for the synthesis of α -oxo acids and their esters.¹⁴⁷

Compound 52	R ¹	R ²	Yield (%)
a	H	H	37
b	H	Bu ^t	97
c	H	CH ₂ Ph	89
d	Ph	H	70
e	Ph	Me	95

The addition of silver nitrate facilitates the formation of alkoxypyridinium salts. Their subsequent decomposition is carried out by heating in methanol or acetonitrile in the presence of Et₃N or in aqueous NaOH at room temperature.¹⁴⁷ A stronger nucleophile, 4-dimethylaminopyridine *N*-oxide, was also used in an oxidative transformation of this kind. However, in this case the intermediate salt was decomposed with the use of 1,8-diazabicyclo[5.4.0]undec-7-ene.¹⁴⁸

Similar oxidative properties are manifested by *N,N*-diethylhydroxylamine, which oxidises, readily and in high yields, various aromatic bromomethyl ketones to arylglyoxals in boiling methanol in the absence of bases.¹⁴⁹ The method is attractive due to its simplicity and serves as a rare example in which α -oxo aldehydes are formed more easily than aromatic α -diketones. The method is not applicable to 2-bromo-1,2-diphenylethanone, 2-chlorocyclohexanone and 2-bromo-1-phenylpropanone.

α -Bromocarbonyl compounds (as well as other activated alkyl halides) react with *N*-phenyltrifluoromethanesulfonamides under mild conditions. The resulting products **53** are readily decomposed with bases to anils **54**, which are, in turn, hydrolysed to α -dicarbonyl compounds **55**.¹⁵⁰

$\text{R}^1 = \text{C}_6\text{H}_{17}$, $\text{R}^2 = \text{Me}$ (79%); $\text{R}^1 = \text{OEt}$, $\text{R}^2 = \text{Pr}$ (67%), C_6H_{13} (62%).

Monoketals of aliphatic diketones **56** were obtained in 43%–87% yields in two stages according to the following scheme:¹⁵¹

$\text{R}^1 = \text{R}^2 = \text{Me}$; $\text{R}^1 = \text{Et}$, $\text{R}^2 = \text{Me}$; $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{Et}$.

The method has the advantage that it provides the possibility of direct regiospecific synthesis of dimethyl ketals with involvement of only one carbonyl group of α -diketones that are difficult to obtain directly from the corresponding dicarbonyl compounds. The method is a good supplement to the synthesis of α -oxo acetals by the oxidation of methyl ketones with diphenyl diselenide as discussed in Section II.1.⁴⁷

It is interesting that the formation of an acetal from an aromatic bromo chloro ketone, namely, 2-bromo-2-chloro-1-phenylpropan-2-one, is accompanied by a rearrangement¹⁵¹ that gives 1,1-dimethoxy-1-phenylpropan-2-one.

Cyclic and acyclic geminal dibromo diketones are transformed under conditions of photochemical oxidation at room temperature to hydrates of the corresponding vicinal triketones **57** in good yields.¹⁵²

4. Oxidation of other classes of compounds with the CX–C=O function and oxidative rearrangements

In certain cases, carbonyl compounds containing nitrogen, sulfur or phosphorus in the α -position are rather accessible and can serve as good precursors in the synthesis of 1,2-dicarbonyl compounds.

A general method for the insertion of an α -oxo group in ketones, esters, amides and lactams has been elaborated. This method is based on photooxidation of α -oxo enamines obtained from the corresponding carbonyl compounds according to the general scheme:

Dicarbonyl compounds obtained by this method are presented in Table 3. The photooxidation is carried out at -78°C with subsequent heating of the reaction mixture to 25°C . The method shows high selectivity. Using the same approach, the allylic vicinal tricarbonyl compound hydrate **57a**, which is a versatile di- and trielectrophilic synthon, was synthesised.¹⁵⁴

The same method was used to obtain polyfunctional α -diketones **58** and **59** from carboxylic acids.¹⁵⁵

$\text{R}^1 = \text{H}$, COOH , $\text{CH}_2\text{COOBu}^t$ (**58**); $\text{R}^2 = \text{H}$, COOBu^t (**59**).

It was shown that treatment of α -hydroxyimino ketones with N_2O_4 in THF or acetonitrile at -20°C gives diketones **7a,e** and triketone **12a** in over 60% yields.¹⁵⁶ Cyclohexane-1,2,3-trione hydrate was synthesised in an analogous way.¹⁵⁶ The reaction is assumed to occur *via* the intermediates **60**, since isotope-labelling experiments have shown¹⁵⁷ that the oxidation of oximes to ketones with NO^+ occurs *via* oxaziridine intermediates.

Table 3. Dicarbonyl compounds obtained by photooxidation of α -oxo enamines.¹⁵³

Compound	Yield (%)	Compound	Yield (%)
PhCOCOMe	68	PhCOCOPh	89
PrCOCOEt	74		82
	81	Cholestanedione (5)	87
PhCOCOOEt	91	4-MeOC ₆ H ₄ COCOOEt	92

Me(CH ₂) ₃ COCOOEt	75		58
	78		

R¹ = Ph; R² = Ph (**7a**), CH₂Ph (**7e**), CPh (**12a**).

Autooxidation of α -hydroxy imines **61** to diketones is rather a general method. Compounds **61** are obtained by the SmI₂-induced coupling of alkyl halides with xyllyl isocyanide and aldehydes.¹⁵⁸ The yields of diketones **62a–f** are higher than 90%.

R¹ = ; R² = CH₂CH₂Ph; R³ = Et (**a**), Prⁱ (**b**);

R² = Prⁱ, R³ = CH₂CH₂Ph (**c**); R² = Et, R³ = Ph (**d**);

R² = (CH₂)₄OBu, R³ = 2-furyl (**e**);

R² = cyclo-C₆H₁₁, R³ = 2-pyridyl (**f**).

Organosamarium intermediates **63** obtained similarly are so nucleophilic that they readily react with esters and carbonates, thus providing a general way to vicinal triketones **64a–c**.¹⁵⁹

R¹ = ; R² = Me (**a**), Et (**b**), OMe (**c**).

Aroylation of α -chloro imines in the presence of 1,3-dimethylimidazolinium iodide is rather a general method for the synthesis of aromatic 1,2-diketones. The oxo imines that are formed readily undergo hydrolysis to give the diketones ArCOCOPh (Ar = Ph, 3-ClC₆H₄, 4-ClC₆H₄, 4-MeOC₆H₄, 4-NO₂C₆H₄) in excellent yields.¹⁶⁰ The method was found to be applicable to the synthesis of heterocyclic diketones ArCOCOR (R = thienyl).¹⁶⁰

Examples of the oxidation of α -diazo ketones and diazo diketones are known.^{161,162} For instance, treatment of α -diazo ketones with triphenylphosphine gave phosphoranes, which were converted to α -oxo aldehydes with nitric acid. Phenylglyoxal was obtained by this method in 70% yield with respect to the starting benzoyl chloride.¹⁶¹ At present, there are reliable methods for direct oxidation of diazo ketones. For example, *tert*-butyl hypochlorite was used in one stage of the synthesis of pentaketones **65a,b**.¹⁶²

R = Bu^t (**a**), Ph (**b**).

Vicinal triketones **66** (in the form of monohydrates) were obtained in nearly quantitative yields by prolonged oxidation (10–30 h) of diazo diketones with dimethyldioxiranes (DMO, 'oxone') in acetone at room temperature.¹⁶³

R¹ = R² = Me, Ph, OEt; R¹ = Me, R² = Ph, OEt; R¹ = Ph, R² = OEt; R¹, R² = (CH₂)₃, CH₂CM₂CH₂, *o*-phenylene.

Oxidation of diazo ketones, that are obtained from substituted α -amino acids and dipeptides, with DMSO provides a general route for the synthesis of homochiral amino oxo aldehydes **67**, which exist as hydrates.¹⁶⁴

It was shown that phenylglycine undergoes oxidation with atmospheric oxygen in ethanol in the presence of an equimolar amount of VO(OEt)Cl₂ to give ethyl phenylglyoxylate.¹⁶⁵ The preparative value of this method is diminished by the side reaction of decarboxylation leading to the formation of a considerable amount of ethyl benzoate.

It is well known that the oxidation of bishydrazones of 1,2-diketones with mercury(II) oxide is one of general methods to synthesise disubstituted alkynes. In the case of diphenylethane-dione (benzil) monohydrazone, oxidation with Ag₂O results in benzil **7a**.¹⁶⁶ The use of some other oxidants mostly gives α -diazo ketones or ketazines, whereas diketones are only formed as by-products (see, *e.g.*, Ref. 167 and the references cited therein).

It was shown that cyclic ketones can be transformed to the corresponding α -diketones **68** by oxidation of their methylthio derivatives under mild conditions (acetone, 25–35 °C).¹⁶⁸ The overall yield of diketones over two stages is 42%–76%. Methylglyoxal was obtained in a similar way.¹⁶⁹

X = (CH₂)_n, n = 5–12.

(Biphenyl)phenylethanedione was isolated in ~90% yield after heating of ketone sulfur-containing derivatives 4-PhC₆H₄COCH(X)Ph (X = SMe, S⁺Me₂Br⁻) with aqueous HBr in DMSO at 55 °C.⁵⁶

It is known that derivatives of dithiane **69**, which are readily formed from aldehydes and 1,3-dithianyllithium, give α -hydroxy ketones in the presence of mercury(II) salts.¹⁷⁰ In another study,¹⁷¹ 1,3-dithiane was used as an acyclic synthon, but the intermediate product **69** was then oxidised with an excess of *N*-bromosuccinimide to give a series of α -diketones **70**, including fluorine-containing ones, in 54%–87% yields.

R¹ = Ph, R² = 2-FC₆H₄, 3-FC₆H₄, 4-FC₆H₄;
R¹ = 2-FC₆H₄, R² = 3-FC₆H₄, 4-FC₆H₄.

The oxidation of α -hydroxyalkyl-1,3-dithianes with NaNO₂ in trifluoroacetic acid to ketones was used¹⁷² for the synthesis of certain alkaloid analogues containing an α -diketone fragment.

Iodine is yet another reagent for desulfurisation of α -oxo thioacetals. For instance, azetidine-2,3-diones were synthesised by refluxing diethyl dithioacetals of 2-oxo β -lactams with iodine in aqueous acetonitrile for 35–45 min.¹¹⁴

Very mild oxidative desulfonylation of α -sulfonyl ketones is carried out with oxaziridine **71**.¹⁷³

The method is unique due to its selectivity, as it makes it possible to obtain a wide range of complex cyclic and acyclic α -diketones containing such reactive functional groups as the azide, allenyl, acetal, furyl and other groups. Unfortunately, the more readily accessible (+)- and (–)-(camphorsulfonyl)oxaziridines turned out to be unsuitable for this reaction.¹⁷³

Various phosphorus and iodine ylides readily formed from β -diketones can serve as convenient precursors of vicinal tricarbonyl compounds.^{164, 174, 175} For example, oxidation of phosphorus ylides with singlet oxygen or ozone was used in the synthesis of allylic tricarbonyl compounds **57** and dioxo diester Bu^tOCOCO-COCH₂CH₂CO₂Et.^{164, 175} Potassium permanganate oxidises β -oxo(triphenylphosphoranylidene)s in a two-phase system to give substituted benzils or 1-arylpropane-1,2-diones in high yields.¹⁷⁶ Ozonolysis of α, α' -dioxoalkyl phenyliodonium **72** at low temperature made it possible to synthesise more than 20 cyclic and acyclic triketones **73** containing various fragments (alkyl, aryl, acetal, carbamido and other groups).¹⁷⁴

The important advantage of this method over the majority of others is that compounds **73** are formed and isolated on a preparative scale in the ketone rather than hydrate form.¹⁷⁴

A rearrangement of diarylactaldehydes that can be used for the synthesis of substituted benzils occurs at room temperature in

the presence of tris(2,4-dibromophenyl)aminium hexachloroantimonate as the oxidant.⁹⁹

X = H; Y = Me, R = 4-MeC₆H₄;

Y = OMe, R = 4-MeOC₆H₄;

X = H, Y = Cl, R = 4-ClC₆H₄; X = Cl, Y = Me, R = 4-ClC₆H₄.

However, diphenylacetaldehyde and D,L-2-phenylpropionaldehyde do not enter into this reaction.⁹⁹

Oxidation of chalcones with thallium(III) nitrate¹⁷⁷ or PhIO¹⁷⁸ also results in benzils. For example, treatment of chalcones **75** with Tl(NO₃)₃ in aqueous solutions of glym in the presence of acids is a convenient way to synthesise benzils. The reaction scheme involves hydroxythallation of the double carbon–carbon bond, oxidative migration of an Ar group in the intermediate **76**, retro-Claisen condensation to give benzoin **77** and subsequent oxidation to diketones.

III. Oxidation of 1,2-diols, epoxides and other vicinally substituted compounds

The oxidation of glycols to α -dicarbonyl compounds can serve as a versatile method for the synthesis of the latter. However, these methods have been developed rather little, except for the industrial synthesis of glyoxal by gas-phase oxidation of ethylene glycol on copper or silver contacts. Various reactions leading to *o*-quinones are also known; these will not be considered in the present review. Much more commonly, syntheses of carbonyl compounds or carboxylic acids utilise the oxidative cleavage of the carbon–carbon bond in vicinal diols. The classic reagents of this type include lead tetraacetate, periodic acid and its salts (of which sodium periodate is particularly popular) (see, e.g., the reviews^{179, 180}). In addition, cleavage of glycols occurs on treatment with KMnO₄, MnO₂, NaBO₃, NaBiO₃ and organobismuth salts (Ph₃BiCO₃), Ce(IV) and Co(II) salts, hypochlorites, pyridinium chlorochromate, I₂ with AgOAc or iodine triacetate (ICl₃, AgOAc), *N*-iodosuccinimide in THF, VO(acac)₂, H₂O₂ in the presence of metal salts, *tert*-butyl peroxide with Al(O^{*t*}But)₃, upon anodic oxidation, etc.^{180–182} Considerable interest of researchers is attracted to the selective monooxidation of 1,2-diols aimed at the synthesis of chiral α -hydroxy ketones.

Probably, the most general reagents used for the oxidation of glycols to dicarbonyl compounds include DMSO, the H₂O₂–peroxytungstate system, *o*-iodylbenzoic acid and TEMPO-based reagents.

Dry DMSO in the presence of (CF₃CO)₂O and triethylamine oxidises acyclic and cyclic 1,2-diols to 1,2-diones at –60 °C.¹⁸³ Benzil **7a** and 1,2-dicarbonyl compounds **78–81** (some of these, in the enol form) were obtained by this method in 54%–98% yields with conservation of the carbon skeleton of the original diols.

Treatment of diols containing the bicyclo[4.1.0]heptane skeleton with DMSO in trifluoroacetic acid results in tropolones **82** and **83**. It is assumed that the reaction occurs through ring expansion of the originally formed bicyclic diketones.

The oxidation of 5 α -cholestane-2 α ,3 β -diol affords a mixture of 2-hydroxy-5 α -cholest-1-en-3-one and 3-hydroxy-5 α -cholest-3-en-2-one in 84% overall yield.¹⁸³ The use of the Swern reagent in this reaction gives poorer results.¹⁸³

DMSO oxidises cyclohexane-1,2-diol and a number of acyclic vicinal diols to the corresponding 1,2-diketones at room temperature in the presence of dicyclohexylcarbodiimide in 60%–75% yields.¹⁸⁴

Diketone **7a** and its 4,4'-dibromo derivative are obtained smoothly and in high yields by oxidation of the corresponding 1,2-diarylethane-1,2-diols with DMSO in aqueous HBr at 110–115 °C.^{59,112}

It was found that *o*-iodylbenzoic acid **84** is a very mild oxidant for alcohols in DMSO at room temperature. It can also oxidise glycols without cleavage of the C–C bond giving the corresponding 1,2-diketones at room temperature in almost quantitative yields.¹⁸⁵

R¹, R² = Me, Ph, (CH₂)₄.

A method for the oxidation of primary and secondary alcohols and 1,2-diols with the reagent **84** has been patented.¹⁸⁶

Hydrogen peroxide usually cleaves glycols. However, it has recently been shown that acyclic vicinal diols are oxidised by H₂O₂ in a two-phase system in the presence of a catalytic amount of the [π-C₅H₅N(CH₂)₁₅Me]₃{PO₄[W(O)(O₂)₂]₄} complex to give diketones in 70%–93% yields.¹⁸⁷ The reaction occurs in a stepwise manner *via* intermediate α -hydroxy ketones. The results of the oxidation of cyclic diols are noticeably poorer: cyclooctane-1,2-dione was obtained in yields as low as 48%–58%, while cyclohexane-1,2-diol gives adipic acid rather than the diketone **4a**.¹⁸⁷

It is well known that such efficient oxidants as TEMPO transform vicinal diols to α -hydroxycarbonyl compounds (see,

e.g., Refs 188 and 189) and oxidise 1,2-diphenylethane-1,2-diol **85** to benzil **7a**.¹⁹⁰ It was shown that the readily accessible 4-acetamido-TEMPO in combination with toluene-*p*-sulfonic acid in chloroform or CH₂Cl₂ can serve as a general reagent for the mild oxidation of linear and cyclic vicinal diols to α -diones.¹⁹¹

At present, the majority of other reagents for the oxidation of glycols are used less commonly. For example, it was shown that *cis*-cyclododecane-1,2-diol is oxidised to cyclododecane-1,2-dione on treatment with tris(triphenylphosphine)ruthenium dichloride [(Ph₃P)₃RuCl₂] in 53% yield.¹⁹² Later, an almost identical result was obtained using *tert*-butyl hydroperoxide in benzene in the presence of a phase-transfer catalyst, namely, PhCH₂N⁺Me₃–OMoBr₄.¹⁹³ Cyclohexane-1,2-diol undergoes oxidation to cyclohexane-1,2-dione **4a** in 51% yield at room temperature on treatment with a ruthenium complex (LPh₄)(RuO₂Cl₃), where L = P or As.¹⁹⁴

It was shown that KMnO₄ in the presence of nonionic tris[2-(2-methoxyethoxy)ethyl]amine, unlike other phase-transfer catalysts, oxidises phenylethane-1,2-diol and the diol **85** to phenylglyoxal and diketone **7a** in high yields.¹⁹⁵ Hydrogen peroxide applied onto the TS-1 zeolite converts one or both of the hydroxy groups in 1,2-diols to carbonyls, while cleavage of the C–C bond occurs only if an excess of the reagent is used.¹⁹⁶ Solvents affect strongly the reaction selectivity. For example, butane-2,3-diol is converted into 3-hydroxybutan-2-one in methanol and to butane-2,3-dione in acetone.

Unlike other periodates, tetrabutylammonium periodate in the presence of AlCl₃ in boiling chloroform oxidises the diol **85** to give mostly the diketone **7a** (yield 70%), and glycol cleavage occurs to a small extent (20% of benzaldehyde).⁸⁷ PhSe(O)Se(O)Ph is another reagent that enables the selective oxidation of the diol **85** to benzil **7a** (refluxing in THF for 3 h, yield 77%).⁸³ Quantitative yield of the compound **7a** in the oxidation of the diol **85** under very mild conditions is also provided by the system *N*-chlorosuccinimide–Me₂Se.⁹⁶ The catalytic system RuO₄[–]–BrO₃[–] cleaves the diol **85** to benzoic acid, whereas *trans*-RuO₃(OH)₂[–]–S₂O₈^{2–} affords benzil **7a** in 65% yield.¹⁹⁷

The mechanism of oxidation of *meso*- and *d,l*-diol **85** with peroxomolybdenum complexes, *viz.*, neutral MoO₅·HMPA and anionic (MoO₅·PICO)[–]–Bu₄N⁺ (PICO is picoline *N*-oxide) was studied.¹⁹⁸

In all cases, the oxidation of the diol **85** results in benzil **7a** and benzaldehyde. The latter is formed due to glycol cleavage of the diol **85**. The ratio of the reaction products is strongly affected by the nature of the substrates and oxidants. For example, the action of MoO₅·HMPA on both *meso*- and *d,l*-diol **85** results almost exclusively in benzaldehyde. However, the (MoO₅·PICO)[–]–Bu₄N⁺ oxidant mostly converts the *meso*-form of the diol **85** to the diketone **7a**, while the *d,l*-diol **85** is converted to benzaldehyde. Benzil **7a** is formed from a complex of the substrate with the oxidant in which the glycol is coordinated as a monodentate ligand, while benzaldehyde is formed from a complex in which the substrate plays the role of a chelating ligand. If the reaction is carried out in air, autooxidation takes place. There is evidence that the reaction occurs in the coordination sphere of the metal according to a homolytic mechanism.¹⁹⁸

A biochemical method was suggested for the transformation of ethylene glycol to glyoxal by treatment with oxidoreductase or microorganisms containing oxidoreductase, at 30 °C in aqueous solutions.¹⁹⁹

Ethylene glycol can also be oxidised to glyoxylic acid. Accessible oxidants based on nitric acid, namely, HNO₃–H₂SO₄–

V_2O_5 ²⁰⁰ and HNO_3 with Co, Al and Cu acetylacetonates,²⁰¹ have recently been suggested for this purpose.

Such an efficient reagent as dimethyldioxirane can oxidise 1,2-diols without cleavage of the C–C bond of the glycol. However, the reaction stops at the step of the formation of hydroxy ketones, while diketones are found in the reaction mixture only as traces, since the carbonyl group that is formed deactivates the methine group as regards further oxidation.²⁰²

Glycol cleavage can be used for the synthesis of α -dicarbonyl compounds. Cleavage of methyl and ethyl D-tartrates in dry ether to the corresponding alkyl glyoxylates in 80%–85% yields on treatment with periodic acid²⁰³ can serve as an example.

Oxidation of epoxides usually results in α -hydroxy ketones. This was found for the first time in the treatment of epoxides with DMSO in the presence of a catalytic amount of BF_3 etherate.²⁰⁴ The same result was obtained on passing air through solutions of epoxides in DMSO. It was assumed²⁰⁵ that the oxidation follows a radical mechanism. It was shown subsequently that the reaction follows an ionic mechanism with epoxide ring opening on treatment with DMSO in the presence of various protic acids (CF_3COOH , H_2SO_4 , $MeSO_3H$, HBf_4 , HNO_3) resulting in the formation of an α -hydroxysulfoxonium salt. In turn, the latter decomposes to α -hydroxy ketones according to Kornblum.^{206, 207} Hydroxy ketones are also formed on treatment of epoxides with DMSO in the presence of molecular sieves²⁰⁸ or clay with microwave heating.²⁰⁹ Epoxysilanes are also oxidised in DMSO in the presence of triflates and tertiary amines to give α -hydroxyacylsilanes.²¹⁰

Unlike the reagents indicated above, the aqueous HBr –DMSO system smoothly converts diphenyloxirane to benzil **7a** in 71% yield; however, bis(α -diketone) **28** is formed from the corresponding bis(epoxide) in 31% yield only.²¹¹

1,2-Diones are formed upon oxidation of α -nitro epoxides.^{212–214} This process occurs in the presence of tetrakis(triphenylphosphine)palladium and triethylamine in boiling benzene and gives satisfactory yields of α -diketones.^{212, 214} The oxidation of nitro epoxides with the $BF_3 \cdot Et_2O$ (or Me_3SiCl)–DMSO system in CH_2Cl_2 at 0 °C followed by the addition of triethylamine gives the corresponding diketones in somewhat higher yields (54%–87%).^{213, 214}

$R^1, R^2 = Ph, Pr, Me, (CH_2)_4Me, (CH_2)_3, (CH_2)_4$.

The same method afforded the triketone ketal **86**.^{213, 214}

The reaction of α -nitro epoxides with $BF_3 \cdot Et_2O$ in acetonitrile in the presence of NaI gave good yields of α -iodo ketones.^{213, 214}

Transformations of vicinal dihalides (or halohydrins) to α -dicarbonyl compounds are not typical in organic synthesis, although dibromination of alkanes or bromination of alkenes followed by transformation to α -diketones can serve as an alternative to hydrocarbon oxidation. These transformations can be performed efficiently with a number of reagents that have appeared in the last few years.

Refluxing of 2-aryl-1,2-dibromo-1-phenylethanes in acetic acid in the presence of tellurium dioxide gives benzil **7a** and its derivatives (yields 19%–82%) as well as the diacetates of the corresponding 1,2-diols and stilbenes.²¹⁵ The diacetates and stilbenes predominate among the products in the case of substrates with electron-withdrawing substituents.

DMSO is a more convenient and accessible reagent for this kind of transformation.²¹⁶ For example, it was found that heating of *meso*- and *d,l*-2-aryl-1,2-dibromo-1-phenylethanes in the aqueous HBr –DMSO system at 110 °C for 4–8 h readily gives benzil **7a** and its derivatives in 70%–80% yields.

$R = H, Me, MeO, Cl, NO_2$.

This transformation occurs also without HBr but requires a longer time.¹¹² Later, this reaction was carried out with many acyclic and cyclic vicinal dibromides under microwave irradiation and gave α -diketones in 51%–75% yields.²¹⁷

2-Bromo-1,2-diphenylethanol and even its methyl ether and formate undergo oxidation to diphenylethanedione in aqueous HBr –DMSO even more readily than 1,2-dibromo-1,2-diphenylethane.¹¹² If the oxidation is carried out without HBr , it follows the same direction but occurs more slowly.¹¹²

$R = H, Me, CHO$.

The cheapest way to oxidise 1,2-dibromo-1,2-diphenylethane to benzil (yield 80%) is heating the substrate in acetic acid in the presence of sulfuric acid.²¹⁸ It was found later that the addition of such compounds as iodine, potassium iodide or sodium sulfite to the reaction mixture accelerates considerably the oxidation of vicinal dibromides.²¹⁹

The possibility of the synthesis of 1,2,5,6-tetraketopyracene (**87**), a structural element of buckminsterfullerene, according to the following scheme was studied:^{220, 221}

Oxidation of the starting 1,2-dioxopyracene (**88**) with sodium dichromate resulted in the cleavage of the diketone carbon–carbon bond. However, the target tetraketone **87** could be obtained by the oxidation of the dibromide prepared by bromination of the diketone **88** with *N*-bromosuccinimide according to the reported procedure.²²² The oxidation of the dibromide was carried out by treatment with the $AgNO_3$ – $MeCN$ system and then with $NaOAc \cdot 3H_2O$ –DMSO.²²⁰ The yield of the tetraketone **87** reached 80% but was irreproducible. Later, the same research

group found that the dioxopyracene **88** could be directly oxidised to the tetraketone **87** by treatment with benzeneseleninic anhydride²²¹ (see Section IV).

Methods are known for the transformation of five-membered heterocycles to α -diketones. Certain 5-hydroxyoxazolines of the type **89** decompose in formic acid at room temperature to give the corresponding α -diketones in good yields. A method based on this reaction was elaborated for the synthesis of α -diketones from α -amino acids, as shown below.²²³

$R^1 = \text{Pr}^i$; $R^2 = \text{Ph}$, $\text{C}\equiv\text{CPh}$; $R^1 = \text{Bu}^s$, $R^2 = \text{Bu}^n$; $R^1 = \text{Ph}$, $R^2 = \text{Bu}^n$;
 $R^1 = \text{CH}_2\text{CH}_2\text{SMe}$, $R^2 = \text{Me}$; $R^1 = (\text{CH}_2)_3\text{NHCOCF}_3$; $R^2 = \text{Bu}^n$, Ph .

A number of acetylenic α -diketones used in the synthesis of tetrasubstituted furans were obtained according to the same scheme.²²⁴

Diaryl-substituted glycolurils **90–92** are oxidised to benzil **7a** and diketone **28** (yield 80%–90%) on heating with nitric acid in aqueous acetic acid in the presence of H_2SO_4 .²²⁵

The oxidation of 4,5-diphenylimidazole to the benzil **7a** occurs at milder conditions than that for glycolurils. It does not require the presence of sulfuric acid and water and affords the products in 80%–85% yield. The reaction involves the intermediate formation of 2-nitro-4,5-diphenylimidazole.²²⁵

IV. Oxidation of alkanes, alkenes, alkynes and their derivatives

Of the classes of compounds listed above, alkynes can be converted to α -dicarbonyl compounds most easily (followed by alkenes and finally alkanes). Table 4 lists the reagents used for the preparative oxidation.

Table 4. Reagents used for the preparative oxidation of alkanes, alkenes, alkynes and their derivatives to α -dicarbonyl compounds $R^1\text{COCOR}^2$.

Substrate	Reagent
$R^1\text{CH}_2\text{CH}_2\text{R}^2$	$\text{Na}_2\text{Cr}_2\text{O}_7 - \text{AcOH} - \text{Ce}(\text{OAc})_3$, $(\text{PhSeO})_2\text{O}$, $\text{O}_2 - (\text{Co}(\text{OAc})_2, \text{Mn}(\text{OAc})_2, \text{NaBr})$; Gif-system: $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O} - \text{Bu}^t\text{OOH} - \text{MeCOCH}=\text{CH}_2$
$R^1\text{CH}=\text{CHR}^2$	SeO_2 , KMnO_4 , $\text{CrO}_3 - \text{AcOH}$, $\text{O}_2 - (\text{Co}(\text{OAc})_2, \text{Mn}(\text{OAc})_2, \text{NaBr})$, OsO_4 , $\text{HBr} - \text{DMSO}$, $\text{I}_2 - \text{DMSO}$, $\text{NaBr} - \text{HCl} - \text{DMSO}$, $\text{Bu}_4\text{NBr} - \text{HCl} - \text{DMSO}$, $\text{Br}_2 - \text{H}_2\text{SO}_4$, $\text{I}_2 - \text{H}_2\text{SO}_4$, $\text{HBr} - \text{H}_2\text{SO}_4$, $\text{NaBr} - \text{H}_2\text{SO}_4$

For many reasons, direct oxidation of alkanes to α -dicarbonyl compounds is a difficult technical problem, and only a few examples of this kind of oxidation are known.

For example, in view of the great practical importance of acenaphthenequinone, processes for its synthesis by direct oxidation of acenaphthene were studied. Such oxidants as H_2O_2 , HNO_3 , permanganates and oxygen under pressure or in the presence of various catalysts were used.²²⁶ None of these methods gave good yields of acenaphthenequinone. The oxidation of acenaphthene with $\text{Na}_2\text{Cr}_2\text{O}_7$ in AcOH with addition of cerium acetate at 40°C does not provide high yield of acenaphthenequinone either (38%–60%). On the other hand, as noted above, sodium dichromate does not oxidise dioxopyracene **88** to the tetraketone **87**. However, this was performed with the use of benzeneseleninic anhydride $(\text{PhSeO})_2\text{O}$, which oxidises compound **88** to the tetraketone **87** in 82% yield on heating in chlorobenzene at 125°C .²²¹

1,2-Diphenylethane and its derivatives undergo oxidation with oxygen in the liquid phase in the presence of $\text{Co} - \text{Mn} - \text{MBr}$ catalysts to give the corresponding diphenylethanediones.^{228–230} If oxygen is passed through a solution of compound **93** in glacial acetic acid containing the tetrahydrates of manganese and cobalt acetates and NaBr , not only the α -ketomethylene groups but also the ethane fragment are oxidised at 110°C , leading to the formation of the hexaketone **94** in 70% yield.²²⁸

A study of the oxidation of 1,2-diphenylethane with oxygen in the presence of Co–Mn–MBr catalysts showed that this process follows the radical mechanism. In the first step, it gives 1,2-diphenylethane-1,2-diol, which is then oxidised to 1,2-diphenylethanone. The latter is transformed to benzil **7a**. The overall selectivity reaches 80%.^{229,230} The selectivity of oxidation is affected only by the reaction temperature and the concentration of $\text{Mn}(\text{OAc})_2 \cdot 4\text{H}_2\text{O}$.²³⁰

Oxidation of pentane and hexane with the $\text{Ph}_3\text{Bi}-\text{Bu}^t\text{OOH}$ system at room temperature initially gives α -diketones, which are then oxidised to carboxylic acid anhydrides.²³¹ In this case, it is the oxygen formed from the hydroperoxide in the coordination sphere of the metal that serves as the actual oxidant.²³¹

Dicarbonyl compounds are also obtained upon oxidative formation or cleavage of the C–C bonds. Oxidation of cyclohexane, cyclooctane and cyclododecane in Gif-systems under the action of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}-\text{Bu}^t\text{OOH}$ in the presence of methyl vinyl ketone results in the corresponding 1-cycloalkylbutane-2,3-diones as the main products.²³² The reaction occurs through the Michael-type addition of the cycloalkane to methyl vinyl ketone followed by the insertion of the *tert*-butylperoxy group at the α -position to the carbonyl group of the adduct, which then slowly eliminates Bu^tOH to give α -diketones.²³²

Oxidative cleavage of the C–C bonds can also result in dioxo carboxylic acids. For instance, the oxidation of the enol forms of cyclic 1,3-diketones with copper(II) salts and oxygen results in acids **95**.²³³

$n = 0$, $R = \text{Me}$; $n = 1$: $R = \text{Me}$, $\text{CH}=\text{CH}_2$, $\text{CH}_2\text{CH}=\text{CH}_2$, Ph .

Over ten years ago, Haines²³⁴ noted that there are probably few reliable methods for the transformation of alkenes to 1,2-dicarbonyl compounds. This statement is no longer wholly true since the late 80's when new oxidising DMSO-based reagents appeared.

Selenium dioxide was among the first reagents that oxidise alkenes to α -dicarbonyl compounds. It oxidises alkenes containing no allylic hydrogen atoms rather successfully on heating them in acetic acid, trichlorobenzene or without a solvent. For example, ethylene and stilbene are oxidised to glyoxal and benzil **7a** in up to 70% yields;^{35,234} styrene is converted to phenylglyoxal along with hydroxylation products,²³⁵ while propene, a representative of allylic alkenes, gives methylglyoxal in only 19% yield.²³⁴

The direction of the oxidation of alkenes with potassium permanganate strongly depends on the reaction conditions. In alkaline media, internal alkenes mostly form 1,2-diols, while in nearly neutral or weakly alkaline media (pH 9–9.5) α -hydroxy ketones are formed.²³⁴ Symmetric cyclic and acyclic alkenes are oxidised with potassium permanganate in cold acetic anhydride (not above 10 °C) to give the corresponding α -diketones in moderate yields.^{236,237} The selectivity of the process is not high as noticeable amounts of 2-acetoxy ketones and dicarboxylic acids are formed. It was noted that the reaction may be hazardous.²³⁷ In addition, attempts to synthesise diketones from cyclohexene and norbornene failed.²³⁴ The oxidation of *E*-alkenes gives somewhat higher yields of diketones than the oxidation of the *Z*-isomers.^{234,236} Styrene can be converted to phenylglyoxylic acid by oxidation with potassium permanganate under alkaline conditions.²³⁸

Oxidation of nonterminal alkenes with permanganate under conditions of phase-transfer catalysis gives α -diols, α -diketones and α -hydroxy ketones along with carboxylic acids. The ratio of the oxidation products can be controlled by varying the conditions.²³⁴ For example, cyclododecane-1,2-dione and decane-5,6-dione were obtained in 69% and 53% yields from the correspond-

ing alkenes in the $\text{KMnO}_4-\text{CH}_2\text{Cl}_2-\text{H}_2\text{O}$ system containing acetic acid and Adogen 464.²³⁹

Such a heterogeneous reagent as $\text{KMnO}_4-\text{CuSO}_4 \cdot 5\text{H}_2\text{O}-\text{Cu}(\text{OAc})_2 \cdot \text{H}_2\text{O}$ in CH_2Cl_2 oxidises cyclooctene and cyclododecene to the corresponding diketones in moderate yields.²⁴⁰ In the absence of copper acetate, the reaction stops in the step of formation of α -hydroxy ketones.²⁴⁰

Oxidation of nonterminal fluoroalkenes with permanganate under strictly controlled conditions (the ratio alkene : $\text{KMnO}_4 = 1 : 0.3-0.7$, acetone : water = 24 : 1; -30 to -20 °C) affords diketones **96** in 30%–80% yields.^{241,242}

$R = \text{CF}_3, \text{Ph}$.

It is assumed that this reaction occurs *via* an intermediate product of hydroxylation of the C=C bond, which undergoes dehydrofluorination to give the target products. Although satisfactory yields are obtained, cleavage of the C–C bond cannot be avoided completely, even at 50% conversion of the starting olefin.²⁴²

Perfluoroalkenes can also be converted to dicarbonyl compounds by catalytic or stoichiometric oxidation with osmium tetroxide. In this case, tetrafluoroethylene is converted to glyoxylic acid in good yield, while perfluorocyclohexene gives perfluorocyclohexane-1,2-dione.^{243,244}

Chromium(VI) compounds are mostly known as oxidants that cleave the C=C bonds. However, a few cases have been reported in which dicarbonyl compounds were obtained upon oxidation of the double bonds with chromium trioxide. For example, CrO_3 in acetic acid was used for the oxidation of a series of 1,2-dihydroisoquinolines to the corresponding 3,4-dioxo derivatives **97**.²⁴⁵

$R^1 = 2,4,6-(\text{NO}_2)_3\text{C}_6\text{H}_2\text{CH}_2$, $R^2 = \text{PhCO}$;

$R^1 = 2,4-(\text{NO}_2)_2\text{C}_6\text{H}_3\text{CH}_2$, $R^2 = \text{PhSO}_2$, $4-\text{NO}_2\text{C}_6\text{H}_4\text{CO}$.

Both stilbene isomers are converted on treatment with a catalytic amount of CrO_3 and an excess of aqueous *tert*-butyl hydroperoxide to give mixtures of oxidation products, *trans*-stilbene oxide being the major component. In this case, approximately equal amounts of benzil **7a**, benzophenone and benzoin benzoate are formed.²⁴⁶ Norbornene was found to be inert under these conditions.²⁴⁶

A study of the liquid-phase oxidation of (*E*)-stilbene with oxygen in acetic acid at 105 °C in the presence of a Co–Mn–bromide catalyst showed that rapid and total conversion of the substrate results in a complex mixture of products [PhCOOH , Ph_2CO , Ph_2CHCHO , PhCOCOPh , PhCH_2COPh , $\text{PhCH}(\text{OAc})\text{COPh}$, $\text{PhCH}(\text{OAc})\text{CH}(\text{OAc})\text{Ph}$, *etc.*] with up to 46% content of benzil **7a**.²⁴⁷ These products are formed from the primary oxidation product, *i.e.* 1,2-diphenyloxirane.²⁴⁷

Peracetic acid oxidises *trans*-1-acetoxy-2-iodo-1,2-diphenylethylene to diketone **7a** in low yield.²⁴⁸

DMSO-based oxidants are much more versatile and convenient reagents for the synthesis of α -dicarbonyl compounds from alkenes. This was first discovered in 1989 for stilbene, which was oxidised readily and in high yield to benzil **7a** in the $\text{HBr}-\text{H}_2\text{O}_2-\text{DMSO}$ system.²⁴⁹ It was found subsequently that hydrogen peroxide accelerates the reaction but does not act as an oxidant. A solution of aqueous HBr in DMSO successfully oxidises stilbenes with both donor and acceptor substituents to

give the corresponding diarylethanediones in 56%–86% yields. It turned out that the first act of the process involves the electrophilic addition of bromine, which is formed *in situ* from HBr and DMSO, to the double bond, but it is the intermediate 1,2-diaryl-1,2-dibromoethanes that undergo oxidation. In this case, DMSO plays a dual role, specifically, it generates a microscopic amount of bromine from HBr (it is this reaction that is accelerated by hydrogen peroxide) and oxidises dibromides by a mechanism resembling that of the Kornblum reaction.^{112, 157} Since the first act of the reaction is the electrophilic addition of bromine to the double bond, it becomes clear why the oxidation of 4-nitrostilbene requires much longer time than that of stilbene, while 4,4'-dinitrostilbene does not undergo oxidation at all.¹¹² Compounds other than hydrogen bromide can be successfully utilised as the bromine sources. For instance, good results were achieved in the NaBr–H₂SO₄–DMSO, NaBr–HCl–DMSO, and Bu₄NBr–HCl–DMSO systems.¹¹⁴ In some cases, passage of air through a solution of HBr in DMSO increases the oxidation efficiency.²⁵⁰

Triple bonds are practically inert with respect to HBr in DMSO. This fact was successfully used to perform selective oxidation of double bonds in the enynes **98** and **99** in the synthesis of acetylenic α -diketones **100** and **101**.²⁵¹

Iodine in DMSO can also oxidise alkenes to dicarbonyl compounds, but it is much less reactive than HBr–DMSO.^{251–254} This reagent oxidises only stilbene and its derivatives containing electron-donating or weak electron-withdrawing substituents (Me, OMe, Cl) at position 4.^{252, 253} The decrease in the reaction rate caused by electron-withdrawing substituents made it possible for the first time to perform selective oxidation of only one bond in 1,4-(*E,E*)-distyrylbenzene (**102**) to give compound **103**.²⁵¹

Styrene, being an alkene with a terminal double bond, is oxidised both with bromine and HBr in DMSO to give phenylglyoxal. This results in a much larger amount of side products than in the oxidation of stilbenes.²⁵⁵

In the oxidation of 3-styryl- and 3,6-distyrylcarbazoles with the HBr–DMSO system, oxidation of the double bonds is accompanied by side processes such as bromination of the carbazole moiety and methylenation of the free NH groups to give dioxo- and tetraoxocarbazole derivatives **104** and **105**.²⁵⁶

These side processes that are beneficial in this case occur due to the reaction of the carbazole moiety with bromine and formaldehyde generated upon the reaction of HBr with DMSO at 120 °C.²⁵⁶

The most efficient method for the oxidation of stilbenes to diketones (yields 50%–81%) is probably refluxing the substrates in acetic acid in the presence of H₂SO₄ containing admixtures of bromine, iodine, HBr, NaBr or sodium sulfite.^{218, 219} As mentioned above, the reaction involves intermediate electrophilic halogenation of double bonds if halogens, hydrogen halides or their salts are used.^{218, 219}

In addition, examples of the specific oxidation of double bonds with the formation of specific types of dicarbonyl compounds are worth noting. Oxidation of compounds **106** with RuO₄ (formed from RuCl₃·3H₂O and NaIO₄) in a mixture of CCl₄ and aqueous MeCN affords macrocyclic bis- α -diketones **107** in yields up to 40%.²⁵⁷

Aroylketene dithioacetals **108** are oxidised with Pb(OAc)₄ in boiling benzene to give acetoxy dithioacetals, which are hydrolysed under mild conditions to compounds **109**. Under similar conditions, their vinylogues **110** undergo oxidative cyclisation according to Nazarov, giving 2-acetoxycyclopentenone derivatives **111**, which are precursors of di- and tri-ketones.²⁵⁸

Oxidation of alkynes to α -dicarbonyl compounds, unlike that of alkanes and alkenes, is one of reliable methods to obtain compounds of this class. Numerous reagents are known to perform this type of transformation successfully, although there is always a danger of cleavage of the carbon–carbon bond both in substrates and in products. The oxidation of alkynes has been covered in reviews and books rather thoroughly,^{4, 5, 40, 234} and in most cases we are going to refer to the newer studies or those not included in these sources.

Alkynes are comparatively resistant against oxygen, and only few examples of their oxidation with oxygen to diketones are known. Passage of air through a solution of diphenylacetylene in acetic acid containing a Co–Mn–MBr catalyst for 3 h at 110 °C gives benzil **7a** in up to 90% yield.²⁵⁹ Oxidation of cyclooctyne with air at low temperatures to give the corresponding α -dione was also reported.²⁶⁰

Ozonisation of both terminal and internal alkynes in alcohols at low temperatures serves as a method for the synthesis of oxo aldehydes and α -diketones. The ozonisation of 1-ethoxypent-1-yne in hexane gave ethyl 2-oxopentanoate.²³⁴

Oxidation of alkynes that do not contain methylene groups adjacent to the triple bond to α -dicarbonyl compounds is carried out with selenium dioxide.^{40, 234} The oxidation is facilitated upon addition of catalytic amounts of sulfuric acid. For example, refluxing diphenylacetylene with SeO₂ in AcOH containing sulfuric acid gives diketone **7a**. The reaction with phenylacetylene

under the same conditions gives phenylglyoxylic acid.²³⁴ Diphenyl diselenide is another selenium-containing reagent that oxidises the triple bond. It converts alkynes to diketone and oxo aldehyde monoacetals in high yields in boiling methanol in the presence of ammonium peroxodisulfate.²⁶¹

$\text{R}^1 = \text{Ph}; \text{R}^2 = \text{H, Ph, 3-Bu}^t\text{C}_6\text{H}_4, 4\text{-FC}_6\text{H}_4, 2\text{-BrC}_6\text{H}_4;$
 $\text{R}^2 = \text{H}; \text{R}^1 = \text{PhCH}_2, \text{Bu}^n, \text{C}_6\text{H}_{13}, \text{HOOCCH}_2; \text{R}^1 = \text{R}^2 = \text{Pr}^n.$

Potassium, zinc and ammonium permanganates are widely used to oxidise alkynes (for the reviews, see Refs 4, 234, 262). To our knowledge, in these reactions terminal alkynes undergo only oxidative cleavage with the formation of carboxylic acids and loss of one carbon atom, whereas α -diketones can be obtained only from internal alkynes. A particularly efficient general method for the synthesis of α -dicarbonyl compounds from alkynes involves the oxidation of the latter with potassium permanganate in aqueous acetone or dioxane under nearly neutral conditions provided by the addition of sodium hydrogen carbonate and magnesium sulfate.²³⁴ Of potassium, magnesium and zinc permanganates, the latter is the most efficient reagent for the oxidation of alkynes in dichloromethane.²⁶³ Potassium permanganate in aqueous acetone proved to be a convenient oxidant of 3,6-di(phenylethynyl)carbazoles to the corresponding 3,6-bis(phenylglyoxylyl)carbazoles.^{264, 265} The mechanism of the oxidation of alkynes with KMnO_4 and the effect of the substrate structure on the process were studied.²⁶⁶ It was shown that the oxidation rate depends on electronic rather than on steric factors.

Certain similarity is observed between the oxidation of alkynes with osmium and ruthenium tetroxides. Terminal alkynes are oxidised with OsO_4 to carboxylic acids. On the other hand, alkynes with an internal triple bond can be oxidised to α -diketones using this reagent.^{234, 267} It was found that OsO_4 forms complexes with alkynes in the presence of pyridine or isoquinoline, $2\text{OsO}_4\text{L}_4\text{R}^1\text{C}\equiv\text{CR}^2$ (where L is pyridine or isoquinoline); these complexes are hydrolysed in the presence of sodium sulfite to the corresponding diketones, R^1COCOR^2 . However, phenylacetylene is converted to benzoic acid under these conditions.²⁶⁸ There are methods for the transformation of alkynes to dicarbonyl derivatives with a catalytic amount of OsO_4 in the presence of co-oxidants, such as potassium chlorate, hydrogen peroxide, *tert*-butyl hydroperoxide and morpholine *N*-oxide.²³⁴ It is believed that OsO_4 is the actual oxidant, while a co-oxidant, for example, potassium chlorate, regenerates OsO_4 from the osmium dioxide formed in the first step.²⁶⁹ Acetylene is oxidised with the $\text{OsO}_4-\text{KClO}_3$ system to give glyoxylic acid,²⁶⁷ and alkoxyalkynes form α -oxo esters in high yields under similar conditions.²⁶⁹ Trimethylsilylalkynes are oxidised to methyl or butyl phenyl(-alkyl)glyoxylates on treatment with a catalytic amount of OsO_4 in the presence of BuOOH in methanol or *tert*-butyl alcohol at 0°C .²⁷⁰ It is believed that α -oxo esters are formed from the primary oxidation products, *i.e.* silylated diketones, on decomposition with an alcohol.²⁷⁰

$\text{R}^1 = \text{Ph, C}_5\text{H}_{11}, \text{C}_6\text{H}_{13}; \text{R}^2 = \text{Me, Bu}^t.$

Ruthenium tetroxide, which is generated *in situ* from RuO_2 dihydrate, RuCl_3 or tris(triphenylphosphine)ruthenium dichloride and such oxidants as NaIO_4 , NaOCl or PhIO or by electrochemical oxidation, serves as an efficient reagent for the transformation of internal alkynes to α -diketones under mild conditions.^{234, 271} Probably, the main advantage of RuO_4 is that it reacts under mild conditions (often at, or below, room temper-

ature) and its high selectivity. For example, benzil **7a** and α -diketones **112–117** with various functional groups are obtained in 27%–95% yields from the corresponding internal alkynes and ruthenium dichloride with NaIO_4 .²⁷²

$\text{R}^1 = \text{Ac, tetrahydropyran-2-yl}; \text{R}^2 = \text{COOMe, OCOBu}^t;$
 $\text{R}^3 = \text{CH}_2\text{Ph, tetrahydropyran-2-yl}; \text{R}^4 = \text{Si}(\text{Bu}^t)\text{Me}_2.$

The same method was used in the synthesis of dioxo amides **118–120** from the corresponding acetylenic carboxamides.²⁷³

Terminal alkynes are converted to carboxylic acids upon oxidation with a catalytic amount of ruthenium tetroxide generated electrochemically from ruthenium dioxide.²⁷¹ On the other hand, dialkyl- and phenylalkylalkynes are oxidised with RuO_4 to give α -diketones in high yields in a two-phase system CCl_4 –saturated aqueous NaCl .²⁷¹

Iodosylbenzene combined with $\text{RuCl}_2(\text{PPh}_3)_3$ in CCl_4 readily oxidises internal alkynes to the corresponding α -diketones.²⁷⁴ The same reagent oxidises alkoxy- and aminoalkynes to α -oxo esters and α -oxo carboxamides in 44%–84% yields.²⁷⁵

$\text{R}^1 = \text{Me, R}^2 = \text{Et}; \text{R}^1 = \text{Pr}^i, \text{R}^2 = \text{Me}; \text{R}^1 = n\text{-C}_6\text{H}_{13}, \text{R}^2 = \text{Me};$
 $\text{R}^1 = \text{Bu, R}^2 = \text{Pr}^i; \text{R}^1 = \text{Ph, R}^2 = \text{Et}.$

$\text{R}^1 = \text{Me, R}^2 = \text{Et}; \text{R}^1 = \text{Pr}^i, \text{R}^2 = \text{Me}; \text{R}^1 = \text{Ph, R}^2 = \text{Me, Et}.$

Thallium nitrate is one more reagent that readily oxidises triple bonds. However, its use in the synthesis of α -dicarbonyl compounds is rather limited. Symmetric dialkylalkynes are converted with $\text{Tl}(\text{NO}_3)_3$ in acidic methanolic medium to give α -hydroxy or α -methoxy ketones, whereas alkylarylalkynes undergo oxidation with 1,2-alkyl shift to give α -branched carboxylic acids.⁵ It is only diphenylacetylene and its substituted derivatives that undergo oxidation on refluxing with $\text{Tl}(\text{NO}_3)_3$ in glym containing HClO_4 to give benzils in 45%–97% yields.²⁷⁶

In recent years, molybdenum and tungsten peroxocomplexes have been extensively studied as oxidants of alkynes.^{277–282} It was

shown that both terminal and internal alkynes undergo oxidation to the corresponding α -oxo aldehydes and α -diketones in rather good yields (55%–90%) on treatment with a $\text{MoO}(\text{O}_2)_2$ –hexamethylphosphoramide complex in the presence of mercuric acetate in a dichloroethane–methanol mixture.²⁷⁷

$\text{R}^1 = \text{Ph}$, $\text{R}^2 = \text{H}$, Ph ; $\text{R}^1 = \text{R}^2 = \text{C}_6\text{H}_{13}$; $\text{R}^1 = \text{Bu}$, $\text{R}^2 = \text{H}$, Ph .

No oxidation occurs in the absence of $\text{Hg}(\text{OAc})_2$. It is known that the action of hydrogen peroxide on Na_2MoO_4 salts [wherein $\text{M} = \text{Mo}(\text{VI})$ or $\text{W}(\text{VI})$] results in oxodiperoxo complexes with the composition $\text{MoO}(\text{O}_2)_2$, which possess strong oxidative properties. It turned out that dilute H_2O_2 oxidises phenylacetylene and hex-1-yne rather readily in the presence of a catalytic amount of molybdates or tungstates (Na_2MoO_4), phase-transfer catalysts, and mercuric acetate. However, the yields of the resulting oxo aldehydes are low, while carboxylic acids are the main products.²⁷⁸ Diphenylacetylene was inert under these conditions. Heteropolyacids, such as $\text{H}_3\text{PMo}_{12}\text{O}_{40}$ and $\text{H}_3\text{PW}_{12}\text{O}_{40}$, manifest higher catalytic activity in the oxidation of alkynes with hydrogen peroxide;^{280–282} these catalysts convert acetylene to glyoxal (yields up to 63%).²⁸⁰ However, phenylacetylene and certain dialkyl- and alkylphenylalkynes are oxidised under these conditions mostly to give carboxylic acids, unsaturated ketones and α -oxo epoxides.^{279, 281, 282} Generally, this type of catalytic oxidation of the triple bond to α -dicarbonyl compounds is no more selective than the oxidation with hydrogen peroxide or peroxy acids. For instance, it is known that trifluoroperacetic acid oxidises diphenylacetylene to afford a mixture of benzil **7a** and benzoic acid.²⁸³ Mixtures of products are also formed upon oxidation of alkynes with hydrogen peroxide in the presence of methylrhodium trioxide MeReO_3 .²⁸⁴ The reaction in the two-phase system CH_2Cl_2 – H_2O converts diphenyl-, dipropyl-, and *tert*-butyl(methyl)alkynes to the corresponding α -diketones (yields 38%–67%), and terminal alkynes (phenylacetylene and non-1-yne) are oxidised to phenyl- and heptyl glyoxalic acids (yields 68% and 47%).²⁸⁴

Nitrogen oxides catalyse the oxidation of acetylene to glyoxal at temperatures from 170 to 250 °C,²⁸⁵ and $\text{Pd}(\text{II})$ catalyses its oxidation in 30%–60% HNO_3 to oxalic acid.²⁸⁶ It was shown that acetylene is not oxidised in HNO_3 at 25 °C or in the HNO_3 – NaNO_2 system, but PdCl_2 – NaNO_2 in nitric acid at 15 °C favours the formation of glyoxal in 40%–50% yield with respect to the acetylene consumed.²⁸⁷ $\text{Hg}(\text{NO}_3)_2$ is less reactive. Methylacetylene was found to be more reactive than acetylene with respect to oxidation, while phenylacetylene gives stable organopalladium compounds that do not undergo further oxidation under the reaction conditions.²⁸⁷

Diphenylacetylene is oxidised in high yield to benzil **7a** under the action of complexes of $\text{Cr}(\text{V})$ with *N,N'*-ethylenebis(salicylideneimine) (salen-complexes). However, phenylacetylene is mostly converted to benzoic acid under these conditions, while only a small amount of phenylglyoxal is formed.^{288, 289}

Phenylacetylene and certain internal alkynes are efficiently oxidised with monoperoxyphosphoric acid (H_3PO_5). However, this reaction produces mixtures of the corresponding α -dicarbonyl compounds with benzoic acid and rearrangement products. The reaction involves α -oxo carbenes as intermediates.²⁹⁰

The oxidation of alkynes with dimethyl- and methyl(trifluoromethyl)dioxiranes also occurs *via* α -oxo carbene intermediates. The reaction results in mixtures of oxidation products, including α -diketones and α -oxo acids.^{291, 292}

Bis(trifluoroacetoxy)- λ^3 -iodanylbenzene **121** smoothly oxidises internal alkynes to α -diketones and terminal alkynes to α -hydroxy ketones.^{293–296} Two equivalents of the reagent **121** selectively oxidise one triple bond in bisphenylethynylbenzene to give acetylenic diketone **100**, while four equivalents of the reagent

oxidise the substrate completely, converting it to the tetraketone **28**.²⁹³

Compound **121** oxidises only one triple bond in diphenylbutadiyne to produce a mixture of diphenyl-1,4-dioxobutene (40%) and acetylenic diketone **101** (30%).²⁹⁶ Compound **121** oxidises diphenylacetylene and its derivatives with electron-donating or moderate electron-withdrawing groups to the corresponding benzils in yields above 70%. However, (4-nitrophenyl)phenylacetylene is converted to 4-nitrobenzil in only 28% yield.²⁹⁴ Despite the high selectivity of the reagent **121** as the oxidant, cleavage of the triple bond cannot be avoided completely. For example, the oxidation of bisphenylethynylidurene gives the acid **123** in addition to the tetraketone **122**.²⁹⁴

The action of compound **121** on 1,4-dihydroxybutynes results, as expected, in the oxidation of the triple bond along with the intramolecular dehydration to give substituted tetrahydrofuran-diones **124** in one step and in high yields.²⁹⁷

$\text{R}^1 = \text{R}^2 = \text{Me}$, $\text{R}^1, \text{R}^2 = (\text{CH}_2)_4$.

Like compound **121**, iodosylbenzene oxidises diphenylacetylene to benzil **7a**. The mechanism of its action is somewhat analogous to the mechanism of oxidation of alkynes with ozone.²⁹⁸

Periodic acid (H_5IO_6) is yet another iodine-based oxidant, which converts diphenylacetylene to benzil **7a** in almost quantitative yield on heating in acetic acid.²⁹⁹ Like I_2O_5 , this oxidant has the advantage that treatment of diphenylacetylene in boiling methanol or ethylene glycol affords mono- and diketals of benzil **7a**, which are difficult to obtain by other methods.²⁹⁹ It is believed that I^+ rather than I^{7+} or I^{5+} is the actual oxidising particle in this case. This opinion is supported by the conversion of diphenylacetylene to mono- and dimethyl ketals of benzil **7a** on heating in methanol with $\text{HgO}-\text{I}_2$.²⁹⁹

N-Bromosuccinimide in dry DMSO is an efficient oxidant of triple bonds in phenylacetylene, diphenyl-, dimethyl- and methylphenylacetylene.³⁰⁰ The reaction can occur even at room temperature. The yield of benzil **7a** reaches 98%, but other alkynes mentioned above form α -dicarbonyl derivatives in lower yields. Diphenylbutadiyne is oxidised to diphenyl tetraketone ($\text{PhCO}-\text{COCOCOPh}$) isolated as the dioxime.³⁰⁰ A certain drawback of

this oxidising system is that DMSO has to be dried thoroughly, as the oxidation of diphenylacetylene does not occur even in the presence of 0.5% water.³⁰⁰ Oxidative reagents based on commercial, non-dried DMSO, *viz.*, HBr, I₂ or PdCl₂ in DMSO,^{253, 254} do not have this drawback. Heating of diarylalkynes in DMSO containing iodine at 115–155 °C provides high yields of benzils.^{253, 254} High reactivity and selectivity of the reagent are confirmed by the fact that it oxidises (4-nitrophenyl)phenylacetylene in 90% yield and does not affect the formyl group in (4-formylphenyl)phenylacetylene, which is very reactive and liable to oxidation.

Various bisphenylethynylarennes are oxidised to the tetraketone **28**, as well as tetraketones **125**, on heating in DMSO with an equimolar amount of iodine (yields 71%–90%).^{253, 254}

Ar = 1,4-C₆H₄, 4,4'-C₆H₄C₆H₄, 4,4'-C₆H₄OC₆H₄, dibenzofuran-3,8-diyl, 4,4'-C₆H₄CH₂C₆H₄, 4,4'-C₆H₄COC₆H₄, fluorene-2,7-diyl, fluorenone-2,7-diyl.

The same reagent was successfully used in the synthesis of 4,4'-bis(arylglyoxylyl)benzophenones from 4,4'-bis(arylethynyl)benzophenones³⁰¹ and a series of fluoro-derivatives of bis- α -diketones, FC₆H₅COCOC₆H₅XC₆H₅COCOC₆H₅F (X = CO, COCO, Het).³⁰²

By decreasing the quantity of iodine to a catalytic amount, it was possible to oxidise only one triple bond in bis(phenylethynyl)benzene and to obtain the diketone **100**.²⁵² It was noted above that the reactivity of iodine in DMSO as an oxidant of the double bonds in stilbenes is low. This enables selective oxidation of only the triple bond in compound **98** giving (*E*)-styrylbenzil **103**.²⁵¹ The acetylene-containing tetraketone **29** is readily converted on treatment with the I₂–DMSO system to the hexaketone **94** in 90% yield.⁵⁹ Thus, the use of a combination of two oxidants, HBr–DMSO and I₂–DMSO, opens for the first time the possibility of the selective oxidation of either triple or double bonds in enynes.

The reactivity of iodine in DMSO decreases abruptly in the oxidation of a sterically hindered acetylenic substrate, *viz.*, mesitylacetylene, although the direction of the oxidation does not change.^{253, 254} A new oxidative process has been discovered recently.³⁰³ Prolonged heating of sterically hindered bis(phenylethynyl)durene with iodine in DMSO gave duroquinone, 2,3,5,6-tetramethyl-4-hydroxybenzil and benzoic acid as the main products, instead of the expected tetraketone **122**. This reaction is a rare example in which iodine in DMSO causes the cleavage of the carbon–carbon bonds. A similar process was observed in the oxidation of the enyne **99**, which resulted in benzil **7a** and benzoic acid instead of the expected diphenylbutenedione.²⁵¹ The I₂–DMSO system also proved to be inefficient in the oxidation of a terminal alkyne, *viz.*, phenylacetylene. In this case, a complex mixture of oxidation products with a content of phenylglyoxal no more than 20% is formed even if the conversion of the substrate is incomplete.²⁵⁵

It was shown^{251, 253, 254, 304} that internal alkynes [diarylalkynes and bis(phenylethynyl)benzenes] are readily oxidised to benzil **7a** and tetraketones **28** and **125** on heating in DMSO in the presence of a catalytic amount of PdCl₂. This reagent proved to be even more selective with respect to the triple bonds than I₂–DMSO. It is totally inert to alkenes. This enables its efficient use in the oxidation of acetylenic compounds containing double bonds.²⁵¹ On the other hand, PdCl₂–DMSO is more sensitive to steric factors in substrates than I₂–DMSO.^{253, 254}

A method for the synthesis of α -diketones **126** from α -acetoxalkynes **127** in high yields was suggested.³⁰⁵ In the first step, substrates **127** are oxidised with complexes of PdCl₂ with acetoni-

trile or benzonitrile under very mild conditions at room temperature. The resulting enol acetates are readily hydrolysed to diketones **126** in the presence of cation-exchange resins.

R¹, R², R³ = H, Alk, cyclo-Alk, Ar.

Anodic oxidation of diarylalkynes in acetonitrile on a graphite electrode gives mixtures of products, of which 1,2,3,4-tetraaryl-but-2-ene-1,4-diones **128** are the main components.³⁰⁶ The corresponding benzils **129** are formed in only 12%–35% yields.

R¹, R² = H, OMe.

Anodic oxidation of diarylbutadiynes **130a,b** under similar conditions results in the respective 1,2-diketones **101** (5%) and **131** (28%) and butyne-1,4-diones **132a,b** (60% and 12%).³⁰⁶

R = H (**101**, **130a**, **132a**), OMe (**130b**, **131**, **132b**).

As shown previously, a mixture of the same products, *viz.*, **101** and **132a**, results from the oxidation of diphenylbutadiyne with bis(trifluoroacetoxy)- λ -3-iodanylbenzene **121**.²⁹⁶

V. Conclusion

Despite the great diversity of oxidative methods for the synthesis of vicinal di- and polycarbonyl compounds (most often, α -diketones), extensive studies in this field are being continued. In our opinion, several most topical problems can be distinguished.

For example, now there are many reliable and general reagents for the oxidation of such substrates as ketones, their α -hydroxy and α -halogeno derivatives and β -diketones. On the other hand, methods for the oxidation of alkenes, vicinal dihalides and especially alkanes have been developed insufficiently. There are almost no versatile reagents for the oxidation of these classes of compounds, except for the recently suggested DMSO-based oxidants suitable for the oxidation of alkenes and substituted 1,2-dibromoethanes. Only after such reagents as HBr–DMSO, I₂–DMSO and PdCl₂–DMSO had appeared, did selective oxidation of either the triple or the double bond in enynes become possible. The results presented in Section IV show convincingly that alkynes rather than alkenes, and even more so alkanes, are the most suitable as substrates in the synthesis of α -dicarbonyl compounds. Thus, the traditional belief that 'alkynes are more difficult to oxidise than alkenes' has to be reconsidered.³⁰⁷

Yet another problem is the obvious lack of reliably proven mechanisms for the oxidation reactions presented in this review. Although a great deal of studies have been carried out, the mechanisms of action of even such well-studied oxidants as SeO₂ and KMnO₄ remain debatable. There are relatively few systematic studies on the quantitative estimation of the effect of the structure of substrates and oxidants on the reactivity. Because of the insufficiency of the theoretical basis, new reagents in this branch

of synthetic chemistry mostly appear incidentally, and the majority of publications are of preparative character.

Finally, it is to be noted that general approaches to the synthesis of compounds with more than three contiguous carbonyl groups have not been developed so far, and only a few syntheses of acyclic pentaketones have been reported. On the other hand, recent non-empirical quantum-chemical calculations show that hypothetical polyketones $R(CO)_nR$ ($n = 6-11$) can be rather stable.³ Synthesis of such compounds is one of the urgent problems of organic synthesis.

Abstract. Data on reactions of *N*-silylated amines, carboxamides, amino acids, and their derivatives with trivalent and pentavalent phosphorus acid halides are summarised. The effect of structural factors on the direction of phosphorylation is discussed. The bibliography includes 133 references.

I. Introduction

The necessity of development of new methods for the synthesis of phosphorus acid amides is associated with the fact that some of these compounds are widely used as bioregulators and key reagents in the synthesis of new medicinal preparations.¹ The phosphoramidite method for the formation of internucleotide bonds remains so far the most efficient in the automated synthesis of oligonucleotides.² However, analysis of literature data on the methods for the preparation of compounds with the P–N bond allows one to reveal certain drawbacks in the popular methods for the synthesis of amides of phosphorus acids.^{3,4} The vast majority of the methods is based on low-selective reactions of phosphorylating reagents with amines or their salts. The use of a large excess of bases (sometimes toxic) hinders purification of the target amides, which creates additional experimental difficulties.

The use of *N*-silylated nitrogen-containing compounds may appear to be the solution of the problem. At present, serious attention has been drawn to the studies on the reactivity of these compounds.^{5,6} The reaction of these silylated compounds with phosphorus acid halides is very attractive for the synthesis of phosphoramidites and phosphoramidates, as it produces volatile halogenosilanes, which can be easily removed from the reaction mixture and repeatedly used in the reaction cycle. Other advantages of the use of silylamines instead of amines have been reviewed.⁵ The ultimate result of this type of reactions definitely depends both on the structural features of the electrophilic phosphorylating agent and on the nature of the silicon–nitrogen

bond that affects the nucleophilicity and configuration of the nitrogen atom.^{7,8}

Since there is no universal scale of nucleophilicity and electrophilicity,⁹ this review compares the reactivity of *N*-silylated nitrogen-containing compounds, which are combined into different groups according to formal structural features, with respect to phosphorus acid halides. In each case, the reaction features that can be attributed to the contribution of the phosphorus component are discussed additionally.

II. Reactions with *N*-silylamines

A characteristic feature of *N*-silylamines is their rather high reactivity with respect to phosphorus acid halides, particularly those of trivalent phosphorus. This may result from changes in hybridisation of the nitrogen atom and, as a consequence, from changes in its nucleophilicity due to the introduction of the silyl group.^{5,7}

The steric factor also exerts a significant effect on the reactivity of silylamines. Generally speaking, the N–Si bond in silylamines is so labile that the latter may act as silylating agents, for example, diethyl(trimethylsilyl)amine (**1**). However, the ability of the Si–N bond to undergo cleavage decreases dramatically with an increase in the volume of the alkyl groups at the silicon atom (*e.g.*, in the case of triisopropyl and *tert*-butyldimethylsilyl groups).¹⁰ A similar effect was also noted in acid hydrolysis of *N-tert*-butyldimethylsilyl- and *N*-triisopropylsilyl-β-lactams.¹¹ Methods for the synthesis of *N*-triisopropylsilylated compounds and their stability have been reviewed.¹² *tert*-Butyldipropylsilylated primary amines appeared to be inert to acylation.¹³ Therefore, this review deals exclusively with the replacement of the trimethylsilyl group at the nitrogen atom by a phosphorus-containing fragment.

1. Reactions with trivalent phosphorus acid halides

It has been shown^{14–21} that reactions of silylamines, mainly amine **1**, with a series of trivalent phosphorus acid chlorides occur under mild conditions.

R₂N = Et₂N (**1**), Me₂N (**2**), .

[†] The review is devoted to the memory of academician M I Kabachnik (1908–1997).

Finally, the reversibility of the reaction of dialkylphosphinous diiodides with the amine **1** in dichloromethane at room temperature has been demonstrated recently.³⁴

Studies of this kind of reactions are complicated by side reactions of phosphoramidites that are formed with organoiodine compounds.^{29, 32, 34} For example, the reaction of the amine **1** with 2-iodo-5,5-dimethyl-1,3,2-dioxaphosphorinane results in the phosphoramidite **7**, which immediately reacts with the product of this reaction, viz., iodotrimethylsilane.²⁹

Unlike acyl fluorides,³⁵ trivalent phosphorus acid fluorides do not react with silylamines. All attempts to carry out such transformations failed.^{29, 36, 37} Thus, the reaction of silylamines with P(III) acid chlorides remains the most suitable for the synthesis of phosphoramidites.

It should be noted that phosphorylation of silylamines in the presence of a base may occur with the preservation of the N—Si bond. For example, the reaction of 2-chloro-1,3,2-diheterophospholanes with *N*-trimethylsilylaniline under mild conditions afforded the corresponding 2-(*N*-trimethylsilyl-*N*-phenylamino)-1,3,2-diheterophospholanes.³⁸

X = O, NPh.

Similarly, Menshutkin's chlorides can react, though partly, at the N—H bond of *N,N'*-bis(trimethylsilyl)trimethylenediamines.^{39, 40}

R¹, R² = H, Me; R³ = Me, Et, Ph.

With disilazanes, it becomes possible to obtain products of substitution of one or two trialkylsilyl groups, depending on the reaction conditions. Monosubstitution occurs with equimolar amounts of the reagents and at low temperature.^{41, 42}

X = Cl, Br.

The resulting *N*-silylamidophosphorodihalidites are thermally unstable and can be transformed to cyclotriphosphazanes on heating of the reaction mixture.^{42, 43}

X = Cl, Br; R = Me, Et.

The reaction of alkylphosphonous dichlorides with methylbis(trimethylsilyl)amine also affords mono- and diphosphoryla-

tion products, depending on the ratio of the reagents,⁴⁴ and boiling of equimolar amounts of the reagents in acetonitrile leads to cyclotetraphosphazanes.^{45, 46}

The synthesis of *N*-trimethylsilyldialkylphosphinamidites by boiling dialkylphosphinous chlorides with an excess of hexamethyldisilazane in the presence of a catalyst was also described.⁴⁷

Trivalent phosphorus acid fluorides are inert with respect to disilazanes.⁴⁸ The Si—N bond remains unchanged after heating a mixture of F₂PCl with (Me₃Si)₂NPF₂ or Me₃Si(Bu^t)NPF₂. This is explained⁴⁹ by *p*_π–*d*_π overlapping of orbitals of the Si, N, and P atoms resulting in a corresponding decrease in the nucleophilicity of nitrogen.

A method for the synthesis of a series of compounds of two-coordinated phosphorus **9** from *N,N,N'*-trisubstituted *N*-(trimethylsilyl)phosphorodiamidohalidites **8**, which had been synthesised from R¹R²NPX₂ and LiN(R³)SiMe₃, was developed.^{50–56}

X = Cl, Br; R¹ or R² are bulky substituents, R³ = Prⁱ, Bu^t, R₃Si, C₆H₂Bu₃¹, adamant-1-yl.

In this case, it was possible to isolate only compounds with bulky substituents at both nitrogen atoms. Otherwise, dimerisation of the imidophosphorous amides **9** to 1,3-diaza-2,4-diphosphetidines takes place.^{52–55}

R¹, R² = Me, Et, Pr.

The nature of the halogen at the phosphorus atom has no significant influence on the elimination of the halosilane.^{50–56} The same method was used for the preparation of the less stable *P,N*-dialkyl(aryl)-^{57, 58} and *P*-aryloxy-*N*-aryliminophosphines.⁵⁹

Reactions of phosphorochloridites with hexa- and heptamethyldisilazanes were studied.^{60, 61} The attractiveness of these reactions is explained by the fact that they allow the syntheses of functionally substituted amides of trivalent phosphorus acids. Unfortunately, phosphorylation of disilazanes occurs under more drastic conditions than phosphorylation of monosilylamines.

X = O, NPh;

Phosphorylation of phosphorus-substituted disilazanes can be accompanied by rearrangement to give compounds containing phosphorus in different coordination states.⁶²

2. Reactions with pentavalent phosphorus acid halides

Since pentavalent phosphorus has lower electrophilicity than trivalent phosphorus, a general decrease in the rates of phosphorylation of silylamines with the corresponding phosphorus(V) acid halides is observed.

The replacement of the chlorine atoms in pentavalent phosphorus acid chlorides by the amino groups in reactions of acid chlorides with amines **1** and **2** is incomplete even on heating.¹⁴

R = Et (**1**), Me (**2**).

Complete replacement of the chlorine atoms in methylenebis(phosphonic dichloride) in its reaction with the amine **2** is possible only on heating.²²

The phosphorylating ability of *N*-methyliminodiphosphonic tetrachloride (**10**) is even lower.⁶³

Nucleophilic substitution of the chlorine atom at a less electrophilic thiophosphoryl centre occurs more readily when the latter is incorporated into a strained four-membered ring, as in compound **11**.⁶⁴

R = Me, Et.

However, the presence of electron-withdrawing and bulky phenyl groups at the nitrogen atom of the silylamine prevents the cleavage of the Si–N bond in this reaction.

Chlorocyclotriphosphazenes also belong to pentavalent phosphorus acid chlorides, but we considered that there is little sense in repeating in this review the previously published data^{65, 66} on their reactions with silylamines.

Unlike trivalent phosphorus acid fluorides, P(V) fluoro-derivatives react with silylamines in some cases. For example, the reaction of *N*-trimethylsilylmorpholine with the mixture of isobutenyl- and 2-chloroisobutylphosphonic difluorides affords products of replacement of one of the fluorine atoms.⁶⁷

R = Me₂C=CH, Me₂CClCH₂.

N-Silylated pyrrolidine and piperidine react rather smoothly with phosphorus oxofluoride POF₃. However, in their reaction with phosphorus oxochloridodifluoride, substitution of the chlorine atom is the first to occur.⁶⁸

Unlike *N*-methyliminodiphosphonic tetrachloride (**10**), *N*-ethyliminodiphosphonic tetrafluoride (**12**) reacts with the amine **1** with the cleavage of the P–N bond.⁶⁹

Although reactions of silylamines with phosphorus acid fluorides are rather interesting from the synthetic point of view, they are little studied. Undoubtedly, this can be explained by the high toxicity of the latter compounds. Phosphorylation of silylamines with phosphorous acid bromides and iodides has not been described in literature.

The reaction of the amine **2** with mixed amidotetrachloride **13** can serve as a characteristic of the relative ability of the halogen atoms in trivalent and pentavalent phosphorus acid halides to be replaced by the amino groups of silylamines.^{70, 71} At –78 °C and with an equimolar ratio of the reagents, the product of the replacement of one chlorine atom at the trivalent phosphorus atom by the dimethylamino group (compound **14**) is formed selectively. The structure of compound **14** is confirmed by ¹H and ³¹P NMR spectroscopic data. An increase in the reaction temperature to 30 °C and exposure of the reaction mixture at this temperature for 1 h result in migration of the dimethylamino group from the trivalent phosphorus atom to the pentavalent one to give compound **15**.

The reaction of the tetrachloride **13** with 2 equivalents of the amine **2** at room temperature affords the product of replacement of both chlorine atoms at the pentavalent phosphorus atom by the dimethylamino groups (compound **16**).

In the authors' opinion, compound **17** is formed as an intermediate in this reaction.

This assumption is supported by the fact that compound **17**, synthesised independently, undergoes rearrangement at room temperature to form compound **16**.

As in the case of P(III) derivatives, the reaction of P(V) acid chlorides with disilazanes can be used for the preparation of *N*-silylated amides.^{72,73}

$\text{R}^1, \text{R}^2 = \text{Alk}, \text{Ar}, \text{AlkO}, \text{ArO}; \text{X} = \text{O}, \text{S}, \text{NR}^4$.

Successful synthesis of these amides requires that appropriate reaction conditions are selected depending on the structure of the phosphorylating agent used. Reactions at room temperature mainly involve more electrophilic MePOCl_2 and 1-chloro-1-oxophosphol-3-ene,⁷² whereas diphenyl phosphorochloridate reacts at 60 °C,⁷³ and phosphinothioic chlorides react only at 130–150 °C.⁷⁴ *N,N*-Bis(trimethylsilyl)-*P*-phenylphosphonothioic diamide is obtained under even more drastic conditions (in the presence of aluminium chloride).⁷⁵ As a rule, reactions of this type afford a monophosphorylation product, except for the reaction of disilazanes with POCl_3 .⁷⁶

The reaction of hexamethyldisilazane with POF_3 afforded the corresponding *N*-silylmonoamide in moderate yield.⁷⁶

Monosubstitution of the chlorine atoms in mixed imidochlorides can be used for the preparation of acyclic oligophosphazenes.⁷⁷

$\text{X} = \text{O}, \text{S}$.

Thus, reactions of both trivalent and pentavalent phosphorus acid chlorides with silylamines are of significant interest for the synthesis of phosphoramidites and phosphoramidates.

III. Reactions with *N*-silylamides

Many *N*-phosphorylated amides and lactams are known to be physiologically active substances with a broad spectrum of action.^{1,78} In addition, certain *N*-phosphorylated amides are used as condensation agents in the synthesis of carboxamides and esters.⁷⁹ The development of convenient methods for their synthesis is therefore of large practical importance.

The introduction of an acyl group into a silylamine molecule changes substantially both the nucleophilic properties of the nitrogen atom and the geometry of the molecule. Studies of the reactivity of silylamides performed by representatives of the Kazan' school of chemists allowed them to elucidate the regularities of the reaction of silylamides with trivalent and pentavalent phosphorus acid chlorides.^{80–87}

Reaction conditions have a significant effect on the direction of the reaction of diethyl phosphorochloridites with *N*-trimethylsilylacetamide (**18**).^{8,80} For example, cleavage of the Si–N bond with the formation of *N*-diethoxyphosphinetriylacetamide takes place at room temperature.

The Si–N bond remains unchanged in the presence of triethylamine; in this case, the reaction product is *N*-trimethylsilyl-*N*-(diethoxyphosphinetriyl), and only heating of the reaction mixture to 110–130 °C brings about the elimination of the acetonitrile molecule and the formation of a Si–O–P bond.

Under similar conditions (room temperature, inert solvent), 2-chlorobenzo-1,3,2-dioxaphospholene reacts with amide **18** to give 2-acetylaminobenzo-1,3,2-dioxaphospholene.⁸¹

Similarly, but in the presence of triethylamine, the reaction of 2-chloro-1,3,2-dioxaphospholane with amide **18** afforded 2-(*N*-acetyl-*N*-trimethylsilylamino)-1,3,2-dioxaphospholane, which is transformed to 2-trimethylsilyloxy-1,3,2-dioxaphospholane on heating.⁸²

The product of disilylation of acetamide, compound **19**, has the structure of an imide in which one of the trimethylsilyl groups is linked with the nitrogen atom, and the second group, with the oxygen atom.^{8,88} Phosphorylation of this compound with phosphorochloridites at room temperature affords *N*-trimethylsilyl-*N*-dialkoxy- or alkoxy(amino)phosphinetriylacetamides. Their structures were confirmed by IR and ¹H and ³¹P NMR spectra.^{82–86} Their conversion into the corresponding trimethylsilyl phosphites was explained by the possible presence of isomeric *N*-(1-trimethylsilyloxyethylidene)phosphoramidites in the reaction mixture.

$\text{R}^1 = \text{R}^2 = \text{OAlk}, \text{R}^1 = \text{OAlk}, \text{R}^2 = \text{NHR}^3$.

The *O*-silylated isomer appeared to be more stable than the *N*-silylated one and was isolated after phosphorylation of compound **19** with dialkyl phosphorochloridithioite.⁸⁵

The reaction under discussion also proceeds in a similar way with other phosphorochloridites. In this case, the ease of the formation of silyl phosphites increases in the following series:⁸³

Isomerisation of the phosphorylation intermediate followed by its decomposition is also observed in some cases.^{86, 89}

If the latter reaction is carried out with an excess of F_2PBr , bisphosphorylated acetamide is obtained. It is formed as a mixture of *N,N*- (**20**) and *N,O*-isomers (**21**), the isomer **20** undergoing rearrangement into the isomer **21**.⁸⁹

Thus, the reaction of trivalent phosphorus acid chlorides with *N,O*-bis(trimethylsilyl)acetamide is a convenient general method for the synthesis of highly reactive trivalent phosphorus acid silyl esters.

The reactivity of disilylamides with respect to phosphorochloridites decreases upon introduction of electron-withdrawing substituents at the carbonyl carbon atom, for example, when methyl group of acetamide is substituted by a phenyl or methoxy group. Methyl *N,N*-bis(trimethylsilyl)carbamate does not react with diethyl phosphorochloridite and 2-chlorobenzo-1,3,2-dioxaphospholene,^{86, 89} and *N,O*-bis(trimethylsilyl)trifluoroacetamide does not react with PF_2Br .⁸⁹

Contrary to silylated primary amides, *N*-silylated secondary amides and lactams can be selectively phosphorylated at the nitrogen atom with phosphorus trichloride and alkylphosphonous dichlorides.^{90, 91}

$n = 1, 2$.

Nevertheless, there is an example of the formation of a mixture of *N*- and *O*-phosphorylation products in the reaction of *N*-methyl-*N*-trimethylsilyltrifluoroacetamide with 2-chlorobenzo-1,3,2-dioxaphospholene.⁹²

It was found recently that the reaction of some trivalent phosphorus acid chlorides with silyllactams **22** may be reversible, and the position of equilibrium is determined by the structure of the phosphorylating agent.⁹³

The reversibility of the process was proved by mixing equimolar amounts of *N*-phosphoryllactams and chlorotrimethylsilane. In this case, the compositions of the reaction mixtures were the same as those in the reactions of phosphorochloridites with silyllactams. The reversibility of the reaction of *N*-trimethylsilyl- β -lactams with trivalent phosphorus acid chlorides was postulated on the basis of indirect data.

Reactions of silylated amides with pentavalent phosphorus acid chlorides are insufficiently studied. It was shown that, as in the case of phosphorochloridites, the reaction of *N,O*-bis(trimethylsilyl)acetamide **19** with phosphorus oxochloride, methylphosphonic dichloride, diethyl phosphorochloridate, diethyl and dimethyl phosphorothiochloridate is accompanied by the formation of silyl phosphates.⁸⁷

Previously, it was found that *N*-silylated lactams react, although under drastic conditions, with alkyl(aryl) methylphosphonochloridates and *N,N*-diethyl-*P*-methylphosphonamidochloridate to form the products of substitution at the nitrogen atom, as in the reaction with phosphorus trichloride.⁹⁴

$\text{R} = \text{OEt}, \text{OPh}, \text{NEt}_2; n = 2, 3$.

A scheme was proposed recently, according to which pentavalent phosphorus acid chlorides $\text{R}^1\text{R}^2\text{P}(\text{O})\text{Cl}$ react with silyllactams **22** both at the nitrogen atom and the oxygen atom of the carbonyl group (Scheme 1).⁹⁵ Strictly speaking, the possibility of silylotropy should be taken into account when estimating the reactivity of *N*-silyllactams; however, under the conditions used,⁹⁵ the trimethylsilyl group had to be bound to the nitrogen atom. Therefore, the nature of the products obtained was explained by the authors from the viewpoint of dual reactivity of the silyllactam system. The formation of *N*-phosphoryllactams **23** may result from both the direct attack at the nitrogen atom and the $\text{O} \rightarrow \text{N}$ isomerisation of the *O*-phosphorylated intermediates which are also the sources of side products, namely, silyl phosphates **24** and pyrophosphates **25**. The predominance of one or another pathway of decomposition of the intermediates depends on different factors including the nature of the organophosphorus fragment. Successive replacement of the alkyl groups in the chloride by

Scheme 1

alkoxy groups decreases the yield of *N*-phosphorylated derivatives **23**. The authors explain this fact by a decrease in the rate of nucleophilic attack by the nitrogen atom on the phosphorus atom in the intermediate and by a larger contribution of other directions of its transformation.

It should be noted that attack on the oxygen atom of *N*-trimethylsilyl- β -lactams by pentavalent phosphorus acid chlorides is hindered by severe steric requirements to the assumed transition state.

The structure of the products formed in the reaction of *N,N'*-bis(trimethylsilyl)ureas with trivalent phosphorus acid chlorides is determined by the nature of substituents at the phosphorus atom.^{96–100}

The attack of phenyl- and methylphosphonous dichloride on the nitrogen atom of the Si–N bond in urea is accompanied by subsequent cleavage of one of the P–N bonds, probably due to the high strain of the corresponding diazaphosphetidine ring.^{96,97}

In the presence of an excess of phenylphosphonous dichloride, the reaction stops at the usual step of replacement of the trimethylsilyl group.⁹⁹

Replacement of the alkyl groups in the starting alkylphosphonous dichlorides by electron-withdrawing groups (CCl₃ or C₂F₅) changes the direction of this reaction resulting in the formation of 1,3,2-diazaphosphetidin-4-ones.^{97,98}

$R^1 = \text{CCl}_3, \text{C}_2\text{F}_5; R^2 = \text{Me, 3-CF}_3\text{C}_6\text{H}_4.$

On the contrary, replacement of the alkyl group in alkylphosphonous dichlorides by a chlorine atom⁹⁷ or a dialkylamino group⁹⁹ favours the formation of bicyclic compounds.

$R = 3\text{-CF}_3\text{C}_6\text{H}_4.$

Phosphorylation of unsymmetrical *N,N'*-bis(trimethylsilyl)ureas **26** with phenyl (chloromethyl)phosphonochloridate is complicated by the attack by the second silylamide group of urea on the carbon atom of the chloromethyl group to give 1,4,2-diazaphospholane-2,5-diones.¹⁰¹

It is interesting that the nucleophilicity of the nitrogen atom in *N,N*-bissilylated sulfamides is so much lower than that in *N*-silyl-carboxamides that the former do not react with phosphonous dichlorides.¹⁰⁰

Reactions of halophosphoranes with silylamides are also ambiguous. The reaction of *N*-methyl-*N*-(trimethylsilyl)trifluoro- and -trichloroacetamides with the chlorophosphorane **27** affords a mixture of *N*- (**28**) and *O*-phosphorylated (**29**) trihaloacetamides. It is noteworthy that, like the product of the reaction of the silylamide **19** with dialkyl phosphorochloridodithioites, the *N*-phosphorylated isomer is less stable and is converted on storage into the *O*-phosphorylated isomer.¹⁰²

R = CCl₃, CF₃.

It is assumed that the reaction of 2,2,2-trichlorobenzo-1,3,2-dioxaphospholene (**30**) with disilylamide **19** occurs through the step of *O*-phosphorylation of silylamide. With the ratio of the reagents 1 : 1, 2-chloro-2-oxobenzo-1,3,2-dioxaphospholene (**31**) is formed. With an excess of silylamide, the reaction affords the silyl phosphate **32**.¹⁰³

N,N'-Disilylated ureas react with fluorophosphoranes to give cyclic phosphoranes **33**.¹⁰⁴

n = 1–3.

Thus, practical application of silylamides requires additional studies on the optimisation of conditions for the synthesis of *N*-phosphorylated amides.

IV. Reactions with *N*-silylated amino acids and other *N*-silylated compounds

N-Silylated amino acids can be regarded as *N*-silylamines that contain a functional group in their alkyl part.

Reactions of *N,O*-bis(trimethylsilyl) derivatives of natural α -amino acids with acyl chlorides were used for the protection of the amino group.¹⁰⁵

N-Acyl derivatives of α -aminoalkylphosphonic acids were synthesised in a similar way.¹⁰⁶

No other examples of this type of reaction have been documented.

However, it turned out that *N*-phosphorylated amino acids can be obtained by the reaction of *N,O*-bis(trimethylsilylated) amino acids with pentavalent phosphorus acid halides.^{107–109}

N-Phosphorylated acids are formed in high yields. Intermediate silyl esters of *N*-phosphorylated amino acids were isolated in the case of glycine derivatives.¹⁰⁷

This type of selective *N*-phosphorylation of *N,O*-bissilylated compounds was also used in the synthesis of *N*-(dialkoxyphosphoryl)hydroxylamines.¹¹⁰

Both silyl groups participate in the reaction of bis(trimethylsilyl)proline with diethylphosphoramidodichloridite, which results in the formation of a bicyclic product (**34**).¹¹¹

Phosphorylation of silylated α -amino ketones occurs at the nitrogen atom. Phosphoro- and prototropic transformations of primary phosphorylation products **35** are observed in this case.¹¹²

X = O, S or unshared electron pair.

The reaction of 1-(*N*-isopropyl-*N*-trimethylsilylamino)-3,3-dimethylbutan-2-one with spiroposphorane **36** was complicated by the formation of an N→P donor-acceptor bond. As a result, the tricyclic compound **37** with the hexacoordinated phosphorus atom was formed.¹¹³

The peculiarities of the reactions of phosphorus acid chlorides with such amino acid derivatives as *N*-silyllactams, which may be also attributed to *N*-silylamides, have been discussed in Section III.

In the studies of the reactivity of compounds containing a silyl group at the imine nitrogen atom,^{114,115} it was found that phosphorochloridites react with aldimines¹¹⁴ and ketimines¹¹⁵ under mild conditions and the *N*-(dialkoxyphosphinetriyl)aldimines that formed undergo rapid dimerisation.

RO = EtO; (RO)₂ = O(CH₂)₂O, 1,2-OC₆H₄O.

Among other *N*-silylated compounds containing a C=N bond, isocyanates and isothiocyanates are worth noting.

Phosphorylation of isocyanatosilanes has been studied very little. Only the syntheses of diethylphosphoramidobisisocyanatide¹¹⁶ and phosphorisocyanatidic difluoride¹¹⁷ have been reported. Recently, the reaction of isocyanatotrimethylsilane with phosphinic chlorides was used in the synthesis of 1,3,4-oxazaphosphol-2-enes.¹⁰¹

Trimethylsilyl isothiocyanate reacts with trivalent and pentavalent phosphorus acid chlorides only on strong heating.^{118, 119}

R = Ph, Me, EtO; X = O, S or unshared electron pair; $n = 0-2$.

Because of the large practical importance of phosphoryl isothiocyanates, which are the products of this reaction and which are widely used as intermediates in the synthesis of pesticides and complexones, attempts were made to decrease the reaction temperature by adding catalysts. The use of tin and titanium tetrachlorides for this purpose was unsuccessful.^{118, 120} On the contrary, when the reaction was carried out in the presence of *N*-methylmorpholine, it became possible to obtain thermally unstable phosphoryl isothiocyanates at 20 °C in high yields.¹²¹

In some cases, the reaction of isothiocyanatotrimethylsilane with pentavalent phosphorus acid chlorides is reversible.¹²² Using the ³¹P NMR method, it was found that the compositions of the reaction mixtures prepared from methylphosphonic dichloride and 2 equivalents of isothiocyanatotrimethylsilane and from methylphosphonic diisothiocyanate and 2 equivalents of chlorotrimethylsilane were identical.

The yield of phosphonic diisothiocyanate may be increased by distilling off the chlorotrimethylsilane that formed in the reaction.

The low yield of dibutylphosphinic isothiocyanate in comparison with those of the corresponding phosphoric and phosphonic isothiocyanates is also explained by the reversibility of the reaction under study.

The use of isothiocyanatoalkoxydimethylsilane instead of isothiocyanatotrimethylsilane increases the reactivity of the Si-N bond in reactions with trivalent and pentavalent phosphorus acid chlorides;¹²³ however, the Si-O bond is cleaved even at low temperatures (20–60 °C) to afford a mixture of products.

Phosphoric acid fluorides are rather low-reactive with respect to Me₃SiNCS even on heating, and the fluorine atom of the

phosphorimide moiety is more reactive than that of the thiophosphoramidate moiety.¹²⁴

The increased reactivity of the Si-N bond in azidotrimethylsilane and the commercial availability of this compound allow one to consider it as a convenient reagent for the synthesis of thermally labile phosphorus acid azides. For example, phosphorochloridites react with Me₃SiN₃ to give high yields of the product even at 0 °C.^{125–130}

R¹, R² = Cl, Cl₃CCMe₂O, Et₂N, Pr₂N; R¹ + R² = O(CH₂)₂O, 1,2-OC₆H₄O.

Pentavalent phosphorus acid chlorides¹²⁷ and chlorophosphoranes¹³¹ behave similarly.

V. Conclusions

Reactions of phosphorus acid halides, particularly chlorides, with *N*-silylated organic compounds are undoubtedly of interest for synthetic chemists, since they can serve as the basis for the development of methods for the synthesis of both new types of compounds and reactive intermediates. However, no strict quantitative analysis of the regularities of this reaction has been carried out so far, which inhibits practical recommendations regarding optimum conditions of this reaction in particular cases in order to reach the required selectivity.

In the recently published special issues of the 'Chemical Reviews' devoted to current problems of the chemistry of silicon¹³² and phosphorus,¹³³ the problems concerning the application of compounds with a nitrogen-silicon bond in the organophosphorus synthesis were not properly taken into account. We hope that the present review fills this gap.

Based on the literature data and their own experience, the authors have the courage to state that the potential of the reactions under discussion has not been totally exploited. In particular, this refers to phosphorylation of biopolymer fragments under mild conditions, for which methods of silylation have been largely developed. In this case, the result of the reaction may be controlled by varying substituents at the silicon and phosphorus reaction centres. Such studies may be carried out in the near future.

This review was written with the financial support of the Russian Foundation for Basic Research (Project No. 96-15-97298).

Abstract. The influence of the nature of the carrier gas and of its pressure on the retention and the height equivalent to the theoretical plate in gas–solid chromatography is analysed. The physicochemical processes responsible for this influence are examined. It is shown that the carrier gas is an active participant in the chromatographic process. The bibliography includes 145 references.

I. Introduction

Gas–solid chromatography is one of the principal versions of gas chromatography and its significance in the solution of important analytical and preparative problems has been increasing continuously.^{1,2}

The compounds being chromatographed, the adsorbent (solid), and the carrier gas as a rule participate in the separation process in gas–solid chromatography. The solid may also play the role of a volumetric adsorbent (for example, palladium may chemisorb hydrogen reversibly³), but few such absorption systems are known and we shall not consider them in the present review. It is noteworthy that inadequate attention has been paid currently to the carrier gas as a participant in the chromatographic process and as a factor capable of improving the separation significantly.

The retention of chromatographed compounds is a result of the adsorption of the analyte compounds/sorbate on a solid with a relatively high specific surface (the adsorbent).¹ In gas–solid chromatography, the retention is determined by the nature of the sorbate, the nature of the adsorbent surface and its structure, and also the nature and pressure of the carrier gas employed.

The first experimental data concerning the influence of the nature of the carrier gas and the retention of the analyte were obtained already in the initial stage of the development of gas–

solid chromatography. Thus, as early as 1962, Zhukhovitskii and Turkel'taub noted that in gas–solid chromatography account must be taken primarily of the influence of the carrier gas on the sorbability of the components of the mixture being separated, because a change in the nature of the carrier gas may alter significantly the separation criteria.⁴ However, in routine chromatography, this fact has not always been taken into account. This can probably be accounted for by the fact that, firstly, permanent gases, the influence of which on the retention parameters is insignificant, were usually employed as carrier gases and, secondly, the accuracy of the measurement of the retention parameters on packed columns, especially in the initial period of the development of gas–solid chromatography, was insufficiently high.

The influence of the nature of the carrier gas on the retention may be predicted by analysing the general relations describing the adsorption equilibria and the relation between these equilibria and the retention volume (see, for example, Refs 1, 2 and 6–9). The equilibrium is characterised by the following functional relations.

1. The equation of the adsorption isotherm for the compounds participating in the chromatographic process:

$$a_i = f(c_i, c_m, a_m), \quad (1a)$$

$$a_m = \psi(c_m, a_i, c_i), \quad (1b)$$

where a_i is the concentration of the adsorbed compound i on the surface of the adsorbent, c_i is the concentration of compound i in the gas phase, c_m the concentration of the carrier gas in the mobile phase (proportional to its partial pressure), and a_m is the concentration of compound m (the carrier gas) on the surface of the adsorbent.

2. The equations for the effective partition coefficient $K_{im\text{ef}}$ (see, for example, Berezkin and de Zeeuw²):

$$K_{im\text{ef}} = \left(\frac{\partial a_i}{\partial c_i} \right)_{c_m} = \left[\frac{\partial f(c_i, c_m, a_m)}{\partial c_i} \right]_{c_m},$$

$$K_{im\text{ef}} = \left(\frac{\partial a_i}{\partial c_i} \right)_{c_m} = \frac{V_{Ni}(c_i, c_m)}{S} = V_s(c_i, c_m), \quad (2)$$

where V_{Ni} is the retention volume for compound i , S the overall surface area of the adsorbent employed, and $V_s(c_i, c_m)$ the specific

retention volume calculated per unit surface of the adsorbent employed.

We may note that the nonideality of the gas phase and its adsorption on the surface of the adsorbent influence the retention. However, as noted in the above monograph,² the role of the second factor is frequently more important.

3. The equation for the retention volume:

$$V_{Ni} = \left(\frac{\partial a_i}{\partial c_i} \right)_{c_m} S = K_{im\text{ef}} S. \quad (3)$$

We may note that the functions a_i and a_m [Eqns (1a) and (1b)] are functions of several variables and their derivatives are therefore expressed as partial derivatives.

Taking into account the general ideas concerning the adsorption of a mixture of gases on the surface of a solid adsorbent (see, for example, monograph by Kiselev and Yashin¹), it follows from Eqn (3) that in the general case V_{Ni} also depends on the nature of the carrier gas, its partial pressure, and its adsorption in the chromatographic system.

If it is assumed that the adsorption of the carrier gas may be neglected, Kiselev's equation follows from Eqn (3) as a special case:^{1,6}

$$V_{Ni} = K_i S. \quad (4)$$

In it, Henry's constant K_i may be expressed by the following equations:

$$K_{im\text{ef}} = K_i,$$

$$K_i = \frac{\partial a_i}{\partial c_i} = \frac{a_i}{c_i}. \quad (5)$$

It follows from the relations quoted above that the partition coefficient depends in the general case on the partial pressure (concentration) of the carrier gas and its nature. Analysis of this relation is of theoretical and practical interest.

We believe that studies on the influence of the nature of the carrier gas on the retention are important because they make it possible, firstly, to refine the real picture of the chromatographic process, secondly, to establish the corresponding general relations, and, thirdly, to assess the carrier gas as a factor actively influencing the principal parameters of the chromatographic separation. Certain examples of the practical use of gas–solid chromatography, reflecting the role of the carrier gas, are presented in Table 1. Evidently, many carrier gases have found an application in gas–solid chromatography — ranging from the inert helium to the vapours of water and organic compounds, but helium, nitrogen, and hydrogen are mainly employed in chromatographic practice.²⁰

Table 1. Examples of the chromatographic systems used in gas-solid chromatography.

Note. The following designations have been adopted: TCD = thermal conductivity detector; FID = flame-ionisation detector; UVD = ultraviolet detector. ^a On capillary columns.

In this review, the authors attempted to survey and analyse the experimental data concerning the dependence of the retention of the compounds chromatographed on the nature and pressure of the carrier gas employed and to assess the possibility of using the carrier gas to increase the selectivity of the separation of the analyte. The physicochemical foundations of the influence of the nature of the carrier gas on the principal characteristics of the chromatographic process are examined for this purpose.

II. The role of the carrier gas in gas–solid chromatography

In the initial period of the development of gas–solid chromatography, nitrogen and air were used as the mobile phase.^{21–23, 53–56} Subsequently, hydrogen²⁵ and helium^{57, 58} also began to be used, which made it possible to improve the characteristics of the chromatographic process by increasing the sensitivity of the thermal conductivity detector. During this period, the principal chromatographic detector was the thermal conductivity detector (TCD). Subsequently individual communications appeared concerning the application of neon,^{32, 59} xenon, and krypton⁶⁰ as carrier gases, but in the main this was associated not so much with the study of the influence of the nature of the carrier gas on the chromatographic process as with the need to employ highly sensitive ionisation detectors.

The first publications about the systematic investigation of organic and water vapours as carrier gases appeared at the end of the 1950s.^{61, 62} However, the saturation of the inert carrier gas with steam had also been used earlier. Thus Turkel'taub *et al.*³⁹ described the chromatographic analysis of a C₁–C₄ hydrocarbon mixture and other gases on silica gel with addition of steam (1 vol.%–8 vol.%) to the usual carrier gas. As the content of steam in the mobile phase increased, a decrease in the retention volumes of the components of the mixture analysed and a change in the shape of the peaks were observed. Similar results were obtained by Booker⁶³ in a study of the chromatographic separation of gaseous hydrocarbons on alumina; he confirmed that the

symmetry of the chromatographic zones was significantly improved after the addition of steam to the carrier gas.

Wiseman⁵⁸ drew attention to the fact that the width of the elution curves for ethyl acetate and isobutyl alcohol was greater when nitrogen was used as the carrier gas. However, a theoretical justification of this phenomenon was not achieved.

Green and Roy¹⁰ are the authors of the first communication in which a significant change in the retention time of the chromatographed compound was noted after the replacement of one carrier gas by another. The investigators presented the following data concerning the separation of a low-boiling gas mixture (H₂, O₂, N₂, CO, CH₄, CO₂, C₂H₄, and C₂H₆) on activated charcoal at 25 °C for five carrier gases: He, Ar, N₂, air, and ethyne. For example, the retention time of methane assumed the following values (min) other conditions being equal: 34 in helium, 22 in argon, 16 in nitrogen, 15 in air, and 5 in ethyne. Thus the retention increased by a factor of ~7 when ethyne was replaced by helium. Satisfactory results in the separation of a complex mixture have been obtained¹⁰ using programmed temperatures (Fig. 1).

A change in the retention volumes when different carrier gases were employed (H₂, He, Ne, and Ar) was noted also in a study of the separation of mixtures of permanent gases on columns with activated charcoals and molecular sieves.⁵⁹

It is known that the sorption of light gases (including carrier gases) in gas–solid chromatography on solid adsorbents may be significant. Thus, carbon dioxide is strongly adsorbed by molecular sieves. Karmen *et al.*³¹ pointed out the possibility of using it as the carrier gas, which made it possible to separate nitrogen and oxygen on molecular sieves. When carbon dioxide was replaced by the inert helium, there was virtually no separation.

Further investigations demonstrated that the nature of the carrier gas influences the retention of the chromatographed compounds and this is characteristic of adsorbents of different types. Thus it has been shown that²⁶ the retention times (retention volumes) of various gases on porous organic polymeric adsorbents of the Porapak Q type diminish appreciably when the heavy

Figure 1. Chromatogram of a gas mixture of organic and inorganic compounds with helium (a) and argon (b) as the carrier gases;¹⁰ (1) hydrogen; (2) oxygen; (3) nitrogen; (4) carbon monoxide; (5) methane; (6) carbon dioxide; (7) ethyne; (8) ethene; (9) ethane. Experimental conditions: column length 3 m, sorbent — activated charcoal (40–60 mesh), temperature programming from 25 °C to 170 °C at 3 K min⁻¹ (a) and to 160 °C (b).

carbon dioxide or gaseous hydrocarbons (ethene and propene) are used as the carrier gas (Table 2).

Vyakhirev and Bruk⁶⁴ investigated the influence of the nature of the carrier gas on the chromatographic separation of mixtures of gaseous hydrocarbons on a silica gel column using hydrogen, nitrogen, and carbon dioxide as the carrier gases. The adsorption isotherms and the Henry adsorption coefficients for various carrier gases calculated from them indicate that the degree of

Figure 2. Adsorption isotherms of n-butane on silica gel at 40 °C.⁶⁴ Carrier gases: (1) carbon dioxide; (2) nitrogen; (3) hydrogen.

adsorption of n-butane in a flow of CO₂ is lower (Fig. 2) than in N₂ and H₂, which can be explained by the stronger adsorption of CO₂ on silica gel. Accordingly the retention of the components in the separation of a mixture of hydrocarbons is smaller in a flow of carbon dioxide than in a flow of nitrogen and hydrogen. The nature of the carrier gas also influences the shape of the adsorption isotherm (Fig. 2). The isotherms for n-butane in N₂ and H₂ have a more convex form (relative to the abscissa axis), while those in CO₂ are less convex. A certain degree of linearisation of the n-butane isotherm in a flow of CO₂ can undoubtedly be accounted for by the stronger adsorption of carbon dioxide on silica gel compared with the adsorption of nitrogen and hydrogen, i.e. by the dynamic modification of the silica gel surface by the adsorbed carbon dioxide molecules.

Turkel'taub and Zhukhovitskii⁶⁵ were some of the first investigators to note that the nature of the carrier gas plays a significant role in gas–solid chromatography. This is manifested by a change in the shape of the recorded peaks and in retention when one carrier gas is replaced by another. The adsorption coefficient of the component decreases sharply if its adsorption characteristics are close to those of the carrier gas, and at the same time the carrier gas exerts a significantly smaller influence on the effectively adsorbed component. Modification of the adsorbent surface by molecules of a heavy carrier gas improves the symmetry of the zones of the chromatographed compounds.

The characteristics of the influence of the carrier gas can be explained qualitatively (and in a number of instances also quantitatively) by competitive adsorption and by the employment of the Langmuir equation for binary mixtures in order to interpret the observed phenomena (see, for example, Kel'tsev's monograph⁶⁶).

Thus the first investigations already showed that the mobile phase plays a more important role in gas–solid chromatography than in gas–liquid chromatography.

Subsequent studies were devoted mainly to the establishment of the general quantitative and semiquantitative characteristics of the influence of the nature of the carrier gas and of its pressure on the retention of the chromatographed compounds and also to the theoretical justification of such influence.

III. Gas–solid chromatography on packed columns

1. Gases as the mobile phase

Hoffman and Evans¹⁵ established a linear relation between the retention times of normal hydrocarbons and the reciprocal of the square of the radius of the atom of an inert monatomic carrier gas. However, this relation is doubtful for the following reasons: firstly, the characteristic quantity (chromatographic constant) for the chromatographed substance is not the retention time but

Table 2. Retention volumes (V_R /ml) of certain gases on a packed column with Porapak Q as the adsorbent and different carrier gases.²⁶

Sorbate	Carrier gas

C ₃ H ₈	220	220	220	180	155	—

the retention volume^{67–69} and, secondly, according to the results obtained by Hoffman and Evans,¹⁵ helium exerts a stronger modifying effect than argon, which conflicts with known data from other investigations.

Brokman *et al.*¹⁶ investigated the influence of the nature of the carrier gas on the interphase equilibrium distribution of the volatile sorbate. The specific retention volume (V_g^T) was selected as the parameter sensitive to the alteration of the nature of the distribution for the given sorbate–sorbent pair at the given temperature. The results obtained, presented in Table 3, enabled the authors to conclude that the distribution constants hardly change on passing from one carrier gas to another. This should imply that the nature of the carrier gas hardly affects the distribution process and that the change in the retention time of n-butane can be explained solely by the different inlet pressures of the carrier gases (two parameters are actually altered — the viscosity and pressure of the carrier gas). It is noteworthy that this is the only study in which it was concluded that the nature of the carrier gas does not influence the retention of the analyte.

Table 3. The specific retention volume of n-butane on a column with activated alumina at a temperature of 100 °C with various carrier gases.¹⁶

Carrier gas	<i>t</i> /min	<i>P</i> ₀ /Torr	James–Martin correction	V_g^T /ml g ^{−1}
H ₂	4.29	1025	0.830	16.8 ± 0.1
N ₂	4.96	1290	0.710	16.6 ± 0.1
He	5.14	1320	0.695	16.9 ± 0.1
Ar	5.24	1420	0.660	16.3 ± 0.1

However, in our view the authors of the above study¹⁶ treated their results incorrectly. The carrier gases arranged in order of decreasing retention volumes (ml g^{−1}) of the chromatographed compounds (*i.e.* in order of increasing influence on the retention volume) form the following series: He (16.9) > H₂ (16.8) > N₂ (16.6) > Ar (16.3). We may note that the accuracy of measurement of the retention volumes in the study under discussion was not less than to within 0.1 ml g^{−1}, so that the sequence presented above ('the influence series') may be regarded as experimentally rigorously established; it confirms the dependence of the equilibrium retention volume on the nature of the carrier gas employed. This sequence is consistent with the adopted idea that the adsorbability of the carrier gas increases in the same series. Thus the conclusion reached by the authors¹⁶ that the retention is independent of the nature of the carrier gas conflicts with their own experimental data.

Gvozdoch *et al.*¹⁴ confirmed the influence of the nature of the carrier gas on the retention of the chromatographed compounds on porous organic polymers (adsorbents). The retention volumes of a series of volatile compounds were measured and compared on Chromosorbs 101, 104, and 106 using strongly adsorbed carrier gases — helium, argon, carbon dioxide, sulfur hexafluoride, and water. The nonpolar Chromosorb 101 is⁶⁷ a copolymer of styrene and divinylbenzene, the polar Chromosorb 104 is a copolymer of acrylonitrile and divinylbenzene, while the nonpolar Chromosorb 106 is a polystyrene with a network structure. Table 4 presents the retention volumes of the sorbates when argon and steam are used as carrier gases. Analysis of the tabulated data shows that the replacement of argon by steam influences significantly the retention of the chromatographed compounds, especially polar ones.

It has been established experimentally¹⁴ that the use of heavy carrier gases induces a decrease in the retention volumes when both the weakly specific adsorbent Chromosorb 101 and the highly specific adsorbent Chromosorb 104 are employed. The influence of the nature of the carrier gas intensifies with increase in its adsorbability on the surface of the porous polymer: the energies of the interaction of the carrier gases investigated diminish in the

Table 4. The retention volumes (V_R /ml) of compounds of different classes on polymeric adsorbents at 150 °C using argon and steam as the carrier gases.¹⁴

sequence H₂O > CO₂ > SF₆ > He. According to Gvozdoch *et al.*,¹⁴ the dependence of the retention volume on the nature of the carrier gas is a result of the influence of two main processes: the adsorption of the carrier gas on the most active surface centres of the porous polymers (and the partial displacement of the sorbate by the carrier gas) and the interaction of the sorbate and carrier gas molecules.

The active role of the carrier gas in gas–solid chromatography and its influence on the retention have been noted also in the monograph Guiochon and Guillemin.⁷¹ Thus, when n-alkanes were eluted on silica gel of the type of Porasil C (with a specific surface of 50–100 m² g^{−1}) using carbon dioxide as the carrier gas at a column temperature of 80 °C, an appreciable decrease (30%–40%) in the retention factor (capacity factor) of the column following an increase in pressure from 1.3 to 5.1 atm was noted.⁷¹ Under these conditions, ~15% of the silica gel surface was covered by adsorbed carbon dioxide molecules.⁷¹

'Heavy' carrier gases may decrease significantly the adsorbability of the chromatographed compounds and hence influence the separation of gases and volatile compounds, especially when molecular sieves are employed. In gas chromatography on zeolites, the actively adsorbed carrier gases (such as steam and carbon dioxide) are hardly employed because they are selectively and strongly adsorbed by zeolites. For example, Kiselev and Yashin⁷² noted that the presence of water and carbon dioxide strongly influences the retention volumes on zeolites. For the stable operation of a column with zeolites, it is therefore necessary to remove thoroughly moisture and carbon dioxide from the carrier gas being analysed.

However, the use of strongly adsorbed carrier gases is in a number of instances justified by the separation of strongly adsorbable sorbates. Thus it has been shown⁷³ that the use of carbon dioxide as the carrier gas appreciably improves the separation of hydrocarbon gases on zeolites at a low column temperature and reduces the duration of analysis compared with the carrier gases employed traditionally (for example, helium or nitrogen). The nature of the carrier gas strongly influences the separation of hydrocarbon mixtures. For example, a six-component mixture of hydrocarbon gases may be fully separated on the NaY zeolite at 20 °C using carbon dioxide as the carrier gas (Fig. 3), whereas traditional carrier gases (hydrogen or helium) do not ensure the separation of this mixture even at elevated temperatures as a consequence of the strong retention of its components.

Figure 3. Chromatogram of C₁–C₄ hydrocarbon gases.⁷³ Experimental conditions: 0.5 m × 4 mm column, adsorbent — NaY, temperature 20 °C. Carrier gases: (a) helium; (b) carbon dioxide.

It is essential to note that the use of He or N₂ as carrier gases on this form of molecular sieve does not lead to the temperature inversion of the elution sequence of the components for the following pairs of hydrocarbon gases: propane–ethene, butane–propene. However, if the carrier gas is CO₂, then at certain temperatures the elution sequence of the above pairs of organic compounds is inverted. An appreciable decrease in the specific retention volumes of hydrocarbon gases has been noted⁷³ when carbon dioxide was used as the carrier gas on packed columns with the NaY and CdY zeolites. This effect is manifested most clearly at low column temperatures when CO₂ is appreciably adsorbed on zeolites. A consequence of this is the deactivation of the adsorbent surface.

The absolute retention of the chromatographed compounds on a given packed column is determined not only by the nature of the adsorbent but also by its form — bulk or surface-layer adsorbent. The amount of the adsorbent per unit volume is significantly greater for the traditional (bulk) adsorbent than for the surface-layer adsorbent, so that the use of the latter makes it

possible to reduce significantly the retention of the chromatographed compounds, *i.e.* to accelerate the analysis.

Andronikashvili, Berezkin, and coworkers investigated the joint influence of the carrier gas, the type of the adsorbent (bulk or surface-layer),^{18, 74} and the nature of the cation in the zeolite⁷⁴ on the chromatographic separation process. The retention times of the individual hydrocarbons in the NaY zeolites in the traditional and surface-layer forms are presented in Table 5. For all the hydrocarbons investigated and for all the carrier gases, a significant decrease in the retention time is observed on passing from the bulky to the surface-layer sorbents. The nature of the carrier gas also influences to an appreciable degree the retention times of the sorbates: the longest retention time is in helium, a shorter one is in nitrogen, and a still shorter retention time occurs in carbon dioxide. If the carrier gas is CO₂, its displacement effect can be made use of in many instances, *i.e.* carbon dioxide may serve simultaneously as a carrier gas and as a displacing gas.^{18, 74}

Using a mixture containing n-alkanes, Andronikashvili *et al.*⁷⁴ showed that the employment of carbon dioxide as the carrier gas and of surface-layer zeolite adsorbents improves significantly the effectiveness of chromatographic columns, reduces the duration of the analysis, and makes it possible to obtain a more symmetrical peak and also to expand appreciably the range of compounds which may be analysed on zeolites. The chromatograms for the separation of a mixture of hydrocarbons are presented in Fig. 4.

Thus, when account is taken of the foregoing, it is justifiable to recommend a wider application of CO₂ as the carrier gas in gas–solid chromatography on zeolites in the form of surface-layer adsorbents.

Parbuzin and Gulians²⁷ proposed a version of gas–solid chromatography using adsorbable carrier gases (hydrogen deuteride and deuterium) as well as protium for the separation of a five-component mixture (hydrogen deuteride and the *o*- and *p*-isomers of hydrogen and deuterium) on a column with the NaA molecular sieve at a temperature in the range between –321 and –161 °C. The employment of the traditional version of gas–solid chromatography using inert carrier gases for the physico-chemical investigation of the adsorption of hydrogen isotopes and isomers is restricted by the ‘zero’ degree of surface coverage of the adsorbent and by the temperature (–173 °C). The appearance of ‘negative’ peaks can be explained by the greater thermal conductivity of certain sorbates compared with that of the carrier gas. The application of deuterium-containing carrier gases which are adsorbed at low temperatures made it possible to obtain extensive

2. The use of pure vapours of polar compounds or their mixtures in an inert carrier gas as the mobile phase for the dynamic modification of adsorbents

The vapours of highly polar organic and inorganic compounds, which are used as the mobile phase in a pure form or as an admixture in a fairly inert carrier gas, exert a strong and frequently nontraditional influence on the retention and the shape of the recorded peaks for the analytes. In this version of gas–solid chromatography, the mobile phase is, firstly, a transporting agent which moves the zones of the compounds separated along the column and, secondly, an agent modifying the adsorbent surface. The adsorbability of the sorbate in the mobile phase–sorbing medium system and hence the retention are altered as a result of the modification (the retention is usually reduced); the phase equilibrium of the sorbate in the mobile phase–adsorbent system is disturbed as a consequence of the nonideality of the mobile phase, which is usually manifested to an appreciable degree at an elevated pressure; the ‘sensitivity of the detector’ to the analytes is changed (in some cases, its increase is observed).

In the first studies employing organic eluents,⁶¹ steam,^{34, 35, 64} and of these substances as additives to the conventional carrier gases,^{39, 52} it was shown that transition to organic and mixed eluents significantly alters in many instances the picture in the gas-chromatographic separation of substances. The nature of the mobile phase influences appreciably both the retention of the chromatographed compound and the shape of the recorded peaks. For example, the vapours of the following substances may be used as the eluent (or its component): water,^{38, 39, 42–25, 62} ethanol,^{41, 48–50} carbon tetrachloride,⁴⁸ n-hexane, n-butyl chloride, ethyl acetate,⁴⁹ etc. Steam is most often employed^{38, 39, 42–45, 62, 75} and in this instance one speaks of a special vapour-phase version of chromatography.

The vapours of organic compounds as the mobile phase in gas–solid chromatography. The characteristic features of the application of gases and organic vapours as carrier gases and also as additives to the usual carrier gases have been examined in detail.^{76, 77} The authors note that in a traditional variant of gas chromatography at low pressures, the mobile phase performed as a rule the function only of the agent transporting the substances being separated along the column, which unjustifiably narrows the role of the carrier gas.

In the literature, it is possible to find numerous examples illustrating the influence of vapour-like mobile phases (VMP) on the results of the chromatographic process. For example, Tsuda *et al.*⁴⁹ present data demonstrating clearly the significant influence of the nature of the carrier gas on the retention volumes and the chromatographic separation of the analytes. Thus, when ethanol is used as the carrier gas and alumina as the adsorbent, the retention volume of benzene constitutes one hundredth of its retention volume when the carrier gas is nitrogen while the adsorbent is the same. The retention of benzene on a column with Porapak Q changes by 60% when the N_2 carrier gas is replaced by CCl_4 vapour. Similar results have been obtained also for other chromatographic systems.

A dependence of the retention volumes of the sorbates on the eluting power of the mobile phase, which is 0.00 for n-hexane, 0.30 for n-butyl chloride, 0.58 for ethyl acetate, and 0.88 for ethanol, is observed in gas–solid chromatography employing VMP (in both liquid and thin-layer chromatography).⁴⁹ With decrease in the eluting power, the retention volumes increase appreciably (Fig. 6), but the general characteristics of the retention, known for the carrier gases employed traditionally, are retained. Thus the linear dependence of the logarithms of the retention volumes of the sorbates on their boiling points is observed for all the vapour systems investigated. Tsuda and Ishii⁴⁸ also noted a change in the elution order for a mixture of n-hexane, cyclohexane, and benzene (Fig. 6). When helium is used as the carrier gas, the compounds are eluted in order of increasing boiling point [n-hexane (69°C),

Figure 6. The change in the retention of C_6 hydrocarbons after the replacement of helium (a) by carbon tetrachloride vapour (b).⁴⁸ Experimental conditions: 1 m $\times$ 3 mm column, adsorbent — Porapak S (80–100 mesh). Sorbates: (1) n-hexane; (2) cyclohexane; (3) benzene.

benzene (80 °C), cyclohexane (81 °C)], while in the case where organic eluents are employed the elution order is determined by the polarisabilities of the chromatographed compounds and the retention time increases in the sequence n-hexane < cyclohexane < benzene.

Kyazimov and Agaeva⁵¹ investigated the retention of compounds of different classes (n-paraffins and aromatic hydrocarbons, n-alcohols, and ketones) on packed Chromaton-filled columns at different temperatures (75–250 °C) in a stream of hexane and ethanol vapours.

Multicomponent vapour-phase eluents are used in gas–solid chromatography and the components of such mixtures may be not only organic vapours but also permanent gases, steam, ammonia, *etc.* Such an approach makes it possible to regulate the selectivity

Figure 7. Chromatographic spectra indicating the influence of the nature of the mobile phase on the retention of sorbates.⁴⁹ Carrier vapour: (1) benzene; (2) ethanol containing 10% of benzene; (3) and (6) ethanol containing 1% of isooctane; (4) and (7) ethanol; (5) and (8) ethanol containing 1% of methanol; flow rate 200 μ l min⁻¹. Sorbates: A = phenol; B = *o*-cresol; C = *m*-cresol; D = *p*-diisopropylbenzene; E = admixture in component D; G = cumene; F = admixture in component G. Adsorbent: (1) and (2) silica gel K-923, 50 cm $\times$ 3 mm column, temperature 140 °C; (3)–(8) aluminium oxide, 1 m $\times$ 2 mm column, temperature 150 °C.

of the chromatographic system within very wide limits by varying the composition of the eluent and the concentration of the polar component. For example, in the analysis of a mixture of α - and β -naphthols on a silica gel column, the retention time of the naphthols increased by 5–8 min if a mixture of ethanol and water vapours⁴⁹ and not pure ethanol served as the eluent.⁴⁹ Similar effects were observed also when the vapours of mixtures of ethanol with methanol, isooctane, benzene,⁴⁹ and hexanes were employed.

The influence of the nature and composition of the eluent on the retention of the sorbate is illustrated in Fig. 7. Tsuda *et al.*⁴⁹ suggested that, when the carrier gas is adsorbed on the adsorbent surface, a thin layer of a modifying film is probably formed, which weakens the interaction of the analysed components and the adsorbent and hence accelerates their elution from the column. According to their data,⁴⁹ the thickness of the film is 2–10 molecules when ethanol is used as the carrier gas and alumina as the adsorbent at temperatures of 100–150 °C.

Steam as the mobile phase in gas–solid chromatography. Many investigators have paid particular attention to water as the mobile phase in gas–solid chromatography. Steam is capable of modifying the surfaces of solid adsorbents. As the mobile phase in gas–solid chromatography, water has the following advantages over other compounds: (1) it is a polar compound actively interacting (usually with formation of hydrogen bonds) with the polar groups, for example, the silanol groups, on the surfaces of solids; (2) the adsorbed water may interact with the polar components of the mixtures analysed, actively altering their retention; (3) water is a relatively stable compound and it can therefore be used for modification at high temperatures; (4) pure water is a comparatively cheap product; (5) water hardly gives rise to a signal when a flame-ionisation detector is used.

In the first communications concerning the employment of steam as the mobile phase⁶² and also in subsequent studies,^{35, 44, 54, 79} an advantage of the steam eluent, such as the blocking of the active centres on solid carriers and adsorbents promoting the appearance of symmetrical peaks in the separation of polar substances and the acceleration of analysis, was pointed out.

Sultanovich *et al.*⁸⁰ showed that, in the separation of high-boiling and polar compounds on Silochrom 80, the replacement of nitrogen as the carrier gas by steam lowers the retention times of the test components and leads to the formation of symmetrical peaks. The authors explained the influence of steam on chromatographic separation, firstly, by the blocking of individual active centres on the adsorbent surface by water molecules and, secondly, by the fact that the surface of Silochrom is covered by a thin water film, formed as a consequence of the multilayer adsorption of water and playing the role of a quasi-stationary phase. Since the usual vapour pressure of water under the conditions of the chromatographic experiment is many times greater than the partial pressure of water in the mobile phase, the thickness of the water film is extremely small and its properties differ from those of ordinary water at the temperature of the analysis. The nonideality of the gas phase can apparently also exert a small influence on the retention.

Thus steam improves the chromatographic properties of adsorbents (and in particular Silochrom) as well as the special (usually irreversible) methods for the modification of silica gels.

When any phenomenon is investigated, it is important to discover definite functional relations. It has been established⁸¹ that an increase in the steam content in the carrier gas leads to more complete deactivation of the active centres (Fig. 8). The logarithms of the retention factor decrease linearly under these conditions, which is naturally most notable in the separation of polar compounds (for example, acetone and ethyl methyl ketone). This feature is of definite interest for the development of analytical methods and their optimisation.

Figure 8. Dependence of the retention factors of sorbates on the content of water vapour in the carrier gas.⁸¹

Experimental conditions: 2 m × 4 mm column, adsorbent — Spherosil, 150–200 μm, column temperature 115 °C, carrier gas — nitrogen + water vapour, flow rate 50 cm³ min⁻¹. Sorbates: (1) 3-methylpentane; (2) cyclohexane; (3) n-heptane; (4) 1,2-dichloroethane; (5) acetone; (6) ethyl methyl ketone.

Rakhmankulov and Vigdergauz⁴³ investigated the possibility of modifying adsorbents by employing steam as the eluent in the pressure range from 1.6 to 7.2 atm in a chromatographic column filled with alumina (Table 6). In the case of nonpolar sorbates, a sharp decrease in the specific retention volume with increase in pressure was noted (by a factor of several tens for high-boiling paraffins). The authors explain this effect by the formation of an adsorbed water layer on the Al₂O₃ surface, although they do not rule out also the influence of the nonideality of the mobile phase. Unfortunately, no direct experiments permitting the characterisation of the state of water on the alumina surface were performed.

Table 6. The specific retention volumes (V_g^T /ml g⁻¹) of sorbates at different pressures of the eluent (steam).⁴³

Sorbate	Eluent pressure /atm

Ethanol	10.6	6.91	6.3	—
Pyridine	14.26	10.82	10.19	8.00

It is of interest that the retention of polar sorbates soluble in water decreased less than that of nonpolar sorbates with increase in the water vapour pressure. A sharp decrease in the retention of n-alkanes leads to a significant increase in the Kovats indices (with n-alkanes as the standard) for polar compounds. For example, the retention index of pyridine at 7.2 atm is higher by 454 units than at

1.6 atm.⁴³ Such results indicate the possibility, in principle, of the group separation of nonpolar and polar compounds at an elevated vapour pressure.

In the separation of polar amines and organic acids, chromatographers encountered certain difficulties due to the reversible, semireversible, and irreversible adsorption of the compounds on the surface of the solid support (see, for example, Berezkin^{82,83}). Modification of the surface of the solid support by acid compounds (for the elution of acids) or basic compounds (for the elution of amines) usually permits a satisfactory solution of this problem.

We may note a non standard, in our view, solution of certain analytical problems in steam chromatography. Nonaka⁴⁴ suggested that an acid or basic modified surface be created by adding an acid (formic acid) or basic (hydrazine hydrate) reagent to the steam, which makes it possible to separate organic acids (with formic acid as the modifying agent) or amines (with hydrazine hydrate as the modifying agent).

Unusual results have been obtained on KY zeolites using a moist carrier gas.⁴² As noted above, the employment of a moist carrier gas is not recommended in gas chromatography. However, interesting results were obtained when the latter was employed. The water absorbed by the zeolite exerts a significant influence on its chromatographic properties (Fig. 9). At low temperatures, where much water is still adsorbed in the zeolite cavities, the specific retention volumes (V_d^T), for example, of ethane, decrease sharply and almost linearly with increase in the partial pressure of steam in the adsorbent–sorbate system. With increase in temperature against the background of an overall decrease in the retention volumes of the sorbates, a tendency towards a retardation of the decrease in V_d^T is manifested appreciably. At the minimum water vapour pressure (0.35 atm) and $T > 100$ °C, the opposite tendency towards an increase in the retention volumes of the chromatographed compounds is observed. An increase in the partial pressure of steam in the zeolite–sorbate system leads to a mutual approach, in terms of time, of the chromatographic zones of the eluted components owing to the intensifying shielding of the adsorption centres (in the first place cations) by water molecules and the duration of the chromatographic separation is also diminished. It is necessary to note that, when a moistened carrier gas is employed, the effectiveness of the separation of volatile compounds on zeolites increases appreciably. Thus the use of steam as the modifying agent for molecular sieves is, in our view, of interest and this version of chromatography can be easily realised in practice.

Figure 9. Dependence of the specific retention volume of ethane on the partial pressure of water vapour.⁴²
Experimental conditions: 1 m × 3 mm column, adsorbent — KY zeolite. Temperature (°C): (1) 60; (2) 80; (3) 100; (4) 120; (5) 140; (6) 160.

Modification of the adsorbent surfaces by water-soluble hydrophilic inorganic salts constitutes a possible new solution of the problem of creating selective polar sorbents for steam chromatography. Only the steam version gas–liquid chromatography has been realised at the present time.^{84–86} A new class of stationary liquid phases (aqueous salt solutions), which we have proposed, is autostable under the conditions of steam chromatography. On contact with steam over a wide range of temperatures, many salts form aqueous solutions which are characterised by a very high selectivity.^{84–86} This principle can undoubtedly serve as the basis of the modification of the surface of the adsorbent: if a salt is deposited on its surface at very low concentrations ($\sim 0.1\%$ – 0.01%), then aqueous salt phases are formed under the conditions of steam chromatography.

In conclusion, we may note that the use of steam significantly expands the possibilities of the traditional gas chromatography and in many instances permits an appreciable improvement of the separation process. It is noteworthy that the characteristics of steam chromatography (with steam or the vapours of other organic compounds) and liquid chromatography are similar. The introduction to the gas-chromatographic practice of its steam version will undoubtedly make it possible to simplify the solution of many practical problems.

IV. Capillary gas–solid chromatography

Capillary gas chromatography is nowadays most actively employed. Thus, according to Berezkin's data,^{87,88} more than 83% of the publications devoted to chromatographic problems relate to capillary gas chromatography; according to McNair's data,⁸⁹ 80% of the gas-chromatographic columns sold are capillary columns. A new type of capillary column — open (tubular) capillary gas–solid columns — has been successfully introduced into analytical practice. The characteristics influencing the changes in the retention of chromatographed compounds, for example characteristics such as the nature and pressure of the carrier gas, assume a particular importance in capillary chromatography. (The influence of these characteristics on the resolution had been established earlier for packed columns.)

A series of publications have been devoted to the theoretical and experimental study of the role of the carrier gas in capillary gas–liquid chromatography.^{90–94} The influence of the average column pressure of the carrier gas in the column on the retention volumes and indices at an inlet pressure > 5 atm at the inlet to the capillary column has been demonstrated experimentally.^{90–92} This is significantly greater than the pressure of the carrier gas in the traditional analytical experiment. The importance and value of the results obtained for the usual routine chromatographic analysis therefore remained obscure.

Berezkin and Korolev^{93,94} were the first to show that the relative retention data (retention factor, relative retention, and retention index) in capillary gas–liquid chromatography depend on the nature of the carrier gas and its average column pressure under the conditions of the traditional analytical experiment, *i.e.* at inlet pressures less than 3–5 atm.

Bearing in mind the common nature of the processes in gas–liquid and gas–solid chromatography, one may expect a dependence of the retention on the pressure and nature of the carrier gas for both types of chromatography.

Berezkin and Volkov²⁰ confirmed a previously established feature of chromatography in a gas–solid system, namely the relation between the retention and the nature of the carrier gas. It was shown that transition from light carrier gases to heavy ones leads to a dynamic modification of the adsorbent surface by the carrier gas molecules and hence to a decrease in the partition coefficients of the chromatographed compounds in the solid adsorbent–carrier gas system and therefore to a decrease in the retention time. The experimental data obtained on a Chrompack capillary gas–solid column (50 m $\times$ 0.32 mm) with alumina at 100 °C may serve as an example illustrating the dependence of the

retention factors of hydrocarbon gases on the nature of the carrier gas:²⁰ the retention for C₃–C₄ hydrocarbon gases are virtually the same when helium and nitrogen are used as carrier gases but decrease significantly when they are replaced by carbon dioxide. For example, the retention factors diminished by $\sim 30\%$ following the replacement of nitrogen by carbon dioxide.¹⁷ Thus, by selecting the carrier gas, it is possible to reduce significantly the duration of the chromatographic experiment.

Two studies by Berezkin and coworkers^{95,96} were devoted to the systematic investigation of the influence of the average column pressure of the carrier gas in the column on the relative retention of the chromatographed compounds in high-performance capillary chromatography in a gas–solid system. Different carrier gases and pressure ranges traditionally employed in analytical capillary gas chromatography (1–5 atm at the inlet to the capillary column) were used. The results of the study of the dependence of the retention factors of hydrocarbon gases on a capillary column with alumina modified by potassium chloride on the average column carrier gas pressure in the column are presented in Table 7.⁹⁶ It is seen that the retention depends both on the nature of the carrier gas and on its column pressure.

Table 7. The retention factors of hydrocarbon gases at different carrier gas pressures in a capillary column with Al₂O₃/KCl (temperature 90 °C).⁹⁶

<i>P</i> /atm	Propene	Butane	But-1-ene
Carrier gas — helium

Carrier gas — carbon dioxide			
1.0	0.64	1.17	2.46
4.1	0.44	0.80	1.58

The influence of steam as the modifier of the Al₂O₃ adsorbent surface on the change in retention in capillary gas–solid chromatography has been noted by de Nijs.⁹⁷ Water is strongly adsorbed on the hydrophilic surface of the polar alumina, which lowers its sorption activity. With increase in the concentration of water in the carrier gas (and hence on the adsorbent surface), the retention factors of the sorbates are therefore reduced.

Not only the nature of the carrier gas but also the characteristics of the chromatographic system as a whole exert a significant influence on the retention of the sorbate. In this connection, one should note the study of Armstrong *et al.*,⁹⁸ who investigated the influence of steam and carbon dioxide on the characteristics of two capillary adsorption columns, in one of which alumina and in the other GasProTM were employed as the adsorbents. Water and carbon dioxide are known to influence strongly the retention and selectivity in the separation of sorbates and also the effectiveness of the operation of the chromatographic column, for example, an alumina column.^{30,99–101} In contrast to columns based on alumina, neither water, nor carbon dioxide nor sulfur-containing gases are adsorbed appreciably on the surface of capillary columns with GasProTM and they do not therefore influence the separation of the analytes and the column characteristics.⁹⁸ Figure 10 presents the results of the study of the influence of the repeated introduction of water samples and aqueous acetone samples on the retention of the analytes. Evidently even repeated introduction of water samples does not affect the column characteristics, the retention, and the separation of the analytes. The retention of the chromatographed compounds hardly depends on the water vapour pressure on the nonpolar adsorbent GasProTM and this

Figure 10. The influence of repeated introduction of samples of water (a) and an aqueous sample of acetone (b) on the retention times of the compounds analysed on a GasPro™ capillary column.⁹⁸ Experimental conditions: (a) 30 m × 0.32 mm column, carrier gas — nitrogen (40 cm s⁻¹), temperature 85 °C; (b) 5 m × 0.32 mm column, carrier gas — helium. Sorbates: (1) methane; (2) ethane; (3) ethene; (4) ethyne.

enabled the authors of the present review to express the view that the principal processes in the carrier gas–chromatographed compound interaction occur on the surface of the solid adsorbent and that the influence of these interactions in the gas phase is slight for the systems investigated.

Many gases and volatile compounds are retained fairly strongly on GasPro™ columns, but in relation to organic compounds of various classes these columns are more inert than those with alumina. Consequently, the compounds analysed, which undergo catalytic degradation on Al₂O₃ at elevated temperatures, may be readily separated and determined quantitatively on GasPro™ columns.

Thus the nature of the carrier gas and its pressure are important characteristics of the chromatographic experiment. The study of the characteristic features of the variation of the retention factors (capacity factors) of the chromatographed compounds on passing from one carrier gas (G₁) to another (G₂) on the same chromatographic column is of practical interest in this connection. The following correlation has been established recently (Fig. 11):¹⁰¹

Figure 11. Correlation between the retention factors using the carrier gases G₁ = H₂, G₂ = N₂ (I) or CO₂ (II).¹⁰¹ Experimental conditions: 50 m × 0.32 mm column, adsorbent — Al₂O₃/KCl, T = 90 °C. Chromatographed compounds: (1) ethane; (2) ethene; (3) propane; (4) propene; (5) isobutane; (6) n-butane; (7) *trans*-but-2-ene; (8) isobutene; (9) *cis*-but-2-ene.

$$k(G_2) = Ak(G_1) + B, \quad (6)$$

where $k(G_1)$ and $k(G_2)$ are the retention factors (capacity coefficients) of the compound when the carrier gases G₁ and G₂ respectively are employed and A and B are constants.

Experimental studies performed using various chromatographic systems revealed the following features of the influence of different carrier gases on the retention.

1. Permanent carrier gases (helium, hydrogen, argon, nitrogen, *etc.*), as well as carbon dioxide exert an appreciable influence on the retention of the chromatographed compounds. The influence of such carrier gases on the retention usually increases in the sequence helium < hydrogen < nitrogen < carbon dioxide. The relations established may be used to reduce (by 20%–30%) the retention, *i.e.* to reduce the duration of the chromatographic process, and for the deliberate alteration of the selectivity of the separation.

2. Steam as well as the vapours of organic compounds (carbon tetrachloride, ethanol, *etc.*) influence to a greater extent the retention process than gaseous eluents. The change in retention is especially significant when 'strong' adsorbents are employed (for example, adsorbents of the type of molecular sieves, organic polymeric adsorbents, *etc.*). A change in the elution sequence of the analytes after the replacement of the mobile phase has been noted for a series of chromatographic systems investigated.

3. On passing from one carrier gas to another, it is possible to determine the retention of the chromatographed compounds for 'another' carrier gas using the linear correlation equation.

The studies of the influence of the carrier gas on retention cannot be regarded as complete. By no means all the new analytical possibilities of gas–solid chromatography, determined by the rational selection of the active mobile phase, have been discussed and examined in the literature. Thus the influence of superheavy carrier gases (for example, SF₆) using specific adsorbents such as molecular sieves, *etc.* has not been investigated systematically.

The expansion of steam chromatography is held back, in our view, by the lack of simple and effective apparatus permitting the performance of the steam chromatographic process on any gas chromatograph.

V. Theoretical aspects of the influence of the nature of the carrier gas and of its pressure on the retention in gas–solid chromatography

1. The retention of a strongly adsorbed sorbate in a poorly adsorbed carrier gas

The mechanism of retention has been discussed in detail in monographs.^{1, 2, 6, 71, 102, 103} Kiselev *et al.*^{6, 103} proposed the concept of the net retention volume for gas–solid chromatography and showed that the net retention volume V_N is directly proportional, firstly, to the surface area of the adsorbent (S) in the column (it is postulated that the accessibility of the adsorbent surface does not change for low degrees of coverage of the latter) and, secondly, to the partition coefficient [see Eqn (3)].

The net retention volume can be determined from the equation

$$V_{Ni} = V_{Ri} - V_M, \quad (7)$$

where

$$V_{Ri} = t_R F j,$$

$$V_M = t_M F j, \quad (8)$$

t_R is the retention time of the sorbate, F the flow rate of the carrier gas at the column outlet, j the James–Martin correction taking into account the pressure drop along the column, V_M is the dead retention volume, and t_M is the dead time.

Naturally Eqn (7) should be modified in relation to specific cases (for example, when it is necessary to take into account the

nonideality of the carrier gas, the nonlinearity of the adsorption isotherm for the chromatographed compound, *etc.*).

In the monograph by Zhukhovitskii and Turkel'taub,⁴ attention is drawn to the fact that in gas–solid chromatography account should be taken primarily of the influence of the carrier gas on the sorbability of the components of the mixture being separated (Table 8). In discussing the results of a study of the retention of the components of four mixtures (propane–butane, helium–methane, carbon monoxide–methane, helium–carbon monoxide) on the AG-2 charcoal using three carrier gases (hydrogen, air, and carbon dioxide) at 25 °C, the authors note that the retention volume of a poorly sorbable substance diminishes sharply when hydrogen is replaced by carbon dioxide.

Table 8. The influence of the nature of the carrier gas on the separation of mixtures using the AG-2 charcoal as the adsorbent (temperature 25 °C).⁴

Carrier gas	Mixture	V_N /ml
Carbon dioxide	propane + butane	25 + 247
Air	ditto	99 + 305
Hydrogen	"	255 + 630
Carbon dioxide	helium + methane	10 + 1739
Air	ditto	151 + 3744
Hydrogen	"	237 + 464
Carbon dioxide	helium + carbon monoxide	10 + 682
Air	ditto	151 + 1235
Hydrogen	"	237 + 1540

At the time of the publication by the monograph of Zhukhovitskii and Turkel'taub,⁴ there was no unambiguous answer in the literature to the question of the dependence of the retention volume on the carrier gas pressure. This is associated, in particular, with the low accuracy of the chromatographic measurements in the initial period of the development of gas–solid chromatography and the limited choice of carrier gases. The introduction into chromatographic practice of capillary columns, characterised by an increased resolution compared with packed columns, made it possible to establish a clear dependence of the relative retention on the carrier gas pressure even in the region of low pressures.

In conclusion, we may note that the development of the theory of retention in gas–liquid chromatography has had a positive influence on the development of gas–solid chromatography. The influence of the interaction of the sorbate with the carrier gas in the gas phase on the retention was demonstrated within the framework of this theory (see the relevant monographs^{77, 104, 105}). The study of the interactions of the chromatographed compound in both gas and stationary (adsorbent) phases became a logical extension of the development of the theory of retention in gas chromatography.

2. The retention of the sorbate taking into account the interactions in the gas and solid phases

The theoretical aspects of the influence of the nature and pressure of the carrier gas on the net retention volume or the partition coefficient in gas–liquid chromatography have been examined in a series of investigations (see, for example, Refs 106–112). It has been shown that the influence of the carrier gas on the retention is determined by the interaction of the molecules of both the sorbate and the carrier gas in the gas phase, on the one hand, and of the carrier gas and sorbate dissolved in the stationary phase, on the other, as well as the change in the properties of the stationary liquid phase when the carrier gas is dissolved in it.

The effects of the carrier gas on the adsorption of the chromatographed compound, and not its interactions with the sorbate in the gas phase, apparently exert the greatest influence on the separation process in gas–solid chromatography. In this

connection, one should note the study by Sato *et al.*,¹⁷ in which the influence of the carrier gas on the absolute retention is considered (within the framework of the Langmuir adsorption theory) as a result of its adsorption. Despite the fact that the results of this approach make it possible to establish the causes of the experimentally observed decrease in the retention volume as a function of the carrier gas, a fully adequate explanation of all the principal features has not been given.

This problem was examined in adequate detail in relation to gas adsorption chromatography for the first time by Locke.¹¹³ For certain chromatographic systems, differing in the type of adsorption isotherm and in the nature of the carrier gas, he proposed a series of equations relating the partition coefficient to pressure and taking into account the nonideality of the carrier gas. As in gas–liquid chromatography (see, for example, Desty *et al.*¹⁰⁷), the partition coefficient in these equations depends on the average column pressure and diminishes with increase in the pressure of the nonideal carrier gas.

Despite the correct and prior formulation of this important problem, the expressions obtained by Locke contained a series of inaccuracies. One of them was noted by Young,¹¹⁴ whilst the remaining ones were discussed by Gzubrut *et al.*¹³

The interphase partition coefficient is defined by the following expression according to Locke¹¹³

$$K = \frac{N_a V_m}{N_m S}, \quad (9)$$

where N_a and N_m are the numbers of moles of the sorbate adsorbed on the adsorbent surface and in the gas (mobile) phase respectively, V_m is the volume of the mobile phase in the column, and S is the surface area of the adsorbent.

According to Locke,¹¹³ the following expression can be written for N_a :

$$N_a = k S f, \quad (10)$$

where k is the adsorption constant and f the fugacity of the sorbate.

The following relation holds for the fugacity:

$$\ln f = \ln P_s + \frac{P_m}{RT} [B_{22} - (1 - y)^2 (B_{11} - 2B_{12} + B_{22})], \quad (11)$$

where P_s is the partial pressure of the sorbate, P_m is the average pressure of the carrier gas, y is the mole fraction of the sorbate in the carrier gas, B_{11} and B_{22} are the second virial coefficients of the pure sorbate and the carrier gas respectively, and B_{12} is the second virial coefficient reflecting the interaction between the molecules of the sorbate and the carrier gas.

Using the same approach and the same assumptions as Locke¹¹³ (namely that the sample size is small and that the adsorption isotherms of the sorbates are therefore linear), Gzubrut *et al.*¹³ established the following expression for the partition coefficient taking into account both the influence of the nonideality of the carrier gas in the gas phase and its adsorption on the adsorbent surface:

$$\ln K = \ln K_0 + \frac{(2B_{12} - V_0)}{RT} P_m, \quad (12)$$

where

$$K_0 = K(P \rightarrow 0), \quad (13)$$

V_0 is the molar volume of the pure sorbate,

$$P_m = P_0 J_3^4, \quad (14)$$

$$J_3^4 = \frac{3}{4} \frac{(P_i/P_0)^4 - 1}{(P_i/P_0)^3 - 1}, \quad (15)$$

and P_i and P_0 are the inlet and outlet pressures of the carrier gas, respectively.

Using the equations presented above, Gzbrut *et al.*¹³ explained the experimental data on the retention of methane obtained on a packed column with Porapak S at 0 °C, using He, Ar, and CO₂ as the carrier gases. It was found that in all cases the influence of the nonideality of the carrier gas on the net retention volume is very much smaller than the influence of the adsorption of the carrier gas. The relative degree of adsorption of the carrier gas increases in the sequence He < Ar < CO₂.

The equations for the retention volume or the retention time taking into account the nonlinearity of the adsorption isotherm have been obtained by numerous investigators. The most general equations, taking into account the deviation of the adsorption isotherm of the sorbate from linearity owing to the intermolecular sorbate–sorbate and sorbate–carrier gas interactions in the gas phase, have been proposed by Valentin and Guiochon:¹¹⁵

$$n_1^g = f \frac{yV_m}{RT}, \quad (16)$$

$$f = P \left(1 - \frac{BP_s}{RT} \right), \quad (17)$$

$$B = B_{11}y^2 + 2B_{12}y(1-y) + B_{22}(1-y)^2, \quad (18)$$

where n_1^g is the number of moles of the adsorbate in the gas phase, y is the mole fraction of the sorbate in the gas phase, V_m is the volume of the gas phase in the column, B is the second virial coefficient of the gas mixture (the carrier gas sorbate), B_{11} and B_{12} are the second virial coefficients of the pure sorbate (1) and the carrier gas (2) respectively, B_{12} is the second virial coefficient characterising the interactions of the sorbate and the carrier gas.

The influence of the nonideality of the mobile phase and of its adsorption on the adsorbent in gas–solid chromatography was taken into account by Martire¹¹⁶ in the equation relating the true specific retention volume $V_{g,0}^T$, which would be observed for an ideal unretained gas or for the ‘zero’ gas pressure, to the measured specific retention volume:

$$\log V_{g,0}^T = \log V_{g,0}^T + \frac{2B_{12}P_m}{RT} \left(1 - \frac{\phi}{y} \right), \quad (19)$$

where B_{12} is the second mixed virial coefficient of the sorbate and the carrier gas, while ϕ and y are the fractions of the sorbate in the adsorbed monolayer and in the gas phase respectively at equilibrium; the equation was obtained on the assumption that a uniform adsorbent is employed.

The ratio ϕ/y is called the retention factor for the given carrier gas. In the derivation of Eqn (19), it was assumed that this coefficient is small and Henry’s law therefore still holds for the carrier gas in the range of pressures employed and that P_m is relatively small, the degree of adsorption of the carrier gas therefore remaining negligible.

Poshkus¹¹ obtained the virial equation for the retention volume taking into account the influence of the pair interactions of the sorbate and carrier gas molecules both in the gas phase ($A_g \dots B_g$) and in the adsorbed state ($A_{ads} \dots B_{ads}$) and also the sorbate–sorbate interactions ($A_{ads} \dots A_{ads}$):

$$V_N(\hat{a}_1) = K_{1,1} + 2(K_{2,11} + 2K_{1,1}B_{11})\hat{a}_1 + K_{2,12} + 2K_{1,1}B_{12}[(\hat{a}_2 - \hat{a}_1) - 2(B_{12} - B_{22})\hat{a}_1\hat{a}_2], \quad (20)$$

where $K_{1,1}$ is Henry’s constant for the sorbate, $K_{2,11}$ and $K_{2,12}$ are the second virial adsorption coefficients taking into account the pair interactions between the adsorbed adsorbate molecules ($A_{ads} \dots A_{ads}$) and between the adsorbed sorbate and carrier gas molecules ($A_{ads} \dots B_{ads}$) respectively B_{11} and B_{22} are the second virial coefficients for the pure sorbate and the pure carrier gas respectively, c_1 and c_2 are the concentrations of the sorbate (1) and the carrier gas (2) respectively, and B_{12} is the second virial coefficient characterising the intermolecular sorbate–carrier gas interactions.

According to Poshkus’s data,¹¹ the relative difference between the quantities V_N and $K_{1,1}$, caused by the influence on V_N by the interactions of the adsorbate and carrier gas molecules, is expressed by the equation

$$\frac{V_N - K_{1,1}}{K_{1,1}} = \left(\frac{K_{2,12}}{K_{1,1}} + 2B_{12} \right) \frac{P_m}{RT}. \quad (21)$$

For a series of sorbate (argon, benzene, cyclohexane)–carrier gas (He, H₂, N₂, Ar)–adsorbent (graphitised thermal black) systems, the contributions of the pair interactions to the retention volume of the sorbate have been estimated theoretically. In the range of temperatures at which the $K_{1,1}$ were determined using He as the carrier gas, the sorbate–carrier gas interactions increase V_N by tenths per cent mainly due to the intermolecular interactions in the gas phase. When other carrier gases are employed (H₂, N₂, Ar), the $A_g \dots B_g$ as well as the $A_{ads} \dots B_{ads}$ intermolecular interactions diminish the true retention volume, the contributions of both interactions being close as regards order of magnitude. At $P = 101$ kPa, the overall influence of the above interactions on V_N may reach several per cent.

Rudzinski¹¹⁷ described in detail and rigorously the dependence of the retention volume on the nonideal interactions of the sorbate in the gas and solid phases.

In all the studies examined above, the specific retention volume was used as the retention parameter. However, for the calculation of this quantity, it is essential to know the amount of the adsorbent in the column, the exact determination of which involves certain difficulties, especially in capillary columns. Furthermore, the specific retention volume is an absolute quantity and in gas chromatography the determination of absolute quantities involves significantly greater errors than the determination of relative retention data. It therefore appeared useful to obtain the corresponding equations for the relative retention data (the retention factor, the relative retention time, the retention index), reflecting their dependence on the pressure (and nature) of the carrier gas.

We employed a new version of the Langmuir equation⁹⁵ based on the allowance for the substitution of the adsorbed carrier gas molecules by sorbate molecules:

$$a_i = \frac{l_i a_{mi} K_i P_i}{1 + K_i l_i P_i + K_{imi} l_m P_m}, \quad (22a)$$

$$a_i = \frac{a_{mi} K_i c_i}{1 + K_i c_i + K_{imi} l_m P_m}, \quad (22b)$$

$$a_i = \frac{a_{mi} b_i P_i}{1 + b_i P_i + b_{mi} P_m}, \quad (22c)$$

where a_i is the surface concentration of the adsorbed compound i , l_i and l_m are constant conversion coefficients for compounds i and m respectively, P_i and c_i are respectively the partial pressure and the concentration of compound i in the mixture with the carrier gas, $K_{imi} = K_i/K_{im}$, K_{im} is the equilibrium constant of the reversible process involving the substitution of the adsorbed compound m by compound i , P_m is the average column pressure of the carrier gas, $c_i = l_i P_i$, $c_m = l_m P_m$, a_{ami} is the capacity of the monolayer for compound i , K_i is the equilibrium constant of the reversible adsorption process involving compound i in the gas–adsorbent system, $b_i = l_i K_i$, and $b_{mi} = l_m K_{imi}$.

The main difference in the treatment of the above equations and the classical equation of the Langmuir adsorption isotherm for a mixture of substances¹¹⁸ consists in the fact that the adsorption coefficient at P_m is determined by the properties of both the carrier gas and the chromatographed compound, which is a consequence of the allowance for the substitution reaction.

The rate of migration of the chromatographic zone w_i for compound i in a chromatographic column filled with the adsorbent may be described by the equation^{119–121}

$$w_i = u \left[1 + \frac{V_s}{V_m} \left(\frac{\partial a_i}{\partial c_i} \right)_{P_m} \right]^{-1}, \quad (23)$$

where u is the linear velocity of the carrier gas in the column, V_s and V_m are the volumes of the solid (adsorbent) and gas phases in the column respectively, a_i is the concentration of the volatile chromatographed compound i in the adsorbent, and c_i is the concentration of the sorbate i in the gas phase.

The equation for the retention time t_i of the chromatographed compound follows from Eqn (23):

$$t_i = \frac{L}{w_i} = \frac{L}{u} \left[1 + \frac{V_s}{V_m} \left(\frac{\partial a_i}{\partial c_i} \right)_{P_m} \right] = t_M \left[1 + \frac{V_s}{V_m} \left(\frac{\partial a_i}{\partial c_i} \right)_{P_m} \right], \quad (24)$$

where L is the column length (the carrier gas pressure drop along the column is not taken into account) and $t_M = L/u$ is the dead time of the column (the retention time of the unretained component).

Having transformed Eqn (24), it is possible to obtain the following simple expression for the retention factor k_i for compound i :

$$k_i(C_i, P_m) = \frac{t_i - t_M}{t_M} = \frac{V_s}{V_m} \left(\frac{\partial a_i}{\partial c_i} \right)_{P_m}. \quad (25)$$

For the special case where the adsorption isotherm is linear ($a_i = K_i c_i$), the following familiar expression for the retention factor is obtained from Eqn (25):⁶⁵

$$k_i = K_i \left(\frac{1}{\beta} \right), \quad (26)$$

where K_i is the distribution constant of the chromatographed compound i between the stationary and mobile phases and $\beta = V_m/V_s$ is the phase ratio in the column.

In the general case, the retention factor can also be represented by the equation⁶⁵

$$k_i = \frac{V_{Ri}(c_i, P_m) - V_M}{V_M}, \quad (27)$$

where V_{Ri} is the retention volume of compound i .

On combining Eqns (25) and (27), we obtain

$$\left(\frac{\partial a_i}{\partial c_i} \right)_{P_m} = \frac{V_{Ri}(c_i, P_m) - V_M}{V_s} = V_V(c_i, P_m), \quad (28a)$$

where V_V is the volume of the sorbent.

If a_i is expressed in units of the surface concentration, then

$$\left(\frac{\partial a_i}{\partial c_i} \right)_{P_m} = \frac{V_{Ri}(c_i, P_m) - V_M}{S} = V_s(c_i, P_m). \quad (28b)$$

Thus the derivative of the adsorption isotherm represents the specific retention volume calculated per unit volume of the sorbent V_V or per unit surface of the adsorbent V_s . We may note that previously (see, for example, Ref. 83), the quantity $\partial a_i / \partial c_i$ was designated in our communications as the effective distribution constant, because $\partial a_i / \partial c_i = K_{i, \text{eff}}$ for a linear isotherm.

In order to obtain the analytical dependence of the retention factor on the carrier gas pressure P_m , we make use of Eqn (25), whilst Eqns (22b) and (22c) are adopted as the expressions for the adsorption isotherm. After simple transformations, we obtain

$$k_i = g_i \frac{(1 + b_{mi} P_m)}{(1 + b_i P_i + b_{mi} P_m)^2}, \quad (29)$$

where $g_i = a_{mi} b_i / \beta l_i$.

Since the adsorption of the traditionally employed carrier gases on the adsorbent is usually extremely slight (*i.e.* $b_{mi} P_m \ll 1$), Eqn (29) can be usefully expanded in Maclaurin's series in $b_{mi} P_m$. We restrict the expansion to the first two terms of this series:

$$k_i \approx k_{i0} - k_{i0} \frac{b_{mi}(1 - b_i P_i)}{(1 + b_i P_i)} P_m = k_{i0} \left[1 - \frac{b_{mi}(1 - b_i P_i)}{1 + b_i P_i} P_m \right], \quad (30)$$

$$k_{i0} = k_i(\text{at } P_m = 0) = \frac{g_i}{(1 + b_i P_i)^2}. \quad (31)$$

We may note that, according to d'Alembert's criterion,¹²² the above Maclaurin's series is convergent if $b_i P_i < 1$. According to our estimate, this condition holds for the sorption of hydrocarbon gases on Al_2O_3 in the range of carrier gas pressures up to 10 atm (*i.e.* in the range of pressures traditionally employed in gas chromatography).

As a result of the expansion in Maclaurin's series, the fraction $(1 - b_i P_i)/(1 + b_i P_i)$ can be expressed approximately as follows:

$$\frac{1 - b_i P_i}{1 + b_i P_i} \approx 1 - 2b_i P_i, \quad (32)$$

so that

$$k_i \approx k_{i0} - k_{i0} b_{mi} (1 - 2b_i P_i) P_m. \quad (33)$$

If $b_i P_i \ll 1$, then Eqn (33) can be represented also in a simpler form:

$$k_i \approx k_{i0} - k_{i0} b_{mi} P_m. \quad (34)$$

Thus the retention factor in gas–solid chromatography is a linear function of the average carrier gas pressure P_m . We may also note that, with increase in carrier gas pressure, we have, firstly, a decrease in the retention factor k_i and, secondly, the first term of Eqn (34) then represents the retention factor of the chromatographed compound at the 'zero' pressure of the carrier gas, *i.e.* precisely the quantity which could be considered as the chromatographic constant of the sorbate.

Table 9. Parameters of Eqn (34) for the following experimental conditions: 50 m $\times$ 0.32 mm quartz capillary column, $\text{Al}_2\text{O}_3/\text{KCl}$ adsorbent, temperature 90 °C, carrier gases — N_2 and CO_2 , inlet pressure at the inlet to the capillary column 1–5 atm.⁹⁵

Sorbate	k_{i0}		$k_{i0} b_{mi}$		Correlation coefficient		Standard deviation	
	N_2	CO_2	N_2	CO_2	N_2	CO_2	N_2	CO_2
Propane	0.887	0.699	0.008	0.062	0.937	0.993	0.005	0.011
Butane	1.703	1.278	0.025	0.117	0.937	0.998	0.014	0.008
But-1-ene	3.708	2.719	0.057	0.286	0.961	0.996	0.024	0.035

In order to check the equation obtained, we used the experimental data for the dependence of the retention factors of hydrocarbon gases on the average pressures of various carrier gases in capillary columns with alumina (Table 9). It follows from the data presented in the table that the $k_i = f_i(P_m)$ relations are linear and are characterised by a negative slope, *i.e.* the linear equation (34) agrees well with the experimental data (the correlation coefficient is > 0.9 in all the cases considered).

A similar approach has been used to obtain the dependence of the relative retention time and the retention index on the carrier gas pressure.

We shall examine the dependence of the relative retention times for two carrier compounds i and j on the average carrier gas pressure P_m :

$$a_{ij} = \frac{k_i}{k_j} = \frac{k_{i0}}{k_{j0}} \left(1 - \frac{b_{mi}(1 - b_i P_i)}{1 + b_i P_i} P_m \right) / \left(1 - \frac{b_{mj}(1 - b_j P_j)}{1 + b_j P_j} P_m \right). \quad (35)$$

Having expanded Eqn (35) in Maclaurin's series in P_m and having restricted the expansion to the first two members of the series, we obtain

$$\alpha_{ij} \approx \alpha_{ij0} + \alpha_{ij0}(b_{mj}\lambda_j - b_{mi}\lambda_i)P_m, \quad (36)$$

where $\alpha_{ij0} = k_{i0}k_{j0}$ is the limiting relative retention at $P_m \rightarrow 0$, $\lambda_i = (1 - b_iP_i)/(1 + b_iP_i)$, and $\lambda_j = (1 - b_jP_j)/(1 + b_jP_j)$.

Since usually $b_iP_i \ll 1$ and $b_jP_j \ll 1$, it follows that λ_i and λ_j are close to unity, so that

$$\alpha_{ij} \approx \alpha_{ij0} + \alpha_{ij0}(b_{mj} - b_{mi})P_m. \quad (37)$$

Thus the relative retention in the region of low carrier gas pressures also depends linearly on the carrier gas pressure. For example, for open capillary columns with the Al_2O_3 as an adsorbent (with KCl as the modifying agent), the experimental dependence of the relative retention for but-1-ene (with propene as the standard) on the average carrier gas pressure P_m is described by a linear equation of type (37). The correlation coefficient in the description of experimental data by Eqn (37) is 0.93 and the standard deviation is 0.092.

Since the retention index is also used in gas-solid chromatography,² we present an expression for the linear dependence of this quantity on the average column gas pressure of the carrier gas in the chromatographic column:

$$I_i = I_{0i} + b_{li}P_m, \quad (38)$$

where I_{0i} is the limiting value of the retention index i as P_m approaches to zero,

$$I_{0i} = 100n + 100 \frac{\log \alpha_{in0}}{\log \alpha_{(n+1)n0}}, \quad (39)$$

where b_{li} is a coefficient:

$$b_{li} = \frac{43.43}{[\log \alpha_{(n+1)n0}]^2} [(b_{mn} - b_{mi}) \log \alpha_{(n+1)n0} - (b_{mn} - b_{m(n+1)}) \log \alpha_{in0}], \quad (40)$$

Here α_{in0} is the limiting retention of compound i relative to the standard, the molecule of which contains n carbon atoms and $\alpha_{(n+1)n0}$ are the limiting retentions of standards (for example, n -alkanes the molecules of which contain $n+1$ and n carbon atoms).

The approach developed by Berezkin and Malyukova⁹⁵ made it possible to develop new ideas concerning the influence of the carrier gas on the relative retentions in gas-solid chromatography. The linear dependences of the relative retention on the average column pressure of the carrier gas agree satisfactorily with experimental data. The general relations established in the above study⁹⁵ can be usefully taken into account in precise analytical and physicochemical studies.

VI. The influence of the carrier gas on band broadening in gas-solid chromatography

The broadening of chromatographic bands during their migration along the column is influenced by the nature of the movement of the carrier gas in the column, the diffusion of the compounds being separated in the mobile and stationary phases, the rate of interphase mass transfer, and the characteristics of the adsorption layer employed.^{6, 71, 107, 123–150} The theory of the broadening of chromatographic bands has been examined in detail in monographs^{2, 65, 71} and other communications.^{20, 125–127, 131–134} For this reason, the authors of this review have written this section in a compact form.

The main contribution to the development of the theory of band broadening in chromatographic columns has been made by Van Deemter,¹³⁵ Golay,^{125–127, 132} and Giddings,^{133, 134} the

results of the theoretical researches of which have been applied successfully in chromatography.

1. Packed columns

Van Deemter's equation is most widely used in chromatography on packed columns.¹³⁵ For gas-solid chromatography, it can be represented in the form of the dependence of the height equivalent to the theoretical plate (H) on the carrier gas flow rate (u):

$$H = A + \frac{B}{u} + C_s u, \quad (41)$$

$$A = 2\lambda d_p, \quad (42)$$

$$B = 2\gamma D_g, \quad (43)$$

$$C_s = C \frac{k}{(1+k)^2} \frac{d_p}{D_s}, \quad (44)$$

where λ is a dimensionless coefficient characterising the nonuniformity of the column packing, d_p the diameter of the particles of the packing, γ is the tortuosity coefficient, D_g is the diffusion coefficient of the sorbate in the gas phase, k is the retention factor, D_s is the diffusion coefficient of the sorbate in the stationary phase, and C is a constant coefficient.

We shall examine the physical meaning of the individual terms of Van Deemter's equation.

The term A takes into account eddy diffusion. Eddy diffusion as a spreading factor in packed columns is due to the multiplicity of the paths followed by the carrier gas in the packing and their nonidentity (for this reason the times of the transfer of individual molecules of the compound by the flow of carrier along the column are different). As a result of the processes indicated above, the chromatographic zones do in fact undergo broadening associated with eddy diffusion.

The term B/u takes into account the longitudinal molecular diffusion. The longitudinal diffusion is determined by the familiar Fick's laws of diffusion, which operate not only in the stationary gas phase but also in the moving flow. The diffusion of the sorbate in the direction of lower concentrations leads to the symmetrical broadening of the band.

The term $C_s u$ takes into account the resistance to mass transfer in the gas-adsorbent system. The quantity C_s is determined by the slowness of the mass transfer between the gas phase and the adsorbent.

The band broadening process is a fairly complex physical phenomenon. For this reason, Van Deemter's equation (like, incidentally, other equations) only approximately describes the principal physical spreading processes in our view. This standpoint is supported also by the fact that a whole series of equations have been proposed for the description of band broadening processes.⁷¹

The most general expression taking into account the principal factors influencing the band broadening in a packed column over a wide range of carrier gas flow rates is the Giddings equation:¹²⁴

$$H = \left[\frac{1}{A} + \frac{1}{C_m u} \right]^{-1} + \frac{B}{u} + C_u. \quad (45)$$

The physical meaning of the quantities A and B/u was elucidated above. Here $B = 2D_g$ (D_g is the diffusion coefficient of the chromatographed compound in the gas phase), $C_m = \beta^2 d_p^2 / 2D_g$ is the coefficient of the resistance to mass transfer in the gas phase associated with the coupled eddy diffusion coefficient, β is a coefficient characterising the multichannel nature of the packing and the diffusion into gas cavities, and the quantity C_u is determined by internal and external diffusion mass transfer.

All the terms of this equation (with the exception of $C_m u$) have been used in the classical Van Deemter's equation¹³⁵ for the description of the broadening of the bands of the chromatographed compounds. The coupled theory of eddy diffusion, developed by Giddings, made it possible to eliminate a series of

contradictions observed in the interpretation of experimental data using Van Deemter's equation (for example, the dependence of the term A on the carrier gas flow rate, the negative values of A , etc.). However, it is fairly difficult to determine the coefficients of the Giddings equation. In certain cases, the use of graphical methods yields satisfactory results.¹³⁶

Keller and Giddings¹³⁷ proposed a version of this equation in the following form:

$$H = \left[\frac{1}{2\lambda d_p} + \frac{1}{\omega(d_p^2/D_g)u} \right]^{-1} + \frac{2\gamma D_g}{u} + \mu \frac{d_p^2}{D_g} u + \nu \frac{d_p^2}{D_g} u^2, \quad (46)$$

where ω , μ , and ν are constants depending on the capacity retention factor of the chromatographed compound. The penultimate term of the equation is determined by the external diffusion mass transfer, whilst the last term is determined by the internal diffusion mass transfer.

When account is taken of the pressure gradient (see, for example, the monograph by Guiochon and Guilleman⁷¹), the component influenced by the properties of the carrier gas (the diffusion coefficient in the gas phase, as well as the pressure drop and the carrier gas flow rate at the column outlet, which also depend on viscosity of the carrier gas) may be isolated from the preceding equation.

$$H_g = \left\{ \frac{2\gamma D_g}{u_0} + \left[\frac{1}{2\lambda d_p} + \frac{1}{\omega(d_p^2/D_g)u} \right]^{-1} + \mu \frac{d_p^2}{D_g} u \right\} f, \quad (47)$$

$$f = \frac{9}{8} \frac{[(P_i/P_0)^4 - 1][(P_i/P_0)^2 - 1]}{[(P_i/P_0)^3 - 1]^2}. \quad (48)$$

The quantity f is a function of the ratio of the inlet and outlet pressures at the inlet to (P_i/P_0) . The dependence of f on P_i/P_0 is presented in Fig. 12. For P_i/P_0 in the range from 1.0 to 7.0, the quantity f increases by $\sim 10\%$. Therefore the quantity f may be neglected in approximate calculations.

Figure 12. Dependence of the correction coefficient f on the ratio of the inlet and outlet pressures of the carrier gas.¹³⁰

It follows from the equations presented above that the properties of the carrier gas employed have an appreciable influence on the height equivalent to the theoretical plate (HETP).

The limiting factor in band broadening is usually the slowness of the mass transfer. In the region of high carrier gas velocities, the use of hydrogen (instead of, for example, carbon dioxide) makes it possible to increase the efficiency of the chromatographic column and hence to reduce the duration of the analysis. This feature of the chromatographic process in the region of high velocities is due to the high diffusion coefficients of the chromatographed compounds in hydrogen.

The few tests of the equations reflecting the dependence of the HETP on the carrier gas flow rate have in the main confirmed them (see, for example, Refs 15, 18, 65, 138, and 139).

Figure 13. Dependence of the column efficiency on the carrier gas flow rate and on the nature of the carrier gas.⁴⁹ Carrier gases: (1) methane; (2) nitrogen, ethane, ethene; (3) carbon tetrachloride; (4) nitrogen; (5) helium.

We may note that the calculated diffusion coefficients in the carrier gas may be used for the estimation of the individual terms of the equations presented above. These methods have been described in detail.^{136, 140} As an example, Fig. 13 presents the $H = f(u)$ relations for various carrier gases obtained on a packed column with Porapak S.

When carrier gases with a lower diffusion coefficient (higher molecular mass) than that of hydrogen are employed, an increase in the efficiency of the chromatographic column is observed at low gas flow rates, but for high-speed analysis it is desirable to employ gases with a high rate of mass transfer, i.e. with a high diffusion coefficient.

2. Capillary gas–solid columns

The term due to eddy diffusion, associated with the multiple path nature of the movement of the gas in packed columns, is absent in the case of capillary columns. The dependence of the HETP on the carrier gas flow rate in capillary gas–solid chromatography has been discussed in greatest detail in the book of Berezkin and de Zeeuw.²

Golay obtained the following equation for the description of the band broadening in open capillary columns with a porous layer and containing a stationary liquid phase:¹²⁷

$$H = \frac{2D_g}{u} + \left[\frac{1 + 6k + 11k^2}{(1 + k)^2} + \frac{(8 + 32k)a_2}{(1 + k)^2} + \frac{8k^2}{(1 + k)^2} \frac{a_1^2}{a_2} \right] \frac{r^2 u}{24D_g} + \left[\frac{k^3}{6(1 + k)^2} \frac{1 + 2a_2}{r_s} \right] \frac{r^2 u}{K^2 D_1}, \quad (49)$$

where k is the retention factor of the chromatographed substance, $a_1 = d/r$ (d is the average length of the twisted channels in the porous layer on the internal walls of the column), r_s is the ratio of the surface areas of the sorbent (liquid phase) and of the capillary wall, $a_2 = d_g/r$ (d_g is the effective thickness of the gas layer in the porous layer of the sorbent located on the inner walls of the column and r is the internal radius of the capillary column), K is the partition (equilibrium) coefficient of the chromatographed compound between the stationary and mobile phases, and D_1 is the diffusion coefficient of the chromatographed compound in the sorbing phase.

The last term, reflecting the resistance to mass transfer in the film of the liquid phase located on the solid carrier, is inversely proportional to r_s . Thus Eqn (49) reflects the fact that, with increase in the porosity of the wall layer, the efficiency of the capillary column should increase (the HETP should diminish with increase in r_s). Hence the idea of creating a capillary with a porous layer of solid carrier on its inner walls was introduced already in the derivation of this equation.

However, it is essential to note that this equation like, incidentally, Golay's other equations, apply directly primarily to gas–liquid–solid (or gas–liquid) chromatography, but, as noted

in the monograph of Berezkin and de Zeeuw,² Eqn (49) may be fully applicable also to gas–solid chromatography if it is assumed that r_s is the ratio of the surface areas of the adsorbent and the capillary wall and D_1 is replaced by D_s , *i.e.* by the diffusion coefficient of the chromatographed compound in the adsorbent layer.

An equation for the dependence of the HETP on the linear carrier gas flow rate for gas–solid chromatography has also been proposed by Giddings.^{133, 134} The Giddings equation does not differ functionally from the Golay equation and the first terms of the Giddings equation are virtually identical with those of the Golay equation. The difference consists, firstly, in the term reflecting the resistance to mass transfer in the adsorption layer located on the inner walls of the capillary column and, secondly, in the allowance for the influence of the carrier gas pressure drop in the column on the band broadening. The Giddings equation can be expressed in the following form:

$$H = \frac{2D_g}{u_0} + \left[\frac{1 + 6k + 11k^2}{24(1+k)^2} \right] \frac{r^2 u}{D_g} f_1 + \quad (50)$$

$$+ \frac{8}{a_k u_m} \left(\frac{k}{k+1} \right)^2 \frac{V_m}{S} f_h u_0 f_2,$$

$$u_0 = \frac{L}{t_M f_2}, \quad (51)$$

$$f_2 = \frac{3}{2} \frac{[(P_i/P_0)^2 - 1]}{[(P_i/P_0)^3 - 1]}, \quad (52)$$

where a_k is the accommodation coefficient, u_m the average velocity of the molecules of the chromatographed compound in the gas phase, V_m the volume of the gas phase in the column, S the overall surface area of the adsorbent layer in the column, and f_h the adsorbent heterogeneity factor.

If the influence of the pressure drop on the band broadening is neglected (*i.e.* it is assumed that $f_2 \approx 1$ and $f_1/f_2 \approx 1$),²⁰ then Eqn (50) can be expressed in the form

$$H = \frac{2D_g}{u} + \left(\frac{C'_m}{D_g} + C_A \right) u, \quad (53)$$

or

$$H = \frac{2D_g}{u} + Cu, \quad (54)$$

$$Hu = 2D_g + Cu^2, \quad (55)$$

(we note that $2D_g = B$), where

$$C = \frac{C'_m}{D_g} + C_A = C_m + C_A, \quad (56)$$

$$C'_m = \frac{1 + 6k + 11k^2}{24(1+k)^2} r^2, \quad (57)$$

$$C_A = \frac{8}{a_k u_m} \frac{V_m}{S} f_h \frac{k}{(1+k)^2}, \quad (58)$$

$$C_m = \frac{C'_m}{D_g}. \quad (59)$$

The coefficients of the resistance to mass transfer were first estimated on the basis of Eqn (55) for buta-1,3-diene on an open capillary adsorption (with alumina as the adsorbent) column were first estimated by the Dutch investigators de Nijs and de Zeeuw.¹⁴¹ They determined the coefficients of the resistance to mass transfer for buta-1,3-diene; in the gas phase, $G_m(\text{He}) = 1.3 \times 10^{-4}$ s and $G_m(\text{N}_2) = 4.6 \times 10^{-4}$ s, whilst in the stationary phase $C_A = 1.8 \times 10^{-4}$ s. The data presented show that the nature of the carrier gas influences the quantity G_m : the smaller the diffusion coefficient (the greater the molecular mass of the carrier gas), the

greater the broadening of the chromatographic band occurring as a result of the increase in the contribution of the resistance to mass transfer in the gas phase and the greater the diminution in column efficiency in the region of high rates.

Berezkin and Volkov²⁰ carried out a similar investigation for the capillary adsorption column with $\text{Al}_2\text{O}_3/\text{KCl}$ (Chrompack, Holland). The results are presented in Table 10. It follows from the tabulated data that the principal contribution to the broadening of the bands of the chromatographed compounds is made by the term C reflecting the resistance to mass transfer.

Table 10. The coefficients of Eqn (55) for hydrocarbon gases separated on a capillary column with alumina.²⁰

Carrier gas	Calculated		Experimental	
	$D_g/\text{cm}^2 \text{ s}^{-1}$	$B/\text{cm}^2 \text{ s}^{-1}$	$B/\text{cm}^2 \text{ s}^{-1}$	C/s

CO ₂	0.11	0.22	0.22	24.0

The influence of the carrier gas on the coefficients of the resistance to external and internal mass transfer for a capillary adsorption column with alumina has been estimated.¹⁴² The data obtained are presented in Table 11. Evidently, the overall coefficient of the resistance to mass transfer for n-butane (C) is smaller by a factor of 2.4 with hydrogen as the carrier gas than in nitrogen and this difference is due to the corresponding difference between the coefficients of the resistance to mass transfer in the alumina layer. In order to employ the column under the conditions of high-speed analysis, it is therefore essential to use hydrogen as the carrier gas.

Table 11. Diffusion coefficients and resistances to mass transfer for n-butane with hydrogen and nitrogen as the carrier gases.¹⁴²

Parameter	Carrier gas	
	hydrogen	nitrogen
$D_g/\text{cm}^2 \text{ s}^{-1}$	0.625	0.162
Coefficient of resistance to mass transfer $/10^{-3}$ s		
C_m	1.8	6.9
C_s	1.8	1.8
C	3.6	8.7

Relatively 'heavy' carrier gases should increase significantly the efficiency of the chromatographic column in the region of low carrier gas flow rates by diminishing the broadening of the chromatographic bands due to longitudinal molecular diffusion. This has been confirmed experimentally.¹⁰¹ Analysis of the experimental data presented in Table 12 and in Fig. 14 made it possible to discover¹⁰¹ the following feature of the band broadening process in capillary gas–solid chromatography: the greatest efficiency of the chromatographic column may be achieved by employing the 'heavy' carbon dioxide and the greatest 'gain' in efficiency is observed for 'light' chromatographed compounds. The maximum column efficiency increases for all the sorbates investigated ($H_{\min}$ diminishes in the following series of carrier gases: hydrogen < helium < nitrogen < carbon dioxide).

Table 12. Parameters of a capillary adsorption column for different carrier gases.¹⁰¹

$H_{\min}/\text{mm}$	0.25	0.29	0.36

The experimental and calculated coefficients of the resistance to mass transfer in the gas phase for certain carrier gases are presented in Table 13. The values of D_g have been calculated¹⁰¹ from the Fuller–Schettler–Giddings equation.¹⁴⁰ It follows from the data in Table 13 that the main band broadening takes place in the gas phase. However, publications have appeared in the literature in which it is noted that the observed dependences of

Table 13. Coefficients of resistance to mass transfer for the following experimental conditions: 50 m × 0.32 mm column, adsorbent — Al₂O₃/KCl, temperature 90 °C.¹⁰¹

Parameter	Chromatographed compound

$C_m(\text{exp})/10^{-3} \text{ s}$	1.8	2.8

the HETP on the linear carrier gas flow rate for capillary adsorption columns are inconsistent with the Golay–Giddings equation (see, for example, Refs 28, 143, and 144).

Thus the consistency of the Van Deemter [Eqn (41)], Golay–Giddings [Eqn (54)], and the extended Golay–Giddings equations with the authors' experimental data and certain literature data has been analysed¹⁴⁴ in order to determine the most suitable equation for the description of the dependence of the HETP on the linear carrier gas flow rate in capillary gas–solid columns with various adsorbents.

The extended Golay–Giddings equation describes satisfactorily the $H = f(u)$ relation in the region of high carrier gas flow rates:¹⁴⁵

$$H = \frac{B}{u} + Cu + Du^2, \quad (60)$$

where

$$B = 2D_g \quad (61)$$

$$C = \frac{1 + 6k + 11k^2}{24(1 + k)^2} \frac{r^2}{D_g} + \frac{2k}{3(1 + k)^2} \frac{d_f^2}{D_1}, \quad (62)$$

$$D = \frac{\sigma^2(tEC)}{(1 + k)^2 L}, \quad (63)$$

r is the internal radius of the capillary column, d_f the film thickness in the column, D_1 the diffusion coefficient in the stationary liquid phase, $\sigma^2(tEC)$ the characteristic of the extra column contribution, and L the column length.

Analysis of the results obtained¹⁴⁴ showed that, among the 32 examples considered, Eqn (54) is the most suitable for the description of experimental data in only two cases (6%), the Van Deemter equation [Eqn (41)] is suitable in nine cases (28%), while the extended Golay–Giddings equation [Eqn (60)] is suitable in 21 cases (66%).

Thus the extended Golay–Giddings equation should be more widely employed for the description of the $H = f(u)$ relation in capillary adsorption columns. However, it is essential to put forward a well founded theoretical interpretation of this relation, because virtually all the examples considered refer to the usual experimental conditions and not to high-speed analysis.

VII. Conclusion

As shown by numerous investigators, the nature of the carrier gas (and its pressure in the chromatographic column) employed in gas–solid chromatography exerts an appreciable influence on the principal chromatographic characteristics of sorbates, namely on the retention parameters and band broadening. Unfortunately, due attention to the role of the carrier gas employed is not always

**Figure 14.** Dependence of the HETP on the linear carrier gas flow rate for certain hydrocarbon gases characterised by different retention factors;¹⁰¹ (a) propene; (b) butane; (c) isobutene.

Carrier gases: (1) hydrogen; (2) helium; (3) nitrogen; (4) carbon dioxide. Experimental conditions: 50 m × 0.32 mm, stationary phase — Al₂O₃/KCl, $T = 90^\circ\text{C}$.

paid in the scientific literature and particularly in chromatographic practice.

The analysis of the results of published studies carried out in the present review indicates a real possibility of a significant improvement of analytical separation with the aid of a simple and nontraditional method such as the alteration of the carrier gas and of its column pressure. It is essential to note that this factor assumes a particular importance for high-performance capillary chromatography.

In the optimisation of the analytical separation process, the dependence of the column efficiency on the carrier gas flow rate is important. The results of the latest studies have shown that the classical Golay–Giddings equation for capillary gas–solid chromatography, reflecting this dependence, is not optimal for the description of experimental data and that this must be taken into account in chromatographic practice.

Abstract. The results of the application of radiation-chemical methods for the preparation of polymeric biomaterials are surveyed and treated systematically. The characteristic features of these methods and their advantages and disadvantages are indicated. The properties of polymeric biomaterials prepared using ionising radiation are examined. Particular attention is devoted to studies carried out during the last 10–15 years. The bibliography includes 492 references.

I. Introduction

Polymeric biomaterials are usually understood as polymeric materials and articles made from them which are used in medicine or biotechnology. Such materials are frequently prepared by the specific modification of well known polymers. The range, scale of manufacture, and importance of biomaterials have increased appreciably during recent years.

A series of reviews and monographs have been devoted to problems of their preparation, properties, and applications (see, for example, Refs 1–6).

Radiation-chemical technology has now become one of the effective methods for the preparation of polymeric biomaterials. The studies on the employment of radiation-chemical methods for the synthesis of polymeric biomaterials have been carried out on the following lines: radiation-induced modification of various polymers and articles made from them in order to obtain haemocompatible polymers (polymers which are in prolonged contact with blood during their employment), polymeric sorbents, prostheses for blood vessels, *etc.*; immobilisation of various biologically active substances (BAS) (enzymes, medicinal drugs, *etc.*) in polymeric matrices using radiation-induced polymerisation; radiation-chemical synthesis of polymeric carriers for medicinal preparations; radiation-induced cross-linking of polymers in order to obtain mechanically strong hydrogels (BAS carriers, dressings, eye lenses, *etc.*).

An advantage of the radiation-chemical methods for the preparation of polymeric biomaterials compared with traditional methods is the purity of the materials (there is no need to add additional ingredients during the synthesis), the possibility of carrying out the processes at reduced temperatures, and the ease of regulation of the rate of the processes by altering the radiation dose rate. Another advantage of the radiation-chemical methods is the fact that the biomaterials can in certain cases be sterilised on the same sources of ionising radiation which were used for their preparation. It is essential to note that in the majority of cases low radiation doses, as a rule not exceeding 30 kGy, are required for the preparation of polymeric biomaterials, which makes it possible to use low-power radiation sources.

A disadvantage of radiation-chemical methods is the necessity to use, as a rule, γ -radiation sources and electron accelerators which are comparatively expensive and difficult to use.

The mechanisms of the radiation-chemical processes, the devices, the dosimetry, and the methods involving the employment of ionising radiation sources have been described in detail in a series of monographs (see, for example, Pikaev and Woods ^{7,8}). In the present review, these questions are not considered.

II. Preparation of haemocompatible polymeric materials

The preparation of haemocompatible polymeric materials is an extremely complex problem. When polymers come into contact with blood, biochemical reactions inducing a change in the physiological functions of blood are initiated and the blood clotting system with subsequent thrombus formation on the surface of the polymer is 'switched on'. Reviews have been devoted to the mechanisms of thrombogenesis on the surface of polymers.^{9–15} Important factors increasing the haemocompatibility of polymers are their properties such as minimal capacity for the adhesion and aggregation of thrombocytes, the lack of activation of blood clotting contact factors, participation in the lysis of the thrombus formed, and a selective capacity for the adsorption of blood plasma proteins, especially albumin. According to current ideas, the first stage, when the polymer comes into contact with blood, is rapid sorption of proteins from blood plasma. The nature and conformational state of the protein determine the subsequent biochemical reactions.

The problems of the sorption of proteins on various polymeric surfaces have been considered in numerous investigations (see, for example, Refs 1, 16, and 17). Unfortunately, at the present time

the level of our knowledge precludes sufficiently effective prediction of the nature and properties of the polymer surface which would fully satisfy the requirement of haemocompatibility.

It is clear from the foregoing that the surfaces of polymers must be modified in order to obtain haemocompatible materials. The following measures are taken for this purpose.

1. Polymers are created with surfaces possessing a reduced adsorption capacity in relation to protein and are close in their nature to the natural medium of the organism. In the main, these are hydrogel surfaces. It has been assumed¹⁷ that both an approximate equality, pairwise, of the dispersion and polar components of the free surface energy of blood and materials and the closeness of the distribution of the above energy parameters, also pairwise, are needed for haemocompatible materials.

2. Polymeric materials with a definite domain structure of the surface (polyurethanes) are created.

3. Polymeric hydrocarbon materials (polyethylenes) are created.

4. Polymers are created the surfaces of which model, in terms of their nature, blood anticoagulants (this is achieved by introducing sulfo- and carboxy-groups into the surface layers of polymers, by generating a negative charge on the surfaces of polymers). It is usually endeavoured to obtain a heparin-like surface, since the widely used method for the preparation of haemocompatible materials by introducing heparin suffers from a series of disadvantages due to the partial loss of activity by the heparin on covalent immobilisation and its weak anticomplement activity and biodegradation.

5. Physiologically active substances (blood anticoagulants, enzymes, *etc.*), interacting with blood components and arresting the thrombogenic process, are introduced into the surface hydrogel layers.

In selecting the method for the modification of the polymer surface, it is essential to bear in mind the principle that the physicochemical parameters of the initial polymer should not change significantly on modification. One of the methods for the modification of polymers is radiation-induced graft polymerisation.

A series of reviews have been devoted to various problems of the radiation-induced graft polymerisation and the methods for carrying it out.^{7, 18–22} Its advantages as a method for the modification of polymeric materials in order to increase their haemocompatibility are, firstly, a high universality which makes it possible to modify over a wide temperature range virtually any polymeric materials (stitches, catheters, tubes, tablets, powders, grafts, *etc.*) and secondly the possibility of creating on the polymer surface of modified layers of different thickness. The thickness of the layer depends on the conditions under which the graft polymerisation is carried out — the dose rate, the choice of the solvent for the monomer, *etc.* The modified layer is then strongly bound to the support and is not washed off on contact with the medium of the living organism.

All these features promote a fairly wide-scale employment of radiation-induced graft polymerisation for the solution of problems associated with the enhancement of the haemocompatibility of various polymeric materials and articles made from them. The principal task of such investigations is the creation of polymers with a functionalised surface, definite hydrophilic-hydrophobic properties, and a negative charge on the surface.^{23–25} A large number of studies have been carried out on the modification of various polymers using highly hydrophilic monomers such as *N*-vinylpyrrolidone, 2-hydroxyethyl methacrylate, and acrylamide and its derivatives.^{26–72} In a series of investigations, fairly complex copolymers have been used for modification.^{73–87} Thus, polyurethanes, polyesters, and natural rubber have been mainly used for the manufacture of blood vessel prostheses.^{88–118}

Table 1 presents data on the employment of the radiation-induced graft polymerisation methods for the modification of polymers. The radiation-induced graft polymerisation was carried out in most cases by the direct method from aqueous alcoholic solutions with low irradiation doses. In certain cases, especially in

the grafting of acrylamide, the method involving preirradiation was used.⁴¹

The investigations carried out led to the preparation of a wide variety of modified polymeric materials with hydrogel surfaces. These materials are fairly strong and soft and exhibit a high swellability in water. The biomacromolecules in such materials are characterised by enhanced diffusion. The polymeric hydrogels obtained by radiation-chemical methods have been tested for haemocompatibility in experiments *in vitro* and *in vivo* on monkeys, sheep, and dogs. The tests for the haemocompatibility of the radiation-grafted polymeric hydrogels revealed the following general features: with increase in the water content from 15% to 85%, the sorption of proteins diminishes, the rate of desorption increases, and thrombogenesis takes place on the hydrogels, but the bond between the thrombus and the hydrogel surface is appreciably weakened compared with the bond between them and the unmodified polymers. The appreciable decrease in the interfacial tension between the hydrogel and the aqueous solution is very important. The hydrogel coating on the polymers should be prepared from very pure monomers. Thus a slight methacrylic acid impurity in 2-hydroxyethyl methacrylate appreciably impairs the quality of the hydrogel coating and its haemocompatible properties.⁹³

Interesting results have been obtained in the study of the copolymers of 2-hydroxyethyl methacrylate (a hydrophilic monomer) with ethyl methacrylate (a hydrophobic monomer) radiation-grafted onto polyethylene (PE).⁹³ For a low water content (~10%), the above graft copolymers were characterised by unexpectedly low thrombocyte adsorption parameters, which was not due to the water content but to the composition of the copolymer. For a higher water content, the adsorption of thrombocytes was inversely proportional to the water content. Evidently, the composition of the copolymers and the state of water in it are important. The surface of radiation-grafted copolymers is very nonuniform (there are mounds, projections, *etc.*) and the thickness of the modified layer is as a rule 15–45 μm . Hoffman *et al.*⁹³ concluded that a definite combination of hydrophilic and hydrophobic sections on the surface is needed to increase the haemocompatibility.

The state of water in radiation-grafted copolymers has been investigated.^{94, 95} The state of water in radiation-grafted PE hydrogels with grafted polyacrylamide has been studied.⁹⁴ It has been established by differential scanning calorimetry (DSC) that the water in hydrogels does not freeze down to -50°C and that the amount of unfrozen water per unit surface of the modified polymer which has undergone equilibrium swelling or per mole of the grafted polyacrylamide depends on the methods used to carry out the graft polymerisation. The presence of unfreezing water in radiation-grafted hydrogels with polyacrylamide chains is due to the rearrangement of the water framework in the hydrogel owing to the formation of a strong hydrogen bond between the H_2O molecule and the carbonyl group of polyacrylamide, which has been demonstrated by IR Fourier spectroscopy.⁹⁴ Data on the employment of the ESCA method for the investigation of the influence of hydration on the state of the grafted chains in a thin layer on the surfaces of polymers ~50 Å thick have been published.⁹⁵ The following systems have been investigated: low-density polyethylene (LDPE) + grafted poly(2-hydroxyethyl methacrylate), LDPE + grafted polyacrylamide, silicone rubber (Silastik) + poly(2-hydroxyethyl methacrylate), and polyurethane (Tufthane) + poly(2-hydroxyethyl methacrylate). The surface was analysed by studying the C_{1s} , O_{1s} , and Si_{2p} peaks. The C/Si , O/Si , C/O , C/N , and O/N peak ratios for the hydrated and dehydrated surfaces of various radiation-grafted copolymers have been published.⁹⁵ These data make it possible to determine the location of the grafted chains in the surface layer of the polymers in the hydrated and dehydrated states. For example, in the case of the grafting of poly(2-hydroxyethyl methacrylate) on polyurethanes, the concentration of the grafted chains on the surface diminishes appreciably after dehydration. On the other hand,

Table 1. Radiation-induced graft polymerisation of monomers for the preparation of various polymers with the aim of regulating haemocompatibility.

Monomer	Conditions in radiation-induced graft polymerisation	Remarks	Ref.
<i>Polymer — polyethylene</i>			
Acrylic acid	post-radiation grafting	the adsorption of antitumour preparations on adsorbents with grafted poly(acrylic acid) was studied	29
	direct grafting from aqueous phase	the hydrophilic properties of the surface were studied in detail	96, 97
	ditto	the carboxy groups were converted into acid chloride groups by treating the surface with thionyl chloride and the latter were used for the covalent binding of BAS	90
Acrylic acid chloride	direct grafting from vapour phase		23, 26
Acrylic acid, acrolein; mixture of monomers	direct grafting from liquid phase	sulfonation of graft copolymer	31
Acrylamide	grafting by the preirradiation method from aqueous and acetone solutions	the amide groups of the grafted polyacrylamide were converted into amino groups; heparin was bound to the amino groups; tests <i>in vivo</i> and <i>in vitro</i>	27
	ditto	polymer tubes were used; tests <i>in vivo</i>	28
	direct grafting from solution	the surface of the modified polymer was studied	33
	various grafting methods, including grafting from the vapour phase, were used		107
Acrylamide, <i>N,N'</i> -methylene-bisacrylamide	direct grafting from 10% aqueous alcoholic solution in the presence of Fe ²⁺		24
Allylamine	direct grafting in the presence of phosphoric acid	phosphoric acid increases the yield of the graft polymer	25
Diallyldimethylammonium chloride, sodium styrene sulfonate	direct grafting		35
2-Hydroxyethyl methacrylate, ethyl methacrylate; mixture of monomers	direct grafting from water–methanol mixture at low dose rates	surfaces with different hydrophilicities were obtained	30, 37
4-Vinylpyridine + 2-(<i>N,N</i> -diethyl-amino)ethyl methacrylate; 4-vinylpyridine + methyl methacrylate; 4-vinylpyridine + methacrylic acid	direct grafting of monomers from vapour phase	alkylation of graft copolymer	32
<i>N</i> -Vinylpyrrolidone	grafting from liquid phase by the preirradiation method		36
Methyl acrylate	direct grafting from water–acetone mixture	hydrazinolysis of graft copolymers	59
Styrene	direct grafting	introduction of sulfonate and sulfonamide groups; tests <i>in vitro</i>	48
2-Hydroxyethyl methacrylate, 2-hydroxyethyl methacrylate + ethyl methacrylate	direct grafting from liquid phase	the structure of the surface was investigated by electron microscopy	93
2-Hydroxyethyl methacrylate, <i>N</i> -vinylpyrrolidone, acrylamide	ditto		106
<i>Polymer — polyethylene, silicone rubber</i>			
2-Hydroxyethyl methacrylate, acrylamide	direct grafting from liquid phase	the state of water was investigated by the DSC and ESCA methods	94, 95

Table 1 (continued).

Monomer	Conditions in radiation-induced graft polymerisation	Remarks	Ref.
<i>Polymer — polypropylene</i>			
2-Hydroxyethyl methacrylate	direct grafting from 20% monomer solution	a grafting maximum is observed for a dose of 5 kGy	39
	grafting by the preirradiation method	hydrophilisation of polypropylene stitch material	98
Monomer mixtures: <i>N</i> -vinylpyrrolidone + acrylic acid; vinyl acetate + crotonic acid	direct grafting	the polyacrylic acid in the modified polymer was partly neutralised with alkali	40
Acrylamide	postradiation grafting after vacuum irradiation of polymer		41
<i>Polymers — polyethylene, polypropylene, polyesters, poly-4-methylpentene, polyvinyltrimethylsilane</i>			
Acrylic acid, methacrylic acid, 4-vinyl-pyridine	grafting from vapour phase	the formation of polyelectrolytic complexes on the surfaces of the polymers was investigated	34
<i>Polymers — polyethylene, polypropylene, polyamides, polyurethanes, etc.</i>			
<i>N</i> -Methyl- <i>N</i> -vinylacetamide	direct grafting from liquid phase	the properties of the surfaces of the modified polymers were characterised by the critical surface tension; polymer tubes were used for modification	89
<i>Polymers — polyethylene, polypropylene</i>			
Vinylidene chloride	direct grafting from gas phase	dehydrochlorination of materials obtained	101–104
<i>Polymer — ethylene-propylene rubber</i>			
2-Hydroxyethyl methacrylate, <i>N,N</i> -dimethylacrylamide, 2-(<i>N,N</i> -dimethylamino)ethyl methacrylate	direct grafting from aqueous medium in the presence of Cu ²⁺ ion		70
Acrylamide, <i>N</i> -vinyl-pyrrolidone, 2-hydroxyethyl methacrylate	direct grafting from aqueous monomer solution	the morphology of the surface and the influence of O ₂ on the grafting were investigated	71
Different vinyl monomers	direct grafting from liquid phase	grafting onto a film, a tube, and a fibre was studied; the surface properties were investigated	42
<i>Polymer — ethene-propene copolymer</i>			
<i>N</i> -Vinylpyrrolidone, 2-hydroxyethyl methacrylate, acrylamide	direct grafting from liquid phase		86
<i>Polymers — polyolefins</i>			
Macromonomers	direct grafting	review of studies on the grafting of macromonomers; macromonomers were obtained by the acylation of the amino groups in enzymes or heparin using acrylic acid chloride	91
<i>Polymer — polytetrafluoroethylene</i>			
Acrylic acid chloride	direct grafting from monomer gas phase		23
<i>N,N</i> -Dimethylacrylamide	direct grafting from liquid phase	the influence of dose rate, solvent, and temperature on the grafting was investigated	45
Acrylamide	grafting by the preirradiation method	the surface of the polymer was investigated by the ESCA method and by scanning electron microscopy	46
<i>tert</i> -Butyl crotonate + methyl acrylate + sulfonic acid	direct grafting from liquid phase	the influence of the graft polymer on the haemocompatibility was investigated	47
Methyl methacrylate phase	direct grafting from liquid phase	modification of blood vessel prostheses	49
Styrene	ditto	the grafted chains were nitrated and the nitro groups were reduced to amino groups	43

Table 1 (continued).

Monomer	Conditions in radiation-induced graft polymerisation	Remarks	Ref.
<i>Polymers — polytetrafluoroethylene, tetrafluoroethene–ethene copolymer</i>			
<i>N,N</i> -Dimethylacrylamide	direct grafting at different dose rates		50
<i>Polymer — tetrafluoroethene–propene copolymer</i>			
<i>N,N</i> -Dimethyl acrylamide	direct grafting from liquid phase	the influence of solvents on the grafting was investigated	76
<i>Polymer — poly(vinyl fluoride)</i>			
2-Hydroxyethyl methacrylate, vinyl acetate, acrylic acid, <i>N</i> -vinylpyrrolidone, 4-vinylpyridine, acrylamide, vinylene carbonate	grafting by the preirradiation method from the liquid phase of the monomer; irradiation by electron accelerator	the kinetics of graft polymerisation were investigated	51
<i>Polymer — poly(vinylidene fluoride–hexafluoropropene)</i>			
Styrene	grafting by the preirradiation method; irradiation by accelerated heavy ions	functionalisation of grafted chains; modification of blood vessel prostheses	62
<i>Polymers — poly(vinylidene fluoride), hexafluoropropene–vinylidene difluoride copolymer</i>			
Styrene	grafting by the preirradiation method; irradiation with accelerated heavy ions	introduction of sulfo groups; formation of a heparin-like surface	87
Organosilicon polymers			
<i>N</i> -Vinylpyrrolidone	direct grafting from monomer solution in methanol or toluene	grafting on silicone rubber tubes	52, 58
	direct grafting from liquid phase	review of studies on radiation-induced grafting of <i>N</i> -vinylpyrrolidone	60
<i>N</i> -Vinylpyrrolidone, 2-hydroxyethyl methacrylate; grafted layer and the degree of grafting mixture of monomers	direct grafting from aqueous monomer	the influence of Cu^{2+} on the distribution of solution in the presence of Cu^{2+} ions	57 the
	direct grafting from 20% aqueous solution	was investigated	
<i>N</i> -Vinylpyrrolidone mixture of <i>N</i> -vinylpyrrolidone and 2-hydroxyethyl methacrylate	direct grafting from aqueous solution of monomers	the influence of the irradiation dose on the grafting and the swelling of the modified polymers in water was investigated	53
			63
2-Hydroxyethyl methacrylate	direct grafting		64
Different hydrophilic monomers	grafting from aqueous solution		67
2-Hydroxyethyl methacrylate, ethyl acrylate; mixture of monomers	direct grafting from water–methanol mixture	the rate of grafting depends significantly on the water : monomer ratio	54
2-Hydroxyethyl methacrylate, ethyl methacrylate; mixture of monomers	direct grafting from aqueous phase	separate grafting of each monomer and of the mixture of monomers; the surface of polymers was investigated by scanning electron microscopy	56
Acrylamide	direct grafting from liquid phase in the presence of Cu^{2+} ions		55
<i>Polymers — polyurethane, silicon rubber</i>			
Acrylamide	direct grafting from liquid phase	sections through films and the swelling of the polymers in water were investigated	38
<i>N</i> -Vinylpyrrolidone	ditto	grafting onto polymer tubes; tests for haemocompatibility <i>in vivo</i>	69

Table 1 (continued).

Monomer	Conditions in radiation-induced graft polymerisation	Remarks	Ref.
<i>Polymer — segmented polyurethane</i>			
<i>N</i> -Vinylpyrrolidone	direct grafting from monomer solution in water	the influence of the degree of swelling and of the irradiation dose on the grafting was investigated	75
2-Hydroxyethyl methacrylate	direct grafting in swollen state	the influence of the degree of swelling and temperature on the grafting was investigated	74
<i>Polymer — polyesterurethane</i>			
2-Hydroxyethyl methacrylate	direct grafting from water–ethanol mixture	modified blood vessel prostheses were obtained; the swelling of the modified polymers was investigated	72
<i>Polymer — polyurethanepolyester (Upjohn)</i>			
<i>N</i> -Vinylpyrrolidone	direct grafting from monomer solution in water, benzene, toluene, and Freon	the influence of temperature on the grafting and the cross-sectional distribution of the grafted polymer was investigated; the grafting was carried out on tubes	77
<i>Polymer — polyurethane</i>			
2,3-Epoxypropyl methacrylate, acrylamide, 2-hydroxyethyl methacrylate	direct grafting from liquid phase	the influence of solvents on the grafting was investigated; the best solvent is acetone	73
Monomers with sulfonate groups	ditto	the haemocompatibility was investigated <i>in vivo</i>	105
<i>Polymer — polyamide 6</i>			
Various monomers	direct grafting from liquid phase	the grafting was carried out from solvents with a specific solubility parameter; modification of polyamide beads; preparation of new adsorbents	61
2-Hydroxyethyl methacrylate, glycidyl methacrylate	ditto	grafting onto polymer beads; the modified beads obtained were used as carriers for affinity chromatography	84
<i>Polymer — poly[bis(trifluoroethoxyphosphazene)]</i>			
<i>N</i> -Vinylpyrrolidone	direct grafting from aqueous monomer solution		67
<i>Polymers — polyphosphazenes</i>			
<i>N</i> -Vinylpyrrolidone	direct grafting from aqueous monomer solution	heparinisation; tests <i>in vivo</i>	68
<i>Polymer — natural rubber</i>			
<i>N,N</i> -Dimethyl acrylamide	direct grafting from monomer solution in CCl ₄		99
	grafting by the preirradiation method as a result of the decomposition of hydroperoxy groups	the haemocompatibility was investigated	108
2-(<i>N,N</i> -Dimethylamino)-ethyl methacrylate	direct grafting from monomer solution in CCl ₄ tubes	grafting onto polymer tubes	92
<i>Polymer — natural leather</i>			
Butyl methacrylate, styrene, methyl methacrylate	direct grafting		81
<i>Polymers — poly(vinyl alcohol), polyamide 6</i>			
Acrylamide, <i>N</i> -vinylpyrrolidone, 2-hydroxyethyl methacrylate, 2-(<i>N,N</i> -dimethylamino)ethyl methacrylate	direct grafting from aqueous solution in the presence of added formamide and tetrahydrofuran	adsorbents for affinity chromatography	44
<i>Polymer — poly(ethylene glycol dimethacrylate)</i>			
2-Hydroxyhexyl methacrylate	direct grafting	the adsorption of γ -globulin on the polymers obtained was investigated	66

Table 1 (continued).

Monomer	Conditions in radiation-induced graft polymerisation	Remarks	Ref.
<i>Polymers — polystyrene, polyester</i>			
<i>N</i> -Vinylpyrrolidone, 2-hydroxyethyl phase methacrylate	direct grafting from liquid phase	hydrophilisation of polystyrene articles for immunodiagnostics; modification of polyester blood vessel prostheses in order to increase haemocompatibility	78
<i>Polymer — polystyrene</i>

<i>Polymer — poly(ethylene terephthalate)</i>			
Acrylamide	direct grafting	modification of blood vessel prostheses	80
<i>Polymer — poly(methyl methacrylate)</i>			
Acrylic acid	direct grafting	binding of enzymes to the polymer surface	88

when poly(2-hydroxyethyl methacrylate) is grafted on the LDPE surface, dehydration does not affect the concentration of the grafted chains in the surface layer while the concentration of polyacrylamide grafted on polyurethanes does not change on the surface after dehydration.

In the case of organosilicon rubbers, the number of grafted chains on the surface diminishes as dehydration proceeds and the grafted chains are gradually immersed in the film. The second process occurring on dehydration is the formation of clusters by the grafted chains. The clusters are formed from several macromolecules. The disposition of the clusters on the surface depends on the degree of dehydration. Hydration significantly increases the concentration of the grafted chains on the polymer surfaces. This is particularly notable in the case of radiation-grafted silicone rubbers. Such data are important for the biomedical employment of the hydrogels obtained by radiation-induced graft polymerisation, since it is essential to take into account the change in the state of the grafted chains in the hydrogels on contact with blood or other biological liquids.

The hydrophilic properties of LDPE with grafted poly(acrylic acid) have been investigated.^{96,97} It was established that the hydrophilic properties are stabilised after a 15%–17% graft (complete surface coverage). The polar component of the free surface energy then increases appreciably and the molecules of poly(acrylic acid) are reorganised under the influence of water.

The preparation of a hydrophilic stitch material by the radiation-induced grafting of 2-hydroxyethyl methacrylate on a single polypropylene fibre has been described.⁹⁸ The influence of solvents and irradiation conditions on the graft has been investigated. Hydrophilic polypropylene filaments were obtained as a result.

The view has been expressed in certain investigations that the modified layer must be of definite thickness for the successful increase in haemocompatibility. In a study of the radiation-induced graft polymerisation of 2-hydroxyethyl methacrylate

and acrylamide on polyolefin films and blood vessel prostheses, it has been established⁷² that the adsorption of proteins is reduced if the amount grafted does not exceed 10%. On the other hand, an appreciable decrease in interfacial tension and in the adsorption of thrombocytes is observed only after the attainment of a 20%–30% graft. The adhesion of thrombocytes diminishes significantly after the film has been coated with albumin. Haemocompatibility (investigated *in vivo* on sheep) as a rule increases significantly only for comparatively high amounts grafted (exceeding 30%).^{33,72,75} The study of the haemocompatibility of high density polyethylene (HDPE) modified by the radiation-induced grafting of polyacrylamide (the tests were carried out *in vivo*) showed³³ that after modification the thromboresistance of the polymer increases several fold. The haemocompatibility of segmented polyurethane after the radiation-induced grafting of *N*-vinylpyrrolidone has been investigated by Hongfei *et al.*⁷⁵ The influence of pH on the radiation-induced grafting of *N*-vinylpyrrolidone has been studied. The surface of the modified polymer is rough and its swelling in water increases exponentially with the amount grafted. An appreciable increase in thromboresistance is achieved in tests *in vivo* after the attainment of a 20% graft.

The haemocompatibility of modified silicone tubes (*in vivo* tests) has been investigated by Chapiro *et al.*⁵² The modification was carried out by the radiation-induced grafting of *N*-vinylpyrrolidone from a solution of the monomer in methanol or toluene. It was established that the haemocompatibility increases significantly after a 33% graft. On the other hand, the adsorption parameters of the proteins have a minimum at a certain thickness of the grafted layer. For example, in a study of the radiation-induced grafting of methoxypoly(ethylene glycol methacrylate) with 2-hydroxyethyl methacrylate by the direct method onto silicone rubber (Silastik), it was observed that the adsorption of fibrinogen has a minimum for an 8% graft.

The texture of the surface also influences the haemocompatibility. The radiation-induced graft polymerisation of *N,N*-dimethylacrylamide on polytetrafluoroethylene and the tetrafluoroethene–ethene copolymer (Aflon) has been investigated.^{27, 50} The influence of the monomer concentration and the dose rate on the haemocompatibility of the modified polymers obtained was studied. It was established that a decrease in dose rate from 1 to 0.1 kGy h⁻¹ increases the haemocompatibility (*in vivo* tests), which is associated with the increase in the smoothness of the surface. Collin *et al.*⁸⁵ studied the adhesion of red blood cells on polycationic carriers, which were prepared by modifying poly(vinyl chloride) grains by means of radiation-induced graft polymerisation of dimethylaminoethyl methacrylate; electron micrographs of the system with adhering cells have been published.

The radiation-induced graft polymerisation of acrylamide on polypropylene (PP) films by the post-effect method in order to render them hydrophilic is also promising.¹⁰⁰

Another method for the preparation of haemocompatible polymeric material involves the creation of hydrocarbon polymers (polyethylenes). For this purpose, vinylidene chloride was radiation-grafted from the gas phase onto polymeric materials with subsequent dehydrochlorination of the modified polymers obtained. These materials are used in endosurgery.^{101–104}

One of the methods of increasing haemocompatibility involves the use of radiation-induced graft polymerisation in order to obtain negatively charged surfaces of polymers containing carboxy, hydroxy and sulfo groups in the surface layers. The communication of Stever *et al.*¹⁰⁵ is devoted to the study of polyurethanes modified by the grafting of propanesulfonate functional groups. It was established in experiments *in vivo* that the haemocompatibility of such polyurethanes increases, the adhesion of blood cells to the surface is low, and the adhering cells do not undergo marked changes. The conversion of the adsorbed fibrinogen into fibrin is blocked and inhibited, *i.e.* the surface modification acts in approximately the same way as heparin — a blood anticoagulant. The radiation-induced grafting of the bisulfite derivative of acrolein mixed with acrylic acid followed by the sulfonation of the grafted layer with sulfurous acid and neutralisation of the sulfo and carboxy groups has been investigated.³¹ Modified materials with a thromboresistant effect were created.

Ratner *et al.*¹⁰⁶ described a study of the influence of the nature of the monomer used for radiation-induced graft polymerisation on the antithrombogenic properties of the modified materials. The authors studied the thrombogenic properties (*in vivo*) of the hydrogels obtained by the radiation-induced grafting of 2-hydroxyethyl methacrylate, acrylamide, a mixture of 2-hydroxyethyl methacrylate and ethyl methacrylate, and a mixture of 2-hydroxyethyl methacrylate and *N*-vinylpyrrolidone on LDPE. The influence of the composition of the copolymer and the water content on the deposition of thrombi is described in detail. It has been noted that the use of radiation-modified polyphosphazenes as haemocompatible materials is promising.⁷⁰ It has been shown⁷² that the number of attached thrombocytes diminishes with decrease in the interfacial free energy (*in vivo* tests in the canine carotid arteries of polyurethane tubes modified by the grafting of 2-hydroxyethyl methacrylate). The interfacial free energy decreases significantly after the grafting of 30% of 2-hydroxyethyl methacrylate. The coating of the graft polymer with albumin or γ -globulin decreases the adhesion of thrombocytes. In a study of the influence of the radiation-induced grafting of acrylamide on LDPE and PP tubes on the antithrombogenic properties, it was established that the best antithrombogenic properties are attained for a 30% graft (the wetting angle is $< 28^\circ$).^{27, 28, 41} The influence of the conditions in the graft polymerisation on the antithrombogenic properties has been demonstrated. When *N*-vinylpyrrolidone is grafted on polyurethane; the best antithrombogenic properties are also attained for a 30%–35% graft (experiments on the blood circulatory system of sheep).⁶⁹ The study of the radiation-induced grafting of acrylamide and acrylic acid on

LDPE and HDPE showed that the radiation-induced graft polymerisation of acrylamide takes place most effectively in the case of HDPE.^{24, 33, 107} The modified PE polymers with grafted polyacrylamide have a low wetting angle and exhibit enhanced antithrombogenic properties in tests *in vivo* in the carotid arteries of rats. The thrombus formation time increases several fold compared with pure PE.³³ The cross-linking of the polyacrylamide chains in the radiation-induced grafting of acrylamide together with the *N,N'*-methylenebisacrylamide cross-linking agent leads to a decrease in thromboresistance.²⁸

The radiation-induced graft polymerisation of *N,N*-dimethylacrylamide on natural rubber tubes has been studied in detail.^{92, 108} It was established that the best solvent for grafting is CCl₄ and that satisfactory haemocompatibility is manifested for a 30% graft.

The presence on the polymer surface of uniformly distributed negatively charged functional groups is important for increasing haemocompatibility.⁴⁷

Studies on the use of radiation-induced graft polymerisation for the modification of blood vessel prostheses made from polyester materials have been carried out in Poland (Institute of Applied Radiation Chemistry, Lodz). Acrylamide was used for the radiation-induced graft polymerisation. The influence of the dose and the monomer concentration on the process was investigated. Grafting results and an increase in hydrophilicity and a decrease in the gas-permeability of the prostheses. Tests on the prostheses demonstrated their fairly satisfactory biocompatibility. Thus acrylamide and its derivatives are promising monomers for increasing the hydrophilicity and biocompatibility of various polymeric materials. Another monomer which being vigorously employed for increasing biocompatibility is the highly hydrophilic monomer *N*-vinylpyrrolidone.^{48, 52, 58, 60, 67, 68, 75, 78} The radiation-induced grafting of *N*-vinylpyrrolidone is as a rule carried out by the direct method from its solutions in water, toluene, or methanol, using low radiation doses. As in the case of acrylamide, after the graft polymerisation of *N*-vinylpyrrolidone the hydrophilicity increases significantly with increasing amount of the grafted material. The antithrombogenic properties of polyesterurethane tubes modified by the radiation-induced grafting of 2-hydroxyethyl methacrylate have been investigated.¹⁰⁹ Tests *in vivo* showed that a considerable amount of graft is required for an appreciable enhancement of the antithrombogenic properties. The radiation-induced grafting of 4-vinylpyridine (4-VP) + 2-(*N,N*-diethylamino)ethyl methacrylate and 4-vinylpyridine + methacrylic acid mixtures on polyethylene catheters has been studied.¹¹⁰ The catheters were tested *in vivo*. The operational lifetime of the catheters depends significantly on the amount of graft. The haemocompatibility of the radiation-grafted PE polymers with poly(2-hydroxyethyl methacrylate) and poly(2,3-dihydroxypropyl methacrylate) has been studied.¹¹¹ In the investigation of the adhesion of thrombocytes on poly(vinyl chloride) with radiation-grafted polyacrylic acid, it was established that the adhesion of thrombocytes diminishes significantly with increase in the amount of graft and with decrease in the wetting angle.¹¹² One of the ways of enhancing the antithrombogenic properties of polymers involves the formation on their surfaces of polyelectrolyte complexes (PEC).^{113, 114} PEC are formed on the surfaces of polymers as a result of the interaction of the radiation-grafted poly(acrylic acid) with polyamines. The appearance of PEC gives rise to the formation of a microheterogeneous structure with alternation of hydrophilic and hydrophobic sections.

Lundell *et al.*⁴⁰ investigated the radiation-induced grafting on the surfaces of PP of mixtures of *N*-vinylpyrrolidone and acrylic acid and also vinyl acetate and crotonic acid. Pronounced antithrombogenic properties were attained after partial neutralisation of crotonic acid with alkali. It was concluded that the negative surface charge plays an important role.^{40–47} It was established⁴² that polymers with grafted poly(vinyl acetate)

(with subsequent partial hydrolysis of the acetate groups) and *N*-methyl-*N*-vinylacetamide exhibit the best haemocompatibility.

The main conclusion which may be reached from the data described above concerning the use of hydrophilic monomers in order to enhance the antithrombogenic properties of polymers is that, with increase in the water content, thrombogenesis diminishes, but, in prolonged tests *in vivo* the minimum thrombogenesis is attained for a definite water content.¹⁰⁵ Radiation-induced grafting of *N*-vinylpyrrolidone as well as acrylamide and its derivatives affords good results. The presence of negatively charged groups on the surface is important.¹¹⁵ The adsorption of enzymes and blood cells diminishes with increase in the amount of graft.¹¹⁶ The presence of certain admixtures in the monomers employed for radiation-induced graft polymerisation influences significantly the haemocompatibility because it can alter the nature of the sorption of proteins.¹¹⁷

An extremely promising aspect of the preparation of antithrombogenic polymeric materials involves the modification of the surface of polymeric materials by radiation-induced graft polymerisation followed by the introduction into the modified layers of physiologically active substances (PAS), which act in the blood clotting stage. The radiation-induced grafting of monomers with active functional groups capable of reacting with the PAS is usually carried out for this purpose. The form of the bond between the PAS and the polymer (covalent, ionic, or physical capture) as well as the microenvironment of the PAS in the polymer are important. Radiation-induced graft polymerisation has been used^{63, 118–122} to obtain modified polymeric materials containing on the surface organic cations to which heparin is attached as a result of the formation of ionic bonds. As an example, styrene was grafted to different polymers with subsequent chloromethylation and quaternisation.¹¹⁸ 4-Vinylpyridine was used for radiation-induced grafting followed by quaternisation.¹¹⁹ Polyolefins, silicone rubber, and polytetrafluoroethylene have been used as the polymers. The modified polymers thus obtained exhibited a satisfactory haemocompatibility, possibly as a result of the partial washing away of heparin during use.¹²³ Another monomer which is employed for grafting to achieve ionic binding of heparin is 2-(*N,N*-diethylamino)ethyl methacrylate.^{124, 125} In all probability, the covalent binding of PAS is more promising. Radiation-grafted polymers with grafted poly(2-hydroxyethyl methacrylate) chains, which were activated by bromocyanogen with subsequent addition of streptokinase (lysis of fibrinogen on the surfaces), were obtained.¹²³ Another method of binding enzymes is the radiation-induced grafting of methacrylic acid followed by the application of the carbodiimide method in order to bind the BAS.^{123, 125} The employment of a spacer for the attachment of biomacromolecules to radiation-grafted polymers is very important in this procedure.¹²³

The binding of albumin to the radiation-grafted hydrogel, obtained by the radiation-induced grafting of a mixture of *N*-vinylpyrrolidone and 2-hydroxyethyl methacrylate, greatly increases when a spacer is used.^{123, 126} The process involving the attachment of PAS to modified polymer surfaces using bromocyanogen is illustrated in Scheme 1.¹²⁶

A significant increase in the sorption of albumin after the modification of polytetrafluoroethylene by the radiation-induced grafting of *N*-vinylpyrrolidone has been established.¹²⁷ The copolymers obtained by the radiation-induced grafting of acrylic acid, 2-hydroxyethyl methacrylate, a mixture of maleic anhydride and acrylic acid, as well as a mixture of acrylic acid and acrylamide, which are used for the immobilisation of human albumin, were grafted by Müller-Schulte and Horster.¹²⁸ In the covalent binding of albumin, bromocyanogen, hydrazine and glutaraldehyde, as well as 1-hydroxybenzotriazole, which ensures the maximum binding of human albumin, were used as the condensing agents. Glutaraldehyde has also been used for the covalent binding of PAS to radiation-grafted polyacrylamide.¹²³

Novel methods for the enhancement of haemocompatibility using radiation-induced graft copolymerisation have been described.^{23–26} One of them consists in the radiation-induced grafting on polymer surfaces of acrylic acid chlorides²³ and subsequent introduction of PAS.²⁶ Modified polymers containing on the surface heparin, various enzymes (for example, fibrinolysin), albumin, *etc.* have been obtained in this way. The simultaneous presence of heparin and enzymes on the polymer surface gives rise to effective thromboresistant properties of polymeric materials.²⁶ Reactive acid chloride groups may be obtained also by treating with thionyl chloride radiation-grafted copolymers with polyacrylic acid.¹²⁹ Another procedure consists in the radiation-induced grafting of allylamine on the polymer surface. The grafting of this monomer was achieved solely in the presence of orthophosphoric acid (suppression of the degradative chain transfer in the polymerisation of allylic monomers). Glutaraldehyde has been used to bind enzymes with an amino group.²⁵ Hydrazide groups may be used for the immobilisation of PAS. The hydrazidation of radiation-grafted copolymers of PE with acrylic monomers has been investigated.^{59, 130}

Methods have been developed for the modification of polymer surfaces by the radiation-induced grafting of macromonomers in the presence of hydrophilic monomers (acrylamide, *N*-vinylpyrrolidone, *etc.*) and a cross-linking agent.^{26, 131–133} The macromonomers may be obtained by introducing an active double bond into the PAS (heparin, enzymes) molecules in acylation by the chlorides of acrylic and methacrylic acids.^{25, 134–136} It was established that the acylation process does not affect the structure of the molecules of the PAS and its physiological activity. The macromonomers are capable of entering into the copolymerisation reaction with various monomers (acrylamide, *N*-vinylpyrrolidone).¹³⁴ The homopolymerisation of macromonomers leads to the formation mainly of products with a low degree of polymerisation.¹³⁶

The radiation-induced grafting of PAS macromonomers jointly with hydrophilic monomers on various polymeric materials afforded biospecific sorbents and modified materials employed in contact with blood. In the latter case, the polymer was modified by grafting the heparin macromonomer and trypsin or fibrinolysin as the fibrinolytic enzyme. It was shown that the polymers modified by a mixture of heparin and trypsin exhibit a higher haemocompatibility than the polymers containing only heparin. The increased thromboresistance of such materials, which has been investigated in experiments *in vitro* and *in vivo*, can be explained by the fact that heparin binds fibrinogen, which is

lysed by trypsin.^{137–139} The grafting of a mixture of acrylamide and the cholesterol ester of *N*-methacryloyl- ω -aminocaproic acid on PE has been investigated.¹⁴⁰ The graft results in the formation on the PE surface of a hydrophilic layer in which cholesterol groups are immobilised covalently. This led to the formation of modified polymers capable of adsorbing heparin selectively from the blood flow.

It has been shown^{89, 141} that the employment of *N*-methyl-*N*-vinylacetamide for the modification of polymers in order to increase their haemocompatibility is promising.^{89, 141} Diverse polymers, modified by grafting *N*-methyl-*N*-vinylacetamide, have been investigated in detail by various physicochemical methods.¹⁴¹ The haemocompatibility of ethylene–propylene rubber, modified by the radiation-induced grafting of acrylamide, *N*-vinylpyrrolidone, and 2-hydroxyethyl methacrylate, has been studied.^{142, 143} The experiments were performed *in vitro*. It was established that there is no linear relation between the amount of the graft and the hydrophilicity, on the one hand, and the degree of haemocompatibility, on the other. The relation is complex.

During recent years, there has been a growth of interest in the use of polyphosphazenes as biomaterials. The radiolysis of polyphosphazenes has been investigated¹⁴⁴ and it has also been established (in experiments *in vivo*) that the modification of polyphosphazenes by the radiation-induced grafting of *N*-vinylpyrrolidone makes it possible to increase their haemocompatibility.¹⁴⁵ The influence of the preliminary ⁶⁰Co γ -irradiation of polyurethane on its coating with albumin has been studied.¹⁴⁶

Radiation-induced graft polymerisation has been used to modify various polymers in order to accelerate the growth of endothelial cells on the surface.^{147, 148}

It has been suggested¹⁰ that the lack of success in the creation of polymeric materials designed for prolonged use in contact with blood within a living organism is associated with the inadequate knowledge of the biochemical processes occurring at the implant–blood interface and also with the attempts to relate to haemocompatibility to any one parameter of the surface (hydrophilicity, free surface, morphology, *etc.*).

Radiation-induced graft polymerisation has been used in a series of investigations^{64, 149, 150} to modify the surfaces of polymeric articles used in contact with blood and its components. Studies have been performed in recent years on the preparation of haemocompatible polymers by radiation-induced graft polymerisation initiated when polymers are irradiated with accelerated heavy ions.⁶²

Studies have been carried out on the use of radiation-induced graft polymerisation for the creation of various medical polymeric materials: blood vessel prostheses, intravenous catheters, implants, tissue-protecting, antiinflammatory, and ophthalmological materials, *etc.* The materials have been called ‘hydrografts’.¹⁵⁰

III. Preparation of special sorbents

Radiation-induced graft polymerisation is used in the creation of carriers for affinity chromatography,^{44, 61, 155} immunoabsorbents,^{156–165} and biospecific sorbents^{66, 148, 166, 167} and also for the growth of endothelial cells.^{147, 168–171}

Effective sorbents for affinity chromatography, obtained by modifying polyamide-6 beads by means of radiation-induced graft polymerisation, have been described. Mainly 2-hydroxyethyl methacrylate, *N*-vinylpyrrolidone, and acrylamide have been used as the monomers.^{44, 61, 151, 153–155} The conditions in the graft polymerisation and primarily the choice of solvents with specific solubility parameters, as well as the choice of swelling agents are very important.^{61, 154} Compared with the known sorbents (agarose), the capacity of the sorbents obtained is appreciably higher in the separation of low-density lipoproteins and antibody immunoglobulin G. The properties of the adsorbents may be varied by varying the conditions in the graft polymerisation. The carriers

obtained for affinity chromatography are cheaper compared with the known and expensive carrier — sepharose with protein A.⁶¹

The sorbents obtained may be used for the removal of excess cholesterol in patients suffering from cholesterinemia.⁶¹

It has been established that, when sorbents based on polyamide-6 modified by radiation-induced graft polymerisation are used, the amount of lectin extracted from mistletoe increases appreciably. Sorbents with immobilised urease may be used for the rapid determination of the content of urea in kidney diseases. The method is based on the continuous and rapid enzymic hydrolysis of urea and the determination of ammonia.¹⁵⁵

The modification of polystyrene plates by the radiation-induced grafting of monomers containing hydrazide groups has been described.¹⁵⁶ The modified plates adsorbed effectively immunoglobulin E and low-molecular proteins. In order to increase the hydrophilicity of polystyrene, it is ⁶⁰Co γ -irradiated. By employing the modified polystyrene plates, it is possible to determine the concentration of immunoglobulin E (down to 0.1 μ g ml^{–1}).¹⁵⁶

The modification of LDPE, poly(vinyl chloride) and polystyrene by the radiation-induced graft polymerisation of methacrylic acid and acrylamide with subsequent immobilisation of the Brucella antigen resulted in the formation of systems for diagnostic tests (ELISA). The sensitivity was improved and the reactivity of the antibodies increased significantly.¹⁶⁴

Methods have been developed for the modification of agarose,⁶⁶ sepharose, and sephadex¹⁶⁶ by the radiation-induced grafting of *N*-acryloyloxysuccinimide with subsequent addition of bovine serum albumin (BSA). The separation of D,L-tryptophans was studied.¹⁶⁶

Radiation cross-linked poly(vinyl alcohol) has been used in affinity chromatography. The carriers based on this polymer are distinguished by a satisfactory morphology, biocompatibility, and a high capacity.^{152, 153}

Blood detoxicants based on modified polypropylene fibres have been obtained.¹⁴⁰ Specific sorbents for the removal of heparin have been created with the aid of radiation-induced grafting.¹⁴⁰

Radiation-induced graft polymerisation has been used to modify various polymers in order to form on their surface a coating comprising endothelial cells.

This problem has been examined in greatest detail by Kirkpatrick *et al.*¹⁴⁷ The radiation-induced graft polymerisation of 2-hydroxyethyl methacrylate, *N*-vinylpyrrolidone and 2-(*N,N*-dimethylamino)ethyl methacrylate on a whole series of polymers (LDPE, polytetrafluoroethylene, polyamide, *etc.*) has been investigated. It was established that the conditions in the graft polymerisation (solvent, composition of copolymers, *etc.*) are very important for the successful growth of cells. Electron micrographs of the surface with layers of endothelial cells have been obtained. It was noted that the presence of OH groups on the surfaces of polymers is important for cell growth.

Methods have been devised for the modification of polymeric materials, as a result of the application of which the polymers can undergo a change in their hydrophilic and hydrophobic properties under the influence of small changes in temperature. This makes it possible to regulate the adhesion and viability of the cultures.¹⁶⁸

IV. Synthesis of polymeric carriers for medicinal preparations

Radiation-induced polymerisation is used in the synthesis of polymeric carriers for medicinal preparations (antibiotics, antiseptics, *etc.*). The following advantages of the radiation initiation of polymerisation in the synthesis of polymeric carriers for medicinal preparations compared with ‘material’ initiation have been noted. Firstly, fairly pure polymers are obtained (without initiator residues). Secondly, it is possible to regulate comparatively easily the molecular-mass characteristics of the polymers by

varying the radiation dose rate. Thirdly, in a number of instances the yield of the polymers is much higher than the yield obtained on initiation with 'material' initiators.

Radiation-induced polymerisation has been used in a series of studies^{172–175} for the creation of copolymers based on *N*-vinylpyrrolidone with undecenoic, oleic, and crotonic acids. Modifying agents for PAS, ensuring a fairly intense hydrophobic interaction between the copolymer and the PAS, are obtained in this case. On initiation using 'material' initiators, it is impossible to obtain copolymers in a sufficiently high yield. The radiation-induced copolymerisation of *N*-vinylpyrrolidone with undecenoic and oleic acids in ethanol for doses of 50–150 kGy (dose rates of 0.23 and 0.04 Gy s⁻¹) has been investigated.¹⁷² It was established that the yield of the copolymer and the rate of copolymerisation depend significantly on the mixture composition, a statistical copolymer without adjacent COOH units being formed. The relative reactivity of the acids is zero, while the reactivities of *N*-vinylpyrrolidone vary in the ranges $0.61 < r < 0.94$ for undecenoic acid and $0.90 < r < 1.31$ for oleic acid. The copolymer units are enriched in *N*-vinylpyrrolidone.

The radiation-induced copolymerisation of *N*-vinylpyrrolidone with crotonic acid in ethanol at different dose rates in the range 0.25–3.26 Gy s⁻¹ has been investigated.¹⁷³ In the initial stage, the rate of polymerisation is proportional to the radiation dose rate raised to the power 0.5, but, with increase in the degree of conversion, the above parameter tends to 0.8. With increase in dose rate and degree of conversion, the molecular mass of the copolymer diminishes. The composition of the copolymer is independent of the dose rate and its molecular mass may be regulated by varying the dose rate. Copolymers with a viscosity-based mean molecular mass of 1.2×10^4 – 7.0×10^4 have been obtained.

The dependence of the molecular mass and the molecular mass distribution in the radiation-induced copolymerisation of *N*-vinylpyrrolidone with crotonic acid (CA) in ethanol or 2-propanol on the dose for a constant monomer ratio *N*-vinylpyrrolidone:CA = 85:15 has been examined.¹⁷⁴ It was established that the molecular mass distribution can be regulated by selecting the radiation dose. It was shown that in alcohols the yield of the copolymer is high (93%–98%) for a dose of 4.5×10^4 Gy. The radiation-chemical yield of the copolymerisation is $(6–7) \times 10^3$ molecules per 100 eV (dose rate 0.28 Gy s⁻¹). The radiation-induced copolymerisation of *N*-vinylpyrrolidone with allylamine and 2-(*N,N*-dimethylamino)ethyl methacrylate in aqueous organic solvents and the properties of the copolymers have been studied. In this process, the copolymers are obtained in a high yield and with a narrow molecular mass distribution in the molecular mass range from 10^3 to 4×10^6 .¹⁷⁵

Thus copolymers based on *N*-vinylpyrrolidone can be obtained by the radiation-induced polymerisation method with a fairly high yield and their molecular mass characteristics may be varied in the required direction by selecting the polymerisation conditions. The rate of polymerisation depends significantly on the mixture composition, while the composition of the copolymer is independent of the dose rate. A distinctive feature of these copolymers is that, together with the strongly hydrophilic component (carboxy groups, *N*-vinylpyrrolidone units), the polymer chain contains a significant hydrophobic component (the hydrocarbon part of the carboxylic acids). Such copolymers are non-toxic.

The radiation-induced copolymerisation of *N*-vinylpyrrolidone with allyl alcohol in ethanol or 2-propanol at a dose rate of 2 Gy s⁻¹ (for doses in the range 30–200 kGy) has been studied by Solovskii *et al.*¹⁷⁶ The radiation-induced and 'material' copolymerisations were compared. The yields in the radiation-induced copolymerisation exceed by a factor greater than 2 the yields in the 'material' polymerisation. The yield of the copolymer is 50%–90% and diminishes with increase in the concentration of allyl alcohol. The maximum yield occurs for a 30% content of the comonomers in the alcohol. Conditions for the preparation of

copolymers with a low molecular mass and a narrow molecular mass distribution have been found.

The radiation-induced copolymerisation of *N*-vinylpyrrolidone with vinyl acetate at 5 °C and a dose rate of 14.5 Gy min⁻¹ has been studied^{177,178} and the copolymerisation constants have been determined.

Panarin *et al.*,¹⁷⁹ investigated the radiation-induced polymerisation of *N*-vinylpyrrolidone under various conditions. The molecular-mass characteristics of *N*-vinylpyrrolidone were determined. An important advance in radiation-induced polymerisation is in this case the possibility of the fine regulation of the molecular-mass characteristics, which is particularly important for this polymer, used as a blood plasma substitute.

The carriers based on *N*-substituted acrylamide and methacrylamide are extremely interesting. The water content in these hydrogels depends significantly on the external conditions (temperature, pressure, *etc.*), which makes it possible to increase the effectiveness of the action of the medicinal preparations immobilised in them.¹⁸⁰

The study of methacrylic acid–triethylene glycol dimethacrylate copolymers as carriers for medicinal substances (insulin) demonstrated their resistance to the action of the acid medium in the stomach and the rapid liberation of the hormone on entering the intestine.¹⁸¹

The radiation-induced copolymerisation of *N*-vinylpyrrolidone with various aminoacrylates and methacrylates has been investigated. Polymeric carriers for BAS with a high molecular mass have been obtained in a satisfactory yield.^{182,183}

The radiation-induced polymerisation of hydrophilic monomers is used for the creation of porous polymeric carriers for the immobilisation of insulin and interleukin. The pore dimensions and the rate of liberation of medicinal substances are regulated by the polymerisation conditions.¹⁸⁴ The radiation-induced copolymerisation of 2-hydroxyethyl methacrylate and methacrylic acid is used to prepare carriers for contraceptives.¹⁸⁵

The radiation-induced polymerisation of acrylamide and *N*-vinylpyrrolidone in aqueous solutions has been investigated.¹⁸⁶ The influence of the dose rate and the concentration of monomers on the rate of polymerisation was studied. The role of the water radiolysis products in the initiation of polymerisation was established and the dependence of the gel formation dose on the concentration of monomers was determined.

The methods for the preparation and properties of antimicrobial polymers have been described in a monograph.¹⁸⁷

Foss and Ebersol¹⁸⁸ used the radiation-induced polymerisation of acrylamide for the preparation of thin (0.25–1 mm) films of polyacrylamide gels with a specified pore distribution. The standard size distribution of pores was ensured by the conditions in the ⁶⁰Co γ -irradiation with computer control. The films were used for the high-resolution separation of proteins by electrofocusing and electrophoretic methods.

The employment of radiation-induced polymerisation for the preparation of polymer microspheres occupies a special place. The formation of microspheres from various acrylates as a result of radiation-induced polymerisation has been examined in a number of studies.^{189–200} The diameter of the microspheres increases with increasing hydrophilicity of the monomer¹⁸⁹ and the nature of the solvent is also important.¹⁹⁰ Polymer microspheres containing amino acids have been obtained with the aid of radiation-induced polymerisation. The microspheres have been used for immunochemical assay in relation to malaria.¹⁹¹

The preparation of microspheres by the radiation-induced copolymerisation of diethylene glycol dimethacrylate with acrylamide has been described in review.¹⁹² The size of the microspheres was 10–10 000 Å. The microspheres are used mainly for immunoassay. The synthesis of microspheres based on polyacrylamide, poly(2-hydroxyethyl methacrylate), poly(methyl methacrylate), and poly(acrylic acid) by radiation-induced suspension polymerisation in methanol has been described.¹⁹⁴ The radiation-

induced grafting of 2-hydroxyethyl methacrylate, acrylamide, and their mixtures on microspheres has been studied.¹⁹⁴

The preparation of microspheres based on polyacrolein, on the surface of which there are aldehyde groups which react readily with proteins, is of significant interest.^{195–197} Cross-linked polyacrolein has been synthesised by the radiation-induced polymerisation of acrolein in bulk or in a water–acetone mixture at temperatures ranging from -15 to 25°C . The yield of this polymer depends on the reaction conditions and may reach 100%. The principal polyacrolein unit is a six-membered oxygen-containing ring and the interchain cross-links are formed by ester bonds; furthermore, free aldehyde groups are present in polyacrolein. It has been established by electron microscopy that polyacrolein consists of microspheres with a particle size of $1\text{--}30\text{ }\mu\text{m}$. The size of the particles depends on the conditions in the preparation of the polymer. The formation of microspheres in the radiation-induced copolymerisation of acrolein with hydroxyethyl methacrylate or poly(ethylene glycol dimethacrylate) in 1% PVA solution at -78°C has been studied.¹⁹⁶ The yield of the copolymers depends on the content of the vinyl monomer. The size of the microspheres increases with increase in the concentration of the vinyl monomer. The properties of the microspheres obtained, containing aldehyde groups, have been investigated.¹⁹⁷ Microspheres of the ‘core–shell’ type, having aldehyde groups on the surface, have been synthesised with the aid of the radiation-chemical modification of polystyrene particles ($0.6\text{ }\mu\text{m}$ in diameter) by acrolein. The structure and properties of the polymers obtained were studied by various methods.¹⁹⁸ It was established that the content of aldehyde groups is 60% of the theoretically possible. A structure was proposed for graft polyacrolein. It was shown that the radical polymerisation of acrolein involves mainly the vinyl bond. The form of the microspheres does not change as a result of the polymerisation.¹⁹⁹

The principal advantages of the preparation of polymer microspheres with the aid of radiation-chemical methods are the high purity of the product (the absence of impurities arising from the initiator) and the possibility of carrying out the polymerisation under a wide range of conditions (temperature, rate of initiation), and this makes it possible to regulate the size of the microspheres comparatively readily. It is sometimes possible to achieve relatively easily the radiation-induced cross-linking of the microspheres, which is difficult to do by traditional methods.

Thus the radiation-induced polymerisation is a promising method for the creation of polymeric materials used as carriers for medicinal preparations. In many instances, it is possible to achieve the synthesis of unique copolymers, the preparation of which with the aid of ‘material’ initiators is very difficult. The vast majority of studies have been devoted to the synthesis of copolymers based on *N*-vinylpyrrolidone. The choice of the solvent, of the radiation dose and of the radiation dose rate is very important for radiation-induced polymerisation, determining the yield of the copolymer and its molecular-mass characteristics.

V. Immobilisation of biologically active substances

1. Immobilisation of enzymes

During recent years, radiation-induced polymerisation has been used for the immobilisation of various BAS in polymer matrices. Such a process is carried out in order to fix the BAS for reuse in order to achieve economies in their employment (some are very expensive), in order to stabilise the BAS in relation to thermal influences, solvents, and pH, in order to prepare polymeric articles of different shape (films, tablets, needles, cylinders, *etc.*), for the controlled liberation of BAS under the conditions of a specific application, and for the employment of effects associated with the polymer matrix (strength, rheology, *etc.*). The immobilisation of BAS in polymer matrices is achieved by the joint polymerisation of monomers mixed with the BAS or by the covalent attachment of these compounds to different polymers with active functional groups. Reviews have been devoted to various aspects of the

preparation of polymeric biomaterials by radiation-induced polymerisation and grafting.^{201–211} A wide range of substances have been used as the BAS: enzymes,^{212–265} yeast cells,^{266–270} haemoglobin,^{271–275} anticancer preparations,^{276–279} chloroplasts,^{280,281} various medicines, antibodies, microorganisms and microbial cells.^{281–297} Polymeric biomaterials with immobilised BAS have a wide range of applications. Allowance for the specific features of particular spheres of their application is important. Table 2 presents data on the immobilisation of BAS using radiation-chemical methods.

The radiation-induced polymerisation for the immobilisation of BAS has the following advantages.^{201,202}

1. The possibility of carrying out the process over a wide range of conditions, including polymerisation at low temperatures of supercooled viscous monomers, solid monomers and multiphase systems.
2. A fairly wide selection of monomers for polymerisation.
3. A decrease in the inhibiting effect of oxygen and other impurities.
4. The absence of residual amounts of the catalyst and the unpolymerised monomer in the polymer. The latter is very important, since a partly unpolymerised monomer has a toxic effect, particularly in the immobilisation of cells.
5. The ease of cross-linking to different extents by selecting the dose absorbed.
6. The comparative simplicity of the preparation of porous and complex composite structures.
7. The simplicity of the manufacture of preparations of any arbitrary shape (tablets, cylinders, needles, *etc.*).
8. A decrease in the deactivation of unstable BAS in the polymer.
9. The high productivity of the immobilisation apparatus when electron accelerators are used as the sources of radiation.
10. The possibility of preparing ultrathin particles and membranes.

There are three main immobilisation methods: covalent binding of the BAS to the polymer — the chemical method, ionic binding or physical adsorption of the BAS, and physical capture of BAS in the polymer. An advantage of the chemical method is the solid-phase fixation of the BAS and the impossibility of its removal on prolonged use. The disadvantage of the method are as follows: a comparatively low yield of the activity of the BAS (a significant loss of activity in the immobilisation process), an appreciable selectivity in relation to the BAS reaction conditions, and the difficulty of its employment for the immobilisation of microorganisms. The chemical immobilisation method works as a result of the formation of chemically reactive functional groups in

the polymer, mainly $-\text{COOH}$, $-\text{OH}$, $-\text{NH}_2$, $-\text{C}=\text{O}$ and others

capable of covalent binding of the BAS. The reactive functional groups are introduced into the polymer by radiation-induced graft polymerisation (for more details, see Section II as well as other communications 2, 4, 18, 26, 210, 211). Mainly the immobilisation of BAS as a result of physical capture, ionic binding, or physical adsorption in polymer matrices is considered in this section. The advantages of the physical capture method are as follows: comparative ease of application, a fairly high reactivity and universality of the BAS (BAS without specific functional groups — various microorganisms, cells, *etc.* — may be used for immobilisation), and the possibility of employing monomers with a wide range of hydrophilic and hydrophobic properties. The physical capture of the BAS in polymers is achieved by means of the radiation-induced polymerisation of the monomer mixed with the BAS.

Radiation-induced polymerisation for the immobilisation of enzymes was first described by Dobo,²¹² who obtained immobilised enzymes in polyacrylamide matrices by the solid-phase polymerisation of acrylamides mixed with the enzyme. Subsequently Kaetsu and co-workers^{201–205} developed a method for the immobilisation of BAS mixed with monomers capable of

Table 2. Immobilisation of BAS in polymer matrices with the aid of radiation-induced polymerisation.

Monomers, immobilisation components	Immobilisation conditions	Remarks	Ref.
<i>BAS — trypsin</i>			
Acrylamide	radiation-induced polymerisation of acrylamide mixed with the enzyme	solid-phase polymerisation using ^{60}Co γ -radiation	212
2-Hydroxyethyl methacrylate, tris(hydroxymethyl)propane triacrylate, 2-hydroxyethyl acrylate, poly(ethylene glycol diacrylate), methoxypoly(ethylene glycol methacrylate)	radiation-induced polymerisation of monomers mixed with aqueous BAS solution; irradiation was carried out at -78°C with a dose of 10 kGy	polymerisation resulted in the formation of a porous structure; the influence of pore size on enzyme activity and the thermal stability of the immobilised trypsin were investigated	216
2-Hydroxyethyl methacrylate	radiation-induced graft polymerisation on polyethylene powder, hydrolysis of the copolymer and the attachment of the enzyme to the functional groups with the aid of the carbodiimide method	the influence of pH on the stability of the enzyme was studied	218
2-Hydroxyethyl methacrylate	radiation-induced graft polymerisation on natural rubber by the preirradiation method	the activity of the immobilised enzyme was studied	221
<i>p</i> -Nitrostyrene	direct radiation-induced graft polymerisation of <i>p</i> -nitrostyrene on polypropylene and poly(vinyl chloride)	the nitro groups in the graft copolymer are converted into isothiocyanate groups	219
	radiation-induced grafting of <i>p</i> -nitrostyrene to different polymers; radiation-induced grafting of polystyrene with subsequent nitration of polystyrene	the mechanism of the action of additives accelerating the graft polymerisation was examined	220
Acrylic acid, acrylonitrile, 2-hydroxyethyl methacrylate, <i>N</i> -vinylpyrrolidone, acrylamide	radiation-induced graft polymerisation using a wide range of monomers; trypsin was attached covalently with the aid of the carbodiimide method or glutaric dialdehyde	preparation of polymer membranes; the study of prospects for the employment of these membranes in the milk industry in order to diminish the allergenic effect of milk (decomposition of proteins with a low molecular mass)	217
<i>BAS — trypsin, glucose oxidase</i>			
2-Hydroxyethyl methacrylate	radiation-induced graft polymerisation by three different methods	it was established that the immobilised enzymes are stable over a wide pH range	222
<i>BAS — α-chymotrypsin, ribose, urease, ribonuclease</i>			
Methacrylic acid esters, acrylamide, and its derivatives	radiation-induced polymerisation of monomers in a mixture with aqueous enzyme solutions; irradiation at -20°C ; dose 5 kGy		224
<i>BAS — α-chymotrypsin, trypsin, glucose oxidase, papain</i>			
Methacrylic acid, 2-hydroxyethyl methacrylate	radiation-induced graft polymerisation of 2-hydroxyethyl methacrylate and methacrylic acid on polyethylene	covalent immobilisation on the grafted chains	259
<i>BAS — α-chymotrypsin, trypsin, fibrinolysin</i>			
Acrylic acid chloride, allylamine	radiation-induced graft polymerisation of acrylic acid chloride on various monomers with subsequent addition of the BAS <i>via</i> the acylation of the acid chloride group; graft polymerisation of allylamine and attachment of the BAS with the aid of glutaric dialdehyde	covalent binding of the BAS	215
<i>BAS — urease</i>			
Acrylamide	starch with grafted polyacrylamide	the dependence of the enzyme activity on the method of application was studied	213
Poly(dimethoxyethoxy)phosphazene	irradiation of enzyme in polymer solution	retention of 80% of enzyme activity	223
<i>BAS — glucoamylase</i>			
Poly(ethylene glycol diacrylate), 2-hydroxyethyl acrylate, tris(hydroxymethyl)propane triacrylate	irradiation by electron accelerator; dose 50 kGy	specimens of planar polymeric materials with immobilised enzymes were obtained	234

Table 2 (continued).

Monomers, immobilisation components	Immobilisation conditions	Remarks	Ref.
<i>BAS — glucoamylase</i>			
Hydroxyalkyl methacrylate, poly(ethylene glycol diacrylate)	radiation-induced polymerisation at a low temperature	the influence of the nature of the monomer on the character of the immobilisation of the enzyme was studied	252, 253
2-Hydroxyethyl methacrylate, <i>N</i> -vinylpyrrolidone, acrylamide	radiation-induced copolymerisation of 2-hydroxyethyl methacrylate with comonomers at a low temperature	immobilisation of enzymes in different copolymers; the influence of the composition of the copolymer on the immobilisation was studied	255
2-Hydroxyethyl methacrylate, diethylene glycol dimethacrylate	radiation-induced polymerisation at reduced temperature of the monomers mixed with an aqueous enzyme solution	the distribution of the enzyme in the polymer matrix and the rate of its liberation were investigated	235
Poly(vinyl alcohol) (PVA)	irradiation of aqueous PVA solutions in the presence of the enzyme up to a dose of 40 kGy	the influence of the irradiation dose on the enzyme activity was studied	236
	PVA was mixed with the enzyme and irradiated on an electron accelerator up to doses of 60–360 kGy	a linear accelerator with a beam energy of 7.5 MeV was used; a PVA strip 20 cm wide and containing the enzyme was irradiated	237
<i>BAS — glucoamylase, β-galactosidase, invertase</i>			
Acrylamide, <i>N,N</i> -dimethylacrylamide, 2-hydroxyethyl methacrylate, <i>N</i> -vinylpyrrolidinone, acrylic acid salts, acrylic acid	electron irradiation on accelerators was employed; radiation-induced grafting of poly(acrylic acid) with subsequent immobilisation of the BAS	the influence of the irradiation dose on the rate of liberation of the enzyme was studied, methods were developed for the preparation of membranes with immobilised enzymes, and procedures were devised for the preparation of spherical particles with immobilised enzymes	225–229
<i>BAS — glucoamylase, AFP-antibodies</i>			
Poly(ethylene glycol dimethacrylate), poly(ethylene glycol diacrylate), tris(hydroxymethyl)propane triacrylate	irradiation on an electron accelerator of thin monomer films containing the BAS at temperatures from –75 to 35 °C and for electron energies of 150–300 KeV	preparation of polymer membranes containing the BAS; the influence of the monomer concentration and of the dose on the enzyme activity was studied	233
<i>BAS — glucoamylase, invertase, β-galactosidase</i>			
Acrylamide	irradiation of enzymes in aqueous acrylamide solution	the method of preparation of the specimens was described in detail; the irradiation doses are given	256
<i>BAS — amylase, yeast cells</i>			
Acrylic acid	radiation-induced grafting of poly(acrylic acid) on low- and high-density polyethylene by the direct method from aqueous solution	covalent binding of the BAS	232
<i>BAS — protease (<i>Bacillus mesentericus</i>)</i>			
Acrylic acid, allyl alcohol	direct grafting of the monomers on polyethylene	preparation of polymers with hydrazide and azide groups; covalent binding	214
<i>BAS — lipase</i>			
2-Hydroxyethyl methacrylate, 2-hydroxyethyl acrylate, poly(ethylene glycol diacrylate), tris(hydroxymethyl)propane trimethacrylate	radiation-induced polymerisation in the presence of the enzyme at a low temperature; dose 10 kGy	the influence of the structure of the polymer matrix and the monomer concentration on the enzyme activity was studied	238
<i>BAS — cellulase</i>			
Hydroxylated acrylates	radiation-induced polymerisation at a low temperature	membranes with different monomer concentrations and different hydrophilicities were prepared	240
Poly(ethylene glycol diacrylate)	radiation-induced polymerisation at a low temperature; dose 10 kGy	the structure and nature of the pores in the polymer matrix and its influence on the enzyme activity were studied	

Table 2 (continued).

Monomers, immobilisation components	Immobilisation conditions	Remarks	Ref.
<i>BAS — cellulase</i>			
Glycidyl methacrylate, polystyrene	radiation-induced polymerisation of glycidyl methacrylate in the presence of polystyrene at -78°C with subsequent immersion in cooled methanol; dose 10 kGy	polymer microspheres were obtained; the influence of the conditions in the preparation on the number and diameter of the microspheres were studied	242
Dispersed polyurethane prepolymer	toluylene and 2-hydroxyethyl methacrylate were mixed; the mixture was kept for several minutes and treated with an aqueous solution of cellulase; irradiation at -78°C ; dose 10 kGy	disperse particles of different size were obtained	243
2-Hydroxyethyl methacrylate	radiation-induced polymerisation at -78°C in the presence of aqueous enzyme solution	discs 1 mm thick were prepared; the influence of the thickness of the disc and the monomer concentration on the enzyme activity was studied	244
2-Hydroxyethyl methacrylate, tetra-ethylene glycol diacrylate	radiation-induced polymerisation of monomers on the surfaces of tubes	tubular enzyme reactors were created	251
2-Hydroxyethyl methacrylate, neopentyl glycol dimethacrylate	radiation-induced polymerisation in the presence of sodium acetate	polymer particles 50–1000 μm in diameter were obtained; the influence of various factors on the enzyme activity was studied	254
<i>BAS — cellulase, cellobiase</i>			
2-Hydroxyethyl methacrylate	radiation-induced polymerisation of aqueous monomer solution in the presence of the enzyme; irradiation at -78°C	discs 1–2 mm thick were prepared; the influence of added silica gel and poly(ethylene glycol) on the enzyme activity was studied	239
Acrylamide	radiation-induced polymerisation of acrylamide	the hydrolysis of plant raw material with the aid of immobilised cellulase is described in detail; methods for the determination of the activity of cellulolytic enzymes are described	245
<i>BAS — catalase</i>			
Acrylamide	radiation-induced polymerisation of the monomer at -78°C in the presence of <i>N,N'</i> -methylene-bisacrylamide	the enzyme was immobilised on polyacrylamide gels modified by acyl azide	246
<i>BAS — glucose oxidase</i>			
2-Hydroxyethyl methacrylate	the enzyme was deposited on a nylon net in the presence of the monomer with subsequent radiation-induced polymerisation	network materials with immobilised enzymes were obtained	248
Acrylic acid, methacrylic acid	radiation-induced graft polymerisation of the monomers on polyethylene	immobilisation using the carbodiimide method	263
<i>BAS — glucose oxidase, α-amylase</i>			
Acrylamide	irradiation of the enzyme mixed with an aqueous acrylamide solution	dose < 5 kGy	296
<i>BAS — glucose oxidase, glucose peroxidase, urokinase</i>			
Hydrophilic monomers	radiation-induced polymerisation at -78°C ; dose 5 kGy	immobilisation of the BAS on the surfaces of polyethylene and poly(vinyl chloride) tubes	249
<i>BAS — penicillin acylase</i>			
Acrylates, <i>N</i> -vinyl-pyrrolidone	irradiation of comonomers mixed with the BAS in the presence of a cross-linking agent — tris(hydroxymethyl) propane methacrylate; irradiation time 3.5 h at -78°C ; dose rate 0.65 Gy s^{-1}	the influence of the nature of the monomer and of the degree of its conversion on the amount of immobilised acylase and the rate of its liberation were investigated	250
<i>BAS — asparaginase</i>			
Methacrylic acid	radiation-induced grafting of poly(methacrylic acid) on porous polypropylene fibres	covalent immobilisation	257
	Radiation-induced grafting by the preirradiation method on ethylene–propylene rubber, a polypropylene film, and a porous polypropylene fibre	ditto	258

Table 2 (continued).

Monomers, immobilisation components	Immobilisation conditions	Remarks	Ref.
<i>BAS — β-galactosidase, pepsin, invertase, phosphatase</i>			
Acrylic acid	radiation-induced graft polymerisation of acrylic acid from aqueous solution on polyamide powder	the modified polyamide powder was used for the immobilisation of enzymes	260
<i>BAS — tryptophan, insulin, albumin, lysozyme, peptides</i>			
2-Hydroxyethyl methacrylate + poly(ethylene glycol)	radiation-induced polymerisation	the influence of the molecular mass of the BAS on the rate of their liberation was investigated	230
<i>BAS — invertase, phosphatase, albumin, trypsin, galactosidase</i>			
Acrylic acid	radiation-induced grafting of poly(acrylic acid) on polyethylene	activation of the graft copolymer by SOCl_2 and attachment of the BAS via the acid chloride groups or by means of the carbodiimide method	262
<i>BAS — albumin, β-galactosidase, phosphatase</i>			
Acrylonitrile	radiation-induced grafting of polyacrylonitrile to nylon	hydrolysis of the graft copolymer and the attachment of the enzymes to the hydrolysed groups; immobilisation of the enzymes in the nylon polymeric materials	265
<i>BAS — horseradish peroxidase</i>			
Acrylic acid, acrylamide	grafting on polyurethanes by the preirradiation method in air; grafting from aqueous solution in the presence of Fe^{2+} ions	immobilisation of the enzyme on the graft copolymers	261
<i>BAS — yeast cells</i>			
Methoxypoly(ethylene glycol methacrylate), glycol methacrylate, hexanediol methacrylate, 2-hydroxyethyl methacrylate	radiation-induced polymerisation of monomer mixtures; irradiation at -78°C	the influence of the composition of the mixture of monomers on the activity of the cells was studied	266
2-Hydroxyethyl acrylate, 2-hydroxyethyl methacrylate, <i>N,N</i> -dimethylacrylamide, <i>N</i> -vinylpyrrolidone methoxypoly(ethylene glycol methacrylate)	polymer hydrogels were obtained by the radiation-induced polymerisation of the monomers in water. Irradiation with ^{60}Co γ -rays at -78°C	the adhesion method for immobilisation on the prepared polymeric materials was used; electron micrographs of the polymer particles are presented; the fermentation of glucose was investigated and the yield of ethanol was determined as a function of the nature of the polymer used for immobilisation	267
Methoxypoly(ethylene glycol methacrylate), 2-hydroxyethyl methacrylate	radiation-induced polymerisation; irradiation at -78°C ; dose 10 kGy	adsorption of the cells on porous polymeric carriers	268
Tetraethylene glycol dimethacrylate	the monomer was deposited on muslin and irradiated with ^{60}Co γ -rays	the specific surface of the modified muslin is important for the enzyme activity	269
2-Hydroxyethyl methacrylate	radiation-induced polymerisation at a low temperature; dose 10 kGy	specimens of different forms were prepared	270
<i>BAS — haemoglobin</i>			
2-Hydroxyethyl methacrylate	radiation-induced polymerisation of the monomer in the presence of haemoglobin	the interaction of haemoglobin with CO and O_2 was investigated	271
Phospholipids with double bonds	radiation-induced postpolymerisation of the phospholipids; preparation of vesicles 200 nm in size	the radiation-stability of haemoglobin within the vesicles was studied	274, 275
<i>BAS — CO-haemoglobin</i>			
2-Hydroxyethyl methacrylate, tetraethylene glycol dimethacrylate	irradiation of the monomers jointly with haemoglobin at -5°C ; dose 5–15 kGy; preparation of semisynthetic blood	the CO-haemoglobin phase was obtained immediately after the removal of blood from the animal and oxyhaemoglobin was saturated with CO; CO-haemoglobin does not induce antibody–antigen reactions; a polymer film containing 0.4% of CO-haemoglobin was prepared	272
2-Hydroxyethyl methacrylate	radiation-induced polymerisation at a low temperature	the absorption of oxygen was studied	273

Table 2 (continued).

Monomers, immobilisation components	Immobilisation conditions	Remarks	Ref.
<i>BAS — antitumour preparations (Ara-C)</i>			
Methyl methacrylate, ethyl methacrylate, butyl methacrylate, 2-hydroxyethyl methacrylate	the immobilisation of anticancer preparations in polymer matrices obtained by radiation-induced polymerisation at room temperature was studied	the influence of various factors on the rate of liberation of medicinal substances from polymer matrices was investigated	231
2-Hydroxyethyl methacrylate with added hydrophobic monomers	radiation-induced polymerisation of the hydrophilic monomer with added hydrophobic monomers	the influence of various factors on the rate of liberation of Ara-C was investigated; it was established that the addition of hydrophobic monomers diminishes the rate of liberation of Ara-C	295
<i>BAS — antitumour preparations (Ara-A)</i>			
Methyl ester of <i>N</i> -acryloyl-L-proline	radiation-induced polymerisation	immobilisation of Ara-A in a thermosensitive gel	247
<i>BAS — antitumour preparations: mitomycin, 5-fluorouracil, 1-(2-tetrahydrofuryl)-5-fluorouracil</i>			
2-Hydroxyethyl methacrylate	immobilisation of anticancer preparations in a poly(2-hydroxyethyl methacrylate) matrix	the effect of ionising radiation on the anticancer preparation was investigated	264
<i>BAS — antitumour preparations: mitomycin, adriamycin, 1-(2-tetrahydrofuryl)-5-fluorouracil</i>			
Diethylene glycol dimethacrylate, tris(hydroxymethyl)propane trimethacrylate	radiation-induced polymerisation at -78°C	the rate of liberation of medicinal substances from polymer matrices was investigated	276
<i>BAS — antitumour preparations: mitomycin, bleomycin, 5-fluorouracil</i>			
Diethylene glycol dimethacrylate	irradiation at -78°C of the monomer in a mixture with anticancer preparations and added polystyrene, poly(methyl methacrylate), polyvinylformal, and poly(ethylene glycol); dose 20 kGy	the specimens were prepared in the form of discs, a powder, etc.; the rate of liberation of medicinal substances from the specimens was studied	277
<i>BAS — antitumour preparation: methoxyprogesterone acetate</i>			
Poly(ethylene oxide)	radiation-induced crosslinking of poly(ethylene oxide) with incorporation of the BAS	tests <i>in vivo</i> and <i>in vitro</i>	278
<i>BAS — antitumour preparation: narciclasine</i>			
2-Hydroxyethyl methacrylate, tris(hydroxymethyl)propane trimethacrylate, methyl ester of poly(ethyleneglycol)	radiation-induced polymerisation; additives regulate the rate of liberation of the medicinal substance	tests <i>in vivo</i> ; the structure of the matrix was investigated	279
<i>BAS — chloroplasts</i>			
2-Hydroxyethyl methacrylate, poly(ethylene glycol) dimethacrylate, methoxypoly(ethylene glycol methacrylate), glycidyl methacrylate, tetraethylene glycol diacrylate, tetraethylene glycol dimethacrylate	radiation-induced polymerisation at -78°C ; dose 10 kGy	the influence of the nature of the monomer on the activity of chloroplasts and the distribution of the chloroplasts in the polymer matrix were investigated	280
<i>BAS — chloroplasts from spinach</i>			
2-Hydroxyethyl methacrylate, poly(ethylene glycol)	radiation-induced polymerisation at -24°C in the presence of additives preventing the deactivation of chloroplasts	the liberation of O_2 and the influence of ^{60}Co γ -radiation were investigated; the stability of chloroplasts increases appreciably on immobilisation	281
<i>BAS — pilocarpine hydrochloride</i>			
Acrylamide	radiation-induced grafting of polyacrylamide on polyester materials by impregnating the monomer with subsequent irradiation	a review article on the modification of polyester blood vessel prostheses by the grafting of polyacrylamide; preparation of polyacrylamide disc containing pilocarpine hydrochloride	282

Table 2 (continued).

Monomers, immobilisation components	Immobilisation conditions	Remarks	Ref.
<i>BAS — salicylic acid</i>			
Methyl methacrylate, methacrylic acid	radiation-induced graft polymerisation of a mixture of methyl methacrylate with methacrylic acid on porous cellulose spheres	the sorption of salicylic acid on a modified polymer from aqueous alcoholic solution was investigated	283
<i>BAS — steroids: cholic acid, testosterone, progesterone, corticosterone</i>			
Styrene	radiation-induced grafting of polystyrene on polytetrafluoroethylene, polyamides, poly(<i>p</i> -xylene); nitration of the graft polystyrene and reduction of the nitro group to an amino group	introduction of the thiosemicarbazide group, which is capable of reacting with the carbonyl group of steroids	284
<i>BAS — acetylcholine, serotonin, secretin, actinomycin</i>			
2-Hydroxyethyl methacrylate, methyl, ethyl, glycidyl, and lauryl (meth)acrylates, acrylic acid, acrylonitrile, vinyl acetate, styrene	radiation-induced polymerisation at 28 °C for 2 h; dose rate 5 kGy h ⁻¹	the rate of liberation of the BAS from the polymer matrices was investigated; it was established that the rate of liberation of medicinal substances may be controlled by selecting the polymerisation conditions	286
<i>BAS — thermolysin</i>			
2-Hydroxyethyl methacrylate, tetradecaethylene glycol dimethacrylate	radiation-induced polymerisation at room temperature	the thermal stability of the immobilised thermo lysin was investigated	287
<i>BAS — medicinal drugs with antiandrogenic properties, steroids, and hormones</i>			
Diethylene glycol dimethacrylate, poly(ethylene glycol dimethacrylate)	the medicinal drugs were mixed with the monomer and irradiated with ⁶⁰ Co γ-rays at -78 °C for 2 h; dose rate 5 kGy h ⁻¹	the rate of liberation of the medicinal substances was investigated; tests <i>in vivo</i> and <i>in vitro</i>	285
Microorganisms			
Acrylic and methacrylic acid chlorides	radiation-induced graft polymerisation of acrylic or methacrylic acid chlorides and covalent binding of photobacteria	a review article on the covalent immobilisation of cells; biosensors based on the immobilisation of photobacteria were made; the functional activity of cells may be regulated	288
<i>A fumarase producing microorganism</i>			
Acrylamide	irradiation of the BAS mixed with an aqueous solution of acrylamide in the presence of a cross-linking agent; dose 0.5 kGy	the immobilised microorganism exhibits a high fumarase activity and converts fumaric acid into L-malic acid; the preparation was produced in the form of grains	289
Enzymes and subcellular organelles			
Acrylic acid, allyl alcohol	radiation-induced graft polymerisation of acrylic acid and allyl alcohol on polyethylene	the enzymes were attached to graft polymers by the carbodiimide method; the stability of the enzymes was investigated; the use of the immobilised enzymes in the hydroxylation reaction was investigated	290
<i>Enzymes, antibodies</i>			
Diallyldimethylammonium chloride	the monomer was deposited on electrodes and irradiated; dose 10 kGy	cross-linked products containing enzymes strongly bound to the electrode were obtained	293
<i>Various BAS</i>			
Diethylene glycol dimethacrylate, acrylamide	radiation-induced polymerisation	preparation of polymer microspheres	191
<i>Various BAS containing an NH₂ group</i>			
Acrolein	radiation-induced polymerisation of acrolein	preparation of microspheres with aldehyde groups for the immobilisation of the BAS	195
<i>Mixture of the BAS isolated from leeches</i>			
Acrylic acid	radiation-induced grafting of poly(acrylic acid) to polyethylene and treatment with SOCl ₂	the components of the BAS are bound covalently to the modified polymer	90

Table 2 (continued).

Monomers, immobilisation components	Immobilisation conditions	Remarks	Ref.
<i>Bacillus Stearothermophilus cells</i>			
Maleic anhydride, styrene vinyl acetate	reaction copolymerisation of the monomers	immobilisation of the cells on the copolymer	291
<i>Microbial cells</i>			
2-Hydroxyethyl methacrylate	2-hydroxyethyl methacrylate deposited on a sheet of paper and irradiated with ^{60}Co γ -rays; a medium for the dilution of microbes was created	it was established that an increase in the hydrophilicity by adding methoxytetraethylene glycol methacrylate leads to an appreciable increase in the activity of the microbes	297
<i>Monoclonal antibodies</i>			
Methacrylic acid	radiation-induced grafting of poly(methacrylic acid) on the ethene-propene copolymer	immobilisation of antibodies with the aid of the carbodiimide method	292
<i>BAS — transferrin, heparin, rabbit antibodies</i>			
Glycidyl methacrylate	radiation-induced grafting of poly(glycidyl methacrylate) on polyethylene and polystyrene	the BAS were attached to the copolymer via the epoxide groups; the biological activity was retained	294

forming glassy viscous liquids in the supercooled state (usually at -78°C , dry ice). In the supercooled state, the BAS are little damaged on irradiation and the yield of their activity is high. Doses of 10 kGy (^{60}Co γ -radiation) and a dose rate of 5 kGy h^{-1} are usually employed for radiation-induced polymerisation. For such doses, the enzyme activity of the BAS hardly changes.

Glass-forming alkyl acrylates and methacrylates of the type $\text{CH}_2=\text{CXCOO}(\text{CH}_2)_n\text{OH}$ and $\text{CH}_2=\text{CXCOO}(\text{CH}_2\text{CH}_2\text{O})_m-\text{OCXC}=\text{CH}_2$, where $\text{X}=\text{H}$ or CH_3 , are usually employed as the monomers. 2-Hydroxyethyl methacrylate is widely used. The presence of water and the enzyme accelerates the radiation-induced polymerisation. The immobilisation process consists of the following stages: mixing of the biocomponent with the monomer, preparation of the mould, cooling, and polymerisation. A mixture of the glass-forming monomer with the usual monomers (styrene, methyl methacrylate, vinyl acetate, acrylamide, etc.) is used in some cases. Aqueous solutions of the BAS at specific pH are normally employed for immobilisation. The phase state of the system is altered on freezing the monomer mixed with an aqueous solution of the BAS. Phase analysis showed that an appreciable proportion of the water begins to crystallise at a temperature below -24°C , forming a suspension of ice in the supercooled monomer.

The radiation-induced polymerisation results in the formation of a porous system and the BAS is partly located on the surfaces of the pores. This immobilisation method has been called the adhesion method. The distribution of the BAS between the aqueous phase and the porous polymer (the degree of adhesion of the BAS on the surface) depends on the nature and concentration of the monomer. The rate of freezing also influences in many instances the pore dimensions. The monomer concentration is very important. With its increase (above 30%), the porosity of the matrix begins to diminish and the activity of the BAS falls. At a monomer concentration in excess of 50%, part of the BAS is captured by the polymer and does not participate in the reaction.

Thus the adhesion method requires the optimum (as a rule $\sim 30\%$) monomer concentration.²⁰¹ Under these conditions, 20%–30% of the activity of the BAS is usually retained and changes little on reuse of the BAS. The hydrophilic or hydrophobic properties of the monomer are very important. With increase in the hydrophilicity of the monomer, the rate of liberation of the BAS during use also increases. In certain cases, this rate may be regulated by mixing hydrophilic and hydrophobic monomers and also by employing mixtures of glass-forming monomers with natural polymers (albumin, collagen, etc.). The

addition of various cross-linking agents as well as BAS adsorbents (for example, silica gel) to the monomers has a significant influence on the rate of liberation of the BAS. By selecting glass-forming monomers and the conditions for the radiation-induced polymerisation, it is possible to regulate the rheological properties of polymer matrices with immobilised BAS.

Another method of obtaining biocomposites involves the mixing of the BAS with the polymer (usually in the form of a powder) and pressing under a pressure of $\sim 100\text{ kg cm}^{-2}$ with subsequent cross-linking under the influence of radiation (with a dose of $\sim 10\text{ kGy}$).²⁰⁴ However, this method is used much more rarely. Its main disadvantage is that it is difficult to achieve a uniform mixing of the BAS with polymers.

The immobilisation of glucoamidase, invertase, and β -galactosidase in polymer gels obtained by the radiation-induced polymerisation of acrylamide, *N,N*-dimethylacrylamide, 2-hydroxyethyl methacrylate, and *N*-vinylpyrrolidone and by the radiation-induced cross-linking of poly(vinyl alcohol) has been described.^{225–228} The influence of the irradiation dose on gel formation processes has been investigated. For each monomer, there is a definite dose above which the enzyme ceases to be liberated. If the *N*-vinylpyrrolidone irradiation dose is above 30 kGy, while that for PVA is above 50 kGy, enzymes are not liberated. By selecting the dose, it is possible to regulate the rate of liberation of the enzyme. Satisfactory results have been obtained using acrylamide and *N,N*-dimethylacrylamide (for a dose of 10 kGy). In the case of 2-hydroxyethyl acrylate, gel formation begins at a dose of 2.5 kGy and the enzyme is liberated within a fairly wide dose range. Yoshida and Kaetsu²³⁵ investigated the immobilisation of glucoamylase in polymer matrices obtained by the low-temperature radiation-induced polymerisation of 2-hydroxyethyl methacrylate (hydrophilic monomer) and diethylene glycol dimethacrylate (hydrophobic monomer) in the presence of the enzyme in an aqueous buffer solution (for a dose of 5 kGy). In the case of the hydrophilic matrix, the glucoamylase was in the gap between a thin polymer layer (polymer membrane), formed on radiation-induced polymerisation, and the porous structure of the polymer, as well as partly in the polymer itself, but in the hydrophobic matrix the glucoamylase was present virtually only on the surface of the porous structure of the polymer. The rates of liberation of glucoamylase from the hydrophilic and hydrophobic polymer matrices were compared. Fluorescence photomicrographs were obtained for the distribution of glucoamylase in various polymer matrices. It was established that the diffusion of glucoamylase diminishes appreciably with

increase in the content of the monomer in the mixture. The highest rate of liberation is observed at a monomer concentration of 10%.

The immobilisation of glucoamylase in thin polymer membranes, formed on irradiation of hydrophilic or hydrophobic polymers by a low-energy electron beam in the presence of an aqueous solution of the enzyme, has been investigated.²³³ The polymers employed were poly(ethylene glycol dimethacrylate) or poly(ethylene glycol diacrylate). Thin polymer membranes with a high enzyme activity were obtained. The influence of the irradiation dose, the energy, and the concentration of the polymer on the enzyme activity of the membranes was studied. In the presence of tris(hydroxymethyl)propane triacrylate (a hydrophobic monomer), the activity of the membranes depends to a considerable degree on the irradiation conditions and the monomer concentration.

The immobilisation of glucoamylase in a poly(vinyl alcohol) gel on electron irradiation²³⁶ has been investigated.^{235, 236} Doses ranging from 60 to 360 kGy were used. At 120 kGy, the enzyme activity fell appreciably, while at 360 kGy it vanished completely. A strip which moved under the beam from the accelerator was used for irradiation. The immobilisation of invertase and glucoamylase in a PVA gel obtained on γ -irradiation of the above polymer in the presence of an aqueous enzyme solution was studied in detail. The irradiation dose is very important. The enzyme was liberated only for doses not exceeding 40 kGy. Up to 70 kGy, the dose does not affect the enzyme activity. A disadvantage of the immobilisation of enzymes in the poly(vinyl alcohol) gel was noted — an unduly high (75%–90%) loss of enzyme activity.

The immobilisation of urease on starch with grafted polyacrylamide has been studied.²¹³ The use of low irradiation doses is important. The activity of urease fell to 60% of the initial value after the enzyme had been used seven times.

Kumakura and Kaetsu²³⁸ investigated the immobilisation of lipase by the low-temperature polymerisation of 2-hydroxyethyl methacrylate, tris(hydroxymethyl)propane trimethacrylate, and poly(ethylene glycol diacrylate) in the presence of an aqueous enzyme solution. All the specimens had a porous structure. The enzyme activity was a maximum in 40% solution of the monomer. It was established that the maximum enzyme activity of the lipase is attained for the optimum hydrophobicity of the polymer matrix. When poly(ethylene glycol) is used in the immobilisation the enzyme activity increases with increase in the number of ethylene glycol units in the monomer molecule.

The communication of Guanghui *et al.*²⁴⁶ is devoted to the study of the immobilisation of catalase on acyl azide-modified porous polyacrylamide particles obtained by the radiation-induced polymerisation of acrylamide in the presence of *N,N'*-methylenebisacrylamide at -78°C . The activity of catalase increases appreciably on immobilisation via glycine groups. The immobilised catalase has been used to decompose H_2O_2 in irradiated wines.

Kaetsu *et al.*²⁰¹ studied the immobilisation of α -amylase in polymer matrices produced from the copolymer of 2-hydroxyethyl methacrylate and poly(tetraethylene glycol diacrylate). The immobilisation was carried out by the radiation-induced polymerisation of a mixture of monomers containing an aqueous BAS solution and using a dose of 10 kGy at -24°C . At a certain temperature, the phase state of the system changes and the ice phase is formed. The biologically active substance is concentrated on the surface of the porous polymer matrix. In the case of a hydrophobic polymer matrix, an appreciable proportion of the BAS remains in the ice, so that the activity of the BAS increases with increase in the monomer concentration. However, starting from a certain monomer concentration, the activity of the test substance diminishes owing to occlusion within the polymer. Photomicrographs of the polymeric composite with the immobilised BAS have been published. In the case of the hydrophilic polymer matrix, the reactions of α -amylase take place as a result of the diffusion of the enzyme in the swollen polymer gel.

A method has been developed for the preparation of spherical particles (100–150 μm) in the copolymerisation of hydrophilic and hydrophobic monomers (neopentyl glycol diacrylate or tetraethylene glycol diacrylate). In this case, the activity of the enzyme is independent of the monomer concentration in polymerisation at -78°C and for a dose of 10 kGy. Methods have been developed for the preparation of tubes and filaments containing immobilised BAS. The immobilisation of α -amylase in poly(2-hydroxyethyl methacrylate) matrices has been investigated²⁹⁶ with the aid of radiation-induced polymerisation (dose 5 kGy). The immobilisation of trypsin using low-temperature radiation-induced polymerisation has been investigated in detail.²¹⁶ The enzyme activity was studied in the hydrolysis of casein (substrate). 2-Hydroxyethyl methacrylate, poly(ethylene glycol diacrylate), and methoxypoly(ethylene glycol methacrylate) were used as the components for the immobilisation of trypsin.

The irradiation of the monomers mixed with an aqueous enzyme solution was carried out at -78°C with a dose of 10 kGy. If the monomers are hydrophilic, the enzyme activity falls with increase in their concentration, whereas in the case where they are hydrophobic the activity passes through a maximum. When 2-hydroxyethyl methacrylate is used, a porous polymer matrix with a pore size of 1 μm at a monomer concentration of 50%–70% is formed. With increase in this concentration, the pore size diminishes. When tris(hydroxymethyl)propane triacrylate (a hydrophobic monomer) is used for immobilisation, a polymer is formed in the form of a suspension with a particle size of 50–200 μm and the enzyme is immobilised on the polymer surface. In the case of poly(ethylene glycol diacrylate), the degree of hydration and the enzyme activity increase with increase in the number of oxyethylene units $-\text{CH}_2\text{CH}_2\text{O}-$ (n). For $n \leq 4$, large formations 100–200 μm in diameter are produced, whereas for $n \geq 9$ a continuous porous structure is formed. If methoxypoly(ethylene glycol methacrylate) is used, a cross-linked structure appears. Such a matrix is soft and hydrophilic and the enzyme is readily trapped in it. The study of the influence of the nature of the polymer matrix on the thermal stability of the immobilised enzyme showed that the highest thermal stability occurs when 2-hydroxyethyl acrylate and 2-hydroxyethyl methacrylate are used. The thermal stability of the enzyme depends on the hydrophilicity of the polymer matrix; the maximum stability is attained on increase in the degree of hydration, which is associated with the influence of the latter on the rigidity of the matrix.

The immobilisation of trypsin in the radiation-induced polymerisation of crystalline monomers (acrylamide, methylenebisacrylamide, and acrylic acid salts) has been investigated.^{212, 229} A deficiency of the polymer matrix was discovered — an unduly high hydrophilicity.

The communication of Carenza *et al.*²³⁰ was devoted to the study of the influence of the molecular mass of proteins and peptides on the rate of liberation of these compounds from hydrogels obtained by the radiation-induced polymerisation of 2-hydroxyethyl methacrylate. It was established that the rate of liberation diminishes linearly with increase in $\log M_w$. The rate of decrease may be regulated by adding poly(ethylene glycol) with different M_w to 2-hydroxyethyl methacrylate. The immobilisation of glucose oxidase, glucose peroxidase, and urokinase on the inner surfaces of poly(vinyl chloride) tubes and on LDPE films has been described.²⁴⁹ The immobilisation method consists in the preliminary radiation-induced polymerisation of 2-hydroxyethyl methacrylate and the subsequent decomposition on the grafted surface of a mixture of the monomer with an aqueous solution of the enzyme. The tube is frozen and irradiated at -78°C (dose 5 kGy).

The structure of the surface depends on the polymerisation conditions and the nature of the monomer. These factors influence the uniformity of the coating. The thinnest and most uniform coatings are obtained when a 1:1 mixture of 2-hydroxyethyl methacrylate and tetraethylene glycol diacrylate is used. A high

stability of the immobilised enzymes was established, which can be partly accounted for by the employment of cross-linked systems. Glucose oxidase and glucose peroxidase have been used to assay glucose in blood.^{234,248} The immobilisation was carried out in such investigations by irradiating the monomers mixed with an aqueous enzyme solution. The mixture was deposited on a nylon net or filter paper in a thin layer and was irradiated in an accelerator (dose 10 kGy). Poly(ethylene glycol diacrylate) and tris(hydroxymethyl)propane triacrylate were used as the components for the immobilisation. The maximum activity of the enzymes was attained at a concentration of the components of 20%–30% and the highest enzyme activity was observed when poly(ethylene glycol diacrylate), deposited on a nylon net, was employed. Polymer sheets with immobilised enzymes were obtained as a result.

The immobilisation of fumarase in a polyacrylamide gel has been described (dose 5–10 kGy).²⁸⁹ A high activity of fumarase was achieved under the conditions of the enzymic synthesis of malic acid from fumaric acid.

The results of the study of the immobilisation of penicillin acylase in polymer matrices of different hydrophilicity (2-hydroxyethyl acrylate, 2-hydroxyethyl methacrylate, *N*-vinylpyrrolidone, *etc.*) by means of low-temperature radiation-induced polymerisation have been described.²⁵⁰ The influence of the monomer:enzyme ratio on the immobilisation was investigated. It was established that the rate of liberation of the enzyme is independent of the nature of the monomer, the degree of polymerisation, and the porosity, but does depend strongly on the presence in the system of the cross-linking agent tris(hydroxymethyl)propane trimethacrylate even in small amounts (~0.03%–0.04%). The enzyme is retained in the polymer matrix as a result of hydrophobic interactions. The activity of penicillin acylase is preserved for a long time in the presence of the cross-linking agent.

A series of publications^{239–244,251,270} have been devoted to questions concerning the immobilisation of cellulase. The immobilisation of cellulase and cellobiase in polymer matrices obtained by the low-temperature polymerisation of 2-hydroxyethyl methacrylate in the presence of an aqueous enzyme solution has been studied in detail.²³⁹ The enzyme activity was determined from the yield of glucose in the decomposition of cellulose. It was noted that in the presence of additives in the monomer [silica gel and poly(ethylene glycol)] the enzyme activity is retained for a longer time. The effectiveness of the additive depends on the monomer concentration. The maximum activity is attained at a monomer concentration of 60%. Discs 12 mm thick containing the immobilised enzyme were obtained.

Kumakura and Kaetsu²⁴⁰ studied the immobilisation of cellulase in polymer membranes prepared from hydroxylated acrylates. The maximum activity of cellulase was attained at a monomer concentration of 20% and for a membrane thickness of 1 mm, which is associated with the formation of the most porous structure of the polymer under these conditions. The dependence of the enzyme activity on the water content in the polymer has a maximum. In the immobilisation of cellulase in the porous polymer matrix formed by the radiation-induced polymerisation of poly(ethylene glycol diacrylate), the pore structure is determined to a large extent by the polymer concentration and temperature.²⁴¹

The enzyme activity depends on the pore size, the degree of hydration, and the particle size of the composite. The degree of hydration of the polymer increases with increase in the number of oxyethylene groups in the monomer.

$$n = 2, 3, 4, 9, 14.$$

Continuous changes in the porous structure associated with the change of the polymerisation phase have been noted in the temperature range from –10 to –40 °C. With increase in pore size, the enzyme activity falls.

Yoshida *et al.*²⁴² achieved the immobilisation of cellulase in polymer microspheres. The latter were formed as a result of the radiation-induced polymerisation of glycidyl methacrylate in the presence of polystyrene and the enzyme with subsequent immersion of the mixture in cooled methanol. The influence of various conditions on the number and diameter of the microspheres was investigated. Soft and hard microspheres with different diameters were obtained. The enzyme activity of cellulase in the soft microspheres was 4.6 times higher than in the hard ones.

The communication of Kumakura and Kaetsu²⁴³ was devoted to the study of the immobilisation of *Streptomyces phalochromogenes* cells (which produce cellulase) using the 2-hydroxyethyl methacrylate + methoxytetraethylene glycol methacrylate mixture. The mixture together with the cells was deposited on paper and irradiated. Paper sheets with immobilised cells were obtained.

The immobilisation of cellulase in poly(2-hydroxyethyl methacrylate) polymer matrices has been described.²⁴⁴ The immobilisation was carried out by the low-temperature polymerisation of 2-hydroxyethyl methacrylate in the presence of an aqueous enzyme solution. The specimens were prepared in the form of discs. The enzyme activity is a maximum at a monomer concentration of 50% and the optimum thickness of the disc is 1 mm. With increase in cellulase concentration, the specific enzyme activity diminishes. Photomicrographs of the specimens with the immobilised cellulase were published. The immobilised cellulase preparation may be used repeatedly. In another study, Kumakura and Kaetsu²⁵¹ immobilised cellulase on the inner surfaces of polyethylene tubes by the low-temperature radiation-induced polymerisation of a mixture of 2-hydroxyethyl methacrylate and tetraethylene glycols diacrylate. The mixture of the monomers with the enzyme was deposited on the inner surfaces of the tubes, frozen, and irradiated (dose 10 kGy). The thickness of the layer of coating was 300 μm, the optimum monomer concentration was 60%–70%, and the enzyme concentration was 0.5%. This immobilisation method can be used to create enzyme reactors. The immobilisation of yeast cells in various hydrogels has been studied and the conditions for the maximum yield of ethanol in the enzyme hydrolysis of a cellulose-containing raw material were discovered.²⁷⁰ Immobilised cellulase has been used for the enzymic hydrolysis of a cellulose-containing raw material: paper waste,^{270,297,298} starch,^{299,300} biomass (wood chips, sugar beet waste, rice straw),^{299,300} and lignin-containing waste.²⁴⁵ After the preliminary irradiation of the cellulose-containing waste (paper, sawdust, *etc.*) with a dose up to 1 MGy, the yield of glucose in the hydrolysis of the raw material increases appreciably (by a factor of ~3),^{297–301} which is associated with the appreciable decrease in the degree of polymerisation of cellulose and the partial breakdown of its structure. The yield of ethanol in the hydrolysis of plant waste after preliminary irradiation has been studied in detail.²⁷⁰ For the successful enzyme hydrolysis of lignin-containing waste, it is desirable to subject it to preliminary irradiation (dose 1 MGy) and grinding. The influence of preliminary irradiation up to different doses on the subsequent hydrolysis of cellulose (from rice, straw, *etc.*) has been described.³⁰¹ The results of the employment of the radiation technique for the conversion of biomass into sugar and its fermentation in order to obtain ethanol have been surveyed in a review.³⁰⁰ The possibility of the reuse of the immobilised enzymes has been studied.

Functional polymers, obtained by radiation-induced graft polymerisation, have been used in a series of studies for the immobilisation of enzymes. A method for the covalent binding of enzymes, based on the grafting of *p*-nitrostyrene to polymers (mainly polyolefins), the reduction of the nitro groups to amino groups, and the conversion of the latter into isocyanate groups, which readily react with enzymes, has been devised.^{210,219,220} In

the case of amino groups, glutaric dialdehyde was used for the covalent binding of enzymes. Another procedure consists in the radiation-induced grafting of styrene with subsequent nitration of the graft copolymer. Trypsin was used as the enzyme.

A method for the immobilisation of asparaginase on porous polypropylene fibres, an ethene-propene copolymer, and a polypropylene film has been created.^{257,258} The first stage is the radiation-induced grafting of acrylic acid, after which asparaginase is attached covalently to the carboxy groups by the carbodiimide method. An enzyme reactor was developed and was tested *in vitro* and *in vivo*. The immobilisation of enzymes and subcellular organisms in polyethylene has also been described.²⁹⁰ The activity and stability of the enzymes were investigated.

The immobilisation of papain, trypsin, glucose oxidase, and α -chymotrypsin on powdered polyethylene with grafted poly(methacrylic acid) and poly(2-hydroxyethyl methacrylate) has been studied.²⁵⁹ The covalent binding of the enzyme was achieved with the aid of the carbodiimide method. It was established that each enzyme requires its own microenvironment. α -Chymotrypsin proved to be the most active. The best results were obtained in the grafting of poly(2-hydroxyethyl methacrylate) with subsequent partial hydrolysis. The covalent immobilisation of invertase, phosphatase, albumin, trypsin, and galactosidase on polyethylene modified by the grafting of poly(acrylic acid) has been described.²⁶² The enzyme was attached by means of the carbodiimide method. The influence of the methods used for grafting and activation of poly(acrylic acid) on the activity of the enzymes was examined.

The immobilisation of horseradish peroxidase on segmented polyesterurethane films has been described.²⁶¹ The immobilisation of glucose oxidase on polyethylene films has been investigated.²⁴² A study has been made of the influence of the degree of grafting, the hydrophilicity, and the electrical properties on the enzyme activity.

The radiation-induced grafting of 2-hydroxymethyl methacrylate has been used to bind trypsin and glucose oxidase to natural rubber.^{221,222}

Cyanuric chloride and toluene-*p*-sulfonyl chloride were used for the covalent binding. The immobilisation conditions and the activity of trypsin have been examined in detail. The immobilisation of enzymes on polyamide materials (with the aid of radiation-induced graft polymerisation of acrylic acid or acrylonitrile) has been described.^{260,264,265} The immobilisation of protease with the aid of radiation-induced grafting of acrylic acid has been investigated.²¹⁴

The reactivity of α -chymotrypsin immobilised on radiation-grafted hydrogels obtained by the grafting of 2-hydroxyethyl methacrylate and methacrylic acid on silicone rubber has been studied.^{302,303} α -Chymotrypsin was bound covalently using *N*-hydroxysuccinimide. The influence of pH and the content of acrylic acid on the enzyme activity was investigated (hydrolysis of *N*-acetyl-L-tyrosine). The rate of hydrolysis is greatly influenced by the negative charge of the hydrogel. The immobilisation of trypsin on a wide range of polymers modified by the radiation-induced grafting of poly(acrylic acid), polyacrylonitrile, poly(2-hydroxyethyl methacrylate), poly(*N*-vinylpyrrolidone), polyacrylamide, *etc.* has been studied in detail.^{213,214} The covalent binding of trypsin was achieved by means of the carbodiimide method or glutaric dialdehyde. The polymer membranes obtained were designed for use in the milk industry.

Methods for the covalent immobilisation of enzymes with the aid of aldehyde groups, which readily react with amines, have been devised.^{198,199,304,305} The methods involve the radiation-induced graft polymerisation of acrolein. The reactivity of the aldehyde groups was studied.

Radiation-induced graft polymerisation is used for the modification of agarose (by grafting a complex of *N*-acryloylsuccinimide and BSA) in order to obtain a material for the chromatographic separation of biomacromolecules.³⁰⁶

Novel methods for the immobilisation of enzymes on polymeric materials have been developed by Platé and Valuev.²¹⁵ This is a new aspect of the use of radiation-chemical methods for the immobilisation of BAS, because it concerns the radiation-induced graft polymerisation of macromonomers formed by the introduction of a reactive double bond into BAS macromolecules.

Thus the nature of the monomer and in the first place its hydrophilic and hydrophobic properties as well as the monomer concentration are important in the immobilisation of BAS with the aid of radiation-induced polymerisation. These factors influence most significantly the activity of the enzyme, the duration of its use, and its thermal stability. Cross-linking agents and BAS adsorbents can be usefully added at a low concentration in a number of instances in order to regulate the rate of liberation of the enzyme. The radiation dose should not exceed 10 kGy in most cases.

The modification of various polymers by the radiation-induced grafting of acrylic acids or 2-hydroxyethyl methacrylate with subsequent binding of the enzymes by the carbodiimide method is employed most frequently for the covalent binding of enzymes. The specific activities of the enzymes fall with increase in their content in the modified layer (a 5%–10% graft is optimal). The method for the covalent binding of the enzyme is very important. Radiation-induced graft polymerisation makes it possible to employ polymers of virtually any nature and form (powders, fibres, films, *etc.*) for the binding of enzymes. The possibility of creating enzyme reactors has been demonstrated.

2. Immobilisation of medicinal preparations

In the employment of radiation-induced polymerisation for the immobilisation of medicinal substances, the greatest advances have been achieved in the immobilisation of antitumour compositions in polymer matrices. The antitumour substances employed have been adriamycin, mitomycin C, and 5-fluorouracil. In many cases, treatment with immobilised antitumour preparations is combined with hormone therapy. The immobilised antitumour substances are used as a rule in the form of polymer tablets or needles which are inserted in the tumour. The application of immobilised antitumour preparations has the following advantages compared with their introduction in the form of injections or orally: a low concentration of medicinal preparations in the blood, the medicine spreads from the administered preparation into a small region. This reduces to a minimum the side effects of the medicines. The duration of the use of the immobilised antitumour preparations is several months. These preparations have undergone extensive tests in many Japanese clinics.²⁰⁴ In the vicinity of the preparation introduced into the tumour, the cancer cells undergo necrosis and the diffusion of the antitumour preparations terminates in the necrosed layer. The rate of liberation of medicinal substances does not change in the course of 40 days. The number of specimens introduced into the tumour, their density, and form (needles, tablets) are very important.

The concentration of antitumour substances in the blood is insignificant. A mixture of poly(ethylene glycol dimethacrylate) (20%) and diethylene glycol dimethacrylate (80%) is usually employed for the immobilisation of the antitumour preparation mitomycin C.²⁰⁴ The behaviour of the immobilised antitumour preparations in the organism and the methods for the treatment of cancer have been examined in a number of studies.^{307–312} Methods whereby immobilised antitumour preparations can be produced have been described in detail in a series of studies.^{204,205,249,276,278,313,314} The low-temperature polymerisation of diethylene glycol dimethacrylate mixed with various polymers [polystyrene, polyvinylformal, poly(ethylene glycol), poly(methyl methacrylate)] is used for the immobilisation of mitomycin, 5-fluorouracil, and bleomycin. It is emphasised that irradiation must be carried out in an oxygen-free medium and the dose must not exceed 10 kGy. Otherwise the activity of the antitumour preparations is significantly reduced.²⁷⁷ Specimens

with the immobilised antitumour preparations are made in the form of a powder, tablets, cylinders, membranes, *etc.*²⁷⁷

The immobilisation of multicomponent cytotoxic (antitumour) agents in polymer matrices based on poly(diethylene glycol dimethacrylate) and poly[tris(hydroxymethyl)propane trimethacrylate] has been studied. The cytotoxic agents employed are mitomycin C, adriamycin, and 1-(2-tetrahydrofuryl)-5-fluorouracil. The rate of liberation of the medicinal preparations is regulated by introducing a pore-forming agent or adsorbent (for example, activated charcoal) into the polymer matrix. The surfaces of the polymers obtained with the immobilised cytotoxic agents have been studied by electron microscopy.²⁷⁶

The immobilisation of the antitumour preparations 5-fluorouracil and mitomycin C by dispersing the preparations in polymer matrices obtained by the radiation-induced polymerisation of 2-hydroxyethyl methacrylate, 2-hydroxyethyl acrylate, and methyl methacrylate has been examined.³¹³ A cross-linking agent — ethylene glycol dimethacrylate — is added for the effective control of the rate of liberation of the medicinal preparations. The rate of liberation of medicines from polymer matrices obtained under different conditions has been studied in detail. The rate of liberation increases with increase in the hydrophilicity of the matrix and diminishes significantly with increase in the content of the cross-linking agent. The influence of the porosity of the matrix on the liberation of medicinal substances has been studied and electron micrographs of the porous structure have been published. A study has been made of the therapeutic effect of immobilised preparations placed in the form of tablets in the vicinity of a tumour (sarcoma) in mice. The slow liberation of the medicinal drugs led to a greater therapeutic effect compared with direct injection.

The methods and results of clinical tests of the local chemotherapy of malignant glioma have been examined. The following immobilised antitumour preparations have been used: adriamycin, 5-fluorouracil, and nimustine hydrochloride.³¹⁴

The preparation of poly(ethylene oxide) gels with immobilised hydroxyprogesterone acetate for the treatment of carcinoma has been described.²⁷⁸ The controlled liberation of adriamycin from polymer needles has been investigated.³¹⁵

Summarising the foregoing, one may conclude that the application of antitumour preparations immobilised in polymeric materials is promising. When they are used, the cancer cells undergo necrosis within the limits of 0.5–1 cm² around the specimen and the diffusion of the antitumour preparations ceases in the necrosed layer. The number of specimens in the tumour and the rate of liberation of the preparation, which may be regulated within wide limits are very important. Side effects are not observed when immobilised antitumour preparations are employed. The technology of the use of immobilised antitumour preparations may be improved by varying the hydrophilic-hydrophobic properties of the polymer matrix and also by using biodegradable polymers (polypeptides or polylactides).

Methods have been developed for the immobilisation of the antitumour preparation narciclasine.^{279, 316} Chemical and radiation methods for the initiation of polymerisation with the aim of its immobilisation have been compared. A study has been made²³¹ of the immobilisation of the antitumour preparation Ara-C in hydrophobic matrices obtained by the radiation-induced polymerisation of alkyl acrylates and methacrylates. It was shown that the rate of liberation of Ara-C may be varied widely by altering the composition of the matrices. The prospects for the employment of thin polymer particles, obtained by emulsion polymerisation (0.1–3 µm particles) or suspension polymerisation (10–100 µm particles), for immobilisation have been noted.²⁰⁵ Significant results in therapy have been achieved in the joint study of immobilised antitumour preparations and hormones. The immobilisation and use of the immobilised hormones (testosterone) have been described.^{317–320} The hormones were immobilised in polymer needles. An important feature is that the hormones enter the organism for a long time in small amounts. Definite successes

have been achieved in the treatment of the cancer of digestive organs, the bladder, pancreas, the brain, *etc.*

Radiation-induced polymerisation has been used in a series of studies^{159, 202, 205, 321–325} for the immobilisation of antibodies in order to investigate the antibody–antigen reactions. The sensitivity of the reactions of the immobilised antibody with the antigen depends on the choice of monomer and its concentration needed to create a porous medium. An important problem is the minimisation of nonspecific reactions of the polymeric carrier with the antigen. For this purpose, it is necessary to make the polymer matrix more hydrophobic. The immobilised preparations are usually made in the form of microspheres or microcapsules. Microspheres obtained by the polymerisation of acrolein or its copolymers with 2-hydroxyethyl methacrylate or methacrylic acid are also used for the immobilisation of antibodies.

Within the framework of the program of the International Atomic Energy Agency, studies with immobilised monoclonal antibodies have been carried out at the Pasteur Institute (Paris).^{205, 292} The immobilisation of the latter is achieved by the low-temperature polymerisation of 2-hydroxyethyl methacrylate.

An advantage of radiation-induced polymerisation for the immobilisation of antibodies is the fairly high purity of the product obtained.^{326, 327} These preparations may be used for immunological assay.

The immobilisation of a calcium antagonist in a prepolymerised poly(2-hydroxyethyl methacrylate) gel has been described.²⁸⁵ The rate of liberation of the medicinal preparation can be varied widely by means of the radiation-induced cross-linking of the gel and the added methyl methacrylate and *N*-vinylpyrrolidone.

The immobilisation of hydrocortisone in gels obtained by the radiation-induced polymerisation of acrylic acid has been investigated. The rate of liberation is regulated by the irradiation dose and by treating the gels with zinc acetate.³¹⁷

3. Immobilisation of blood components

Haemoglobin has been immobilised in a poly(2-hydroxyethyl methacrylate) polymer matrix using radiation-induced low-temperature polymerisation.^{271–273} Special attention was devoted to the selection of the optimum immobilisation conditions in order to protect the haemoglobin. Haemoglobin is convenient for the study of the state of the immobilised molecule in a polymer matrix, since it has a characteristic optical absorption. The haemoglobin in the membrane was subjected to reversible oxygenation, which may take place to almost the same extent as in native haemoglobin. A method for the preparation of semisynthetic blood based on immobilised carboxyhaemoglobin has been described.²⁷² Radiation-induced polymerisation has been used for the immobilisation of erythrocytes in the form of cells without haemolysis.

The radiation-induced polymerisation of phospholipids has been used for the immobilisation of haemoglobin.^{274, 275} The phospholipids contained two long polymerisable octadecadienyl groups. Artificial red blood cells were obtained by encapsulating haemoglobin with the aid of the radiation-induced polymerisation of bilayer phospholipids — liposomes. The artificial blood cells proved to be mechanically stable and readily withstood freezing. The oxygen transport is similar to the transport by native haemoglobin. Tests *in vivo* (on mice) were carried out and indicated the biocompatibility of such cells.

Methods have been developed for the preparation of polycationic carriers for red blood cells.⁸⁵ The carriers were formed by the polymerisation and grafting of 2-(*N,N*-dimethylamino)ethyl methacrylate. The grafting was carried out on poly(vinyl chloride) beads by a method involving preliminary irradiation. 2-(*N,N*-Dimethylamino)ethyl methacrylate was polymerised in bulk in the presence of tris(hydroxymethyl)propane trimethacrylate and also in suspension and in emulsion. Cationic immunoadsorbents were obtained. Their adsorption capacity was determined. The density of the positive charges on the adsorbent is important.

4. Immobilisation of yeast cells and microorganisms

In a series of studies,^{202, 266, 269, 328, 329} radiation-induced polymerisation has been used for the immobilisation of yeast cells in order to employ the resulting preparations for the synthesis of ethanol from plant waste.

The nature of the carrier, especially its porosity, plays an important role. The porous matrix is formed as a result of the copolymerisation of methoxypoly(ethylene glycol methacrylate) and 2-hydroxyethyl acrylate. The yeast cells are adsorbed on this matrix, are coated by methoxypoly(ethylene glycol methacrylate), and are polymerised at -78°C (dose 10 kGy).²⁶⁸ The activity of *Saccharomyces formosensis* cells (yeast cells) on polymeric carriers obtained by the radiation-induced polymerisation at -78°C of mixtures of 45% of methoxypoly(ethylene glycol methacrylate) containing 23 ethylene glycol units, 45% of hexane diol methacrylate, and 10% of water (fine pores and a low water content) or 15% of methoxypoly(ethylene glycol methacrylate), 15% of 2-hydroxyethyl methacrylate, and 70% of water (structure with wide pores). In the first case, the immobilised cells had an activity greater by a factor of 6 than in the second case. As a rule, the activity of the immobilised cells increases with increase in the water content.²⁶⁶ The influence of the composition of the monomer mixture and the conditions in the immobilisation of yeast cells on the yield of ethanol has been studied in detail.²⁶⁷ Conditions have been found for the multiplication of the yeast cells and for the manifestation of their high activity. A significant role of water in the activity of the cells was observed. A study has been made²⁶⁹ of the immobilisation of *Trichoderma reesei* (QM 9414) cells. Muslin was used as the carrier, which was coated with a solution of the monomer mixed with the cells and irradiated. It was shown that the concentration of the monomer used for immobilisation exerts a significant influence on the activity of the cells.

The capture of the microorganism producing fumarase in a cross-linked polyacrylamide gel has been investigated. A preparation with a high enzyme activity and an increased thermal stability was obtained.³³⁰ The immobilisation of bacteria in hydrophilic gels based on poly(ethylene glycol) and poly(propylene glycol) led to the creation of a bioreactor.³³¹ The rate of liberation of testosterone was regulated by immobilising it in a thermosensitive gel obtained by the radiation-induced polymerisation of the methyl ester of acryloyl-L-proline.³³²

A method for the covalent immobilisation of luminescent bacteria on the surface of a polyethylene film has been developed with the aid of the radiation-induced graft polymerisation of methacryloyl chloride on the film.^{288, 333}

5. Immobilisation of photosynthetic substances and organelles

Chloroplasts and chlorophyll may be immobilised with the aid of low-temperature radiation-induced polymerisation.^{202, 280, 281} The immobilisation of chloroplasts extracted from spinach was achieved by the radiation-induced polymerisation of 2-hydroxyethyl methacrylate in the presence of special additives which prevent the deactivation of the chloroplasts. The liberation of O_2 and the influence of γ -radiation on this process were investigated. The influence diminishes appreciably on irradiation at reduced temperatures (-24 and -78°C). The chloroplasts immobilised at reduced temperatures in a hydrophilic polymer matrix exhibited a stable long-term liberation of O_2 : more than 700 h at 4°C . The thermal stability of chloroplasts increases appreciably on immobilisation.

The photoreductive activity of chloroplasts falls to zero after 5 min at 50°C , whilst immobilised chloroplasts retain their activity for more than 60 min.²⁸¹ The influence of the nature of the monomer and its concentration on the activity of immobilised chloroplasts was investigated.²⁸⁰ 2-Hydroxyethyl acrylate, poly(ethylene glycol diacrylate), poly(ethylene glycol dimethacrylate), methoxypoly(ethylene glycol methacrylate), glycidyl methacrylate, glycidyl diacrylate, tetraethylene glycol diacrylate, and tetraethylene glycol dimethacrylate were used as the monomers. The

optimum monomer concentration was 10%. The best monomer for immobilisation proved to be a mixture of methoxypoly(ethylene glycol methacrylate) and 2-hydroxyethyl acrylate. The activity of the immobilised chloroplasts (liberation of O_2) was high and was retained for 30 days. When hydrophobic monomers were used, the activity of the chloroplasts decreased rapidly as a function of time.

6. Preparation of polymer implants

Technical procedures and methods used for the immobilisation of BAS (radiation-induced polymerisation) may be employed for the preparation of implants of various kinds, mainly for the therapy of damaged sections of the skin and also for the creation of prostheses. Methods have been developed for the preparation of collagen implants by irradiating mixtures of monomers or polymers with collagen.^{334–336} The implants are satisfactorily compatible with blood and do not give rise to inflammation. The implants are used in surgery and can be employed as substrates in biotechnology.³³⁴ Prostheses based on polyesterurethane with a radiation-modified inner surface have been investigated. The modification was achieved by the radiation-induced grafting of 2-hydroxymethyl acrylate or acrylamide on the inner surfaces of the tubes. The prostheses were studied *in vivo*. The histological and mechanical properties were investigated. Their improved thromboresistance was established.³³⁷ A method has been developed for the modification of polymer fillers used in dental technology. The fillers based on glass or quartz fibres were modified by the radiation-induced grafting of acrylic acid from the vapour phase. The physicochemical properties of resins containing different amounts of the modified filler were studied in detail. The advantages of the modified filler employed compared with the filler modified by silanes were noted.³³⁸ Polymeric-ceramic materials for dentistry have been created by irradiating mixtures of alumina and acrylic acid.³³⁹ Implants for the therapy of the skin on sections of the human body damaged by burns have been created with the aid of radiation-induced graft polymerisation.^{340, 341} Silicone rubber modified by the grafting of hydrophilic monomers or natural rubber modified by vulcanisation are normally employed for this purpose.³⁴¹ A method for the hydrophilisation of silicone contact lenses has been created with the aid of radiation technology. As a result of hydrophilisation, the wetting angle decreases from 150° to 20° and the hydrophilic effect persists for a long time.³⁴²

Radiation-modified polymers have been used for the initiation of the growth of various cells.^{147, 343, 344}

7. Preparation of 'smart' polymers and their use for the immobilisation of biologically active substances

'Smart' polymers have acquired in recent years an increasing importance for medicine and biotechnology. This is the term given to polymers capable of responding to small changes in the environment (temperature, pH, electric field, *etc.*).³⁴⁵ 'Smart' polymers with immobilised BAS are used for the liberation of medicinal substances under certain conditions, usually at a specified temperature or pH. 'Smart' polymers are normally obtained by traditional methods, but radiation-induced polymerisation has also come to be employed recently for this purpose.^{165, 247, 332, 346} Among the 'smart' polymers, the greatest number of publications have been devoted to poly(*N*-isopropylacrylamide) (poly-*N*-IPAA).^{345, 347} This polymer has a lower consolute temperature (LCT) of $\sim 32^{\circ}\text{C}$ in water, *i.e.* close to the temperature of the human body. Phase separation, caused by the conformational transition of the poly-*N*-IPAA macromolecule from a loose globule to a compact coil,^{345, 348, 349} which is accompanied by a sharp decrease in the size of the macromolecule, takes place above 32°C .³⁵⁰

The radiation-induced polymerisation of *N*-isopropylacrylamide has been investigated.^{351–353} Poly-*N*-IPAA gels have been obtained by irradiating aqueous solutions of the monomer. The gel formation dose is 71 Gy (dose rate 1 kGy h^{-1}). The temper-

ature dependence of the swelling in water of these gels, obtained for different doses, has been studied. It was established that the degree of collapse of the gels beyond the phase transition point depends significantly on the dose, which was explained by the structure of the polymer network. An important factor is that by selecting the dose it is possible to achieve a fairly fine regulation of the degree of collapse of the gels.

The radiation-induced copolymerisation of *N*-isopropylacrylamide in water and the cross-linking of the resulting gels have been investigated³⁵² by nuclear magnetic resonance. The influence of solvents on the radiation-induced polymerisation of *N*-isopropylacrylamide and the molecular mass of the resulting polymers have been studied.³⁵³ The lower consolute temperature of the resulting polymers is in the range 30.5–31.50 °C and depends little on the polymerisation conditions.³⁵³

The radiation-induced copolymerisation of *N*-isopropylacrylamide with *N*-acryloyloxysuccinimide has been investigated.³⁵⁴ The resulting copolymer was used for the immobilisation of bovine serum albumin, horseradish peroxidase, and monoclonal antibodies. It was shown that the dose at which the copolymer was obtained influences significantly the immobilisation process. The lower consolute temperature of the copolymers is in the range 30–35 °C and depends little on the concentration of the comonomers and the chain length. Asparaginase was immobilised in the gel obtained. The influence of temperature and the pH on the activity of the immobilised BAS was studied.

Radiation-induced copolymerisation led to the formation of copolymers of *N*-isopropylacrylamide and methacrylic acid.³⁵⁵ pH-Sensitive hydrogels were obtained by the radiation-induced copolymerisation of polydimethylsiloxane, containing vinyl groups, with *N*-isopropylacrylamide and acrylic acid. The lower consolute temperatures of the copolymers depend on the pH. The immobilisation of indomethacin³⁵⁶ and amylase³⁵⁷ in gels has been investigated and it has been established that indomethacin and amylase are slowly liberated from the hydrogels at 37 °C and pH 1.4 (the conditions in the stomach), but at pH 7.4 (conditions in the intestine) the liberation of the medicinal substances is appreciably accelerated. The copolymers of *N*-isopropylacrylamide with polydimethylsiloxane containing vinyl groups have been used for the immobilisation of progesterone. These copolymers were obtained for a dose of 10 kGy (dose rate 5 kGy h⁻¹). They have the same LCT as pure poly-*N*-IPAA. The gels contract rapidly on passing through the LCT. The microdomain structure of the gels was established.³⁵⁸ Thermosensitive gels based on alanine derivatives have been obtained.³⁵⁹ Radiation-induced graft polymerisation of *N*-isopropylacrylamide on silicone rubber has been studied.³⁶⁰ The hydration of the resulting graft copolymers has been investigated as a function of temperature and the copolymer composition. The unusual character of the hydration, influenced by the phase transitions in the grafted chains, was established.⁷⁹

The preparation of another 'smart' polymer — the methyl ester of poly(acryloyl-L-proline), which is synthesised by the radiation-induced polymerisation of the methyl ester of acryloyl-L-proline — has been described.^{352, 361} This polymer has a LCT of 14 °C.³⁶¹ The LCT of the polymer may be regulated either by the radiation-induced copolymerisation with 2-hydroxypropyl methacrylate³⁶¹ or by adding sodium dodecyl sulfate.³⁶² The coil–globule transitions and the cross-linking of the methyl ester of poly(acryloyl-L-proline), obtained by radiation-induced polymerisation, have been investigated.³⁶³

Testosterone was introduced into the gel of the methyl ester of poly(acryloyl-L-proline) by means of radiation-induced polymerisation. It was established that testosterone is uniformly liberated from the gel (30 mg per day) in the course of 54 weeks (tests on rats). The gel shrinks on the surface during dehydration, forming a rigid membrane barrier lacking micropores. Compact clusters are formed above the LCT.

A gel of the methyl ester of poly(methacryloyl-D,L-alanine) has been obtained by the radiation-induced polymerisation of the

methyl ester of methacryloyl-D,L-alanine.^{364, 365} The kinetics of the swelling and dehydration of the gel were investigated. It was established that, on dehydration at 40 °C, a bark (skin) is formed on the surface of the gel, closing the pores. The gel was studied by scanning electron microscopy. The gel contracts rapidly on heating.³⁶⁴ The radiation-induced grafting of the methyl ester of acryloyl-L-proline on polymeric materials irradiated by heavy ions has been studied.^{365, 366} The influence of surfactants on the phase transitions in polymers with amino acid side groups has been investigated.³⁶⁷

The antitumour preparation 9-β-D-arabinofuranosyladenine (Ara-A) was immobilised in a thermosensitive gel based on the copolymer of 2-hydroxyethyl methacrylate, styrene, and the methyl ester of acryloyl-L-proline cross-linked by nonaethylene glycol dimethacrylate. The gel was obtained by radiation-induced copolymerisation. The phase transition occurs at 14 °C. The gel shrinks rapidly on passing through the phase transition point. The liberation of Ara-A was investigated at 10–37 °C. The gel operates *via* a pulsating mechanism resembling a pump. Rapid shrinkage and liberation of Ara-A take place at 37 °C.³⁶⁸ Thermosensitive gels, obtained by the radiation-induced cross-linking of poly(methyl vinyl ether) (PMVE) dissolved in water, have been described.^{369–372} The phase transition is at 38 °C. Porous and fibrous gels were obtained and their swelling was studied under various conditions. Artificial muscles and fingers have been created on the basis on the PMVE gels.³⁶⁹ According to the data of Kobra *et al.*,³⁷⁰ the LCT for aqueous PMVE solutions is in the range 34–38 °C. By selecting the irradiation conditions, it is possible to obtain PMVE gels with high rates of swelling and dehydration.^{370–371} Aqueous 50% solutions of PMVE and doses of 60–110 kGy are used. A characteristic feature of the PMVE gels is larger volume changes compared with other thermosensitive gels. On heating, the gels contract rapidly and a microporous structure develops.^{372, 373} The transitions in the PMVE gels have been investigated.³⁷⁴ The immobilisation of exo-1,4-α-D-glucosidase in the PMVE gel has been described.³⁷⁵ The formation of glucose from maltose with the aid of this enzyme has been investigated and a marked influence of temperature on the activity of the enzyme has been established, this being associated with a phase transition in the gel.³⁷⁴

A series of data on the application of radiation-induced polymerisation and cross-linking for the creation of 'smart' polymers and their employment for the immobilisation of various medicinal preparations have been presented in reviews.^{346, 376–378} The problems of the employment of radiation-induced polymerisation for the creation of signal-sensitive systems consisting of a biosensor, an activator, and a reservoir have been considered.^{346, 378} Special systems with a biosensor for glucose are being developed. They are switched on in accordance with the on–off principle for the liberation of specific portions of insulin immobilised in gels.^{377, 378} New thermosensitive hydrogels have been obtained by the radiation-induced copolymerisation of vinyl ethers of glycols with various alkyl vinyl ethers.³⁷⁹ Certain theoretical problems associated with 'smart' polymers have been considered in a review.³⁸⁰

VI. The use of radiation-induced cross-linking for the preparation of polymeric biomaterials

The interest in the preparation of polymeric biomaterials by radiation-induced cross-linking has grown significantly at the present time. Such cross-linking is most frequently used to prepare hydrogels, mainly based on polyacrylamide poly(vinyl alcohol), poly(ethylene oxide), and poly(*N*-vinylpyrrolidone).^{381–383} An advantage of the radiation-induced cross-linking is the comparative simplicity of its implementation, the possibility of the wide scale regulation of the network density by selecting irradiation conditions (dose rate, dose), the possibility of using reduced temperatures, the purity of the product obtained (the absence of initiators), and simultaneous sterilisation. The radiation-cross-

linked hydrogels are used as BAS (enzymes, medicinal substances, *etc.*) carriers, implants, prostheses, eye lenses, medical membranes, dressings, and biological media for the study and culturing of microorganisms.

The methods of preparation and properties of hydrogels based on radiation-cross-linked polyacrylamide have been studied in greatest detail.^{384–401} The formation of gels of this compound on irradiation of aqueous acrylamide solutions over a wide range of conditions (monomer concentration, dose, and dose rate) has been investigated.^{282, 384, 388, 398}

The dose for gel formation is in the range 0.1–2.5 kGy. It falls rapidly with increase in the monomer concentration and increases with increase in dose rate. On irradiation of aqueous acrylamide solutions up to high doses, decomposition with formation of aldehydes and carboxylic acids takes place.³⁸⁸ The mechanism of the cross-linking of polyacrylamides is associated with the abstraction of a hydrogen atom from a tertiary carbon atom.³⁸⁷ Various procedures for the preparation of gels based on polyacrylamide have been studied.³⁹⁵ Using radiation-induced polymerisation, it is possible to obtain readily hydrogels of this polymer with a wide range of properties (hydrophilicity, modulus of elasticity, swellability, *etc.*). The hydrogels formed as a result of the radiation-induced copolymerisation of acrylamide and maleic acid exhibit a satisfactory biocompatibility with the serum prepared from human blood.³⁹¹

Methods have been developed for the preparation of dressings based on radiation-cross-linked polyacrylamide gels^{282, 385} as well as polymer eye lenses.²⁸² A three-stage radiation technology for the manufacture of dressing hydrogels to achieve the healing of extensive areas of burns and its advantages over other technologies have been described.⁴⁰¹ Polyacrylamide, obtained by radiation-induced polymerisation, has been used as the coating agent in X-ray films in order to economise on silver.³⁸⁶

A series of studies^{397, 402–420} have been devoted to the preparation of hydrogels by the radiation-induced cross-linking of poly(vinyl alcohol). The mechanism of the formation of its gel on irradiation in water and the properties of the gels,^{402, 403} in particular their swelling,³⁹⁷ have been studied in detail. The hydration of poly(vinyl alcohol) gels leads to crystallisation. Biomembranes for the selective transport of macromolecules as well as materials used as cartilage for joints have been obtained from radiation-cross-linked poly(vinyl alcohol).⁴⁰⁶ Radiation methods for the immobilisation of heparin,⁴⁰⁷ cellulase, urease,⁴⁰⁹ glucoamylase, and invertase⁴⁰⁵ as well as other BAS in poly(vinyl alcohol) hydrogels have been developed. Data on the use of radiation-cross-linked poly(vinyl alcohol) hydrogels for the fixation and controlled liberation of BAS have been presented in a review.⁴¹¹ A disadvantage of such gels is their low mechanical strength. The use of poly(vinyl alcohol) hydrogels as dressings has been described⁴¹⁸ and its advantage over muslin has been noted: homogeneous adhesion to the entire wound and easy removal without damaging the skin. Schemes for the preparation of heat-resistant hydrogels have been described^{418, 419} and methods have been proposed for the improvement of their mechanical properties.⁴¹⁸

Radiation-cross-linked poly(ethylene oxide) hydrogels have been investigated in fair detail.^{397, 421–431} A characteristic feature of such gels is an anomalous decrease in swelling and an increase in the modulus of elasticity on drying, caused by the formation of additional units as a result of crystallisation. The possibility of obtaining porous gels in which the pore size can be varied widely as a function of the irradiation dose is very important. The structure of the ultrahigh-molecular poly(ethylene oxide) after γ -irradiation has been investigated.^{430, 431} It has been suggested that radiation-cross-linked hydrogels of this polymer be used as the medium for the culturing of microorganisms.⁴²⁹ The preparation of biocompatible materials based on radiation-cross-linked poly(ethylene oxide),⁴²⁰ the hydrophobic properties of which may be enhanced by the radiation-induced grafting of butadiene, styrene, or ethene,⁴²⁰ has been described.⁴²⁰

Hydrogels based on poly(*N*-vinylpyrrolidone) are highly hydrophilic and are satisfactorily biocompatible.^{432–442} The methods of preparation of such gels by the irradiation of aqueous *N*-vinylpyrrolidone solutions have been studied in detail.^{438, 443} The radiation-induced cross-linking and degradation of poly(*N*-vinylpyrrolidone) have been studied.⁴³⁵ The radiation technology for the preparation of gels of this polymer, used as a material for the treatment of burns and trophic ulcers, has been described in detail.^{436, 440} These materials are sold in Poland under the commercial names HDR^R and AQUA-Gel^R. A therapeutic system based on the poly(*N*-vinylpyrrolidone) gel has been developed for use in obstetric practice to accelerate births and to induce abortions. In this case, the gel consists of a thin rod containing prostaglandin. The methods for the preparation of such gels have been described in detail.^{432, 436} Data on the biological and physical properties of the hydrogels used as dressings have been described and compared with the usual muslin bandages.⁴⁴¹ The influence of the irradiation dose on the mechanical properties of poly(*N*-vinylpyrrolidone) gels filled with agar and poly(ethylene glycol) has been studied (Fig. 1).⁴⁴²

Figure 1. Dependence of the elongation before rupture (*a*) and of the tensile strength (*b*) on the irradiation dose for poly(*N*-vinylpyrrolidone) gels 2.5±0.5 mm thick. (1) Gels filled with agar and poly(ethylene glycol); (2) gels filled with agar.

The technology for the preparation of hydrogels for dressings has now been developed in fair detail and they have undergone extensive clinical tests.⁴³⁹ An important factor is the possibility of obtaining gels for dressings containing medicinal preparations (for example, chloramphenicol).⁴⁴⁰ In the case of large wounds, such a hydrogel is significantly more effective than the usual dressings. Radiation-cross-linked hydrogels based on poly(*N*-vinylimidazole), the properties of which are close to poly(*N*-vinylpyrrolidone) gels,^{444, 445} as well as radiation-cross-linked gels based on microbial poly- γ -glutamic acid with a high moisture-absorbing capacity⁴⁴⁶ and hyaluronic acid gels with a high biocompatibility⁴⁴⁷ have been obtained. Practical advice concerning the preparation of various hydrogels — optically homogeneous and with a minimal content of the residual monomer — has been given.⁴⁴⁸

Interesting studies have been carried out in order to obtain polymeric materials based on collagen.^{334–336, 449–454} The formation of gels on irradiation of collagen solutions has been studied in detail.^{449, 454} These solutions have been used for the creation of radiation-modified medical implants.^{449–451, 454} Collagen coatings on silicone rubber, subsequently radiation-cross-linked and sterilised, are used in medicine.⁴⁵³ Another natural product employed for the preparation of biomaterials is gelatin.^{454–457} The radiolysis of gelatin has been studied and the conditions for the formation of three-dimensional structures on irradiation of its solutions have been discovered.⁴⁵⁴ It has been suggested that a radiation-cross-linked composition comprising poly(vinyl alcohol) and gelatin be used as a dressing.⁴⁵⁷

Gels based on polyphosphazenes have been investigated.⁴⁵⁸ A new method has been proposed⁴⁵⁹ for the preparation of hydrogels using natural polymers: gelatin, dextran, and albumin. The method consists in the functionalisation of natural polymers by introducing into them double bonds with subsequent cross-linking by γ -irradiation. The method makes it possible to introduce a large amount of a BAS into the hydrogels.

Radiation-induced cross-linking has been used for the preparation of medical articles made from polysiloxanes: biologically inert porous cord, syringe tubes, capillaries,⁴⁶⁰ and various implants.^{461–463} In the radiation-induced cross-linking of polydimethylsiloxane under specially pure conditions, its haemocompatibility increases significantly.⁴⁶² The radiation-cross-linked polyvinylmethylsiloxane has been used to prepare thin membranes for the making of medicinal preparations (for example, levonorgestrel).⁴⁶³

The radiation-induced cross-linking of trans-1,4-polyisoprene has been used to create thermoshrinking materials for the tying of large blood vessels. The materials have undergone extensive tests *in vitro* and *in vivo* (on dogs).^{464, 465} Radiation modification makes it possible to improve the properties of medical prostheses based on polyolefins.⁴⁶⁶ Polymeric biomaterials with enhanced adhesion to human skin have also been obtained with the aid of radiation-induced cross-linking.^{466, 467}

The manufacture of a synthetic dressing, obtained by the radiation-induced grafting of hydrophilic monomers on polyurethane, has been initiated in Israel. The material is water-impermeable and transparent, is readily attached to the skin, and is permeable to medicinal drugs. The material is manufactured under the name Omiderm.⁴⁶⁸

A pilot plant has been created for the manufacture of radiation-cross-linked natural rubber latexes.⁴⁶⁹ The production of the plant is 1000 tonnes of the product per year (Malaysia). These materials are used to manufacture high-quality medical gloves, thin-walled articles, *etc.*^{469–471} Radiation-induced cross-linking polymerisation is particularly important in the manufacture of polymeric biomaterials for ophthalmology. Procedures for the hydrophilisation of contact lenses by the radiation-induced graft polymerisation of *N*-vinylpyrrolidone^{472–476} or hydroxyethyl methacrylate^{477, 478} have been described. Methods have been developed for the preparation of an artificial cornea and contact lenses with a high swellability in water from radiation-cross-linked poly(vinyl alcohol) with added sodium chondroitin sulfate.⁴⁷⁹

Ionising radiation has been used to ensure complete hardening and to minimise the amount of residual monomer in the preparation of contact lenses.^{480–482} In order to increase significantly the permeability of the contact lenses to oxygen, it is suggested that they be irradiated with accelerated heavy ions having a mass of 2–100.⁴⁸³ Hydrogel materials for soft contact lenses have been created with the aid of radiation-induced polymerisation.^{484, 485} These materials are produced in China.⁴⁸⁵

Radiation-cross-linked collagen, isolated from the sclera of animal eyes, has found an application in the manufacture of ophthalmological materials. This material has been used for the creation of temporary allodrainages in antiglaucoma operations.⁴⁸⁶

Thus the use of ionising radiation for the preparation of polymer hydrogels is promising. Considerable progress has been achieved in the study of the mechanisms of the radiation-induced cross-linking of hydrogels and their practical applications have expanded, particularly in the preparation of polymeric materials used for the rapid healing of various wounds.

An advantage of the radiation-induced cross-linking is the possibility of regulating comparatively easily not only the network density but also the nature of the radiation-induced cross-linking itself by varying the dose rate and the polymer concentration. It has been established that, at a low polymer concentration and at a high dose rate, intramolecular cross-linking predominates over intermolecular cross-linking.^{487, 488}

VII. Conclusion

The scale and level of studies on the employment of radiation-chemical methods for the preparation of polymeric biomaterials designed for application in medicine and biotechnology has expanded significantly in recent years. Certain advantages of these methods compared with traditional ones have been clearly established. The use of ionising radiation for the preparation of polymeric biomaterials is one of the examples of the application of atomic energy for the benefit of humanity.

Considerable advances have been achieved in the employment of low-temperature radiation-induced polymerisation for the immobilisation of various BAS. The immobilisation of antitumour preparations has been studied in greatest detail and extensive investigations of their application in clinics have been performed.

Low-temperature radiation-induced polymerisation has been applied in the immobilisation of enzymes designed for the enzymic hydrolysis of plant waste (Japan). Extensive studies on the use of the radiation-chemical technology for the processing of plant raw material have been carried out in Russia.

Sorbents which have increased significantly the effectiveness of the chromatographic separation of mixtures of certain BAS have been created with the aid of radiation-induced graft polymerisation. Much work has been done on the application of radiation-induced graft polymerisation for the modification of polymeric materials in order to increase their haemocompatibility.

A whole series of novel methods for the immobilisation of BAS using radiation chemistry have been developed in our country.¹

Studies on the employment of radiation-chemical methods for the preparation of a wide variety of polymer hydrogels have been developed very successfully. Some of them (in the form of dressings and polymer eye lenses) have been introduced into clinical practice (Poland, Israel, China). Immunodiagnostic sets employing the radiation-induced polymerisation of 2-hydroxyethyl methacrylate are being manufactured on an industrial scale [K Vacek (Czech Republic), private communication]. The immunodiagnostic sets are used to determine the activity of phagocytes. The radiation-induced graft polymerisation of organotin monomers has been used to prepare modified polymers with fungicidal properties.⁴⁸⁹

New extremely promising aspects of the application of radiation-chemical methods for the preparation of 'smart' polymers designed to be used in biotechnology and medicine have appeared in recent years. They are designed in particular for the deliberate introduction of medicinal substances at the required site in the human organism and also for the preparation of polymer membranes responding to changes in the environment (pH, temperature, *etc.*), which may find an important application in medicine and biotechnology. In all probability, there is a great future for this aspect of the application of radiation-chemical methods.

Studies on the use of ionising radiation for the creation of polymeric biomaterials are being coordinated by the International Atomic Energy Agency (IAEA) and are being prosecuted most vigorously in the USA and Japan.⁴⁹⁰

Significant advances have been achieved by specialists in Poland.^{491, 492}

Hydrogels are being developed most vigorously at the Institute of Applied Radiation Chemistry at the Technical University of Lodz in Poland. Two of the polymer hydrogels developed for the treatment of bed sores, burns, wounds, and transplanted skin tissues and also in the therapy of ulcers have become commercially available in a number of European countries.⁴⁹² The development of materials for an artificial pancreas (it produces insulin), graft tissues for blood and other vessels, and materials for employment in ophthalmology and dentistry is in the completion stage.⁴⁹²

There is no doubt that one may expect in the immediate future the appearance in the market place of new polymeric biomaterials obtained with the aid of radiation-chemical methods.

VII. Hetero-analogues of alkynyl carbocations	849

Abstract. Published data on carbenium ions containing $C \equiv C$ bonds both directly conjugated with the carbenium centre and separated from it are surveyed and described systematically. Ammonium, diazonium, iminium, phosphonium and iodonium cations containing alkynyl groups, which can be regarded as heteroanalogues of alkynylcarbenium ions, are also considered. The bibliography includes 283 references.

I. Introduction

The chemistry of unsaturated carbenium ions is constantly attracting the attention of researchers. The range of objects containing unsaturated carbenium ions is fairly broad: they vary from stable salts used as reagents with unique properties to extremely reactive intermediates the stability of which is comparable to that of the methyl cation.

Unsaturated carbocations with a variety of structures are known. However, all of them can be classified as two main types: (1) cations with a tricoordinated carbenium centre (trisubstituted ions) and (2) cations with a dicoordinated carbenium centre (disubstituted ions). In the former type of cations, the multiple bond is located in the α -position in relation to the positively charged atom (or is farther removed from it along the chain), whereas in the latter type of cations, an atom forming the multiple bond acts as the carbenium centre.

The first type of unsaturated cations comprises allyl cations **1**^{1–7} including functionally substituted ones^{8,9} and their hetero-analogues — 2-azaallenium ions **2**,^{10–15} iminocarbenium ions **3**^{16,17} and α -oxocarbenium ions **4**.^{17–21}

The second type includes vinyl (**5**)^{22–27} and phenyl (**6**)^{17,26–29} cations as well as acylium (**7**)^{2,26,30} and nitrilium (**8**)^{26,31,32} cations.

The species, which arise when a carbenium centre is generated near a triple carbon–carbon bond, occupy a special place among unsaturated carbocations. They can be related to either of the two types mentioned above, because in some cases, these species behave as destabilised (compared to the dimethylvinyl- and even ethyldimethyl-carbenium) tertiary cations (alkynylcarbenium ions **9**),¹⁷ whereas in some other cases, they behave as vinyl ions stabilised by conjugation (allenyl ions **10**).²³

It is obvious that in reality, the charge in the three-carbon chain is substantially delocalised, the degree of delocalisation and, hence, the structure and the behaviour of the cations **11** being dependent on the nature of the substituents R^1 , R^2 and R^3 and the reaction medium. These cations have been considered in numerous studies, the results of which have not yet been surveyed. The stabilised species **10** are discussed in several reviews devoted to vinyl cations.^{22,23,26,33} However, in our opinion, it is more correct

S M Lukyanov, A V Koblik, L A Muradyan Institute of Physical and Organic Chemistry, Rostov State University, pr. Stachki 194/2, 344104 Rostov-on-Don, Russian Federation. Fax (7-863) 228 56 67

to regard them as acetylene derivatives in which the triple bond is activated by a cationic substituent. This approach has been proposed in studies^{34,35} dealing with the reactions of acetylene derivatives with nucleophiles. The use of acetylene derivatives with cationic substituents proved to be more efficient than the introduction of neutral electron-withdrawing groups^{36–38} or the use of acetylene derivatives of the push–pull type (for example, compounds **12** and **13**^{39,40}).

In this review we consider the ions **11** as alkynylcarbenium ions the properties of which are determined by the degree to which the multiple bond in these species retains the nature of a triple carbon–carbon bond.

II. Alkynyl carbocations in transformations of acetylene derivatives

Alkynylcarbenium ions have been postulated as intermediates in acid-catalysed transformations of functionally substituted acetylene derivatives. First of all, this refers to the Meyer–Schuster and Rupe rearrangements (see a review⁴¹ and studies^{42–44}). Long before alkynylcarbocations were detected experimentally (see Section III), it had been concluded that acid-catalysed propargyl rearrangements^{45–47} can occur *via* the intermediate formation of carbocations the structure of which allows realisation of two reaction pathways.⁴⁸ These pathways usually compete, the predominance of either of them being determined by the structure of the initial α -hydroxyacetylene **14**.

the Rupe rearrangement

the Meyer–Schuster rearrangement

In both cases, α,β -unsaturated carbonyl compounds **18** and **19** are formed. The main difference between these two routes is determined by the carbon atom in the acetylenic fragment which is hydrated and, hence, forms the carbonyl group. The Rupe rearrangement occurs *via* alkynylcarbenium intermediates **15**, which are capable of being deprotonated to enynes **17**. Protonation of the β -carbon atom in the enyne **17** with the addition of water to the α -carbon atom is energetically the most favourable route. However, when the cationic intermediate is stabilised by, for example, aryl groups, participation of the allenyl cation **16** in the reaction becomes more favourable. This cation is hydrated at

the β -carbon atom of the acetylenic fragment (the Meyer–Schuster rearrangement).

Other functional derivatives of acetylene also can enter into this type of rearrangement. α -Chlorinated alkynes **20** are converted into allene compounds **21** or **22**, depending on the reaction conditions.^{48,49} In the latter case, the reaction also gives products **23** and **24**.⁴⁹

3-Methoxy-1,3,3-triphenylprop-1-yne **25** rearranges under various conditions, and the structure of the rearrangement products implies that the reaction occurs predominantly *via* the most stable cationic intermediates.⁵⁰

(a) MeOH, 100% H₂SO₄; (b) HCl.

In the presence of copper and silver salts, the acetates of tertiary alkynols **23** are converted exclusively into α,β -unsaturated aldehydes **27**.⁴⁶

R¹ = Me; R² = (CH₂)₂CH = CMe₂, (CH₂)₂C(Me) = CMe₂;
R¹, R² = (CH₂)₄, (CH₂)₅.

It has been suggested that alkynyl carbocations can arise even under Grignard reaction conditions.⁵¹

When hydroxy ketones of the acetylene series **28** react with dry HCl in CCl₄, they undergo an unusual rearrangement to give vinyl-substituted α,β -diketones **29**.⁵²

R = Me, Et, Prⁱ.

A series of studies describe^{53–57} the transformations of 1-ethynyl-1-hydroxyphthalans **30** yielding the corresponding α,β -unsaturated ketones **31**.

$\text{R}^1 = \text{Me, Ph; R}^2 = \text{Me, Bu}^t, \text{Ph, 4-MeC}_6\text{H}_4$.

Alkoxyalkynols **32–34** are converted into α,β -unsaturated esters **35–37** under mild conditions.^{58–60}

Four possible mechanisms, including those involving alkynylcarbenium ions, have been discussed for these transformations.⁵⁹ It has been noted that none of the schemes provides a satisfactory explanation for the formation of the *cis*-isomers of the compounds **36** and **37**, which possess higher energies than the corresponding *trans*-isomers.

Acid-catalysed transformations of a large series of symmetrical and asymmetrical alkynediols **38** have been described in detail.⁶¹ The pathway of these reactions, which occur presumably with participation of alkynylcarbenium ions, depends on the structure of the substrates and the nature of the acid catalysts and the solvents.

$\text{R}^1 - \text{R}^4 = \text{Me, Et, Pr}^i, \text{Bu}^t, \text{Ph, 4-MeC}_6\text{H}_4, \text{PhCO, 2-pyridyl, (CH}_2\text{)}_5$; Hal = Cl, Br, I;

Acid catalyst: $\text{H}_2\text{SO}_4, \text{HCl, HBr, HI, HI-I}_2, \text{AcCl, HCOOH}$;

Solvent: THF, EtOH, AcOH, $\text{Me}_2\text{CO, CCl}_4, \text{AcOH-dioxane}$.

The structures of the products formed in these transformations reflect the typical reactions of carbenium intermediates,² namely, deprotonation, addition of nucleophiles, alkyl migrations and electrophilic aromatic substitution.⁶¹ The same typical reactions are observed in many other cases. Thus tertiary β -alkynols **39** undergo the Rupe rearrangement.⁴¹

On treatment with dilute H_2SO_4 , bitertiary 1,2-diols of the acetylene series **40** undergo not only the Meyer–Schuster rearrangement yielding enones **43** (or subsequent dehydration to dienones **44**) but also the pinacolic rearrangement to give alkynones **42**. Undoubtedly, this process occurs *via* the alkynyl carbocations **41**. The transformation of the compounds **40** affords as well stable dihydrofurylium salts **45**.^{62,63}

The use of the Meyer–Schuster and Rupe rearrangements, accompanied by sextet rearrangements with group migrations and ring transformations, for the synthesis of compounds that are difficult to prepare by other methods has been described in a review.⁴¹ These transformations are possible when tertiary or, at least, secondary alkynyl carbocationic intermediates are fairly stable. In this connection, the formation of the vinylic cation **46**, which rearranges to give dihydrofuran **47**, deserves attention.⁶⁴

Based on dehydration of hydroxyacetylenes **49**, an interesting preparative approach has been developed for the transformation of alicyclic ketones **48** into diketones **51** and furans **52**.^{65,66}

R = Me, Ph, 3,4-(MeO)₂C₆H₃, 4-NO₂C₆H₄; X = CH₂, CHMe, CHPh, CPh₂ (**51**, **52**);
 R = 4-MeOC₆H₄, 2,4-(NO₂)₂C₆H₃; X = SO₂, NTs, NCO₂Et (**52**).

Tertiary alcohols of the acetylene series **53** have been used to synthesise enynes **54** and **55**.⁶⁷

Dehydration of secondary alkynols of the general formula **56** occurring on treatment with various acidic reagents (HCl, CF₃COOH, polyphosphoric acid) affords unusual enyne furan derivatives **57**.^{68–72}

R¹ = H, Me; R² = H, Pr, Bu, C₅H₁₁, C₆H₁₃, CH₂OMe, C≡CPh, Ph;
 R³ = Et, Bu^t.

On heating in aqueous dioxane (60 °C) in the presence of toluene-*p*-sulfonic acid, the alcohols **56** recycle to cyclopentenones **59**, **60**, which can serve as valuable starting compounds for the synthesis of prostanoids.⁷² In early experiments, the yields of these products were very low (~10%), due to substantial resinification of the reaction mixtures; however, later, the yields were brought to 80% as a result of stabilisation of the intermediate alkynyl carbocations by complex formation (see Section V).

The Rupe rearrangement in the presence of the solid superacid 'Nafion-H' has been proposed as an improved method for the synthesis of alicyclic and linear α,β-unsaturated ketones **61** (⁷³ (see also Ref. 74).

R¹ = Me, Et; R² = Me; R¹, R² = (CH₂)_n, n = 3–6; R³ = H, Me.

The Meyer–Schuster rearrangement has been used to prepare fulvenes **63** (which are intermediates in the synthesis of spiro compounds) based on 3-methyl-2-azafluorenone **62**.⁷⁵ A new method for the preparation of *S*-phenyl thioesters **65** consists in the reaction of phenylthio-substituted alkynols **64** with the trimethylsilyl ester of polyphosphoric acid.⁷⁶

R¹ = Et, Prⁱ, Bu, Bu^t, PhCH₂CH₂, BuCH₂, PrCH=CH,
 PhCH=CH, BuC≡C; R² = Bu; R¹, R² = (CH₂)_n, n = 4–6.
 PPSE is the trimethylsilyl ester of polyphosphoric acid.

The specific structure of the initial hydroxyacetylene may result in an unusual route of the propargyl rearrangement. Thus treatment of ethynyl-containing alcohols **66**, **67** and **69** with a 35% solution of HClO₄ in THF gave rise to dienones **68** and **70**, which are difficult to prepare by other methods and which are used in the synthesis of di- and tri-terpenoids.⁷⁷

Perfluorobutyl-substituted alkynols **72** have been found⁷⁸ to behave unusually under the Rupe reaction conditions: dehydration does not occur at all; nevertheless, a carbonyl group appears at the α-carbon atom of the multiple bond. The α-hydroxy ketones **73** thus formed are converted into a mixture of hydroxy ketones **74** and furanones **75** upon prolonged (60 h) refluxing in HCOOH as a result of the acyloin rearrangement involving the perfluorobutyl group.

R = Me, Et.

Mention should be made of the unusual pinacolic rearrangement of 1,2-glycol derivatives of the acetylene series **76**, which gives rise to α,β -unsaturated alkynones **77**. These compounds are used as chiral synthons in syntheses of biologically active compounds.⁷⁹

$$R^1 = \text{Ph, Bu}^t\text{Me}_2\text{Si, Ph}(\text{CH}_2)_3; R^2 = \text{H, Bu, PhCH}_2\text{OCH}_2; R^3 = \text{H, Bu.}$$

This stereospecific 1,2-rearrangement occurs due to the fact that the ability of the ethynyl substituent for migration to the carbenium centre is much lower than that of the alkenyl substituent activated by the Me₃Si group.⁷⁹

Acid-catalysed esterification of alcohols **78** resulting in the formation of mixed orthoesters **79** and the subsequent Claisen rearrangement of ketene acetal **80** afford allene esters **81**.⁸⁰ This type of transformation of orthoesters is known⁸¹ to involve cationic intermediates. These reactions have been used to synthesise compounds **82** and **83**, analogues of juvenile hormones⁸² and sex pheromones⁸³ of insects.

$$R^1 = \text{H, Me}; R^2, R^3 = \text{H, Me, Pr, (CH}_2)_5; R^4 = \text{H, Me.}$$

The Meyer–Schuster rearrangement initiated by SOBr_2 has been used to carry out stereospecific synthesis of chiral 1,3-disubstituted bromoallenes (*R*)-**85** from alkynols (*R*)-**84**⁸⁴ and to synthesise the α,β -unsaturated aldehydes **27** in the presence of polyanadiummorganosiloxanes.^{85, 86}

R = Me, Bu^t.

$$R^1 = H, Me; R^2 = 4-Pr^iC_6H_4, 4-Bu^iC_6H_4, 4-MeOC_6H_4, 4-MeC_6H_4, 2,4-Me_2C_6H_3.$$

A reaction of cyclopropenylum salts which is accompanied by rearrangement with cyclopropene ring opening and gives alkynyl-carbenium dications **87** has been described;⁸⁷ the dications **87** were converted into tricarbenium ions **88** stabilised by electron-donating substituents. The principle of coupling of positively charged building blocks used here seems promising for the synthesis of extended polycationic systems consisting of allyl-cationic and/or cyclopropenylum fragments stabilised by electron-donating groups.

Treatment of ethynyl ketones **89** with PCl_5 affords 1,3-dichloroallenes **91** *via* intermediate chloro(ethynyl)carbenium ions **90**.⁸⁸ Participation of ethynyliminium ions **93** has also been assumed in the transformations of azomethines of the acetylene series **92**.⁸⁹

R = Me, Prⁱ, Ph.

Ar = 2-MeC₆H₄, 4-ClC₆H₄.

Ionic hydrogenation of alkynols **94** (treatment with trialkylsilanes in the presence of trifluoroacetic acid) involves reduction of the hydroxyl group.⁹⁰ The mechanism proposed for this reaction includes transformation of the alcohol into carbocation **95**, which adds the hydride ion detached from the silane.⁹¹

R¹ = Me, Et, Ph; R² = H, Me, Et, Prⁱ, Bu^t; R³ = Me, Et, Bu, Ph.

In the greater part of the publications listed above, the formation of alkynylcarbenium ions was merely postulated based on the general considerations about the mechanisms of acid-catalysed propargyl rearrangements and transformations of functional derivatives. However, alkynylcarbenium ions have ceased to be hypothetical species long ago. They have been repeatedly detected by spectroscopy (Section III); numerous reliable examples of stable alkynylcarbenium salts have now been described (Section V).

III. Spectroscopic studies of alkynyl carbocations

The first attempts to detect experimentally alkynylcarbenium ions were based on the study of the kinetics of solvolysis. The few studies devoted to this topic are surveyed in several publications.^{33, 92, 93} However, they provided only kinetic evidence for the participation of carbocationic intermediates in solvolysis but gave no information about the structure of these species. It has been noted that the allenyl cations **10** are contributing structures in relation to the propargyl cations **9** and that the ions in question can be generated by solvolysis of both haloalkynes **96** and haloallenes **97**.

In general, the experimental data obtained for the solvolysis of both series of derivatives under a variety of conditions indicate that these reactions follow the S_N1 mechanism and that the halides **96** react much faster than the corresponding allenyl isomers **97**.⁹²⁻⁹⁵

Attempts to elucidate the nature of unsaturated cationic intermediates have also been made in studies dealing with electrophilic addition to cumulenes. Thus, it has been found that hydrochlorination of penta-1,2,3-triene **98** in aqueous ethanol gives 1,2- and 1,4-addition products (**100** and **101**, respectively) in 1 : 4 ratio, whereas in a 4 : 1 sulfolane-CH₂Cl₂ mixture, the ratio of these products is 1 : 1.⁹³

The relative stability of the ethynyl carbocations with respect to the stabilities of secondary, tertiary and allylic cations can be derived based on the rates of solvolysis of the series of derivatives

102. The results obtained indicate that substituents R can stabilise the cationic intermediate **103** (the rate of solvolysis for R = H was taken to be unity).¹⁷

More definite information about the structure of the unsaturated cations in question can be obtained by NMR spectroscopy. The first direct observation of alkynyl carbocations **105** was reported by Richey *et al.*⁹⁵ in 1965. These cations aroused particular interest due to the fact that they could be regarded as a sort of vinylic cations (see Section I). The ¹H NMR spectrum of the solution resulting from extraction with CCl₄ of the product formed upon careful addition of 1,1-di(*p*-methoxyphenyl)but-2-yn-1-ol **104** to concentrated H₂SO₄ proved the formation of the cations **105** under these conditions.

Ar = 4-MeOC₆H₄.

Dilution of this solution by water or aqueous alkali results in the recovered initial alcohol **104** together with a minor amount of the rearranged product **106** (*i.e.* $k_2 \gg k_3$). The signal for the methyl protons of the propynyl fragment ($\delta = 2.6$ ppm) in the cation **105** is substantially shifted downfield in relation to this signal for the initial alcohol **104** ($\delta = 1.87$ ppm); this is due to the substantial charge delocalisation between the tertiary carbenium centre and the multiple bond.

It was shown in the same study⁹⁵ that the cation **108a** is generated both from alcohol **107** and from a mixture of dienyne **109** and **110**; this was proved by the data of ¹H NMR spectra in which the signals for the methyl protons at the ends of the unsaturated chain (Me^a, Me^b) almost coincide.

Compound	Chemical shift, δ /ppm		
	Me ^a	Me ^b	Me ^c
107	1.78		
108a	2.65	2.76	1.10
109	1.93		
110	1.93		

A large series of ethynyl- and propynyl-carbenium ions **9a-h**, **105** and **108a,b** have been obtained by mixing solutions of the corresponding tertiary alcohols in liquid SO₂ with a solution of

Table 1. Chemical shifts of the protons of substituent R³ in the ¹H NMR spectra of ethynyl- and propenylcarbenium ions.⁹⁶

Compo- und	R ¹	R ²	R ³	δ(R ³) /ppm	Δδ
9a			Me	2.47	0.63
9b	Ph	Ph	Me	2.88	1.06
9c	Ph	Me	Me	2.94	1.12
9d	MeC≡C–	MeC≡C–	Me	2.76	0.89
9e			H	5.58	3.35
9f	4-MeOC ₆ H ₄	4-MeOC ₆ H ₄	H	5.70	3.05
9g	Ph	Ph	H	6.96	4.35
9h	Ph	Me	H	7.24	4.76
105	4-MeOC ₆ H ₄	4-MeOC ₆ H ₄	Me	2.60	0.73
108a	–	–	Me	2.63	0.85
108b	–	–	H	6.32	4.00

antimony pentafluoride in fluorosulfonic acid (the ratio SbF₅:FSO₃H = 1:3 by volume) at –78 °C. Table 1 presents the ¹H NMR spectra of these mixtures recorded at –60 °C.⁹⁶

The chemical shifts of the methyl group protons in the compounds **9a–d**, **105** and **108a** and the ethyne protons in **9e–h**, **108b** as well as the downfield shifts of these signals (Δδ) with respect to the signals of the corresponding protons in the initial alcohols point to substantial deficiency of the electron density on the carbon atoms of the acetylenic fragment. This deficiency becomes more pronounced as the carbenium ions become less stable, *i.e.* the ability of the substituents at the tertiary carbenium centre to delocalise the charge decreases.

More comprehensive data on the ¹H NMR spectra of the above cations and some other alkynyl carbocations can be found in reviews.^{33,97}

Olah *et al.*⁹⁸ attempted to generate alkynylcarbenium ions by treating tertiary alkynyl chlorides with SbF₅ or a solution of SbF₅ in SO₂. However, these experiments were unsuccessful due to the large amount of side products. Therefore, the researchers⁹⁸ used again the corresponding tertiary alcohols, which were treated as described in the study cited above.⁹⁶ As a result, they recorded the ¹H NMR spectra of the cations **9b** and **9i–n** (Table 2).

Table 2. Chemical shifts of methyl group protons in the cations **9b**, **i–n**.⁹⁸

Compound	R ¹	R ²	R ³	δ/ ppm
9b	Ph	Ph	Me	2.88
9i	Ph	Ph	Ph	–
9j	Ph	Me	Ph	3.14
9k	Me	Me	Ph	3.39
9l	Me ^a	Me ^a	Me ^b	3.67(a), 3.13(b)
9m	Me ^a	4-Me ^b C ₆ H ₄	Me ^c	3.05(a), 2.45(b), 2.59(c)
9n	Me ^b	Me ^a	Ph	3.11(a), 2.82–3.00(b, c)

Several conclusions were drawn from analysis of the ¹H NMR spectra of these cations.⁹⁸ Thus the downfield shift of the signal of the protons of the methyl group bound to the tertiary carbenium centre increases in the sequence **9m** < **9n** < **9j** < **9k** < **9l**, *i.e.* following the decrease in charge delocalisation by the other two substituents. The positive charge in the ion **9l** (δ^{Me} = 3.67 ppm) is markedly redistributed, with respect to that in the *tert*-butyl cation (δ^{Me} = 4.35 ppm),⁹⁹ with participation of the propynyl fragment;

this is also manifested as a downfield shift of the signal of the methyl protons in the cation **9l**. Nevertheless, an alkynyl group is unable to delocalise the charge efficiently (at least, as efficiently as does the vinyl group), because the attempts to generate alkynyl carbocations from the secondary alcohols RCH(OH)C≡CPh (R = Ph, Me) failed.⁹⁹ Under the conditions reported, instantaneous polymerisation occurred even at –60 °C.

The alkynoyl cations RC≡C–C⁺=O (R = H, Me, Ph) are quite stable; for these species, ¹H and ¹³C NMR spectra have been recorded¹⁰⁰ and substantial charge delocalisation over the conjugation chain has been demonstrated. Tris(*tert*-butylethynyl)methanol **111** readily reacts with strong acids even at room temperature. However, a satisfactory ¹H NMR spectrum of cation **112** was obtained only upon cooling a solution of the alcohol **111** in chlorosulfonic acid below 3 °C. The spectrum exhibits a singlet with δ = 1.86 ppm due to the *tert*-butyl group protons (note for comparison that the protons of the alkyl group in the initial alcohol **111** are responsible for a signal with δ = 1.70 ppm).¹⁰¹

It is of interest that bright colouring of acidic solutions of tris(alkynyl)methanols was mentioned in publications back in the 1920s (see Ref. 101 and references therein).

The alkynyldihydroxycarbenium ions RC≡C–C⁺(OH)₂ (R = H, Me, Ph) arising upon protonation of the corresponding propiolic acids by FSO₃H in liquid SO₂ (–78 °C) or in SO₂ClF (–120 °C) have been detected by NMR spectroscopy.¹⁰²

A fairly comprehensive study of the ¹³C NMR spectra of a series of phenylethynylcarbenium ions (together with benzyl- and naphthylcarbenium cations) has been reported by Olah *et al.*¹⁰³ They analysed in detail the degree of positive charge delocalisation as a function of the nature of the substituents at the carbenium centre. In particular, the ¹³C NMR spectra of protonated carbonyl compounds **113** were discussed.

Olah *et al.*¹⁰⁴ have analysed the ability of an alkynyl group to delocalise positive charge in comparison with this property of other groups. This was done using a series of carbenium dications **114** generated from the corresponding diols or dihalo-derivatives on treatment with FSO₃H, SbF₅–FSO₃H or SbF₅–SO₂ClF.

According to the data of ¹H and ¹³C NMR spectra, *para*-phenylene and cyclopropyl groups possess the best capacity for charge delocalisation. The –CH=CH– group occupies an intermediate position, and the –C≡C– group exhibits the poorest charge delocalisation capacity. In the tetraphenyl-substituted dications **114** (R = Ph), the charge is mainly concentrated on the carbenium centres and also in the *ortho*- and *para*-positions of the terminal phenyl groups.¹⁰⁴

The ¹³C NMR spectra of dications of the type **114** were compared with those of the diphenylpropynylcarbenium (**9b**) and diphenylallyl (**115**) cations.^{100, 104} The relationship between the chemical shifts of the carbon atoms implies that in symmetrical dications **114** (R = Ph, X = –CH=CH–, –C≡C–), the charge is delocalised to a lesser extent than in the corresponding ions **115** and **9b**. When the initial alcohol molecule contains no electron-

releasing groups attached to the potential carbenium centre and capable of charge delocalisation, dications of the type **114** ($R = \text{Me}$) are not formed. Attempts to ionise 2,5-dimethylhex-3-yne-2,5-diol **116** result in a complex mixture of carbocations. As has already been mentioned, systems of this sort (**38**, Section II) readily undergo various types of isomerisation such as the Rupe and Meyer–Schuster rearrangements.

Other spectroscopic methods have also been used to study alkynylcarbenium ions. Stable alkynylcarbenium salts have been characterised by IR spectroscopy (Section V). Electronic spectroscopy has been used to detect cationic intermediates and to measure their lifetimes.^{33,95} The dependence of the electronic spectra of cations **117** on the nature of the substituent in the arylolefinyl fragment has been studied in order to develop new ethynyl analogues of triphenylmethane dyes, which intensely absorb light in the region 700–800 nm.¹⁰⁵

It has been found that introduction of a triple carbon–carbon bond in the structure of a triarylmethane dye makes this cationic species planar, because one of the aryl groups moves away from the trigonal unit; this is accompanied by a strong bathochromic shift of the absorption band to the visible region of the spectrum. In addition to the decrease in the steric strain between the *ortho*-hydrogen atoms in the aryl groups, it becomes possible to influence the electron density distribution over the whole cation by varying the nature of substituent R .

Degradation of the molecular ions of allene hydrocarbons has been proposed to give the propargyl cation ($\text{HC}\equiv\text{C}-\text{CH}_2^+$).⁷ The most intense peaks (about 100%) in the mass spectrum of iodoallene **118** are the peaks of fragment ions with m/z 107, 91, 79 to which structures of the ethynylcarbenium ions **119**, **122** and **120**, respectively, were assigned.¹⁰⁶

The use of various spectroscopic techniques for identification of alkynylcarbenium ions is discussed in Section V using particular synthetic examples.

IV. Quantum-chemical calculations

The mechanism of the Meyer–Schuster rearrangement has been studied theoretically using *ab initio* calculations for *O*-protonated 3-methylbut-1-yn-3-ol **124** and the product of its rearrangement, 3-methylbuta-1,2-dien-1-ol **125**. Based on the results of these

calculations, it was concluded that the transition state of the **124** → **125** rearrangement is a complex consisting of a carbocation and a water molecule acting as the migrating species.¹⁰⁷

To rationalise the predominant 1,4-addition to penta-1,2,3-triene **98**, which could not be explained based merely on the data of ^1H and ^{13}C NMR spectra of alkynyl carbocations (Section III), *ab initio* calculations of the charge distribution in three cations (**126**–**128**) have been performed.⁹³

The calculations showed that in these three cations, the charge is mostly concentrated on the propargyl sp^2 -hybridised centre. As the number of methyl groups in the cations **126**–**128** increases, nucleophilic attack at this position becomes more favourable.⁹³ Since the stability of alkynyl carbocations is insufficient for them to be directly observed by spectroscopic methods (Section III), it is difficult to follow the variation of the stability of these species over a wide range of structures starting from the simplest one and to estimate the contributions of the resonance structures **9** and **10** as functions of the degree of substitution.

Valuable information on the geometrical parameters of a series of alkynylcarbenium ions **129** and charge distribution in these species found by *ab initio* calculations has been reported by Dorado *et al.*¹⁰⁸

$X, Y, Z = \text{H, Me, F, NH}_2.$

For cations **129**, the lengths of the $\text{C}_\alpha-\text{C}_\beta$, $\text{C}_\beta-\text{C}_\gamma$, $\text{C}_\alpha-\text{X}$, $\text{C}_\alpha-\text{Y}$ and $\text{C}_\gamma-\text{Z}$ bonds, bond angles and the relative energies have been calculated. In general, it was noted that the propargyl form **9** predominates in those cases where the substituent X , substituent Y or both of them either withdraw σ -electrons from the C_α atom or donate π -electrons to the unsaturated fragment. Conversely, the same effects of the substituent Z increase the contribution of the allenyl structure **10**. These effects are especially pronounced for fluorinated cations.

The change in the ratio of the $\text{C}_\alpha-\text{C}_\beta$ and $\text{C}_\beta-\text{C}_\gamma$ bond lengths (and, correspondingly, in the bond orders) depending on the number and positions of substituents in cations **129** presents particular interest. Upon introduction of any substituent other than hydrogen (Me, F, NH_2) to the C_γ atom, the $\text{C}_\alpha-\text{C}_\beta$ bond becomes shorter, while the $\text{C}_\beta-\text{C}_\gamma$ bond becomes longer than the corresponding bonds in the cation **129** in which $X = Y = Z = \text{H}$. Conversely, accumulation of substituents at C_α causes the opposite tendency. The average $\text{C}_\alpha-\text{C}_\beta$ and $\text{C}_\beta-\text{C}_\gamma$ bond lengths for trisubstituted cations have been determined. For $X = Y = Z = \text{Me}$, these values are 1.381 and 1.204 Å, and for $X = Y = Z = \text{F}$, they are 1.399 and 1.196 Å, respectively. Thus, introduction of substituents into the C_α position makes the $\text{C}_\alpha-\text{C}_\beta$ bond 'more single' and the $\text{C}_\beta-\text{C}_\gamma$ bond 'more triple'. The values for charge distribution determined in the study cited¹⁰⁸ are consistent with the fact found by Olah *et al.*¹⁰⁰ that the positive charge on the C_α atom is approximately twice as large as that on the C_γ atom.

A detailed theoretical study of a series of alkynylcarbenium ions including the unsubstituted propargyl cation and methyl- and phenyl-substituted ions of the type **129** has been reported by Mayr *et al.*¹⁰⁹ As in the previous publication,¹⁰⁸ *ab initio* calculations for

the bond lengths, charge distributions and stabilisation energies for methyl- and phenyl-substituted allenyl cations were carried out. The bond lengths calculated by the two groups of researchers^{108,109} and the conclusions based on them virtually coincide. Thus the C_α – C_β bond in the nonsubstituted propargyl cation (**129**, $X = Y = Z = H$) (1.360 Å) is somewhat shorter than the length of the single C–C bond in propyne (1.484 Å) but longer than the double C=C bond in allene (1.288 Å); at the same time, the C_β – C_γ bond in this cation (1.215 Å) is longer than the triple bond in propyne (1.170 Å) but shorter than the double bond in allene. Phenyl substituents at the tertiary C_α atom elongate the C_α – C_β bond and simultaneously shorten the C_β – C_γ bond more substantially than methyl substituents.

The calculations performed¹⁰⁹ made it possible to predict the reactivity of the alkynyl carbocations **11** with respect to nucleophilic reagents. The propargyl structure **9** is responsible for the addition to C_α and the allenyl form **10** provides the attack at C_γ . Hard nucleophiles add predominantly to the C_α position, because the positive charge on this atom is always greater than that on the C_γ atom; therefore, under conditions of kinetic control, propargyl derivatives **130** are mostly formed. The formation of allenyl derivatives **131** can be explained by assuming thermodynamic control of the addition.

Soft π -nucleophiles should also add predominantly to the C_α atom, because, according to the results of calculations, this site is characterised by the highest LUMO coefficients.¹⁰⁹

However, as substituents R^1 – R^3 stabilising the cations **11** are introduced in the molecule, the addition to the C_β – C_γ moiety becomes more and more pronounced, because these substituents stabilise intermediate **132** but not **133**. The formation of the allylic cations **132** can be demonstrated by reactions of alkynylcarbenium ions with alkenes and dienes (the Diels–Alder reaction).

V. Synthetic applications of alkynyl carbocations

The first systematic studies on the possibility of practical application of alkynylcarbenium ions as reactive intermediates for building various cyclic and polyfunctional systems were carried out in the late 1970s and the early 1980s by a group of German scientists headed by Mayr.¹¹⁰ Alkenes and dienes of various structures were used as nucleophilic substrates.

1. Reactions of alkynyl carbocations with unsaturated compounds

The alkynylcarbenium (allenyl) cations **11** are ambident electrophilic species. Five variants of the addition of unsaturated substrates (alkenes **134** and 1,3-dienes **135** both linear and cyclic) can be conceived theoretically. Figure 1 shows the structures of cationic adducts **A**–**Q** arising upon the reaction of the ions **11** with unsaturated substrates. The carbon atoms of the substrates **11**, **134** and **135** participating in the formation of new covalent bonds are designated by letters. The alkenes **134** and the 1,3-dienes

Figure 1. Variants of cycloaddition of alkynylcarbenium ions to alkenes and dienes. The letters designate the fragments of molecules formed upon the reaction.

135 are considered to be symmetrical, *i.e.* positions C(1) and C(2) in the substrate **134** and positions C(1) and C(4), C(2) and C(3) in the substrate **135** are equivalent.

The addition of alkynyl carbocations of the type **11** to the alkenes **134** and the dienes **135** can yield linear carbenium ions (**A**, **C**) or allylic (**B**, **E**, **O**, **P**, **Q**) or vinylic (**D**, **F**, **G**, **H**, **I**–**N**) cations.

The reactions of alkynyl carbocations with cyclopentadiene (CPD) have been studied most comprehensively.^{110–116} The ions were generated by treatment of the corresponding halides with silver trifluoroacetate in pentane in the presence of CPD.¹¹⁰ After hydrolysis of the reaction mixture, obtained from 3-bromopropyne **20a**, with aqueous ammonia, 4-(prop-2-ynyl)cyclopent-2-en-1-ol **138a** was isolated as the major product containing a slight amount of bicyclic ketone **139a**. Under the same conditions, the transformation of 3-chloro-3-methylbut-1-yne **20b** gave three products **138b**, **139b** and **140** in nearly equal amounts.^{110,113}

R = H(**9o**, **20a**), Me(**9p**, **20b**); X = Cl, Br.

Since cyclopentadiene is highly sensitive to acidic reagents, in more recent studies,^{111,112} the researchers employed a milder catalyst, namely, the efficient homogeneous catalytic system $\text{ZnCl}_2\text{--Et}_2\text{O--CH}_2\text{Cl}_2$, which is formed upon dissolution of zinc chloride (1 mole) in diethyl ether (1.5 moles) and dilution of the resulting solution with dichloromethane.¹¹³

It has been noted¹¹⁰ that the reaction route depends on the structure of the alkynylcarbenium ion. The reaction conditions are also fairly significant. In the presence of an ethereal solution of ZnCl_2 , the halides **20b,c** mentioned above do not react with CPD but instead, they are converted into allenyl halides.¹¹³

X = Cl (**20b**), Br (**20c**).

Trisubstituted haloalkynes **141** react with CPD to give products of [4 + 2]- and [4 + 3]-cycloaddition **147** and **148**, respectively.^{111,113}

R¹ = Me, Et, (CH₂)₄; R² = Me, Et, Ph, 4-MeOC₆H₄, 4-BrC₆H₄; X = Cl, Br.

In some cases, side products, enynes **149** and **150**, have been isolated from the reaction mixtures. Apparently, these compounds result from dehydrochlorination of the initial haloalkynes **141**. Another side product, compound **152**, forms upon the addition of two CPD molecules to the dimethyl-(phenylethynyl)carbenium ion **9k**.^{112,113} It is assumed that [2 + 2]-cycloaddition of the ethynyl fragment of the ion **9k** to one of the C = C bonds in CPD giving allylic cation **151** also occurs to a small extent. This cation is sufficiently stable, so that it has time to add one more CPD molecule. The subsequent rearrangements of the cations give the compound **152**.

The reaction of 3-chloro-1,3-diphenylpropyne **153** with CPD gives three isomeric products of [4 + 2]-cycloaddition **154–156** in a total yield of 28%.¹¹³

The structures of the products **147**, **148** and **154–156** formed in these transformations indicate that the addition of CPD to alkynyl carbocations having geminal substituents (or a phenyl group at the secondary carbenium centre) involves the sp^2 carbon atom (C_α) and one of the sp atoms (C_β or C_γ). This can give only the vinylic cations **143–146** (Fig. 1, ions I, J, L, N). Allylic cations of the types P and Q (Fig. 1), which are energetically more favourable, are not formed. Of the four possible routes of transformation of the cations **142**, only two are realised, namely those in which the ions **145** and **146** are formed intermediately. This is due to the fact that, according to calculations,¹¹³ the bicyclic vinylic cations **143** and **144** are characterised by much higher energies. It is noteworthy that the alternative pathway to the vinylic halides **147** consisting in the isomerisation of the initial haloalkynes **141** to haloallenes followed by their reaction with CPD has been rejected,¹¹³ because it was found that 1-halo-3-methylbuta-1,2-dienes do not react with CPD under these conditions.

As has already been noted (Section III), not only functional acetylene derivatives but also the corresponding allene derivatives can serve as the precursors of the alkynyl carbocations **11**. In fact, the reaction of cyclopentadiene with 1-bromo-3-methylbuta-1,2-diene in the presence of silver trifluoroacetate affords a mixture of polymers from which allenylcyclopentenols **158** and **159** (ratio 83:17, total yield ~15%) and traces of the compounds **138b** and **161** were isolated.¹¹³

Thus, 3-chloro-3-methylbut-1-yne **20** and isomeric bromoallene react with CPD under the same conditions to give absolutely different products. Although in the latter case, the yields of the reaction products are too low for reliable conclusions to be made, it should be noted that the CPD molecule adds to that carbon atom in the alkynylcarbenium ion precursor from which the halogen atom is eliminated. In all probability, this situation is due to the very low stability of ethynylmethyl carbocations of the type **9** with a terminal triple bond.

Alkynyl carbocations with three aryl substituents are much more stable (see also Sections III and IV). The attempts to generate triphenylethynyl carbocations by treatment of chlorotriphenylallene **162** with the $\text{ZnCl}_2 - \text{Et}_2\text{O} - \text{CH}_2\text{Cl}_2$ catalytic system resulted in complex product mixtures of an unknown composition. Therefore, silver trifluoroacetate was used, which ensured that transformations of the cationic intermediates were irreversible, because the cations were bound by the trifluoroacetate anions.^{114,115} Treatment of a mixture of chlorotriphenylallene **162**, CPD and CF_3COOAg in pentane with an alcoholic solution of KOH gave a mixture of the compounds **26**, **164**, **166**, **167**, **172** and **173** in a total yield of 95%.

However, it can be seen from the above scheme that only 9% of the alkynyl carbocations **9i** are bound by trifluoroacetate anions yielding the α,β -unsaturated ketone **26** as the final product. The prevailing process is addition of CPD to the cation **9i**. It was shown in special experiments^{114,115} that the tertiary alcohol **172** rearranges to the secondary alcohol **173** on treatment with toluene-*p*-sulfonic acid. Nevertheless, according to ^1H NMR spectroscopy, dissolution of allenylcyclopentenol **164** and the tertiary alcohol **167** in a mixture of FSO_3H and liquid SO_2 at -70°C affords only the bicyclic vinylic cation **166**. Thus, the allylic cations **170** are intermediates on the pathway to the alcohols **172** and **173**, while the cations **163** react with CPD to give the ions **166**. These results led the investigators to the conclusion that the [2+2]-cycloadditions $9i \rightarrow 163$, $9i \rightarrow 166$ are stepwise processes, whereas the [4+2]-cycloaddition $9i \rightarrow 170$ is a concerted process.

The addition of CPD to the terminal *sp*-hybridised carbon atom in the cation **9i** might be a result of the structure of the initial chloroallene **162**. However, when phenyl-substituted alkynol **174** was made to react with CPD in the presence of fluorosulfonic acid, compounds **167** and **168** were obtained as the major products after hydrolysis of the reaction mixture (the ratio **167**:**168**:**26**:**175** = 9:4:4:3, total yield ~35%).^{114,116}

The tricyclic ketone **175** is formed in a high yield on treatment of the alcohols **172** and **173** or specially synthesised compound **176** with acids. A mechanism for this process was proposed, which includes electrocyclic ring closure in the cationic intermediate **170** and acid-catalysed rearrangements of compound **177**.^{114,116}

Treatment of chlorotriphenylallene **162** with SbCl_5 affords dark-red crystals of hexachloroantimonate **178**. Hydrolysis of this salt gives rise to a mixture of the alcohol **174** and the ketone **26** in 11 : 14 ratio. The reaction of the salt **178** with CPD (liquid SO_2 , -30°C) and subsequent alkaline hydrolysis yields the products **167**, **168** and **177** described above in a ratio of 4 : 5 : 1 (total yield $\sim 30\%$).¹¹⁶

Thus, the data presented here permit the conclusion that the triphenyl-substituted ethynyl carbocation **9i** always adds a CPD molecule at the terminal sp -hybridised carbon atom, irrespective of the nature of the preceding compound. The cycloaddition involves only the C_β and C_γ atoms, *i.e.* only allylic cations **166** and **170** (type **P** and **Q** cations, see Fig. 1) are generated.

Unlike cyclopentadiene, which enters into both [2+4]- and [3+4]-cycloaddition reactions with dialkyl-substituted alkynyl carbocations,^{111,113} cyclohexadiene and cycloheptadiene react only according to the [2+4]-cycloaddition pattern in the presence of ZnCl_2 , and cyclooctadiene gives only 1,4-addition products **181a,b** (Scheme 1).^{117,118}

Compound	R	n	E/Z	Yield (%)
180a	Me	2	1 : 1	22
180b	Ph	2	only <i>E</i>	54
180c	Me	3	1 : 1	22
180d	Ph	3	only <i>E</i>	50
181a	Me	4	—	10
181b	Ph	4	—	29

This difference in the behaviour of alicyclic 1,3-dienes is due to different energies of both the corresponding cationic intermediates and the final products, which result from different degrees of strain in the rings.

The reaction of 4-chloro-4-methylbut-2-yne **182** with anthracene in the presence of ZnCl_2 gives rise to the product resulting formally from [4+2]-cycloaddition to the isomeric chloroallene **183**.¹⁰⁷ The reaction of furan with the same cation yields acyclic product **184**.¹⁰⁷

The addition of linear 1,3-dienes **186a–g** and 1,2-dimethylenecyclohexane **186h** to the propynylcarbocation **11a–c** in the presence of the $\text{ZnCl}_2\text{–Et}_2\text{O–CH}_2\text{Cl}_2$ system occurs only at the sp^2 -hybridised carbon atom and gives linear allylic cations **187**. Subsequent transformations of the cations **187** are largely determined by the structures of both reactants.^{119,120}

$\text{R}^1 = \text{R}^2 = \text{R}^3 = \text{Me}$ (**185a**, **11a**); $\text{R}^1 = \text{R}^2 = \text{Me}$, $\text{R}^3 = \text{Ph}$ (**185b**, **11b**); $\text{R}^1 = \text{R}^3 = \text{Ph}$; $\text{R}^2 = \text{H}$ (**185c**, **11c**); $\text{R}^4 = \text{R}^5 = \text{R}^6 = \text{R}^7$ (**186a**); $\text{R}^4 = \text{Me}$, $\text{R}^5 = \text{R}^6 = \text{R}^7 = \text{H}$ (**186b**); $\text{R}^4 = \text{R}^5 = \text{R}^6 = \text{H}$, $\text{R}^7 = \text{Me}$ (**186c**); $\text{R}^4 = \text{R}^5 = \text{Me}$, $\text{R}^6 = \text{R}^7 = \text{H}$ (**186d**); $\text{R}^4 = \text{R}^5 = \text{H}$, $\text{R}^6 = \text{R}^7 = \text{Me}$ (**186e**); $\text{R}^4 = \text{R}^7 = \text{Me}$, $\text{R}^5 = \text{R}^6 = \text{H}$ (**186f**); $\text{R}^4 = \text{R}^6 = \text{R}^7 = \text{Me}$, $\text{R}^5 = \text{H}$ (**186g**); $\text{R}^4\text{–R}^5 = (\text{CH}_2)_4$, $\text{R}^6 = \text{R}^7 = \text{H}$ (**186h**).

Most often, allyl chlorides **188**, which are thermodynamically more stable than their isomers **189**, are formed as the major products of these reactions. Upon the reactions of the chlorides **185a,b** with buta-1,3-diene **186a** and the reaction of chloride **185c** with penta-1,3-diene **186c**, isomeric allyl chlorides **189** were also isolated (the **188** : **189** ratios were 4 : 1, 1 : 1 or 2 : 1, respectively). Cyclic vinyl chlorides **191** were the only products formed upon the reaction of the chloride **185b** with 1,2-dimethylenecyclohexane **186h** and the reaction of **185c** with the diene **186f**. It should be noted that the formation of six-membered cyclic vinyl halides **191** is of special interest, because the allyl-cation intermediates **187** are alkynylcarbenium ions in which the triple carbon-carbon bond is separated from the carbenium centre by one methylene unit (see Section VI).

It was shown^{119,120} that dimethylpropargyl chloride **185c** does not add to buta-1,3-diene **186a** or isoprene **186b**. When the chloride **185a** is made to react with the diene **186e** or the chloride **185b** reacts with the dienes **186e,f,g**, the reaction mixtures polymerise. Only the reaction of the chloride **185b** with the diene **186e** did give bicyclic diene **192** (yield 23%) which resulted from the addition of two molecules of the diene **186e** to the cation **11b**.

Four cyclisation pathways can, in principle, be conceived for the alkynylallylic cations **187**: those leading to four- (*a*), five- (*b*), six- (*c*) and seven-membered (*d*) vinylic cations.

(*a*) $C_\beta + C_1$; (*b*) $C_\gamma + C_1$; (*c*) $C_\beta + C_2$; (*d*) $C_\gamma + C_2$.

Obviously, pathways *a* and *b* are energetically unfavourable, because **194** contains a strained four-membered ring, and in **195**, the geometry of the vinyl cationic fragment differs substantially from the linear geometry inherent to it.¹²⁰ The latter statement is also true for the isomer **196**. Only the cation **191** in which the carbenium centre is exocyclic and is stabilised by the neighbouring phenyl substituent is energetically favourable. This is especially clearly seen for the diene **186h**, which reacts with the chloride **185b** yielding the species **187** [$R^4, R^5 = (CH_2)_4$] the geometry of which is rigidly fixed by the cyclohexane ring.

Considerable synthetic and theoretical interest is aroused by rearrangements of alkynylcarbenium ions **197** in which the multiple bond and the carbenium centre are separated by one or more sp^3 -hybridised carbon atoms. π -Cyclisation of cations of the type **197**, where $n = 1$ (homopropargyl rearrangement^{22–24, 26, 27, 121}) and $n = 3$ (see Ref. 22, for more details, see Section VI) is a well-known reaction. The reactions of alkynyl carbocations with dienes described above are examples of cyclisation of cations of the type **197** with $n = 2$; the reactions with alkenes also belong to this type.¹²²

Chlorobenzylidenecyclobutanes **201** and chlorocyclopentenes **203** are formed upon [2 + 4]- or [3 + 4]-cycloaddition of the alkynyl carbocations **11a–e** to alkenes **198a–c**.¹²²

$R^4 = R^5 = H$ (**198a**); $R^4 = H, R^5 = Me$ (**198b**); $R^4 = R^5 = Me$ (**198c**).

A stepwise mechanism with participation of carbocationic intermediate **199** was proposed for this reaction. The formation of this intermediate was proved by the isolation of enynes having mainly structure **204** as side products. The two routes for cyclisation of the intermediates **199** are determined by the stabilising influence of the phenyl substituent, which is attached directly to the vinylcarbenium centre in structure **200**. When the molecule contains no phenyl substituent, the reaction affords product **202** having a less strained structure.¹²²

The reaction of the triphenyl-substituted cation **9i** with alkenes follows a fundamentally different pathway¹²³ leading to [2 + 2]-cycloaddition products.

$R^4 = R^5 = H, R^6 = R^7 = Me$ (**a**); $R^4 = H, R^5 = R^6 = R^7 = Me$ (**b**); $R^4 = R^5 = R^6 = R^7 = Me$ (**c**); $R^4 = H, R^5 = R^6 = Me, R^7 = H$ (**d**); $R^4 = R^5 = H, R^6 = Ph, R^7 = Me$ (**e**); $R^6 = Me, R^4 - R^7 = (CH_2)_4$ (**f**).

The alkenes **198a,b,d,f** are converted into methylenecyclobutenes **207a,b,d,f**, while in the case of tetramethylethylene **198c**, α -methylstyrene **198e** and trimethylethylene **198b** (with excess FSO_3H), fast electrocyclic opening of the four-membered ring occurs, resulting in the formation of bicyclic structures **208b,c,e**. When the alcohol **174** reacts with vinyl ether **209**, some of the arising ethoxycarbenium ions **210** undergo dealkylation, typical of this type of species,¹²⁴ to give aldehyde **211**. However, most of the ions **210** have time to cyclise yielding a new ethoxycarbenium ion, which is converted into aldehyde **212**.

Turning back to Fig. 1, which shows all the possible variants of cationic intermediates, one can conclude that the studies described above have provided experimental evidence for the formation of eleven of these ions, namely, **A** (**199**), **B** (**136**, **142**, **187**), **C** (**205**, **210**), **E** (**157**, **163**), **H** (**200**), **J** (**145**, **191**), **K** (**202**), **N** (**137**, **146**), **O** (**206**), **P** (**166**) and **Q** (**160**, **170**). Cyclopropylvinyl cations (**D**, **F**) have been reported^{22, 23, 97} to be quite stable. As regards structures (**G**, **I**, **L** and **M**), they are energetically so unfavourable that their formation is considered¹¹³ to be doubtful irrespective of the structure of the initial compounds and reaction conditions. It is obvious that the increase in the stability of the ion **11** upon introduction of two aryl substituents to the sp^2 -carbenium centre increases the contribution of the alkynylcarbenium structure **9**. This is consistent with the data obtained by spectroscopy and quantum-chemical calculations (see Sections III, IV), which indicate that the $\text{C}_\alpha\text{--C}_\beta$ bond in the cations **129** is elongated, while the $\text{C}_\beta\text{--C}_\gamma$ bond is shortened. The attack on these cations by nucleophilic agents is mainly directed at the sp -carbon atom remote from the cationic centre, as in acetylene derivatives activated by electron-withdrawing substituents, while cycloaddition follows the $[2+2]$ pattern involving the two sp -carbon atoms.

Conversely, the introduction of substituents, able to delocalise positive charge, into the acetylenic fragments results in the predominance of the allenyl form of the cation **10** and causes the nucleophile to attack the sp^2 -carbon atom. It has been shown above for phenylethynylcarbenium ions (**9i–k**, **n**, **117**, **132**, **142**) that a similar influence can be exerted by the vinyl group. Thus the reaction of halogenated enynes **213** with buta-1,3-dienes **186c,i** in the presence of a homogeneous catalytic system, $\text{ZnHal}_2\text{--Et}_2\text{O--CH}_2\text{Cl}_2$ ($\text{Hal} = \text{Cl}, \text{Br}$), affords alkenyldenecyclohexenes.¹²⁵ A valuable product formed in this reaction is the perfume δ -damascone **214**.

$\text{R}^1, \text{R}^2, \text{R}^3, \text{R}^4 = \text{Me}, \text{Et}; \text{Hal} = \text{Cl}, \text{Br}$.

Similarly to allylic cations, alkynylcarbenium ions can act as efficient dienophiles in low-temperature Diels–Alder reactions.¹²⁶ Thus the reaction of 1,1-diphenylprop-2-yn-1-ol **215** with 2,4-dimethylpenta-1,3-diene **186g** gave tricyclic compound **217** in 70% yield.¹²⁶ Presumably, this product is formed in two successive cyclisations *via* the ethynyl carbocation **9g** and the cyclic allylic cation **216** (corresponding to structure **Q**, see Fig. 1). However, the reaction of the cation **9g** with cyclohexadiene does not stop at the stage of formation of the 1 : 1 tricyclic adduct **218**. This adduct undergoes one more $[2+2]$ -cycloaddition to give alcohol **219** (the total yield after 20 s at 25 °C is 80%). The proposed reaction scheme was confirmed by isolation of the compound **218** (yield 62%) from this reaction carried out with a tenfold excess of cyclohexadiene and its subsequent transformation into the final product **219** under the same conditions.¹²⁶

Neither styrene nor the indene derivative **217** reacts with the cation **9g** under the described conditions. The high reactivity of the compound **218** was explained¹²⁶ by the strained character of the double bond in the five-membered ring.¹²⁶

Cyclisation of alkynylcarbenium ions **220** and **222** was used to prepare alkynyl derivatives of adamantane **221**¹²⁷ and fused heterocycles **223**.¹²⁸

X = O, S, NMe, NPh.

The participation of the sp^2 -hybridised carbenium atom in the cyclisation is due to the fact that the greatest charge is concentrated on this atom and also to the geometry of the intermediate **222**, which hampers the attack of the sp -hybridised carbon atom.

Heteroatoms (O, S, N) adjacent to a carbenium centre are known to exert a stabilising influence on carbocations.¹²⁴ In the presence of acids (HCOOH, CF₃COOH), aldehydes of the acetylene series **224** are converted into alkynylhydroxycarbenium ions **225**, which can react with cyclic dienes according to three pathways: (1) the Diels–Alder reaction giving cycloaddition product **227**, (2) nucleophilic addition of the C≡C bond to the diene molecule giving compounds of the type **228** and (3) the Michael condensation of two furan molecules with one aldehyde molecule^{129, 130} affording alkynes **229**.

R = CHO (a), (EtO)₂CH (b), COOEt (c), CONMe₂ (d), CN (e), H (f), Bu (g), Ph (h, 54%), 4-ClC₆H₄ (i, 20%).

It has been shown^{129, 130} that cyclopentadiene and cyclohexa-1,3-diene react with the aldehydes **224a,c** to give only cycloaddition products **227a,c** in high yields. The reactions of anthracene and diphenylfulvene with the same aldehydes **224a,c** give rise to mixtures of compounds **227** and **228** in which the Diels–Alder reaction products predominate. The third pathway, which is

similar to the known reaction of aldehydes with dimerone,¹³¹ occurs only for the aldehydes **224d,e,g–i**. The products **229h,i** were obtained in only moderate yields (20% and 55%, respectively). The route of the reaction of the aldehydes **224** with furan depends on the nature of the acid used. For example, the aldehydes **224d,e** react with furan in the presence of HCOOH giving rise to mixtures of the compounds **227d,e** and **228d,e**. In the presence of CF₃COOH, no cycloaddition products **227** are formed; instead, mixtures of compounds **228** and **229** are produced. This difference in the reaction pathways is due to the fact that in trifluoroacetic acid, which is stronger than formic acid (pK_a 0.23 for CF₃COOH and pK_a 3.75 for HCOOH¹³²), acyloxycarbenium ions **230** can be formed, which are less stable than the hydroxycarbenium ions **225**.³² As a result, the diene adds to the sp^2 -hybridised atom of the alkynyl carbocation.

The addition of acetylenic esters **231** to alkenes is catalysed by Lewis acids and occurs either as nucleophilic addition at the triple bond or as [2 + 2]-cycloaddition.^{133, 134} The reaction presumably involves the intermediate formation of complexes **232**, which can be regarded as stabilised¹²⁴ dialkoxycarbenium ions.

R = H, Cl, COOMe.

True ethynyldialkoxycarbenium ions **234** generated, for example, from orthoester **233** proved, as expected, to be extremely reactive dienophiles.¹³⁵ They add to dienes at low temperatures (0 to –78 °C) to give cyclic products **235** or **236** in good yields. These examples demonstrate successful application of alkyl propiolates in Diels–Alder reactions.¹³⁵

Ionisation of acetals of the acetylene series having a phenylselenenyl substituent (**237**) affords alkoxy-carbenium cations **238**, which add silyl ethers of enols **239a,b** at the carboxonium fragment.¹³⁶ The alkylation of the acetals **237** with organoaluminium or organozinc compounds occurs in a similar way giving rise to ethoxyalkylacetylenes **241** or **242**.

R¹–R² = (CH₂)₄, R³ = OSiMe₃ (a); R¹ = Ph, R² = H, R³ = OSiMe₃ (b).

A series of studies devoted to reactions of acetals of acetylenic aldehydes with CH acids in the presence of boron trifluoride etherate deserve attention.^{137–140} Acetone, methyl ethyl ketone,¹³⁷ ethyl acetoacetate, methyl acetoacetate,^{138, 140} acetylacetone and cyclohexane-1,3-dione¹³⁹ have been used as substrates in the reactions with alkynal acetals **244** and butynedial tetraethyl acetal.¹⁴⁰

Compound	R ¹	R ²	R ³	Yield (%)
245a	H	H	H	71
245b	H	Me	H	26
245c	H	CO ₂ Et	H	75
245d	H	CO ₂ Et	Ph	75
245e	H	COMe	H	37
245f	Me	CO ₂ Me	H	18
245g	Me	CO ₂ Me	Ph	18

The researchers cited claim^{137–140} that in these reactions, acetals are not converted into alkoxy-carbenium ions like **238** and propose at least six hypothetical schemes with four- and six-centre cyclic transition states. However, none of the schemes consider the role of the catalyst, boron trifluoride etherate. In addition, in our opinion, some of the observations made by the authors rather attest to the participation of alkoxy-carbocations. Thus alkynal diethyl acetals are converted into ethoxycyclohexenone **246**, and dimethyl acetals give the corresponding methoxy derivative. When a mixture of acetals is used, a mixture of methoxy- and ethoxy-cyclohexenones is formed.

The idea of activating acetylene derivatives by cationic substituents attached directly to the triple bond has found synthetic implementation in cycloaddition reactions involving iminium derivatives of the acetylene series. Viehe *et al.*^{34, 141} have developed a method for the synthesis and studied the properties of ethynyl-substituted amidium salts **249** unknown previously. These salts proved to be substantially more efficient dienophiles than other acetylene derivatives activated by electron-withdrawing substituents. The salts **249** were prepared by *O*-alkylation of the amides

248 synthesised using the Viehe salts (phosgene iminium chlorides) **247**.³⁴

R¹ = Ph, R² = R³ = Me (**a**); R¹ = Bu^t, R² = R³ = Me (**b**);
R¹ = H; R² = R³ = Me (**c**); R² = H, R³ = Me (**d**); R² = R³ = H (**e**).

The amidium salts **249** remain unchanged in air and are much more stable than their dialkoxy-carbenium heteroanalogues **234**. A systematic study of their ¹³C NMR spectra showed that the carbon–carbon triple bond is substantially polarised; this decreases the energy demands and considerably facilitates the Diels–Alder and 1,3-dipolar cycloaddition reactions.

The salts **249a–e** readily react with cyclopentadiene at room temperature according to the [4 + 2]-cycloaddition pattern to give stable salts **250**. The reaction of the ethynyl-substituted salts **249c,d** with tetraphenylcyclopentadienone under the same conditions gives rise to polysubstituted benzene derivatives resulting from aromatisation of the adduct **251** formed initially.³⁴

R = H, Me.

The ethynylcarbenium salts **249d,e** readily enter into 1,3-dipolar cycloaddition at room temperature. Thus the reaction with ethyl diazoacetate yields pyrazole derivatives **252**, and the addition of the salt **249d** to the azomethine 1,3-dipolar fragment of munchnnone **253** opens up the way to imidates of the pyrrole series.³⁴

Among the alkynes containing resonance-stabilised cationic substituents, the best known are those containing a propynyliminium fragment of the general formula

$\text{R}^1 = \text{H}, \text{Alk}, \text{Ar}; \text{R}^2 = \text{H}, \text{Alk}, \text{Ar}, \text{NR}^3\text{R}^4, \text{OR}^5, \text{SR}^5, \text{Hal}; \text{R}^3, \text{R}^4 = \text{H}, \text{Alk}, (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$.

These are propynyliminium ($\text{R}^2 = \text{H}, \text{Alk}, \text{Ar}$), propynylamminium ($\text{R}^2 = \text{NR}^3\text{R}^4$) and propynylamidium (**249**) ions.¹⁴² The propynyliminium ions **256** can be prepared by treatment of easily accessible enamines **254** with trifluoromethanesulfonic anhydride.¹⁴²

$\text{R}^1 = \text{H}$ (a), Me (b), Ph (c); $\text{R}^2 = \text{Me}, (\text{CH}_2)_2\text{O}(\text{CH}_2)_2$; $\text{Tf} = \text{CF}_3\text{SO}_3$.

Elimination of TfOH from the iminium triflate **255** is carried out either thermally or in the presence of a tertiary amine. This procedure is suitable only for the aryl-substituted enamines, because enamines containing an aliphatic substituent in the acyl fragment are deprotonated to give diene amines of the type $\text{R}^1\text{C}(\text{NR}_2)=\text{CH}-\text{C}(\text{OTf})=\text{CR}_2$.

The IR spectra of the salts **256** exhibit intense absorption bands in the region of 2190–2200 ($\text{C}\equiv\text{C}$) and 1590–1630 ($\text{C}=\text{N}$) cm^{-1} . The ^{13}C NMR spectra of these triflates have been studied.¹⁴²

Propynyliminium salts similar to **256** react with enamines **257** according to the [2+2]-cycloaddition pattern and with diphenylisobenzofuran and anthracene according to the [2+4]-cycloaddition scheme.¹⁴²

$\text{R} = \text{H}$ (a), Me (b), Ph (c).

The propynylamidium salts **249** form no cycloaddition products with anthracene.³⁴ In turn, the propynyliminium salts **256** do not react with tetraphenylcyclopentadienone.¹⁴²

2. Reactions of alkynyl carbocations with nucleophiles

The propynylamidium cation arising upon *O*-alkylation of the amide **259** has been used to prepare 2-(2-chlorophenylethynyl)-benzimidazole **260** and 2-amino-3*H*-1,5-benzodiazepine **261**.¹⁴³

Treatment of 1,3-dichlorotrimethinecyanine **262** with aliphatic amines gives ynamine amidines **264** via unstable chloriminium cations **263**.¹⁴⁴

Methods for generation and properties of another type of alkynyl carbocations — alkynylvinyl cations **267** — were simultaneously described by Japanese¹⁴⁵ and German¹⁴⁶ scientists, working independently. The former researchers¹⁴⁵ studied sol-

volysis of 2-bromo enyne **265** and 1-halobuta-1,2,3-triene **266** in aqueous ethanol. Ethoxycumulene **268** was detected in the reaction mixtures.

Unlike the well-known ethynylvinyl derivatives with terminal functional groups,¹⁴⁷ the isomeric 1-alkynylvinyl compounds of the type **269** have been little studied.

X = OR, SR, NR₂.

Hanack *et al.*¹⁴⁶ proposed a method for the synthesis of alkynyl triflates **269**, which can serve as the precursors of α -alkynylvinyl cations of the general form **270**. The method consists in treatment of ketones of the acetylene series **271a–c** with trifluoromethanesulfonic anhydride in the presence of a non-nucleophilic sterically hindered base, 2,6-di-*tert*-butyl-4-methylpyridine **272**.

R = H (**a**), Me (**b**), Bu^t (**c**).

A somewhat different approach, based on silylated ethynyl ketones, has been proposed by Stang *et al.*¹⁴⁸ These compounds are converted into ethynylvinyl triflates **269a** and **273a,b** upon successive treatment with trifluoromethanesulfonic anhydride in the presence of the base (**272**) and with potassium fluoride in methanol.

R = H (**269a**), Me (**273a**), Ph (**273b**).

The reaction mixtures resulting from solvolysis of the triflate **269b** in 80% aqueous ethanol and 80% trifluoroethanol have been found to contain products **274–278** the formation of which has been explained by the participation of the cationic intermediate **270b**.¹⁴⁶

Alcohol	Yields of solvolysis products (%)				
	274	275	276	277	278
EtOH	30	15	4	3	0
CF ₃ CH ₂ OH	24	0	20	0	28

The composition of the products of solvolysis depends on the alcohol used. These results imply that the cation **270b** reacts mainly in the form of the alkynylvinyl cation. This is consistent with kinetic measurements. It was shown¹⁴⁶ that the propynylvinyl triflate **269b** is solvolysed in 50% aqueous ethanol 70 times faster than the triflate MeC(OTf)=CH₂ and 35 times faster than the triflate PrC(OTf)=CH₂;¹⁴⁶ this points to a stabilising influence of the ethynyl fragment on the neighbouring vinyl cationic centre.

The above synthesis of 1-(1-alkynyl)vinyl triflates **269** from ethynyl ketones **271**¹⁴⁶ involves intermediate formation of alkynylacyloxycarbenium cations **279**, **281**. The route of their deprotonation to the final products **269** depends on the nature of the substituents R¹ and R².¹⁴⁹ It was shown that only in the case of the acetylenic ketones **271a–c**, does the reaction occur unambiguously to give the compounds **269a–c**. The alkynyl ketones **271d** and **271e** form complex mixtures of products. Thus the ketone **271d** gave the expected triflate **269d** in 70%–75% yield. In addition, the reaction mixture contained the isomeric triflate **280** (25%–30%, the ratio *E*:*Z* = 1:1).

Treatment of the ketone **271e** with trifluoromethanesulfonic anhydride affords mainly the triflate **280** (85%–90%, the ratio *E*:*Z* = 1:1) and only 10%–15% of the triflate **269d**.

It can be seen from the above scheme that in both cases, the major reaction products result from deprotonation of the intermediates in the alkynyl carbocation form **279**, **281**.

The addition of anhydrous HCl to 3-chloro-3-methylbut-1-yne **282** affords 16 reaction products. The main products are (*E*)-1,3-dichloro-3-methylbut-1-ene **285**, 1,1,3-trichloro-3-methylbutane **286** and (*Z*)- and (*E*)-1,3-dichloro-2-methylbut-2-ene **284**. The intermediate formation of dimethylethynyl carbocation **283** was postulated.¹⁵⁰

In the presence of H_3PO_4 , the alcohol **285** reacts with 2- and 1-naphthols to give products of *O*-alkylation (**287**, **289**), aromatic electrophilic substitution (**290**) and cyclisation (**288**, **291**) (Scheme 2).¹⁵¹

When the reaction mixture is kept in the presence of an acid, the compound **287** isomerises to **288**, and the compound **289** isomerises to **291**; apparently, isomerisation involves dissociation of the thermodynamically less favourable naphthol ethers under the action of acids.

When triarylcycloallenes **292** are irradiated with a mercury lamp at -30°C in CH_2Cl_2 solutions of alcohols, alkoxy-substituted cycloallenes **293** are formed.¹⁵² This reaction is believed to proceed *via* alkynylcarbenium ions.

A ferrocenyl residue is known to stabilise efficiently a carbenium centre adjacent to it.¹⁵³ The treatment of ferrocenyl(phenylethynyl)-methanol **294a** or -ethanol **294b** with acids resulted in the synthesis of stable phenylethynylcarbenium salts **295a,b**. They react with nucleophiles at the sp^2 -hybridised carbon atom to give charged or neutral ferrocenyl derivatives of the type **296–299**.¹⁵⁴ Bis-ferrocenyl cations in which the two ferrocene fragments are linked by one or two acetylene (or butadiyne) bridges have been studied by spectroscopy.¹⁵⁵

R = H (**a**), Me (**b**); X = BF₄, ClO₄.

Fc is ferrocenyl, Py is pyridine.

3. Alkynyl-substituted heterocyclic cations

The cationic fragment of the alkynyliminium cations of the type **256** described above can be a part of an aromatic heterocycle. These cations are the most stable due to the charge delocalisation with participation of the aromatic system.

The protonation or alkylation of the nitrogen atom in alkynyl-substituted pyridines and quinolines proved to be an efficient method for activating the acetylene fragment towards reactions with various nucleophiles. Thus 2-phenylethynylquinoline **300** readily adds water in acid media.¹⁵⁶

Scheme 2

The alkylation of the quinoline **300** with dialkyl sulfates or with esters of toluene-*p*-sulfonic acid yields quaternary salts **301**, which are quite stable in alkaline solutions and are fairly reactive towards S- and N-nucleophiles and CH-acids.¹⁵⁶

N-Alkylated salts of nitrogen-containing heterocycles readily add to phenylethynylquinolinium salts giving rise to cyanine dyes **302**.¹⁵⁶

Phenylethynylpyridinium salts **303**–**305**, which add nucleophiles at the C≡C bond, have been obtained by *N*-methylation of the corresponding ethynylpyridines.¹⁵⁷

Yet another method for the synthesis of the alkynylquinolinium salt **301** is based on the interaction of *N*-methylquinolinium iodide with propynylmagnesium bromide. The subsequent oxidation in the presence of HClO₄ affords the corresponding perchlorate.¹⁵⁸ The IR spectrum of this salt contains an intense absorption band at about 2230 cm⁻¹ corresponding to the triple carbon–carbon bond; this confirms the salt structure. As in the case of quinolinium salts with a phenylethynyl substituent, the addition to the propynyl group is also directed at the end of the triple bond that is more distant from the heterocycle. This gives enamine **306**.

Cyanine dyes containing quinaldine (**307**), 2-methylbenzothiazole (**308**), 2,3,3-trimethylindolenine (**309**) and *N*-methylrhodamine (**310**) residues are synthesised in a similar way.

Acetylenic analogues of cyanine dyes containing a carbon–carbon triple bond in the conjugated chain between two heterocycles can be prepared by different methods. Thus perchlorate **312** was synthesised by dehydrochlorination of *meso*-chlorocarbocyanines **311**.^{159, 160}

It has been shown by electronic spectroscopy and X-ray diffraction analysis that the alkyne structure **312a** is energetically more favourable than the cumulene structure **312b**. Study of a series of similar conjugated systems containing different heterocycles showed that in this case, an equilibrium of the type **313a** $\rightleftharpoons$ **313b** is established; the isomer in which the positive charge is concentrated on the more basic heterocycle (for example, on a benzimidazole rather than benzothiazole ring) predominates in the mixture. The experimental results and spectroscopic data were confirmed by quantum-chemical calculations.¹⁶⁰

Dyes with similar structures **316** and **319** have been obtained by condensation of the chlorovinylquinolinium salt **314** with betaine **315**¹⁶¹ or by condensation of benzothiazolium salts **317** and **318** with each other.¹⁶²

Synthesis, spectral characteristics and chemical properties of dyes including compounds **320** in which an acetylenic fragment connects two heterocyclic cations have been reported.¹⁶³

3-Azaindolizine derivatives **323** are formed upon cyclisation of 2-ethynylpyridine-*N*-imides **322**. The latter, in turn, are obtained by *N*-amination of 2-alkynylpyridines **321** followed by treatment with potassium carbonate in the presence of DMF.^{164, 165} Similar cyclisation of 2-alkynylquinoline **324** and alkynylisoquinolines **325**, **326** yields pyrazolo[2,3-*a*]quinolines **327** and pyrazoloisoquinolines **328**, **329**.¹⁶⁵

R = H, Me, Bu, CH₂OH, Ph.

R = Bu, CH₂OH, Ph.

Transformations of 2-alkynyl-*N*-phenacylpyridinium salts **330** follow different pathways depending on their structures and reaction conditions.¹⁶⁶ The monosubstituted 2-alkynylpyridines **321** are converted into the alkynylpyridinium salts **330** on treatment with phenacyl bromide. Refluxing of **330** in benzene in the presence of a base (potassium *tert*-butoxide, 1,5-diazabicy-

clo[5.4.0]undec-5-ene) affords the corresponding ylides, which cyclise to 3-benzoylindolizines **331**; in boiling acetic acid, the salts **330** are converted into 1-benzoylindolizines **332**.

On treatment with bases, 6-methylpyridinium salts **333** give 10%–15% of 2-phenylcyclazines **335** in addition to 3-benzoylindolizines **334**.¹⁶⁶

Unlike the examples described above, 6-amino-2-alkynylpyridines **336** are converted into 1-azaindolizinium salts **337** just upon treatment with phenacyl bromide; treatment of the salts **337** with a solution of sodium carbonate yields 1-azacyclazines **338**.¹⁶⁶

Data on these and other related reactions have been surveyed in a review.¹⁶⁷ Synthesis of a reverse transcriptase inhibitor *via* a 2-alkynylpyridinium intermediate has been described in a recent study.¹⁶⁸ An interesting reaction is the conjugated addition of organozinc-copper reagents to (2-propynylidene)morpholinium triflate **339**. Hydrolysis of the addition products gives α,β -unsaturated ketones **340** and **341**, respectively.¹⁶⁹

(a) $\text{IZnCu}(\text{CN})\text{C}_6\text{H}_4\text{X}$; $\text{X} = 2\text{-CN, 4-CN, 3-COOEt}$;
(b) $\text{IZnCu}(\text{CN})\text{CH}_2\text{CH}_2(\text{CH}_2)_n\text{X}$; $n = 0, 1$; $\text{X} = \text{CN, COOEt}$.

In recent years, extensive studies on cyclic oxonium ions, pyrylium cations containing alkynyl substituents, have been carried out. The first representative of these stable alkynylcarboxonium ions, namely, 2,6-diphenyl-4-phenylethynylpyrylium perchlorate, was prepared by the reaction of 2,6-diphenylpyrylium perchlorate **342** with lithium phenylacetylide and subsequent oxidative dehydration of the pyran intermediate.¹⁷⁰ Later, other lithium acetylide derivatives have also been involved in this reaction.¹⁷¹ Three possible structures, **343**–**345**, have been proposed for the reaction intermediate;¹⁷⁰ based on the data of IR spectroscopy, the allene species **344** was preferred. The IR spectrum of salts **346** contains an absorption band at 2210 cm^{-1} typical of acetylene derivatives.¹⁷⁰

It has been found that the outcome of this reaction depends on the nature of the solvent.¹⁷² When the reaction between the salt **342** and lithium phenylacetylenide was carried out in diethyl ether, only 4-phenylethynylpyran **343a** was formed. The replacement of ether by tetrahydrofuran resulted in the formation of the [2+2]-cycloaddition product **347**. The researcher cited believe¹⁷² that it is formed *via* dimerisation of allenylpyran **344a**.

Later, this difference between the routes of nucleophilic addition to the pyrylium salt **342** was explained¹⁷³ by different conditions of metallation of phenylacetylene. In fact, Doney *et al.*¹⁷² used an equimolar amount of a standard solution of *n*-butyllithium, whereas other investigators^{170,171} employed an excess of butyllithium, which then remained in the reaction mixture and acted as a base during the isomerisation of the compound **343a** to **344a**.¹⁷³

Study of dyes containing carbon–carbon triple bonds have led to the synthesis of acetylenic analogues of triarylmethane dyes, which are able to acquire an alleno-quinoid structure and, hence, they exhibit interesting photochemical properties. Alcohols **350** can be synthesised by the reaction of organometallic derivatives of arylacetylenes **348** with the corresponding esters **349**. The compounds **350** were converted into the corresponding 4-arylethynylpyrylium salts **352** by treatment with 70% HClO₄ in a 2:1 C₆H₆:EtOH mixture.¹⁷⁴

R¹ = H, Me₂N; R² = Me, Et; M = Li, MgBr.

The IR spectra of the salts **352** exhibit absorption bands at about 2170 cm⁻¹. It has been assumed that under the reaction conditions, the trialkynylcarbenium ions **351** undergo the Meyer–Schuster rearrangement to give arylethynyl-substituted pentene-1,5-diones, which then form the pyrylium ring.^{175,176} This was confirmed using simpler systems. Thus treatment of alcohol **353** with an acid gives rise to the 4-acetonilpyrylium cation **355** *via* alkynylcarbenium intermediate **354**.¹⁷⁷

Recently it has been shown that non-symmetrical 2,4-diphenylpyrylium perchlorate **356** adds lithium phenylacetylenide at the free α -position yielding unstable *2H*-pyran intermediate **357**. Oxidative dehydration of the latter affords extremely explosive 2-phenylethynylpyrylium perchlorate **358**.¹⁷⁸ Conversely, *2H*-pyran intermediates **360**, obtained analogously from 2-unsubstituted 1-benzopyrylium salts **359**, are stable and can be isolated. 4-Phenylethynyl-1-benzopyrylium salts **363** were synthesised in the same way from 1-benzopyrylium salts **362** unsubstituted at the 4-position.¹⁷⁸

R¹ = Ph, Bu^t; R² = H, Me, Et.

The IR spectra of the salts **358**, **361** and **363** exhibit absorption bands in the region of 2180–2200 cm⁻¹ typical of C≡C triple bond vibrations. This means that in phenylethynylpyrylium salts, this bond is retained, the positive charge being concentrated in the heteroaromatic ring. This conclusion has been confirmed by MINDO/3 quantum-chemical calculations¹⁷⁸ according to which the C(1)–C(2) bond length in species **364** (0.1209–0.1210 nm) is close to the length of a C≡C triple bond, whereas the C(2)–C(3) bond (0.1429–0.1437 nm) is substantially longer than the corresponding bond in an allenyl cation¹⁰⁹ (see Section IV).

R = H, Me.

The above reactions of the pyrylium salts **342**, **356** and 1-benzopyrylium salts **359**, **362** with lithium phenylacetylenide are, in essence, examples of nucleophilic substitution in the aromatic nucleus, little studied so far. Processes of this type involving heteroaromatic cations as the substrates are known mainly for azinium salts.¹⁷⁹ Study of nucleophilic aromatic substitution with pyrylium salts as substrates is of interest because it does not require substrate activation. In addition, the low nucleofugal activity of hydrogen in the non-charged intermediates (*i.e.*, pyran systems) permits conducting the S_N^H (AE) process¹⁷⁹ in two separate stages.

Besides the nucleophilic substitution of a hydrogen atom in a pyrylium cation by an alkynyl group, alkynylpyrylium salts can also be synthesised by forming a pyrylium ring. Two examples of this type, namely, cyclisation of trialkynyl carbocations **351** and **354**, are shown above.^{174, 177} However, methods for the synthesis of pyrylium salts involving two or three components^{175, 176} are not very suitable for the preparation of alkynyl-substituted derivatives, because of the high probability of involvement of the triple bond in condensation. Only few examples of synthesis of 4-phenylethynylpyrylium salts such as **365** and **366** by the reaction of 3-phenylprop-2-ynal diethyl acetal with cyclic ketones like 1-tetralone or cyclohexanone have been reported.¹⁸⁰

Alkynylpyrylium salts **368** are obtained by oxidative dehydrogenation of the corresponding 4*H*-pyrans **367** on treatment with triphenylmethyl perchlorate (yields 92%–95%), an Ac₂O–HClO₄ mixture (yields 53%–71%) or BF₃·Et₂O (yields 43%–82%),¹⁸¹ or by cyclisation of difficultly accessible 3-alkynylpentane-1,5-diones **369** on treatment with HClO₄ in acetic anhydride, acting as dehydrating and dehydrogenating agent (yields 78%–84%).¹⁸²

R¹, R² = H, Me; Ar = Ph, 4-MeC₆H₄, 4-MeOC₆H₄.

The combination of the highly stable heteroaromatic cation and the alkynyl fragment in the molecules of **368** makes these compounds fairly useful for organic synthesis. Thus the presence of the cationic pyrylium fragment efficiently activates the C≡C bond towards nucleophilic substitution reactions. Nucleophilic reagents, irrespective of their structure, attack the triple bond in the alkynyl substituent at the end that is remote from the heterocycle. It should be emphasised that the reactivity of the pyrylium fragment in the compounds formed in these reactions remains virtually unchanged. Therefore, after the nucleophilic reaction of the alkynyl group, diverse transformations of the oxygen-containing heterocycle can be performed by treatment with the same or other nucleophilic reagents.

For example, 2,6-diaryl-4-phenylethynylpyrylium perchlorates **368** (R¹ = R² = H) easily add hydrogen halides to give halo-derivatives **370**.¹⁸¹

Ar = Ph, 4-MeOC₆H₄; Hal = Cl, Br.

It might be expected that the reactions of **368** with water or alcohols would afford 4-phenacylpyrylium derivatives **371** (or the corresponding alkyl ethers) upon hydration of the triple bond or addition of alcohols. However, refluxing of the salts **368** with water, methanol or ethanol resulted in the isolation of monomethinecyanines **374** the structures of which were confirmed by IR and ¹H NMR spectroscopy and by X-ray diffraction analysis of the pyridinium analogue **376** (Ar = Ph) prepared by the reaction with NH₃.¹⁸³ The pathway to these monomethinecyanines includes hydration of the triple bond in the initial salts **368** yielding benzoylmethylenepyran **372**. However, the reaction does not stop at this stage, and the hydration products **372** react with the 4-phenylethynylpyrylium salts **368** as C-nucleophiles according to the [2+2]-cycloaddition pattern. The final products **374** result from electrocyclic ring opening in the cyclobutene intermediates **373**.

Ar = Ph, 4-MeOC₆H₄.

The 4-phenacylpyrylium salt **378** and benzoylmethylenepyran **379** have been obtained only when the 3,5-dimethyl-substituted 4-phenylethynylpyrylium salt **368** (R¹ = R² = H, Ar = Ph) was treated with alcohols and the resulting vinyl ethers **377** were dealkylated.¹⁸⁴ Apparently, the methyl groups decrease the elec-

The formation of the cyclobutene intermediate in the reaction of the salts **368** with the benzoylmethylenepyran **372** is apparently due to the fact that the pyran and pyrylium rings can approach each other as a result of π - π donor-acceptor interaction, and this creates favourable conditions for [2 + 2]-cycloaddition. When the salts **368** react with indoles, the reactants do not come close to each other in this way, and, hence, intramolecular proton transfer occurs. This interpretation is quite consistent with the outcome of the reaction of the pyrylium perchlorate **368** ($R^1 = R^2 = H$, $Ar = 4\text{-MeOC}_6\text{H}_4$) with vinyl ether **388** involving a similar proton transfer.¹⁸⁶ The structure of the reaction product **389** was confirmed by the ^1H NMR spectrum.

The 4-phenylethynylpyrylium salts **368** are also able to enter into [2 + 4]-cycloaddition reactions. Thus norbornadiene derivatives **390** containing a positively charged heteroaromatic ring were

obtained for the first time by the reaction of **368** with cyclopentadiene.¹⁸⁷

R¹, R² = H, Me; Ar = Ph, 4-MeOC₆H₄.

When solutions of the norbornadiene derivatives **390** are exposed to the light of a mercury lamp ($\lambda_{\text{max}} = 546 \text{ nm}$) or to sunlight, they undergo fast photochemical transformation into quadricyclanes **392**. However, these products are readily hydrated under the reaction conditions, which unfortunately precludes the possibility of thermally induced back reaction.

The pyrylium salts **368** add alcohols and aromatic amines (aniline, *p*-toluidine, *N*-methylaniline) as well as *tert*-butylamine to the *sp*-hybridised carbon atom that is remote from the pyrylium ring; this gives enaminyopyrylium salts **394**.¹⁸⁴ It should be emphasised that in the case of pyrylium salts containing no ethynyl substituent, the reactions with ammonia and amines involve the pyrylium fragment and are used typically to prepare pyridines and pyridinium salts.¹⁷⁶ Unlike normal pyrylium salts, the compounds **394** are deprotonated on treatment with ammonia (at R⁴ = H) to unsaturated imines **395** rather than exchange the oxygen atom in the ring for nitrogen. However, ammonium acetate and methyl-, butyl- and benzyl- amines attack the pyrylium ring in the salts **368**, which gives rise to alkynyl-substituted pyridine derivatives **396** and **397**.¹⁸⁴

R¹, R² = H, Me; Ar = Ph, 4-MeOC₆H₄; R³ = Bu^t, Ph, 4-MeC₆H₄; R⁴ = H, Me.

R¹, R² = H, Me; Ar = Ph, 4-MeOC₆H₄; R³ = Me, Bu, PhCH₂.

The acetylenic fragment in the 4-phenylethynylpyridinium salts **397** is still sufficiently activated to add one more amine molecule; this affords aminovinylpyridinium salts **398**.

Unlike monocyclic pyrylium salts, 1-benzopyrylium salts do not tend to exchange the ring oxygen atom for nitrogen.¹⁸⁸ Therefore, it comes as no surprise that 4-phenylethynyl-1-benzopyrylium salts **363a,b** are converted into aminovinyl derivatives **400a,b** on refluxing with an equimolar amount of an aliphatic amine or benzylamine followed by treatment with HClO₄.¹⁸⁹ However, when the salt **363b** is mixed with excess amine at room temperature, the products of the amine addition at the 2-position of the ring — 2-alkylaminoflavones **401** — are rapidly formed. On treatment with HClO₄ they easily decompose giving the initial salt **363b**. Thus, this addition is reversible and kinetically controlled. Refluxing of the salts **363a,b** with a two- or three-fold excess of an amine in acetonitrile for 1–5 h affords 4-(2-hydroxyphenyl)pyridinium salts **402**. The same products are formed under similar conditions from the aminovinyl salts **399a,b**, which are evidently formed as intermediates in the transformation of the 4-phenylethynyl-1-benzopyrylium salts **363**.

R¹ = H (**a**), Me (**b**), R² = PhCH₂, Bu^t, Buⁱ.

R = Me, Buⁱ, PhCH₂.

R¹ = H (**a**), Me (**b**); R², R³ = Me, Buⁱ, PhCH₂.

It is obvious that the 2-aminoflavones **401** are not formed as intermediates in this thermodynamically controlled recyclisation. However, the formation of aminoflavones proved to be the key stage in the transformation of the 4-phenylethynyl-1-benzopyrylium salts **363a,b** into 2*H*-chromeno[3,4-*b*]pyrroles **404**.¹⁸⁹ These products are formed in 36%–75% yields upon refluxing of the

salts with excess primary amines in ethanol. Presumably, ethanol acts as a competing nucleophile and suppresses the formation of the 4-alkylaminostyryl salts **399**. The unstable adducts **401** have enough time to undergo ring cleavage yielding phenol intermediates **403**, which again cyclise to chromenopyrroles **404**. The structure of one of the tricyclic products **404** was established by X-ray diffraction analysis.¹⁸⁹

$R^1 = \text{H, Me}; R^2 = \text{Me, Bu}^i, \text{PhCH}_2$.

Recently, unexpected recyclisations of the 3-methyl-2-phenyl-4-phenylethynyl-1-benzopyrylium perchlorate **363b**, which occur on its refluxing with a two- or three-fold excess of aromatic amines, have been reported.¹⁹⁰ Treatment of the salt **363b** with aniline in dichloroethane or acetonitrile gives 4-anilino-2-phenyl-1-benzopyrylium salt **405a**. On treatment with *p*-toluidine under the same conditions, the pyridinium (**402b**) and 4-(*p*-toluidino)-1-benzopyrylium (**405b**) perchlorates are formed. It has been noted above that the compounds **402** result from recyclisation of the 4-aminovinyl-1-benzopyrylium salts **399**. It has been suggested and confirmed experimentally¹⁹⁰ that the compounds **399** can arise as intermediates in the recyclisation of the salts **363b** to the 4-(*R*-amino)-1-benzopyrylium salts **405a,b**.

$R = \text{Ph (a), 4-MeC}_6\text{H}_4 \text{ (b)}$.

4-Phenylethynylthiopyrylium salts **406** have been obtained recently from 4-phenylethynyl-4*H*-pyrans **367** (yields 30%–40%) and from 3-phenylethynylpentane-1,5-diones **369** (yields up to 80%) on treatment with hydrogen sulfide in the presence of boron trifluoride etherate.¹⁹¹

Bis-thioxanthene cumulene **407** has been prepared within the framework of studies aimed at the synthesis of π -electron-donating systems for charge transfer complexes possessing metallic conduction. When this product is treated with concentrated sulfuric acid, it is readily oxidised to acetylenic dication **408**, but does not undergo the expected triple bond protonation.¹⁹²

(a) 1. BuLi, THF, -78°C ; 2. , -40°C

(b) SnCl_2 , HCl, Et_2O , -80°C .

Development of a simple method for the synthesis of 3-acylmethylene-2,3-dihydrofurans from diacetylenic vicinal diols^{193,194} has led to the preparation of the dihydrofurylium salt **413** containing a conjugated enyne fragment. Apparently, the transformation of the diol **409** to the furan **412** occurs via the intermediate formation of dialkynyl carbocation **410** and cyclic alkynyl carbocation **411**, which then undergoes the Meyer–Schuster rearrangement.

Comparison of the electronic spectra of the cation **413** ($\lambda_{\max} = 509$ nm) with those of some other 4-styryldihydrofurylium salts containing H, Me, Et or Ar instead of the phenylethynyl group has demonstrated that the bathochromic shift caused by the $\text{PhC}\equiv\text{C}$ group is twice as large as that caused by Ph. This is due to the fact that the triple bond efficiently participates in charge delocalisation.¹⁹⁴

To summarise the foregoing, it can be concluded that all the methods that are, in principle, suitable for generation of carbenium ions have been used to generate alkynyl carbocations.²

The most widely used procedure is detachment of a nucleofugal species from functional acetylene derivatives of the propargyl type containing one, two or three heteroatomic functions at the sp^3 -hybridised carbon atoms [Eqns (1)–(3)].^{135, 136} Methods based on abstraction of nucleofuges from functionally substituted enynes, allenes and cumulenes [Eqns (4)–(6)] are more difficult for practical implementation and, therefore, are used more rarely.^{113–115, 128, 145, 146} In the two latter cases [Eqns (5), (6)], the appearance of a carbenium centre results as well in the formation of a $\text{C}\equiv\text{C}$ triple bond. The oxidative dehydrogenation of ethynylpyran systems^{171, 181} [Eqn (7)] also belongs to this type of reactions.

X = Hal, OH, OAlk, OAc.

X = Br, TfO.

E = H, CF_3SO_2 .

The general approach to the generation of carbocations consisting in the addition of a cationic electrophile to an unsaturated system has also been used for the preparation of alkynylcarbenium ions. Compounds used most often as the precursors are alkynones^{88, 129, 130, 146} [Eqns (8), (9)], amides^{34, 143} [Eqn (10)], linear imines⁸ and nitrogen-containing heterocycles^{156–158, 165–166} [Eqns (11), (12)]. The protonation of terminal cumulenes [Eqn (13)] is represented by only one example.¹²⁷ Electrophilic reactions of enynes deserve a more detailed discussion, which is presented in the last paragraphs of this Section.

One more fundamental approach to the generation of alkynylcarbenium ions is formation of a carbon–carbon triple bond in cationic structures. Known examples are deprotonation of iminium salts and quaternised nitrogen-containing heterocycles followed by elimination of a nucleofuge (Hal^- , CF_3SO_3^-)^{142, 144, 159–161} [Eqn (14), (15)].

Several studies have been reported in which a carbenium centre near a triple bond was generated *via* 1,2-migration during the pinacol rearrangement;⁷⁹ an example of two-electron oxidation of cumulene to a dication, which is a rarely encountered type of process in the preparative chemistry of carbocations, has also been described.¹⁹²

In the case of conjugated enynes, electrophilic reactions of enynes, which have been mentioned among the methods for generation of alkynyl carbocations, proceed ambiguously.^{4, 195} Therefore, generation of alkynylcarbenium ions from these substrates is problematic. However, it is known that cations of the type **9**, which are not detected even in superacidic media (see Section III), can be readily prepared or even isolated as dicobalt-hexacarbonyl (DCHC) complexes of the type **414**.¹⁹⁶ The DCHC complexes **415** derived from a number of enynes, namely, isopropenylacetylene, 1-ethynylcyclohexene, 1-ethynylcyclopentene, have been used to conduct a large series of Ad_E reactions according to a two-stage pattern. The natures of the electrophile X^+ and the nucleophile Y^- in these reactions can be varied independently, due to the high stability of the alkynylcarbocationic intermediates **416**.^{196–198}

414

415

416

secondary homopropargyl cations **437**. The latter are converted into the corresponding ethers **438**.^{27, 212, 213, 215}

Nf = $C_4F_9SO_2$; $R^3 = CF_3CH_2$.

Compound	R^1	R^2	Yield (%)	
			438	439
434a	Me	H	3	95
434b	H	Me	63	34
434c		$(CH_2)_6$	68	32

The homopropargyl rearrangement is important from the synthetic viewpoint as a facile and convenient method for the preparation of cyclobutanones containing diverse substituents including those fused with carbocycles.

The processes of cyclisation of alkynyl carbocations **197** ($n = 2$) with two methylene units between the triple bond and the carbenium centre are described in detail in Section V.1. It is noteworthy that upon the solvolysis of pent-4-ynyl triflates $R-C\equiv C-(CH_2)_2CH_2OTf$, no cyclic products have been detected.²⁶ This is due to the extremely high strain in the five-membered cyclic vinylic (*i.e.* cyclopent-1-enyl) cations (see structures **K**, Fig. 1, and **202**). Meanwhile, the cyclobut-1-enyl cations **429** and **435** are quite stable owing to delocalisation of the positive charge over three carbon atoms across the ring.^{27, 216} Therefore, the cation **441** is, in essence, a bridged non-classical ion in which the C(3) atom is equidistant from the ends of the double bond.

The cyclopent-1-enyl cations **202** can arise during this process if the cationic intermediates are sufficiently stabilised by appropriate substituents. Thus protonation of 1,2,4-trimethyl-3-methylene-4-(prop-2-ynyl)cyclobut-1-ene **442** affords bicyclic ketone **445**. The reaction scheme includes the formation of cyclobutenyl-allyl cation **443**, which cyclises to bicyclic vinylic cation **444**.²¹⁷ The structure of the cation **443** was confirmed by its ^1H NMR spectrum (in HSO_3F-SO_2FCl , $-120^\circ C$).

A variation of the degree of substitution in the substrate sharply changes the reaction route. Under the same conditions, cyclobutenes **446** substituted in the side chain afford polymethylated styrenes **450**, presumably according to the following scheme:²¹⁸

$R = H, Me$.

The spectral characteristics of the cationic intermediates formed in this process have been described in detail.²¹⁹ It is clear that the cations **443** and **447** correspond to structure **B**, the cations **444** and **448**, to structures **L** and **M** and the ion **449**, to allylic cation **Q** (see Fig. 1). Two other theoretically possible cation structures with participation of a $C\equiv C$ triple bond are also formed during this transformation.

Protonation of propynyl-substituted cyclohexadienols **451** and **452** and methylenecyclohexadienes **453** results in the formation of cations **454**. The subsequent [1,2]-migration or two successive migrations of the propynyl fragment give rise to substituted benzenes.²²⁰ Evidently, these rearrangements are energetically favourable because they lead to ring aromatisation.

In alkynyl carbocations **456** in which the carbenium centre and the acetylenic fragment are separated by three carbon atoms, due to the close arrangement of groups in space, conditions are created for the formation of cations **457** and **459**. The predominance of one of these ions is determined by their relative stability, which depends on the substituents present in the initial acetylene derivative.

$R^1 = R^2 = H$, $X = \text{OTf}$ (a); $R^1 = \text{Me}$, $R^2 = H$, $X = \text{OTf}$ (b);
 $R^1 = \text{Ph}$, $R^2 = H$, $X = \text{OTs}$ (c); $R^1 = H$, $R^2 = \text{Me}$, $X = \text{OTs}$ (d);
 $R^1 = R^2 = \text{Me}$, $X = \text{OTs}$ (e).

Thus solvolysis of terminal hex-5-ynyl triflate **455a** in trifluoroethanol results in the formation of an open-chain ether ($X = \text{OCH}_2\text{CF}_3$, 58%) and cyclohexene derivatives **458a** (12%) and **458f** ($X = \text{OCH}_2\text{CF}_3$, 24%).²² Conversely, the methyl homologue **455b** is converted by approximately 85% into cyclopentane derivatives **460a** (67%) and **460f** (17%). The introduction of a terminal phenyl group (compound **455c**) stabilises the exocyclic vinylic cation **459** to even a greater extent; therefore, the transformation of **455c** gives almost exclusively methylenecyclopentane derivatives **460g** ($X = \text{OAc}$). The secondary tosylates **455d**, e behave in a similar way.²²

The alkynylcarbenium (**456**) and vinylic (**457**, **459**) cations can arise as intermediates in cascade cyclisations used in elegant syntheses of steroids. Within the framework of a general approach to the preparation of testosterone, biomimetic syntheses of some of its precursors have been reported.^{221–223}

(a) CF_3COOH , EtNO_2 , -78°C , 80%; (b) CF_3COOH , Me_3N , EtNO_2 , -25°C , 30%; (c) Cl_3CCOOH , Me_2CHNO_2 , 0°C , 45%–65%

The treatment of thioketal **461** with SnCl_4 has given a mixture of cyclisation products **462**–**464** in 12%, 55% and 32% yields, respectively.²²⁴

The synthetic potential of an approach to the synthesis of steroids, which, in principle, imitates the transformation of squalene into polycyclic products occurring in living organisms, has been discussed.^{221–225} It was noted that the propynyl group plays a special role, since it makes possible the formation of both five- and six-membered rings *via* two vinyl cationic intermediates. Using this scheme, linear compounds can be converted in one stage into tetracyclic systems with seven chiral centres, this reaction being highly stereoselective (see also relevant reviews^{226, 227}).

Cyclisations of alkynylvinyl cations **466** formed upon solvolysis of vinyl triflates **465** afford vinylic cations **467** and **469**, which are then converted into cyclopentenyl ketones **468** and cyclohexenones **470**, respectively. These ketones are unstable under the solvolysis conditions and rearrange into the corresponding α,β -unsaturated ketones.^{228, 229}

The dependence of the reaction route on the mutual orientation of the carbenium centre and the acetylenic fragment can be clearly followed for the solvolysis of cycloalkynyl esters. Thus cyclodec-5-ynyl derivatives **471** are mostly converted into decalone **473** *via* cation **472**. Only traces of bicyclo[5.3.0]decan-2-one **474** were found in reaction mixtures.^{22, 26, 230, 231}

Solvolysis of 4-nitrobenzoate **475** containing a nine-membered ring yields almost quantitatively bicyclic ketone **476**,^{22, 230} whereas in the case of isomeric ester **477**, the triple bond does not participate in the solvolysis at all.²³⁰

$X = \text{OTs}$, 4- $\text{NO}_2\text{C}_6\text{H}_4\text{COO}$.

Further progress of the studies described above resulted in the development of a new approach to the generation of fairly unstable phenyl cations of the type **6**.^{27, 229, 232} Suffice it to say that these cations are 20–25 kcal mol⁻¹ less stable than the propen-2-yl cation $\text{H}_2\text{C}=\text{C}^+\text{CH}_3$,²⁹ and it was not until 1985 that they were obtained for the first time by solvolysis.²⁸ The intermediate formation of the phenyl cations **480** was confirmed by the detection of functional derivatives of benzene **481** and **482** among the products of solvolysis of conjugated diene triflates **478**. Benzyl ethers **483** result from transprotonation of the cationic intermediate **479**.

X = H, Et, CF_3CH_2 .

Solvolysis of cyclic diene vinyl triflate **484** in the presence of LiBr gives bromo-substituted tetrahydronaphthalene **485**.²³³ Naphthyl cations **487** have been generated in the same way from enol triflate **486**.^{27, 234}

When the carbon–carbon triple bond is further removed from the carbenium centre, the cyclisation becomes virtually impossible.^{22, 26}

Another, barely studied, type of cations with a triple carbon–carbon bond, namely the alkynyl cations $\text{R}-\text{C}\equiv\text{C}^+$, should also be mentioned. These species are extremely unstable; their energy is 130 kcal mol⁻¹ higher than that of primary vinyl cations or phenyl cations described above.²³⁵ Phenylethynyl cations were detected for the first time in the mass spectra of arylazoethynylbenzenes **488**.²³⁶

Alkynyl cations can be generated in solution only by the nuclear-chemical method²³⁵ (see also Ref. 237). Reactions of 1,4-diethynylbenzene **489** containing tritium atoms with benzene and brominated hydrocarbons were studied. The β -decay of tritium yields a helium atom, which is the best leaving group.

The intermediate formation of alkynyl cation **490** was proved by chromatographic isolation of the products of its reactions **491**, **492**.²³⁵

Recently, in order to find pathways to ethynyl cations, nitrosation of enamines, bis-silylated at the nitrogen atom, has been studied.²³⁸ In the multicomponent reaction mixtures formed upon these reactions, some products that could have arisen with participation of the ions in question were detected.

It has been proposed to use alkynyllead triacetates **494**, which are formed *in situ* on treatment of alkynyltrimethylstannanes **493** with lead tetraacetate, as synthetic equivalents of alkynyl cations; these compounds permit easy introduction of an alkynyl group

into 1,3-dicarbonyl compounds and nitronates. The reaction products are formed in 47%–87% yields.²³⁹

R = H, Me(CH₂)₅, Ph, Me₃Si.

VII. Hetero-analogues of alkynyl carbocations

The principle of activation of a carbon–carbon triple bond by means of a positively charged substituent can be realised in compounds containing an acetylene fragment and a heteroatomic cation. Unlike alkynylcarbenium ions, onium cations **495** containing an ethynyl group cannot have allenyl structure like **10**.

X = N, P, Hal.

An obvious merit of these systems is the possibility of removing the activating heterocationic fragment from the molecule after a transformation of the acetylene group.³⁵

1. Alkynylammonium and alkynyldiazonium ions

Alkynylammonium ions **496** are usually regarded as intermediates in the formation of ynamines **497** from alkynyl halides.³⁶ As a rule, these species are unstable, although in some cases, they have been isolated as salts and characterised. Thus the ethynylammonium salt **499** was prepared from methyl bromopropiolate **498**. The IR spectrum of this salt exhibits an absorption band typical of acetylene derivatives at about 2180 cm⁻¹.²⁴⁰ Organyl chloroethynyl sulfides **500** react with tertiary amines to give quite stable salts **501**, which are soluble in water and alcohols. The acetylene absorption band in the IR spectra of these salts (2205 cm⁻¹) is shifted to shorter wavelengths with respect to this band in the spectra of the initial sulfides (2170 cm⁻¹).²⁴¹

R¹ = Et, Bu; R², R³, R⁴ = Et, (CH₂)₅.

During studies on nucleophilic substitution at an acetylenic carbon atom, fairly unstable ethynyltriethylammonium bromide

502 has been isolated. Upon mixing with an alkaline solution of KI and HgCl₂, this salt was converted into stable mercurioethynylammonium iodide **503**.^{242, 243}

An unusual type of hydration of a C≡C triple bond without a catalyst has been performed²⁴⁴ by irradiation of 4-ethynyl-*N,N*-dimethylaniline **504**. This reaction was assumed²⁴⁴ to occur *via* the formation of radical cation **505**.

Published data on alkynylammonium cations are scarce. A comprehensive review of the available information can be found in a paper by Katrizky²⁴⁵ devoted to the synthesis and spectroscopic characteristics of heterocyclic ynammonium salts. Since these salts cannot be prepared from highly nucleophilic 4-dimethylaminopyridine, acridone **506** was used as the heterocyclic substrate. This permitted the *N*-alkylation and quaternisation stages to be conducted separately. *N*-Alkynylacridinium salts **508**, **510** were prepared *via* two routes, namely, by *O*-acylation of *N*-alkynylacridones **507** and by dehydroxylation of pseudo-bases **509** with trifluoromethanesulfonic acid.²⁴⁵

R = Me, Ph, 2,4,6-Me₃C₆H₂.

In the ¹³C NMR spectra of the salts **510**, the signal of the triple-bond carbon atom, more distant from the heterocycle, is shifted downfield (on the average, by 12–14 ppm) in relation to its position in the spectra of the precursors **507**, **509**. On treatment with nucleophiles, the salts **510** are converted into stable ynamines of the type **509**, the attack of the nucleophile being directed at the 9-position of the acridinium ring.²⁴⁵

After several unsuccessful attempts to prepare alkynyldiazonium salts, Hanack *et al.*²⁴⁶ described the synthesis of phenylethynyldiazonium salt **512** from α -bromo-1-phenylacetyl chloride **511**. The salt **512** obtained at –30 °C was made to react with nucleophiles without isolation. It was found that nucleophiles first add to the C≡C triple bond. The alkenyldiazonium salts **513** thus formed eliminate a nitrogen molecule. The initial salt **512** itself cannot abstract a nitrogen molecule, because the energy of the alkynyl cation that would result from this process is extremely high (see Section VI).

A method for the synthesis of a new family of heterocyclic ylides **525** based on reactions of alkynylphosphonium salts with sodium azide has been developed.²⁵⁰ Phenylethynylpyridines **528** have been obtained by the reaction of the salt **516a** with pyridine *N*-oxides.²⁵⁵

The use of alkynylphosphonium salts in the synthesis of heterocycles comprising the addition of nucleophiles to a triple C≡C bond and subsequent cyclisation with the removal of the activating triphenylphosphine fragment has been demonstrated³⁵ in relation to reactions of the salt **516a**.

Numerous syntheses based on propynylphosphonium salts have been described in a number of studies^{256–258} and have been surveyed in a review.²⁵⁹

3. Alkynyliodonium ions

Alkynyl derivatives of tricoordinated iodine have been known since 1965. The interest in the chemistry of tricoordinated iodine, which has sharply increased in recent years,²⁶⁰ has stimulated studies of its ethynyl derivatives. Phenyl(phenylethynyl)iodonium chloride **529** was synthesised in a yield of up to 20% by the reaction of lithium phenylacetylide with λ³-iodanylbenzene dichloride. The IR spectrum of this salt²⁶¹ contains a characteristic absorption band in the region of 2170 cm^{−1}. On storage for several hours at room temperature, the salt **529** spontaneously decomposes to give iodobenzene and chloro(phenyl)acetylene. Phenyliodanyl bis(trifluoroacetate) **531**, capable of oxidising terminal triple bonds in compounds **530**, proved to be a more efficient reagent.²⁶²

R³ = H, CF₃CO.

The reagent **531** was used for efficient transformation of alkynols and arylalkynols **532** into 1,3-dihydroxy 2-carbonyl derivatives **534** via alkynyliodonium intermediates **533**.²⁶³

The first method, really suitable for the preparative-scale synthesis of alkynyliodonium salts, is based on the reaction of alkynes with hydroxy(tosyloxy)iodanylbenzene **535**. Short-term refluxing of the reagents in CHCl₃ gave alkenyl (**536a–e**) and alkynyl (**537d,f–h**) iodonium salts.^{264, 265}

Alkylethynyliodonium salts **538** can be prepared only in those cases where the alkyl group in the alkyne (Prⁱ, Buⁱ) creates steric hindrance hampering nucleophilic attack on the triple bond.²⁶⁶ This strategy was also employed to synthesise 4-alkoxyphenyl-ethynyliodonium salts **539** containing long alkyl chains.²⁶⁷

IV. Synthetic potential of the Kabachnik – Fields reaction	867
V. Conclusion	879

Abstract. The published data of the last decade concerning the mechanism of the Kabachnik – Fields reaction and its significance for the chemistry of organophosphorus compounds as a method for the synthesis of α -amino phosphonates and their numerous functionally substituted derivatives and analogues, such as phosphinates and phosphine oxides, are generalised and systematised. The review discusses the classical version of the Kabachnik – Fields reaction, its modifications with the use of phosphorus chlorides, neutral esters and inorganic phosphorus acids, as well as chemical processes simulating separate steps of the reaction, *viz.*, hydrophosphorylation of imines and amination of α -hydroxy phosphonates. Data on the practical application of α -amino phosphonates are presented. The bibliography includes 253 references.

I. Introduction

The Kabachnik – Fields reaction corresponds to the classical methods for the synthesis of organophosphorus compounds. It was discovered in 1952 independently by Kabachnik and Medved'¹ and Fields.² The reaction occurs in a three-component system consisting of a hydrophosphoryl compound, a carbonyl compound (aldehyde or ketone), and an amine and results in α -aminoalkylphosphonates commonly named as α -amino phosphonates (AP).

During the subsequent two or three decades, no intense studies in this field were carried out. However, after the discovery in the late 1960's that AP possess practically useful properties, mainly biological activity (see Ref. 3 and references cited therein), and isolation of phosphorus-containing amino acids from natural sources,⁴ the areas of chemistry, biology and medicine related to the synthesis and study of the properties of AP show a real renaissance. As a confirmation it can be noted that more than 5000 studies on this topic had been published by 1993.⁵ By now, this number has increased greatly. The prospects of using AP in

various areas of science and engineering stimulated the development of new ways for the synthesis of AP, including polyfunctional ones. However, in our opinion, none of numerous approaches to the synthesis of AP is as general as the Kabachnik – Fields reaction.

However, no generally accepted viewpoint on the mechanism of this reaction has been developed until recently. The data concerning this matter were isolated and often contradictory. Only in recent years have kinetic and other special studies aimed at a deep study of the Kabachnik – Fields reaction and the establishment of its mechanism been carried out. As a result, the contradictions were resolved to a considerable extent; however, the reviews generalising and analysing these studies are lacking.

On the contrary, the synthetic aspects of the Kabachnik – Fields reaction have been developed rather widely and discussed in monographs^{6–12} and reviews.^{13–19} However, new and important results that deserve thorough consideration have also been obtained in this area during the last five years.

The purpose of the present review is to systematise, analyse and generalise the data published basically in the 1990's and related to the study of the mechanism of the Kabachnik – Fields reaction and its use for the synthesis of AP. Earlier publications will be cited only to the extent required for the understanding of the essence of the problems under discussion. In order to rank the Kabachnik – Fields reaction, estimate its significance among numerous other methods for the synthesis of AP and reveal its synthetic potential, we considered it necessary to present data on the basic methods for the synthesis of AP. Due to the abundance of data in this field, the topic is inevitably covered superficially, and we confine ourselves to the analysis of only the latest publications. Whenever necessary we have to refer the reader to the literature cited in these papers.

Chemical processes that simulate separate steps of this reaction and its versions and involve other derivatives of three-coordinate phosphorus, such as neutral esters, chlorides, inorganic acids and their silyl derivatives instead of hydrophosphoryl compounds, are discussed in more detail. We believe that the reactions of the silyl derivatives with carbonyl compounds and amines or amides in a three-component system may also be rightfully attributed to reactions of the Kabachnik – Fields reaction type. As will be shown below, reactions of P(III) derivatives often produce hydrophosphoryl compounds that react exactly in the same way as those in the 'classical' system.

Uspekhi Khimii 67 (10) 940–968 (1998); translated by S S Veselyi

[†] The review is devoted to the memory of Academician M I Kabachnik (1908–1997).

Special attention is given to the hydrophosphorylation of imines. On the one hand, this represents one of the steps of the Kabachnik–Fields reaction and, on the other hand, a version of the Pudovik reaction, which was described in 1952²⁰ almost simultaneously with the pioneer research by Kabachnik and Medved' (and published in the same volume of *Doklady Chemistry*). In addition, we found it necessary to present brief information on the main areas where AP are used.

II. Application areas and principal methods for the synthesis of α -amino phosphonates

1. Application areas of α -amino phosphonates

It is believed³ that aminomethylphosphonic acid was first mentioned in the literature in 1943.²¹ Being structural analogues of α -aminocarboxylic acids **1**, α -aminoalkylphosphonic acids **2** (APA) possess diverse biological activities. For this reason, they attract steady attention of chemists, biologists, pharmacologists, physicians and other specialists who study biologically active compounds.^{3, 11, 16, 18, 22, 23} Organophosphorus analogues of almost all proteinogenic amino acids have been synthesised. APA isostructural to tyrosine have been isolated from natural sources (see Ref. 24 and references cited therein).

APA resulting from replacement of the carboxy groups in 'normal' amino acids by the phosphonate groups inhibit the enzymes or receptors to which natural amino acids normally bind. Therefore, APA are their antagonists (see Refs 3, 25 and references cited therein). The inhibitory action of APA predetermines their physiological activity as antibacterials, neuroactive agents, antibiotics, carcinostatic, cytotoxic and other compounds of pharmacological importance.³

Much attention is given to the use of AP (the acids themselves, *i.e.*, APA, their mono- and diesters and some other derivatives) in peptide synthesis.^{3, 26–31} Phosphonopeptides represent models of the tetrahedral transition states (activated complexes) in the hydrolysis of natural peptides.^{32–34} In addition, they exhibit diverse and rather high physiological activities, such as pesticide,³⁵ fungicide³⁶ and growth-controlling³⁷ ones. Phosphonopeptides are inhibitors of thrombin³⁸ and pepsin³⁹ and are used as haptens of antigens affecting the production of antibodies.⁴⁰ They also manifest other kinds of physiological activities.³

Numerous studies have been devoted to the synthesis and study of APA possessing herbicidal properties. Of these, *N*-(phosphonomethyl)glycine, $^{-}\text{HO}_3\text{PCH}_2\text{N}^+\text{H}_2\text{CH}_2\text{COOH}$ is known under the trade name glyphosate and used most widely (see Ref. 41 and references cited therein). Its numerous analogues have also been obtained.⁴²

A series of studies^{43–45} have dealt with the development of methods for the synthesis of α -aminofluorenylphosphonates, -phosphinates and -phosphine oxides. As structural analogues of a synthetic phytohormone morfactin, they represent an interesting class of plant growth regulators and herbicides. Wide prospects of practical application of this type of AP stimulated in-depth spectroscopic studies of their structures.⁴⁵ Attempts at establishment of quantitative structure–biological activity relationships were also made.⁴⁶ It should be noted that the relation between the structure of a number of neutral AP and their antimicrobial⁴⁷ and fungicide⁴⁸ activities is well described by correlation equations.

Although the biological activity is certainly a very valuable and the most attractive property of AP, this by no means confines the prospects of their practical use. APA themselves, as well as their derivatives and analogues, correspond to polyfunctional organophosphorus compounds. They can form complexes, in which they act as mono-, bi- and polydentate ligands.⁴⁹ The

electron-donating atoms of nitrogen and phosphoryl oxygen serve as coordination centres, the acid groups of APA form the corresponding salts, and the suitable functional groups specially introduced to nitrogen and phosphorus atoms and α -carbon atoms can provide additional bonding to metal ions. The same properties are used as a stereocontrolling factor in enantioselective synthesis of AP (see below).

Kabachnik was one of the first to study the complexing properties of AP,^{50–52} using linear and cyclic (cyclopentand) AP as the complexones. Recently, the first X-ray characteristics of an AP metalcomplex, *viz.*, a coordination compound of Cu(II) with *O*-ethyl hydrogen α -(2-pyridyl)-*N*-isopropylaminomethylphosphonate, have been obtained.⁵³ Complexes of chromium with fluorenylphosphonates have been synthesised.⁵⁴ In recent years, complexes of AP with lanthanides and actinides have been proposed for diagnostics with the use of the NMR technique.^{55, 56}

Extraction processes involving AP have been studied. It was shown that APA can be used in hydrometallurgy.⁵⁷ Processes for gold extraction with neutral AP and efficient separation of Au(III) from the commonly accompanying ions, Fe(III) and Cu(II),⁵⁸ as well as extraction of Pd(II) in strongly acidic media have been reported.⁵⁹ The acid–base properties of *O*,*O*-dialkyl *N*,*N*-dialkyl- α -aminoalkylphosphonates have been studied. As expected, they appeared to be weaker bases than amino acids. The $\text{p}K_{\text{BH}}$ values (in aqueous propan-2-ol) are 9.2–9.7, whereas $\text{p}K_{\text{BH}}$ of histamine is ~ 5 . Substituents at the α -carbon atom and nitrogen do not affect essentially the AP basicity.

Due to the ability of AP to complexation, they can serve as carriers for α -hydroxy and α -amino acids through lipophilic liquid membranes,⁶⁰ which is a new promising direction for their utilisation. *N*-Bornyl-AP,⁶¹ (*d*)-*N*- α -methylbenzyl-AP and other linear and cyclic AP,^{62, 63} as well as calix[4]arenes with α -amino phosphonate fragments in the bottom and top rings were chosen for molecular recognition of substrates.⁶⁴ Generally, the latter derivatives appeared to be more efficient transport agents than their acyclic analogues. The flux of α -hydroxy acids is most strongly affected by the nature of substituents at the α -carbon atom in AP. It is remarkable that the AP studied can also be used for the separation of D- and L-forms of α -hydroxy and α -amino acids.⁶⁰

The results of these studies are in good agreement with the data obtained in a study of the thermochemistry of AP.^{65–67} Specific features of dissolution of neutral AP in solvents of various nature (hexane, CCl_4 , CHCl_3) characterise these compounds as distinct proton acceptors. However, with respect to sufficiently strong bases, for example, pyridine, AP behave as proton donors. Calculations of the enthalpy of solvation showed the predominant effect of steric factors of the substituents on the liability to biphilic reactions of this kind.⁶⁸

Finally, it is worthy of mentioning that analytical methods for the determination of enzyme inhibitors, including APA esters, have been developed.⁶⁹

2. Principal methods for the synthesis of α -amino phosphonates

No simple and versatile methods for the synthesis of AP existed before the discovery of the Kabachnik–Fields reaction. Single attempts at the preparation of AP mentioned in the early studies^{1–3, 70, 71} did not satisfy the researchers because of multi-step syntheses and low efficiency. The credit for the intense progress in studies on the chemistry and biology of AP in the last decade should be given to the development of a series of highly efficient one-pot or two- or three-step methods for the synthesis of AP. The Kabachnik–Fields reaction occupies the leading position among these methods. It is now believed that the Kabachnik–Fields reaction and its constituting separate steps are the most convenient methods for the synthesis of AP, including homochiral ones (see Section IV).

The basic problem in the synthesis of AP is the formation of the aminoalkylphosphonate fragment, $\text{P}(\text{O})\text{—C—N}$. Therefore,

$R^1, R^2 = \text{Alk, Ar, AlkO, ArO, H, OH, OSiR}_3$;

(a–d) — see the text.

the synthetic routes shown in Scheme 1 are of prime interest. However, prior to the discussion of the synthetic versions presented in the scheme, it should be mentioned that the stereochemical aspects of these reactions are very important.

As in case of α -amino acids, the biological activity of AP is largely determined by the absolute configuration of the stereogenic α -carbon atom. Of the four possible diastereomers of the antibiotic alaphospholine **3**, the (*S,R*)-diastereomer manifests the greatest activity against pathogenic microorganisms. The three other stereoisomers are much inferior to this compound in activity (see Ref. 72 and references cited therein).

The first synthesis of an optically active APA was carried out in 1972.⁷³ The most comprehensive information on the methods for the stereoselective synthesis of AP is presented in the review by Kukhar' *et al.*¹⁸ containing the data published before the middle of 1992. Since then, a large number of publications describing new ways for the enantioselective synthesis of AP have appeared; the main attention in the present review is given to these methods.

The strategy for the synthesis of AP that envisages the formation of the amino phosphonate framework, $\text{P(O)}-\text{C}-\text{N}$, is based mainly on the use of the Kabachnik–Fields reaction in a three-component system 'phosphite–carbonyl compound–amine' and its various versions [Scheme 1, pathway (a)]. As will be shown below, the Pudovik reaction, *i.e.*, catalysed or non-catalysed addition of hydrophosphoryl compounds to imines [pathway (b)], as well as nucleophilic amination of hydroxy phosphonates [pathway (c)], represent separate steps of the two- (or more)-step Kabachnik–Fields reaction. We shall consider these three most important methods for the synthesis of AP separately in Section III.

In the present section, we pay the main attention to the strategy designated as pathway (d) in Scheme 1 (C-, N-, P-

modification). Numerous methods for the synthesis of AP based on this approach assume that a preliminarily created combination of phosphoryl, α -carbon and amine fragments is used as the key synthon. The synthesis of the target AP, including peptides, homochiral APA, *etc.* is carried out by introduction of the desired functional groups to the α -carbon atom (C-modification), to the nitrogen atom (N-modification) and to the phosphorus atom (P-modification). It should be noted that this strategy is being developed intensely in recent years. Special attention has been paid to the stereocontrolled functionalisation of AP at all the reaction centres specified above. Data published before the middle of 1992 have been systematised in a review (Ref. 18). Here we present only the studies that have not been mentioned there and in subsequent publications.

a. C-Modification

It is known that the carbon atom bonded with the phosphoryl group, which has considerable electron-withdrawing properties, possesses a pronounced anionoid character. This circumstance is widely used in organic and organometallic synthesis, for example, for functionalisation of the α -carbon centre or for olefination of carbonyl substrates by the Horner–Wittig–Emmons reaction.⁷⁴ Generation of carbanions from AP and their subsequent C-functionalisation is a popular approach for the synthesis of diverse polyfunctional AP by reactions of α -phosphoryl amino carbanions with appropriate electrophilic reagents. In these processes, the following starting compounds are used: APA or their esters containing the P(O)CH(R)N moiety with a terminal primary, secondary or tertiary amino group or imines incorporating the $\text{C}=\text{N}-\text{CH(R)P(O)}$ fragment. The latter are usually obtained by the reaction of AP having a primary amino group with aldehydes or ketones.⁷⁵ Other procedures, *e.g.*, the reaction of α -oxo phosphonates with primary amines⁷⁶ or the reaction of dialkyl phosphites with hexahydrotriazine, have also been reported.⁷⁷

C-Alkylation of acyclic AP [Scheme 2, pathway (a)] is used rather seldom, probably because of their rather low CH-acidity. The α -phosphoryl carbanion is probably insufficiently stable due to the presence of an electron-withdrawing phosphoryl group and an electron-donating amino group.

Nevertheless, easy introduction of a methyl, phenylthio, and other heteroatomic groups to the α -carbon atom of AP **4** (THF, -70°C) by treating phosphoryl carbanions with appropriate halogen-containing reagents of the RX type has been described recently.⁷⁸

$\text{LDA} = \text{LiNPr}_2$;

$\text{R} = \text{SiMe}_3$ (79%), SnBu_3 (52%), SPh (60%), Me (70%).

However, in the series of heterophosphacyclanes containing endo- and exocyclic nitrogen atoms, the method for the synthesis of AP discussed above [Scheme 2, pathway (a)] is much more popular. A scheme for the synthesis of APA by alkylation of a five-membered cyclic ephedrine derivative **5** can be given as an example.⁷⁹

Scheme 2

(a) Ephedrine, NEt_3 , THF; (b) BuLi , THF, -70°C ; (c) RX , -70°C ;
(d) conc. HCl , 110°C , 20 h; (e) Me –; *de* is diastereomeric excess.

Homochiral 2-benzoylaminoethyl-3,4-dimethyl-2-oxo-5-phenyl-1,3,2-oxazaphosphorinanes **5a** and **5b** ('chiral phosphorus'), epimeric at position 2, were separated by column chromatography and subjected to C-alkylation under mild conditions to give enantiomers **6a** and **6b**. Subsequent hydrolysis of compounds **6a** and **6b** resulted in the APA (*S*)-7 and (*R*)-7, respectively. Later,⁸⁰ this strategy was used for the synthesis of APA 7 from enantiomeric oxazaphosphorinanes with the exocyclic chloromethyl group.

Pht is phthaloyl.

In recent years, functionalisation of methylphosphonates has been carried out according to the electrophilic amination scheme (see Ref. 72 and references cited therein). Strictly speaking, these processes do not conform to the strategy of C-alkylation of AP [Scheme 2, pathway (a)], as the amino group is not 'yet' present at the α -carbon atom of the starting phosphonates. However, since we are speaking of reactions of α -phosphoryl carbanions, we considered it appropriate to mention here this method for the synthesis of AP.

The reaction of oxazaphosphorinanes **8** with Pr^iLi and then with azodicarboxylate results in products of the addition to the $\text{N}=\text{N}$ bond. Their subsequent hydrolysis gives the APA 7.⁸¹

The same reaction was carried out with bicyclic phosphonamide **9**.⁸²

In the reaction with oxazaphosphorinane, aryl azide serves as the aminating reagent.⁸³

(a) BuLi ; (b) 2,4,6- $\text{Pr}_i^3\text{C}_6\text{H}_2\text{SO}_2\text{N}_3$; (c) Ac_2O .

In all cases, high diastereoselectivity of amination and high chemical yield of APA 7 were achieved (see also Ref. 18).

Successful use of carbanions stabilised by 1,3,2-diheterophosphacyclic substituents in the C-modification is, probably, largely caused by the rather high CH-acidity and, accordingly, high stability of these systems. It is known that incorporation of a four-coordinate phosphorus atom in a ring increases its electron-withdrawing properties.⁷⁴ This is particularly pronounced in the chemical behaviour of 1,3,2-diheterophosphorinanes.⁸⁴

A similar effect is achieved in the case of iminomethylphosphonates [Scheme 2, pathway (b)]. Charge delocalisation by two acceptor substituents, *viz.*, the imino and phosphoryl groups, lowers the energy of a carbanion.

Enantioselective syntheses of AP by C-modification, *i.e.*, alkylation of an α -imino carbanion with alkyl halides, carbonyl compounds and unsaturated electrophilic reagents, have been performed successfully with camphor derivatives **10** and a number of similar structures.

It was shown recently that high diastereomeric excess (*de*) in C-modification can be achieved due to the chelation effect⁸⁵ provided by the introduction of suitable functional groups capable of forming intramolecular hydrogen bonds, as, *e.g.*, in structure **11**.

The carbanions generated from phosphorus-containing Schiff's bases **10** ($\text{R} = \text{Et}$) enter into the Michael reaction.⁸⁶ Adducts **12** undergo cyclisation in acidic medium to 5-oxo-2-pyrrolidinylphosphonate subsequent reduction of which results in diethyl 2-pyrrolidinylphosphonate.

Secondary processes occurring after the electrophilic step of C-modification of AP expand the synthetic potential of phosphorylated imines. More often, however, the alkylation product is subjected to acid hydrolysis in order to obtain APA.⁸⁷

It has to be noted that the carbonyl compounds from which imine synthons are obtained can be regenerated by acid hydrolysis of phosphorylimines.¹⁸ This strategy for the synthesis of AP has been expanded⁸⁸ for isocyanomethylphosphonate **13**.

- (a) BuLi or Bu^tCH₂OK; (b) R¹—, BF₃·OEt₂; (c) MsCl, Et₃N; (d) Bu^tCH₂OK; (e) HCl, MeOH.

(1-Aminocyclopropyl)phosphonates **16** were obtained by alkylation of the phosphonate **13**-derived carbanion with epoxides to give the hydroxy phosphonate **14**. The mesylate of **14** obtained from the latter undergoes cyclisation in the presence of bases to give a cyclopropane intermediate subsequent methanolysis of which in acidic medium results in the target product **16**. Other examples of similar reactions are described in Ref. 18.

b. N-Modification

This type of AP reactions is responsible for their inhibitory effect with respect to enzymes and enables the involvement of APA and their esters in peptide synthesis. These processes were analysed in the reviews cited above,^{3, 16, 34, 38, 39} and their examination is beyond the scope of our review; we shall describe only some of the results obtained in this field lately.

Fluorenylmethyl chloroformate was used as an acylating agent in the synthesis of α-(9-fluorenylmethoxycarbonyl-amino)alkylphosphinates.⁸⁹

α-Aryl-(N-benzyl)aminomethylphosphonates react with β-tri-phenylgermylpropionic acid to afford germylated AP derivatives.⁹⁰

DCC is dicyclohexylcarbodiimide; HOBT =

Germylated AP manifest high antitumour activity that surpasses the efficiency of nongermylated AP derivatives in assays with sarcoma-180.⁹⁰

Acylation of AP containing a primary amino group with asymmetrical anhydride **17** results in a mixture of both possible N-acylated products.⁹¹

The readily occurring reaction of APA with ethyl orthoformate⁹² results in a mixture of (*N*-formyl)amino- and (*N*-ethoxymethylene)imino derivatives of alkylphosphonates.

The well-known method to increase the nucleophilicity of the nitrogen atom by introduction of a trialkylsilyl group ('silyl activation') was successfully used in peptide synthesis in the *N*-acylation of APA **7b** with benzyl chloroformate.⁹³

It should be noted that this synthetic technique has also been used in the synthesis of phosphorus analogues of glycine containing the dimethylphosphine oxide group.⁹⁴

N-Silylated AP add to acetone, benzaldehyde and *p*-bromobenzaldehyde at room temperature.⁹⁵

Distillation of (*N*-methyl-*N*-silyloxyalkyl)phenylmethylphosphonates results in their dissociation to the original AP and carbonyl compounds.

Nucleophilic reactions involving the nitrogen atom of AP are not limited to the substitution processes. Other reactions characteristic of primary, secondary and tertiary amines are also typical of AP. Among these, reactions of quaternisation and especially reactions of addition to unsaturated compounds are well studied.

An unusual sigmatropic [2,3]-rearrangement of *N*-allyl-ammoniomethyl phosphonates occurs in the presence of bases.⁷⁸

In this case, quaternisation of the tertiary amine centre is followed by the Cope rearrangement into the corresponding C-substituted AP, *viz.*, 1-aminobut-3-enylphosphonate.

Of addition reactions, those of AP with aryl isocyanates have been studied in detail.^{96–100} Comparative study of the kinetics of addition of amines and their α -phosphorylated analogues, *i.e.*, AP, to phenyl isocyanate revealed similarity of the addition mechanisms. In both cases, a concerted mechanism of addition is postulated with a four-centred transition state in which the C–N bond is formed in the activated complex somewhat earlier than the N–H bond.^{96–98}

$\text{R}^1 = \text{Alk}, \text{Ar}; \text{R}^2 = \text{H}, \text{Alk}, \text{Ar}, \text{CH}_2\text{P}(\text{O})(\text{OR})_2; \text{R}^3 = \text{Ar}.$

The small activation enthalpies and the high negative activation entropies are in good agreement with this conclusion. As was to be expected, AP are appreciably less active in this reaction than their aliphatic analogues, *i.e.*, dialkylamines. This is due to a decrease in the nucleophilicity of the amino group in the AP molecule due to the electron-withdrawing effect of the phosphoryl group. In a series of phosphorylated nucleophiles, good agreement between their reactivities and steric effects of the substituents at the phosphorus atom is observed, as follows from high correlation factors of the corresponding equations.⁹⁶

Reactions of AP with perfluoro-*N*-methylformimine probably occur according to the addition–elimination scheme.¹⁰¹ The synthetic result of this reaction, which occurs under very mild conditions, depends on the degree of substitution at the α -amino group. Primary α -phosphorylalkylamines are transformed to the corresponding α -(*N*'-trifluoromethylcarbodiimido)alkylphosphonates.

Secondary amines react with the elimination of one molecule of hydrogen fluoride and form α -(perfluoro-*N*-methylformamidino)alkylphosphonates under the same conditions.

c. P-Modification

In the chemistry of AP, this type of reactions is normally represented by saponification and esterification of phosphorus acid derivatives. Though these reactions play an important role in the synthesis of APA and their esters, they are of no special interest in the context of this review. Of recent studies, we shall mention only Ref. 102.

Selective mono-esterification of APA occurs with sterically hindered alcohols in the presence of bromo[tris(dimethyl-amino)]-phosphonium hexafluorophosphate (BroP) or *N,N,N',N'*-bis(tetramethylene)chloronium tetrafluoroborate (TPyCIU).

d. Other methods

The simplest and rather common method for the synthesis of AP is reduction of nitrogen-containing organophosphorus compounds that already have a phosphonate framework with the α -nitrogen atom under the action of various hydrogenating agents.

For example, α -nitro phosphonates can easily be transformed to AP even at room temperature in almost quantitative yields.¹⁰³

Reduction of hydroxyiminophosphonate with sodium borohydride occurs in the presence of MoO_3 or $NiCl_2$ (see Ref. 104).

Reductive amination of α -oxo phosphonates in the presence of triacetoxyborohydride gives the corresponding AP in moderate yields.⁷⁶

This reaction occurs in two steps: Schiff's bases are formed in the first step and reduced in the second step.

Other reactions of unsaturated organophosphorus compounds containing, or devoid of, a potential amino group were used in the synthesis of AP. Ethyl (diethoxyphosphoryl)diazooacetate is obviously inserted as a carbene into the N–H bond of amines and amides.¹⁰⁵

R = Alk, Ar, Ac, COOBu^t etc.

The reaction takes place under drastic conditions, viz., refluxing in toluene in the presence of palladium salts.

Diethyl azidoalkylphosphonate undergoes 1,3-dipolar cycloaddition with alkynes to give 4,5-disubstituted 1-(1-diethoxyphosphorylalkyl)-1,2,3-triazoles in high yields (85%–92%).¹⁰⁶

Reactions of unsaturated organophosphorus compounds with nitrogen-containing 1,3-dipoles are well studied and are discussed in a review.¹⁰⁷

Vinylphosphonates are attractive synthons when choosing a strategy for the synthesis of AP. Recently,¹⁰⁸ a convenient method to involve them in the reaction with *N*-tosyliminophenyl- λ^3 -iodane in the presence of Cu(II) or Cu(I) triflate has been described.

Catalytic hydrogenation of the aziridine intermediate occurs regioselectively to give the AP **18**. The solvent used in this reaction affects essentially the rate of the process. For example, a 70%–80% yield of compound **18** is reached in 10 min in acetonitrile, in 1–3 h in CH_2Cl_2 , and in 76–90 h in benzene. Enantioselective synthesis of AP from vinyl-phosphonates and -phosphinates was also carried out with the use of nickel complexes of natural amino acids. As a result, the latter undergo condensation at the terminal carbon atom of the phosphorus reagent.^{18, 109}

Polyfunctional AP can be obtained by functionalisation involving other unsaturated fragments as well. For example, bisphosphonates **19** were synthesised¹¹⁰ which represent the Diels–Alder adducts of maleic anhydride with furan derivatives of AP.

Yet another promising strategy for the synthesis of AP has found quite a limited use so far. This is phosphorylation of unsaturated compounds containing the nitrogen atom at the α -position to the double bond, for example, enamines and similar compounds.

The so-called electrophilic version of the Pudovik reaction makes an exception.

It is known¹⁰ that hydrophosphorylation of enamines under classical conditions of the Pudovik reaction, which is base-catalysed addition, could not be carried out until the late 1980's. A simple one-step method for the synthesis of AP was created only after the discovery of the electrophilic version of the Pudovik reaction, which occurs with vinyl ethers, enamines and other electron-excess alkenes and five-membered cyclic alkylene-phosphorous acids characterised by an increased proton-donor ability.^{111–115}

R¹ = Alk, Ar; R² = H, COOEt, COMe etc.;

R³ = (CH₂)₅, CH₂CH₂OCH₂CH₂, Me₂;

R⁴, R⁵ = CH(Me)CH(Me), CH(Me)CH₂, CMe₂CMe₂, CH₂CMe₂CH₂, *o*-C₆H₄; R⁴ = R⁵ = CHF₂CF₂CH₂, ClCH₂CH₂.

Synthetic, kinetic and thermochemical studies^{8, 111–115} of this reaction together made it possible to establish its mechanism. It consists of pre-equilibrium transfer of a proton from the phosphorous acid to the enamine and addition of the cyclophosphite anion to the α -carbon atom. As is frequently observed in electrophilic addition of proton-containing reagents, the addition occurs according to the Markovnikov rule. However, this method was found to be unsuitable for the hydrophosphorylation of amino-butenones.¹¹⁶ Enamino ketones with *N*-methyl and *N*-phenyl groups react without participation of the carbon–carbon double bond. Dibutylphosphine oxide adds to the ketone carbonyl group,

and the second phosphine oxide molecule replaces the amino group to give the diphosphorylated unsaturated alcohol **20**.

It is rarely possible to employ the classical nucleophilic Pudovik reaction for the synthesis of AP.¹¹⁷ For example, the addition of diethyl phosphite to *N*-acetylaminomethylidenemalononic ester gave the AP **21**, which served as the starting reagent in the synthesis of phosphonohistidine **22**.

This reaction was successful due to the presence of three strongly electron-withdrawing substituents in the unsaturated electrophilic reagent, *viz.*, two ethoxycarbonyl groups and an acylamino group.

Finally, we shall note the unusual synthesis of AP through 1,2-phosphorylotropic migration in a series of *N*-acylated derivatives of α -aminoalkyl compounds of three-coordinate phosphorus.¹¹⁸

R¹ = CCl₃, H(CF₂)₄, H(CF₂)₆; R² = PhCO, P(O)(OEt)₂, P(O)Ph₂;

R³ = R⁴ = AlkO, Alk₂N, Ar.

The α -amino alcohol formed in the first step of the reaction esterifies the P(III) halide to give the P(III) alkoxy derivative, which then undergoes isomerisation to the corresponding AP.

The material presented in this section shows that essential progress in the creation of new types of AP has been achieved during the search for practically useful compounds. The ever-increasing complication of the AP structures demands a wider use of diverse approaches for the functionalisation of the starting substances. However, the analysis of the results obtained shows that the main problem in AP chemistry, *viz.*, the formation of the α -alkylaminophosphinyl fragment P(O)–CR₂–N, can be best solved using the Kabachnik–Fields reaction. This explains, first of all, the keen interest of researchers in the studies of various aspects of the Kabachnik–Fields reaction in the last decade. This primarily corresponds to the investigations into the reaction mechanism, as the desired synthetic result can only be achieved on the basis of in-depth understanding of the factors governing this complex process.

III. The mechanism of the Kabachnik–Fields reaction

As noted above, the Kabachnik–Fields reaction, *i.e.*, a three-component reaction of hydrophosphoryl compounds with ammonia, amines or other NH-compounds and aldehydes or ketones, is a unique method for the formation of the AP framework [N–C–P(O)]. However, a common viewpoint on the mechanism of this reaction has not been worked out until recently, as the conclusions were based mainly on synthetic studies. Spectral and kinetic data were obtained later.

The main problem in the understanding of the mechanism of the Kabachnik–Fields reaction is the determination of the sequence of separate steps of this process. In their early studies, Kabachnik and Medved' believed that it was similar to the Rodionov reaction employed for the synthesis of β -amino acids or the Zelinsky reaction, *i.e.*, the formation of amino nitriles upon treatment of aldehydes with ammonium cyanide (see Refs 1, 119–121 and references cited therein).

Studies of the reaction of hydrophosphoryl compounds with aldehydes¹ and ketones¹¹⁹ made it possible to suggest a scheme of aminoalkylation of hydrogen phosphites and phosphonites,^{120, 121} which involves the addition of a hydrophosphoryl compound to the C=O bond with subsequent replacement of the hydroxy group of the α -hydroxy phosphonate by the amino group.

Fields² used primary and secondary amines instead of ammonia in a three-component mixture containing dialkyl phosphites and carbonyl compounds. For example, exothermic reaction of diethyl phosphite with diethylamine and formaldehyde gives *N,N*-diethylaminomethylphosphonate in 94% yield. Fields² believed that the reaction occurred as the Mannich reaction, *viz.*, the reaction of an amine with an aldehyde first produces an α -amino alcohol, which reacts with a hydrophosphoryl compound to give finally an AP.

In the opinion of Fields,² the reaction with primary amines might also occur through intermediate imines. An imine formed in the first step, *i.e.*, the product of dehydration of an α -amino alcohol, readily added a hydrophosphoryl compound.

Thus, in the studies of the Kabachnik–Fields reaction,² the important assumption has been made that aminoalkylation of hydrophosphoryl compounds could occur through a step of formation of an imine and its subsequent involvement in the Pudovik reaction.

The experimental fact that the methoxy group in methoxymethylphosphonate is not exchanged for the amino group on heating with ammonia provides evidence in support of the 'imine' pathway of the Kabachnik–Fields reaction.¹²² In addition, hydroxy phosphonates, *i.e.*, addition products of dialkyl phosphites to carbonyl compounds, do not react with ammonia under the mild reaction conditions used by Fields.² The hydroxy group can be replaced by the amino group only in the presence of sodium alkoxide. It is believed to cause the decomposition of a hydroxy phosphonate into the original compounds, *viz.*, hydrogen phosphite and a carbonyl compound.¹²² The process subsequently goes through a step of formation of an imine, which adds a hydrophosphoryl compound according to the Pudovik reaction scheme.

The reversibility of the formation of hydroxy phosphonates received a convincing experimental confirmation in the studies by Gancarz *et al.*^{5, 123–125} It was found that hydroxy phosphonates obtained from aliphatic and aromatic aldehydes and ketones decompose into the original hydrophosphoryl and carbonyl compounds under certain conditions in the presence of primary or tertiary amines (butylamine, triethylamine), as well as amines in the presence or in the absence of proton donors (ethanol). Hence, the formation of hydroxy phosphonates under conditions of the Kabachnik–Fields reaction does not necessarily imply that the formation of the ultimate AP should definitely occur according to the ‘hydroxy phosphonate’ pathway. As shown above, the phosphite and carbonyl compound formed upon decomposition of hydroxy phosphonates can give the final AP according to the ‘imine’ pathway, *viz.*, through condensation of a carbonyl compound and an amine into an imine and its subsequent hydrophosphorylation.

At first glance, this viewpoint does not explain the participation of secondary amines in the Kabachnik–Fields reaction. However, according to the data obtained by Petrov *et al.*,¹²² in this case either the addition of hydrophosphoryl compounds to iminium salts or the Mannich reaction occur. The possibility of the latter pathway is confirmed by the formation of AP in the reaction of dialkyl phosphites with *N,N,N',N'*-tetraethylmethylenediamine or with ethoxymethyldiethylamine.

X = NEt₂, OEt.

On the other hand, it was found^{123–125} that hydroxy phosphonates are not only formed reversibly from aromatic ketones under conditions of the Kabachnik–Fields reaction but also are irreversibly converted to phosphates according to the well-known phosphonate–phosphate rearrangement scheme.

R¹, R² = Ar;

Relative reaction rate constants: $k_1 = 100$, $k_2 = 1$, $k_3 = 6$.

The fastest step of the reaction is the formation of a hydroxy phosphonate. Its rearrangement to a phosphate occurs six times faster than the decomposition to the original compounds.

It is necessary to emphasise that both Kabachnik with Medved' and Fields have made their conclusions on the sequence of the reaction steps without carrying out special mechanistic studies. Therefore, they did not contrast the two possible routes of the aminoalkylation of hydrophosphoryl compounds, *viz.*, the ‘hydroxy phosphonate’ and ‘imine’ pathways. The experimental data reported in their and other studies cited above^{2, 119–121} as well as in some later publications^{122, 126, 127} allow one to assume that, depending on the nature of the reactants (hydrophosphoryl and carbonyl compounds and amines), the reaction mechanism and the sequence of steps can vary.

An assumption was made^{128–130} that the formation of AP *via* hydroxy phosphonates occurs with amines whose basicity is

sufficiently high ($\text{p}K_{\text{a}} > 6$). Otherwise ($\text{p}K_{\text{a}} < 6$), the ‘imine’ mechanism operates. This conclusion is based on the shift of signals in the ³¹P NMR spectrum of diethyl phosphite in its mixtures with amines. The δ ³¹P value is the higher the more basic the amine. Furthermore, it was considered^{129, 130} that the increase in the yield of AP in the Kabachnik–Fields reaction with weakly basic amines upon addition of crown ethers confirmed the scheme discussed above.

The idea that the mechanism of the Kabachnik–Fields reaction displays certain dualism seems quite reasonable. However, not all of the statements given in Ref. 129 appear to be convincing, and some of the postulates seem unlikely. Thus the suggestion that weakly basic amines can protonate the phosphoryl oxygen atom of a phosphite and the amide anion thus formed adds to a carbonyl compound to form methylolamine and/or imine¹²⁹ is wrong, in our opinion, as the amines are too weak acids to protonate the weakly basic oxygen atom of the P=O group.

A confirmation that the Kabachnik–Fields reaction can follow both of the pathways discussed here, *viz.*, ‘hydroxy phosphonate’ and ‘imine’, was obtained^{131–139} by the authors of the present review in a complex study including kinetic, spectroscopic and preparative methods.

We studied three-component systems containing a hydrophosphoryl compound, a carbonyl compound, and an amine, in which the nature of each reagent and the reaction conditions (solvent, additives of various types) were varied widely. We also studied the possibilities of bimolecular processes in the following pairs: hydrophosphoryl compound–carbonyl compound, hydrophosphoryl compound–amine, hydroxy phosphonate–amine, and hydrophosphoryl compound–imine. It was found that each of the reaction partners affects somewhat the reaction efficiency and its pathway.

A kinetic study of the reaction in the system dialkyl(methyl or pentyl) phosphite–benzaldehyde–aniline and reactions in the pairs PhNH₂ + PhCHO, dipentyl phosphite + PhCHO, and dipentyl phosphite + PhN=CHPh has made it possible to establish that the ‘imine’ mechanism operates in this case.¹³¹ UV spectroscopic study of the reaction kinetics permitted detection of an increase in the optical density of the mixture due to the formation of an imine chromophore in the beginning of the process. The formation of an imine is the fastest reaction of all reactions possible in this system. It is catalysed by a dialkyl phosphite. The reaction of phosphites with benzaldehyde in the absence of acidic additives (formic acid or aniline hydrochloride) does not occur at all. Pyridine, whose basicity is equal to that of aniline, but which cannot serve as a proton donor and does not participate in the reaction, does not catalyse it. Hence, the basicity of aniline is insufficient to catalyse the addition of dialkyl phosphites to benzaldehyde. This rules out the intermediate formation of hydroxy phosphonates.

Thus, due to low basicity, aniline manifests proton-donor properties and forms a pre-reaction complex of the type **23** with the phosphite. The reaction of the complex **23** with benzaldehyde results in an imine hydrophosphorylation of which gives the target AP.

A study of this system in solvents of different nature, *viz.*, in benzene (neutral medium) or propan-2-ol (a potential proton donor), in the presence and in the absence of acidic admixtures made it possible to reveal the effect of acid catalysis on the rate of each step of this reaction. The use of a strong proton donor, such as HCOOH, always accelerates the reaction by the general acid catalysis mechanism. This effect is most pronounced in a polar solvent, *viz.*, propan-2-ol. Propan-2-ol itself is inefficient as a

proton donor. It manifests only solvation effects, slowing down the reaction in some cases due to the formation of H-complexes with basic reagents.

Different kinetics were observed if the relatively weak base, aniline, was replaced by the appreciably more basic cyclohexylamine **24**.¹³⁶ It was found that the reaction of amine **24** with benzaldehyde is very slow and results in benzylidenecyclohexylamine, which is practically insoluble both in the selected media and in the majority of organic solvents. Attempts of addition of dialkyl phosphites to *N*-cyclohexylbenzylideneamine even in the presence of strong acids and bases failed.

These data indicate that in the system 'hydrophosphoryl compound–amine **24**–benzaldehyde', the 'hydroxy phosphonate' mechanism operates. According to this pathway, the reaction starts with the addition of a phosphite to benzaldehyde catalysed by the amine **24** (the Abramov reaction), followed by the replacement of the hydroxy group by the cyclohexylamino group.

A special ³¹P NMR study made it possible to detect the formation of the hydroxy phosphonate **25** in all cases. If a catalytic amount of the amine **24** is used, the phosphonate **25** is the sole reaction product. As the amine concentration increases, the signal intensity for the final product (AP) increases, while that for the phosphonate **25** decreases. In the system with aniline discussed above, the formation of the hydroxy phosphonate was never detected.

The results of these studies lead to the conclusion on the decisive role of the amine basicity. Variation of the nature of the amine enables 'switching' of the reaction from one pathway to the other.

To estimate the effect of the carbonyl component on the reaction pathway, the same complex of studies was carried out in the system 'dialkyl phosphite–aniline–substituted benzaldehyde'. Electron-donating *p*-methoxy and *p*-dimethylamino groups and electron-withdrawing *p*-bromo and *m*-nitro groups were used as the substituents. It was found that in all cases the 'imine' reaction pathway (Scheme 3) was realised and its general laws were obeyed. However, on switching from electron-donating substituents to electron-withdrawing ones, the rate of imine formation increases both in the carbonyl compound–amine pair and in the three-component system.

On the other hand, unlike benzaldehyde, its derivatives with both electron-donating and electron-withdrawing substituents undergo the Abramov reaction with phosphites to produce the corresponding hydroxy phosphonates. Moreover, simultaneous formation of both an imine and a hydroxy phosphonate was reported. The rate of the Abramov reaction for the aldehydes with electron-donating substituents exceeds the rate of imine formation by almost an order of magnitude. However, this does not suggest that the 'hydroxy phosphonate' mechanism is preferable kinetically, since, first, the Abramov reaction is reversible, and, second, the ability of transformation of hydroxy phosphonates to AP depends on the basicity of the amine. Weakly basic amines cannot replace the hydroxy group in a hydroxy phosphonate molecule. Thus, even if the formation of the latter is preferable kinetically, thermodynamic control directs the reaction with weakly basic amines to the 'imine' pathway.

In some cases, *e.g.*, for anisaldehyde, the ratio of rates of all pairwise reactions possible under the Kabachnik–Fields reaction conditions allows both reaction pathways. However, even in this case, the reaction follows mainly the 'imine' pathway, while the 'hydroxy phosphonate' pathway is minor if aniline is used as the amino component.¹³⁷

In the general case, the basicity of the amine is the crucial factor that determines the reaction pathway, in particular, the possibility of formation of pre-reaction complexes **23** or **26** (Scheme 3). Weakly basic amines, which can act with hydrophosphoryl compounds as H-donors, direct the reaction to the 'imine' pathway [pathway (a)].

Strong bases enable nucleophilic interaction of the pre-reaction complex **26** with carbonyl compounds and thus favour the 'hydroxy phosphonate' direction. An important role belongs to the reactivity of reactants, which affects the ratio of rates of decomposition of the hydroxy phosphonate and replacement of the hydroxy group in it by the amino group according to the pathway **29** → **30**. An intermediate case is possible as well: a biphilic reaction of a hydrophosphoryl compound with an amine with the formation of the complex **27**. This version assumes the probability of parallel reactions through both pathways.

The importance of consideration of all factors in the determination of the reaction pathway is clearly seen where salicylaldehyde is used in the reaction.¹³⁸ Irrespective of the amine basicity, the reaction with salicylaldehyde occurs exclusively according to the 'imine' pathway. The reason for this is the thermodynamic instability of the hydroxy phosphonate obtained from this aldehyde in the Abramov reaction.

The nature of the hydrophosphoryl compound is also of significant importance.¹³⁹ As will be shown below (Section IV) and as follows from Scheme 3, the acid–base interaction of a hydrophosphoryl compound with an amine is the crucial factor that determines the direction of the reaction. Replacement of the alkoxy groups by alkyls in a hydrophosphoryl compound, *i.e.*, going from dialkyl phosphites to dialkyl phosphinites and especially to phosphinous acids, alters the ability of a hydrophosphoryl compound to form a pre-reaction complex with an amine. High basicity of the phosphoryl oxygen atom in dibutylphosphinous acid and the decrease in PH-acidity of the hydrophosphoryl compound due to the replacement of electron-withdrawing alkoxy substituents at the phosphorus atom by electron-donating alkyl groups is the reason for the 'switch' of the reaction pathway from the 'hydroxy phosphonate' pathway, which is typical of dialkyl phosphites, to the 'imine' one if cyclohexylamine **24** is used as the amine component.

Scheme 4

Although phosphinous acids undergo smooth addition to carbonyl compounds, even in the absence of catalysts, the effect of the pre-equilibrium step, which involves the formation of the complex **31** and the addition of cyclohexylamine **24** to benzaldehyde catalysed by dibutylphosphinous acid, is more essential. An alternative mechanism involving nucleophilic attack of the dibutylphosphinite anion on the carbonyl carbon atom is noncompetitive in this case.

In a three-component system ‘dibutylphosphinous acid–salicylaldehyde–cyclohexylamine’, the hydrophosphoryl compound can enter into nucleophilic reactions both with an amine, which determines the ‘imine’ mechanism of the Kabachnik–Fields reaction, and with salicylaldehyde. However, in the latter case, the product of the Abramov reaction, *viz.*, compound **33**, does not react with cyclohexylamine, and the product of the Kabachnik–Fields reaction, *viz.*, aminomethylphosphine oxide **34**, is not formed (Scheme 4).

High stability of the hydroxy phosphonate **33** precludes its decomposition into the original components. Both addition processes resulting in the imine **32** and hydroxy phosphonate **33** are competitive, and compound **33** is the side reaction product. This result confirms once again the general scheme of the Kabachnik–Fields reaction (Scheme 3) and explains numerous experimental observations that the purity and yield of the reaction product increase if the reaction is carried out not in a three-component system but rather in a stepwise manner, for example, with isolation of the imine.^{140, 141} It is difficult to interpret unequivocally the competitive reactions of two nucleophiles in a system ‘hydrophosphoryl compound–carbonyl compound–amine’, *viz.*, the phosphite (the Abramov reaction, the ‘hydroxy phosphonate’ pathway) and the amine (the ‘imine’ pathway), in terms of electrophilicity of the carbonyl carbon atom.^{142, 143} It was not possible to reveal the relationship between the preference of attack by a particular nucleophile (amine or phosphite) and the steric requirements for the formation of adducts.¹⁴² It is believed^{142, 143} that the experimental results obtained from kinetic data and density functional¹⁴³ calculations are best explained from the HSAB standpoint. According to this concept, hard acids (aliphatic aldehydes and ketones) react faster with the hard bases (amines). Soft bases, *i.e.*, phosphites, preferably react with soft acids, such as aromatic carbonyl compounds. Similar opinions have also been expressed earlier.¹⁴⁴ We believe that these observations are only estimates that cannot rationalise the diversity of factors that determine the reaction pathway (for example, its changes on varying the substituents at the phosphorus atom in a hydrophosphoryl compound¹³⁹).

The general mechanism of the Kabachnik–Fields reaction presented in this section (Scheme 3) has much larger interpretative and predictive power.

IV. Synthetic potential of the Kabachnik–Fields reaction

The ample synthetic potential of the Kabachnik–Fields reaction has allowed it to occupy a deserved position in the arsenal of preparative chemistry of organophosphorus compounds. The

possibility of variation of the functional groups in the carbonyl and amine components, the involvement of various types of derivatives of trivalent (three-coordinate) phosphorus in the reaction, the rather mild reaction conditions and the possibility of further one-pot modification of the resulting AP, all these attractive aspects of the three-component method for the synthesis of AP by the Kabachnik–Fields reaction stimulated the search of newer substrates for this reaction. Here we make an attempt to classify the versions of the Kabachnik–Fields reaction according to the starting P(III) compound.

1. The classical version

a. Reactions of hydrophosphoryl compounds

The scope of the Kabachnik–Fields reaction and its applicability to various types of hydrophosphoryl compounds, aldehydes and ketones, and secondary amines and ammonia outlined in the early studies satisfied to a certain extent the needs for the synthesis of AP with rather simple structures. The results of these studies are covered in reviews.^{6, 12} The scope of compounds that are being used in this reaction has now expanded appreciably.

First, this refers to the synthesis of AP containing heterocyclic substituents at the C- and N-centres.

Pyridine, pyrrole and imidazole derivatives were synthesised by a one-pot procedure using diethyl phosphite and benzhydrylamine.¹⁴⁰ In the presence of hydrochloric acid, the benzhydryl protective group is removed and the process goes through condensation and hydrolysis to give the corresponding α -amino-hetarylmethylphosphonic acids.

The reaction of heterocyclic aldehydes with benzylamine and dibenzyl phosphite occurs at elevated temperature and results in *O,O,N*-tribenzyl phosphonates. Consecutive addition of the amine and the phosphite to the aromatic aldehyde assumes the initial formation of a Schiff's base.¹⁴⁰

The alkaloid cytosine reacts with aliphatic and aromatic aldehydes and dimethyl phosphite under mild conditions in the presence of catalytic amounts of crown ethers to give the corresponding AP.¹⁴⁵ On refluxing in benzene, amino phosphonate derivatives of cytosine form internal salts.

R	Pr ⁱ	Ph	4-MeOC ₆ H ₄
Yield (%)	78	80	90

It should be noted that dealkylation involving the dimethoxyphosphoryl group can complicate the Kabachnik–Fields reaction, especially if weakly reactive aromatic aldehydes, that are most susceptible to this process, are used.¹⁴⁶

Phosphorylmethyl derivatives of aminotetrazoles are readily formed in the reaction with dibutyl phosphite and *p*-fluorobenzaldehyde.

R = H (**a**), NH₂ (**b**); R' = (BuO)₂P(O)CH(C₆H₄F-*p*)NH.

5-Aminotetrazole (**35a**) reacts with dibutyl phosphite on the amino group at position 5 to give compound **36**, whereas in 1,5-diaminotetrazole (**35b**) it is the amino group at the nitrogen atom that undergoes phosphorylation. Taking into account the tendency of 1,5-diaminotetrazole (**35b**) to form Schiff's bases, the 'imine' pathway of the reaction resulting in the AP **37** seems to be preferential.¹⁴⁷

In a search for biologically active AP, aminomethyl-diphenylphosphine oxides¹⁴⁸ as well as bisphosphonate derivatives of tetrahydropyran, its thio and seleno analogues¹⁴⁹ have been synthesised recently.

R¹ = H; R² = CH₂Ph, (CH₂)₂Ph, 2-pyridyl; R¹ = R² = CH₂Ph.

The use of appropriate bifunctional amines in the Kabachnik–Fields reaction allows the synthesis of heterocyclic compounds. For example, chiral phosphorylated oxazolidine is formed in a one-pot procedure from (*R*)-(-)-phenylglycinol, formaldehyde and dimethyl phosphite in boiling methanol.¹⁵⁰

Heterocyclisation was successfully used in the synthesis of 3-amino-2-oxo-1,2-oxaphosphacyclanes.¹⁵¹ A one-pot synthesis of AP **38** from 4-benzyloxy-2-butanone, ammonia and diethyl phosphite followed by its hydrogenolysis results in alkanol **39**. Intramolecular transesterification of the latter gives the 1,2-oxaphospholane.

AP used in membrane extraction were obtained recently from calix[4]arene. Modified calix[4]arene platforms with (phosphorylalkyl)aminoalkyl fragments in the top and bottom rings were prepared from dialkyl phosphites and the appropriate carbonyl compounds.^{60, 64}

Regiospecific amination of calix[4]arene gave compound **40**, and in the 'top' rim of its platform two phosphorylalkyl groups were introduced.

The amino phosphonate fragments in the 'bottom' rim were obtained using a calix[4]arene platform carrying β-aminoethoxy groups.

Four amino phosphonate groups were introduced in a similar way using a tetrakis(aminomethyl) derivative of calix[4]arene. As a result of the reaction, all phosphorus-containing fragments were located in the 'top' rim.

Modification of calix[4]arene with diethyl *N*-benzylamino-methylphosphonate gave a tetrasubstitution product in the 'partial cone' conformation.

$\text{R} = \text{CH}_2\text{Ph}$.

Orthoformate was successfully used instead of carbonyl compounds in the classical version of the Kabachnik–Fields reaction. In this case, two phosphoryl groups rather than one can be attached to the carbon atom. Condensation of dibenzylamine and diethyl phosphite with orthoformate (1 : 3 : 1.2, refluxing for 24 h) gives dibenzylaminomethylenediphosphonate (yield 58%).¹⁵²

The reaction of benzylamine with one equivalent of $\text{HC}(\text{OEt})_3$ and four equivalents of diethyl phosphite at 160°C with subsequent acidification of the reaction mixture gave diaminomethylphosphonate $(\text{PhCH}_2\text{NH})_2\text{CHP}(\text{O})(\text{OEt})_2$ in 34% yield.¹⁵²

This version of the reaction makes it possible to introduce organophosphorus groups of different structures into an AP during one chemical process. For example, a phosphite and a phosphonite participate in a one-pot synthesis of phosphonato-phosphinate **41**.¹⁵³

(a) Δ ($-\text{EtOH}$); (b) H_2O , Δ ($-\text{R}^3\text{OH}$); $\text{R}^1 = \text{H}, \text{Me}$; $\text{R}^2 = \text{Me}, \text{Bu}$;

$\text{R}^3 = \text{Et}, \text{Pr}^i$.

The drawback of this method is that it gives, along with asymmetrical phosphonato-phosphinates, a small amount of symmetrical bisphosphonates and bisphosphinates. This can be avoided if phosphorus-containing groups are introduced successively. For example, α -phosphonoacetal, alkylphosphonite and aminopyridines react under these conditions to give compound **41** exclusively.

The scope of the classical version of the Kabachnik–Fields reaction is expanded if carbamates, amides of carboxylic and phosphorus acids and some other compounds are used as the amine component.

Benzyl carbamate, an aliphatic or aromatic aldehyde and diethyl phosphite react at room temperature in the presence of a mixture of acetic acid and thionyl chloride [method (a)] or acetyl chloride [method (b)] to give moderate to high yields of AP containing an *N*-benzyloxycarbonyl group, which can easily be removed if necessary.¹⁵⁴

(a) AcOH , SOCl_2 , 20°C , 20 min, Δ , 2–12 h;

(b) AcCl , 0–5 $\rightarrow$ 20°C (43%–98%).

A modification of this method was suggested for the Kabachnik–Fields reaction with α -halocarboxamides.¹⁵⁵ Their condensation with aromatic aldehydes and hydrophosphoryl compounds occurs in the presence of an alcoholic solution of HCl or *p*-toluenesulfonic acid in acetic anhydride.

The diastereoselectivity of condensation of chiral cyclic carbamates and ureas according to the scheme of the Kabachnik–Fields reaction depends largely on the nature of the cyclic compound. The highest diastereomeric excess (*de*) in the one-pot synthesis of AP from diethyl phosphite, benzaldehyde and compounds **42**–**44a–c** containing an amino group is reached for derivatives of camphorsulfonic acid **44a–c**.¹⁵⁶

R = N(cyclo-C₆H₁₁)₂ (**a**), NPr₂ⁱ (**b**), C₆H₄OMe-4 (**c**).

Starting compound	42	43	44a	44b	44c
Yield of AP (%)	71	84	75	73	77
de (%)	14.4	34.1	99	96.4	96.2

If benzaldehyde is replaced by other aldehydes (anisaldehyde, α -naphthaldehyde or *p*-tolualdehyde) in the reaction with carbamates **44**, the *de* remains at about 99%. The *de* is small (56%) only in the case of cyclohexanecarbaldehyde.

It is noteworthy that both hydrophosphoryl compounds and their salts can participate in this condensation.¹⁵⁷

R² = H, Me, Et, Buⁱ, Ph, *p*-MeOC₆H₄.

The AP **45** obtained this way were used as synthons in the development of a new approach to the synthesis of functionalised indoles.¹⁵⁸ The reaction between diphenyl phosphite, benzyl carbamate and *p*-nitrobenzaldehyde in acetic acid results in the AP **46**.

Dephosphonylation of amino phosphonate **46** by the Horner–Wittig–Emmons reaction with *o*-nitrobenzaldehyde gives the enamine **47**, which is converted in two steps to the C-substituted indole **48**. The use of α -aminophosphine oxide

provides a convenient method for the synthesis of thio- and selenoamides.¹⁵⁹ In this reaction, generation of a carbanion is followed by cleavage of the P–C bond under the action of two equivalents of sulfur or selenium.

R¹, R² = Me, Ph, (CH₂)₂O(CH₂)₂; R³ = H, Alk, alkenyl; X = S, Se.

The use of acetyl chloride as the condensation agent makes it possible to introduce an organophosphorus radical to the amine centre of AP if *O,O'*-diethyl phosphoramidite is used as the amine component.¹⁶⁰

R = Pr, Prⁱ, Ph, *p*-MeC₆H₄, *p*-MeOC₆H₄, *p*-Me₂NC₆H₄.

b. Reaction of inorganic phosphorus acids

This version of the Kabachnik–Fields reaction is also named¹⁶¹ the Moedritzer–Irani reaction in the name of the researchers who were the first to use inorganic phosphorus acids of the lowest oxidation state for the synthesis of APA in a three-component system 'hydrophosphoryl compound–carbonyl compound–amine'.⁷¹

Reaction of orthophosphorous acid with formaldehyde is known to occur almost quantitatively. Since both primary and secondary amines can be involved, the Mannich reaction mechanism is considered most probable for these reactions,⁷¹ although other mechanisms are not ruled out either.

Attempts at expanding this version of the Kabachnik–Fields reaction to aliphatic aldehydes and ketones failed.¹⁶² The 'imine' version of the reaction is preferable for these compounds (see below).

Acylamides readily undergo condensation with aldehydes and phosphorous acid under the action of acetic anhydride.¹⁶³

R = Me, Prⁱ, Ph, 3-NO₂C₆H₄, 4-ClC₆H₄, 4-MeC₆H₄;

R' = PhCOO, PhCO, Ac.

Presumably, the condensation of an aldehyde with an amide is followed by decomposition of the condensation product to APA **49**.¹⁶³

The reaction of 1,2-cyclohexanediamine **50** with formaldehyde and phosphorous acid occurs in a low yield.¹⁶¹ The yield of tetraphosphonate **51** increases considerably if 1,2-cyclohexanediaminotetraacetic acid is phosphorylated with a mixture of H₃PO₄ and PCl₃.

The reaction of 1,2-cyclohexanediamine **50** with formaldehyde and diethyl phosphite results in a bicyclic bisphosphonate.¹⁶¹

Hypophosphorous acid in a mixture with formaldehyde undergoes polymer-analogous Kabachnik–Fields reaction with polycaprolactam. This method has been used for the synthesis of materials with low flammability.¹⁶⁴

Salts of hypophosphorous acid with (*R*)-(+)- or (*S*)-(–)-1-phenylethylamine react with aldehydes in boiling ethanol to form homochiral APA.¹⁶⁵ The protective group at the nitrogen atom is easily removed by a standard method, and the intermediate phosphonous acid is converted into the APA.

$\text{R} = \text{Pr}^i, \text{Bu}^i, \text{cyclo-C}_6\text{H}_{11}, \text{Ph}, \text{PhCH}_2.$

Recently, an efficient method for the synthesis of AP has been developed in which 80%–90% aqueous solutions of hypophosphorous acid is used as the hydrophosphoryl compound. In this case, orthoesters and acetals were used instead of carbonyl compounds, and 1,3,5-tribenzylhexahydro-1,3,5-triazine **52** was chosen as the amine component.

The reaction of triazine **52** with triethyl orthoacetate and H_3PO_3 gives an amino phosphinate under very mild conditions and in high yield.¹⁶⁶

A three-step synthesis of a phosphinate containing both an α -hydroxy and an α -amino group in different *P*-alkyl substituents simultaneously¹⁶⁷ involves the initial formation of a phosphonite from 2,2-dimethoxypropane and hypophosphorous acid, its subsequent transesterification to the more hydrolytically stable isobutyl phosphonite **53** and the reaction of the latter with triazine **52** to give the AP.

In these cases, commercial 50% hypophosphorous acid can be used following its concentration *in vacuo*. The efficiency of this approach in comparison with the methods based on the use of anhydrous H_3PO_2 is noteworthy (see Ref. 166 and references cited therein).

2. Reactions of trivalent phosphorus chlorides

This version of the Kabachnik–Fields reaction based on phosphorus trichloride was used in the synthesis of APA in 1978.¹⁶⁸

The method is equally applicable to alkyl(aryl)dichloro- and dialkyl(aryl)chloro-phosphines.^{169, 170} It is considered¹⁷⁰ that the process starts with condensation of an amide with a carbonyl compound. The alkylidenebisamide **54** thus formed is phosphorylated to AP **55**, hydrolysis of which results in an APA.

The method was expanded to a wide set of amides, carbonyl compounds and P(III) chlorides (see Ref. 171 and references cited therein). Another interpretation of aminomethylation of P(III) chlorides is considered in detail in Ref. 171.

The method based on the use of PCl_3 was applied successfully to the synthesis of α -aminoarylalkylphosphonic acid³⁶ and its monoesters,¹⁷² as well as a large number of APA containing fluorinated aryl substituents.¹⁷³ Aminomethylol synthons¹⁷⁴ or hexahydrotriazine derivatives were also used as aminoalkylating agents.^{174, 175} The latter compounds have repeatedly been used in the synthesis of AP. *N,N,N*-Tribenzylhexahydrotriazine is reversibly formed in the condensation of formaldehyde with *O*-benzylhydroxylamine and undergoes conversion to *O*-benzylformaldoxime on gentle heating, which reacts with P(III) chlorides in acidic medium to give the corresponding APA.¹⁷⁵

The mechanism of aminomethylation of P(III) chlorides is rather complex. It can be different in each particular case. For instance, in the system 'benzyl carbamate–aromatic aldehyde–phenyldichlorophosphine–acyl chloride',¹⁷⁶ the addition of the amide to the aldehyde occurs first, and then acylation of the resulting acylaminoalkanol produces compound **56**.

The reaction of the acylated carbamate **56** with the starting amide gives the diamide **57**. The acetic acid evolved converts phenyldichlorophosphine into phenylphosphinic chloride. The latter cleaves the N–C bond in diamide **57** and converts it into the final amidomethylphosphinic chloride **58**.

A similar reaction of aryldichlorophosphines, aromatic aldehydes and 5-amino-1,2,4-triazole occurs in the presence of cation-exchange resins (D-72, Amberlyst-15) and results in 6-phospha-4,5,6-trihydroimidazo[2,3-*e*]-1,2,4-triazole. It is believed¹⁷⁷ that the Schiff's base is formed first and then adds aryphosphinic chloride.

Intramolecular dehydrochlorination of the addition product results in the final bicycloamidophosphinate.

3. Reactions of neutral phosphites and their analogues

Reactions of natural α -amino acids with trialkyl and triaryl phosphites have long and successfully been used in peptide synthesis. As a rule, the non-classical Arbuzov reaction occurs in this case (see, *e.g.*, Ref. 178).

A three-component system 'phosphite–carbonyl compound–amine' was successfully used in a number of syntheses of AP derivatives of urea and thiourea.

Triethyl phosphite undergoes condensation with an aldehyde and phenylurea in the presence of boron trifluoride etherate on refluxing in toluene to give the corresponding AP.¹⁷⁹

A similar reaction of a thiourea¹⁸⁰ and *N*-substituted thioureas¹⁸¹ occurs with triphenyl phosphite in the presence of glacial acetic acid. Under certain conditions, both amino groups of thiourea can be involved in this reaction.

The stereochemistry of condensation of chiral carbamates and thioureas with benzaldehyde or aliphatic aldehydes and triaryl phosphites in the presence of acetic acid depends on the chirality of the starting amine: (+)-AP are obtained from chiral (+)-carbamates and ureas; accordingly, (–)-AP are formed from (–)-amides.¹⁸² The reaction occurs *via* an immonium salt with subsequent *syn*- or *anti*-attack of the phosphite on the iminium carbon atom.

Ar = Ph, 2-MeC₆H₄.

The 'triphenyl phosphite' version of the Kabachnik–Fields reaction was successfully used for the synthesis of C-hetaryl derivatives of AP.^{183–185}

The mechanism of these reactions has not been discussed in detail. However, in this case the reaction begins most probably with the interaction of the aldehyde with the amino component. The smooth reaction of phosphinites and phosphonites with chloralurea¹⁸⁶ can probably serve as a model of the second step of the 'trialkyl phosphite' version of the Kabachnik–Fields reaction.

As in the classical version of the Kabachnik–Fields reaction, in this case it is possible under certain conditions to carry out cyclisation by the one-pot technique, for example, in the *N*-phosphonoalkylation of (*R*)-(–)-phenylglycinol;^{187, 188} in the latter case glutaraldehyde replaces formaldehyde in a three-component mixture.¹⁸⁸

The reaction can also be carried out stepwise.¹⁸⁷ For example, *N*-benzylphenylglycinol reacts with an aldehyde to form oxazolidine with high diastereomeric excess. The latter reacts with

trimethyl phosphite in the presence of SnCl_4 to give an oxazaphosphorinane.

Polydentate ligands, *viz.*, bisphosphinate triaminocyclohexanes, were obtained by the ‘phosphonite’ version of the Kabachnik–Fields reaction with diethyl methylphosphonite and paraform.¹⁸⁹

It is possible to introduce two phosphorylmethylene groups into a 1,3,5-triamino-2,4,6-trimethylcyclohexane molecule due to the fact that all of its methyl groups occupy the equatorial positions, while all amino groups occupy the axial ones.

4. Reactions in two-component systems

As discussed above, reactions in two-component systems resulting in APA and their esters and involving interactions in the pairs hydrophosphoryl compound–imine and hydroxy phosphonate–amine are, in essence, separate steps of the Kabachnik–Fields reaction. It is often impossible to distinguish between three- and two-component systems. This can depend on the order of mixing the reactants.

On the other hand, it has repeatedly been noted that it is often preferable to carry the reaction out in a stepwise way rather than to use a one-pot three-component process: the chemical yield and *de* of the AP are generally higher in two-component processes. The methods that have been developed most extensively recently include enantioselective addition of hydrophosphoryl compounds to imines and replacement of the hydroxy group in hydroxy phosphonates by the amino group under the Mitsunobu reaction conditions.¹⁹⁰ We shall give these processes the most attention in our review.

a. Addition of hydrophosphoryl compounds to imines

The addition of hydrophosphoryl compounds to imines, discovered simultaneously with the Kabachnik–Fields reaction, corresponds to the Pudovik reaction type²⁰ and has been covered rather comprehensively in reviews.^{6,10} Some examples of asymmetric synthesis of AP in the ‘imine’ version are discussed in another review.¹⁸ However, many new studies have been published in recent years which are to some extent relevant to the problem under discussion. Important data on the mechanism of the ‘imine’ method and the catalytic effects observed have been obtained.

The ‘imine’ method should be preferred when choosing the strategy for the synthesis of AP if it is necessary, first, to reach the maximum diversity of functional groups at the N and C atoms in the target AP and, second, to enable conditions for the maximum stereoselectivity of addition of hydrophosphoryl compounds to the $\text{C}=\text{N}$ bond.

The reaction of hydrophosphoryl compounds with the Schiff’s bases studied in detail by Pudovik²⁰ continues to draw the attention of researchers due to the simplicity of the procedure and useful properties of the AP obtained in this way.

The reaction occurs in a condensed phase or in a solution in the presence of acidic and basic catalysts or without them at all, sometimes upon simple mixing of the reagents.^{191,192}

The reaction of hydrophosphoryl compounds with the Schiff’s bases containing fluorine atoms in the *N*- and/or *C*-aryl fragments ($\text{Ar} = 2\text{-}, 3\text{-}, 4\text{-FC}_6\text{H}_4$; $2\text{-}, 3\text{-}, 4\text{-F}_3\text{CC}_6\text{H}_4$; $2\text{-}, 4\text{-F}_3\text{CCOC}_6\text{H}_4$; $3,4\text{-F}_2\text{C}_6\text{H}_3$ and others)^{193–195} allows one to obtain biologically active fluorinated AP. The reaction occurs on heating of the starting reagents to 90–110 °C without a catalyst. *N*-Pentafluorophenylaldimines add dimethyl phosphite even more readily.¹⁹⁶

Aryl-substituted AP are formed as a mixture of diastereomers (chiral α -carbon atom). The presence of each of the stereoisomers is confirmed by analysis of ^1H and ^{13}C NMR spectra. In some cases, these diastereomers could be separated by column chromatography.

Bisamino phosphonates of various structures were synthesised by addition of hydrophosphoryl compounds to bisimines.^{192–195}

The NMR and mass spectroscopic, as well as other characteristics of bisamino phosphonates have been studied.^{197–199}

Numerous *N*-substituted AP derivatives, mainly *N*-benzyl ones, were obtained for use in peptide synthesis. The addition of hydrophosphoryl compounds to *N*-benzylbenzylideneimines occurs very readily. Lower dialkyl phosphites react at room temperature to give the corresponding AP in very high yields.^{36,200,201}

Longer reaction time and higher temperature are needed with the lengthening of the alkyl chain in the hydrophosphoryl compound (R'). For example, at $\text{R} = n\text{-C}_5\text{H}_{11}$, the reaction at 80 °C takes 8 h or longer. A similar effect is caused by replacement of the *C*-aryl group by C_6F_5 (however, there are exceptions: see Ref. 196).

N-Protected alkylideneimines,²⁰² perfluoroisopropylidene-*N*-acylimine,²⁰³ *N*-tritylmethylenimine,⁷⁵ and many other compounds (see the review¹⁸ and references cited therein) also add hydrophosphoryl compounds rather easily, usually on heating in the absence of catalysts, giving AP in high yields.

The ‘imine’ method is widely used in the synthesis of hetaryl derivatives of AP. In this case, the structures of heterocyclic

fragments can be varied widely. An array of *C*-pyridine derivatives have been obtained by addition of diethyl phosphite *in situ* to the appropriate Schiff's bases.²⁰⁴ 1-, 2- and 3-formylpyridines readily react with amines in a toluene solution, forming the corresponding aldimines, which are hydrophosphorylated in a one-pot procedure.

R = Bu, Ph, CH₂Ph, CHPh₂.

One-step syntheses of 1-(2-aminoethyl)pyridyl-1-arylmethylphosphonates²⁰⁵ and analogous APA monoesters were carried out in a similar way.²⁰⁶ It is noteworthy that the addition of dialkyl phosphites to the Schiff's bases containing a pyridine fragment under mild conditions (at room temperature, in the absence of catalysts) has been reported.²⁰⁷

The results obtained in a study of the reaction of hydrophosphoryl compounds with imines containing furan and thiophene rings are also worth noting. 5-Hydroxymethylfurfural readily reacts with ethyl- and benzylamines to give the corresponding aldimines.

R = CH₂Ph, CH₂-furan, Bu^t, (*R*)- and (*S*)-CHMePh; R' = Et, CH₂Ph.

Subsequent addition of diethyl phosphite gives (in the case of chiral amines) a diastereomeric mixture of AP in 2:1 ratio.²⁰⁸ When pure enantiomeric amines are used, the resulting imines react with dibenzyl phosphite to give a mixture of AP, from which individual stereoisomers can be isolated by chromatography.

The same scheme was used for the synthesis of (2-furyl)aminomethylphosphonic acid.²⁰⁹

R = CH₂Ph, CPh₃; R' = Et, CH₂Ph.

N-Benzylated imines add hydrogen phosphites in toluene without catalyst or in acetonitrile with a catalytic amount of CF₃COOH. *N*-Tritylated imines give an AP just upon mixing the reagents. It was reported that an attempt at detritylation of an AP resulted in destruction of the AP with cleavage of the P–C bond. Similar fragmentation of AP has also been observed in other cases.^{203, 204, 210}

Bis(amino phosphonates) containing terminal 2-furyl groups were obtained and used as monomers for the synthesis of polymeric materials with low flammability.^{211, 212}

The addition of the hydrophosphoryl compound occurs at room temperature in the presence of catalytic amounts of sodium alkoxide.

Important observations related to the activation of addition of dialkyl phosphites to hetarylimines with an *N*-thiophene or *N*-pyrrole fragment were obtained.^{213, 214} The addition of a hydrophosphoryl compound can occur on prolonged heating (72–96 h) of a mixture of the reactants at 60 °C. The process is accompanied by formation of side products. Attempts to optimise conditions of the synthesis of AP by carrying out the reaction in various solvents failed in general: this only increased the time of conversion.

On the other hand, sonochemical (ultrasonic) activation of the addition reaction was found to be rather efficient. Both in a condensed phase and in a solution, even short sonication increases abruptly the temperature of the reaction mixture, hence the yield of AP increases and the reaction time is decreased to 5–120 min. This phenomenon was explained²¹³ using EPR spectroscopy with a spin trap: phosphinyl radicals were detected during sonochemical activation.

The uninitiated reaction occurs by a concerted mechanism with a four- or five-centred transition state. This mechanism agrees with the stereochemical result of addition to furfuraldimine.²⁰⁸

A method for the introduction of heterocyclic fragments into an AP molecule by addition of a hydrophosphoryl compound to the endocyclic C=N bond in unsaturated five- and six-membered cyclic imines was developed. In these cases, the amino phosphonate fragment C–N is included in the heterocycle. Chiral 2*H*-5,6-dihydro-1,3-thiazines react with dialkyl phosphites to give diastereomeric AP in a ratio from 52:48 to 88:12, depending on the substituents in the imine and in the phosphite.²¹⁵

R¹ = H, Me, Et; R² = Me, Et, Bu^t, CMe₂CH₂Cl;

R¹, R² = (CH₂)₄, (CH₂)₅; R³ = Me, Et.

The addition of hydrophosphoryl compounds to 2*H*-1,4-benzothiazines and 2*H*-1,3-oxazolidines occurs under the same conditions.¹⁰⁰

Hydrophosphorylation of cyclic imines catalysed by chiral lanthanide catalysts results in a high *de* (up to 98%).²¹⁶ In the presence of chiral titanium catalyst, the reaction is nonstereospecific. The mechanism of asymmetric induction of cyclic imines has not been discussed.

Hydrophosphorylation of oximinium salts, which is a version of the ‘imine’ method for AP synthesis, has been performed in only a few cases. In our opinion, this is rather a promising method. The addition of diphenyl phosphite to the C=N⁺ bond of a nitron is carried out in the presence of an alkylating agent, *viz.*, triethyloxonium tetrafluoroborate, at room temperature in 3 h.²¹⁷ The processes is nonstereospecific; however, rather high enantioselectivity is observed for chiral nitrones [R¹ = CH(Me)Ph].

R¹ = Me, CH(Me)Ph; R² = Ph, MeOC₆H₄; R¹, R² = (CH₂)₃.

The addition of alkyl phosphinites to phosphonyliminium salt **59** also occurs nonstereospecifically.²¹⁸ In this case, two chiral centres are induced in the AP, *viz.*, the α-carbon atom and the phosphinate phosphorus atom.

R¹ = Me, Ph; R² = Et, Bu.

Broad diversity of possibilities for the synthesis of AP by the ‘imine’ pathway is due to the variability of the substituents not only in the imine but also in the phosphorus-containing addend. Inorganic phosphorus acids and various silylated organophosphorus compounds have been used for the synthesis of APA.

It has already been noted¹⁶² that attempts to use phosphorous acid in the classical three-component version of the Kabachnik–Fields reaction was not always successful. The ‘imine’ method turned out to be more efficient.¹⁶²

R¹ = Me, Et, Bu^t, PhCH₂; R² = Prⁱ, Ph, 4-ClC₆H₄, 2-HOC₆H₄.

The addition to the intracyclic bond of 3,4-dihydroisoquinoline, resulting in 1,2,3,4-tetrahydroisoquinoline-1-phosphonic acid, occurs successfully.¹⁶² It is believed that the reaction occurs in an autocatalytic mode with preliminary protonation of the nitrogen atom.

Under certain conditions, phosphorous acid can be a reducing agent with respect to an imine. In this case, it is not the AP that is formed as the final product but rather an isomeric amido phosphate, which is believed¹⁶² to result from the reaction of the intermediate amine with metaphosphoric acid.

The phosphorus analogue of histidine **62** was obtained by the addition of hypophosphorous acid to the oxime **60**. The phosphinic acid **61** obtained in 19% yield was transformed in an almost quantitative yield into the target product **62** by oxidation with sulfonyl chloride in glacial acetic acid.²¹⁹

The addition of inorganic phosphorus acids to both C=N bonds of bisimines was carried out. The reaction of geminal diimine **63** with hypophosphorous acid²²⁰ gives, contrary to expectations, bisphosphinic acid **64** rather than a cyclic phosphonic acid.

A similar reaction of diimine **65**, which is carried out by prolonged storage of the reaction mixture (20 °C, 20–25 days), gives a five-membered cyclic phosphinic acid **66**²²¹ and a linear product **67** formed due to addition to one of the C=N bonds.

It is of note that the ratio of products **66**:**67** in a crystalline state is 1:4, whereas their ratio is 1:1 in dioxane solution, according to ³¹P NMR data.²²¹ The possibility of mutual transformation of compounds **66** and **67** during dissolution and isolation from the solution cannot be ruled out.

Silyl ethers of phosphorus acids of low oxidation states behave in reactions with imines similarly to phosphorous acid, its esters and other hydrophosphoryl compounds. For example, tris(silyl) phosphite in the presence of Lewis acids (ZnCl₂, BF₃·OEt₂) or strong protic acids (CF₃COOH, *p*-MeC₆H₄SO₃H) forms a product of phosphonosilylation of imines.²²² On refluxing in methanol, desilylation of the adduct occurs, resulting in the corresponding APA isolated as a hydrochloride.

For example, the substituents in the benzene ring weakly affect both the chemical yield and the *de* in the reaction of imines obtained from 1-phenylethylamine and *para*-substituted benzaldehydes with dialkyl phosphites²³⁴ (Scheme 5).

Scheme 5

X	H	Me	OMe	Cl	Br	F
Yield of 70 (%)	80	84	72	79	77	80
<i>de</i> (%)	61	54	60	56	54	56

R	Me	Et	Pr ⁱ	Bu ⁿ	Bu ⁱ	Ph
Yield of 70 (%)	85	85	61	74	72	78
<i>de</i> (%)	43	61	83	68	71	80

Catalyst	AlCl_3	$\text{BF}_3 \cdot \text{OEt}_2$	ZnCl_2	TsOH	—
Yield of 70 (%)	77	80	75	72	65
<i>de</i> (%)	70	61	−30	−50	−16

The increase in the volume of substituents at the phosphorus atom decreases the chemical yield but increases the *de*. The yield and *de* are considerably affected by catalysts used for this purpose, such as Lewis acids. A negative *de* upon changing the catalyst means the predominance of the other enantiomer, *i.e.*, the change in the direction of stereoinduction.

In the general case, a pronounced effect of catalysis is observed: the degree of conversion increases in comparison with non-catalysed addition. However, a catalyst basically affects the ease of the reaction. A catalysed process occurs at room temperature, while a non-catalysed one requires heating of the reaction mixture to 140 °C. The different effect of AlCl_3 and BF_3 on *de*, on the one hand, and ZnCl_2 and TsOH , on the other, is explained²³⁴ by the different character of the donor-acceptor interaction between the imine and the catalyst. Whereas Lewis acids form A-type chelate complexes due to the transfer of *n*- and π -electron density to the vacant orbitals of the central atom with *s-cis*-arrangement of the C=N fragment and aryl substituent, ZnCl_2 and TsOH interact only with the imine nitrogen atom, causing a P-nucleophile to attack an imine in conformation B.

The effect of catalysts⁷² and of the way of the phosphite anion generation²³⁵ on the stereochemistry of the hydrophosphorylation of imines containing a complementary functional group that can provide chelation has been studied in detail. The imine **71** adds diethyl phosphite without a catalyst in 120 h. In the presence of Lewis acids or CF_3COOH , the reaction occurs faster. In all cases, a mixture of diastereomers **72a** and **72b** with low *de* is formed.

R = cyclo- C_6H_{11} .

Catalyst	Time /h	Yield (%)	<i>de</i> (%)
—	> 120	87	38
ZnCl_2	7	84	48
MgCl_2	> 48	40	38
CF_3COOH	> 48	48	14

It is believed that the stereocontrolling role of Lewis acids consists in the formation of chelates. However, this effect appears to be insufficient to ensure high diastereoselectivity of the hydrophosphorylation step.

At the same time, high diastereoselectivity is reached if lithium diethyl phosphite is used.

R = cyclo- C_6H_{11} .

Conditions	Yield (%)	<i>de</i> (%)
$(\text{EtO})_2\text{PHO}$, Bu^iOLi , CH_2Cl_2 , −70 to 25 °C	38	94
$(\text{EtO})_2\text{PHO}$, BuLi , THF, −78 to 25 °C	75–80	94–96

The chelate structure of the intermediate with *trans*-arrangement of the nucleophile and the stereo-controlling phenyl group is responsible for this impressive stereochemical result. The yield of the adduct depends on the reaction conditions and the method of generation of the phosphite anion. The best result was achieved using butyllithium as the base.

The stereochemically individual imine **73** obtained by the condensation of the appropriate amine with cyclohexanecarbaldehyde adds lithium diethyl phosphite to give the *R,R*-isomer of an *N*-protected AP with *de* > 95%.²³⁶

R = cyclo- C_6H_{11} .

Scheme 6

The reaction of the same aldehyde with diethyl phosphite and (*S*)- α -phenylethylamine is less stereospecific: a mixture of diastereomeric AP (ratio *S,S*:*S,S* = 5:1) is formed (see Ref. 236).

R = cyclo- C_6H_{11} ;

(a) (*S*)- $\text{PhCH}(\text{Me})\text{NH}_2$, MeOH; (b) 3 HP(O)(OEt)_2 , 3 days, 25 °C.

High stereospecificity of reactions was achieved by addition of phosphites to bis-silylated imine **74** in the presence of lithium ions (Scheme 6).²³⁷ Enantiofacial preference of attack on the imine carbon by the P(III) atom is due to the formation of a highly-organised cyclic transition state **75** due to chelation by a Li^+ ion. The addition of dialkyl phosphites to the imine **74** catalysed by BF_3 is not accompanied by formation of a cyclic transition state and/or intermediate. In this case, the attack by a phosphite in acyclic complex **76** can occur on the two sides with equal probability. This causes the formation of a diastereomeric mixture of products.

The absence of stereoselectivity was also noted in the case of boron trifluoride-catalysed addition of chiral cyclic diamidophosphite **77** to imines.²³⁸ The reaction occurs under very mild conditions; it is also possible to use TiCl_4 as the catalyst, while SnCl_4 chlorinates the cyclophosphite to the corresponding chlorophosphate.

Catalytic asymmetric synthesis of AP with the use of a wide range of imines and dimethyl phosphite was carried out in the presence of an asymmetric lanthanide-based catalyst.³³

$\text{R}^1 = \text{Me}, \text{Et}, \text{Pr}^i, \text{PhCHMe}, n\text{-C}_5\text{H}_{11}, \text{cyclo-C}_6\text{H}_{11}$;

$\text{R}^2 = \text{Tr}, \text{CHPh}_2, 4\text{-MeOC}_6\text{H}_4$.

The reaction occurs with excess of a hydrophosphoryl compound in THF at room temperature or on gentle heating (50–60 °C). A chelate heterobimetallic complex involving a lanthanide, the chelating ligand BINOL³³ and potassium ions (potassium carbonate) is used as the catalyst. The catalytic cycle is presented in Scheme 7.

The first step of the process is deprotonation of the phosphite and generation of potassium dimethyl phosphite, which is coordinated by the lanthanide with formation of the complex **78**; the latter reacts with the imine to give the optically active K salt of AP **79**. Replacement of the K^+ ion by a proton at the amine centre results in the complex **80**. In the final step, the product of catalytic asymmetric synthesis **81** is liberated from the coordination sphere. In this process, the lanthanum complex acts as a polyfunctional asymmetric catalyst of AP synthesis with high *de* (96%). A drawback of the method is the rather small number of catalytic cycles. This is probably due to the too high acceptor ability of the lanthanum complex with respect to AP.

b. Reaction of hydroxy phosphonates with amines

As noted above, the reaction of hydroxy phosphonates with amines is a model of the 'hydroxy phosphonate' pathway of the Kabachnik–Fields reaction. It has been studied in much more detail than the alternative 'imine' route, *i.e.*, hydrophosphorylation of imines. Relatively little convincing evidence has been obtained that the Kabachnik–Fields reaction occurs through the step of formation of α -hydroxyalkylphosphoryl intermediates. Moreover, as already mentioned, in certain cases the formation of hydroxy phosphonates is undesired for successful use of the Kabachnik–Fields reaction for preparative purposes.

Nevertheless, there are many examples of transformation of hydroxyalkylphosphoryl synthons to the corresponding aminoalkylphosphoryl products by the reaction of hydroxy phosphonates with amines (see Refs 13 and 122 and references cited therein). In recent years, conditions for carrying out this process in a preparative and stereocontrolled way have been found.

The condensation under the action of the azodicarboxylate–triorganylphosphine system (the Mitsunobu reaction¹⁹⁰) has found use for replacement of the hydroxy group by the amino group in a one-pot procedure.^{239–242} Hydroxy phosphonates and phosphine oxides obtained by the Abramov reaction from the appropriate hydrophosphoryl and carbonyl compounds by treatment with the Mitsunobu reagent **82** and HN₃ are converted with inversion of the configuration to α -azido phosphonate **83**. The reaction of triphenylphosphine with phosphonate **83** by the Staudinger reaction results in phosphimine intermediate **84**. The latter is hydrolysed to the target AP.

In the one-pot procedure, the intermediate azide and phosphimine are not isolated. Since the Mitsunobu reaction with secondary alcohols, including the above hydroxy phosphonates, occurs stereospecifically by the S_N2 mechanism, the formation of the azido phosphate involves inversion of configuration of the α -carbon atom. Subsequent phosphimination and hydrolysis do not involve this centre.

The Mitsunobu reaction described here, which enables conversion of hydroxy phosphonates to the corresponding azides, has been used²⁴³ for the stereoselective conversion of monosilylated α,β -dihydroxy phosphonates. Optically active silyloxy phosphonates result from the reaction of *threo*- α,β -dihydroxy phosphonates with chlorosilane in the presence of bases.

Depending on the nature of the substituents R and R' and the base used, the ratio of β - and α -silylated products **85** : **86** is from 1 : 1 to 99 : 1. Most often, the regioisomer **85** predominates ($>90\%$). Its amination²³⁹ involves exclusively the carbon atom carrying the hydroxy rather than the silyloxy group and is accompanied by inversion of configuration.

$Ar = 4-MeOC_6H_4$, TBDMS = Bu^tMe_2Si .

The Mitsunobu reaction is used in the synthesis of potential haptens, *viz.*, *N*-hydroxy- α -amino phosphonates, for the condensation of hydroxy phosphonates with *N*-phenoxycarbonyl-*O*-*tert*-butoxycarbonylhydroxylamine.²⁴⁴

As a rule, the reaction goes only in one direction, *viz.*, with the formation of AP (40%–75%). α -Hydroxy-2-phenylethylphosphonate is an exception, it undergoes intramolecular (rather

than intermolecular) dehydration to give 62% of styrylphosphonate $PhCH=CHP(O)(OCH_2Ph)_2$.

V. Conclusion

Despite the impressive progress in the synthesis and studies of properties of AP, not all the problems have been solved. The problem of stereocontrol in the 'imine' method for the synthesis of AP is still urgent, to say nothing about the enantioselective synthesis using a three-component system in the one-pot version. It is easy to predict that the basic efforts in studying the AP chemistry will be concentrated in this direction, and the Kabachnik–Fields reaction is promising for solving these problems.

The prospects of chemical modification of AP with introduction of new, more and more complex groups, including those with definite configurations, to C-, N- and especially P-centres are far from exhausted.

This aspect of AP chemistry is closely related to the problem of the effect of phosphorus-containing groups on the adjacent reaction centre.^{96,97} The attention to α -functionalised organophosphorus compounds has increased abruptly in recent years. This is evident, for example, from recent publications on the chemistry of α -phosphorylated alcohols (α -hydroxy phosphonates),^{97,245} α -halogeno phosphonates,²⁴⁶ α -oxo phosphonates,²⁴⁷ and α -phosphonoalkyl phosphites.²⁴⁸ Reactions that occur at the α -carbon centre and formally do not involve the phosphorus atom are still largely controlled by the phosphorus-containing fragment. It not only determines the type and rate of the reaction but also, in some cases, changes the reaction rate by a few orders (see, for example, Ref. 249) and even changes the reaction mechanism.⁹⁷ A large number of studies deal with the problem of the quantitative estimation of the effect of phosphorus-containing groups (see Refs 250–252 and references cited therein). This problem still remains the focus of attention of experts in quantitative organic and organometallic chemistry.²⁵³ The quantitative estimation of the dependence of the reaction pathway both of AP and components of the Kabachnik–Fields reaction on the structure is an important problem which is waiting for solution.

One may believe that the area of the application of AP will be much expanded. In addition to the search for new biologically active compounds of high efficiency among APA, their derivatives and analogues, an abrupt growth of interest should be expected to the prospects of practical application related to their complex-forming properties. These applications may primarily include the use of AP as recognising agents (synthetic receptors) and chiral ligands in metal complexes, as well as selective highly-efficient complexones, extraction agents and analytical reagents.

Analysis of the data presented above allows one to consider the discussed area of chemistry as not only rather topical but also having wide prospects in the future.

VII. Conclusion	903

Abstract. The review is concerned with the electronic and molecular structure and physicochemical properties of all types of technetium clusters with acido ligands described to date. As a typical cluster-forming metal, technetium possesses a number of specific, anomalous cluster-forming properties that can be interpreted in terms of greater capability of outer diffuse $5s(5p)$ AOs to participate in the formation of additional M–M bonds in technetium acido clusters as compared to analogous clusters of other transition d -elements. Theoretical interpretation of the electronic and molecular structure and properties of technetium clusters has been confirmed by experimental data (X-ray analysis, magnetochemistry, and EPR, optical, X-ray photoelectron and X-ray emission spectroscopy). The experimentally observed increased stability of technetium clusters with odd numbers of ‘metallic’ electrons and a decrease in the effective charge on Tc atoms upon formation of the M–M bonds are discussed. Recently found ‘anomalous’ properties of technetium and rhenium compounds with ferrocenium cations (in particular, unusual low-temperature electron emission on X-ray irradiation) are also considered. The bibliography includes 101 references.

I. Introduction

Compounds with metal–metal bonds (clusters) were first isolated and structurally characterised early in the 1960s. Several thousands of clusters are known to date.¹ Among all compounds of transition elements belonging to this type, only about 80 technetium-containing clusters with acido ligands have been described.² This is mainly due to difficulties encountered in the synthesis of complexes of radioactive elements. However, a great interest has been expressed in such technetium clusters, because they possess a set of ‘anomalous’ structural and other physicochemical properties.³ In the present review, generalisation of experimental data on the known technetium acido clusters[†] has been made with primary emphasis on studies of physicochemical characteristics of these compounds (optical spectra in the visible, UV, and IR

regions, magnetochemistry, X-ray emission spectra, X-ray photoelectron spectra, ^{57}Fe Mössbauer spectra, electric conductivity and other properties) and comparison with those of mononuclear technetium complexes. All fundamental physicochemical properties of technetium acido clusters insufficiently covered in previous reviews^{1–3} are considered in particularly great detail.

All technetium acido clusters known to date have been systematised according to their electronic and molecular structure and to the method of their synthesis.² The nuclearity of the cluster, *i.e.*, the number of metal atoms forming direct metal–metal (M–M) bonds in the metal core of a cluster, is the basis of classification. In accordance with this principle, all technetium clusters are subdivided into di- and polynuclear clusters. Further classification is based on the electronic structure of the M–M bonds in the metal core of clusters and their molecular structure (*e.g.*, dinuclear d^4-d^4 clusters of the ‘lantern’ structural type or trigonal-prismatic hexanuclear clusters with metal–metal bonds of high order). The main structural types of technetium clusters are shown schematically in Fig. 1. The most important physicochemical properties of these clusters will be considered below.

II. Optical spectra of technetium clusters in the visible, UV, and IR spectral regions

1. Electronic spectra

No information on systematic studies of the optical spectra of technetium clusters has been reported to date. At best, spectral parameters of particular compounds were reported, and their qualitative assignment was made by analogy, *e.g.*, with rhenium compounds.^{4–7} This is first of all due to difficulties in recording and interpreting the spectra, since this requires rigorous quantum-chemical calculations and precise spectroscopic measurements on single crystals in polarised light. The most precise spectroscopic studies have been carried out only for two clusters, *viz.*, $\text{K}_3[\text{Tc}_2\text{Cl}_8] \cdot 2\text{H}_2\text{O}$ ⁸ for which scattered-wave self-consistent field (SCF– X_{α} –SW) quantum-chemical calculations⁹ have been performed, and for $[\text{Tc}_2(2\text{-PyO})_4\text{Cl}]$ (where 2-PyO is the 2-hydroxypyridine alcoholate)¹⁰ for which it has been possible to obtain suitable single crystals with all molecules oriented along the z axis of the tetragonal unit cell. The results of these studies have been described in detail;¹ therefore, it is hardly reasonable to repeat

[†] Here, we are dealing with compounds with metal–metal chemical bonds and weak crystal field ligands that are anions of mineral acids: Cl^- , Br^- , I^- , SO_4^{2-} , *etc.*

Figure 1. The main structural types of technetium acid clusters:² (a) $[\text{Tc}_2\text{X}_8]^{n-}$ ($\text{X} = \text{Cl}, \text{Br}; n = 2, 3$); (b) $\{[\text{Tc}_2\text{L}_4\text{X}_m]^{n-}$ ($\text{L} = \text{SO}_4^{2-}, \text{AcO}^-, \text{Bu}^t\text{COO}^-, 2\text{-PyO}^-; \text{X} = \text{Cl}, \text{Br}, \text{H}_2\text{O}, m = 1, 2; n = 0, 1, 2$); (c) $[\text{Tc}_2\text{X}_6]^{2-}$ ($\text{X} = \text{Cl}, \text{Br}$); (d) $[\text{Tc}_6(\mu\text{-X}_6)\text{X}_6]^{n-}$ ($\text{X} = \text{Cl}, \text{Br}; n = 0, 1, 2$); (e) $[\text{Tc}_8(\mu\text{-X}_8)\text{X}_4]^{n-}$ ($\text{X} = \text{Br}; n = 0, 1$); and (f) $[\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6]^{2-}$. The positions of bridging or axial ligands are shown by dashed lines.

them in this review. We consider in brief only the most important conclusions drawn in these studies.

The optical spectra of the cluster $\text{K}_3[\text{Tc}_2\text{Cl}_8] \cdot 2\text{H}_2\text{O}$ in the region of the $\delta\text{-}\delta^*$ transition have been recorded at 300 and 3.7 K.⁸ They belong to the lowest-energy electronic spectra. Fine structure associated with vibronic interaction and caused by progression in the $\nu'(\text{M-M})$ frequency (320 cm^{-1} for the electronically excited state), i.e., $\nu', 2\nu', 3\nu', \text{etc.}$, is observed in these spectra. Since the M-M bond in the excited state is weaker than that in the ground state, the frequency ν' is about 50 cm^{-1} lower than the frequency of the ground electronic state $\nu(\text{M-M})$. It should be noted that the $\nu(\text{M-M})$ frequency is observed in the Raman spectra and is symmetry-forbidden in the IR spectra. The spectra of the $[\text{Tc}_2(2\text{-PyO})_4\text{Cl}]$ single crystal at 5 K in the region of the $\delta\text{-}\delta^*$ transition as well as in other regions appear to be much more complicated, since not only a progression based on the $\nu'(\text{M-M})$ frequency (339 cm^{-1}), but also vibrations of the Tc-O and Tc-N bonds with frequencies ν'_2 and ν'_3 (264 and 298 cm^{-1} , respectively) are observed.¹⁰ Thus, the O-O band is followed by peaks corresponding to the ν'_1, ν'_2 and ν'_3 frequencies. Moreover, not only the expected extension of progressions to all possible overtones of frequencies ν'_1 and ν'_2 , but also progressions based on combination frequencies are observed in the spectra. Thus, Cotton *et al.*¹⁰ have identified vibrations with frequencies $5\nu'_2, 4\nu'_2 + \nu'_1, 3\nu'_2 + \nu'_1, 2\nu'_2 + 3\nu'_1, 2\nu'_2 + 4\nu'_1$, and $5\nu'_1$ in the fifth group of peaks (see also Ref. 8).

Electronic absorption spectra of solutions of potassium octachloroditechnetate in hydrochloric acid in the UV and visible regions have been studied,^{4,11} and the results (the dependence of the extinction coefficients ϵ_{max} on the HCl concentration) are

listed in Table 1. As can be seen, the HCl concentration affects strongly the positions of the lines and the extinction coefficient in spectra of octachloroditechnetate ions, which is due to additional complexation and hydrolysis (see below).

Table 1. Dependence of the extinction coefficients of $[\text{Tc}_2\text{Cl}_6]^{3-}$ on the HCl concentration.^{4,11}

^a Measured in litre mol⁻¹ cm⁻¹.

Selected parameters of the electronic absorption spectra of technetium clusters are listed in Table 3. These data are far from being complete and thus can be used mainly for qualitative analysis. It is likely that the only exception is the $\pi\text{-}\delta^*$ transition ($\lambda_{\text{max}} \approx 600\text{--}700\text{ nm}$) that can be identified for all $d^4\text{-}d^5$ complexes by analogy with the $[\text{Tc}_2\text{Cl}_8]^{3-}$ ions. The absorption bands of this optical transition correlate well with the quantity $10Dq^4$ characterising the strength of the crystal field of the ligand environment in the dinuclear complexes in question. It should be noted that an analogous tendency is also observed for most of other bands.

The electronic spectra of polynuclear technetium clusters are characterised by the absence of clearly defined absorption bands and by a monotonic increase in the optical density with increase

in energy.⁴ This is due to a large number of allowed electronic and vibronic transitions close in energy in the molecules of these compounds, which precludes their experimental observation because of limited resolution of spectrometers.

Despite the small number of reliable theoretical assignments of electronic spectra of technetium clusters, they are successfully employed by experimentalists, *e.g.*, in studies of the mechanism and kinetics of reactions in solutions.^{2,4,11,15,17} Typical changes in the absorption spectra of potassium octachloroditechnetate in hydrochloric acid solutions in the presence and in the absence of atmospheric oxygen are shown in Fig. 2. Based on these data, the kinetics and mechanisms of acid hydrolysis, complexation, disproportionation with the cleavage of M–M bonds, oxidative addition of atmospheric oxygen to a multiple M–M bond and cycloaddition of multiple M–M bonds with the formation of polynuclear clusters occurring in the system under consideration and characterising the stability of octahalotechnetate ions in solutions of hydrohalogenic acids have been studied. Each reaction dominates under particular conditions depending on the chemical nature of the solvent, concentration of dinuclear complexes and complexing agent, temperature, *etc.* Based on kinetic experiments on the stability of octahaloditechnetate ions in solutions of hydrohalogenic acids, it has been possible to calculate the effective rate constants for some of the reactions listed above and, in particular, to establish that the stability of these ions in solutions and their thermal stability in the solid state is determined by the strength of the M–M bonds and decreases in the series Cl > Br > I.²

2. Vibrational spectra

The vibrational spectra of technetium clusters have been studied somewhat more thoroughly. However, most of them are not very informative, since the fundamental vibrational modes of cluster fragments themselves are observed in the long-wave region. Moreover, the most interesting $\nu(\text{M} - \text{M})$ vibrations are forbidden in the IR spectra due to the centrosymmetric structure of most of the clusters and are allowed in the Raman spectra that cannot be

Figure 2. Typical changes in the absorption spectra of solutions of $\text{K}_3[\text{Tc}_2\text{Cl}_8] \cdot \text{H}_2\text{O}$ in hydrochloric acid in the absence (a) and in the presence of atmospheric oxygen (b, c) at initial concentrations of octachloroditechnetate(II, III) ions of less than 5×10^{-4} mol litre⁻¹ (a, b) and more than 5×10^{-3} mol litre⁻¹ (c). The duration of the oxidation of $[\text{Tc}_2\text{Cl}_8]^{3-}$ with oxygen (b, c) and of disproportionation of $[\text{Tc}_2\text{Cl}_8]^{3-}$ (a) increases uniformly in the order of increasing the numbers of spectra in the series (1–10).^{4,17}

recorded in many cases because of an intense dark colour of the compounds. Thus, only the IR spectra containing bands corresponding to stretching and bending vibrations of the atoms in cations or to characteristic vibrations of the Tc–X bonds (X is a ligand) can be observed for most of the technetium clusters. In this case, the Tc–X type of vibrations can be isolated from a set of more complex normal vibrations only by convention, since these can hardly be considered as characteristic ones because of large masses and strong mutual influence of the ligands. As has been mentioned in the previous Section, vibronic spectra can serve as yet another source of information on the cluster vibrational modes. However, vibrational progressions observed in this case will be characteristic of the electronically excited state of the cluster rather than of its ground state.¹⁸

Thus, all available information on the vibrational spectra of technetium clusters is reduced mainly to characteristic atomic vibrations in the cations in the region $4000\text{--}400\text{ cm}^{-1}$ and to vibrations of cluster anions (or molecules) themselves in the region $400\text{--}50\text{ cm}^{-1}$. Since the anions of different chemical nature have little effect on the cations, the absorption bands corresponding to characteristic vibrations of the same cations in different compounds differ insignificantly in most of spectra. In this connection, the IR spectra in the region $4000\text{--}400\text{ cm}^{-1}$ can be used mainly for qualitative analysis, and it makes no sense to consider them in this review, since they are rather characteristic of the cations themselves. Apparently, the IR spectra of differently hydrated hydroxonium cations and certain bridging bidentate (*e.g.*, carboxylate or sulfate) ligands are the exceptions, since they can contain essential information on the formal charge and on the electronic and molecular structure of the cluster fragments. Let us consider the results obtained from these spectra in more detail.

The absorption bands corresponding to stretching and bending vibrations of the OH groups in technetium clusters with differently hydrated hydroxonium cations¹⁹ are listed in Table 4. The results obtained indicate that the pattern of the IR spectra depends on the character of bonding of the OH groups in crystals of the compounds in question. For instance, since only isolated H_3O^+ ions are present in the crystals of compound **7**, only two bands corresponding to the $\nu(\text{OH})_{\text{H}_3\text{O}^+}$ and $\delta(\text{H}-\text{O}-\text{H})_{\text{H}_3\text{O}^+}$ vibrations are observed in its IR spectrum (see Table 4). Only water molecules of crystallisation are present in the cluster **1**; therefore, only absorption bands due to the $\nu(\text{OH})_{\text{H}_2\text{O}}$ and $\delta(\text{H}-\text{O}-\text{H})_{\text{H}_2\text{O}}$ vibrations are observed in the IR spectrum of this compound. As can be seen, their positions differ considerably from those of corresponding absorption bands of hydroxonium cations.

Several bands due to stretching and bending vibrations of the OH groups are simultaneously observed in the IR spectra of compounds **2–5** and **8** (see Table 4). This is probably due to the fact that the bridging hydrogen atoms in the $[\text{H}(\text{H}_2\text{O})_2]^+$ and $[\text{H}_3\text{O}(\text{H}_2\text{O})_3]^+$ cations are closer to one of the oxygen atoms while to the other oxygen atom they are bonded by a strong hydrogen bond. Therefore, the absorption bands corresponding to vibrations of both H_3O^+ ions and H_2O must be observed in the IR spectra of hydrated hydroxonium cations. It should be noted that in this case the frequencies of $\delta(\text{H}-\text{O}-\mu\text{-H})$ absorption bands must be intermediate between those of the $\delta(\text{H}-\text{O}-\text{H})_{\text{H}_2\text{O}}$ and $\delta(\text{H}-\text{O}-\text{H})_{\text{H}_3\text{O}^+}$ vibrations. A much larger number of bands corresponding to bending vibrations must be observed in the case of partially deuterated differently hydrated hydroxonium ions (see Table 4). Thus, IR spectra, as well as the experiments on thermal

dehydration and magnetic measurements, can be used to establish¹⁹ the structure of clusters if their crystals contain differently hydrated hydroxonium cations, whereas X-ray analysis provides no unambiguous solution of this problem. Yet another example of this type is provided by the IR spectra of compound $(\text{Bu}_4\text{N})_2[\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6]$ in which no absorption bands corresponding to vibrations of the OH groups are observed. In contrast to the initial assumptions,²⁰ this indicates that the $[\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6]^{2-}$ anion contains no OH groups.

The IR spectra of μ -acetato dinuclear $d^4\text{--}d^5$ technetium complexes have been studied and all absorption bands have been assigned.²¹ Previously,⁷ the IR spectra of analogous dinuclear $d^4\text{--}d^4$ technetium and rhenium clusters have been studied; however, no complete assignment of the absorption bands has been performed. From comparison of the results obtained it follows that, in contrast to analogous dinuclear complexes of other elements (*e.g.*, copper acetates), the splitting (Δ) between the frequencies of symmetric $\nu_s(\text{C}-\text{O})$ and antisymmetric $\nu_{as}(\text{C}-\text{O})$ vibrations of the bridging acetate anions in technetium clusters is extremely small ($\sim 20\text{ cm}^{-1}$). It should be noted that a tendency for the Δ value to decrease is observed on going from monodentate acetate ions to bidentate ones and that the anomalously small value of this splitting is probably due to a specific influence of strong Tc—Tc bonds. The frequencies of the $\nu(\text{Tc}-\text{X})$ vibrations are appreciably shifted towards the long-wave region relative to analogous frequencies of other halide technetium complexes without bridging ligands. This indicates appreciable weakening of the Tc—X bonds in μ -acetato technetium complexes as compared to analogous bonds in other halide Tc complexes (Table 5). From these data altogether it has been suggested²¹ that the compounds under consideration have the ‘lantern’ type of structure (see Fig. 1*b*), *viz.*, two technetium atoms form a strong Tc—Tc bond, four bridging acetate ions additionally bind Tc atoms to one another, while two halide ions are in axial positions with respect to the M—M bonds and are in essence ionically bonded to the technetium atom. This assumption has been completely confirmed by X-ray analysis.^{22–24}

Using the IR spectra, the structures of sulfate dinuclear technetium complexes have also been determined.¹⁶ The parameters of the IR spectra and the assignment of bands of two sulfate dinuclear technetium complexes, $\text{K}_2[\text{Tc}_2(\text{SO}_4)_2] \cdot 2\text{H}_2\text{O}$ and $\text{K}_4(\text{H}_3\text{O})_2[\text{Tc}_2(\text{SO}_4)_6]$, are listed in Table 6. The IR spectrum of the former compound contains absorption bands in the region $330\text{--}3530\text{ cm}^{-1}$ with maxima at 3450 and 1655 cm^{-1} corresponding to stretching and bending vibrations of coordinated water molecules, respectively. Four groups of bands each split by the crystal field are observed in the regions of both stretching and

Table 5. Frequencies of absorption bands (cm^{-1}) in the long-wave IR spectra of technetium halide clusters and their assignment.^{28, 29}

bending vibrations of sulfate ions; this corresponds to distortion of the tetrahedral SO_4^{2-} ion to the idealised C_{2v} symmetry due to the formation of bidentate bridging bonds between the sulfate ions and the Tc_2^{6+} fragment,²⁵ which is analogous to those found in the structure of the $[\text{Re}_2(\text{SO}_4)_4]^{2-}$ anion.^{26, 27}

The IR spectrum of compound $\text{K}_4(\text{H}_3\text{O})_2[\text{Tc}_2(\text{SO}_4)_6]$ is characterised by a more intense absorption band in the region $\sim 2950 \text{ cm}^{-1}$, which can be assigned to the $\nu(\text{OH})_{\text{H}_3\text{O}^+}$ vibrations (see Table 6). Three groups of broad bands are observed in the region of stretching and bending vibrations of the S—O bond in the spectrum of this compound; this is characteristic of monodentate sulfate ions with C_{3v} symmetry.²⁵

Later, the assumptions¹⁶ concerning the structure of compound $\text{K}_2[\text{Tc}_2(\text{SO}_4)_4] \cdot 2\text{H}_2\text{O}$ made on the basis of IR spectra, the results of chemical analysis and data of thermogravimetric analysis and other physicochemical methods were confirmed by X-ray study of a single crystal synthesised by the author of this review.[‡]

The assignment of the absorption bands of a number of di- and poly-nuclear halide technetium clusters is given in Table 5 and the long-wave IR spectra of several polynuclear technetium clusters are shown in Fig. 3. The following major tendencies are observed for compounds of similar structure, *viz.*, the absorption bands corresponding to the $\nu(\text{Tc}-\text{X})$ and $\delta(\text{Tc}-\text{Tc}-\text{X})$ vibra-

[‡] X-Ray analysis has been done by P A Koz'min, M D Surazhskaya, and T B Larin and the results of these investigations have been described in Ref. 2.

**Figure 3.** The long-wave IR spectra of polynuclear technetium clusters:^{28, 29} (a) $(\text{FeCp}_2)_2[\text{Tc}_8\text{Br}_{14}]$; (b) $(\text{FeCp}_2)_3[\text{Tc}_6\text{Cl}_{14}]$; (c) $(\text{Bu}_4\text{N})_3.[\text{Tc}_6\text{Cl}_{14}]$; and (d) $[\text{H}(\text{H}_2\text{O})_2]_2[\text{Tc}_8\text{Br}_{14}]$.

tions are, as a rule, shifted towards the low-energy region as the formal oxidation state of technetium decreases and the replacement of ligands in the series Cl, Br and I occurs. As has already been noted, vibrations of the M—M bonds are symmetry-forbidden and are not observed in the IR spectra of most of dinuclear clusters; however, in polynuclear clusters this exclusion is removed, and certain $\nu(\text{Tc}-\text{Tc})$ and $\delta(\text{Tc}-\text{Tc}-\text{X})$ vibrations can also be observed in the IR spectra. Thus, the stretching vibrations of the M—M bonds of F_{1u} ; E' and A'' ; and B_{1u} , B_{2u} and B_{3u} symmetry types are expected to be observed in the spectra of octahedral, trigonal-prismatic, and tetragonal-prismatic clusters, respectively. For lack of sufficient experimental data, unambiguous assignment of all vibrational frequencies for polynuclear clusters is currently impossible. Therefore, their long-wave IR spectra can be used mainly for qualitative analysis and determination of the structure. Thus, a large number of relatively narrow absorption bands in this spectral region is almost unambiguous evidence for the polynuclear nature of the clusters, while the positions of these lines can be tentative evidence for the formal oxidation state of technetium.

The use of IR spectra of technetium and rhenium complexes with ferrocenium cations for the solution of analytical and structural problems has been described.^{28, 29} The composition

Table 6. Frequencies (cm^{-1}) and relative intensities of bands in the IR spectra of sulfate dinuclear technetium complexes.¹⁶

Compound	$\nu(\text{OH})$	$\delta(\text{H}-\text{O}-\text{H})$	$\nu(\text{S}-\text{O})$	$\nu(\text{Tc}-\text{O})$	$\delta(\text{O}-\text{S}-\text{O})$	Other bands
$\text{K}_2[\text{Tc}_2(\text{SO}_4)_4] \cdot 2\text{H}_2\text{O}^a$	3450 (s, br)	1655 (w)	1295 (s), 1230 (w); 1185 (sh), 1155 (s); 1070 (m), 1041 (m); 915 (s), 850 (m)	698 (m)	698 (s); 600 (m), 585 (m); 532 (sh, w), 522 (w); 465 (m)	381 (m), 335 (s, br) $\delta(\text{O}-\text{Tc}-\text{O})$, 250 (sh, br), 200 (m), 181 (w), 158 (m), 152 (w), 118 (m), 78 (s)
$\text{K}_4(\text{H}_3\text{O})_2[\text{Tc}_2(\text{SO}_4)_6]^b$	2950 (sh, br)		1230 (sh, br), 1155 (s); 1045 (s); 965 (s), 850 (sh)	675 (m)	605 (s); 535 (w); 483 (m)	290 (s, v br) $\delta(\text{O}-\text{Tc}-\text{O})$ 156 (s, v br), 80 (w, br)

^a Sulfate ions have C_{2v} symmetry in the complex $\text{K}_2[\text{Tc}_2(\text{SO}_4)_4] \cdot 2\text{H}_2\text{O}$. ^b Sulfate ions have the C_{3v} symmetry in the complex $\text{K}_4(\text{H}_3\text{O})_2[\text{Tc}_2(\text{SO}_4)_6]$.

and structure of these complexes suggest that the lines corresponding to vibrations of ferrocenium cations, technetium or rhenium anions, and hydrated hydroxonium cations {in the case of compound $(\text{FeCp}_2)_4[\text{H}_3\text{O}(\text{H}_2\text{O})_4]_2 \cdot [\text{TcCl}_6]_3$ } must be observed in their IR spectra. According to the published data,³⁰ if ferrocene and ferrocenium have the $D_{5d}(D_{5h})$ point symmetry, then vibrations of $A_{2u}(A_2'')$ and $E_{2u}(E_2'')$ symmetry types must be active in their IR spectra. It has been shown^{28,29} that all most intense vibrational lines of ferrocene are also observed in the IR spectra of technetium and rhenium compounds with ferrocenium cations. The only exception are the absorption bands in the region $480\text{--}820\text{ cm}^{-1}$, where only one composite line in the region $670\text{--}560\text{ cm}^{-1}$ is observed instead of very intense bands corresponding to the nonplanar $\rho_{\text{CH}}(A_{2u})$ vibrations and $\nu(\text{Fe}-\text{Cp})$ (E_{1u}) stretching vibrations characteristic of pure ferrocene; this line is probably due to the interaction between the above two vibrations. It is known³⁰ that interaction between these types of vibrations [as well as a shift of $\nu(\text{Fe}-\text{Cp})$ towards the high-frequency region] characterises an increase in covalency of the $\text{Fe}-\text{Cp}$ bonds. It should be noted that neither absorption bands corresponding to the $\nu(\text{Fe}-\text{Cp})$ (E_{1u}) vibrations in the IR spectrum of compound $(\text{FeCp}_2)_2[\text{Tc}_8\text{Br}_{14}]$ nor the bands corresponding to bending skeletal $\nu(\text{Cp}-\text{Fe}-\text{Cp})$ (E_{1u}) vibrations in the spectra of all compounds studied are observed. All bands in the IR spectra of compounds containing $[\text{Tc}_6\text{Cl}_{14}]^{3-}$ and especially $[\text{Tc}_8\text{Br}_{14}]^{2-}$ anions are considerably broadened and diffuse (see Fig. 3). Analogous effects have been found for certain specimens preliminarily frozen to $\sim 78\text{ K}$. It has been pointed out that this phenomenon can be due to the effects of vibronic interaction in the molecules.^{29,30}

As to the absorption bands corresponding to stretching and bending vibrations of isolated hydroxonium cations in the cluster $[\text{Fc}(\text{Cp}_2)_4[\text{H}_3\text{O}(\text{H}_2\text{O})_4]_2[\text{TcCl}_6]_3$, it is difficult to identify them because of the superposition of more intense lines of ferrocenium cations. Nevertheless, certain bands in the region of $\delta(\text{H}-\text{O}-\text{H})$ bending vibrations (at $1620, 1555, 1510$, and 1058 cm^{-1}) can be identified unambiguously. The conclusion that the effect of ferrocenium cations on the vibrational spectra of anions is not so significant as the reverse effect of various anions on the vibrations in ferrocenium cations is yet another important result.^{28,29} Nevertheless, this effect persists and manifests itself mainly as a shift of frequencies of these vibrations. Similar shift of the frequencies of stretching and bending vibrations of technetium anions due to the effect of various cations has been found;³¹ it has been shown that the absorption bands of the anions are shifted towards the low-frequency region as the average size of cations increases. For pertechnetate ions, an increase in the cation size is accompanied by a decrease in the splitting of the $\nu(\text{Tc}=\text{O})$ stretching band. Comparison of published data (see Refs 28, 29 and 31) shows that

the extent to which the anions are affected by the ferrocenium cations, the effective radius (R_{eff}) of which is larger than $3\text{ \AA}$, approaches that of $(\text{Me}_4\text{N})^+$ and $(\text{Et}_4\text{N})^+$ having similar R_{eff} . It should be noted that the absorption bands in the long-wave IR spectra of compound $(\text{FeCp}_2)_2[\text{Tc}_8\text{Br}_{14}]$ are also considerably broadened and some of them are missing (see Fig. 3), as is the case of the short-wave IR spectra. This may also be associated with vibronic interactions.^{28,29}

The IR spectroscopic studies of ferrocenium salts with Tc- and Re-containing anions^{28,29} have shown that:

1. All compounds correspond to the expected composition and structure.

2. The absence of additional absorption bands in the IR spectra of the compounds obtained (except for the bands corresponding to anionic and cationic vibrations) indicates that no formation of new types of directed chemical bonds occurs except for those expected from the composition and structure of these compounds.

3. Strong mutual influence of the ferrocenium cations and the technetium (rhenium) anions is observed, which increases in the series of anions $[\text{TcO}_4]^- < [\text{Re}_2\text{Br}_8]^{2-} \approx [\text{Tc}_6\text{I}_{14}]^{3-} < [\text{TcCl}_6]^{2-} < [\text{Tc}_6\text{Cl}_{14}]^{3-} < [\text{Tc}_8\text{Br}_{14}]^{2-}$ and is probably due to the strengthening of vibronic interaction in this series.

The assignment of absorption bands in the long-wave IR spectra of $[\text{Tc}_2\text{X}_8]^{n-}$ ($\text{X} = \text{Cl}, \text{Br}; n = 2, 3$) dinuclear technetium clusters with a simpler structure has been performed.^{1,4,5,8,32} Thus, the IR spectra of these anions contain two absorption bands with E_u and A_{2u} symmetry corresponding to the $\nu(\text{Tc}-\text{X})$ stretching vibrations and one A_{2u} band corresponding to the $\delta(\text{X}-\text{Tc}-\text{X})$ vibrations, while their Raman spectra contain two absorption bands with A_{1g} symmetry corresponding to the $\nu(\text{Tc}-\text{Tc})$ and $\nu(\text{Tc}-\text{X})$ vibrations and one band with E_g symmetry. The frequencies of these bands in the spectra of different anions are listed in Table 5.

Complete normal coordinate analysis for the $[\text{Tc}_2\text{X}_8]^{n-}$ dinuclear complexes ($\text{X} = \text{Cl}, \text{Br}; n = 2, 3$) has been performed, the bands in their IR and Raman spectra (including those of isotope-substituted complexes) have been assigned, and ten force constants have been calculated.⁶ The structural characteristics of these ions used in the calculations and the force constants obtained are listed in Table 7. The assignment of bands in the IR and Raman spectra of analogous rhenium and osmium dinuclear complexes with D_{4h} and D_{4d} symmetry, respectively, has also been performed.⁶ The calculations reproduce well the major regularities expected from the data of X-ray studies. Thus, from Ref. 6 and the data in Table 7 it follows that for all the complexes in question the bond stretching force constants $f_d(\text{M}-\text{M})$ and $f_d(\text{M}-\text{X})$, as a rule, decrease as the ligands are replaced in the series F, Cl, Br and I and n increases. It should be noted that these

Table 7. Bond lengths ($d/\text{\AA}$), bond angles (α/deg) and force constants ($f/\text{mdyn A}^{-1}$) for $[\text{Tc}_2\text{X}_8]^{n-}$ ($\text{X} = \text{Cl}, \text{Br}; n = 2, 3$) ions.⁶

Note. The subscripts d and α at the force constants f correspond to stretching and bending vibrations, respectively; the direction of the vibrations is given in parentheses.

changes and changes in analogous interatomic distances due to ligand replacement and the decrease in the formal oxidation state of the metal occur in the opposite directions. Of all the complexes studied, the largest $f_d(M-M)$ value was obtained for the $[Tc_2Cl_8]^{3-}$ anion with a formal $M-M$ bond order of 3.5 for which the shortest $M-M$ distance has been found experimentally.²

In conclusion of this Section, it should be noted that many problems associated with the assignment and interpretation of the optical spectra of technetium clusters remain unsolved due to the complex structure of these compounds, the lack of sufficient experimental data (which is often due to the impossibility of obtaining them with currently available instruments) as well as to the absence of reliable theoretical calculations. However, the available data can well be used for qualitative structural analysis.

III. Magnetochemistry of technetium oxo and halide complexes

Among experimental methods of studying the electronic structure of coordination compounds, magnetochemical measurements occupy a particular place since they make it possible to determine the number of unpaired electrons in the molecule, the magnitude of intermolecular exchange interactions, and in some instances

can even serve as immediate evidence for the relative order of some MOs in the molecules of these compounds. Sometimes, magnetochemistry can be used as an analytical and, to some extent, as a structural investigation technique.³³ However, no information on systematic studies of magnetochemical properties of technetium complexes has been reported so far.³⁴ The results available^{35,36} have not been systematised, contain no data on diamagnetic corrections for technetium and thus are unreliable. In connection with the foregoing, in this review we discuss the magnetic properties of technetium complexes in which Tc atoms have different oxidation states and which have been studied by the static magnetic susceptibility method and by EPR spectroscopy.

The data of magnetic measurements for technetium compounds are listed in Table 8. Since no diamagnetic corrections for technetium ions are known, they were obtained by extrapolating the data on diamagnetic corrections for neighbouring elements in the Periodic Table (Mn, Re, Mo and Ru).³⁴ The results of calculations of the electronic structure of technetium oxo and halide complexes are shown in Fig. 4. As can be seen, in most cases the experimental data are in good agreement with theoretical predictions. Let us consider the most typical cases in detail.

Pertechnetates are tetrahedral d^0 complexes. The recently found distortion of these complexes^{37–44} has virtually no effect on their diamagnetic properties, except for weak temperature-

^a Compounds are diamagnetic. ^b Temperature-independent paramagnetism.

Figure 4. Results of extended Hückel (EH) calculations of the electronic structure of technetium complexes.^{2,34} The presence of electrons in the HOMO is depicted schematically by small double vertical lines.

independent paramagnetism (TIP)[§] observed in some cases (see Table 8 and Fig. 4). It should be noted that according to Fig. 4, the $[\text{TcO}_4]^{2-}$ ions formed in the one-electron reduction of pertechnetates, must possess weak paramagnetism corresponding to one unpaired electron, which is observed experimentally.^{45,46}

Technetium(V) oxohalide complexes are characterised by the d^2 electronic configuration of the central atom. The ground electronic state of the molecules of these compounds must be spin-paired because of a symmetry breakdown in the nearest environment of technetium (e.g., to C_{2v} for $[\text{TcOX}_4]^-$, see Ref. 47); in fact, these compounds also possess diamagnetism or TIP (see Table 8, Fig. 4).³⁴

Technetium(IV) halide complexes are characterised by the d^3 electronic configuration and octahedral structure of the nearest coordination sphere of the Tc atoms. According to theoretical predictions (see Fig. 4), these compounds have a triply degenerate t_{2g} highest occupied molecular orbital (HOMO) and, hence, they must possess paramagnetism corresponding to the spin $3/2$ ($\mu_{\text{eff}} \approx 3.87 \mu_B$).

From the data in Table 8 it can be seen that only for several technetium(IV) compounds are the magnitudes of the effective magnetic moments μ_{eff} close to the pure spin value; in most cases, they are much smaller. Previously,⁴⁸ similar effects of a decrease in μ_{eff} of analogous rhenium halide complexes have been rationalised by intermolecular exchange interactions occurring along the $\text{Re}'-\text{X}'\cdots\text{X}''-\text{Re}''$ chains. It has also been shown⁴⁸ that similar antiferromagnetic interactions can occur at $\text{X}'\cdots\text{X}''$ distances up to $\sim 5 \text{ \AA}$. Thus, antiferromagnetic exchange interactions in technetium(IV) complexes are also the most plausible explanation of the decrease in their effective magnetic moments.

In fact, as can be seen from the data in Table 8, a decrease in the size of the outer-sphere cation and an increase in the anion size (halide ion) leads to an increase (in the absolute value) in the Weiss constant characterising the strength of antiferromagnetic exchange interactions. However, in the case of rather bulky tetraalkylammonium cations, the $[\text{TcX}_6]^{2-}$ anions are 'pushed

apart' by these cations to such an extent that the exchange interactions along the $\text{Tc}'-\text{X}'\cdots\text{X}''-\text{Tc}''$ chains become impossible (the $\text{X}'\cdots\text{X}''$ distances between adjacent $[\text{TcX}_6]^{2-}$ octahedra are $\sim 6 \text{ \AA}$).⁴⁹ An even greater decrease in μ_{eff} is observed for technetium dioxide (see Table 8). According to the published data,⁵⁰ it is assumed that the metal-metal (Tc-Tc) bonds can be formed in the TcO_2 molecule; this may be an additional reason for the decrease in μ_{eff} compared to its pure spin value for technetium(IV).

As can be seen from the data in Table 8, the magnetic properties of most of the compounds considered above are first of all due to the electronic configuration of the Tc atoms, the symmetry of their nearest ligand environment and intermolecular exchange interactions. The magnetic properties of all other technetium compounds listed in Table 8 cannot be explained by these reasons only, since their electronic structures are strongly affected by the M-M bonds localised on pairs of Tc atoms or delocalised over the polynuclear metal core. In these complexes, the M-M interactions result in appreciable shortening of the Tc-Tc distances compared to analogous distances in compact metallic Tc.^{1,2,51} The compounds studied^{2,51} can be divided into two structural types, viz., dinuclear complexes (clusters) with multiple M-M bonds and polynuclear clusters.

Dinuclear d^4-d^4 complexes. Classical quadruple M-M bonds formed by $\sigma(4d_{z^2})$, $2\pi(4d_{xz}, 4d_{yz})$ and $\delta(4d_{xy})$ orbitals of the M-M bonds (see Fig. 4) are characteristic of these compounds.^{1,2,51} These complexes have an eclipsed conformation of ligands (the idealised D_{4h} symmetry, see Fig. 1a,b) and Tc-Tc distances in the range from 2.16 to 2.19 $\text{\AA}$.² All compounds are characterised by the absence of unpaired electrons, therefore their magnetic susceptibility is temperature-independent (see Table 8).

Dinuclear d^4-d^5 complexes are formed as a result of one-electron reduction of the compounds belonging to the preceding group and also have an eclipsed conformation of ligands^{1,2,51} (see Fig. 1a,b). As could be expected from Fig. 4, one unpaired electron is shared by two Tc atoms that form an M-M bond of high order (the Tc-Tc distances in d^4-d^5 complexes lie within the limits 2.10–2.15 $\text{\AA}$)^{1,2,51} in the molecules of these compounds. It has been shown^{3,9,52-54} that this electron occupies the b_{1u} HOMO (the δ^* M-M orbital) formed mainly by the $4d_{xy}$

Figure 5. EPR spectra:³⁴ (a) $\text{K}_3[\text{Tc}_2\text{Cl}_8] \cdot 2\text{H}_2\text{O}$ at 78 K (the z crystal axis is perpendicular to the direction of the magnetic field strength); (b, c) $(\text{Me}_4\text{N})_3\{[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_6]\text{Cl}_2\}$ at 293 and 78 K; (d, e) $(\text{Me}_4\text{N})_2.[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_6]$ at 78 and 293 K, respectively; DPPH is diphenylpicrylhydrazide.

orbitals of two technetium atoms. Thus, the M—M bonds in these complexes are of formal order 3.5. Let us present the essentials of this proof, since they are of importance for considering the electronic structure of the compounds mentioned.²

EPR signals of all compounds belonging to this type are observed both in the crystalline state and in solutions. Typical EPR spectra of $\text{K}_3[\text{Tc}_2\text{Cl}_8] \cdot 2\text{H}_2\text{O}$ single crystal and $\text{K}_3[\text{Tc}_2\text{Cl}_8] \cdot 2\text{H}_2\text{O}$ solution in hydrochloric acid are shown in Figs 5 and 6, respectively. The EPR spectra of polycrystalline specimens are, as a rule, structureless lines with half-width ~ 500 Γ and effective g -factor $g_{\text{eff}} = 2.09 \pm 0.02$. Clearly defined fine structure is observed in the single-crystal spectra, though their parameters are similar to those listed above. Well-resolved spectra of solutions of these complexes can hardly be obtained because of the impossibility of achieving high technetium concentrations; where it is possible, the spectra are similar to that shown in Fig. 6.⁴ EPR spectra of glassy frozen solutions of d^4 – d^5 complexes have also been studied.^{9, 52–54} It has been established that all dinuclear d^4 – d^5 clusters studied have similar spectral patterns with the parameters coinciding within the limits of experimental error:

Figure 6. Typical EPR spectrum of Tc_2^{5+} complexes in solutions of HCl at 293 K $\{[\text{Tc}_2\text{Cl}_8]^{3-}$ in 4.0 M HCl $\}$.⁴

$g_{\parallel} = 1.85 \pm 0.03$, $g_{\perp} = 2.13 \pm 0.03$, $A_{\parallel} = -(188 \pm 5) \times 10^{-4} \text{ cm}^{-1}$, $A_{\perp} = -(75 \pm 5) \times 10^{-4} \text{ cm}^{-1}$ and $P = (5 \pm 1) \times 10^{-4} \text{ cm}^{-1}$. The spectra display strong anisotropy: lines of parallel orientation are observed in the region from 1600 to 5550 Γ , while those of perpendicular orientation and, probably, peaks of additional absorption are observed in the region from 2400 to 3900 Γ . From the data in Table 8 it can be seen that despite the chain structure of some of the compounds in question {e.g., $[\text{Tc}_2(\text{AcO})_4]\text{X}$ ($\text{X} = \text{Cl}, \text{Br}$)}, intermolecular exchange interactions have no effect on their magnetic properties (the μ_{eff} values are close to the spin-only value corresponding to one unpaired electron and are temperature-independent).^{2, 22–24, 51}

Thus, even qualitative analysis of the data on the magnetic susceptibility of d^4 – d^5 complexes and their EPR spectra suggests that the only unpaired electron does occupy the $\delta^*(b_{1u})$ MO,⁴ since only in this case can one expect that magnetic parameters will exhibit low sensitivity to the chemical nature of ligands. According to the results of SCF- X_{σ} -SW calculations of the electronic structure of the $[\text{Tc}_2\text{Cl}_8]^{3-}$ ion,⁹ the δ^* MO is the only MO of all unoccupied MOs to which the electrons of ligand atoms make no appreciable contribution (see Fig. 4). A more reliable proof of this fact is known that is independent of the results of theoretical calculations of the electronic structure.^{3, 52, 53} Thus, the possible ground electronic states in the molecules of d^4 – d^5 complexes and values of g -factors predicted by the theory of EPR spectra (the spin Hamiltonian method^{55, 56}) have been considered. All possible ‘reasonable’ energy permutations of the MO levels were taken into account when analysing the experimental values of g -factors (see Fig. 4). From the data obtained it follows that qualitative agreement between theory and experiment can be achieved only if the b_{1u} MO is the highest occupied molecular orbital.

Dinuclear d^5 – d^5 complexes are characterised by extremely short interatomic Tc—Tc distances (~ 2.04 Å), a chain structure, and idealised D_{4d} symmetry of the ligand environment (staggered conformation, see Fig. 1 c).^{57, 58} The molecular and electronic structure of these compounds has been considered in detail.² According to calculations^{2, 18} (see Fig. 4), the e_2 orbital formed by ‘cross’ overlap of the $4d_{xy}$ and $4d_{x^2-y^2}$ orbitals of two Tc atoms in the molecules of these compounds is the HOMO; formally, it is a low-energy δ bonding orbital. Considerable distortion of the idealised D_{4d} symmetry in the complexes results in the removal of degeneracy of the e_2 level and in partial increase in its δ bonding nature. Thus, the formation of formally quintuple M—M bonds in these compounds was first observed⁵⁷ in contrast to, e.g., analogous d^5 – d^5 osmium complexes with triple M—M bonds.^{58, 59} Cotton *et al.*⁵⁸ interpreted the M—M bonds in d^5 – d^5 technetium complexes as triple ones and their shortening as the result of changes in the diffuseness of the σ , π and δ components of these bonds due to changes in the formal technetium oxidation state.

From the data in Fig. 4 it follows that the $[\text{Tc}_2\text{X}_6]_n^{2n-}$ ions must be spin-paired (see Table 8). However, weak EPR signals of polycrystalline specimens of dinuclear d^5 – d^5 technetium complexes are observed in some instances. The parameters of these signals indicate that the specimens contain small amounts ($< 5\%$) of impurities (related paramagnetic d^4 – d^5 complexes).

Polynuclear complexes (clusters). Most of these compounds have an island structure⁵¹ (see Fig. 1 d, e, f), except for two octanuclear $[\text{Tc}_8\text{Br}_{13}]_n^{n-}$ clusters ($n = 0, 1$) with a chain structure.^{60, 61} This would seemingly simplify the interpretation of the magnetic properties of this class of compounds, since in most cases there is no need to take into account intermolecular exchange interactions. However, the interpretation of the results of magnetochemical experiments on polynuclear technetium complexes appeared to be the most complex. This is first of all due to the complexity of the system of M—M bonds and high molecular weights of the compounds in question (and, hence, to the small contribution of spin-only paramagnetism to the magnetic susceptibility and to commensurable contributions of the Langevin diamagnetism and the Van Vleck paramagnetism), large relative

error of magnetic susceptibility measurements in the vicinity of zero values, strong effects of even small amounts of low-molecular-weight paramagnetic impurities as well as to a considerable uncertainty in the values of diamagnetic corrections for this class of compounds. In connection with the foregoing, the results of magnetochemical experiments were interpreted using EPR spectroscopy (as a tool for qualitative and semiquantitative analysis) and the results of theoretical calculations.

Trigonal-prismatic clusters. The following technetium compounds with this structure are known: $(\text{Et}_4\text{N})_2 \cdot \{[\text{Tc}_6\text{Br}_6(\mu\text{-Br})_6]\text{Br}_2\}$, $(\text{Me}_4\text{N})_3\{[\text{Tc}_6\text{X}_6(\mu\text{-X})_6]\text{X}_2\}$ ($\text{X} = \text{Cl}, \text{Br}$), $(\text{Me}_4\text{N})_2[\text{Tc}_6\text{Cl}_6(\mu\text{-Cl})_6]$, $(\text{Bu}_4\text{N})_3\{[\text{Tc}_6\text{Cl}_6(\mu\text{-Cl})_6]\text{Cl}_2\}$ and $(\text{FeCp}_2)_3\{[\text{Tc}_6\text{Cl}_6(\mu\text{-Cl})_6]\text{Cl}_2\}$. The metal core of these clusters has the shape of a trigonal prism with an equilateral triangle as the base (see Fig. 1 *d*). The lateral edges of the prism correspond to the $\text{M}-\text{M}$ bonds of formal order 3.0–4.0 (2.16–2.21 Å), while the edges of the prism base correspond to those of formal order 0.5–1.0 (2.55–2.75 Å). These clusters have the idealised D_{3h} symmetry.

Generally, there is no agreement between the calculated values^{2,54} and the experimental results (see Table 8). In fact, according to extended Hückel (EH) calculations, the $\{[\text{Tc}_6\text{Br}_6(\mu\text{-Br})_6]\text{Br}_2\}^{2-}$ and $[\text{Tc}_6\text{Cl}_6(\mu\text{-Cl})_6]^{2-}$ ions are in a spin-paired ground electronic state; however, experimental studies show that there is ~ 0.1 and ~ 0.2 unpaired electron per each cluster molecule, respectively, and that an EPR signal with $g_{\text{eff}} = 1.97$ is observed (Fig. 5 *d, e*) for a polycrystalline specimen of the latter compound. It should be noted that a weak temperature-dependent paramagnetic component of the total magnetic susceptibility of these clusters can hardly be associated with the presence of mechanical impurities of other paramagnetic polynuclear clusters, since according to X-ray phase analysis data obtained with an accuracy of 5% to 10% (sensitivity of the method), both compounds contain no impurities. Thus, this paramagnetic component can be due to either the nature of the compounds under consideration or the presence of a very small amount of paramagnetic mono- or di-nuclear technetium complexes. However, the fact that EPR signals with such parameters as those of the spectra shown in Fig. 5 *d, e* could not be observed for any of the paramagnetic impurities of mono- or di-nuclear technetium complexes possible in this case is against the latter assumption.

The interpretation of magnetochemical data for the compound with ferrocenium cations appeared to be all the more complex.²⁹ In fact, strong paramagnetism (~ 5 unpaired electrons per molecule) of this compound (see Table 8), the lack of similarity between its EPR spectrum (broad spectra with $g_{\text{eff}} \sim 2$) and spectra of compounds with similar anions and different tetraalkylammonium cations close in their size (Figs 7, 8; *cf.* Fig. 5), temperature-independent behaviour (down to ~ 4 K) of all magnetic parameters as well as physicochemical properties of other technetium and rhenium clusters with ferrocenium cations indicate altogether that their electronic structure is unusual and complex. In this connection, the magnetic properties of all compounds with ferrocenium cations will be considered in Section VI.

To a first approximation, the paramagnetism of $\{[\text{Tc}_6\text{X}_6(\mu\text{-X})_6]\text{X}_2\}^{3-}$ ion corresponding to one unpaired electron per cluster (except for ferrocenium-containing compounds) is well described by theory^{2,34} (see Table 8, Fig. 4). However, no adequate description of EPR spectral parameters of these compounds ($g_{\parallel} \approx 2.00$, $g_{\perp} \approx 1.63$) can be obtained using the EH calculations. In fact, calculations of the electronic structure of trigonal-prismatic technetium clusters^{34,62,63} suggest that the HOMO in these clusters can be either the a'_2 ($\delta_{\text{M}-\text{M}}$) MO or the a'_2 ($\pi_{\text{M}-\text{M}}^*$) MO. However, it has been reported⁶⁴ that none of these variants of the electronic structure as well as all other possible variants based on the energy permutations of the MOs in the HOMO–LUMO region can explain the values of g -factors observed experimentally (the analysis of g -factors was performed

Figure 7. EPR spectra:^{4,18,34} (*a, b*) $(\text{Me}_4\text{N})_3\{[\text{Tc}_6(\mu\text{-Br})_6\text{Br}_6]\text{Br}_2\}$ at 293 and 78 K, respectively; (*c, d*) $(\text{Bu}_4\text{N})_2[\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6]$ at 293 and 78 K, respectively.

Figure 8. EPR spectra:^{28,29} (*a, b*) $(\text{Bu}_4\text{N})_3\{[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_2]\text{Cl}_2\}$ at 300 and 78 K, respectively; (*c–e*) $(\text{FeCp}_2)_3\{[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_2]\text{Cl}_2\}$ at 300, 78 and 4 K, respectively; and (*f*) $(\text{FeCp}_2)_2[\text{Re}_2\text{Br}_8]$ at 300 and 78 K, respectively.

analogously to that for d^4-d^5 complexes). Thus, magnetochemical experiments show that further refinement of theoretical MO schemes is required.

Such refinements have been carried out and reported.^{18,34,64} According to the results obtained, the experimental magnetic and structural properties of trigonal-prismatic clusters are not contradictory to the idea that there is an MO with a'_1 symmetry between the HOMO and the LUMO of these clusters. This orbital, composed mainly of diffuse $5s$ ($5p$) orbitals of the Tc atoms, is a $2\sigma_g$ bonding orbital in the direction of both vertical and horizontal $\text{M}-\text{M}$ bonds in the metal core of the clusters (see Fig. 1 *d*). In other words, it seems likely that EH calculations^{34,62,63} overestimate the interaction of δ^* and π^* MOs of the dimers in horizontal directions and underestimate the extent of participation of the $5s$ and $5p_z$ AOs in the formation of multiple $\text{M}-\text{M}$ bonds.

In conclusion of this Section let us consider the interpretation of magnetic and other physicochemical properties of certain trigonal-prismatic technetium clusters. For instance, the analysis of the magnetic susceptibility of the cluster $(\text{Me}_4\text{N})_2$.

$[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_6]$ (see Table 8) shows that it obeys the Curie–Weiss law; a weak signal with a relative intensity of 0.2 of that of the $[\text{Tc}_6\text{X}_{14}]^{3-}$ signal and $g_{\text{eff}} \approx 1.97$ is observed in the EPR spectra of $[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_6]^{2-}$, which means that the compound under consideration is paramagnetic.³⁴ Since the $[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_6]^{2-}$ ion has an even number of ‘metallic’ electrons, paramagnetic properties can be manifested if the ground electron state is a triplet. Weak EPR signals and small μ_{eff} values as compared to those expected from the theory for the triplet state suggest that only a part of $[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_6]^{2-}$ clusters is paramagnetic in real crystals. Assuming that the relative intensity of the EPR signal (0.2) corresponds to the portion of triplet paramagnetic clusters, one can evaluate the magnetic moment of the hypothetical paramagnetic cluster using the formula $\mu^2 = \mu_{\text{eff}}^2/0.2$ (see Ref. 33); the result obtained ($\mu = 2.77 \mu_B$) is rather close to the theoretical magnetic moment of a triplet species with $g_{\text{eff}} = 1.97$. Attempts to explain experimentally observed temperature dependences of the magnetic susceptibility and intensity of the EPR signal by the influence of the Boltzmann population of the triplet excited state, intermolecular exchange interactions or splitting of the triplet state levels in the crystal field have failed.

The simultaneous presence of singlet and triplet $[\text{Tc}_6(\mu\text{-Cl})_6\text{Cl}_6]^{2-}$ clusters in crystals can be explained by sensitivity of the multiplicity of the ground state of the cluster to slight changes in its structure. In real crystals, a transition from the singlet ground state of the cluster to its triplet state can occur due to the presence of defects (vacancies, dislocations, disorder in the ligand environment, etc.) or, which is more probable in our opinion,⁶⁴ due to fast kinetic S – T exchange with involvement of delocalised MOs formed mainly by the $5s(5p)$ orbitals of the Tc atoms.

The latter assumption is also supported by the long-wave IR spectra of trigonal-prismatic technetium clusters (Fig. 3) and unusual physicochemical properties of clusters with ferrocenium cations. In fact, the properties of the last-mentioned compounds taken altogether can be explained^{28,29} as a result of the formation of conduction bands and, perhaps, heavy-fermionic bands formed involving delocalised $5s(5p)$ orbitals of the Tc atoms and $4s$ orbitals of the Fe atoms of ferrocenium cations. The values of the g -factor in the EPR spectra of these compounds, close to that of the free electron, metallic type of the temperature dependence of conductivity, and unusual temperature dependence of the Mössbauer and X-ray photoelectron spectra are evidence for the formation of such bands. A more detailed theoretical interpretation of these properties will be given in Section VI of this review.

Tetragonal-prismatic clusters. This group comprises the following compounds: $\{[\text{Tc}_8(\mu\text{-Br})_8\text{Br}_4]\text{Br}\} \cdot 2\text{H}_2\text{O}$, $[\text{H}(\text{H}_2\text{O})_2] \cdot [\text{Tc}_8(\mu\text{-Br})_8\text{Br}_4]\text{Br}$, $[\text{H}(\text{H}_2\text{O})_2]_2\{[\text{Tc}_8(\mu\text{-Br})_8\text{Br}_4]\text{Br}_2\}$, $(\text{Bu}_4\text{N})_2 \cdot \{[\text{Tc}_8(\mu\text{-Br})_8(\text{Br}, \text{I})_4]\text{I}_2\}$, $(\text{FeCp}_2)_2\{[\text{Tc}_8(\mu\text{-Br})_8\text{Br}_4]\text{Br}_2\}$. Clusters belonging to this type are close in structure to the trigonal-prismatic ones. Their major distinction lies in the fact that in this case the metal core of the cluster is a prism with a rhombus in its base (Fig. 1e). According to the conventional count rule of valence electrons in clusters with acido ligands,^{65,66} the first of the above compounds must have 43, while each of the others must have 44 ‘metallic’ electrons. The calculated electronic structure of a cluster with 44 valence electrons is shown in Fig. 4.^{34,62} As can be seen, these compounds must be spin-paired, whereas the $[\text{Tc}_8\text{Br}_{13}] \cdot 2\text{H}_2\text{O}$ cluster must possess a trivial paramagnetism with μ_{eff} corresponding to one unpaired electron. Indeed, the experimental data (see Table 8) show that only the compound $[\text{Tc}_8\text{Br}_{13}] \cdot 2\text{H}_2\text{O}$ has unpaired electrons; other clusters are characterised by TIP with large χ'_M values due to the high molecular weights of the clusters and their structural peculiarities [$\chi'_M(\text{TIP}) = (570 \pm 150) \times 10^6$ CGSE units].

Magnetic properties of the ferrocenium-containing bromide octanuclear cluster are of particular interest. From the data in Table 8 it can be seen that paramagnetism of this compound

obeys the Curie–Weiss law and corresponds to about two unpaired electrons per ferrocenium cation. No EPR signals of this compound are observed either at room temperature or at a liquid nitrogen temperature. Comparison of experimental results with the magnetic properties of ferrocenium-containing trigonal-prismatic chloride clusters considered above and $(\text{FeCp}_2)_2[\text{Re}_2\text{Br}_8]$ (this compound possesses trivial paramagnetism corresponding to about two unpaired electrons per formula unit and signals with $g_{\text{eff}} = 2.003$ are observed in its EPR spectra^{28,29}) shows that: (1) the EPR signals of all compounds in question are not due to localisation of the unpaired electrons on ferrocenium cations (this is also confirmed by the absence of EPR spectra of ferrocenium chloride and other ferrocenium compounds under the same conditions); (2) the EPR signals of the above clusters cannot also be due to localisation of the unpaired electrons on the cluster fragments, since in this case the recorded EPR spectra would be similar to those of the clusters with tetraalkylammonium cations; and (3) the paramagnetism of ferrocenium cations can affect the overall static magnetic susceptibility. Thus, it is most likely that all experimental facts as well as other unusual properties of the compounds under study,^{28,29} are due to fast dynamic electron transfer from the anion to the cation over distances 5 to 6 Å in a band formed by the overlap of upper $ns(np)$ AOs of the cluster anions and ferrocenium cations (see also Section VI).

Octahedral clusters. This group comprises the following compounds: $(\text{Bu}_4\text{N})_2[\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6]$, $[\text{H}_3\text{O}(\text{H}_2\text{O})_3]_2 \cdot [\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6]$ and $[\text{H}_3\text{O}(\text{H}_2\text{O})_3]_2[\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6] \cdot 4\text{H}_2\text{O}$ (see Table 8), which are characterised by octahedral metal cores (see Fig. 1f). However, in contrast to the classical $[\text{M}_6\text{X}_8]^{4+}$ clusters ($\text{M} = \text{Mo}, \text{W}; \text{X} = \text{Cl}, \text{Br}, \text{I}$),⁶⁶ three of the eight positions of the bridging halide ligands in the technetium clusters remain statistically unoccupied. This effect of the distortion of octahedral clusters leads to their stabilisation despite the presence of nine ‘excess’ metallic electrons as compared to the stable electronic configuration of the $[\text{M}_6\text{X}_8]^{4+}$ clusters. The above technetium clusters each contain 33 valence electrons. Their electronic structures are depicted schematically in Fig. 4. It can be seen that these clusters possess trivial paramagnetism with μ_{eff} corresponding to one unpaired electron, which is confirmed by the data in Table 8. A typical EPR spectrum of one of the compounds in question shown in Fig. 7 is characterised by hyperfine structure and $g_{\text{eff}} \approx 2$.

Thus, the magnetochemical studies^{18,34} have shown that it is of crucial importance to know experimental magnetic properties of the maximum possible number of technetium compounds. Magnetochemistry of di- and polynuclear technetium clusters is of particular interest, since the magnetochemical studies of these compounds in combination with other methods of physicochemical analysis and theoretical calculations make it possible, first, to identify the above compounds and reveal the presence of impurities and, second, to study the electronic structure of these clusters that often have no close analogues. It should be noted that in some instances magnetochemical studies in combination with X-ray studies can provide valuable information on the composition and the formal oxidation state of technetium. For example, in such a way the formal charges of cluster anions in the compounds $\{[\text{Tc}_8\text{Br}_4(\mu\text{-Br})_8]\text{Br}\} \cdot 2\text{H}_2\text{O}$, $[\text{H}(\text{H}_2\text{O})_2]\{[\text{Tc}_8\text{Br}_4(\mu\text{-Br})_8]\text{Br}\}$, $[\text{H}_3\text{O}(\text{H}_2\text{O})_3]_2[\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6]$ and $[\text{H}_3\text{O}(\text{H}_2\text{O})_3]_2[\text{Tc}_6(\mu_3\text{-Br})_5\text{Br}_6] \cdot 4\text{H}_2\text{O}$ ^{9,61,67,68} have been determined. In fact, it was impossible to locate hydrogen atoms in the structures of these clusters using the results of X-ray studies only; however, magnetic measurements made it possible to determine the number of unpaired electrons in the anions and, hence, the number of ‘metallic’ electrons, the oxidation state of technetium and thereby the anionic charges in the clusters.

IV. X-Ray photoelectron study of the structure of technetium complexes

1. Binding energies of the core electrons of technetium atoms

Table 9 presents the binding energies of the core electrons (E_b) in technetium clusters and some mononuclear complexes. It is note-

worthy that the lines corresponding to $E_b(\text{Tc } 3d_{5/2})$ are singlets in all compounds; judging by the half-widths of the lines ($l_{1/2} \leq 2.0$ eV), it is impossible to assign them to two or more chemically or structurally nonequivalent types of the Tc atoms. This conclusion is of particular importance for clusters with fractional oxidation state of technetium and $[\text{Tc}_2\text{X}_6]^{2-}$ anions

Table 9. Binding energies of the core electrons (E_b/eV) of Tc and halogen atoms in the X-ray photoelectron spectra of technetium compounds and the effective charges on Tc atoms calculated by the Pauling electronegativities (EN) and EH methods.^{70–74}

Notes. The binding energies are given relative to a peak from adsorbed vapours of diffusion oil [$E_b(\text{Cl } 1s) = 284.3$ eV]. The errors of the binding energy determination are ± 0.2 eV, those of half-widths $l_{1/2}$ are ± 0.1 eV. The binding energies of bridging atoms are underlined. The Z'_{EN} values were determined for compounds with M—M bonds, pertechnetates and binary compounds only from the correlation for mononuclear complexes (curve *a* in Fig. 9). The Z'_{EH} values were determined only for those compounds for which the experimental chemical shifts in X-ray emission spectra^{75–77} and X-ray photoelectron spectra^{70–74} are known.

(see Table 9) in which the Tc atoms formally either have different oxidation state or occupy strongly nonequivalent positions in the structure. Thus, equalisation of the electron density on technetium atoms occurs in all complexes. For most clusters such an equalisation of the electron density due to the formation of multiple M–M bonds could be assumed on the basis of their structural,^{1, 2, 19, 31, 51, 67} magnetic,^{18, 34} spectroscopic^{8, 52, 53, 54} and other physicochemical properties; however, in the case of $[\text{Tc}_2\text{X}_6]^{2-}$ compounds and octanuclear clusters a conclusion that the Tc atoms are structurally nonequivalent would be the most probable.^{19, 57, 67, 69} However, the half-widths of the Tc $3d_{5/2}$ lines in the X-ray photoelectron spectra of these compounds are even smaller as compared to half-widths of the same lines in the spectra of other technetium complexes including mononuclear ones.^{70–74} This indicates strong delocalisation of the electron density in such clusters.

It is known that the chemical shifts in X-ray emission and X-ray photoelectron spectra often correlate with the effective charge on the atom considered.^{75–78} The method based on Pauling electronegativities (EN)^{78–80} is one of the simplest methods used in the effective charge calculations. As a rule, the effective charges (Z_{EN}) calculated using this method correlate almost linearly with binding energies.^{78–80} However, the EN method makes it possible to calculate the Z_{EN} values determined only by conventional valence bonds. If an additional bonding occurs in a compound (*e.g.*, due to hydrogen or π -donor bonds, trans-effect, dative bonds, multiple homopolar bonds, surface effects, *etc.*), then the Z_{EN} values can differ substantially from the experimental effective charges; however, this difference itself will be indicative of such additional effects.^{79, 80} It should be noted^{79, 80} that effective charges determined experimentally by different physicochemical or theoretical methods can differ considerably for the same compound, since each method is characterised by specific ‘sensitivity’ to an effective space region around the atom in question.

Using the EN calculations carried out in the framework of a unified approach,^{70, 74} it has been possible to reveal the reasons for changes in the binding energies of the core electrons of the Tc atoms; this is necessary for determining the oxidation state of technetium in newly synthesised compounds. In other words, this method allows one to understand specific features of the structure of technetium compounds with M–M bonds. It should be noted that, although EN calculations are approximate and arbitrary, this method has some advantages over the traditionally used purely qualitative description of changes in the binding energies of the core electrons depending on the oxidation state of the atom and on the electronegativity of the ligands surrounding this atom, since it relates these two parameters on which the binding energy depends in most instances. Of course, this method lacks sufficient physical grounds characteristic of more rigorous computational methods such as, *e.g.*, the MO LCAO method. However, as a rule, EN calculations make it possible to obtain almost linear correlations between the effective charges^{78–80} and the binding energies, especially, for compounds of similar composition and structure.

The Z_{EN} values were calculated using the following electronegativities (χ) of technetium obtained by interpolating the χ values for Re, Mo, Mn, and Cr in different oxidation states:^{79, 80} $\chi(\text{Tc}^{\text{I}}) = 1.10$, $\chi(\text{Tc}^{\text{II}}) = 1.40$, $\chi(\text{Tc}^{\text{III}}) = 1.60$, $\chi(\text{Tc}^{\text{IV}}) = 1.80$, $\chi(\text{Tc}^{\text{V}}) = 1.95$, $\chi(\text{Tc}^{\text{VI}}) = 2.10$ and $\chi(\text{Tc}^{\text{VII}}) = 2.25$. The Z_{EN} calculations were performed^{70–74} according to the Batsanov procedure^{79, 80} assuming the absence of M–M bonds and other peculiarities of the molecular, crystal and electronic structure capable of affecting the $\chi(\text{Tc})$ value. Thus, it has been assumed *a priori* that in the case of systematic deviations of Z_{EN} values from the experimental effective charges (Z'_{EN}) for the clusters (see Table 9) these deviations must be due to a specific effect of the M–M bonds, since the nature of the M–X bonds in mono-, di- and poly-nuclear clusters remains unchanged in most instances, except for the M– μ -X and M–X_{ax} bonds.

Figure 9. Dependence of the chemical shifts of binding energies of the core electrons [$\Delta E_b(\text{Tc}3d_{5/2})$] in technetium compounds on the effective charge on the Tc atoms (Z_{EN}) calculated by the Pauling electronegativities method (the numbering of points corresponds to that of the compounds in Table 9): (a) correlation for mononuclear complexes (filled circles); (b) correlation for compounds with M–M bonds, di- and polynuclear clusters with acido ligands (open circles) and for binary compounds (sulfides and oxides, open triangles).⁷² For visual aids, correlation lines are drawn.

The dependence of the $\Delta E_b(\text{Tc}3d_{5/2})$ values on Z_{EN} for technetium complexes is shown in Fig. 9. It can be seen that all experimental points fall on two curves. The curve *a* closely resembles an almost straight line and describes the dependence $\Delta E_b(\text{Tc}3d_{5/2}) = \varphi(Z_{\text{EN}})$ for compounds containing no Tc–Tc bonds. The points that obey the dependence $\Delta E_b(\text{Tc}3d_{5/2}) = \varphi'(Z'_{\text{EN}})$ and correspond to the technetium compounds with strong Tc–Tc bonds and to binary compounds fall on curve *b*. The curve *b* in Fig. 9 is much below the curve *a*. This is a direct consequence of neglecting the effect of homopolar multiple Tc–Tc bonds on the electronegativity of Tc atoms, which leads to overestimation of the Z_{EN} values as compared to the ‘true’ effective charges (Z'_{EN}) obtained within the framework of the EN model. Thus, the Z'_{EN} values for technetium clusters can be determined either by introducing some corrections to the technetium electronegativity or from experimental $\Delta E_b(\text{Tc}3d_{5/2})$ values using the correlation curve for mononuclear complexes (see Fig. 9, curve *a*).

Comparison of the curves *a* and *b* in Fig. 9 as well as comparison of Z_{EN} and Z'_{EN} values (see Table 9) shows that the formation of the metal–metal bonds in technetium clusters leads to a decrease in Z_{eff} on the metal atoms. It should be noted that no analogous decrease in Z_{eff} is observed upon the formation of M–M bonds in clusters of other transition *d* elements with similar structures and properties. At first glance, it may appear that this technetium ‘anomaly’ is only a consequence of inadequacy of the procedure for calculating the Z_{EN} values. However, this is not the case. To make sure that Z_{eff} values decrease as the M–M bonds are formed in the case of technetium, it is sufficient to compare the experimental values of changes in the binding energies of the core electrons (ΔE_b) for some transition *d* elements (Table 10); for molybdenum, the opposite is observed (Z_{eff} increase as the M–M bonds are formed), while the Z_{eff} values remain unchanged for rhodium and most of other elements. In fact, from the data in Table 10 and Refs 19, 51, 70–74, 78 and 81–85 it follows that the mean change in the ΔE_b value corresponding to a change of unity in the formal oxidation state of a metal M (M = Tc, Re, and Mo) in complexes with similar stoichiometry and structures is ~ 0.7 eV. Analogous changes in ΔE_b on going from mononuclear d^3 complexes to dinuclear d^4 – d^4 ones are +1.2 eV for Tc, +0.7 eV for Re and –3.3 eV for Mo. Data obtained by X-ray emission spectroscopy^{86–88} allowed one to draw analogous conclusions that Z_{eff} values increase in the case of the Mo–Mo bonds.

Table 10. Chemical shifts of binding energies (ΔE_b) of the core electrons of transition metals in their clusters relative to those of pure metals (averaged values, according to the reported data^{19, 51, 70–74, 78, 81–85}).

Cluster	ΔE_b / eV	Cluster	ΔE_b / eV
[Re ₂ Cl ₈] ^{2–}	3.0	[Ta ₆ Cl ₁₂] ²⁺	2.6
(ReCl ₃) _n	2.7	[Ta ₆ Cl ₁₂] ⁴⁺	2.6
(ReCl ₂) _n	2.0	[Mo ₂ Cl ₈] ^{4–}	3.6
[Nb ₆ Cl ₁₂] ²⁺	2.6	(MoCl ₂) _n	3.3

[Tc ₆ (μ-Cl) ₆ Cl ₆] ^{n–}	1.0	[L ₂ Pd(AcO) ₂] ₂	2.7
[Tc ₂ Cl ₈] ^{2–}	1.9	[Cr ₂ Cl ₉] ^{3–}	2.6
[Tc ₂ Cl ₆] ^{2–}	1.1		

It is clear that in the general case the effective atomic charge must depend on the formal order of the bond between this atom and another atom, since a redistribution of the electron density of valence electrons mostly occurs as the bond order increases. This appreciably changes the conditions of shielding of the positive nuclear charge by outer electrons. Simultaneously, when two atoms approach each other as a result of the increase in the order of the interatomic bond, their inner atomic electron shells must undergo an increasing repulsion, which brings about the opposite result, *viz.*, a decrease in the extent of shielding of the positive nuclear charge due to the formation of the multiple bond. Since each physical method is characterised by specific ‘sensitivity’ to an effective space region around the atom M, the net change in Z_{eff} will strongly depend on many factors and can be either positive or negative, or be equal to zero.

A theoretical explanation for the effect of a decrease in Z_{eff} on the Tc atoms in the formation of M–M bonds consists in the following:⁶⁴ in contrast to clusters of other *d* elements, it is highly probable that the outer 5*s* (5*p*) AOs of technetium clusters participate in the formation of ‘metallic’ bonding MOs. Thus, it has been shown experimentally⁶⁴ and theoretically⁸⁹ that the *a*₁′ MO composed mainly of 5*s* (5*p*) orbitals of six Tc atoms represents the HOMO in the trigonal-prismatic technetium clusters [Tc₆X₁₄]^{3–} (X = Cl and Br) (see also Section III). Since these outer AOs possess an increased capability of shielding the positive nuclear charge, their participation in the formation of the M–M bonds results in a decrease in Z_{eff} . It should be noted that an analogous conclusion that Z_{eff} values of the Tc atoms are decreased upon the formation of M–M bonds was drawn on the basis of analysis of changes in the chemical shifts in the K_{α1} X-ray emission spectra of technetium compounds.^{76, 77}

The effective charge on the Tc atoms have also been evaluated using extended Hückel calculations.^{71–73} This semiempirical MO method allows one to take into account the effect of M–M bonds. Therefore, the effective charge obtained by EH calculations (Z_{EH}) can correlate directly with the chemical shifts in the spectra of Tc compounds without introduction of corrections for the M–M bonds. However, a strong parametrisation effect on the results of calculations hampers the use of EH calculations. To diminish this effect, only the results of calculations for the chloride technetium complexes ([TcCl₆]^{2–}, [Tc₂Cl₈]^{2–}, [Tc₂Cl₈]^{3–}, [Tc₂Cl₆]^{2–}, and [Tc₆Cl₁₄]^{3–}) were used. The more detailed consideration of the general procedure for calculations and parametrisation, and the procedure for determination of the effective charge (Z'_{EH}) using EH calculations and the data of X-ray emission spectroscopy (XES) and X-ray photoelectron spectroscopy (XPES) simultaneously is given in Section V. These values are listed in Table 9.

The dependence of $\Delta E_b(\text{Tc } 3d_{5/2})$ on Z_{EH} is shown in Fig. 10. Comparison of the data in Figs. 9 and 10 and the Z'_{EN} and Z'_{EH} values shows that Z_{eff} calculated by the EN and EH methods differ considerably; however, they are related by an unambiguous monotonic dependence. In addition, common to both mononuclear complexes and clusters is the observed dependence of the $\Delta E_b(\text{Tc } 3d_{5/2})$ values on Z_{EH} rather than on Z_{EN} . This is under-

**Figure 10.** Dependence of the chemical shifts of binding energies of the core electrons $\Delta E_b(\text{Tc } 3d_{5/2})$ in technetium compounds on the effective charge on the Tc atoms (Z_{EH}) calculated by the EH method (the numbering of points corresponds to that of the compounds in Table 9).⁷²

standable since the EH calculations (in contrast to the EN calculations) take into account electronic effects due to the formation of the M–M bonds.

2. Binding energies of the core electrons of halogen atoms

Table 11 lists the binding energies of the core electrons of the halogen atoms [$E_b(\text{X})$] in clusters of transition *d* elements. As can be seen, the $E_b(\text{X})$ values vary depending on the nature of the halogen–metal bonds. For technetium clusters, the smallest $E_b(\text{X})$ values have been found for axial halogen atoms in carboxylate dinuclear complexes with the ‘lantern’-type structure (see Table 9). Since the $E_b(\text{X}_{\text{ax}})$ values are close to analogous values for pure ionic compounds,⁷⁸ it can be assumed that all Tc–X_{ax} bonds are ionic. It should also be noted that these types of bonds of halogen atoms are much weaker due to the trans-effect of multiple metal–metal bonds. Previously,^{78, 84, 85} an analogous phenomenon has been observed experimentally for dinuclear Re and Rh complexes.

Table 11. Binding energies (E_b / eV)^a of the core electrons of halogen atoms in clusters of transition *d* elements (averaged values, according to the reported data^{19, 51, 70–72, 78, 81–85}).

Cluster-forming metal	$E_b(\text{Cl } 3p_{3/2})$			$E_b(\text{Br } 3d_{5/2})$			$E_b(\text{I } 4d_{5/2})$		
	ax	eq	brid-ge	ax	eq	brid-ge	ax	eq	brid-ge

K ^b	197.5	—	—	67.8	—	—	—	—	—

Note. The following notations are used: ax is axial, eq is terminal (equatorial), and br is bridging. ^a The error of binding energy determination is ± 0.4 eV. ^b Potassium halides. The binding energies are given relative to the C1*s* line (284.3 eV).

Figure 11. Binding energy X-ray photoelectron spectra of the core electrons of the halogen atoms in polynuclear (1, 3, 5) and mononuclear (2, 4) chloride (a), bromide (b) and iodide (c) complexes: (1) $(\text{Me}_4\text{N})_2[\text{Tc}_6\text{Cl}_{12}]$; (2) $\text{K}_2[\text{TcOCl}_5]$; (3) $[\text{Tc}_8\text{Br}_{13}] \cdot 2\text{H}_2\text{O}$; (4) $(\text{NH}_4)_2[\text{TcBr}_6]$; and (5) $[\text{Tc}_8\text{I}_{13}] \cdot 2\text{H}_2\text{O}$. Dashed lines represent the deconvolution of experimental spectra by the least squares method assuming a Lorentzian shape of single peaks.

The $E_b(\text{X})$ values for the equatorial (terminal) halogen atoms in the technetium clusters correspond to the binding energies of the core electrons of the terminal halogen atoms in mononuclear halide complexes (see Table 9). The $\text{Tc}-\text{X}_{\text{eq}}$ bond lengths are also close to those of the $\text{Tc}-\text{X}$ bonds in halide Tc^{V} and Tc^{IV} complexes.^{1,2,31,90,91} The $E_b(\text{X})$ values for these types of halogens indicate weak ionicity of the $\text{Tc}-\text{X}_{\text{eq}}$ bonds.⁷⁸

The largest $E_b(\text{X})$ values are observed for the bridging halogen atoms in polynuclear clusters (see Table 9); they are close to the $E_b(\text{X})$ for the halogen elements,⁷⁸ which indicates that the $\text{Tc}-(\mu\text{-X})$ bonds are covalent.

As can be seen from the data presented, the structure and composition of technetium complexes can be qualitatively and semiquantitatively judged from the $E_b(\text{X})$ values of the halogen atoms. Indeed, the structures of polynuclear technetium clusters contain all three types of halogen atoms, whereas two lines corresponding to $E_b(\text{X})$ of the terminal and bridging halogen atoms with relative intensities proportional to the stoichiometric amount of these halogen atoms in the cluster are observed in the X-ray photoelectron spectra of these compounds (Fig. 11). It is likely that the peaks corresponding to axial halogen atoms or halide ions are not observed in the spectra due to their low relative intensity.

The 'sensitivity' of the chemical shifts in the X-ray photoelectron spectra to the coordination type of halide ligands can serve as a convenient tool for tentative analysis of the structure. In some instances, the data obtained by X-ray photoelectron spectroscopy significantly complement the information obtained by X-ray analysis and chemical analysis. Thus, an attempt to establish unambiguously the exact stoichiometric composition of a bromide–iodide octanuclear technetium cluster using X-ray analysis⁹² and chemical analysis has failed. Only additionally taking the X-ray photoelectron spectra has made it possible to establish the stoichiometry, composition and structure of the cluster $(\text{Bu}_4\text{N})_2[\text{Tc}_8(\mu\text{-Br})_4(\mu\text{-I})_4\text{Br}_2\text{I}_2]_2$ (see Table 9).

3. Binding energy X-ray photoelectron spectra

The binding energy X-ray photoelectron spectra of a number of technetium compounds have been considered.^{71–73} The experimental spectra have been compared with the results of theoretical SCF-X α -SW calculations for K_2TcCl_6 ⁹³ and $\text{K}_3\text{TcCl}_8 \cdot 2\text{H}_2\text{O}$.⁹ It has been shown that at a qualitative level the calculations represent satisfactorily the fine structure of X-ray photoelectron spectra in most cases. However, the spectra of solids are not always well resolved due to line broadening. The approximate

character of the theoretical calculations makes it possible, as a rule, to determine only the order in which the MOs are arranged on the energy scale rather than the exact absolute values of their vertical ionisation potentials. Despite these drawbacks the following qualitative conclusions were drawn:^{71–73}

1. The high-lying MOs ($\delta_{\text{M}-\text{M}}$ and $\delta^*_{\text{M}-\text{M}}$ orbitals according to the calculations and EPR spectroscopy data^{9,52,53,94}) appear to be separated in energy from other MOs on going from $[\text{TcCl}_6]^{2-}$ to $[\text{Tc}_2\text{Cl}_8]^{3-}$.

2. Replacement of Cl atoms by μ -bridging acetate ions results in a higher degree of mixing in energy between the π -components of the $\text{M}-\text{M}$ and $\text{M}-\text{L}$ bonds; however, the $\delta_{\text{M}-\text{M}}$ and $\delta^*_{\text{M}-\text{M}}$ components remain (though to a lesser extent) separated from other MOs. This is probably due to the formation of cyclic closed π -systems of the type

3. Replacement of the axial ligands in the $\{[\text{Tc}_2(\text{A}-\text{CO})_4\text{Cl}_n]^{(n-1)-} (n = 1 \text{ or } 2)\}$ anion by Br^- does not result in considerable changes in the patterns of the binding energy spectra, which indicates a small contribution of AOs of the axial ligands to the $\delta_{\text{M}-\text{M}}$, $\pi_{\text{M}-\text{M}}$ and $\pi_{\text{M}-\text{L}}$ MOs, since the axial ligands form mainly ionic bonds with the Tc atoms and only due to the trans-effect^{78,84,85} do they somewhat weaken the σ component of the $\text{M}-\text{M}$ bonds, which is hardly observed in this spectral region.

4. There is even greater separation in energy of the δ component of the $\text{M}-\text{M}$ bond from other types of MOs in the complex $\text{K}_2[\text{Tc}_2\text{Cl}_6]$, which is due to specific features of the bond formation in d^5-d^5 complexes with an idealised D_{4d} symmetry. According to the data reported in Ref. 57, the formation of δ bonds in $\text{K}_2[\text{Tc}_2\text{Cl}_6]$ occurs due to 'cross' overlap of the $4d_{xy}$ and $4d_{x^2-y^2}$ orbitals of the Tc atoms. This results in considerable decrease in the vertical ionisation potential of δ MO, since the $4d_{x^2-y^2}$ AOs of technetium participate mainly in the formation of the σ bonds with ligands. It should be noted that this energy separation of the σ MO is not observed in the complex $\text{K}_2[\text{Tc}_2\text{Br}_6]$,¹⁸ since the Br^- ions, being ligands of weaker field and lower electronegativity as compared to the Cl^- ions, do not cause such a substantial decrease in the vertical ionisation potential of δ MOs.

5. The formation of high-lying MOs in polynuclear clusters occurs mainly involving δ MOs and π MOs of dinuclear clusters,^{2,51,62,63,64} which results in an increase in their vertical

ionisation potentials. Therefore, in most cases no low-energy lines corresponding to separated high-lying MOs are observed in the X-ray photoelectron spectra of polynuclear clusters and lines corresponding to all components of the M – M bonds are strongly mixed in energy. The exception is the complex $(\text{Me}_4\text{N})_2[\text{Tc}_6\text{Cl}_{12}]$ and clusters with ferrocenium cations (peaks near the Fermi level are observed in their X-ray photoelectron spectra).²⁹ This is probably due to the formation of a conduction band in these compounds involving high-lying $5s(5p)$ orbitals of the Tc atoms.

V. Chemical shifts in X-ray K_α emission spectra of technetium compounds

In the preceding Section we have considered the X-ray photoelectron spectra of technetium compounds^{70–74} and demonstrated their efficiency for studying the electronic structure of clusters. Here, the results of joint XES and XPES studies of the electronic structure of technetium compounds are presented and the experimental results obtained are compared with those of semiempirical EH calculations.

Table 12 presents the experimental and theoretical results.^{75–77} The interdependence of the experimental chemical

Table 12. Experimental values of the chemical shifts in the X-ray emission spectra ($\delta E_{\text{K}_\alpha}$) and X-ray photoelectron spectra ($\Delta E_{3d_{5/2}}$) spectra of technetium compounds (with respect to metallic Tc) and the calculated effective partial charges on Tc atoms.⁷⁷

^a Results of EH calculations. ^b These compounds were used to calculate C_{nl} and δ_{nl} in Eqn (1). The partial charges Q_{nl} and q_l were determined from Eqns (1) and (2) using the Z_{EH} effective charges and the Hartree–Fock approximation, respectively (see text).

Figure 12. Correlation between the chemical shifts in the $K_{\alpha 1}$ X-ray emission spectra ($\delta E_{K_{\alpha 1}}$) and X-ray photoelectron spectra ($\Delta E_{3d_{5/2}}$) of technetium compounds⁷⁷ (the numbering of points corresponds to that of compounds in Table 12). The scatter of experimental data is shown by dashed lines.

shifts in the X-ray emission (δE) and X-ray photoelectron (ΔE) spectra is shown in Fig. 12.

According to the effective ion model,⁹⁸ the δE and ΔE values depend on the effective charge of the central atom (Q) as follows:

$$\delta E = C_{5s}Q_{5s} + C_{4d}Q_{4d} + Q_{5s}(Q_{5s} - 1)\delta_{5s} + Q_{4d}(Q_{4d} - 1)\delta_{4d} + Q_{5s}Q_{4d}\delta_{5s,4d}; \quad (1)$$

$$\Delta E = Q_{5s}\Delta E_{5s} + Q_{4d}\Delta E_{4d} + Q_{5s}(Q_{5s} - 1)\Delta_{5s} + Q_{4d}(Q_{4d} - 1)\Delta_{4d} + Q_{5s}Q_{4d}\Delta_{5s,4d} + \varphi_M, \quad (2)$$

where Q_{nl} is the partial charge remaining on an atom after the nl -electron has been involved in the formation of a bond, $C_{nl}(\Delta E_{nl})$ is the line shift in the X-ray emission spectrum (or in the X-ray photoelectron spectrum) after abstraction of the nl -electron; δ and Δ are the respective corrections, which correspond to the changes in the electrostatic energy of electrons due to the emission of an X-ray quantum and φ_M is the Madelung constant.

Since for transition d elements $Q = Q_{ns} + Q_{(n-1)d} + Q_{np}$ and Q_{np} is small and remains virtually constant on going from one compound to another (see, e.g., the data of EH calculations for Tc compounds in Table 2), it can be neglected. Then, in the general case, δE and ΔE can be represented as functions of $Q_{5s} + Q_{4d}$. The experimental dependences of δE and ΔE on $Q_{5s} + Q_{4d}$ (obtained from EH calculations) have been reported.⁷⁷ It has been shown that the dependence $\Delta E = f(Q_{5s} + Q_{4d})$ is close to a linear one, whereas the dependence $\delta E = \varphi(Q_{5s} + Q_{4d})$ is less unambiguous. The values of the coefficients C_{5s} , C_{4d} , δ_{5s} , δ_{4s} and $\delta_{5s,4d}$ were determined after substituting the $Q_{5s} + Q_{4d}$ values taken from EH calculations into Eqn (1) and solving the system of five linear equations with five unknowns.⁷⁷ To reduce systematic errors due to inaccuracy in the parametrisation, the data calculated only for the chloride compounds $[\text{TcCl}_6]^{2-}$, $[\text{Tc}_2\text{Cl}_8]^{3-}$, $[\text{Tc}_2\text{Cl}_8]^{2-}$, $[\text{Tc}_2\text{Cl}_6]^{2-}$ and $[\text{Tc}_6\text{Cl}_{12}]^{2-}$ were used.⁷⁷ For comparison, analogous coefficients⁷⁷ calculated by the Hartree–Fock SCF method for the isolated Tc atoms in the approximation of two alternative

configurations ($4d^65s^1$ and $4d^5s^2$) have also been used. It has been shown that, at least except for sign, the values of all the coefficients in question (C_{5s} , C_{4d} , δ_{5s} , δ_{4d} and $\delta_{5s,4d}$) are close. This indicates indirectly that EH calculations provide a good basis for theoretical description of δE at qualitative and semiquantitative levels.

A one-to-one correspondence between the ΔE and $Q_{5s} + Q_{4d}$ values has been established by extrapolating the $\Delta E = f(Q_{5s} + Q_{4d})$ dependence to all other technetium compounds for which the X-ray emission and X-ray photoelectron spectra have been measured.⁷⁷ At this point, it has been assumed that φ_M is independent of $Q_{5s} + Q_{4d}$ or varies monotonically as the latter parameter varies; this has been strictly substantiated only for compounds with similar structure and composition. Then, substituting the $Q_{5s} + Q_{4d}$ value found into Eqn (1) and using the coefficients of this equation calculated in the EH approximation, one could calculate the Q_{5s} , Q_{4d} and Q_{4p} partial charges (see Table 12). To pass to another, more physically well-founded scale of effective charges, the values of coefficients of Eqn (1) calculated by the Hartree–Fock method were used assuming that Z_{eff} of technetium ($Z_{\text{eff}} = q_s + q_d$) in KTcO_4 coincides with the effective charge of ruthenium in RuO_4 and is equal to 1.71.^{96,97} From the fact that the metal atoms in both d^0 complexes have the same oxygen environment and that the electronegativities of the Tc and Ru atoms are almost equal it follows that these charges are approximately equal.^{79,80} Having calculated the partial charges q_s and q_d on technetium atoms in KTcO_4 from Eqn (1) and assuming that the found value of the ratio Q_{5s}/q_s (3.57) remains almost constant, it was also possible to calculate⁷⁷ the q_s and q_d values for all other technetium compounds for which EH data are available (see Table 12). These calculations have shown that all the experimental results can be described by the following equation:

$$\delta E = (37.5 \pm 2.1) - (156.0 \pm 2.9)(q_s + q_d). \quad (3)$$

Since the correlation coefficient of the linear dependence (3) for nine experimental points is 0.999, it was assumed that δE for all other compounds is also described by this equation. Simultaneous solution of Eqns (1) and (3) performed under this assumption allowed one to find q_s and q_d values for all other technetium compounds. The results obtained⁷⁷ are listed in Table 12. The effective charges on the Tc atoms calculated using the two different procedures differ considerably in magnitude. However, all main tendencies and regularities of changes in Z_{eff} on going from one compound to another are the same for both scales of effective charges.^{75–77}

1. The Q_{5p} values and their changes for all compounds are small, which indicates that the extent of participation of the $5p$ AO in the formation of chemical bonds is small. The Q_{5s} (q_s) and Q_{4d} (q_d) values decrease regularly as the formal oxidation state of technetium decreases, which points to increasing covalency of chemical bonds in this series of compounds.

2. A tendency for Z_{eff} to increase with increase in the Tc oxidation state, total electronegativity of ligands in the series $\text{F} > \text{O} > \text{Cl} > \text{Br} > \text{S} \approx \text{I}$ and the polarising capacity of cations $Z_{\text{cat}}/R_{\text{cat}}$ is observed for compounds containing no $\text{M}–\text{M}$ bonds.

3. A ‘loss of sensitivity’ of Z_{eff} to the electronegativity of ligands, the nature of cation and the formal oxidation state of technetium with increase in the number of electrons participating in the formation of $\text{M}–\text{M}$ bonds is observed for compounds with $\text{M}–\text{M}$ bonds. In some cases the Z_{eff} value in technetium clusters changes upon insignificant change in the formal oxidation state of Tc or in the structure of the cluster (see, e.g., compounds **41** and **42**, **43** and **44**, **1** and **3**, **5'** and **5''**, and **25** and **3'** in Table 12).

The partial charges of ligands in technetium compounds (Table 13) have been determined from the analysis of $q_s + q_d$ values, comparison of these values with $Z_{\text{eff}}(\text{Ru})$ ^{96,97} and using the dependence of $q_s + q_d$ on Z_{EH} for the ligands.⁷⁷

The algebraic sums of charges on all atoms in Tc compounds have been calculated from the data in Tables 12 and 13.⁷⁷ These

Table 13. Partial charges on ligands and cations in technetium compounds.⁷⁷

Ligand, cation	Charge	Ligand	Charge	Ligand	Charge

O _{eq} {[TcO ₄]} [−]	−0.64(1)	Br _{eq}	−0.32	CO	−0.03

Note. The last significant figures of the maximum deviations from average charge values are given in parentheses.

sums differ considerably from zero for binary compounds, which is probably associated with great differences in the nature of ligand bonding with technetium (apparently, one cannot use the same $q_s + d$ value for the ligands in all these compounds). Systematic deviations of the sums of charges from zero are observed for compounds with M–M bonds (di- and polynuclear clusters). *A priori* this may be due either to the same reasons as for binary compounds or to systematic changes (as a rule, a decrease) in Z_{eff} of the Tc atoms caused by the M–M bonds. The latter assumption seems to be more reasonable, since X-ray photoelectron spectra of technetium compounds indicate that Z_{eff} of halide ligands of the same structural type are constant irrespective of the presence of M–M bonds in the compounds^{67,69,81} (see Section IV).

The averaged deviations of $\Sigma q_s + d$ from zero calculated per two Tc atoms using the above procedure for di- and polynuclear clusters of different structural types are equal to −0.22 (dinuclear d^4 – d^4 clusters), −0.44 (dinuclear d^4 – d^5 clusters), −0.80 (dinuclear d^5 – d^5 clusters), −0.53 (trigonal-prismatic clusters) and −0.17 (tetragonal-prismatic clusters).⁷⁷

As can be seen, the decrease in Z_{eff} due to the formation of M–M bonds is a maximum in the case of dinuclear d^5 – d^5 clusters. This correlates with the shortest M–M distance (2.04 Å) in their molecules.⁵⁷ The influence of relatively long M–M bonds (~ 2.6 Å)² on the Z_{eff} value is minimal. It is likely that the effect of multiple M–M bonds in polynuclear prismatic clusters is more pronounced than, *e.g.*, in d^4 – d^4 complexes, owing to the additional contribution from several weaker M–M bonds.

Thus, the results obtained^{75–77} confirm again that the formation of M–M bonds may cause changes in the effective charges on the metal atoms.^{3,51,70–73,87,88} We believe that this phenomenon is due to the specific effect of the system of M–M bonds on the electronic structure of clusters. Therefore, the M–M bonds in technetium clusters (as well as in a number of clusters of other elements) can be considered as specific additional ligands affecting Z_{eff} on the metal core atoms of the clusters.

Later, another approach to the interpretation of the data on chemical shifts in the $K_{\alpha 1,2}$ and $K_{\beta 1,3}$ lines in X-ray emission spectra of molybdenum, technetium and ruthenium compounds was proposed.^{75–77} These results were generalised by Batrakov *et al.*⁹⁸ who have analysed two independent sets of experimental parameters corresponding to $\delta K_{\alpha 1,2}$ and $\delta K_{\beta 1,3}$ in contrast to the chemical shifts for technetium compounds that we have considered previously. However, a considerable increase in the number of parameters directly determined in the experiments does not allow one to interpret the experimental results unambiguously. Thus, *e.g.*, Batrakov *et al.*⁹⁸ had to make some assumptions on the electron configuration of the reference compound (TcO₂ in the

ionic state 1+ or 3+ has been used as reference compound for technetium compounds). However, from the above discussion it follows that it is just technetium dioxide that can scarcely be used as reference compound, because some of its electronic properties make it different from most other technetium compounds (see also Section IV, Tables 9 and 12 and Figs 9 and 12). Moreover, our calculations performed using a representative random sample of experimental $\delta K_{\alpha 1,2}$ and $\delta K_{\beta 1,3}$ values taken from Ref. 98 and the approach described above in this Section showed that the final conclusions do not differ fundamentally from those drawn in Ref. 77. In this connection it is not expedient to consider the data and, especially, the interpretation of results obtained by Batrakov *et al.*⁹⁸ in detail. We will restrict ourselves to major conclusions only.

The diagram of the chemical shifts of the centres of gravity of the Tc $K_{\alpha 1,2}$ and Tc $K_{\beta 1,3}$ doublets for technetium compounds (see Ref. 98) is shown in Fig. 13. As can be seen, in the coordinate system used all experimental points fall on five curves corresponding to different types of technetium compounds, *viz.*, oxides, iodides, bromides, chlorides and clusters (including metallic technetium). It should be noted that similar dependences have been obtained for technetium compounds⁹⁸ in the coordinates of partial charges Q_{4d} and Q_{5s} which were determined using the approach described above. It was confirmed that the formation of M–M bonds (M = Tc, Mo) results in changes in the effective charges on the atoms of these metals, which is also an important result of this study.

Figure 13. Diagram of the chemical shifts of the centres of gravity of the Tc $K_{\alpha 1,2}$ and Tc $K_{\beta 1,3}$ doublets in the X-ray emission spectra for technetium compounds according to Batrakov *et al.*⁹⁸ The numbering of points corresponds to those of compounds in Tables 9 and 12; the point No. 64 corresponds to (Me₄N)₂[TcI₆].

VI. Compounds with ferrocenium cations

Considering various methods of investigation of technetium clusters, we shall dwell on the ⁵⁷Fe Mössbauer spectroscopy of ferrocenium-containing complexes. Table 14 presents the parameters of the ⁵⁷Fe Mössbauer spectra of compounds with ferrocenium cations. As can be seen, the parameters of the Mössbauer spectra depend strongly on temperature and the chemical nature of the anion. At room temperature, doublet (singlet for two compounds) spectra are observed; the chemical shifts δ in the

^a The specimen was preliminarily frozen to 5 K. ^b The specimen was preliminarily frozen to 78 K.

spectra depend slightly on the nature of the anion and the quadrupole splitting A decreases for the anions in the series: $[\text{TcO}_4]^- > [\text{Re}_2\text{Br}_8]^{2-} > [\text{Tc}_6\text{I}_{14}]^{3-} > [\text{PF}_6]^{2-} > [\text{TcCl}_6]^{2-} > [\text{Tc}_6\text{Cl}_{14}]^{3-} \approx [\text{Tc}_8\text{Br}_{14}]^{2-}$. Spectral line broadening is observed as the temperature decreases. Additional lines appear in the spectra of compounds with the $[\text{TcCl}_6]^{2-}$, $[\text{Tc}_6\text{Cl}_{14}]^{3-}$ and $[\text{Tc}_8\text{Br}_{14}]^{2-}$ anions; the parameters of one of these lines are close to those of the Fe^{2+} signal in pure ferrocene³⁰ (see Table 14 and Fig. 14). For cluster anions, this is observed even at 78 K, whereas for ferrocenium hexachlorotechnetate(IV) this is observed only at 5 K (at 78 K, the spectrum of this compound is appreciably broadened and can be deconvoluted into two doublets with small A by the least squares method assuming a Lorentzian lineshape). The spectrum of ferrocenium pertechnetate at 5 K is a broad singlet; however, attempts at its deconvoluting into components failed.

Physicochemical studies^{28, 29} of compounds with ferrocenium cations (see also Sections II–IV) allow one to draw the following principal conclusions:

1. All compounds possess anomalous peculiarities of electronic structure due to the changes in their physicochemical properties with time and temperature.

2. Anomalous properties increase for the series of anions as follows: $[\text{TcO}_4]^- \approx [\text{Re}_2\text{Br}_8]^{2-} \approx [\text{Tc}_6\text{I}_{14}]^{3-} < [\text{TcCl}_6]^{2-} < [\text{Tc}_6\text{Cl}_{14}]^{3-} < [\text{Tc}_8\text{Br}_{14}]^{2-}$.

The following explanation of this anomaly was proposed.^{28, 29} It was shown⁶⁴ that the probability of participation of outer ns (np) technetium (rhenium) AOs in the formation of coordinate bonds formed by this atom increases in the above series of anions (except for the iodide cluster). This is due to the fact that the $4d$ AOs become destabilised to a greater extent than diffuse $5s$ ($5p$)

AOs capable of effective interaction at comparatively long distances ($> 2.5 \text{ \AA}$) as the formal oxidation state of technetium (the effective charge on its atoms) decreases. There are also low-lying MOs formed by diffuse $4s$ ($4p$) orbitals of Fe atoms in ferrocenium cations.⁹⁹ An approach of Fe and Tc atoms within a distance of $\sim 5 \text{ \AA}$ (it is this distance that is observed in ferrocenium complexes of technetium) must result in direct electron overlap of ns (np) orbitals of the Fe and Tc atoms and, hence, in the formation of conduction bands. Indeed, all compounds possess temperature-independent semiconductor-type conductivity. This indicates that the Fermi levels of the ferrocenium cations and technetium (rhenium) anions in these compounds are inside or near the sp conduction bands. This may result in tunnelling of the valence sp electrons between the anions and cations at frequency ω . Such a dynamic electron transfer along the anion–cation chains can be detected using only those physical methods that have a better time resolution than the average lifetime of the valence electron in the proximity of the atom under observation. In other words, these changes can be detected using photoelectron spectroscopy with a time resolution (τ) of $10^{-16} - 10^{-17} \text{ s}$, whereas only an averaged picture can be obtained using such integral methods as static magnetic susceptibility, heat capacity and conductivity measurements, X-ray analysis, *etc.* The results obtained by Mössbauer, EPR, and IR spectroscopy with a time resolution of 10^{-7} s , $\sim 10^{-9} - 10^{-10} \text{ s}$ and $10^{-11} - 10^{-13} \text{ s}$, respectively, will be intermediate due to line broadening in spectra caused by dynamic electron transfer and vibronic interaction.

In the context of the proposed explanation of the properties of compounds with ferrocenium cations,^{28, 29} attention must be focused on the magnetic properties (see Sections III and IV) and changes in the photoelectron spectra of these compounds at low

Figure 14. ^{57}Fe Mössbauer spectra of: (a) FeCp_2 at 300 K; (b, c) $(\text{FeCp}_2)_3 \cdot \{[\text{Tc}_6\text{Cl}_6(\mu\text{-Cl})_6]\text{Cl}_2\}$ at 300 and 80 K; (d, e) $(\text{FeCp}_2)_2[\text{PF}_6]$ at 300 and 80 K.

temperatures. Thus, Table 9 presents the experimental parameters of X-ray photoelectron spectra of several technetium and rhenium compounds (see also Refs 28 and 29). From these data it follows that the X-ray photoelectron spectra of the compounds with ferrocenium cations recorded at room temperature for the first time do not differ fundamentally from those of other technetium and rhenium compounds. All major spectral regularities correspond to those described above (see Sections IV.1–IV.3). The only exception is the increased binding energy corresponding to the $\text{Tc } 3d$ line in the case of $(\text{FeCp}_2)_2[\text{Tc}_8\text{Br}_{14}]$. However, anomalous electron emission is observed at a temperature of about 100 K instead of conventional X-ray photoelectron spectra of the compounds with ferrocenium cations and $[\text{TcCl}_6]^{2-}$, $[\text{Tc}_6\text{Cl}_{14}]^{3-}$ and $[\text{Tc}_8\text{Br}_{14}]^{2-}$ anions. No temperature dependence of spectra of other compounds has been found.

The phenomenon of anomalous electron emission consists in the following.^{28,29} The lines of the conventional X-ray photoelectron spectrum (Fig. 15) become diffuse and disappear as the temperature of the specimens decreases below a specific threshold value (~ 100 K). The spectrum of inelastic electrons observed simultaneously with the lines of the X-ray photoelectron spectrum loses its true shape and also disappears against the background of a group of very intense lines; the structure and number of these lines vary substantially on fast freezing of the specimen. The amplitudes of the most intense peaks are approximately 2 orders of magnitude larger than the intensities of the lines in the conventional X-ray photoelectron spectrum, which usually results in overloading of the detector even at the minimum power of the X-ray radiation source (100 W for an HP 5950A spectrometer). Further cooling of the specimens leads to substantial increase in the upper boundary kinetic energy (UBKE) of emitted electrons (from 10 to ≥ 1500 eV). The UBKE changes analogously with the increase in duration of exposure of the specimens in which approximate temperature equilibrium was reached to X-ray radiation. The UBKE decreases slowly until the anomalous emission ceases and the conventional X-ray photoelectron spectrum recovers as the specimens undergo slow unfreezing. The

Figure 15. Dynamics of anomalous electron emission for a $(\text{FeCp}_2)_2[\text{Tc}_8\text{Br}_{14}]$ specimen preliminarily cooled to ~ 100 K after switching on the X-ray radiation source (at a beam power of 200 W) during data collection (1000 eV/256 channels) in one scan (data collecting time of 210 s). Start of data collection after switching on the X-ray radiation source: (a) 0 min; (b) 4 min.; and (c) 8 min. (Here E is the kinetic energy of electrons).^{28,29}

qualitative and quantitative spectral pattern is reproduced within short time intervals (~ 5 min) under conditions of relative stabilisation of the specimen temperature. To a first approximation, the intensities of the peaks were found to be proportional to the power of the X-ray tube of the spectrometer. With an accuracy of ~ 0.1 s, no time lag was found on switching off the X-ray tube. The kinetic energy of emitted electrons can exceed the energy of exciting X-ray quanta (1486.6 eV).

The second peculiarity of the X-ray photoelectron spectra of compounds with ferrocenium cations is that the spectra recorded repeatedly at room temperature (after freezing of the specimens to 78 K followed by their unfreezing) can differ from those recorded initially at the same temperature. These differences include^{28,29} the following features: (1) the peaks corresponding to the core electrons of the Fe atoms correspond in the repeatedly recorded spectra to three nonequivalent states of these atoms {compounds with $[\text{Tc}_6\text{Cl}_{14}]^{2-}$ and $[\text{Tc}_8\text{Br}_{14}]^{2-}$ anions} and (2) the same holds for the peaks corresponding to the core electrons of the halogen atoms {the compound with the $[\text{TcCl}_6]^{2-}$ anion}. These data could indicate that the compounds with ferrocenium cations are initially in the metastable state and are stabilised on freezing. However, the temperature dependences of the heat capacity and the magnetic susceptibility of the compounds studied show that no phase transitions occur in the temperature range from 300 to 100 K. Thus, the effects observed are due to pure electronic peculiarities of the structure of the compounds under consideration. It should be noted that the Mössbauer and IR spectra (see Sections II and VI, respectively) of the specimens that were preliminarily frozen repeatedly recorded at room temperature also differ somewhat from those recorded initially.[†]

Phenomena similar to that observed^{28,29} are known: exoelectron emission (see, e.g., Ref. 100) and mechanoemission.¹⁰¹ It is likely that the charges accumulated in the specimen subjected to X-ray radiation are to a great extent responsible for the appear-

[†] Changes in the specimens caused by freezing cannot be due to any chemical processes, since the specimens are stable towards water sorption on the surface; no changes in the chemical composition were found.^{28,29}

ance of anomalous electron emission.⁷⁸ The peculiarities of the low-temperature X-ray photoelectron spectra of some compounds with ferrocenium cations observed in the experiments may be due to the multiphoton photoeffect similar to the laser effect.^{28, 29}

As has been mentioned in Section III, the magnetic properties of compounds with ferrocenium cations are also anomalous. In fact, as can be seen from the data in Table 8, in all cases there is more than one unpaired electron per ferrocenium cation. It is obvious that the effective number of unpaired electrons may be increased due to the partial unpairing of the occupied cationic and anionic MOs composed mainly of *ns(np)* AOs and forming the conduction bands. The effective number of unpaired electrons may also change appreciably due to the changes in the vibronic interaction caused by temperature changes. In this case the paramagnetism of the compound will be the sum of the contributions of *d* electrons of the cations and anions and *s* electrons of the conduction band. Because of the fast dynamic electron transfer (the *s*–*d*–*s* exchange), the lines in the EPR spectra of the compounds will be appreciably broadened or unobservable {as in the case of compound with the [Tc₈Br₁₄]^{2–} anion}. The central, more narrow component of the EPR spectra will correspond mainly to *d* electrons of cations and anions, whereas the broader component will correspond to the electrons of the *s* conduction band.

VII. Conclusion

The experimental and theoretical substantiation of the participation of the outer 5*s* (5*p_z*) orbitals of the Tc atoms in the formation of bonding 'metallic' MOs in technetium clusters with the formal oxidation state of Tc no more than 2.0 is presented in this review. On the one hand, this effect results in strengthening of the M–M bonding in technetium clusters containing a formally 'excess' number of 'metallic' electrons (*i.e.*, the number exceeding that corresponding to the closed shell of the bonding MOs composed of 4*d* AOs). On the other hand, it enhances shielding of the positive nuclear charges (a decrease in *Z*_{eff}) of the Tc atoms in technetium clusters, thus decreasing the Coulomb repulsion in the formation of M–M bonds and increasing the contribution of electron correlation effects to the ground electronic state of the system. Thus, it also leads to an increase in the cluster-forming properties of technetium. This theoretical substantiation agrees well with the descriptions of the 'anomalous' properties of technetium clusters reported earlier.^{3, 51}

V. Introduction of phosphorus-containing fragments <i>via</i> a chain of atoms (spacer)	918

Abstract. Data on the synthesis, conformational behaviour and complexing properties of calix[4]resorcinolarene and calix[*n*]arene derivatives modified by phosphorus-containing fragments are surveyed. The bibliography includes 123 references.

I. Introduction

The chemistry of calixarenes — cyclic products of condensation of phenols with aldehydes — has vigorously developed during the last 20 years. Calixarenes are readily accessible compounds (many of them can be easily obtained by a one-stage synthesis); they contain reactive sites permitting modification of the structure. In addition, they are capable of forming inclusion complexes of the ‘host–guest’ type both with charged and non-polar molecules.

The first mention of the interaction of phenols with aldehydes¹ dates back to 1872 (A Bayer); however the structure of the reaction products has remained barely known for almost 70 more years. It was not until the 1940s that tetrameric cyclic structures **A** and **B** were ascribed to the products of condensation of *p*-alkylphenols with formaldehyde in an alkaline medium² and to the products of acid-catalysed reaction of resorcinol with aldehydes.³

Uspekhi Khimii 67 (11) 995–1012 (1998); translated by Z P Bobkova

The term ‘calixarene’ was brought into use by Gutsche *et al.*⁴ to characterise the shape of these cyclic tetramers, which resembles a bowl (‘calix’ is the Greek for bowl or cup). Although later it was found^{5–7} that these macrocycles can also exist in other conformations, this term has been adopted to denote the whole class of [1,*n*]-metacyclophanes (including compounds **C**).

Calixarenes are widely used as molecular platforms for the development of pre-organised three-dimensional receptors.^{5–8} Upon functionalisation of the phenolic groups, the aromatic rings and the bridging fragments in the initial macrocycles by appropriate organic or organoelement reagents, the receptor capacity can be increased by a large factor. The number of publications dealing with calixarene derivatives doubles every three years.⁸ The number of patents also swiftly increases, indicating that these compounds are important not only for theoretical studies but also for practical purposes and for industry. The latest achievements in the studies of organic derivatives of calixarenes were summarised in a special issue of the journal *Gazzetta Chimica Italiana* (No. 11 in 1997), which was based on the contributions to the 4th International Conference on Calixarenes held in Parma (Italy) from August 31 to September 4, 1997.

Organic derivatives of phosphorus are of special interest for functionalisation of calixarenes, because phosphorus compounds play an important role in many biological and catalytic properties. The complex-forming ability of organophosphorus groups, the strictly definite size of the molecular cavity in the initial calixarene and the possibility of introducing fragments with a specified spatial orientation open up the way to the synthesis of a new generation of receptors capable of recognising complex molecular images. However, the size and the vicinity of functional groups in the supramolecular systems impart some specific features to their chemical behaviour. This makes development of an efficient methodology for selective functionalisation of calix[*n*]arenes a fundamentally important task. Studies on phosphorylation of calixarenes were started in the late 80s – early 90s. This review is the first attempt to describe systematically experimental data now accumulated along this line.

II. O-Phosphorylation of calixarenes by P(III) compounds

The pioneering investigations dealing with the reactions of P(III) compounds with calixarenes were published by a group of American scientists,^{9–13} who accomplished a series of studies dealing with functionalisation of the hydroxy groups in *p*-tert-butylcalix[4]arene (**1**).

It was shown that the inner cavity of calix[4]arene can stabilise the 'hypervalent' hexacoordinated state of the phosphorus atom. The reaction of the compound **1** with tris(dimethylamino)-phosphine¹⁰ is accompanied by elimination of two dimethylamine molecules and gives spirocyclic zwitter-ionic product **2a** ($\delta_{\text{P}} = -120$ ppm, $J_{\text{P-H}} = 737$ Hz).

The two apical positions are occupied by an $\text{N}^+ \text{HMe}_2$ group and a hydrogen atom, the bond of the latter with phosphorus being directed inside the aromatic cavity; this was confirmed by NMR spectroscopy and X-ray diffraction analysis.^{12, 13} On treatment of the compound **2** with one equivalent of butyllithium, the dimethylammonium group is deprotonated, which results in the formation of salt **3**. When the zwitter-ion **2** is thermolysed at 200°C or treated with strong acids ($\text{CF}_3\text{CO}_2\text{H}$ or HBF_4), dimethylamine is eliminated and cage phosphite **5** is produced. Spectral studies (^1H and ^{31}P NMR) showed that the reaction with HBF_4 occurs *via* the formation of pentacoordinated phosphorane intermediate **4** ($\delta_{\text{P}} = -22$ ppm). Oxidation of phosphite **5** with *tert*-butyl hydroperoxide affords the corresponding phosphate **6**; according to X-ray diffraction analysis, this product occurs in a conformation intermediate between *1,2-alternate* and *partial cone*. The reaction of the phosphite **5** with one equivalent of *n*-butyllithium gives product **7** with a hexacoordinated phosphorus atom.

The same group of researchers¹⁴ succeeded in the introduction of more than one phosphorus atom in the calixarene platform. Treatment of the compound **1** with di[bis(*N,N*-dimethylamino)phosphino]methane in dichloromethane at room temperature gives rise to disubstituted product **8**.

An X-ray diffraction study showed that the compound **8** is the (*R,S*) isomer in relation to the phosphorus atoms. Binding of the remaining hydroxyl groups upon the reaction with tris(diethylamino)phosphine gave the product **2b** and diphosphine. Keeping compound **8** in toluene for 14 h at 100°C resulted in the evolution of two moles of diethylamine and the formation of product **9** containing no free hydroxyl groups. Subsequently this product can be converted into bisphosphonate **10** or bis(phosphonothioate) **11**. NMR monitoring of the formation of the bis(phosphonothioate) **11** showed that reaction consists of two stages. The monothio-derivative formed initially is responsible for two ^{31}P NMR signals, with $\delta_{\text{P}} = 84$ and 179 ppm ($J_{\text{P-P}} = 29$ Hz). To convert this compound into the bithio-derivative, an additional heating for 24 h is required. When the compound **8** is made to react with electrophilic reagents such as phenyl azide, methyl iodide and tetrachloro-1,2-benzoquinone, compounds **12–14** are formed in which only one phosphorus atom of the diphosphino-methylene bridge has changed its coordination. The products **12** and **14** are unstable and rapidly decompose.

Synthesis of polyfunctional phosphinite derivatives has been reported in several studies.^{15–17} Both *p*-*tert*-butylcalix[4]arene **1** itself and its 1,3-diethers **15** have been subjected to phosphorylation by chloro(diphenyl)phosphine. Treatment of these substrates with lithium diisopropylamide or butyllithium at a temperature below 50 °C followed by reaction with Ph_2PCl results in the selective formation of bis(phosphinites) **17**. These products exist in a *cone* conformation, except for the compound **17a** in which fast interconversion of the *cone* and *partial cone* conformations occurs. When Et_3N is used as the base in boiling THF, the compound **15d** can be converted only into the monophosphinite **16d** having a *cone* conformation. Under the same conditions, the calixarene **1** is converted into 1,3-bisphosphinite as a mixture of two conformers, the *cone* and the 1,2-*alternate*.

The structures of the 1 : 1 complexes formed by **16d** with Au(I) cations and the 2 : 1 complexes with Pd(II) and Pt(II) cations have been studied by X-ray diffraction analysis.¹⁸

Deprotonation of the dimethyl ether **15a** by Bu^nLi in THF followed by the reaction with Ph_2PCl at room temperature also gives a mixture of conformers, *cone* **18** (25%) and 1,2-*alternate* **19** (60%). At lower temperatures (–78 °C), the content of the conformer **19** increases to 82%; the two possible 1,2-*alternate* structures of this compound undergo fast interconversion.¹⁵

(a) Bu^nLi , THF; (b) Ph_2PCl .

It has been noted¹⁹ that treatment of the calixarene **15a** with two equivalents of KH followed by reaction with Ph_2PCl results in the selective formation of diphosphorylated product **20** in a *partial cone* conformation.

The data of dynamic ^1H NMR in solution point to the occurrence of a dynamic equilibrium between the *cone* **18** and *partial cone* **20** conformations, the former conformer predominating (the ratio **18** : **20** = 2.7 : 1).¹⁶ The number of introduced diphenylphosphinite fragments can be controlled by preliminary methylation of the phenolic hydroxy groups by methyl tosylate in the presence of potassium carbonate.¹⁹

The complex-forming ability of the phosphinite ligands **16d** and **17** in relation to transition metal cations [Pt(II), Pd(II) and Rh(I)] has been studied.^{16,17}

The introduction of P(III) atoms into the lower rim of calix[4]arene by preliminary silylation of hydroxy groups has been described by Schmutzler *et al.*^{20,21} Treatment of the calixarene **1** with hexamethyldisilazane gives rise to 1,3-disubstituted derivative **21**.

The reaction of this product with PF_2Cl affords mono- and bis-difluorophosphites, which are converted into monofluorophosphite **22** upon elimination of Me_3SiF or PF_3 . The macrocycles **21** and **22** occur in a *cone* conformation.

In order to synthesise completely *O*-phosphorylated calix[4]-arenes, the compound **1** is first converted into the corresponding tetraanion by treatment with a strong base (Bu^nLi or KH). The highly nucleophilic tetraanion is made to react with phosphorus-containing electrophiles with P–Cl bonds. Thus the reaction of the lithium derivative **23a** with *N*-substituted 2-chloro-4-oxobenzotriazaphosphorinanes or 2-chloro-4,6-dioxobenzotriazaphosphorinane yields calixarenes **24a–c**. The macrocycles **24d,e** were synthesised by similar reactions of the sodium derivative **23b** with 3-*tert*-butyl-2-chloro-1,3,2-oxazaphospholidine and chloro(diphenyl)phosphine.^{22–24} The stereochemical outcome of the above reactions is determined by the nature of the organophosphorus group entering the molecule. The compounds **24a,d,e** exist exclusively in a *cone* conformation,²³ whereas for compounds **24b,c** all of the four possible conformers are formed.²¹ Under similar conditions, calix[6]arene is converted into hexakis(diphenylphosphinite),²⁴ while calix[8]-

arene gives octaphosphorylated derivatives with diphenylphosphine and 1,3,2-oxazaphospholane fragments.²²

The cyclophane **24c** in a *cone* conformation reacts with dichloro(cycloocta-1,5-diene)platinum(II) giving 1:1 *trans*-complex **25**, in which two phosphorus atoms are coordinated to the Pt(II) cation.²⁰ The tetrakis(phosphinites) **24e** and **24d** also form stable complexes. For example, homodimetal complexes of **24e** with $\text{Fe}(\text{CO})_3$,²³ $[\text{Pd}(\text{COD})\text{Cl}_2]$ and $\text{Pt}[\text{COD}]\text{Cl}_2$ (COD is cycloocta-1,5-diene)²⁵ and a polymeric 1:1 complex of **24d** with copper(I) chloride²³ have been obtained. The tetradentate ligand **24e** is capable of forming both dimeric complexes, for example, $\{(\text{24e})[\text{Rh}(\text{CO})\text{Cl}]\}_2$, and binuclear heterometal complexes, for example, $\{(\text{24e})\{\text{NiCl}_2\}\{\text{Mo}(\text{CO})_4\}\}$.²⁵

Phosphorylation of the calix[4]arene **1**²⁶ and the calix[6]arene **26**²⁷ with phosphorus(III) chloride (in some cases, in the presence of Et_3N as a base) yields cyclic bisphosphites **27** and **28**.

The product **27** is hydrolytically unstable; an attempt to recrystallise it from methanol resulted in the isolation of the initial calixarene **1**. According to X-ray diffraction data, the lone electron pairs of the phosphorus atoms in the compounds **27** and **28** point in the same direction; this makes them promising bidentate ligands for complexation with many *d*- and *f*-metal cations. Thus the compound **28** forms *cis*-complexes with Pd(II), Pt(II) and Re(I). In the complex $[\text{PdCl}_2\text{L}]$, the metal coordinates the bisphosphite fragments at an angle of 90 °C. Calix[6]arene derivatives containing cyclic (**29**) and acyclic (**30**) phosphorus fragments were synthesised by the reaction of calixarene **26** with phosphorous diethylamide.²⁸ These compounds were found²² to exhibit antioxidant properties.

Due to the conformational flexibility of calix[4]resorcinol-arenes **31**,^{29,30} their phosphorylation can follow two major pathways: (a) functionalisation of separate hydroxy groups or (b) cyclophosphorylation of two neighbouring hydroxy groups.

$R = \text{Ph}$ (a), Me (b), Bu^t (c), C_6H_{13} (d), C_7H_{15} (e), C_9H_{19} (f), $\text{C}_{11}\text{H}_{23}$ (g), $(\text{CH}_2)_2\text{Ph}$ (h).

It is obvious that the reaction route depends both on the nature of the phosphorylating reagent (most of all, the number of reaction sites) and on the conformation of the macrocycle. The most favourable conformation of octol **31** for cyclophosphorylation is the *crown* conformation (C_{4v} symmetry). In this conformation, the aromatic rings are directed upwards and form a bowl-like cavity, stabilised by a system of intramolecular hydrogen bonds.^{29,30} Monochlorophosphines, monochlorophosphites, dichlorophosphines and aminophosphines are usually employed as phosphorylation agents.

Phosphorylation using aminophosphines is distinguished by experimental simplicity and mild reaction conditions (room temperature).³¹

A series of P(III)-containing cavitands **32** have been prepared by the reactions of calixarenes **31b-e** with a number of aminophosphines (the reactants were taken in 1 : 4 molar ratio).³²⁻³⁷

(a) 4 equiv. $(R'_2N)_2PX$; $R' = \text{Me}, \text{Et}$; $X = \text{NMe}_2, \text{NEt}_2$; $E = \text{O}, \text{S}$.

The influence of the nature of the substituent R in the bridging fragment on the reaction route has been studied.³⁶ It was found that the reaction of tris(diethylamino)phosphine with tetraphenyl-octol **31a** mainly follows pathway (a). Even when the ratio of the reactants is 1 : 2, the proportion of the cyclophosphorylation product is only 23%. In the case of tetramethyloctol **31b**, product mixtures containing both cyclic and acyclic phosphorus-containing fragments are formed at various ratios of the reactants. For tetrabutyl-octol, cyclophosphorylation becomes the prevailing process; when the reactant ratio is 1 : 4, only pathway (b) is realised. It was suggested³⁶ that the dependence of the phosphorylation route on the nature of the substituent R is a consequence of the calix[4]resorcinol-arene preorganisation (*i.e.* the position of the conformation equilibrium in the given solvent). Bulky alkyl radicals stabilise the *crown* conformation, due to lipophilic interactions with one another, and thus they promote cyclophosphorylation. The reactions of aminomethylated calix[4]resorcinol-arenes at a 1 : 4 reactant ratio also follow pathway (b).

Recently triaminophosphines were used to phosphorylate *p*-*tert*-butylcalix[5]arene. This substrate reacts with $\text{P}(\text{NMe}_2)_3$ to afford monocyclic aminophosphine, *O,O'*-(dimethylaminophosphinediyl)calix[5]arene.³⁸

It is noteworthy that, unlike ordinary aminophosphines, aminophosphine cavitands **32** are stable against alcohols, water and oxygen and add sulfur only under rigorous conditions. Oxidation of these compounds or addition of sulfur gives macrocyclic phosphoroamidates or phosphorothioamidates **33**. Octaphosphorylated macrocycles **34** react with sulfur in a similar way.

$R = \text{Ph}, \text{Me}$; $X = \text{NEt}_2, \text{OMe}$; $Y = \text{NEt}_2$.

When calixarenes **31d,e** were made to react with methyl and ethyl phosphorous diamides, the phosphates **33** were isolated from the reaction mixture instead of the expected macrocyclic phosphites **32**; the latter proved to be extremely unstable and were easily oxidised to phosphates by atmospheric oxygen. The macrocyclic phosphites **32** were detected only in the reactions of **31d,e** with heptyl and octyl phosphorous diamides.³⁹

$R' = \text{Me, Et}$; $X = \text{OC}_7\text{H}_{15}, \text{OC}_8\text{H}_{17}$; $Y = \text{OMe, OEt}$.

Phosphorylation of the calixarene **31e** with (–)-menthyl tetraethylphosphorous diamide under mild conditions with different ratios of the reactants affords completely and partially phosphorylated optically active derivatives containing both cyclic phosphite groups and acyclic menthyl phosphorous amide fragments (for example, compound **35**). When the ratio of the reactants is 1 : 2 and the reaction conditions are more drastic the ‘ball’ structure **36** is formed.⁴⁰

$R = \text{C}_7\text{H}_{15}$, R' is menthyl.

The reaction of the calixarene **31d** with 2-chloro-1,3,2-benzodioxaphospholene at any ratio of the reactants gives phosphite **37**, occurring in an equilibrium with a slight amount of spiroposphorane **38**.⁴¹

$R = \text{CH}_2\text{CH}_2\text{Ph}$

Cavitands containing acyclic phosphinite (**39**) and cyclic phosphonite (**40**) fragments have been prepared by the reaction of the calixarene **31h** with chloro(diphenyl)phosphine and dichloro(phenyl)phosphine, respectively, in the presence of pyridine.⁴² The high complexation capacity of these calixarenes was confirmed by introducing them into reactions with Pt(II) and Au(I) salts. The structures of the resulting complexes (their composition is 1 : 4 or 1 : 8) depend on the nature of the metal (its coordination number). For the 1 : 4 complex, an unusual arrangement of the AuCl groups was established. Three of these groups are located at the upper rim of the calixresorcinolarene due to coordination to the phosphorus atom, while the fourth AuCl group resides in the macrocycle cavity; as a result, solvent molecules are arranged in the intermolecular space rather than inside the cavity. Only in the presence of amines, does the inclusion *endo*-complex **41** form. This property of the complex was used for extraction of alkali metal picrates.⁴²

An unusual μ_3 - and μ_4 -bridging position of halide anions has been established by X-ray diffraction analysis for inclusion complexes **42** and for the complexes $[\text{Py}][\mathbf{40} \cdot \text{Ag}_4(\mu\text{-Cl})_4 \cdot (\mu_4\text{-Cl})]$ and $[\text{Py}][\mathbf{40} \cdot \text{Cu}_4(\mu\text{-Cl})_4 \cdot (\mu_3\text{-Cl})]$, in which one of the Cl^- anions is located in the cavity formed by the four cationic centres.^{43,44} However, the bridging anion is only weakly fixed in the complex and can be easily replaced by other halide anions.

The use of phosphorus(III) halides for phosphorylation of calix[4]resorcinolarenes has been described.^{45,46} The reaction of the macrocyclic compound **31b** with excess PCl_3 affords cyclic phosphorochloridites, similar to compounds **32** ($X = \text{Cl}$), rather than octakis(phosphorodichloridites) **34** ($X = Y = \text{Cl}$).⁴⁵ The structure of the reaction products was confirmed by the data of IR

spectroscopy, mass spectrometry and elemental analysis. The halogen atom in these compounds can be readily replaced by a methyl or dimethylamino group upon the reaction with MeMgI or Me₃SiNMe₂, respectively. The latter reaction gives the cyclic phosphorous amide **32b**, which reacts with tetrachloro-*o*-benzoquinone or hexafluoroacetone yielding spiroposphorane structures containing four σ⁵λ⁵ phosphorus atoms.

The octakis(phosphorodifluoridite) **34** (X = Y = F) was formed in the reaction with PF₂Cl⁴⁶ only when the calix[4]resorcinolarene **31g** had been first treated with excess BuⁿLi. This product was relatively unstable and decomposed over a period of 24 h at –35 °C to give PF₃ and a mixture of various compounds containing P(=O)F(O) and P(=O)F₂ fragments.

III. O-Phosphorylation of calixarenes by P(V) compounds

Phosphorylation of the tetrahydroxy-derivative **1** with diethyl phosphorochloridate was carried out in the presence of sodium hydride,²² potassium carbonate in THF⁴⁷ or triethylamine in chloroform.^{48,49} In all cases, the reaction gave bisphosphate **43a**, which exists in a *cone* conformation.

R = P(O)(OEt)₂, X = Bu^t (a), H (b).

Synthesis of the compound **43a** by the Atherton–Todd reaction (diethyl phosphite–triethylamine–tetrachloromethane, 0 °C) has been reported.^{50–53} The phosphorylation of 25,27-dihydroxy-26,28-dimethoxy-*p*-*tert*-butylcalix[4]arene with diethyl phosphorochloridate in the presence of NaH⁴⁷ gives bisphosphate in the 1,2-*alternate* conformation in which the methoxy groups are oppositely directed with respect to the main plane of the macrocycle.

A detailed study⁴⁹ of the reaction of the compound **1** with diethyl chlorophosphate in the presence of triethylamine in chloroform has shown that under these conditions, in addition to the previously described bisphosphate **43a**, occurring in a *cone* conformation, a 1,2-*alternate* with *anti*-orientation of the diethoxyphosphoryl groups with respect to the main plane of the macrocycle is also formed (its structure in the crystal was determined in another study⁵⁴). The content of this compound in the reaction mixture changes from 9% to 15% following an increase in the excess of triethylamine. Phosphorylation of unsubstituted calix[4]arene under the same conditions gives the bisphosphate **43b** exclusively in a *cone* conformation. Alkylation of the phenolic hydroxy groups in the phosphate **43a** with ethyl iodide in the presence of NaH (THF : DMF = 4 : 1) gives rise to 5,11,17,23-tetra-*tert*-butyl-25,27-diethoxy-26,28-bis(diethoxyphosphorylox-y)calix[4]arene in a *partial cone* conformation.⁴⁹

Phosphorylation of the calixarene **1** with excess diethyl phosphorochloridate⁵⁰ or diethyl phosphite⁵⁵ under phase transfer catalysis conditions (CCl₄–H₂O, 50% NaOH, tetrabutylammonium bromide) yields tetraphosphorylated derivative **44**.

When a less lipophilic catalyst (tetraethylammonium bromide) is used, the reaction affords a mixture of the tetrakis(phosphate) **44** in a *partial cone* conformation and bis(phosphate) **45**, which contains both cyclic and acyclic phosphate fragments.⁵⁶ Complex-forming properties of a number of phosphates based on calix[4]arene have been studied by extraction.⁵⁷ It was found that the introduction of these compounds in the organic phase markedly increases the extraction of lanthanide picrates; however, no pronounced selectivity was observed.

R = P(O)(OEt)₂

Mild oxidation of the compound **1** gives rise to spirodienone **46**, which can be used as the starting compound in the synthesis of mono- and 1,2-di-substituted calixarenes.^{58,59} In particular, treatment of this compound with lithium diisopropylamide (THF, –78 °C) followed by the reaction of the resulting mono- or dilithium salt with excess diisopropyl phosphorochloridate and subsequent reduction of the spirodienone fragment result in the formation of the correspondingly phosphorylated calixarenes **47**.

R = P(O)(OPri)₂, R' = H (a); R = R' = P(O)(OPri)₂ (b);
(a) Me₃PhN⁺Br₃[–], CH₂Cl₂, 0 °C; (b) LiNPr₂[–], THF, –78 °C;
(c) ClP(O)(OPri)₂; (d) EtOH, HBr.

Synthesis of asymmetrically substituted phosphorylated calix[4]arenes **50** has been described by Markovskii *et al.*⁶⁰ The treatment of 1,3-bis(diethoxyphosphoryl)calix[4]arenes **43a,b** with sodium hydride in boiling benzene followed by interaction with electrophilic reagents, such as benzoyl chloride or methyl bromoacetate, affords asymmetrically substituted calix[4]arenes **50a–c** of the AABH type. The use of diethyl phosphorochloridate as an electrophilic reagent gives rise to triphosphorylated calixarenes **50c**.

$R^1 = \text{H or Bu}^t$, $R^2 = \text{P(O)(OEt)}_2$, $R^3 = \text{CH}_2\text{C(O)OMe}$ (**50a**), PhCO (**50b**), P(O)(OEt)_2 (**50c**).

The key stage in the synthesis is the formation of the unstable monoanion of **48** and its *O,O*-phosphorotropic rearrangement to the 1,2-bis(diethoxyphosphoryl)calix[4]arene monoanion of **49**; the rearrangement occurs *via* phosphorane **51**, which was detected by ^{31}P NMR spectroscopy.

51

All these products exist in a *cone* conformation, while the asymmetrically substituted calix[4]arenes **50a,b** have C_1 symmetry and are formed as racemic mixtures, which is indicated by doubling ($\Delta\delta = 0.01$ ppm) of the phosphorus signals in the ^{31}P NMR spectra recorded in a chiral solvent.

O-Phosphorylation of calix[5]-, -[6]- and -[8]arenes is less studied. Data on selective phosphorylation are available only for calix[6]arene. Selective functionalisation of the hexahydroxy-derivative **26** by diethyl phosphorochloridate and *O,O*-diethyl phosphorothiochloridate has been performed and the conformational behavior of the products synthesised has been studied.^{61,62} In the case of diethyl phosphorochloridate, the reaction was carried out with various amounts of triethylamine in boiling chloroform. In all cases, the obtained product mixtures were analysed by HPLC and separated by column flash chromatography. This gave mono-, 1,3-bis-, 1,4-bis-, and 1,2,4-tris(phosphorylated) derivatives **52a-d**.

52m ($R = \text{P(O)(OEt)}_2$)

Depending on the reaction conditions, the optimum yields of these compounds vary from 28% to 56%. It is of interest that in another study,⁴⁸ 1,3,5-tris(phosphorylated) product was obtained in 60% yield under the same conditions.

The fully substituted derivative **52e** was synthesised in 20% yield under conditions of phase transfer catalysis in the CH_2Cl_2 –50% NaOH system in an excess of diethyl phosphorochloridate. The use of anhydrous solvent and solid alkali permitted the yield to be increased to 37%.⁶¹ Under the same conditions, pentakis(diisopropoxyphosphoryloxy)calix[5]arene²⁶ (in a *cone* conformation) and octakis(diethoxyphosphoryloxy)calix[8]arene⁶³ have been obtained. It was also noted⁶³ that phosphorylation of the compound **26** with diethyl phosphorochloridate can give not only the product **52e** but also the pentaphosphorylated derivative **52m** with one cyclic phosphate fragment. The use of sodium hydride as a base in a THF–DMF mixture (10:1) affords the compound **52e** as a *flattened 1,2,3-alternate* conformation in 75% yield.⁶⁴

When the calixarene **26** is made to react with a large excess of less reactive *O,O*-diethyl phosphorothiochloridate in the CH_2Cl_2 –50% aqueous NaOH system, the 1,4-bis(thiophosphorylated) product **52f** is formed selectively in 60%–70% yield. Variation of the conditions of phase transfer catalysis makes it possible to synthesise also mono-, 1,3-bis-, and pentakis-thiophosphorylated derivatives **52g-i**.⁶⁵ The phosphates **52j-l** were prepared by phosphorylation of partially methylated calix[6]arenes under similar conditions.⁶⁶ Study of the mono- (**52g**)⁶² and 1,4-bis(thiophosphorylated) (**52f**)⁶¹ products by X-ray diffraction analysis and ^1H NMR spectroscopy (solution in CDCl_3) showed that they exist in a *pinched cone* conformation (C_{2v} symmetry), in which the two opposite methylene bridges are directed towards the centre of the macrocycle. It is notable that 1,4-diphosphorylated compound **52c** exists in a *1,2,3-alternate* conformation. According to NMR spectroscopy, the macrocycle **52j** in CDCl_3 solutions exists as an equilibrium of two conformers, *cone* (C_{3v} symmetry) and *1,2,3-alternate* (C_s symmetry), the former conformation being 4 kJ mol⁻¹ more stable.⁶⁶ The researchers believe⁶⁶ that the *cone* conformation is stabilised due to the weak $\text{CH}-\pi$ interactions of the methyl groups, which, according to X-ray diffraction analysis, are directed inside the ring.

52a

Study of partially phosphorylated and thiophosphorylated *p*-*tert*-butylcalix[6]arenes, for example **52a**, by dynamic NMR has shown⁶² that these macrocycles participate in, at least, three dynamic processes: (a) interconversion of the macrocyclic ring; (b) redistribution of hydrogen bonds; (c) interconversion of two *pinched cone* conformations.

Monosubstituted derivatives proved to be conformationally more rigid than 1,3- and 1,4-disubstituted derivatives. This is due to the fact that the activation energy of conformation transitions depends on the number of hydrogen bonds, which can be formed by the hydroxy groups that remain free. The contributions of hydrogen bonding to $\Delta G^\ddagger$ are 45 and 31 kJ mol⁻¹ for the mono- and di-substituted derivatives, respectively.

The calix[4]arenes **53**, containing two or four dihydroxyphosphoryl groups on the 'lower' rim of the macrocycle, were prepared in high yields⁶⁷ from readily accessible bis- and tetrakis-diethoxyphosphoryl derivatives of calixarenes **43** and **44**.

R = H, X = H, Y = (HO)₂PO (a);

R = Bu^t; X = H, Y = (HO)₂PO (b); X = Y = (HO)₂PO (c).

When these products are treated with excess bromotrimethylsilane in a solution in anhydrous chloroform, the corresponding silyl esters are prepared in quantitative yields. On treatment of these compounds with methanol, the labile P–O–Si bond ruptures; this gives the acids **53** as colorless crystalline compounds, readily soluble in polar organic solvents (alcohols, DMSO, DMF) and in aqueous solutions of alkali; they are stable in aqueous alcohols and in amine–alcohol mixtures for several days. The compounds **53a–c** are relatively strong acids [*p*K_a 2.85, 3.10 and 2.90 (aqueous methanol)]. They form 1 : 1 and 1 : 2 *exo*-complexes with *tert*-butylamine, α -phenylethylamine and ephedrine; the complexes exist in a solution in deuterated methanol as contact ion pairs.⁶⁷

In order to develop selective agents for the transfer of lithium cations through liquid membranes, the phosphates **54** were synthesised by the reaction of 25,26,27-trimethoxy-28-hydroxy-*p*-*tert*-butylcalix[4]arene with alkyl phosphorodichloridates followed by hydrolysis.⁶⁸ Spectral data indicate that the compounds **54a–c** occur in solution as mixtures of two conformers, a *cone* and a *partial cone*, the equilibrium being sensitive to the influence of the medium.

R = Me (a), Et (b), Prⁿ (c).

The fraction of the *cone* conformation in which all the four dipoles point in the same direction increases with increase in the solvent polarity. It is noteworthy that the complexation of the compounds **54** with Li⁺ and Na⁺ cations occurs more readily for

the *cone* conformation of the calixarenes; therefore, no macrocycles in the *partial cone* conformation were found in the complexes.

Pyrolysis *in vacuo* (230–240 °C) of mono-, bis-, and tetrakis-phosphates **43**, **44** and **47**, irrespective of the number of phosphorus-containing groups, gives the same product, pyrophosphate **55**, in which all the hydroxy groups are bound intramolecularly.^{26, 69} This means that the formation of the compound **55** involves stages of fragmentation and intermolecular migration of the phosphate groups. Study of the crystal structure of the pyrophosphate **55** showed that the two terminal oxygen atoms and the oxygen atom of the P–O–P bridge are directed away from the plane of the molecule. The conformation of the pyrophosphate can be defined as a *pinched* or *flattened cone*. Pyrolysis of a mixture of regioisomers of phosphorylated *p*-*tert*-butylcalix[6]arenes yields isomeric bridged bis(phosphates) **56**, which differ in the arrangement of the phosphoryl oxygen atoms (either *syn*- or *anti*-).

Yet another pathway to phosphorus-containing bridged macrocyclic structures is reaction of the compound **1** with phosphorus halides. Thus refluxing of **1** with POCl₃ in chloroform in the presence of Et₃N gives rise to the mono-bridged system **57**. At higher temperatures (xylene, 85 °C), the reaction affords structure **58** with two bridges, which might be a mixture of stereoisomers with different spatial arrangements of the P–Cl and P=O bonds.²³

Interestingly, pyrolysis of the compound **57** also gives the pyrophosphate **55**. Glode *et al.*⁷⁰ have studied the reactivity of the compound **57** towards nucleophilic reagents such as water, alcohols and orthoformates. It was found that the halogen atoms can be successfully substituted by hydroxy or alkoxy groups to give the corresponding acids or esters; these reactions do not involve the P–O–C bonds.⁷⁰

R = H, Me, Et.

When the calixarene **1** is treated with three equivalents of PCl_5 , the macrocyclic compound **59**, containing three phosphorus atoms, is formed.^{71,72} According to ^{31}P NMR spectroscopy, one of these atoms forms a phosphonium cation upon linking to the three phenolic groups, a second phosphorus atom forms the quasiphosphonium group OPCl_4 , while the third atom occurs as the PCl_6^- anion ($\delta_{\text{P}} = 8.1$, -66.0 and -296 ppm, respectively). The X-ray diffraction analysis of the compound **59** confirmed the presence of tetra-, penta- and hexa-coordinated phosphorus atoms. The macrocycle conformation is intermediate between a *partial cone* and *1,2-alternate*.⁷³ All the three phosphorus atoms in the compound **59** are reactive. On treatment with SbCl_5 , the PCl_6^- anion is replaced by SbCl_6^- ; reactions with nucleophiles occur as substitution at the P–Cl bond and, under more rigorous conditions, also at the P–O bond.

For example, the reaction of **59** with water gives phosphate **60** in which the P–O–C bonds remain intact. However, upon prolonged action of acids or alkali, the 1,2,3-linked phosphate is converted into 1,2-phosphate **61** as a result of hydrolysis of one P–O–C bond. The compounds **60** and **61** contain free hydroxy groups and can be easily converted into the corresponding esters on treatment with diazomethane or orthoformates. Reactions with sulfur-containing nucleophiles give phosphorothioates **62** and **63**, the character of binding in the lower rim of calix[4]arene remaining invariable; this points to high stability of phosphates and phosphorothioates bound to the 1,2,3-positions of the calixarene system. According to ^1H and ^{13}C NMR spectroscopy and X-ray diffraction analysis, the compounds **60–63** occur in a *partial cone* conformation.^{71,72,74,75}

The reaction of the calix[6]arene **26** with four equivalents of PCl_5 yields hexakis(chlorophosphate) **64**, which, like **59**, is capable of exchanging the PCl_6^- anion for the SbCl_6^- .⁷²

X = O (**56**), S (**65**).

The reactions with water and hydrogen sulfide afford the phosphate **56** and phosphothioate **65**. The phosphoryl oxygen and sulfur atoms point in the same direction in relation to the main plane of the macrocycle. This makes these compounds promising chelating agents for cations of many *d*- and *f*-elements.

The reaction of the compound **26** with ethyl phosphorodichloridate gives rise to cyclic mono- and bis-phosphates.⁷⁶ The reaction route depends on the nature of the base used. In the presence of CsF, monophosphate is formed, while the use of calcium hydride results in the formation of the diphosphorylated product.⁷⁶ The spatial structure of the macrocycles obtained was not determined.

The calix[4]resorcinolares **31** are readily phosphorylated by traditional reagents, chlorides of acids of tetraordinated phosphorus and the (RO)₂PHO–CCl₄–Et₃N ternary system. The reactions of the octahydroxy-derivative **31** with excess diorganyl phosphorochloridates and triethylamine (20 °C, THF) afford octaphosphorylated cyclophanes **66**.^{77–79}

The reaction outcome depends on the nature of the radical in the diorganyl phosphorochloridate. Even when excess phosphorylating reagent is used, the reactions with diethyl and dipropyl phosphorochloridates give tetraphosphorylated products **67** together with octasubstituted derivatives. In the case where diisopropyl phosphorochloridate is employed, the reaction stops at the stage of formation of the tetraphosphorylated product, due to the steric hindrance during the process and the low solubility of the corresponding tetrasubstituted products, resulting in their removal from the reaction area.⁷⁹ The tetrakis(phosphates) **67** were obtained by using a large excess of the reagent (**31**: phosphorochloridate: triethylamine = 1:5:5) and by treating the compound **31** with the (RO)₂PHO–CCl₄–Et₃N ternary system (**31**: reagent = 1:10). It should be noted that in early studies,^{77,78} the structure with alternating positions of the phosphoryl groups along the macrocycle rim had been assigned to the tetrakis(phosphates) formed in these reactions; however, later it was found⁷⁹ that a structure of the type **67** in which the phosphoryl groups occupy the opposing positions is more probable. The tetrakis(phosphates) **67** were further modified. Thus hydrolysis of the phosphate groups in **67**, *via* the intermediate synthesis of the corresponding trimethylsilyl ester, gave tetrakis(dihydroxyphosphoryloxy)tetrahydroxycalix[4]resorcinolarene **67g**.⁸¹ Reaction of the free hydroxy groups in **67** with 4-chlorosulfonylbenzo-15-crown-5 in the presence of triethylamine gave the derivative **67h**.⁸²

A study of the conformational behaviour of the tetrakis(phosphates) **67** by dynamic NMR spectroscopy has shown that at room temperature, fast pseudo-rotation of the *boat*–*boat* type occurs, which consists in the mutual transition of the two pairs of opposing benzene rings between the perpendicular and coplanar arrangements with respect to the main macrocycle plane.⁷⁹

Estimation of the complex-forming properties of the cyclophanes synthesized showed that they can form stable complexes both with some metal cations and with neutral aromatic molecules. The phosphoryl groups present in the molecule impart pronounced ionophoric properties to it. When the octakis(phosphate) **66d** is used as an ion transferring agent, the rate of transfer of alkali and alkaline earth metal picrates through a liquid membrane increases 1.3–9.0-fold compared to that attained with 15-crown-5; however, the transfer is almost nonselective.⁷⁹ The compound **67h** has demonstrated selectivity towards potassium cations.⁸² The octakis(phosphates) **66c,d**, owing to their lipophilic cavity, form crystalline ‘host–guest’ complexes with aromatic compounds, toluene and *m*-cresol.⁷⁹ Later,⁸⁰ the structures of several complexes of this type in solution and in the solid state were studied by X-ray diffraction analysis and NMR spectroscopy. The cyclophane **67g** forms ‘host–guest’ complexes with benzene, toluene, anisole, xylenes, phenol and 1-phenylalanine in aqueous solutions. The complexes result from inclusion

of a ‘guest’ molecule into the cavity formed by the preorganised pentyl radicals.⁸¹

R¹ = Me; R² = Et (**a**), Prⁿ (**b**), Ph (**c**), *p*-MeC₆H₄ (**d**);
R¹ = n-C₅H₁₁, R² = Ph (**e**).

X = H, R¹ = Me; R² = Et (**a**), Prⁿ (**b**), Prⁱ (**c**), Buⁱ (**d**);
X = H, R¹ = n-C₅H₁₁; R² = Et (**e**), Prⁱ (**f**), H (**g**);

Tetrakis(phenylenephosphoryloxy)[1.4]metacyclophane **68a** was synthesised by the reaction of the octahydroxy-derivatives **31b** with four equivalents of *o*-phenylene phosphorochloridate and triethylamine.^{78,79}

Since the phosphorus atoms are located closely to the hydroxy groups of the neighbouring aromatic rings, intramolecular nucleophilic addition of the hydroxy groups to the P=O bonds occurs to give spirophosphorane structure **69a**. The driving force of this process is formation of the energetically more favourable penta-coordinated phosphorus atom in the dioxaphospholane ring. This reaction is reversible; the position of the equilibrium depends on the temperature and the nature of the solvent. On treatment with triethylamine, the **68a** ⇌ **69a** equilibrium shifts towards the more acidic form, **68a**. A similar equilibrium is observed for the **68b** ⇌ **69b** system. In pyridine, which is capable of binding to a pentacoordinated phosphorus atom,⁸³ the equilibrium shifts towards the spirocyclic tautomer **69b**.

X = H (**a**), SiMe₃ (**b**).

When the compound **31f** ($R = C_9H_{19}$) was made to react with excess bis(chloromethyl)phosphinic chloride (acetone, K_2CO_3), instead of the expected bis(chloromethyl)phosphinic acid derivatives, octakis(chloromethylphosphonate) was isolated, due to the extremely easy rupture of one of the P–C bonds in the phosphinate. The product exists in solution as dimer **70** formed according to the ‘head-to-head’ pattern due to intermolecular hydrogen bonds.⁸⁴

The first representatives of monophosphorylated cyclophanes **71** were prepared by refluxing in benzene of aminomethylated octahydroxy-derivatives with diethyl phosphorochloridate.⁸⁵

The use of organyl phosphorodichloridates or organylphosphonodichloridates for phosphorylation of the cyclophanes **31** has been reported.^{84, 86–88} The reaction with alkyl and aryl phosphorodichloridates in acetone in the presence of triethylamine results in the formation of diastereoisomeric cavitands **72**, which differ in the spatial arrangement of the P=O groups in the four phosphocine rings: *i* (the P=O group points to the centre of the upper rim) and *o* (the P=O group points outwards).^{86, 87} The reaction with ethyl phosphorodichloridate proceeds with a low yield (12%), owing to the competing intermolecular cross-linking of the calixarene fragments, resulting in the formation of polymers. The use of aryl phosphorodichloridates permits the yields of the target products to be increased to 50%–80%. The reaction gives all of the six possible stereoisomers, although three of them, *iiio*, *iioo* and *iooo*, proved to be more preferable (the proportion of each isomer was determined by HPLC). The proportions of the *iiii* (compound **72**) and *oooo* isomers in the reaction mixture are not

higher than 10%; in some cases, they do not form at all. It is quite natural that as the substituent R^3 becomes larger, the content of the *iiio* isomer increases, whereas the content of the *iooo* isomer correspondingly decreases. It is clear that the receptor capacity of the macrocyclic compounds obtained depends on the spatial arrangement of the phosphoryl groups. The *iiii* and *iiio* isomers are the most promising complex-forming agents. Thus the *iiio* isomer forms a complex with cyclohexylammonium ($K_a = 1370$ litre mol^{−1}) as a result of three-point hydrogen binding, whereas the *iioo* and *iooo* isomers do not form complexes of this type.

$R^1 = Ph, Alk; R^2 = H, Br; R^3 = OEt, OAr$.

It has been reported⁸⁸ that the *iiii* stereoisomer of compound **73** is formed as the major product in the reaction of the octahydroxy-derivative **31a** with phenylphosphonic dichloride. The publication does not present the conditions of the synthesis. The product was identified as having the *iiii* configuration based on its C_{4v} symmetry (although the *oooo* isomer has the same symmetry). The strong complexing properties of the reaction product served as additional evidence for its *iiii* configuration. The compound **73** forms stoichiometric complexes with alkali metal and alkylammonium cations, characterised by association constants of 10^8 – 10^{10} litre mol^{−1}; the composition of the complexes is 1 : 1 (K^+ , Rb^+ , Cs^+ , NH_4^+ , $MeNH_3^+$, $BuNH_3^+$) or 1 : 2 (Li^+ , Na^+).

The reaction of the long-chain calix[4]resorcinolarene **31f** with chloromethylphosphonic dichloride in the presence of triethylamine gives completely phosphorylated product **74**; when potassium carbonate is used as the base, partially phosphorylated product **75** is formed.⁸⁴

The use of $POCl_3$ (in the presence of pyridine as the base) for introduction of phosphate groups has been reported.⁸⁹ In relation to *C*-undecylcalix[4]resorcinolarene, it was shown that at various ratios of the reactants (ranging from 1 : 1 to 1 : 39), complex mixtures of cyclic and acyclic phosphates with different numbers of phosphate fragments (from 1 to 6.3) are formed. Complete phosphorylation was not attained even with a large excess of $POCl_3$. These compounds exhibit surfactant properties and form stable complexes with UO_2^{2+} .

IV. Phosphorylation of the aromatic rings in calixarenes

Phosphorylation of the aromatic rings in calixarenes gives rise to a new type of receptors in which, unlike *O*-phosphorylated derivatives, the molecular cavity of the cyclophane can also be involved in the molecular binding of a substrate. The presence of organophosphorus compounds in the upper rim of the macrocycle permits the receptor to interact both with polar or ionic groups of a substrate and with non-polar fragments, the latter being included in the molecular cavity of the cavitand. Thus, multi-point 'host-guest' binding is attained, which is known to increase sharply the efficiency and selectivity of complex formation.^{90,91} Moreover, P–C bonds are thermally and hydrolytically more stable than P–O bonds, which are formed upon phosphorylation of the lower rim of calix[*n*]arenes.

The first representative of this type of cyclophanes, tetrakis(diphenylphosphino)calixarene **76**, was synthesised by successive reactions of the tetramethyl ether of *p*-tetrabromo-calix[4]arene **76a** with butyllithium and chloro(diphenyl)phosphine.⁹² Nevertheless, the Arbuzov reaction catalysed by nickel(II) salts is now the simplest and the most efficient method for direct phosphorylation of the upper rim of calix[4]arenes.⁹³

76a–d

R = Br (**a**), PPh₂ (**b**), P(O)(OPr^{*i*})₂ (**c**), P(O)Ph₂ (**d**).

The reaction of the compound **76a** with triisopropyl phosphite or isopropyl diphenylphosphinite gives the corresponding tetraphosphorylated calix[4]arenes **76c,d** in high (75%–80%) yields.

The same approach was used in another study⁹⁴ in order to prepare bis- and ABAB-tetrakis-phosphorylated derivatives. The reactions of *O*-alkylated dibromides **77a,b** with triisopropyl phosphite or alkyl diphenylphosphinite in the presence of NiBr₂ gave bisphosphonates **78a,b** and bis(phosphine oxide) **79** (Scheme 1). Treatment of the compounds **78** and **79** with octyl chloromethyl ether in the presence of SnCl₄ resulted in the introduction of CH₂Cl groups into the free *p*-positions of the

R = R' = Me (**a**); R = Me, R' = C₁₂H₂₅ (**b**).

(a) P(OPr^{*i*})₃, NiBr₂; (b) C₈H₁₇OCH₂Cl, SnCl₄; (c) AlkOPPh₂;

(d) P(OPr^{*i*})₃, R = R' = Me.

aromatic rings. It is of interest that in the case of the methyl ethers **78a** and **79**, the chloromethyl derivatives are formed in high yields (60%–70%); when the dodecyl ether **77b** is used, the yield decreases to 26%. It has been reported that the size of the alkyl radical has a considerable influence on the kinetics of phosphorylation of calix[4]resorcinolarenes.^{95,96} This was explained by assuming formation of different types of aggregates in the solution. The subsequent substitution of the chlorine atom by phosphorus-containing nucleophiles gave rise to ABAB-tetrakis-phosphorylated cyclophanes **80–82**.

The first representative of calixarenes containing a low-coordinate phosphorus atom, phosphinylidenemethylcalixarene **83**, was synthesised as a mixture of stable *Z*- and *E*-stereoisomers capable of forming complexes with transition metals, by the following reaction:⁹⁷

V. Introduction of phosphorus-containing fragments *via* a chain of atoms (spacer)

A vigorously developing route of the functionalisation of calix[4]-arenes aimed at producing more efficient and selective complex-forming agents is introduction of organophosphorus groups in which phosphorus atoms are not attached directly to the lower or upper rim of the macrocycle but are linked to the calixarene platform *via* a chain of other atoms (spacer). This approach makes it possible to extend substantially the synthetic potential in the construction of new macrocyclic receptors.

Deprotonation of 1,3-bis(ethoxycarbonylmethyl) calix[4]-arene derivative **84a** with sodium *tert*-butoxide and subsequent alkylation of the resulting dianion with $\text{Ph}_2\text{P}(\text{O})\text{CH}_2\text{OTs}$ gives rise to bis(phosphine oxide) cyclophane **85a** in a *cone* conformation.⁹⁸

$\text{R} = \text{C}(\text{O})\text{OEt} \text{ (a)}, \text{C}(\text{O})\text{NEt}_2 \text{ (b)}, \text{CH}_2\text{OMe} \text{ (c)}, \text{C}(\text{O})\text{NHCH}(\text{Me})\text{Ph} \text{ (d)}.$

When potassium *tert*-butoxide is used as the base in this reaction, the product **85a** is formed in a *partial cone* conformation. The crucial influence of the nature of the cation on the stereochemical outcome of the reaction was explained by the difference in the energy of binding of potassium and sodium cations to the intermediate diphenoxide. The harder sodium cation interacts more strongly with phenoxide anions and thus it fixes the *cone* conformation of the calixarene platform. When the compounds **85** are refluxed with phenylsilane in toluene, the phosphine oxide group is quantitatively reduced to give the corresponding bis(phosphine) macrocycles **86**; according to X-ray diffraction and ^1H and ^{13}C NMR data, this product also occurs in a *cone* conformation.⁹⁸ The compounds **86** can act as both *cis*- and *trans*-chelating ligands. *cis*-Complexes are formed upon the reactions of the calixarene **86a** with $\text{PtCl}_2(\text{PhCN})_2$ and $[\text{Rh}(\text{COD})\text{Cl}]_2$ (**87**) in the presence of AgBF_4 . The reaction of the compound **86a** with RuCl_3 and CO in boiling 2-ethoxyethanol affords the complex **88** with *trans*-P,P stereochemistry in a quantitative yield.⁹⁸

$\text{R} = \text{CH}_2\text{CO}_2\text{Et}$; COD is cycloocta-1,5-diene.

This method was used to prepare a series of metal-containing calixarenes^{99–104} able to participate in catalytic processes. Based on the bis(phosphine) cyclophanes **86**, a number of new Pt(II), Pd(II), Rh(I) and Ru(II) complexes were prepared. The reaction of the compound **86c** with the platinum(II) bis(triphenylphosphine) complex in boiling THF is accompanied by displacement of a PPh_3 molecule and the chloride anion from the metal coordination sphere and yields the cationic complex **89**.

$\text{R} = \text{C}(\text{O})\text{NEt}_2 \text{ (86b, 90)}, \text{CH}_2\text{OMe} \text{ (86c, 89)}$;
(a) $(\text{Ph}_3\text{P})_2\text{PtHCl}$, THF; (b) $(\text{Ph}_3\text{P})_2\text{PtHCl}$, CH_2Cl_2 .

The replacement of the ester side groups by amide groups, which interact more strongly with cations, crucially changes the reaction route. In this case, both triphenylphosphine ligands are replaced and neutral hydrido complex **90** is formed. Apparently, this outcome is due to the participation of two amide groups in the interaction with Pt(II); this accelerates the formation of intermediate species with pentacoordinated platinum and facilitates the ligand substitution.^{101–103}

The structure of the complex **90** was studied. Two-dimensional (ROESY) NMR spectra and X-ray diffraction data attest convincingly that the hydride ion, responsible for the resonance signal at $\delta = -15.04$ ppm ($J_{\text{H-Pt}} = 1150$ Hz, $J_{\text{P-H}} = 15$ Hz), points to the centre of the calixarene cavity.^{101, 103} The stereochemistry of the Pt–H bond can be changed by involving the amide groups in complex formation. Thus the reaction of the complex **90** with silver tetrafluoroborate yields hydrido complex **91** in which the Pt–H bond is directed outwards.^{102, 103}

X is a donor.

In this environment, the hydride becomes much more reactive and can participate in various reactions. It is of interest that addition of a strong donor to the complex **91** results in displacement of the amide group from the coordination sphere yielding complex **92**, in which hydrogen is again directed inwards. This reaction makes it possible to change the reactivity of the hydride ion and creates conditions for the synthesis of bimetal hydrido complexes upon reactions with bidentate donors.¹⁰³

Selective introduction of one, two or four $\text{CH}_2\text{P}(\text{O})\text{Ph}_2$ substituents into the lower rim of *tert*-butylcalix[4]arene **1** was attained by using NaH and an appropriate alkylating reagent.^{105, 106}

 (c) 2.5 equiv. NaH, 2.2 equiv. $\text{Ph}_2\text{P}(\text{O})\text{CH}_2\text{OTs}$, THF–DMF, 25%;
 (d) 6 equiv. NaH, 4.2 equiv. $\text{Ph}_2\text{P}(\text{O})\text{CH}_2\text{OTs}$, THF–DMF, 70%.

When iodomethyl(diphenyl)phosphine oxide is employed as the alkylating reagent, the reaction gives, depending on the temperature and the amount of NaH used, either mono- (**93**) or 1,3-bis-(phosphine oxide) **94**. The reaction with more reactive hydroxymethyl(diphenyl)phosphine oxide tosylate allows the synthesis of the corresponding 1,2-di- (**95**) and tetra-substituted (**96**) derivatives. According to NMR and X-ray diffraction analysis, the cyclophanes **93**–**96** occur in a *cone* conformation; they are widely used as complexing reagents and membrane transferring agents for various metal cations.^{107–109} The reduction of the compound **96** with phenylsilane gives a tetrakis(phosphine) ligand capable of forming polynuclear complexes.^{105, 110}

A new series of polyfunctional phosphine oxide derivatives of calix[4]-, -[6]- and -[8]arenes **97**, containing $(\text{CH}_2)_2\text{P}(\text{O})\text{Ph}_2$ fragments, have been modelled and synthesised for the extraction and complexation of actinide and lanthanide ions.¹¹¹ The synthetic strategy is presented in the scheme.

R = Bu^t, H; n = 4, 6, 8.

The properties of these compounds as extractants have been studied.^{112–115}

The further development of the methods for functionalisation of calixarenes followed the path of introduction of groups containing both an organophosphorus fragment and another binding site into the upper or lower rim of the macrocycle. Cavitands with the carbamoylmethylphosphine oxide

$[\text{NHC}(\text{O})\text{CH}_2\text{P}(\text{O})\text{Ph}_2]$ ^{116–118} and α -aminophosphonate $[\text{NHC}(\text{O})\text{CH}_2\text{P}(\text{O})(\text{OR})_2]$ ¹¹⁹ groups have now been obtained.

It has been shown¹¹⁶ that the extraction properties of the traditional extractant for actinides, (*N,N*-diisopropylcarbamoylmethyl)octylphenylphosphine oxide (CMPO), can be markedly improved by grafting four or five carbamoylphosphine oxide groups to the upper rim of calix[4]- or -[5]arenes **98** and **99**.

It is worth noting that the extraction capacity of the specially synthesised¹¹⁶ linear analogues of receptors **98** and **99** — the dimer and the trimer **100a,b** — was equal to that of the initial CMPO.

These results demonstrate the synergistic effect of combining carbamoylphosphine oxide fragments with the calixarene platform within the same molecule. The compounds **98** and **99** were prepared by aminolysis of *p*-nitrophenyl diphenylphosphorylacetate with *O*-tetra- or *O*-pentaalkyl ethers of *p*-aminocalix[4]- or -[5]arenes. The calixarenes **98** occur in a *cone* conformation, whereas **99** can be a mixture of *cone*, *partial cone* and *1,3-alternate*, because for mixed ethers with two methoxy groups, inversion of the macrocycle is possible.

Several studies have been devoted to the introduction of carbamoylmethylphosphonate fragments into the calix[4]resorcinolarenes **31** and to the extraction properties of the products towards a number of metal cations.^{117, 118} Mono-, 1,2-bis-, 1,3-bis-, tris- and tetrakis(carbamoylmethyl)phosphonates and -phosphine oxides **101** were synthesised starting from tetrakis(bromo-methyl)calix[4]resorcinolarene. The conditions for partial functionalisation were created at the stage of formation of the aminomethyl derivatives. The amino group was introduced *via* phthalimide derivatives, by their hydrazinolysis. The transition to the cyclophanes **101** was accomplished either by acylation of the amines with chloroacetyl chloride followed by Arbuzov introduction of the phosphorus-containing fragment or by aminolysis of *p*-nitrophenyl diphenylphosphorylacetate.

R = H: L = Ph (**a**), OEt (**b**); R = Prⁿ: L = Ph (**c**), OEt (**d**).

Study of the extraction of Na^+ , Cs^+ , Sr^{2+} , UO_2^{2+} , Fe^{3+} and Eu^{3+} with the compounds **101** showed that Na^+ and Cs^+ are not extracted, while the degree of extraction of Sr^{2+} reaches 85%. The cavitands containing three or four carbamoylmethylphosphine oxide groups were found to be the most efficient extractants. As the number of these groups decreases, the efficiency of extraction and its selectivity with respect to Eu^{3+} decrease. Interestingly, 1,2-disubstituted cavitands are more efficient than the 1,3-isomers.

Calixarenes **102** and **103**, which contain α -amino phosphonate fragments in the lower and upper rims of the macrocycle, have been constructed as receptors and membrane transferring agents for α -amino acids occurring in the zwitter-ionic form.¹¹⁹

These compounds were synthesised by the Kabachnik – Fields reaction from the corresponding 1,3-bis(aminoalkyl)-derivatives, diethyl phosphite and a carbonyl compound (yields 50% – 65%). The calixarenes **102** and **103** occur in a *cone* conformation.

It should be noted that transfer of highly hydrophilic amino acid zwitter-ions through lipophilic organic membranes is a difficult task due to the very high energy of hydration of these species. Therefore, the receptor should interact efficiently with as many active sites in the substrate as possible. As applied to α -amino acids, this can be interaction with the carboxylate and ammonium groups and with the side chain, which normally does not contain any polar or charged substituents. The presence of α -amino phosphonate fragments, containing both proton-donor (NH bond) and proton-acceptor (P=O bond and the lone electron pairs of nitrogen) groups together with the calixarene molecular cavity in the receptor molecule ensures efficient transport of α -amino and α -hydroxy acids.^{120, 121} The cavitands **102** and **103** exhibited high selectivity of transfer of α -amino acids, the compounds **102** being more efficient towards histidine, and **103**, towards *d,l*-phenylalanine.

A water-soluble receptor for the uranyl ion UO_2^{2+} was synthesised by introducing six phosphonic acid fragments $[\text{CH}_2\text{P}(\text{O})(\text{OH})_2]$ into the calix[6]arene upper rim. This was done by the Arbuzov reaction of the corresponding chloromethyl derivatives with triethyl phosphite and subsequent hydrolysis.^{122, 123}

This review surveys the main routes of functionalisation of calix[4]resorcinolarenes and calix[*n*]arenes by organophosphorus compounds of various types and clearly demonstrates the great potential and the prospects for the use of these macrocycles for complex formation and molecular recognition (extraction, mem-

brane transfer) of both charged and neutral substrates and for the assembly of novel supramolecular systems.

Synthesis and properties of β,β -bisfunctionalised ketene N,N -acetals

V A Makarov, V G Granik

Contents

I. Introduction	923
II. Synthesis of disubstituted ketene N,N -acetals	923
III. Properties of ketene N,N -acetals	930
IV. Conclusion	938

Abstract. Data on the synthesis of β,β -disubstituted ketene N,N -acetals as well as their physicochemical properties and reactions with electrophilic and nucleophilic reagents are generalised. Special attention is paid to the synthesis of various heterocyclic compounds based on these compounds. The bibliography includes 182 references.

I. Introduction

Ketene S,S -, S,N - and N,N -acetals[†] **1–3** draw the chemists' attention due to their high reactivity and the prospects of their broad and versatile synthetic utilisation, in particular, for the synthesis of heterocyclic compounds.

Compounds **1** have been considered in comprehensive reviews.^{1–4} These reviews cover the properties and transformations of N,S -acetals **2** to a considerably smaller extent. Ketene N,N -acetals **3** have been discussed there rather incompletely.

The results of the use of ketene N,N -acetals for the synthesis of heterocyclic compounds are generalised in the review;⁵ however, it mostly discusses monosubstituted ketene N,N -acetals **3** ($Y = H$). On the other hand, a considerable number of studies have been devoted to the synthesis and transformations of disubstituted ketenes **3** in which X and Y are functional, mostly electron-acceptor substituents. The present review considers the methods for the synthesis of ketene N,N -acetals, their physicochemical and chemical properties and prospects of their use in the synthesis of various heterocyclic systems.

II. Synthesis of disubstituted ketene N,N -acetals

1. Synthesis based on ketene S,S - and N,S -acetals and ketene dihalides

The majority of publications concerning the synthesis of ketene N,N -acetals **3** deal with the reactions of substituted ketene S,S - (**1**) or N,S -acetals (**2**) with amines.^{6–39} It is well known that the alkyl(aryl, hetaryl)thio group (SR) is a 'good leaving group', and its replacement by an amine-containing fragment is usually not problematic. However, replacement of one alkylthio group in ketene S,S -acetals **1** by the amino group results in a considerable decrease in the reactivity of the other SR-substituent due to the strong electron-donor effect of the amino group. Thus, it is possible to obtain asymmetrical N,N -acetals **3** in several stages from N,S -acetals **2**. A typical example of such a sequential synthesis of ketene N,N -acetals is presented in Ref. 29.

In some cases, ketene S,S -acetals were made to react with ethylenediamines.^{8, 10, 12, 13, 17, 23, 24, 28, 30, 33–36, 39} This resulted in 2-methyleneimidazoline derivatives **4a**.¹⁰ If substituted propane-1,3-diamines are used instead of ethylenediamine derivatives,^{12, 28, 33} hydrogenated pyrimidine derivatives **4b** are formed.

$X = COR', CO_2R', CN, Ar; Y = COR', CO_2R', CN; n = 2$ (**a**), 3 (**b**).

Reactions of cyclic ketene S,S -acetal **5** with various diamines, including *o*-phenylenediamine derivatives (see also Refs 14, 17, 19, 24, 30, and 34) and 1,8-diaminonaphthalene, have been studied.²⁸ It was found that the rate of formation of cyclic systems **6–8** depends on the nature of the diamine. The reaction of ketene S,S -acetal **5** with butane-1,4-diamine derivatives ($n = 4$) or aromatic amines occurs much more slowly than that with ethane(-propane)diamines ($n = 2, 3$).

[†] Other names for these compounds, such as ketene amins, highly polarised or 'push-pull' enamines, and enediamines are also widely used in the literature.

The reaction of *S,S*-acetals **1** or *S,N*-acetals **2** with various compounds containing the unsubstituted amino group opens up no less wide prospects for the synthesis of diverse derivatives of ketene *N,N*-acetals. For example, spiro compounds **9** incorporating two enediamine fragments have been synthesised from ketene *S,S*-acetals and the tetramine **10**.⁴⁰

The reaction of *S,N*-acetal **11a** with hydrazine afforded 3-amino-2-cyano-3-hydrazinoacrylamide.²² Reactions of substituted acetals **11b** with various amidines and guanidines result in the corresponding 'push-pull' enamidines **12**.^{20, 21}

2-Bis(methylthio)methylenindane-1,3-dione reacts with trimethylsilylmethylamine on refluxing in methanol to give a mixture of mono- and disubstituted products **13** and **14**.³²

Monoaziridino-*R*-amino derivatives of ketene *N,N*-acetals **15** are formed upon successive introduction of, first, monosubstituted amines and then ethyleneimine in the reaction with ketene *S,S*-acetals **16**. The action of the iodide ion on compounds **15** results in ketene acetals of the imidazolidine series **17**.¹⁸ Direct reaction of ethyleneimine with compounds **16** gives bisaziridino derivatives of ketene *N,N*-acetals **18**.¹⁸

X = ArCO, HetCO.

Ketene *S,S*-acetals **5** can react even with such weakly basic compounds as carboxamides. This reaction gives *N*-acyl derivatives of ketene *S,N*-acetals **19** as the final products. The latter readily give *N*-acylketene *N,N*-acetals **20** on treatment with primary amines.²⁹

Reaction of ketene *S,S*-acetals with anthranilamide³⁷ or glycylamide¹⁶ results in the corresponding pyrimidinone (**21**) or imidazolidone (**22**) derivatives.

X, Y = CN, CO₂Et.

The reaction of ketene *N,S*-acetals with pyrrolyl-1-magnesium bromide readily gives ketene *N,N*-acetals **23** containing the pyrrole ring as one of the amine moieties.³¹

X = CH₂, O.

It should be noted that ketene *S,S*-acetals in which the sulfur atoms are incorporated in the cyclic systems can also be converted to ketene *N,N*-acetals. For example, 1,3-dithiolane **24** reacts with *N,N'*-substituted ethylenediamines to give imidazolidine derivatives **25**.⁸

R = Ar, ArAlk.

The reaction of substituted 1,3-dithietanes **26** with *o*-phenylenediamine results in benzodiazepine derivatives **27**, which are oxidised in alkaline medium to give ketene *N,N*-acetals of the benzoimidazole series **28**. These compounds have also been obtained by independent synthesis from alkyl 2,2-bismethylthiomethylenecyanoacetate and *o*-phenylenediamine.¹⁹

Chlorination of ketene *S,S*-acetals in acetic acid readily gives ketene dichlorides, which represent convenient starting compounds for subsequent synthesis of ketene *N,N*-acetals. For example, acetal **29** was obtained by the reaction of the appropriate dichloride **30** with aniline.⁴¹

Similar reactions are also known for other ketene dichlorides, *viz.*, 2-dichloromethyleneindane-1,3-dione⁴² and 2-dichloromethylene-4,5-dichlorocyclopent-4-ene-1,3-dione,⁴³ as well as for some ketene dibromides⁴⁴ and ketene diiodides.⁴⁵

2. Synthesis based on ketene *O,O*- and *O,N*-acetals and related compounds

Ketene *O,O*-acetals and related compounds are promising starting reagents for the synthesis of ketene *N,N*-acetals. For example, bisalkoxymethylenemalonodinitriles **31** react with sodium cyanamide under mild conditions with formation of the sodium salt **32**, which gives *N*-cyanoketene *N,N*-acetal **33** on heating with methylamine.⁴⁶ Dimethoxymethylenemalonodinitrile **31** ($\text{R} = \text{R}' = \text{Me}$) reacts similarly with ammonia and ethylenediamine.⁴⁷

$\text{R} = \text{R}' = \text{Et}$; $\text{R}, \text{R}' = (\text{CH}_2)_2$.

The reaction of the 1,3-dioxolane derivative **34** with various diamines results in cyclic ketene *N,N*-acetals, while the reaction of compound **34** with aromatic diamines requires more drastic conditions than that with aliphatic ones.⁴⁸

Amino(aryloxy)methylenemalonodinitrile (**35a**) and ethyl amino(aryloxy)methylenecyanoacetate (**35b**) react with amines to give the corresponding enediamine derivatives **36a,b**.⁴⁹

$\text{X} = \text{CN}$ (**a**), CO_2Et (**b**).

3. Synthesis based on thiourea derivatives

It is well known that ketene *S,S*- and *S,N*-acetals react with amines rather smoothly, since the alkylthio group is a 'good leaving group' (see Section 1). Yet another group of reactions based on the replacement of the RS group, *viz.*, the reactions of compounds containing the reactive methylene group with *S*-alkylisothioureas, also result in the corresponding 'push-pull' enediamines. For instance, treatment of *N,N'*-dibenzyl-*S*-methylisothiourea with nitroacetone in alkaline medium gave a small yield ($\sim 20\%$) of β -nitro- β -cyanoenediamine **37**.⁵⁰ Cyclic thiourea derivatives react similarly.^{51–57} For example, the reaction of compound **38** with arylacetone results in cyclic acetals **39**.

Isothiuronium salts also react with compounds containing the reactive methylene group in the presence of sodium hydride.⁵⁸ For example, the reaction of salt **40** with malonodinitrile results in the corresponding symmetric enediamine.

Not only *S*-methyl derivatives of isothiuronium salts, but also compounds with more complex *S*-substituents can serve as starting compounds in the synthesis of ketene *N,N*-acetals.⁵⁹ Treatment of salts **41** containing an electron-acceptor group at the sulfur atom with sodium hydride in tetrahydrofuran gives enediamines **42** in moderate yields. It is believed⁵⁹ that this reaction gives intermediate ylides, which then undergo cyclisation to thiiranes **43**. Elimination of the sulfur atom from the thiirane ring results in compounds **42**.

R = CO₂R', Bz.

In the same study,⁵⁹ a method is proposed for the synthesis of ketene *N,N*-acetal **44** with the use of diethyl diazomalonate and tetramethylthiourea as the starting compounds.

An interesting method for the synthesis of enediamine **45** is described in Ref 60.

It was reported⁶¹ that ketene *N,N*-acetals can also be obtained from thiourea derivatives without preliminary S-alkylation. For example, enediamine **46** is obtained by condensation of compound **47** with malonodinitrile.

It is evident from the scheme shown above that the formation of the enamine moiety is accompanied by the pyrazole ring closure.

4. Synthesis based on 'activated' amides and ureas

It is known that 'activated amides', *i.e.*, amide acetals, imidates, imidoil chlorides and related compounds, are rather promising starting reagents for the formation of various enamine systems. Enediamines, including highly polarised ones, are obtained by the condensation of 'activated amides' with compounds having a reactive methylene group.⁶²⁻⁶⁴ For example, imidoil chloride **48** reacts readily with such compounds as ethyl cyanoacetate, malonodinitrile and dimedone in dimethyl sulfoxide in the presence of sodium hydride to give substituted ketene *N,N*-acetals.⁶⁵

X = CN, CO₂Et.

Chloroamidines **49** obtained by the action of phosgene on tetraalkylurea are converted to 'push-pull' enamines **50a-c** in the reaction with ethyl malonate and ethyl cyanoacetate or malonodinitrile.⁶⁶

X = Y = CN (**a**), CO₂Et (**b**); X = CN, Y = CO₂Et (**c**).

Derivatives of cyclic ureas, particularly imidates, also react readily with compounds that incorporate a reactive methylene unit.⁶⁷

The urea acetals **51** can undergo condensation with ethyl cyanoacetate or malonodinitrile to afford ketene *N,N*-acetals **50a,c**.^{68, 69}

X = CN, CO₂Et.

Orthoamidoesters **52** also enter into similar reactions to give aminals **53**.^{70, 71} It should be noted that compounds **52** are much more reactive than urea acetals **51**.

The bisamidinium salt **54** obtained by the reaction of an urea derivative with trifluoromethanesulfonic acid was also used for the synthesis of 'push-pull' enediamines **53**.⁷²

X, Y = CN, CO₂Et.

A modified procedure has been reported,⁷³ in which salt **54** was initially treated with 4-dimethylaminopyridine, and its condensation with malonodinitrile was carried out only thereafter.

Bis(dialkylamino)malononitriles, like urea acetals, can undergo condensation with compounds containing the reactive methylene unit. For example, the reaction of bis(dimethyl-amino)malonodinitrile with alkyl malonate or acetoacetate in the presence of sodium hydride in acetonitrile gives enediamines **55**.⁷⁴

X = CO₂R', COMe.

5. Synthesis based on various *S*-, *N*- and *C*-cyano derivatives

A number of studies deal with the synthesis of enediamines under consideration by addition of the cyano group to the reactive methylene unit. For example, the reaction of organic thiocyanates with β -diketones in the presence of nickel acetylacetonate gives ketene *S,N*-acetals, which can react with amines (in particular with morpholine) to afford ketene *N,N*-acetals in high yields.⁷⁵

Cyanamide and its derivatives react in a similar way.^{76–80} For example, the reaction of cyanamide with ethyl acetoacetate in the presence of nickel acetylacetonate results in the amina **56**.

Cyanamide reacts similarly with β -dicarbonyl compounds in the presence of SnCl₄.⁸¹

Another way for the synthesis of ketene *N,N*-acetals is based on the reaction of tricyanomethane (cyanoforn) and related compounds with amines.^{82, 83}

Trichloroacetonitrile proved to be a convenient starting reagent in the synthesis of the target enamines. Its condensation with CH₂-acids initially gives (α -trichloromethyl)enamines, in which the CCl₃ group is readily replaced by the amino group with the formation of enediamines.^{84–86} The reaction of trichloroacetonitrile with benzoylacetonitrile followed by the reaction of the resulting compound **57** with 2-aminopyridine can be presented as an example.⁸⁶

Similar replacement of the CCl₃ and CF₃ groups in enamines by the amino groups with the formation vicinal ethylenediamine derivatives has been reported.^{87, 88}

Reactions of trichloromethyldialkylamines **58** with compounds containing reactive methylene groups also result in ketene *N,N*-acetals.⁸⁹ For example, compounds **58** react with malonodi-

nitrile to give chloroenamines **59**. The latter react with aniline to afford enediamines **60**.

Finally, the reaction of tetracyanoethylene with primary amines (*e.g.*, pentylamine) readily yields symmetrical enediamines. Secondary amines can also be used in this reaction.^{90, 91}

6. Synthesis based on enamine derivatives

α -Chloroenamines⁹² and α -chloroenamides⁹³ react with amines to give ketene *N,N*-acetals. For example, the reaction of chloroenamidine **61** with a secondary amine results in the product **62**.⁹³

A wide range of β,β -disubstituted ketene *N,N*-acetals have been synthesised by C-acylation of β -monosubstituted α,α -diaminoethylenes.^{94–99} Cyanoacetic acid in the presence of Ac₂O,⁹⁴ acetic anhydride,⁹⁵ isocyanates, isothiocyanates,^{96, 97} and benzoyl-isothiocyanate were used as acylating agents.^{98, 99}

Scheme 1

- (a) Ac₂O, R–R = (CH₂)₂, X = CO₂Et;
(b) R'NCY, R' = Bz, R–R = (CH₂)₃, X = CSAr, Y = S;
(c) R'NCY, R' = Bz, X = NO₂, Y = S;
(d) R'NCY, R' = Ph, X = CN, Y = O, S;
(e) NCCH₂CO₂H, Ac₂O, X = NO₂.

It has been shown⁹⁷ that acylation of enamines **63** with isocyanates occurs not only at the β -carbon atom but also at the amino group.

X = CH₂, n = 1, 2; X = O, n = 2.

β -Alkylation of β -monosubstituted ketene aminaals with compounds containing reactive halogen has also been reported.¹⁰⁰

R = CO₂Et, Ph; Hal = Cl, Br.

A series of ketene aminals have been synthesised by acylation of derivatives of 2-methylimidazoline,¹⁰¹ 2-alkylbenzimidazoles^{102–104} and 2-methyltetrahydropyrimidines.¹⁰⁵ Examples of such syntheses based on 2-alkylbenzimidazoles are shown in the scheme below.

2-Methylbenzimidazole also undergoes bisformylation according to Vilsmeier in the presence of phosphorus oxychloride.¹⁰⁶

The reaction of 1,3-dimethyl-2-methylenebenzimidazoline (**64**) with compounds of general formula O=C=Y, where Y = O, S, NPh,¹⁰⁷ or with 1,4-naphthoquinone¹⁰⁸ results in ketene *N,N*-acetals **65** or **66a**, respectively. Acylation of compound **64** with acyl halides or related halogen-containing compounds in triethylamine gives the enediamines **66b–d**.¹⁰⁸

(b) RCl, Et₃N, R = MeCO (**66b**), Bz (**66c**), MeSO₂ (**66d**).

7. Synthesis based on pyrimidine derivatives

One of the most peculiar preparative methods for the synthesis of 'push-pull' enamines is that starting from pyrimidines with a strong electron-acceptor substituent at position 5 of the pyrimidine ring. In 1967, it was found¹⁰⁹ that the action of organic or mineral acids on such pyrimidines results in easy opening of their ring. For example, the reaction of substituted pyrimidine **67** with acetic, chloroacetic, trifluoroacetic or hydrochloric acids results in

the opening of the pyrimidine ring and formation of the enediamine **68**.

It was established¹⁰⁹ that if X is a tertiary amino group, the yields of enediamines **68** range from 50% to 95%. If X is a secondary amino group, the yields of compounds **68** are much lower. For example, if X = NHMe, the yield of the product is 18%, and if X = NH₂, it becomes impossible to obtain the corresponding enamine at all. In the latter case, the halogen at the pyrimidine ring is replaced by the hydroxy group.

The following mechanism of the pyrimidine ring opening has been proposed (Scheme 2).¹¹⁰ First, the nitrogen atom of the starting pyrimidine is protonated. The resulting pyrimidinium cation adds a molecule of water at position 2. Then elimination of the substituent from position 6 occurs with simultaneous opening of the pyrimidine ring at N(1)–C(2) bond. Subsequent *N*-deformylation of the resulting nitrile finally results in the enamine.

Scheme 2

The effect of the extent of substitution of the amino group in 4-amino-6-chloro-5-nitropyrimidines on the processes that occur on their heating in acetic or trifluoroacetic acids has been studied in detail.¹¹¹ This confirmed the conclusions¹⁰⁹ that ketene aminals **68** are formed in good yields if a tertiary amino group is present at position 4.

The action of trifluoroacetic acid on pyrimidine derivatives containing a primary or secondary amino group at position 4 was monitored by ¹H NMR spectroscopy.¹¹²

X	NHMe	NHEt	NHPr ⁱ	NHBut ⁱ	NH ₂
Yield of compound 68 (%)	47	20	21	25	30
Yield of compound 69 (%)	53	80	79	75	70

The formation of 'push-pull' enamines of the type **68** is also observed upon ring opening of 5-formyl-, 5-cyano- and 5-carboxypyrimidines.^{112,113} However, compounds of this type tend to form pyrimidones **69** to a greater extent than nitropyrimidines.

The mechanism of the pyrimidine ring opening shown in Scheme 2 has been confirmed.¹¹² The authors managed to isolate and identify the *N*-formyl derivative **70**. It was also found that prolonged heating of 5-formylpyrimidines in an acidic medium results in compounds **70**, then 3,3-diamino-2-formylacrylonitrile derivatives **71** are formed, and finally their C-deformylation occurs to give cyanoenediamines **72**.¹¹²

It was shown¹¹⁴ that treatment of 4-amino-6-chloro-5-formylpyrimidines with an alkali also results in ketene *N,N*-acetals.

It is of note that heating of 4-chloro- or 4-methoxy-5-nitro-6-X-pyrimidines in an alkaline medium made it possible to obtain potassium cyanonitroacetamide **73**.¹¹⁵

X = SC(S)NEt₂, Y = OMe; X = Y = Cl.

Ring opening of 4,6-dichloro-5-nitropyrimidine can be achieved on heating with secondary amines. However, treatment of chloronitroisothiazole with piperidine or morpholine gives β -cyano- β -nitroenamines **74** rather than enediamines.¹¹⁶

X = CH₂, O.

The bisketene aminal **75** was obtained according to the following scheme:¹¹⁷

The reaction of 4-chloro-5-nitro-6-R-pyrimidines with *S*-alkyl(aryl)isothiuronium salts on heating in an alkaline medium results in substituted pyrimidines **76**. Subsequently, the products **76** were converted to 'push-pull' enamines **77**, which then underwent cyclisation into substituted *sym*-triazines.¹¹⁸

R = Cl, OMe; X = Alk, Ar.

It has recently been shown¹¹⁹ that 4-arylamino-6-chloro-5-nitropyrimidines are transformed to enediamines **68** on boiling in dilute HCl to give considerable amounts of the corresponding 4-arylamino-5-nitropyrimidin-6-ones **69**.

A peculiar method for the synthesis of nitroenediamines containing a tetrazole moiety at the β -position is based on the reaction of 4-amino-6-chloro-5-nitropyrimidine derivatives with sodium azide.¹²⁰

Bromination of methylenedihydropyrimidine **78** gives a mixture of cyclic enamines.¹²¹

8. Miscellaneous methods for the synthesis of ketene aminals

The reaction of triethylammonium (2-chloro-1,3-dioxindan-2-yl)dichloromethanesulfonate (**79**) with various amines results in ketene *N,N*-acetals **80–82**.¹²²

In certain studies, carbodiimides have been used for the synthesis of ketene aminals. This reaction was first described in 1899 with the synthesis of enediamine **83** from *N,N'*-diphenylcarbodiimide and diethyl malonate as an example.¹²³

Compound **83** can also be obtained by the reaction of *N,N'*-diphenylthiourea with sodium diethyl malonate.¹²⁴

Dicyclohexylcarbodiimide and other carbodiimides react with Meldrum's acid to give the corresponding enediamines.^{125, 126}

Vinyl azides have also been used as the starting compounds in the synthesis of ketene N,N -acetals.^{127,128} For example, the reaction of vinyl diazide **84** with diaminopropane gave a small yield of cyclic product **85**.

The reaction of ketene N,S -acetals with sodium azide probably gives vinyl azides **86** as intermediates, which are then converted into heterocyclic ketene aminals **87**.¹²⁹

The reaction of 2-diazo-1,3-diketones with tetraaminoethylene derivatives results mainly in enediamino diketones **88**.¹³⁰

The synthesis of four-membered heterocyclic compounds, viz., diazetidine derivatives incorporating the enediamine moiety, has been reported.¹³¹ For example, condensation of N -(thioacyl)-carbamic acid derivative **89** with *para*-substituted anilines yields cyclic products **90**.

Heating of 1-hydroxy-5-methyl-1,2,3,4,4a,5-hexahydro-1,4a-propanopyrido[1,2-*a*]benzimidazole (**91**) with acetic anhydride in toluene results eventually in ketene aminal of the benzimidazole series **92**.¹³² This process is believed¹³² to occur according to the following scheme:

III. Properties of ketene N,N -acetals

1. Physicochemical parameters

The major characteristics of ketene N,N -acetals is the direct polar conjugation of two α -amino groups with β,β -electron-acceptor substituents. Naturally, this conjugation affects the spectral and other physicochemical properties of ketene N,N -acetals. For example, according to X-ray diffraction data, abrupt elongation of the $\text{C}=\text{C}$ bond in β,β -dinitroenediamines is observed, while the $\text{N}-\text{C}$ bonds are much shortened. This can be rationalised as the superposition of the following resonance structures:

The lengths of the $\text{C}=\text{C}$ bonds in β,β -dinitroenediamines lie within 1.451–1.474 Å, those of the $\text{N}-\text{C}$ bonds lie within 1.315–1.316 Å and those of the $\text{C}-\text{NO}_2$ bonds lie within 1.399–1.494 Å.⁴⁵ It is known¹³³ that the barrier to *cis-trans*-isomerisation in β,β -diacyl N,N -acetals **93** ('rotation' around the carbon-carbon double bond) is extremely low and is $\Delta G^\ddagger < 8 \text{ kcal mol}^{-1}$ (to compare with enamines, see Refs 134–136).

If weaker electron-acceptor substituents are present in the molecule (for example, in compounds **94** and **95**), the rotation barrier increases to 15 and 21 kcal mol^{-1} , respectively.¹⁰ The same trend is observed if the electron-donor effect of the α -substituents decreases. For example, for ketene S,S -acetal **96**, $\Delta G^\ddagger > 25 \text{ kcal mol}^{-1}$. It is essential that in the cases where the formation of intramolecular hydrogen bonds in diacyl ketene aminals is possible, *cis-trans*-isomerisation is slowed down considerably. For example, the ^1H NMR spectrum of compound **97** (in CDCl_3) contains a double set of signals corresponding to the *E*- and *Z*-isomers, whereas one series of signals is observed in a solvent that favours the scission of intramolecular hydrogen bonds ($\text{DMSO}-d_6$).^{8,77,78}

In cyclic enediamines **98**, the rotation barriers are also very low and are ~ 12 – 13 kcal mol $^{-1}$ (see Refs 137, 138). It is of note that replacement of the C=O group in the β -substituent by the C=S group increases the $\Delta G^\ddagger$ to ~ 30 kcal mol $^{-1}$. This effect is related to the stabilisation of the ground state and destabilisation of the transition state.¹³⁹

IR spectra of 'push-pull' enediamines containing the carbonyl group are their important characteristics, the absorption bands of the CO groups are observed in the region below 1650 cm $^{-1}$. This indicates strong conjugation of the carbonyl groups with the electron-donor, substituted α -amino groups.^{59, 77, 126, 140, 141} ^{13}C NMR spectra of this type of compounds are also rather characteristic.^{28, 78, 142} For example, the signal for the C $_\beta$ atom in N -benzoylenediamino diketones **97** is in the region $\delta \sim 87$ – 100 ppm, while the signal for the C $_\alpha$ atom is at $\delta \sim 161$ – 163 ppm. These chemical shifts indicate that the electron pairs of the nitrogen atoms participate in the 'enamine conjugation'.

A detailed study of ^1H and ^{13}C NMR spectra carried out for nitrocyanoenediamines **99**¹⁴³ showed that the stereochemistry of these compounds is determined by the possibility of formation of intramolecular hydrogen bonds between the amino group and the nitro group.

^{13}C NMR spectra of compounds **99** are also characterised by an upfield shift of signals for the C $_\beta$ atom ($\delta \sim 90$ – 103 ppm), while the signals for the C $_\alpha$ atoms are in the region $\delta 157$ – 170 ppm. Specific conformation features of cyclic 'push-pull' ethylenes with sterically hindered electron-donor and electron-acceptor groups were studied.^{144, 145} It was shown that the electron-donor and electron-acceptor fragments in these compounds are turned relative to the central carbon-carbon double bond. The tautomerism in ketene aminals and related compounds was studied.^{102, 146, 147} It was shown that compound **100** exists predominantly in the tautomeric form **100a**.

The position of tautomeric equilibrium depends on the solvent. For example, the equilibrium **101a** $\rightleftharpoons$ **101b** in CHCl_3 , dioxane, methanol and water is shifted towards the enamine **101a**, whereas in DMSO and DMF it is shifted towards the enol **101b**. In acetonitrile, a mixture of tautomers **101a,b** is formed.¹⁴⁶

It was shown⁷⁹ that diacyl ketene aminals represent bases and are protonated on the oxygen atom.

However, if the amino group has a strong electron-acceptor substituent, these compounds are strong organic acids. For example, the ionisation constants ($\text{p}K_\text{a}$) of N -cyano- β,β -dicyano-ketene aminals **102** in water are ~ 2.6 – 2.8 , *i.e.*, they are even stronger acids than formic acid ($\text{p}K_\text{a}$ 3.75)

Finally, the pronounced effect of direct polar conjugation in 'push-pull' enamines is also characterised by their high dipole moments.⁵⁸ For example, the dipole moments of imidazoline or pyrimidine derivatives of ketene N,N -acetals are ~ 8 D, while it is only 6.5 D for such a strongly polarised compound as N -phenyl-sydnone.¹⁴⁸

2. Reactions of β,β -disubstituted ketene N,N -acetals with electrophilic and nucleophilic reagents

The presence of two α,α -amino groups in ketene aminals increases the nucleophilicity of the C $_\beta$ -position considerably, and hence increases the possibility of attack on this position by electrophilic reagents. For example, it is known¹⁴⁹ that the reaction of ketene aminals **103** with *tert*-butyl hypochlorite smoothly gives the corresponding chloroamidines **104** in high yields despite the presence of two substituents at the C $_\beta$ -atom.

$\text{R}^1 = \text{Ph, Me, Pr}^i$; $\text{R}^2, \text{R}^3 = \text{CN, CO}_2\text{Et}$.

Nitration of 'push-pull' enediamines under various conditions has been studied.¹⁵⁰ It was found that the use of a mixture of nitric and sulfuric acids resulted in C $_\beta$ -nitration and N -nitrosation, while in a mixture of HNO_3 and trifluoroacetic anhydride, C $_\beta$ - and N -nitration occurred. In the latter case, the order of nitration steps on the C $_\beta$ and N atoms has not been determined. Nitration of the ketene alinal **105** under various conditions results in products **106** and **107**.¹⁵⁰ It is essential that compound **107** is also formed upon nitration of β -monosubstituted 'push-pull' enediamine **108** with an HNO_3 –trifluoroacetic anhydride mixture.

A method for reductive elimination of one NO₂ group from the C_β atom in compound **107** upon treatment with potassium iodide has been described.¹⁵¹

The reaction of β,β-disubstituted ketene *N,N*-acetals with acyl halides results in *N*-acylation products.⁸⁸ If dimethyltrichloromethylamine is used as the acylating reagent, the reaction occurs at the nitrogen atom to give the derivative **109** containing the chloroformamidine moiety.

(a) BzCl, R¹ = H, R², R³ = CN, CO₂R⁴;
(b) CCl₃NMe₂, R¹ = Me, R² = R³ = CN.

Alkylation of ketene amins is an important reaction that characterises enamines and deserves separate discussion. For example, the alkylation of thioamides **110** with methyl iodide occurs mostly on the sulfur atom. In addition to *S*-methyl derivatives **111**, *N,S*-dimethyl derivatives **112** are formed.¹⁵²

Oxidation of amins **111** with mercuric acetate in acidic medium results in enediamines **113**.¹⁵²

It should be noted that the oxidation of the ammonium salts of cyano(ethoxycarbonyl)thiocarbamoylmethanes with mercury(II) oxide readily gives ketene amins.¹⁵³

Enediamino ketone **114** undergoes alkylation with triethyloxonium tetrafluoroborate or dimethyl sulfate on the oxygen atom to give the corresponding complex **115**, which, in turn, can react with alkoxide anions to produce alkoxydienediamine **116**. Compound **116** is a convenient starting reagent for the synthesis of various dienamines, e.g., dienediamine **117** or dienetriamine **118**.⁷⁰

Yet another reaction of ketene amins with electrophilic reagents worthy of note is that of enediamino diketones with the Lawesson reagent (LR). For example, enediamino diketone **119** can be converted to the corresponding enediamino dithione **120**.⁸

LR = $p\text{-MeOC}_6\text{H}_4\text{P}(=\text{S})_2\text{P}(=\text{S})_2\text{C}_6\text{H}_4\text{OMe-}p$.

A series of reactions of ketene amins with nucleophilic reagents has been described.¹²⁵ For example, acid hydrolysis of a Meldrum's acid derivative **121** resulting in the β-monosubstituted derivative **122** is worth mentioning. The same authors described degradation of compound **121** upon treatment with ethanolic alkali.

Monodeacylation of enediamino diketones has been described.¹² For example, the action of the hydroxy or methoxide anion on diketones **123** results in ketones **124**.

A possible version of the mechanism of this process includes the addition of the nucleophile at the carbonyl group.¹²

A version involving the attack of the nucleophile on the α-position may not be ruled out, either.

Recently,¹⁵⁴ an important method for C-deacylation of enediamino diketones upon treatment with cobalt acetate with intermediate formation of chelate complexes **125** and **126** has been suggested.

Elimination of the β -formyl group in acidic medium has been described⁹³ for ketene aminals incorporating the formamidine moiety.

N-Acylketene *N,N*-acetals readily undergo N-deacylation on treatment with sodium methoxide in methanol.⁸⁰

The transformation of β -substituents in 'push-pull' enamines under the action of nucleophilic reagents has been reported.^{47, 48, 92} For example, treatment with hydrobromic acid gives bromoimines,⁹² and heating with aniline hydrochloride results in salts of ketene aminals. Treatment with alkali converts the cyano group in 'push-pull' enamines into the carbamoyl group.⁴⁸

If a ketene amina contains two unsubstituted amino groups, it can react with diethyl malonate to give a cyclic diacylketene amina.⁴⁷

Diverse transformations of the cyano group in dicyanodiaminoethylene **127** have been discovered in a study of its reaction with chloromethylenemalononitrile.¹⁵⁵

In addition, one should note such a reaction involving ketene *N,N*-acetals as thermolysis of compounds **128** based on Meldrum's acid.^{9, 25} The result of this process depends on the reaction temperature and the nature of the *N*-substituent.

It has been found recently¹¹⁹ that the 'push-pull' enamines **129** with at least one nonsubstituted amino group readily react with amidacetals to give the corresponding amidines **130** and **131** and the reaction rate depends on the extent of substitution of the other amino group ($\text{NH}_2 > \text{NHMe} > \text{NMe}_2$).

Transamination was studied using enamide **131** as an example. It is known¹⁵⁶ that enamides undergo transamination more readily than the corresponding enamines. However, it was found that compound **131** reacts in a non-standard way due to the additional α -amino-containing fragment, and replacement of enamide fragments is accompanied by the reaction on the *meso*-carbon atom of the amidine group.¹¹⁹

A very important property of ketene *N,N*-acetals is their ability to form chelate complexes with metals^{115, 157–160} and boron compounds.^{161–166} This enabled the development of a new direction of heterocyclic synthesis that opens a route to diverse azaheterocyclic compounds (see below). We consider here only some of the unusual properties of chelate complexes, which provide the possibility to perform processes non-characteristic of the starting ligands.

It is known^{167, 168} that enamines incorporating a primary amino group react with amide and lactam acetals primarily on the NH_2 group. If boron chelates are used, an opportunity appears to perform reactions on the active methylene group without involving the amino group. For example, it has been shown^{161–162, 165} that the chelate **132** reacts with dimethylformamide and dimethylacetamide acetals selectively on the CH_2 group to give compounds **133**.

3. Synthesis of heterocyclic compounds based on ketene *N,N*-acetals

a. Four-membered heterocycles

Benzoylation of ketene amins results in azetine derivatives.⁸⁸

The formation of diazetidine derivatives¹³¹ has been discussed above (see Section II.8).

b. Five-membered heterocycles

The closure of pyrrole rings according to the Thorpe–Ziegler and/or Dieckmann reaction starting from ketene *N,N*-acetals of the benzimidazole series has been described.¹⁴

$\text{X} = \text{CN}, \text{CO}_2\text{Et}; \text{Z} = \text{NH}_2, \text{OH}$.

The pyrrole ring could also be obtained by cyclisation of amins **134** on refluxing in dioxane.¹⁰⁰

Synthesis of pyrazole derivatives occupies an important place in the chemistry of ‘push-pull’ enamines. For example, the strategy of chelate synthesis considered above was also found to be very efficient for the synthesis of various substituted pyrazole-containing systems.^{162, 165} An example of this kind of synthesis is shown in the Scheme 3.

Scheme 3

Similar synthesis of indazole derivatives **135** from the chelate **133** and hydrazine hydrate has been described.¹⁶⁵

A wide range of substituted pyrazoles have been obtained by transamination of the dialkylamino group in ketene amins with hydrazine hydrate followed by cyclisation on the cyano group.^{50, 84, 113, 143, 169, 170} For example, 3,5-diamino-4-pyrazole has been obtained this way.

Similarly, the hydrazino group can replace the good leaving group, *viz.*, CHAl_3 .⁸⁷ For example, this method was used to obtain alkyl 3,5-diaminopyrazole-4-carboxylates.

Cyclisation can involve not only cyano groups but also other functional groups.^{85, 86}

N-Aminoketene amins obtained in a different way can also be used as starting compounds in the synthesis of fused pyrazoles.⁵² An example of such a synthesis based on compound **136** is shown in the scheme:

The synthesis of pyrazolylbenzimidazole **137** is based on the reaction of *gem*-formyl groups of the starting benzimidazole with hydrazine hydrate.¹⁰⁶

Several studies^{171, 172} dealt with the synthesis of imidazole derivatives from 'push-pull' enamines (see also Ref. 18). For example, the reaction of ethyl diaminomethylenecyanoacetate with phosgene or diethyl oxalate results in imidazolidinediones.¹⁷¹

Imidazoles are formed from salts of alkyl dicyanoacetate or tricyanomethane and amino acids,¹⁷² ketene amins being the intermediate products.

Substituted isothiazoles were synthesised by the oxidation of the appropriate enediaminothioamides.^{26, 98}

The synthesis of tetrazoles from ketene amins has already been discussed above (see Section II.8).¹²⁹

Finally, the reaction of hydrazinoenamine **138** with carbon disulfide results in the closure of both the pyrazole and pyrimidine rings to give a purine isoster, viz., pyrazolo[3,4-*d*]pyrimidine **139**.²²

c. Synthesis of six-membered heterocycles

Thiapyran derivatives were obtained according to the following scheme.¹⁴⁵

A few studies^{166, 173} deal with the synthesis of substituted pyridines based on ketene amins with the use of the chelate synthesis strategy.

Recyclisation of pyrazolylketene acetal **140** at high temperature results in pyrazolo[3,4-*b*]pyridone **141**.⁷

Methyl bisanilinomethylene cyanoacetate undergoes cyclisation into quinolinone **142**.¹⁵

Similar cyclisations have been described in Refs 128 and 140.

Intramolecular cyclisation of substituted β -cyanoacetyl- β -nitroketene *N,N*-acetals results in 4-pyridone derivatives **143a,b**.⁹⁴ It is of note that the hydroxypyridine tautomeric form predominates for pyridone **143a** ($R = H$), whereas the pyridone form predominates for pyridone **143b** ($R = Me$).

Intramolecular cyclisation of ketene *N,N*-acetal **144** upon treatment with sodium hydride to give benzopyridone **145** has been reported.¹⁸

Finally, the synthesis of various pyridones based on alkoxy-dienediamine vinylogues **146** and **147** should be noted.⁷⁰

Thermolysis of *N*-acylaminals **148** results in substituted oxazin-6-ones **149**.²⁹

Another method for the synthesis of substituted 1,3-oxazin-6-ones has also been reported.¹⁷⁴

$R = Me, Ph$.

The majority of studies devoted to the synthesis of heterocyclic compounds from ketene amins deal with the synthesis of pyrimidine derivatives. In this case, chelate synthesis is also an important approach to their synthesis.

The use of boron chelates **132** has enabled the synthesis of substituted pyrimidines **150** and **151**.^{161, 163, 164}

The condensation of β -diketones with *N*-cyanoamidines ($R^3 = Me, Ph$) or dicyanoguanidine ($R^3 = NH_2$) in the presence of nickel acetate, which is required for the formation of reactive chelates, occurs through intermediate derivatives of ketene *N,N*-acetals with their subsequent cyclisation into substituted 2,4-diaminopyrimidines.^{160, 175}

Enediaminodicarbonyl compounds react with isocyanates to give pyrimidines.^{176,177} For example, cyclic aminal **152** was converted into pyrimidinone **153** by treatment with phenyl isocyanate.

Ketene aminals with the *N*-ethoxycarbonylcarbamoyl substituent¹⁰³ (**154**) or with the *N*-benzoylthiocarbamoyl substituent¹⁷⁸ (**155**) at the β -position undergo cyclisation into pyrimidine derivatives on heating or under conditions of basic catalysis.

Enediamino diketones **156** react with aryl isocyanates giving intermediate 4-arylamino-5-acetylpyrimidin-2-one derivatives **157**, which are converted into pyrido[2,3-*d*]pyrimidines **158** under the reaction conditions.¹⁷⁹

Pyrimidine derivatives **159** have been obtained as products of the reaction of 6-aryl-2,2-dimethyl-1,3-dioxin-4-ones with ketene aminals.^{180,181}

The ethoxycarbonyldicyanomethane salt **160** reacts with methyl 3-aminothiophene-2-carboxylate and amino acid esters to give ketene *N,N*-acetals which can undergo cyclisation into pyrimidine and thieno[3,2-*d*]pyrimidine derivatives.¹⁴²

Compound **61** reacts with aniline in acetic acid to give the intermediate ketene aminal **161**, which then undergoes cyclisation into pyrimidinone imine **162**.⁹³

α,α -Diamino- β -carbamoyl- β -cyanoethylene derivatives are transformed on heating with methyl orthoformate to give substituted 4-amino-5-cyanopyrimidin-6-ones.⁹⁷

Cyclisation of 'push-pull' enaminoamidines **163** under various conditions results in moderate yields of 6-amino-2-phenylpyrimidine derivatives.²⁰

Alkoxydienediamines are also convenient starting compounds for pyrimidine synthesis.⁷⁰ For example, diamine **116** reacts with amidines to give substituted pyrimidines **164**.

Finally, let us mention an unusual synthesis of 4,6-bis(dimethylamino)-5-nitropyrimidine **165** from diamidine **131**.¹⁸²

Compound **165** is also formed upon treatment of diamidine **131** with DMF diethyl acetal. The following scheme of this non-trivial transformation was suggested:¹⁸²

d. Seven-membered heterocycles

Simultaneous closure of five- and seven-membered heterocycles in the reaction of amination **166** with triamine **167** to give compound **168** has been reported in a study¹³ dealing with the synthesis of diazepine derivatives from ketene amination.

A different approach¹⁹ to the synthesis of benzodiazepines has been considered in Section II.1.

IV. Conclusion

To sum up the data presented in this review, it can be stated that a fruitful direction based on the use of β,β -bifunctionally substituted ketene N,N -acetals in organic synthesis has been created by now. The preparative availability of these compounds and their high reactivity form considerable prospects for their application in

the synthesis of diverse organic and especially heterocyclic systems that are of interest both in theoretical and practical aspects.

The authors are grateful to Dr. Christoph Hooch (BYK GULDEN, Germany) for his help in using the databases.

This review has been written with financial support of the Ministry of Science and Technology of Federal Republic of Germany [the project 'Transform' 01 KX9812 — Bundesministerium für Forschung und Technologie (BMFT)].

Abstract. Characteristic features of the synthesis of isoalkanes and arenes from CO and H₂ in the presence of oxide, metallic and zeolite-containing catalysts are considered. Primary attention is paid to cobalt–zeolite systems. The bibliography includes 96 references.

I. Introduction

Nowadays, petroleum is the main source of hydrocarbons. However, since petroleum resources are limited, development of methods for production of hydrocarbons from coal, natural gas, oil shales, plant biomass, *etc.* becomes a topical task. One of these methods is the Fischer–Tropsch synthesis, which includes three stages: (1) production of synthesis gas (a mixture of hydrogen and carbon monoxide) by gasification of solid raw materials (coal, peat, biomass, *etc.*) or reforming of natural gas; (2) synthesis of hydrocarbons from synthesis gas; (3) upgrading (hydrocracking, hydroisomerisation) of the resulting mixture giving commercial products. The term ‘Fischer–Tropsch synthesis’ is often used in the literature to denote only the second stage of the process, that is, production of a mixture of liquid and solid hydrocarbons from synthesis gas. It is in this sense that we use this term in this review.

The synthesis of hydrocarbons from carbon monoxide and hydrogen in the presence of Group VIII transition metals is a widely employed polymerisation reaction on heterogeneous catalysts. This process yields mostly alkenes and alkanes the yields and composition of which depend on the nature of the catalyst and the reaction conditions.

In some countries, iron and cobalt catalysts are used in industrial syntheses of hydrocarbons from non-petroleum raw materials. At present, catalysts of this type are preferred because they are highly selective in relation to the formation of paraffins the proportion of which in the synthesis products usually exceeds 90%.

Cobalt catalysts are traditionally used to produce linear alkanes. These products can be separated to give petrol (C₅–C₁₀) and diesel (C₁₁–C₁₈) fractions of liquid hydrocarbons and a wax fraction (synthetic ceresin C₁₉₊).

Mixtures of liquid hydrocarbons are mostly needed to produce components of engine fuels, detergents, solvents and some medicines and perfumes. At present, production of fuels is the predominant field of application of the Fischer–Tropsch products.

The hydrocarbon mixtures synthesised from CO and H₂ are not finished liquid fuels. However, the main characteristics of the diesel fraction obtained on Co catalysts conform to those required of diesel fuels (for example, its cetane number is greater than 50). In contrast, the substantial amount of linear alkanes (70% or more) present in the petrol fraction considerably reduces the possibility of using it directly in internal combustion engines.

Figure 1 presents the plots for the octane numbers of individual hydrocarbons of various homologous series.¹ It can be seen

Figure 1. Octane numbers of individual hydrocarbons of various homologous series.

(1) saturated hydrocarbons (paraffins and naphthenes); (2) isoparaffins; (3) olefins; (4) aromatic hydrocarbons.

Received 8 September 1997

Uspekhi Khimii 67 (11) 1032–1043 (1998); translated by Z P Bobkova

that aromatic compounds possess the highest octane numbers and that the octane numbers of isoalkanes are markedly higher than those of the corresponding linear alkanes (especially when the number of carbon atoms in the molecule is large). Thus, isoparaffins, aromatic compounds and cycloalkanes, which are formed in relatively small amounts in the Fischer–Tropsch synthesis in the presence of traditional Co catalysts, are the desirable components of high-octane petrols. These compounds can be produced from linear alkanes by isomerisation, cyclisation and cracking; aromatics can also be obtained by dehydrogenation.

At present, it is considered expedient to use branched alkanes for increasing the octane numbers of petrols, because these substances give less harmful exhausts into the atmosphere upon transformations in internal combustion engines than do aromatic hydrocarbons, which are also used to improve the quality of petrol. A fairly promising method is direct production of hydrocarbon mixtures with increased contents of isoalkanes from synthesis gas. This can be accomplished using oxide and metal-containing catalysts.

II. Oxide catalysts

Let us consider synthesis of branched hydrocarbons from CO and H₂ in the presence of oxide catalysts.¹ For example, the process catalysed by TiO₂, ZrO₂ or CeO₂ (375–475 °C, 30–60 MPa) gives isobutane as the major product, its yield being 20–50 g m⁻³ of synthesis gas.[†]

The synthesis of branched hydrocarbons from CO and H₂ in the presence of oxide catalysts includes apparently the following stages: formation of methanol and dimethyl ether, hydrocarbon chain growth, dehydration of higher alcohols and hydrogenation of alkenes to give isoalkanes.^{2,3}

In the presence of mixed oxide catalysts such as TiO₂–Al₂O₃, ThO₂–ZnO and ZnO–Al₂O₃ at 400–450 °C and 2.5 MPa, synthesis gas is converted into hydrocarbons in a yield of 105 g m⁻³ at a degree of CO conversion of 70%–80%. Liquid hydrocarbons (C₅₊) account for about 57 g m⁻³ of the products formed.³ At temperatures above 450 °C, gaseous hydrocarbons are mainly produced (up to 50–70 g m⁻³ of isobutane), whereas below 375 °C alcohols are formed as the major products. In addition to isoparaffins, the reaction products contain unsaturated aliphatic hydrocarbons (more than 90% of which are branched), and small amounts of aromatic hydrocarbons and naphthenes.

To produce high-quality petrols from CO and H₂, catalysts consisting of aluminium, tungsten, zirconium, uranium and lanthanide oxides with ZnO, Cr₂O₃ and CuO present as additives have been developed. These catalysts are active at > 10 MPa and at temperatures above 350 °C.⁴ A two-stage process for production of olefins and high-octane petrol from synthesis gas in the presence of iron and oxide catalysts has also been proposed.⁵ The first stage is carried out over the Fe₃O₄ (96.8%)–Al₂O₃ (2.4%)–K₂O (0.8%) catalyst at 310 °C and at 1–3 MPa and affords a mixture of alkenes in a yield of 171 g m⁻³. In the second stage catalysed by ThO₂, the remaining CO and H₂ are converted at 400–450 °C and 28–30 MPa into petrol (yield 137 g m⁻³).

The process of selective production of branched hydrocarbons from CO and H₂ on oxide catalysts has not yet found practical application, because it usually requires relatively drastic conditions. In addition, most often, the yield of the main products of this synthesis in the presence of oxide catalysts is rather low. Therefore, hybrid or bifunctional metal-containing catalysts, which are active under milder conditions, are considered to be more promising for the synthesis of branched hydrocarbons.

[†] The activity of catalysts in the Fischer–Tropsch synthesis is usually estimated based on the yield of hydrocarbons produced from 1 m³ of synthesis gas under normal (or standard) conditions (s.t.p.). The maximum theoretical yield of hydrocarbons amounts to 208.5 g m⁻³ (s.t.p.).

These catalytic systems combine the properties of hydrogenating catalysts (to convert CO and H₂ into hydrocarbons) and catalysts for hydrocarbon transformations (in particular, isomerisation).

It is known^{6–9} that hydrocarbons can undergo various transformations in the presence of solid acids. Mixed oxides (for example, amorphous aluminosilicate) and zeolites belong to this class of catalysts. Deposition of metal salts onto solid acids or introduction of reducible cations into zeolites by ion exchange gives (after reduction of the metal cations) bifunctional catalysts, which combine the properties of metallic and acidic contacts.

Hydrocarbons or intermediates formed from CO and H₂ with participation of the metallic component of the catalyst can undergo secondary transformations on the oxide (acid) surface. The majority of these transformations resemble homogeneous catalytic reactions occurring in the presence of strong acids. Therefore, it is usually assumed that the mechanisms of these processes are similar.

III. Transformations of hydrocarbons on acidic catalysts

In reactions occurring on solid acidic catalysts (as well as in homogeneous acid-catalysed reactions), carbocations play an important role. These species are generated on bifunctional catalysts upon proton transfer from a Brønsted acid site to an alkene formed on the metallic phase.

Carbocations can be classified into carbenium and carbonium ions. Carbenium ions contain a positively charged carbon atom coordinated to three alkyl groups or three hydrogen atoms (R₃C⁺). Carbonium ions are based on a pentacoordinated positively charged carbon atom surrounded by the same substituents, at least one of them being hydrogen (R₄C⁺H).

The formation of carbocations on solid acids Z (in particular, on zeolites) includes the following reactions:⁹

According to reaction (1), a zeolite proton reacts with an alkene to give a carbenium ion. Reaction (2) describes protonation of alkanes resulting in a carbonium ion. The latter is then converted into a smaller carbenium ion upon elimination of an alkane molecule or molecular hydrogen. Both reactions occur on Brønsted acid sites. It should be noted that process (1) occurs more rapidly and at lower temperatures than process (2).

Transformations with hydride ion transfer can also occur on Lewis acid sites.

The formation of carbenium ions on bifunctional metal-containing catalysts occurs mostly by reaction (1), *i.e.* these ions result from the transfer of a proton from a Brønsted acid site to an alkene formed on the metallic phase. The proton transfer is terminated as a result of fast hydrogenation of unsaturated fragments on metal particles. The presence of a metal permits the reaction temperature to be decreased by ~100 °C.⁹ Simultaneously, isomerisation and cracking of isomerised hydrocarbons occur on acid sites. The rearrangements and cleavage of alkylcarbenium ions are the rate-determining steps.

In bifunctional catalysts, a metal ensures the occurrence of hydrogenation–dehydrogenation reactions, whereas the role of a solid acid (zeolite or a mixed oxide) consists in the formation of

carbocations on acid sites. These cations undergo isomerisation and destruction and then they are desorbed, mostly as alkenes. The latter are converted into alkanes upon hydrogenation on the metal component of the catalyst. The classical transformation chart can be represented as follows:

In accordance with this scheme, carbenium ions result from protonation of alkenes. These ions can rearrange and be desorbed as isomers, or they can be cracked (β -cleavage). Thus, cracking and isomerisation are competing processes. In the general case, isomerisation of alkanes with high molecular masses occurs at lower temperatures than hydrocracking.⁹

Alkylcarbenium ions can participate in the following transformations:⁹ intramolecular hydride shift, skeletal isomerisation, intermolecular transfer of a hydride ion from a carbenium ion to a substrate molecule to give a new carbenium ion and an alkene (this is normally the slowest step occurring on the strongest acid sites of the catalyst),¹⁰ alkylation by alkenes resulting in the formation of longer alkylcarbenium ions, β -cleavage yielding shorter alkylcarbenium ions and alkene fragments and deprotonation (chain termination). All alkylcarbenium ions formed from both neutral molecules and various intermediates can enter into the above reactions.

In the presence of bifunctional catalysts, lower alkanes participate in more complex processes, namely, dehydrogenation and oligomerisation of 'internal alkenes' (those with an internal double bond) followed by cracking of the oligomers.¹¹

IV. Zeolite-containing catalysts

In recent years, studies have been started on bifunctional catalysts that combine the properties of traditional Fischer–Tropsch catalysts (redox function) and selective zeolite catalysts (acid–base function). Both types of catalytic sites are involved in consecutive and parallel transformations.¹² Alkenes formed from CO and H₂ on the metal-containing component of the catalyst are converted on the zeolite into aromatic and branched aliphatic hydrocarbons, while alkanes are cracked, which increases the petrol fraction.

The catalytic sites for acid–base reactions are hydroxy groups of the zeolites or water molecules dissociated in the cation field.¹³ The zeolite hydroxy groups can result from the following processes:

(a) hydrolysis

(since the sodium form of a zeolite is the salt of a weak acid and a strong base, this equilibrium is shifted to the right, and aqueous suspensions of zeolites are normally alkaline);

(b) decomposition of the ammonium form of a zeolite

(c) heterolytic dissociation of water molecules in the field of a polyvalent cation and the zeolite framework atoms

where M is metal.

The aluminium atom has a vacant *p* orbital; occupation of this orbital results in withdrawal of the electron density from oxygen in the [Al–O(H)–Si] group and thus in polarisation of the O–H bond. Thus, the OH group in the [SiOH] fragment, which exhibits weakly acidic properties when incorporated in silica gel, behaves as a strong Brønsted acid site in the presence of aluminium atoms.

Bifunctional catalysts are usually prepared on the basis of HZSM-5 zeolite. This choice is due to the following reasons:⁸ the average size of the zeolite pores is 5.5 Å, which facilitates selective formation of molecules containing less than 10 carbon atoms, *i.e.* hydrocarbons of the petrol fraction; the strong acid sites of HZSM-5 are responsible for oligomerisation, cracking and aromatisation; this zeolite is stable against coking, because the presence of medium-size pores prevents the formation of coke precursors; the zeolite is stable under hydrothermal conditions and resistant against dealumination, which is possible under the Fischer–Tropsch synthesis conditions because this reaction yields a substantial amount of water.

The high selectivity of zeolites of the HZSM-5 type towards the formation and subsequent transformations of light hydrocarbons is determined by their structure. In the pores containing strong acid sites, organic molecules are adsorbed according to the 'tail-to-tail' pattern.¹⁴ In the majority of cases, only alkenes and/or carbonium ions containing five or fewer carbon atoms are able to participate in reactions occurring in zeolite channels with a size of ~ 9 Å; therefore, the oligomers formed in these reactions contain not more than 10 carbon atoms. In addition, HZSM-5 zeolites 'control the movement of molecules': the reactants enter the zeolite structure through sinusoidal channels, whereas the products are removed through linear channels. As this takes place, alkenes, which slowly diffuse through the pores, are transformed into branched alkanes. The absence of back diffusion is a crucial factor determining the use of HZSM-5 zeolites in catalytic transformations.

The use of HZSM-5 and other high-silica zeolites as supports for the catalysts for the synthesis of hydrocarbons from CO and H₂ has been started quite recently.^{15–17} To increase the content of aromatic hydrocarbons or isoalkanes in the synthesis products, two types of catalysts are usually employed, namely, hybrid systems comprising an oxide catalyst for methanol synthesis and a zeolite (for example, Zn/HZSM-5 and Zn–Cr/HZSM-6)¹⁶ and also bifunctional systems based on metallic catalysts of the Fischer–Tropsch synthesis and zeolites. Both types of catalysts have advantages and drawbacks. Systems of the former type permit selective and highly efficient synthesis of mixtures of aromatic hydrocarbons; however, they are insufficiently stable (the period between catalyst regenerations varies from one to several months). Systems of the latter type are characterised by a lower productivity but they are suitable for the synthesis of both aromatic hydrocarbons and branched paraffins.

V. Synthesis of aromatic hydrocarbons and isoalkanes on zeolite-containing catalysts

Zeolite-containing catalysts based on Group VIII transition metals are usually prepared by co-precipitation or ion exchange followed by activation with hydrogen. The transition metal cations occur initially within the zeolite structure and on its surface and can be reduced almost completely.¹³ In the general

case, the degree of reduction depends on the method of cation activation with hydrogen, the nature of these cations and the reactivity of their oxygen environment in the zeolite. In addition, it depends on the degree of dispersion of the initial compound containing the transition element and on the diffusion processes in the zeolite during reduction.

The Co–O bond of an isolated cobalt species in a zeolite framework is ionic.¹⁸ The reduction of cations in the coordination sphere of these zeolites occurs at temperatures above 450 °C,¹⁹ cation-exchange zeolites behaving as ordinary salt systems.

The mechanism of reduction of transition metal cations in zeolites differs from the mechanism of reduction of the corresponding metal oxides.²⁰ The latter is irreversible, the hydrogen that has reacted being removed as water. On the contrary, in zeolites, the protons are retained by the framework where they form hydroxy groups.

Cations located in different crystallographic positions have different electrostatic environments and, therefore, different reducibilities.²¹ The reducibility depends also on the silicon to aluminium ratio in the zeolite framework,²² *i.e.* on the Si–O bond length, the residual charge on the framework, and the effective charge on the cation itself.

The character of localisation of cations and their reducibility depend appreciably on the catalyst pretreatment conditions. In particular, dehydration leads to the destruction of aqua complexes of transition metal cations; the cations migrate to positions with higher degrees of coordination unsaturation, which decreases their reducibility.²³

After reduction, transition metals can occur in zeolite-containing catalysts as separate atoms, clusters or crystallites with a size of ≥ 100 Å located on the external surface of the zeolite.¹³ It should be noted that decationised zeolites contain large amounts of strong proton-releasing and electron-withdrawing sites. Thus, the use of a zeolite support makes it possible to prepare catalytic systems differing in the degree of metal dispersion and in the strength of its interaction with the surface.

The activity of the most widely used Co catalysts for the Fischer–Tropsch synthesis is determined to a large extent by the nature of the zeolite support.²⁴ Thus the yield of liquid hydrocarbons on the Co catalysts supported on X and Y zeolites is higher than those on similar specimens based on zeolite A and mordenite. The highest yield of liquid products (166 g m^{-3}) over this series of specimens, attained on the Co–MgO/NaX catalyst, was 1.3 times higher than that on the Co–MgO/kieselguhr catalyst with the same component ratio (the latter catalyst was close in composition to the commercial one).

The nature of synthetic zeolites has a substantial influence on the polymerising and isomerising properties of Co catalysts for the Fischer–Tropsch synthesis.²⁵ An increase in the $\text{SiO}_2:\text{Al}_2\text{O}_3$ ratio in a zeolite results in an increased content of high-boiling products in the catalysate and in an increased proportion of normal aliphatic hydrocarbons in these products.

Catalysts containing A, X, Y or M zeolites in the H-form or with exchangeable Ca^{2+} , Mg^{2+} and ZrO^{2+} cations are less active in the synthesis of hydrocarbons from CO and H_2 than catalysts containing zeolites in the Na-form.²⁵ The highest yield of liquid hydrocarbons ($125\text{--}130 \text{ g m}^{-3}$) was achieved on catalysts containing NaX and NaY zeolites ($\text{SiO}_2:\text{Al}_2\text{O}_3 = 2.8\text{--}5$).²⁶ When more acidic catalysts were used, the proportion of iso hydrocarbons reached 50 mass %.

The composition of the products is substantially influenced by the nature of the exchangeable cation.²⁷ Thus introduction of Mg^{2+} by ion exchange into NaX zeolite used as a support increases the yield of liquid products 1.5-fold. Simultaneously, the proportions of branched hydrocarbons and alkenes in the catalysate decrease.

The catalytic properties of metal zeolite systems depend on the methods of their preparation and modification and on the operation conditions.⁶ For example, the cobalt particles in the Co/HZSM-5 catalyst prepared by impregnation of the zeolite with an aqueous solution of cobalt nitrate²⁸ are 3 times larger than those in the specimen prepared using dicobaltoctacarbonyl $\text{Co}_2(\text{CO})_8$.²⁹

The initial system used to produce the 9.5 mass % Co/HZSM-5 catalyst contains cobalt nitrate as amorphous particles with a size of ~ 20 Å.³⁰ After calcination in a flow of air, the nitrate is converted into the oxide Co_3O_4 . The reduction in a flow of hydrogen at 350 °C affords cobalt crystallites with a size of ~ 300 Å, which remain virtually unchanged during the Fischer–Tropsch synthesis, and the cobalt oxide CoO (~ 90 Å). The ratio of these components, equal to 4, remains approximately the same after treatment with synthesis gas, *i.e.* the catalyst is not reduced during the synthesis.

The Co/HZSM-5 catalysts prepared by impregnation contain cobalt in two states: exchangeable non-reducible Co^{2+} ions within the zeolite structure and crystalline Co_3O_4 on its external surface.¹⁵ The latter can be reduced with hydrogen to metallic cobalt and CoO. Specimens containing only exchangeable cobalt ions do not exhibit catalytic activity in the synthesis of hydrocarbons from CO and H_2 .

After preliminary reduction with hydrogen of the 30 mass % Co/HZSM-5 catalyst prepared by mixing basic cobalt carbonate with the support, the degree of Co reduction is 52%–58%.³¹ The rest of the cobalt occurs as Co^{2+} . Treatment of the catalyst with synthesis gas results in partial oxidation of the metal on the catalyst surface: the degree of Co reduction decreases to 31%–35% and Co_3O_4 (14%–17%) is formed. As the Si:Al ratio in the zeolite increases, the Co^0 surface concentration somewhat decreases, resulting in a decrease in both the total catalyst activity and the yield of liquid products.

Catalysts produced by impregnation or mixing and containing a metallic cobalt phase on the surface of HZSM-5 zeolite crystals are fairly active in the Fischer–Tropsch synthesis (the degree of CO conversion reaches 60%).¹⁵ At 280 °C, these catalysts permit the synthesis of aromatic hydrocarbons, the yield and composition of which depend on the composition of the catalyst and the method by which it was prepared. Thus the hydrocarbon mixtures obtained on the 8.5 mass % Co/HZSM-5 catalyst prepared by mechanical mixing of the components contained up to 49 vol. % of aromatic compounds, whereas the content of aromatics in the products of synthesis on 7.5 mass % Co/HZSM-5 catalyst prepared by impregnation was not more than 20 vol. %.

A number of Co/HZSM-5 catalysts containing from 3 mass % to 9 mass % of the metal and prepared by various methods have been studied.³² The following methods were used: decomposition of $\text{C}_5\text{H}_5\text{Co}(\text{CO})_2$ on the zeolite (specimen **I**), impregnation of the support by an aqueous solution of cobalt nitrate (specimen **II**) and mechanical mixing of cobalt oxide with the zeolite (specimen **III**). The conversion of synthesis gas at 2.1 MPa and 280 °C on any of these specimens increased with an increase in the cobalt loading. When the Co concentration was 9 mass %, the highest yield of liquid hydrocarbons C_{5+} (74%) was attained on catalyst **I**. This specimen contained much less ion-exchangeable cobalt than catalyst **II**. The rest of the cobalt in **I** occurred as Co_3O_4 on the external surface of the zeolite. Catalyst **III** did not contain exchangeable cobalt ions at all. Thus, the metallic component had no influence on the acidic properties of HZSM-5 zeolite, and this catalyst was best suited for the synthesis of aromatic hydrocarbons from CO and H_2 . The concentration of aromatics in the liquid products obtained on this catalyst was ~ 51 vol. %. The liquid products produced on specimens **I** and **II** were enriched in alkenes (their content was 14 vol. % and 22 vol. %, respectively).

The Co/HZSM-5 catalysts employed for the synthesis of aromatic hydrocarbons are prepared conventionally by mechanical (dry) mixing of Co_3O_4 and the zeolite to keep the latter in the H-form. Mixtures formed in the presence of these catalysts

contain up to 70 mass % of aromatic hydrocarbons.^{15, 25, 33} However, the yield of the products is not more than 10–20 g m⁻³, which is largely due to the low porosity of the catalyst samples. The yield of liquid aliphatic hydrocarbons in the presence of analogous catalysts prepared by co-precipitation (using basic cobalt carbonate) and promoted by magnesia reaches 150–170 g m⁻³.^{25, 34} It has been found³⁵ that the nature of the initial cobalt compound used to prepare the Co/HZSM-5 catalyst influences the yield and the composition of the liquid products formed. The syntheses were carried out at a pressure of 0.1 MPa, a temperature of 220–280 °C, volume ratio H₂:CO = 1 and a gas hourly space velocity of 100 h⁻¹. The use of basic cobalt carbonate makes it possible to increase the catalyst porosity (the specimen is loosened during reductive decomposition of the carbonate) and increases the yield of liquid products (up to 42 g m⁻³) and the selectivity of their formation (up to 44%). However, simultaneously the content of aromatic hydrocarbons decreases markedly (to 42%).

The introduction of 0.4 mass % to 1.5 mass % of ThO₂ into the 9 mass % Co/HZSM-5 catalyst prepared by mechanical mixing of the components substantially increases the degree of conversion of synthesis gas (up to 74%) and the selectivity of the formation of the petrol fraction of hydrocarbons (to 70%).³² The proportion of aromatic compounds in the liquid products decreases to 26% but, nevertheless, the octane number of the products is 90. It has been shown by IR spectroscopy that when the Co/HZSM-5 catalyst contains ThO₂, the relative concentration of the Brønsted acid sites in the zeolite diminishes; this accounts for the lower yield of aromatic compounds. A ⁵⁹Co NMR study has shown the presence of α - and β -cobalt phases in the Co/HZSM-5 catalyst.³³ The reduced Co–ThO₂/HZSM-5 specimen contained no hexagonal cobalt. In addition, upon the introduction of ThO₂, the size of the cobalt particles arising decreased from 40 to 10 nm;^{32, 36} this facilitated adsorption of synthesis gas and ensured higher product yields.³² However, after treatment of the catalyst with synthesis gas for 48 h at 280 °C, the size of Co crystallites again increased (apparently, due to sintering of metal particles) and the yield of aromatic hydrocarbons decreased. A similar decrease in the content of aromatic hydrocarbons in the liquid products of the synthesis on Co/HZSM-5 catalysts prepared using CoCO₃ has been observed upon introduction of 2%–3% of Mg, Zr or La oxides into the catalysts.³²

The synthesis carried out under relatively mild conditions (0.1 MPa, 250–280 °C) in the presence of the Co–Ni–ZrO₂/HZSM-5 catalyst gave aromatic hydrocarbons with a selectivity of 30 mass %–35 mass %.³⁷ A decrease in the space velocity, an increase in the temperature or an increase in the zeolite proportion in the catalyst resulted in a higher content of aromatic hydrocarbons in the C₆₊ fraction.

A study dealing with the adsorption properties of bifunctional cobalt–zeolite catalysts prepared by mechanical (dry) mixing of the components has shown that the adsorption isotherm deviates noticeably from the corresponding curve for the initial zeolite.³⁵ This implies destruction of the zeolite during the catalyst preparation, the degree of destruction being dependent on the duration of the mechanical impact on the specimen.

The hydrogenating activity of cobalt can be decreased by introducing Cu into the catalyst. The yield of methane on a mechanical mixture of 4% Co/SiO₂ and HZSM-5 zeolite is 1.7 times higher than that on the 4% Co/SiO₂ specimen itself (2.1 MPa, 280 °C, H₂:CO = 1). However, the proportion of methane formed in the presence of the 6% Co–0.05% Cu/SiO₂ + HZSM-5 specimen under similar conditions is only 1.2 times higher than that on 6% Co–0.05% Cu/SiO₂. Thus, the addition of copper decreases somewhat the efficiency of methane formation.³⁸

When developing and employing bifunctional catalysts, one should bear in mind that the rate of synthesis of aromatic hydrocarbons on these catalysts at a given temperature and at the optimum activity of HZSM-5 cannot be higher than the rate of

formation of alkenes on the metallic component of the catalyst (the Fischer–Tropsch component).⁸ The temperature for the synthesis of aromatic compounds is normally 280 °C. At this temperature, zeolite is active towards aromatisation of alkenes, and methane formation on the Fischer–Tropsch component is not too pronounced. The maximum rate of formation of aromatic hydrocarbons from alkenes at 280 °C is 0.084 g (g of HZSM-5)⁻¹ h⁻¹.⁸ At the same time, a catalyst for the Fischer–Tropsch synthesis (for example, 4% Co/SiO₂) can ensure formation of 0.123 g of alkenes per hour under similar conditions. It is the ratio of 0.084 to 0.123 that determines the ratio of the components in the bifunctional 4% Co/SiO₂ + HZSM-5 catalyst.

The main problem associated with the use of bifunctional zeolite catalysts is their deactivation during the interaction with synthesis gas. The deactivation is due to the following factors:⁸ deposition of inactive carbon on the metallic component, sintering of metal particles and coking of the zeolite component. The first and the second processes result in a gradual decrease in the overall rate of the synthesis gas conversion. The third process diminishes the selectivity of formation of aromatic hydrocarbons due to a decrease in the number of active sites capable of converting alkenes.

An attempt has been made to regenerate the Co–ThO₂/HZSM-5 catalyst by conducting redox cycles, because oxidative treatment favours the removal of the carbon deposits. However, in each regeneration cycle, cobalt particles sintered, and this retarded the reforming of synthesis gas. In order to suppress metal sintering during the oxidative regeneration of bifunctional zeolite-containing catalysts, the use of oxygen enriched in ozone was proposed.⁴⁰

Synthesis of branched alkanes from CO and H₂ can also be carried out in the presence of bifunctional catalysts containing Group VIII noble metals.⁴¹ Most often, these catalytic systems exhibit low activities. Conversely, Co/HZSM-5 catalysts are highly active: at an atmospheric pressure and a temperature of 175–200 °C, they permit production of liquid hydrocarbons (C₅–C₁₀), containing 60%–80% of isoparaffins, in 46%–59% yield with respect to the converted CO.⁴²

In the presence of 10% Co–6% MgO/HZVM catalysts (SiO₂:Al₂O₃ = 30–104) prepared by co-precipitation and containing high-silica zeolites, analogues of HZSM-5, the degree of conversion of carbon monoxide is 70%–100% at 175–200 °C.⁴³ On these catalysts, liquid hydrocarbons enriched in isoalkanes can be synthesised selectively in 70%–90% yield. The C₅–C₁₀ fraction prepared on a catalyst supported on a zeolite with a silica modulus (the SiO₂:Al₂O₃ ratio) of 30–68 contains 36%–46% of isoalkanes. The zeolite silica modulus has an influence on the yield of isoalkanes, the highest yield being attained at SiO₂:Al₂O₃ = 68. An increase in the reaction temperature from 175 to 220 °C permits selective synthesis of C₅–C₁₀ hydrocarbons containing more than 50% of isoalkanes.

The influence of the synthesis conditions on the formation of isoalkanes on Ru–Pt catalysts has been studied.⁴¹ It was found that the shorter the contact time, the higher the yield of branched hydrocarbons. When the *W*:*F* ratio (*W* is the mass of the catalyst, and *F* is the space velocity of synthesis gas through the catalyst) was proportional to the residence time and was equal to 7 (g of the catalyst) h mol⁻¹ (2% Ru–2% Pt/HY, 240 °C, 1.5 MPa, CO:H₂ = 2:3), the iso to normal ratio (iso/*n*) for C₄ and C₅ hydrocarbons was an order of magnitude higher than that expected from the thermodynamic viewpoint (this ratio cannot be achieved upon hydroisomerisation of linear alkanes). As the residence time increased, the iso/*n* ratio reached the theoretical (thermodynamic) value. This means that the ratio of branched to linear alkanes is controlled by kinetic factors, and an increase in the residence time leads to gradual hydroisomerisation of branched alkanes into linear alkanes.

It was found⁴¹ that the Fischer–Tropsch synthesis on Ru/zeolite catalysts yields alkenes as the primary products. The predominant formation of branched alkanes in the initial reaction

stage may be due to transformation of alkenes on the zeolite acid sites followed by hydrogenation on ruthenium. It can be expected that the ratio of the synthesis products would be determined by the relative reaction rates on the acidic and metallic sites. Since raising the temperature usually enhances the hydrogenating activity of a catalyst, the iso/n ratio simultaneously decreases. A decrease in pressure results in lower iso/n ratios, because hydrogenation is facilitated at low partial pressure of CO. The highest iso/n ratio (ranging from 10 to 40 for various C_{4+} hydrocarbons) on the 2% Ru–2% Pt/HY catalyst was attained at a pressure of 1.5 MPa.⁴¹ As the pressure increased, this ratio substantially decreased. The $W:F$ ratio remains constant upon a pressure increase, whereas the real residence time (*i.e.* the residence time of hydrocarbons in a catalyst layer) becomes longer, and this causes a decrease in the iso/n ratio. It was found that this ratio is inversely proportional to the selectivity of methane formation.

When the reaction is carried out on the 2% Ru–2% Pt/HY catalyst, the iso/n ratio in the C_{4+} hydrocarbons depends on the nature of the support and increases in the order $AS < CaY < DAHY < HY$ (where AS is a synthetic amorphous aluminosilicate, and DAHY is dealuminised HY).⁴¹ As the Si:Al ratio in the zeolite increases, the degree of CO conversion diminishes, whereas the selectivity of CH_4 formation grows. The H-forms of zeolites with higher silica moduli give lower yields of isoalkanes. These results are inconsistent with those obtained in other studies,^{44, 45} according to which Ru/zeolite catalysts with higher Si:Al proportions give products characterised by greater iso/n ratios. This inconsistency may be due to the fact that the iso/n ratio is determined by the relationship between the rates of various steps involved in the synthesis of isoalkanes from CO and H_2 , which depend on the nature of the metal and the type of the zeolite used. To elucidate the general regularities of the synthesis of hydrocarbons from CO and H_2 , it is necessary to study systematically various catalysts under identical conditions.

VI. The mechanism of the Fischer–Tropsch synthesis

The surface of supported Co catalysts contains two types of metal-containing active sites **A** and **B** (Scheme 1).^{46–49} Sites of type **A** are metallic cobalt crystallites; on these sites, CO undergoes dissociative adsorption giving surface carbon, which is hydrogenated yielding methane. Thus, sites **A** are responsible for CO methanation. On the same type of sites, as a result of CO dissociation, adsorbed oxygen appears, which is able to react with carbon monoxide to give CO_2 (or with hydrogen to give water). Type **B** sites comprise metallic cobalt and an oxide component. They might be located at the Co–oxide interface.⁵⁰ The oxide component can be represented by cobalt oxide resulting from incomplete

reduction of the initial cobalt salt, by an oxide support or by a surface mixed oxide formed upon interaction of cobalt, the support and an oxide promoter during high-temperature pretreatment of the catalyst (calcination and/or reduction).

On the metallic part of site **B**, reagents are activated giving intermediates of the type COH_x or CH_x ; these species spill over to the oxide part of the site on which they polymerise. The oxide part of site **B** is normally a Lewis acid site (L-site). It affects the neighbouring metallic cobalt in such a way that some of the electron density shifts from the metal to the support⁵¹ yielding $Co^{\delta+}$. Carbon monoxide is adsorbed on site **B** in the molecular form; apparently it binds simultaneously to both components of the site.

It is also possible that CO is adsorbed on the interface in such a way that its oxygen atom binds to the oxide component of the active site.^{52, 53} In this case, the Lewis acid site located near the Co–oxide interface weakens the C–O bond in the carbon monoxide molecule and increases the rate of its hydrogenation.⁵⁴

The role of metallic cobalt in active site **B** is not limited to adsorption of CO (which is also adsorbed efficiently by cobalt oxide); cobalt also ensures hydrogen activation and transport to the polymerisation site. In the case where hydrogen can be delivered to the polymerisation site without participation of the metal (for example, by dissociative adsorption of C_2H_2 on an oxide⁵⁵), CH_x radicals can polymerise directly on the oxide.

It should also be noted that in addition to the two types of metal-containing active sites mentioned above, the surface of Co catalysts for the Fischer–Tropsch synthesis contains Lewis and Brønsted acid sites of various strengths, which are located on the oxide surface and are able to participate in secondary transformations of the intermediates formed from CO and H_2 . In addition, the energetic characteristics of sites of a particular type (**A** or **B**) can differ owing to the inhomogeneity of the catalyst surface.

VII. Distribution of the products of the Fischer–Tropsch synthesis

The process of formation of hydrocarbons from CO and H_2 is an example of catalytic hydropolymerisation. The distribution of the products formed in this reaction can be described using the Schulz or Flory equations, which virtually coincide for high chain growth rates.⁵⁶ In particular, the Schulz equation is written as follows

Scheme 1

(a) Proposed by Bartholomew in 1989; (b) proposed by Lapidus in 1991.

$$g_n = (\ln^2 \alpha) n \alpha^n,$$

where g_n is the weight fraction of a product containing n carbon atoms, and α is a factor of the hydrocarbon chain growth characterising the ratio of the probabilities of chain growth and chain termination.

In some cases, the distribution of the products of the Fischer–Tropsch synthesis does not conform to the classical Schulz–Flory distribution; this is due to the fact that there are at least two centres of chain growth on the catalyst surface, polymerisation on which occurs by different mechanisms.^{57–59} For example, it has been suggested⁶⁰ that hydrocarbons, the chain growth of which is characterised by factors α_1 and α_2 , can arise in the following way:

The ratio of the α_1 - to the α_2 -products is determined by the hydrogen pressure.

It has been assumed⁶¹ that on different active sites of the surface, different intermediates can be formed, which are converted, in their turn, into different surface compounds. According to these views, all the reactions occurring on the surface including the formation of the primary complex are reversible.

VIII. Secondary transformations in the Fischer–Tropsch synthesis

The deviation of the product composition from the Schulz–Flory distribution can also be explained by assuming that the alkenes formed from CO and H₂ are adsorbed once again on one or several active surface sites.^{62,63} In particular, the readsorption of alkenes substantially decreases the overall rate of the surface chain termination by changing the direction of the hydrogen elimination step, which leads to alkenes with a double bond located at the end of the molecule (terminal alkenes).⁶⁴

Study of the compositions of the products formed on the Fe/SiO₂ catalyst has demonstrated that there are two types of distribution, namely, a ‘classical’ distribution obeying the Schulz–Flory law and a ‘non-classical’ distribution, which does not obey this law.⁶⁵ The non-classical distribution appears because the primary reaction products can be rapidly converted into isomeric secondary products on the acid sites of the catalyst. The secondary transformations include double bond shift, *cis*–*trans* isomerisation, cyclisation and aromatisation.

There exists a direct correlation between the content of silica gel in a precipitated iron catalyst and the selectivity of this catalyst towards the formation of internal alkenes and branched hydrocarbons.⁶⁶ The content of alkenes with an internal double bond increases with an increase in the proportion of silica gel in the catalyst. Terminal alkenes are known to isomerise on silica gel,⁶⁷ alumina⁶⁸ and zeolites.⁶⁹ In the presence of these catalysts, alkenes undergo the following transformations (listed in order of increasing difficulty of transformation): *cis*–*trans* isomerisation, double bond shift, skeletal isomerisation, cyclisation, hydrogen transfer and polymerisation. These reactions occur on Brønsted and Lewis acid sites.

It is generally believed that termination of a growing alkyl chain upon elimination of a β -hydrogen atom yields terminal alkenes, whereas termination occurring by interaction of hydrogen with the α -carbon atom in the chain affords linear alkanes.⁷⁰ The formation of small amounts of *cis*- and *trans*-alkenes as the primary products occurs apparently in those rare cases where the growing carbon chain comes in contact with the active site of the catalyst through its β -carbon atom, the chain being terminated upon elimination of δ -hydrogen.

As the content of SiO₂ in the support of the Fe catalyst increases, the yield of alkenes with an internal double bond increases, whereas the amount of terminal alkenes simultaneously decreases; therefore, it can be concluded that internal alkenes

result from isomerisation of terminal alkenes on silica gel, which occurs according to the following scheme:⁶⁶

This mechanism implies that isomerisation proceeds on the same sites on which hydrocarbons are synthesised from CO and H₂ and that the two hydrogen atoms attached to the third carbon atom can be removed with equal probabilities to give *cis*- and *trans*-isomers in a ratio close to unity. This mechanism explains adequately the composition of the products formed on Fe catalysts supported on a material devoid of SiO₂.

In the presence of silica gel, the probability of isomerisation of terminal alkenes increases, because this support contains Brønsted acid sites. In this case, the scheme of formation of the *cis*- and *trans*-isomers can be represented as follows:⁷¹

The interaction of an acid site proton with the double bond of an alkene yields a carbenium ion. Elimination of a hydrogen atom from the adjacent carbon gives rise to a *cis*- or *trans*-alkene. This mechanism accounts for the predominance of the *cis*-isomers in the reaction products, since it is known that on acidic catalysts (which include SiO₂) *cis*-isomers are formed predominantly.⁷²

The secondary transformations of the hydrocarbons produced from CO and H₂ have been studied using the precipitated catalysts 14% Co/SiO₂ (I) and 15% Co/SiO₂ + HZSM-5 (II).³⁸ In addition, a two-stage process was carried out using two consecutively connected reactors, one of which (the first stage) contained the 14% Co/SiO₂ catalyst, while the other one (the second stage) contained HZSM-5. The tests were carried out at a pressure of 2.1 MPa, a temperature of 280 °C, and the ratio H₂:CO = 1. The degree of conversion of CO on specimen I reduced at 350 °C reached 50%, and the content of C₅+ hydrocarbons in the carbon-containing products of the synthesis was 72%. The C₅+ fraction consisted of alkanes (63%), alkenes (34%) and aromatic compounds (3%). In the case of the two-stage process with catalyst I in the first stage and the zeolite at the second stage, the yield of liquid hydrocarbons somewhat decreased (to 65%). However, the C₂–C₄ alkenes formed in the first stage (~8%) were converted almost completely on HZSM-5. As a consequence, the content of aromatics in the liquid products increased to 33%. The proportion of C₃–C₄ alkanes markedly increased (from 7% to 21%), that of methane remained virtually unchanged (14%) and the content of C₅+ hydrocarbons diminished to 65%. When the 14% Co/SiO₂ catalyst was mixed with HZSM-5 (specimen II) and the synthesis was carried out in one stage, the methane formation was enhanced (up to 25%), whereas the yield of C₅+ hydrocarbons and the content of aromatics in them barely changed with respect to those attained in the two-stage process. This led to the assumption that methane is formed in a secondary reaction (apparently, hydrogenolysis of light alkanes) occurring on metallic cobalt. This assumption is supported by the fact that the yield of C₂–C₄

alkanes on catalyst **II** is lower than that in the two-stage process (15% and 21%, respectively). This type of side reaction proceeds to a noticeable extent only on catalyst **II** in which cobalt particles occur in tight contact with HZSM-5 zeolite.

Hybrid catalysts $\text{RuNaY} + \text{SO}_4^{2-}/\text{ZrO}_2$ consisting of a mechanical mixture of ion-exchange RuNaY zeolite and sulfidised zirconium oxide have been studied.⁷³ It was found that under the synthesis conditions (0.1 MPa, 250 °C, $\text{H}_2 : \text{CO} = 1 : 1$), the propene formed initially on the Fischer–Tropsch component (RuNaY) undergoes two subsequent transformations on the sulfidised zirconium oxide, which behaves as a superacid, namely, hydrogenation through hydrogen transfer to give propane and transformations giving C_4+ alkanes. The formation of C_4+ hydrocarbons from propene follows an oligomerisation–cracking mechanism with hydrogen transfer.¹¹

Propene is formed on the Fischer–Tropsch component and is readsorbed on the acid sites of the hybrid catalyst where it oligomerises to give heavier products. The resulting C_4 fragments can be converted into C_4 and C_5 surface groups, which, in turn, react with propene giving rise to C_7 and C_8 hydrocarbons, respectively. The probability of interaction with propene for the C_5 fragments is higher than that for C_4 , since heavier hydrocarbons are more readily adsorbed and more difficultly desorbed.^{74,75}

The formation of branched oligomeric intermediates during the conversion of alkenes on zeolites depends appreciably on the concentration and the strength of acid sites.⁷⁶ A higher concentration and a higher strength of acid sites lead to more branched oligomeric alkene intermediates. Oligomers synthesised on strong acid sites form larger amounts of isoalkanes.

The transformations of linear alkenes on acid sites of the catalysts can follow two routes:⁷³ (1) alkenes undergo direct skeletal isomerisation to isoalkenes and subsequent hydrogenation *via* hydrogen transfer; (2) oligomers formed on acid sites decompose. The fact that the amount of isobutane produced is larger than its equilibrium amount⁷⁷ indicates that isoalkanes are mainly formed *via* reaction (2).

It should be noted that hydrogen transfer is also catalysed by acid sites.^{78–80} Upon the hydrogen transfer reactions, some of the alkene molecules are saturated with hydrogen at the expense of other alkene molecules and/or oligomers attached to the catalyst surface. Consequently, oligomers giving off hydrogen become more unsaturated. Polymerisation of these highly unsaturated fragments results in the formation of coke precursors.⁷³

The presence of the metallic component in the hybrid catalyst stabilises its activity towards isomerisation of hydrocarbons.^{75,81,82} This can be explained in the following way. Molecular hydrogen is adsorbed on the metallic phase of the catalyst and undergoes homolytic dissociation. The atomic hydrogen thus formed spills over to the support, migrates to a Lewis acid site and then gives off an electron, being thus converted into H^+ . The interaction of the proton with oxygen located near the L-site affords a Brønsted site, which is also capable of participating in acid-catalysed reactions. This is accompanied by weakening of the L-site which has accepted the electron. Thus, the catalyst is deactivated to a lesser degree. Another possible explanation is neutralisation of carbocations on the catalytic surface by hydride ions, which result from heterolytic dissociation of hydrogen on the metal.⁷³ The appearance of hydride ions decreases the lifetime of intermediates and prevents their subsequent transformations.

The compositions of the products obtained upon cracking of oct-1-ene on DAHY zeolite and upon the Fischer–Tropsch

synthesis on the 2% Ru–2% Pt/DAHY bifunctional catalyst were found to be similar.⁸³ However, the products of catalytic cracking contain larger amounts of branched alkanes in the C_4 and C_5 fractions (especially in the initial stage of the reaction). This is explained by the increase in the lifetime of a carbenium ion due to the low reactivity of hydrogen in the absence of a metal, which results in a higher probability of isomerisation of the carbenium ion before it is desorbed. The presence of a metallic component in the catalyst favours hydrogenation of alkenes to alkanes;^{84,85} this promotes the formation of large amounts of linear saturated hydrocarbons and accelerates the spillover of hydrogen to acid sites. Therefore, to equalise the functions of hybrid catalysts, it is necessary that they contain similar numbers of metallic and acid sites.

The distribution of the Fischer–Tropsch synthesis products formed on the 2% Ru–2% Pt/zeolite catalyst shifts towards lighter hydrocarbons in the series $\text{NaY} < \text{HY} < \text{DAHY}$.⁸³ The number of strong acid sites of the zeolites determined by the method of temperature-programmed desorption of NH_3 ($T_{\text{max}} > 350$ °C) increases in the same sequence. Among the products of the synthesis catalysed by the DAHY-containing material, mono- and di-branched alkanes predominate. This is due to the fact that relatively strong acid sites are unsuitable for skeletal isomerisation.⁸⁶

Under conditions of the Fischer–Tropsch synthesis, the growing linear chain is chemically bound to the surface. This bond ruptures upon elimination of β -hydrogen from the hydrocarbon yielding a terminal alkene or upon α -hydrogenation giving rise to a linear alkane.⁸⁷ The latter is inert under the Fischer–Tropsch reaction conditions;⁸⁸ therefore, it does not participate in secondary transformations. Meanwhile, terminal alkenes can be partly hydrogenated or involved once again in the hydrocarbon chain growth after readsorption.^{89,90} Upon the repeated adsorption of alkenes, the possibility of chain termination as a result of hydrogenation decreases, resulting in a higher probability of chain growth and a greater alkane : alkene ratio.^{62,91}

The probability of secondary reactions involving terminal alkenes substantially increases with an increase in the number of carbon atoms in the molecule.^{92,93} Correspondingly, the alkane : alkene ratio^{94,95} and the probability of chain growth^{62,95} also increase. The probability of secondary transformations of alkenes is normally assumed to be proportional to the contact time. Some investigators^{63,93} believe that the contact time increases appreciably as the chain becomes longer, because hydrocarbons with longer chains are better soluble in heavy products of the Fischer–Tropsch synthesis, which fill the catalyst pores. However, the dependence of the solubility on the chain length cannot be determined or calculated; therefore, this parameter is difficult to use as a quantitative characteristic. In addition, this interpretation does not seem to be fully justified because the presence of a liquid phase does not influence the chemical potential and, hence, the secondary transformations.⁶² The dependence of the chain length on the residence time might also be due to transport limitations (*i.e.* diffusion). When there are no transport limitations, the components of the gas and liquid phases of the reaction system are in thermodynamic equilibrium. Therefore, in this case, neither the residence time of the products in the reaction area nor the kinetic driving force (volatility or chemical potential) depend on the presence of the liquid phase.⁶² The secondary transformations of hydrocarbons are not influenced by the liquid phase either. When there are external-diffusion limitations, the number of carbon atoms in the molecules being formed depends on the factor of the hydrocarbon chain growth α and on the concentration of alkenes. In this case, the residence time of hydrocarbons in the pores filled with a liquid increases and, hence, the probability of secondary transformations also increases.

An attempt has been made⁸⁸ to elucidate the reason for the dependence of the rate of secondary reactions on the hydrocarbon chain length using cobalt foil as a model catalyst. Diffusion

limitations were modelled using a foil coated preliminarily by wax. When a non-coated foil was used, there were no such limitations. Below we consider the results of this study in more detail.

The ratio of the rates of hydrogenation and repeated involvement of readsorbed alkenes in the chain is determined by a large number of parameters, in particular, CO and H₂O pressures.⁶² Under the conditions studied (0.1 MPa, 220 °C, H₂:CO = 1, polycrystalline cobalt), virtually all readsorbed alkenes should be hydrogenated. Thus, the distribution of hydrocarbons up to C₁₄ cannot deviate from the Schulz–Flory distribution, *i.e.* it cannot depend on secondary transformations. The chemisorbed intermediates which undergo hydrogenation differ from those involved once again in the chain growth.

To be repeatedly involved in the synthesis, an alkene should be chemisorbed on a vacant site on the catalyst surface. Under the conditions of the Fischer–Tropsch synthesis, vacant sites are scarce, because the surface is occupied almost completely by various fragments.⁹⁵ In order to occupy a growth site which has become vacant, an alkene should compete with CO and H₂. It is unlikely that an alkene molecule that has moved far away from a vacant active site would reach it before it is occupied again. Of all the alkenes present in the reactor, only those located in the close vicinity of a site have a chance to be readsorbed.

Thus, the probability of the repeated involvement of alkenes in the chain is intimately connected with their concentration at the interface in the physically adsorbed layer and with their average concentration over the whole reactor (*i.e.* the contact time). The alkene concentration at the interface is influenced, in addition to the transport limitations, by the preferred physical adsorption and solubility. Chemisorption of alkenes is a non-activated process. On passing from a physically adsorbed state to chemisorption, there is no competition between the reactions. Thus, the rate of readsorption is controlled only by the effective 'rate of collisions', which depends on the concentration of the molecules in the physical adsorption region at the interface, *i.e.* on the total contact time in the physically adsorbed layer and on the alkene concentration in wax. The chemisorbed phase occurs in a steady state; however, there is no equilibrium between the physically and chemically adsorbed phases.

As a consequence, at low degrees of CO conversion on the Co foil, the alkane/alkene ratio grows exponentially as the chain is lengthened. The coating of the foil with wax results in lower yields of alkanes and a less pronounced dependence of the alkane/alkene ratio on the chain length. These findings can be explained by the fact that the rate of readsorption of alkenes increases exponentially with chain length. A model was proposed which assumes competitive participation of alkenes in the readsorption, so that the readsorption rate is proportional to the alkene concentration at the catalyst–wax interface. Thus, the dependence of the alkane/alkene ratio on the chain length is determined by the solubility of hydrocarbons and by diffusion limitations; the latter, in turn, are caused by the predominant physical adsorption in the boundary layer. Under normal synthesis conditions (when the degree of CO conversion is high), the transport limitations are more significant.

IX. Conclusion

The foregoing leads to a number of general conclusions concerning the current state of the problem of catalytic synthesis of isoalkanes and aromatic hydrocarbons from CO and H₂.

The transformation of CO and H₂ on oxide catalysts giving mainly isoalkanes ('iso-synthesis') normally requires high pressures.⁹⁶ In this case, the yield of liquid hydrocarbons is low, and the overall catalyst activity is not sufficiently high.

A more promising method is the synthesis of isoalkanes as mixtures with linear alkanes on catalysts containing high-silica zeolites together with Group VIII metals. Apparently, either intermediates or alkenes which undergo skeletal isomerisation serve as the source of isoalkanes. Aromatic hydrocarbons can also be formed on these catalysts but this requires higher temperatures.

The zeolite component of the catalyst ensures the occurrence of isomerisation and aromatisation processes. Isomerisation occurs on the Brønsted and Lewis acid sites. Isomerisation of alkenes is more efficient on bifunctional metal-containing catalysts. Thus, the transformation of CO and H₂ on the Co–MgO/HZVM catalyst affords hydrocarbons (yield 70%–90%) containing 36%–40% of isoalkanes.⁴⁰

The 'two-sites' model for the Co catalysts for the Fischer–Tropsch synthesis that we proposed previously makes it possible to divide all the active sites on the catalyst surface into three main types, namely, methanation sites (Co⁰), hydrocarbon chain growth sites (Co^{δ+}–M_xO_y) and isomerisation and cyclisation sites (acid sites).

The deviation of the product composition from the Schulz–Flory distribution is due to the repeated adsorption of alkenes on one or several active sites. Readsorption of alkenes and their involvement in growing chains results in an appreciably decreased total rate of hydrocarbon chain termination and in a change in the step of hydrogen elimination giving terminal alkenes. Thus, readsorption of alkenes followed by their skeletal isomerisation and hydrogenation ensure the formation of isoalkanes. Yet another pathway to isoalkanes is decomposition of unsaturated branched oligomers on acid sites and subsequent hydrogenation.

Of course, it is as yet impossible to draw ultimate conclusions about the true mechanism of the formation of isoalkanes and aromatic hydrocarbons under the Fischer–Tropsch synthesis conditions. However, in all probability, a fairly important role in the processes catalysed by cobalt-containing catalytic systems is played by unsaturated intermediates and by their subsequent readsorption with involvement in the growing hydrocarbon chain or their oligomerisation and isomerisation.

Abstract. The results of studies on the structures and mechanical properties of polymeric materials subjected to isostatic treatment and extrusion in the solid state, mainly rigid-chain and network polymers, polymer blends, and reinforced compositions, are described systematically and surveyed. The bibliography includes 204 references.

I. Introduction

The modification of polymers, the manufacture of which has been undertaken on an industrial scale, is one of the principal trends in the creation of materials with a required set of characteristics. Various procedures for the deliberate alteration of the structures and properties, including methods such as chemical and physical modification, are employed. Despite the advances achieved on these lines, the search for new modification methods, among which methods involving treatment by the application of pressure are promising, is being continued.

A high hydrostatic pressure induces both reversible and irreversible changes in the physical and mechanical properties of materials, promotes the formation of their new modifications, and makes it possible to achieve the synthesis of products the preparation of which is impossible under normal conditions.^{1–7} The first experiments using high pressure were carried out more than 100 years ago but since then the interest in its employment for scientific and technological purposes has not weakened.

In order to obtain materials with the required performance properties, various methods based on the employment of high pressures, are used namely pressing, rolling, stamping, drawing, *etc.* They are distinguished by the scheme underlying the stressed state of the material and the hydrostatic component of the stress tensor.⁸ Among the technological processes based on the direct application of a high hydrostatic pressure, the greatest development has been achieved in isostatic pressing and hydrostatic

extrusion.^{7,9–17} The isostatic pressing method is used basically in the treatment of powders. Its advantages include extremely effective mechanical characteristics of the final products, the possibility of obtaining articles of any shape, however complex, the simplicity of equipment, and the ease of automation. Virtually all the advantages of the plastic deformation of materials, including the most favourable scheme underlying the stressed state, the reduction to a minimum of frictional forces, and the plasticisation effect determined by the application of pressure, are applied in the hydroextrusion method. Using the advantages of the method listed above, it is possible to alter the structure and the strain–strength characteristics of the treated material.

Compared with other substances, for example metals, polymers are much more sensitive to the effect of pressure, but the first few studies which considered various aspects of the influence of high pressure on polymers were carried out comparatively recently.^{18–22} Active interest in the study of the properties of polymers under pressure began to be manifested in the 1960s while the fundamental theoretical and experimental results, which clarify the role of high pressures in the establishment of a set of mechanical and performance properties of polymeric materials, were obtained in the 1970s–1980s, which may be regarded as the period of the most vigorous development of this field.^{23–30}

The methods for the treatment of polymers by the application of pressure, used for their structural modification, can be divided conventionally into two groups. The first comprises various procedures based on the application of an isostatic treatment; isostatic pressing of polymer powders, treatment by the hydrostatic compression of articles in the form of a block, and structure formation under pressure. This group of methods is characterised by a spherical external stress tensor. The second group includes methods based on the joint operation of a high pressure and shear stresses (the total external stresses tensor): deformation using Bridgman anvils, ultrasound, and shock waves; pressing; elastic-deformation grinding; solid-state extrusion; *etc.*

This review deals with structural modification methods, which are some of the most promising as regards practical employment — different versions of the isostatic treatment and solid-state extrusion. They are characterised by a high effectiveness, ease of technological application, and the possibility of treating comparatively large volumes of the polymeric raw material. The main bulk of studies devoted to isostatic treatment or solid-state extrusion have been carried out on flexible-chain amorphous or amorphous-crystalline homopolymers. Their results have been reflected to a large extent in a series of review articles and monographs, for example in the studies described in Refs 25, 26, 30, and 31. In the present review, attention is therefore

concentrated on the less well known aspects of the problem, namely on questions concerning the modification of rigid-chain and network polymers and polymer composites. New aspects of the development of the structural modification methods under discussion, in particular the solid-state extrusion of a powdered billet, are examined in greater detail.

II. Isostatic treatment of crystallisable polymers

1. Crystallisation under pressure

The vast majority of studies on isostatic treatment have been devoted to crystallisation under pressure. The main bulk of such investigations have been carried out on polyethylene (PE).^{25,32–39} In the first experiments, it was already observed that pressure not only increases the crystallisation temperature but also induces certain structural changes in the polymer. Thus Matsuoka and Maxwell³² obtained at high pressures PE with an unusually high density, which they explained by more effective chain packing. Subsequently, Wunderlich⁴⁰ showed that crystallisation under a high pressure entails not only more satisfactory chain packing but also leads to the formation of crystals of a new type — crystallites with extended chains (CEC). The pressure corresponding to the onset of the formation of CEC is in the range 300–350 MPa according to the phase diagram.⁴¹

There are two main hypotheses concerning the appearance of CEC.³⁴ According to the first, the CEC are formed on nuclei consisting of straightened chains or packs of chains,³⁵ whilst according to the second, folded lamellae are thickened under pressure and are gradually converted into CEC.^{36,37}

The molecular mass distribution (MMD) has a significant effect on the course of crystallisation. For example, it has been shown³⁸ that the curves for the distribution of the thickness (length) of crystallites in the direction of molecular chains and of the molecular mass (M) distribution are identical for $M < 10\,000$. For $M > 10\,000$, mixed crystallites are formed. Fractions with narrow MMD crystallise in two stages,⁴² while the crystallisation of specimens with a broad MMD usually involves a single stage. In mixtures of fractions, fractionation and segregation take place during crystallisation, which results in the formation of a eutectic-like mixture of crystallites comprising fully straightened molecules with a low M and crystallites made up of molecules with a high M having both straightened and folded shapes.³⁹

The principal differences in the morphology of PE specimens, obtained at atmospheric and high pressures, are as follows. In the pressure-modified PE, the lamellar thickening occurs only up to a certain limiting extent, the twisting of the lamellae is not observed, and spherulitic formations with a fanlike structure are present. The latter are characterised by a tangential orientation of the C -axes.

The formation of CEC on crystallisation from the melt under pressure has been observed for a series of other polymers^{43,44} and copolymers.⁴⁵ Together with the formation of CEC, phase transformations occur in many polymers during crystallisation under pressure, as a result of which it is possible to obtain materials with a new crystal system. For example, it has been noted²³ that, together with the orthorhombic phase, a triclinic phase is present in PE crystallised at 436 MPa. If the crystallisation of syndiotactic polypropylene (PP) is carried out at pressures amounting to several hundreds of megapascals, it is possible to obtain a new crystalline modification.⁴⁶ Poly(vinylidene fluoride) (PVDF), crystallised at 507 MPa, consists of a mixture of two phases with different melting points (T_m); the PVDF obtained at atmospheric pressure consists of a single phase.⁴⁷ The transition to a new modification on crystallisation under high pressure has been noted also for polybut-1-ene.²⁵

The study of the crystallisation kinetics showed that a high pressure as a rule slows down the crystallisation process, *i.e.* a higher degree of supercooling of the melt is required in order to attain the same rate of crystallisation as at atmospheric pressure.^{48,49} At the same time a nonmonotonic dependence of the

rate of crystallisation of PE on pressure, due to changes in the kinetics of the growth of crystals and the phenomenon of topomorphy has also been discovered.⁵⁰

The structural transformations listed above, which occur in polymers as a result of crystallisation under pressure, induce changes in their properties. As a rule, denser packing appears in the polymers and the degree of crystallinity and T_m measured under atmospheric conditions increase.^{32,40} Thus the differences between the densities (ρ) of high-density polyethylene (HDPE) specimens, obtained at normal and elevated pressures, amount to 2%.³² The dynamic Young's modulus of pressure-modified polyethylene is twice as high, its strength is greater, but its plasticity is lower. A similar effect has been obtained for polytetrafluoroethylene (PTFE) and polypropylene.²⁵ The increase in the density of PE and the formation of CEC on crystallisation under pressure cause a decrease in its compressibility and in the intensity of γ -relaxation.³⁵

2. Annealing under pressure

The influence of annealing under pressure has also been investigated mainly in relation to PE.²⁵ It was established that, when PE specimens comprising crystals with folded chains (CFC) are annealed, the rearrangement of the structure with CFC to a structure containing CEC is observed in the corresponding temperature ranges.⁵¹ This has been confirmed by the appearance of a second (high-temperature) fusion peak and the results of morphological investigations; lamellae with transverse dimensions exceeding by more than an order of magnitude the dimensions of the lamellae in the unannealed specimens are formed after such annealing. There is a simultaneous increase in ρ for the annealed material, which reaches values characteristic of the structure with CEC. Slight changes in T_m , ρ , and morphology are observed during the annealing of specimens with the CEC structure, indicating a further improvement of their structural arrangement. It is assumed⁴⁰ that the formation of CEC during the annealing of PE under a high pressure takes place in accordance with a mechanism similar to the mechanism of crystallisation under the conditions of hydrostatic compression, *i.e.* via the isothermal thickening of lamellae.

Similar features (an increase in the degree of crystallinity, an improvement in the structure, and an increase in T_m and ρ) have also been established in the course of the annealing of other amorphous-crystalline isotropic polymer specimens.^{25,46} During annealing under pressure, oriented polymers exhibit a more complex behaviour. For example, uniaxially extended HDPE specimens undergo a phase transformation in addition to the increase in the thickness of the crystallites, in T_m , and in ρ already mentioned.⁵² A proportion of the material undergoes the transition from the orthorhombic modification to the oriented triclinic modification. At the same time, there is a sharp increase in the degree of crystallinity; the intensity of the amorphous halo for the annealed specimen is five times smaller than for the original specimen.⁵²

In the course of the annealing of oriented specimens of syndiotactic PP, the formation of a new high-pressure crystalline modification was observed.⁴⁶ The annealing of oriented PVDF specimens also induces a phase transition in the solid state with retention of the primary orientation.⁴⁶ The phase formed then has ρ higher by 10% compared with ρ for the low-pressure phase. Annealing under pressure (by crystallisation under pressure) of isotropic and oriented polymer specimens is reflected in their mechanical properties. In particular, a significant increase in the moduli of elasticity has been noted.^{53,54}

An improvement in the properties of the polymers can be achieved in a number of instances also by isostatic treatment at room temperature. The imposition of an hydrostatic pressure onto PTFE specimens with an increased porosity leads to the 'healing' of the micropores at pressures up to 80 MPa.⁵⁵ On further increase in pressure, the 'healing' process is retarded. Thermal activation analysis showed that the 'healing' of the

pores is associated with the viscous flow of the macromolecules. It continues until the free volume is 'exhausted'.

The contact between the polymer and the pressure-transmitting medium is very important in the isostatic treatment. In the absence of appropriate insulation, the negative effect of the medium can abolish the positive role of pressure or can impair the properties of the created material.⁵⁶

3. Isostatic treatment of powders

The component methods for the treatment of polymer powders are extrusion, pressing with subsequent free sintering, pressing with sintering under pressure, and casting under pressure.⁵⁷ The choice of a particular procedure is determined both by the properties of the polymer and by the nature of the technical problem to be solved. The advantage of the pressing-free sintering scheme consists in the possibility of the effective manufacture of long articles by separating the pressing and sintering operations. However, in order to obtain good-quality articles, it is necessary to achieve the highest possible density and uniformity of its distribution with respect to length and the cross-section of the billet. It has been shown in relation to PTFE of brands F-2M, F-4, F-4MB, F-40, and F-40-P⁵⁸ that the isostatic treatment makes it possible to obtain the above properties with retention of the specified form of the article, provided that this operation is carried out after preliminary pressing of the powder. Hydrostatic pressures of 200–250 MPa are sufficient for the attainment of the state with the minimum porosity (Fig. 1).

Figure 1. Pressure dependence of the density of polytetrafluoroethylenes for different powders: (1) F-4; (2) F-4MB; (3) F-2M.

A mathematical model describing the isostatic pressing of polymer powders and permitting the determination of the values of the principal technological parameter (the pressure) has been proposed.⁵⁹ The isostatic pressing process is regarded as consisting of two stages. The first stage is associated with the relative displacement and rotation of individual particles. The second involves elastic deformations of the particles filling the existing free space. After the removal of the external pressure, the polymeric material is loosened as a consequence of the reversibility of the elastic deformations and its density returns to the level attained at the end of the first stage. The relative density of the pressed polymer powder is therefore always less than unity. Comparison of the calculated and experimental $\rho(P)$ relations for PTFE confirms that the model is consistent with the isostatic treatment under consideration.⁵⁹

In the practical application of powder technologies, moulding methods, differing from isostatic pressing, for example pressing in a rigid die of complex shape or pressing in special shells are widely used. The technological problems arising under these conditions are associated with the determination of the force necessary to attain the specified density, with the estimation of the pressure exerted on the walls of the die, with the calculation of the

distribution of density with respect to the volume of the billet, *etc.* The parameters of the model,⁵⁹ found in experiments involving isostatic treatment, may be used to calculate the force parameters of the processes indicated.

III. Isostatic treatment of glassy polymers

1. The influence of pressure on the properties of amorphous polymers

There have been extremely few studies devoted to the influence of the isostatic treatment on the structure and properties of amorphous polymers. This is evidently associated with the possibilities for structural rearrangements which are much smaller than for crystalline polymers. Fairly detailed studies on polymeric glasses have been carried out.⁶⁰ It has been shown for a series of amorphous polymers that cooling of the specimens at 150 MPa from a temperature exceeding the glass transition temperature (T_g) to room temperature makes it possible to increase ρ compared with the original state by $\sim 1\%$. The state with increased density is metastable, but relaxation under atmospheric conditions proceeds slowly. With increase in temperature, this process accelerates, but at $T < T_g$ there is no complete transition to the original state. Compaction of the glass is characterised by increased values of the dynamic modulus of elasticity and a lower dielectric constant.

Higher values of ρ for a polymer vitrified under pressure have also been established in another study.⁶¹ Here the instability of the material was noted. The nature of the recovery of ρ when the material is heated depends on the pressure employed: in the original stage of the recovery of ρ , the rate of the process is higher the higher the pressure P .

There have been few technological studies devoted to the application of a high hydrostatic pressure for the structural modification of polymers. Among them, mention should be made primarily of Shturman's studies^{62,63} in which the favourable effect of annealing under pressure on the mechanical and performance characteristics of a series of polymers and polymer composites was demonstrated. For example, annealing of impact-resistant polystyrene promotes an increase in its strength, impact strength, and antifriction properties. A similar thermomechanical treatment of glass-reinforced polyamide specimens significantly increased their hardness together with an increase in the ultimate bending strength and impact strength. It is believed⁶² that the strengthening effect is due to the compaction of the surface layer and the appearance in the latter of compressive stresses which increase the cohesive strength of the polymers. The molecular mass of the polymers also increases under the influence of temperature and pressure (the content of low-molecular fractions diminishes), which is correspondingly reflected in their properties.

2. The structures and properties of network polymers obtained under the conditions of hydrostatic compression

The chemical reactions as a result of which network polymers are formed are accompanied by the formation of a three-dimensional network structure. Compared with linear glassy polymers, one may expect new effects in the course of their isostatic treatment, in particular irreversible changes in structure and properties induced by the high pressure.

The study of the kinetics of the curing of network polymers under the conditions of hydrostatic compression showed that in the vast majority of cases the rate of this process increases with increase in pressure^{64–69} and the increase is extremely significant. For a series of epoxide compositions, the increase in the reaction rate constant (k) at 250–350 MPa reaches several orders of magnitude.^{64,67} The volume activation effect ($\Delta V^\ddagger$) for these reactions is negative and the increase in k with increase in pressure follows from the familiar relation.⁷⁰

$$\left(\frac{\partial \ln k}{\partial P} \right)_T = - \frac{\Delta V^\ddagger}{RT}.$$

The nature of the influence of pressure is determined both by the type of the reagents selected and their proportions. For example, in the presence of an excess of an epoxide oligomer (EO) there is a possibility of the solvation of the reaction centres, which prevents their interaction, as a result of which the intensity of the effect of the pressure diminishes.⁶⁹ The results of studies by different investigators^{64–69,71} involving the determination of k agree well. The shortening of the gel and glass formation times during the curing of EO by amines under the conditions of hydrostatic compression has been observed.⁷¹

Under the influence of pressure, the structure-formation process may be retarded as well as being accelerated. This result has been established, for example, in the curing of EO by an amine complex of boron trifluoride^{66,67} and is associated with the influence of pressure on the equilibrium constant (K) for the dissociation of this complex to the amine (A) and BF_3 , initiating the polymerisation

Under the influence of pressure, the equilibrium in this reaction shifts to the left and the concentration of BF_3 in the reaction mixture falls, which means that the rate of curing of the EO diminishes.

It has been established^{65–69} that the differences in the kinetics of the chemical reactions occurring at pressures from 0.1 to 250 MPa are quantitative. This makes it possible to postulate the absence of an appreciable influence of pressure in the selected range (0.1–250 MPa) on the curing mechanism and hence on the molecular level of the structural arrangement of the epoxide polymers (EP). At the same time, the data obtained for poly(ethylene glycol dimethacrylate)⁷² indicate that at sufficiently high pressures there is a possibility of changes in the structure of the molecular chains. Analysis of the IR spectra of poly(ethylene glycol dimethacrylate) showed that the nature of the disposition of the methacryloyl groups changes in the pressure range 600–2000 MPa, which is manifested by an increase in the probability of their 'tail to tail' addition. The most significant rearrangement of the molecular structure is observed at $P \leq 800$ MPa. An increase in pressure hardly influences the type of addition of the polymethacrylate chain units.

The influence of hydrostatic pressure on the topological and supermolecular structures of network polymers is more effective than its influence on the molecular level of the structural arrangement. Fig. 2 presents thermomechanical curves for specimens of a series of EP cured at different pressures.⁷³ The following compositions were employed: a blend of the epoxybisphenol A[†] resin

Figure 2. Thermomechanical curves for the epoxide polymers EP-4 (1, 2), EP-5 (3, 4), and EP-1 (5, 6) at different pressures (MPa): (1), (3), and (5) 0.1; (2), (4), and (6) 200.

[†] Bisphenol A ('dian' in Russian) is 2,2-bis(4-hydroxyphenyl)propane (Translator)

ED-20 and polyepichlorohydrin cured with monocycloethylenetriamine (EP-1); epoxyaniline resin cured with a eutectic mixture of aromatic diamines (EP-2); epoxybisphenol A resin cured with bis(4-amino-3-chlorophenyl)methane (EP-3); the epoxybisphenol A resin ED-20 cured with methyltetrahydrophthalic anhydride (EP-4); a blend of a flexible-chain block oligomer comprising an epoxide resin and acid oligomer and a diglycidyl ester cured with methyltetrahydrophthalic anhydride (EP-5); a blend of the epoxybisphenol A resin ED-20 and oligomeric diglycidyl esters based on diethylene glycol cured with triethanolamine titanate (EP-6); the epoxybisphenol A resin ED-16 cured with the methyltetrahydrophthalic anhydride (EP-7).

Curing under pressure results in an increase in T_g and in the initial temperature of forced rubber elasticity and a decrease in the deformability of the polymers in the region of rubber elasticity. These facts indicate the intensification of intermolecular interaction. Pressure exerts the greatest influence on EP with large units (EP-4) or long chains between cross-links (EP-5). The increase in T_g reaches 30 K and the relative decrease in the quasiequilibrium elastic deformation reaches 30%. The latter is equivalent to the corresponding increase in the equilibrium modulus of elasticity, *i.e.* the increase in the rigidity of the polymer network. In the case of EP with compact units (EP-1), the changes under consideration are less pronounced. These findings indicate that the change in T_g under the influence of pressure is caused predominantly by the change in the packing of the units. The structure produced is 'frozen' at $T < T_g$ and is retained after the removal of the pressure. The appearance of anomalies on the thermomechanical curves for the modified EP-1 and EP-5 specimens in the vicinity of T_g is apparently a consequence of the relaxation of the 'frozen' compressive stresses.

The main parameter of the topological structure of the type of polymers considered is the concentration of the network cross-links (ν). Table 1 presents the values of ν for certain EP investigated.⁷⁴ For all the compositions, the curing under the conditions of hydrostatic compression promotes an increase in ν and the highest values of $\Delta\nu$ are attained for EP-4 and EP-5 ($\Delta\nu$ was estimated as the ratio of the increment in ν , caused by the pressure, to the value of ν for the control specimen).

Table 1. Effective concentrations of network cross-links in EP.⁷⁴

Polymer	$10^{-20} \nu / \text{cm}^{-3}$	$\Delta\nu$ (%)	Polymer	$10^{-20} \nu / \text{cm}^{-3}$	$\Delta\nu$ (%)
EP-1	$\frac{7.3}{7.8}$	7	EP-4	$\frac{5.7}{8.1}$	42
EP-3	$\frac{12.1}{13.9}$	15	EP-5	$\frac{3.6}{4.4}$	22

Note. The values of ν above the horizontal line correspond to control specimens and those below the horizontal line were obtained at a pressure of 200 MPa.

The results of the thermomechanical analysis agree with pulse NMR data,⁶⁸ according to which structure formation under pressure increases the 'nuclear' glass transition temperature (T_g'), corresponding to the temperature of the appearance of two 'kinetic phases' with the nuclear magnetic transverse relaxation times T_{2b} and T_{2c} , and diminishes molecular mobility (Fig. 3). At $T > T_g'$, the changes in molecular mobility are observed only for the most mobile (T_{2b}) fragments of the polymer network, which indicates the influence of pressure also on the linear chains between the cross-links.

Differences between the internal friction spectra for the pressure-modified and control EP specimens have been demonstrated.⁷⁵ This indicates a lower intensity of the small-scale relaxation processes and a narrower set of relaxation times corresponding to these processes.

Figure 3. Temperature dependences of the nuclear magnetic relaxation times T_{2b} (1, 3) and T_{2c} (2, 4) and of the proton population p_c (5, 6) for EP-1 at different pressures (MPa): (1), (2), and (5) 0.1; (3), (4), and (6) 150.

Three endothermic maxima appear on the differential scanning calorimetric (DSC) curves for the cured EP specimens (Fig. 4). They correspond to regions with different scales of the 'unfreezing' of molecular mobility: the low-temperature maximum *I* is associated with the 'unfreezing' of the noncooperative motion of segments at sites with a lower packing density (β -transition); the maximum *II* at 440 K corresponds to the cooperative glass α -transition; the high-temperature maximum *III* at 490 K is due to the molecular mobility in the rubbery state.⁷⁶ Comparison of curves 1 and 2 in Fig. 4 shows that treatment with pressure leads to a decrease in the intensity of the maximum *I* and its shift towards higher temperatures (*I'* on curve 2), which is caused by the suppression of the small-scale molecular motion at the level of the segments (sections of the chain). The second maximum for the modified polymer is also located at higher temperatures (*II'* on curve 2). The intensity of the molecular motion does not then change.

Figure 4. DSC curves for EP-1 at different pressures (MPa): (1) 0.1; (2) 100. *I*–*III* and *I'*–*III'* — see text.

Thus the set of data obtained by thermomechanical analysis, pulse NMR, internal friction spectroscopy, and DSC makes it possible to assume that the curing of the EP under the conditions of high pressures induces appreciable changes at the topological and supermolecular levels of the structural arrangement, manifested by an increase in the effective density of the cross-links and intensification of the intermolecular interaction.

This conclusion conflicts at first sight with the results of a study⁷⁷ in which the structure formation in EP was also investigated under the conditions of high pressures. According to these results, the specimens cured at 500–1000 MPa have lower values of T_g than those cured at atmospheric pressure. Estimation of the degree of cross-linking of the modified EP demonstrated that this process does not go to completion in the specimens indicated. Possibly the negative effect of pressure appeared because the investigators did not apply a correction for the temperature regime in the curing process. The change in T_g with increase in pressure is known to be $0.15\text{--}0.3\text{ K MPa}^{-1}$. By tradition, in the epoxide resin curing practice the final curing temperature for the composition is chosen so that it exceeds the expected glass transition temperature.⁷⁹ In this case, the highest degree of conversion is attained. When the temperature regime corresponding to atmospheric pressure is applied in the region $P > 500\text{ MPa}$, the specimen is vitrified, for the reason mentioned above, before it attains the necessary degree of conversion. The reaction is inhibited and an undesirable result appears as a consequence.

There is also a possibility of another mechanism of the loosening of the polymer network on curing EP under pressure, which is analogous to that of Ozerkovskii *et al.*⁷² In considering the pressure dependence of ν for PDMA, the authors of this investigation suggested that in the network polymer cross-linked to the limiting extent an equilibrium is established between the cross-links, leading to a decrease in the volume of the system and the loosening cross-links. Calculation showed that at high pressures ν decreases, because, starting with a certain critical concentration, the cross-links prevent the packing of the network skeleton.

In contrast to EP, for bis(methacryloyloxyethyleneoxycarbonyloxyethylene) oxide (MECDE) polymerised at 85–550 MPa, a decrease in the glass transition and enforced rubber elasticity temperatures as well as an increase in deformability in the rubbery state are observed with increase in pressure.⁷⁹ According to the authors,⁷⁹ this is caused by the changes occurring at the molecular level in the structural arrangement of MECDE. On polymerisation under pressure, there is an increase in the probability of the isotactic addition of units in the main macrochains of MECDE. Lower values of T_g are more characteristic of this modification than of the modification with the atactic type of addition of units.

A microstructure, the morphological unit of which is a globule, is at the uppermost level in the 'structural hierarchy' of network polymers.^{78,80,81} The globular character of the microstructure is manifested either on the surface of a section after etching or of the break produced by the application of a load. In the first case, the weakest sections of the polymer network are etched away, *i.e.* the globular relief reflects the chemical rupture front, the velocity of which is inversely proportional to the molecular packing density.⁸² In the second case, the rupture takes place at the interglobular boundaries.⁸³ This makes it possible to regard the globule as a local thickening of the three-dimensional network, manifested as a particle on etching or mechanical rupture.⁸²

Comparison of the microstructures of control EP specimens and specimens cured at high pressures shows that the dimensions of the globular formations and the thicknesses of the boundaries separating them diminish under the influence of hydrostatic pressure and the structure becomes more uniform.^{62,68,84,85} Table 2 presents the results of optical microscope studies of a series of epoxide compositions, illustrating this postulate. When the resolution of the microscope is high, it is seen that each globule consists of smaller formations. The results of electron microscope studies of the EP structure⁸⁴ are correlated with optical microscope data, which indicates a link between the observed morphological formations. The more finely disperse structure of the EP obtained under a high pressure compared with the structure of the EP cured at atmospheric pressure is due to the fact that the acceleration of the structure formation processes entails the

Table 2. The average sizes of the globules (d) and the content of groups of globules of different sizes at different pressures.^{62, 68}

formation of a larger number of centres with reacted reactive groups, which create a basis for the subsequent formation and establishment of the heterogeneous morphology of the EP.⁸⁶

The influence of pressure on the microstructure of MECDE is analogous to its influence on the structure of EP. Electron microscope studies⁷⁹ have shown that polymerisation under the conditions of hydrostatic compression is responsible for the decrease in the size of the globules from 500 Å (at 0.1 MPa) to 300–350 Å. Increasingly more pronounced aggregates with an elongated shape, consisting of a set of globules arranged one on top of another, are formed with increase in pressure.

An interesting result has been obtained in a study⁸⁷ devoted to the structure of a phenol–furfural composition based on iron tris(hydroxymethyl)phenoxide (Fe-TMP). In the original composition, the Fe-TMP forms ionic clusters which coagulate in the course of structure formation in the system with formation of associated species. High pressure promotes the latter process and leads to the appearance of larger metal-containing particles. At the same time pressure influences the physicochemical processes occurring in these particles during the curing of the composition, which alters their phase structure from amorphous to crystalline. The increase in the size of the cluster is accompanied by the appearance of a large amount of magnetite and an increase in the degree of order in its structure.

The pressure-induced changes at different levels of the structural arrangement of network polymers are reflected in their mechanical properties. In the first place, one should point to the increase in density, which has been noted in numerous investigations (see, for example, Refs 75, 79, and 85). This can be explained by the fact that pressure prevents the formation of macroscopic defects in the form of pores or cracks and promotes a decrease in free volume as a result of a more effective packing of the polymer. In the region of comparatively low pressures, the $\rho(P)$ relation is linear, but, as P increases, it approaches asymptotically a certain limiting value.⁷⁹

Table 3 lists the strain–strength characteristics of MECDE specimens at different pressures, established in compressive tests.⁷⁹ Evidently, with increase in pressure, the modulus of elasticity (E) and the ultimate tensile strength (σ_t) increase to certain values. In the range 425–500 MPa, these parameters diminish. The extremum change in mechanical properties may be caused by the competition between the changes at the microlevels (ρ) and topological levels (v) of the structure and at the level of the macrochains. At a comparatively low pressure, effects associated with the increase in ρ and v predominate. The mechanism of the

addition of methacryloyl groups predominates in the region ≥ 400 MPa.⁷²

The results of compressive tests on EP specimens cured at atmospheric and elevated pressures agree^{74, 85} with the data of the above study.⁷⁹ The more effective mechanical properties of the modified EP can be accounted for by the intensification of the intermolecular interaction and a decrease in structural inhomogeneity on curing under the conditions of hydrostatic compression. The most significant changes in properties are attained when the epoxide compositions deviate greatly from stoichiometry, whereupon the number of unreacted epoxide groups increases significantly. The intermolecular interactions at the boundary between the globular and interglobular phases are appreciably weakened under these conditions with a consequent sharp decrease in the strength characteristics of the control specimens. The density of the cross-links in the polymer increases under the influence of pressure (the degree of inhomogeneity diminishes) and the connectivity between the supermolecular formations is enhanced, which promotes the retention of fairly high strengths.

The data obtained in tensile tests on EP are similar. Fractographic investigations⁷⁵ have shown that modification by pressure does not entail a change in the rupture mechanism. The differences between the fractograms of the specimens compared are merely quantitative; in the modified EP, the structural elements of the fractograms are smaller.

A promising method of improving the mechanical properties of polymers is believed to be the cure under pressure of reinforced compositions, especially if one employs fillers with a low surface energy or fillers tending to undergo sedimentation. Fig. 5 presents the distribution of microhardness along sections of cylindrical

Figure 5. Distribution of the microhardness H_μ in cylindrical specimens of EP-2 (1, 2) and EP-2 with 10 mass% of graphite (3, 4) at different pressures (MPa): (2) and (4) 0.1; (1) and (3) 200. d = Diameter of the cylinder.

Table 3. The strain–strength properties of MECDE at different pressures.

P /MPa	$10^{-3}E$ /MPa	σ_t /MPa	P /MPa	$10^{-3}E$ /MPa	σ_t /MPa
0.1	2.20	230	340	2.60	250
85	2.35	235	425	2.55	245
170	2.35	220	550	2.40	230
255	2.45	230			

EP-2 specimens obtained at different pressures. The level of microhardness H_μ for the modified polymer is higher compared with the control specimen, while the scatter of the values is approximately the same. When finely dispersed graphite powder is introduced, the picture changes sharply: a slight increase in inhomogeneity in the distribution of H_μ is observed for the polymer obtained under the conditions of hydrostatic compression, while in the control specimens the maximum deviation of H_μ from the mean reaches 20% for a filler content of 10 mass%–30 mass%. Such a change in H_μ in the latter case is caused by the separation of the composition into layers as a consequence of sedimentation processes. The viscosity of the cured composition increases under the influence of a high hydrostatic pressure, with a consequent suppression of the sedimentation processes, the microstructure of the composite becoming more homogeneous.

The dielectric properties of EP obtained at atmospheric and elevated pressures have been investigated.⁷⁵ It was established that the specific electrical volume resistance (ρ_v) of the modified polymers is higher than that of the control specimens and that the highest differences between the ρ_v are observed for specimens in the rubbery state. The EP investigated exhibited the ionic type of conductivity and the increase in ρ_v is therefore accounted for by the decrease in the mobility of the ions induced by the higher values of ρ and v for the modified polymers. The temperature dependences of ρ_v , the dielectric loss factor ($\tan \delta$), and the dielectric constant (ϵ') are correlated.⁷⁵ The maxima in $\tan \delta$ and ϵ' caused by the α -relaxation in the modified EP, as well as the corresponding break in the $\rho_v(T)$ relation, are located at higher temperatures compared with the corresponding maxima for the control specimens. Furthermore, the modified polymers have lower absolute values of ϵ' .

Studies on the thermal stability of EP showed⁸⁸ that appreciable differences between the characteristic temperatures of the objects compared were not observed for specimens in the form of a block. When the modified specimens are ground, an increase in the original thermal degradation temperature compared with the corresponding temperature of the control specimen is observed. Analysis of the change in the thermal degradation temperature in the course of the annealing of the ground specimens in oxygen and under an inert atmosphere led to the hypothesis that curing under pressure influences the nature of the packing of the molecular chains, as a result of which the most 'vulnerable' chemical bonds are shielded from oxygen.

Polymers based on interpenetrating polymer networks (IPN) have great potential possibilities for structural modification. Such polymers are obtained by simultaneous or consecutive curing.⁸⁹ In a series of studies, Lee and Kim^{90–93} examined the influence of hydrostatic pressure on the structures and properties of simultaneously cured IPN in relation to the polyurethane–polystyrene (PU–PS) system. The characteristic features of the behaviour of the PU–PS compositions, consisting of blends of linear polymers or of polymers of the type of semi-IPN, were discovered. It was established that, in the course of synthesis under the conditions of hydrostatic compression, ρ of the final reaction product increases (the increase in ρ is observed in the range 0.1–250 MPa, while in the region of higher pressures ρ is independent of pressure). The nature of the temperature dependence of the mechanical loss factor also varies with increase in pressure. The $\tan \delta(T)$ relation for the compositions synthesised at atmospheric pressure has two maxima corresponding to each component of the composition (Fig. 6). In the synthesis under a high pressure, the positions of the temperature maxima are displaced towards one another and ultimately the maxima merge, forming a single peak. This peak is produced as a result of the degeneration of the PU maximum. The glass transition temperature of the dominant phase (PS) decreases with increase in pressure and this is the reason for the low slope of the relation $T_g(P)$ at ~ 1000 MPa. The authors associate the observed effect with the increase in the compatibility of the phases both for the blend of linear polymers and for the semi-IPN and IPN (Fig. 7).

Figure 6. Temperature variations of the mechanical loss factor for the polyurethane–polystyrene IPN system containing 50 mass% polyurethane at different pressures (MPa): (1) 0.1; (2) 250; (3) 1000.

The results of electron microscope studies indicate that the morphology of the PU–PS system, synthesised at atmospheric pressure, consists of a fairly homogeneous structure made up of the PU and PS phases. With increase in the synthesis pressure, fully dispersed domains are formed in the PU phase, their size diminishing with increase in the compatibility of the phases. At 1000 MPa, the size of the domains is 30–50 Å, which corresponds to the molecular level of the blending. The size of the domains increases with increase in the cross-linking density in the IPN. The results of the study of the morphology of the IPN PU–PS system by dynamic mechanical analysis and electron microscopy agree satisfactorily.

In the case of the semi-IPN and the blend of linear polymers obtained at atmospheric pressure, the PU phase forms a matrix, but with increase in pressure a tendency towards the dispersion of this phase is manifested. Such a tendency is most notable for systems in which the PU component has a linear structure.

Prolonged annealing of the pressure-modified PU–PS blends at 0.1 MPa and $T < T_g$ promotes the partial restoration of the $\tan \delta(T)$ spectrum characteristic of control specimens synthesised under atmospheric conditions. With increase in the annealing temperature to $T > T_g$, complete phase separation (characteristic of the control specimens) takes place, which is indicated by the identity of the mechanical loss spectra of the annealed and control specimens.

Figure 7. Dependence of the glass transition temperature T_g on the synthesis pressure for the polyurethane–polystyrene system. (1) IPN; (2) semi-IPN; (3) polymer blend.

The characteristic features of the structure formation in and the properties of the consecutively cured IPN synthesised under pressure have been investigated^{94–96} in relation to epoxide allyl polymers. Diethylene glycol bis(allyl carbonate) (DEGBAC) and epoxybisphenol resins (EO) were used as the allyl monomers. The study of the prepolymerisation (formation of the allyl network) kinetics by rotational viscometry and by measuring ρ_v showed that together with accelerating the process and increasing the average degree of polymerisation, pressure induces or intensifies the gel effect. Under these conditions, even a comparatively slight increase in the original DEGBAC concentration alters the direction of the reaction towards the formation of the network product.

The pressure-induced changes in the structure and properties of the prepolymer are inherited on final curing of the composition (curing of the epoxide component) at 0.1 MPa. According to the results of thermomechanical analysis, high glass transition and rubber elasticity temperatures are characteristic of polymers obtained under pressure, but the vitrification temperature range is comparatively narrow. Fig. 8 presents the dependences of T_g for epoxide allyl compositions on the DEGBAC concentration corresponding to different conditions in the synthesis of the prepolymer. The increase in DEGBAC concentration, starting from a certain value, leads to a linear growth of T_g . The change in v induced by an increase in the content of the allyl component and by pressure is correlated with the 'behaviour' of T_g (Table 4).

Figure 8. Dependence of the glass transition temperature T_g for epoxide-allyl polymers on the DEGBAC concentration. P (MPa): (1) 0.1 (control specimen); (2) 200.

Table 4. The structures and properties of epoxide-allyl polymers obtained at different pressures.

[DEGBAC] (%)	$10^{-20} \nu$ /cm ⁻³	T_g /K	ΔT_g /K	ΔC_p /kJ kg ⁻¹ K ⁻¹	H_μ /MPa
16	6.0	343	50	0.24	150
	7.8	353	30	0.21	180
	7.0	343	60	0.29	220
17	9.2	358	30	0.21	180
	7.6	343	60	0.38	250
18	9.2	358	20	0.21	185

Note. The quantities above the horizontal line represent the characteristics of the control specimens and those below the horizontal line represent the characteristics of the specimens obtained using a pressure of 200 MPa.

The study of the relaxation and thermophysical properties of the polymers obtained at DEGBAC concentrations ensuring the formation of type IPN polymer–polymer structures demonstrated the following. In the region of T_g , a symmetrical tan δ

maximum and a jump in heat capacity (ΔC_p) are observed. Higher values of T_g , a narrower vitrification range (ΔT_g), and lower values of ΔC_p have been noted in pressure-modified polymer compositions.

The existence of a single glass transition temperature and its linear dependence on the concentration of the allyl component in the compositions investigated indicate a high degree of interpenetration of the epoxide and allyl polymers.^{97,98} The influence of pressure on the change in the compatibility of the networks and the morphology of the polymers is difficult to trace for such systems. Nevertheless, the experimental results permitted a series of conclusions. The characteristic differences between the values of T_g , ΔT_g and ΔC_p for the polymers (Fig. 8 and Table 4), associated with the use of a high pressure in the prepolymerisation state, indicate the presence of a modifying effect of the pressure. Pressure affects primarily the degree of polymerisation of DEGBAC: for identical original concentrations of the allyl monomer, a higher degree of conversion of the prepolymer synthesised under the conditions of hydrostatic compression is observed and the probability of the formation also of a denser network of chemical bond cross-links therefore increases. In the curing of EO, the differences between the densities of the allyl networks are retained, which is reflected in the values of ν and T_g for the polymers compared.

The uniformity of the polymer structures may be inferred to some extent from the values of ΔT_g and ΔC_p : ΔT_g and ΔC_p diminish with increase in homogeneity.⁷⁶ Hence it follows that pressure promotes the homogenisation of the structures of polymer compositions. This is indicated also by the results of small-angle X-ray scattering studies: the scattering intensity in the case of specimens obtained using hydrostatic pressure is much lower than in the control specimens (Fig. 9). This effect may be induced by different causes, for example, by the extensive penetration of the EO into the allyl network in the preparation of the prepolymer under a high pressure and also by the formation of a less defective allyl network. Ultimately the factors considered improve the compatibility of the networks.

Figure 9. Results of the study of epoxide-allyl polymers (DEGBAC content 18 mass%) by the small-angle X-ray scattering method for prepolymerisation at different pressures (MPa): (1) 0.1; (2) 200.

The results of the measurements of the microhardness H_μ , which serves as a measure of the local plasticity (Table 4) agree with this conclusion. The lower values of H_μ for the pressure-modified polymers may be induced by the plasticisation phenomenon caused by the increase in the compatibility of the networks.⁹⁹

3. Preparation of oligomeric products by fusion under pressure

The modifying effect of pressure may be used not only for the preparation of network polymers and polymer-polymer systems but also in the synthesis of their reactive components. The effect of hydrostatic pressure on the fusion of the epoxybisphenol A resin ED-22F and bisphenol A has been examined¹⁰⁰ and a study has been made of the fractional composition of the reaction product. In a study of the fusion kinetics, use was made of the method involving the titration of the reaction groups: the epoxide (E), alcoholic OH (A), and phenolic OH (P) groups. The fractional composition was studied by the gel-chromatographic method.

Figure 10 presents typical chromatograms of the reaction product obtained on fusion of the epoxide resin for 1 h. The assignments of the peaks are presented in Table 5. The influence of the duration of exposure and pressure on the fractional composition of the epoxide resins is reflected in the data in Table 6 and the change in the molecular parameters is reflected in the data in Table 7.

Figure 10. Chromatograms of the product of the fusion of an epoxide resin with bisphenol A. *P* (MPa): (I) 0.1; (II) 100; the numerals opposite the curves represent the numbers of the peaks in Table 5.

Table 5. The retention times (τ), the degrees of polycondensation (m), and the molecular masses of the product of the fusion of an epoxide resin with bisphenol A (Fig. 10).

^a These polymeric products are not represented by individual peaks on the chromatogram but are 'located' in the tail part of peak No. 6.

^a These polymeric products are not represented by individual peaks on the chromatogram but are 'located' in the tail part of peak No. 6.

Despite a certain scatter of the parameters presented in Table 7, the acceleration of the process by the pressure can be clearly traced. Pressure leads to an increase in the proportion of the high-molecular fractions and in the degree of polycondensation (Table 6). On the other hand, an integral parameter such as polydispersity changes comparatively little.

The synthesis (chain growth) under pressure of oligomeric products may be represented by the following simplified scheme:¹⁰¹⁻¹⁰⁵

It may be accompanied by a side reaction — chain branching:

Table 6. Variation of the fractional composition of epoxide resins in the course of their synthesis.

Time /h	Content of fraction (%) for different degrees of polycondensation

Note. The average molecular masses (the number-average $\bar{M}_n$, the mass-average $\bar{M}_w$, and z -average $\bar{M}_z$ molecular masses) were calculated using chromatographic data, while the average functionalities were obtained from the formulae $\bar{f}_n^E = \bar{M}_w c_E / 1000$, $\bar{f}_w^E = \bar{M}_z c_E / 1000$, $\bar{f}_n^P = \bar{M}_n c_P / 1000$, and $\bar{f}_n^A = \bar{M}_n c_A / 1000$, where c_E , c_P , and c_A are the concentrations of the E, P, and A groups in the polymer blend. The selectivity is designated by b .

It is believed¹⁰⁵ that the polar complex tertiary amine (R_3N)–phenol (HOPh) interacts with the epoxy-group in the main reaction and that the reaction proceeds in accordance with the scheme

The kinetics of this process are described by the second-order equation

$$-d[E]/dt = k[E][R_3N]_0,$$

because the concentration of the reaction complex $R_3N \cdots HOPh$ is determined exclusively by the concentration of the tertiary amine. Bearing in mind that $[R_3N] = \text{const}$ in the course of the reaction,¹⁰² the process considered may be described by a first-order kinetic equation for the specified R_3N concentration.

In reality the process is much more complicate, because the complexes P_m , P_mE , and P_mA ($m = 1 - \infty$), where m is the degree of association of the phenol in the complex and A is the amine, are formed reversibly in the system. The complexes P_mA with $m = 1$ and 4 are reactive. All these features significantly complicate the kinetic description of the fusion process because H-complexes and (or) contact ion pairs may be regarded as the reactive species in the chain propagation and branching reactions:¹⁰²

The low acidity of the alcohol formed in the chain propagation reaction precludes its competition with phenol in the complex formation process. For this reason, the side reaction is hindered in the presence of phenol and may be neglected to a first approximation.^{101–103}

Table 7 presents the effective reaction rate constants (k) calculated from the consumption of the epoxy-groups (a first-order equation). Evidently, the approximate constancy of k is observed under the conditions investigated. This factor confirms the hypothesis that the main contribution to the rate of the given reaction comes from the amine–phenol complexes and not from the free ions.¹⁰²

The fact that the formal-kinetic descriptions of the reactions at 0.1 and 100 MPa are the same may be interpreted as evidence in support of the constancy of the mechanisms of these processes in the system investigated. This permits the employment of the known pressure dependence of k (Zhulin¹⁰⁶) for the calculation of the volume activation effect ($\Delta V_0^\ddagger$) corresponding to atmospheric pressure:

$$\log \frac{k_P}{k_0} = -\frac{\Delta V_0^\ddagger \Phi}{T},$$

where Φ is a function of pressure. With the aid of this relation and the values of k presented in Table 7 $\Delta V_0^\ddagger = -12.0 \text{ cm}^3 \text{ mol}^{-1}$ was found. The value of $\Delta V_0^\ddagger$ obtained differs significantly from that established for the analogous polycondensation process:⁶⁷ $\Delta V_0^\ddagger = -27.0 \text{ cm}^3 \text{ mol}^{-1}$ (interaction in the epoxide–amine system with formation of a network polymer). Consequently the influence of pressure on the interaction in the epoxide–phenol system is appreciably weaker than in the epoxide–amine system, which may be associated both with the differences in the transition states and with the solvation of the transition state in the epoxide–phenol system by oligomeric molecules, which may play the role of a ‘solvent’ (the volume activation effect for the viscous flow of such a solvent is positive¹⁰⁶).

Using the approach based on the cascade theory of branching processes,¹⁰⁷ the selectivity of the process investigated was estimated¹⁰⁰ as the ratio of the rate constants for the side and main reactions. It was established that the synthesis of epoxide resins under the conditions of hydrostatic compression improves the selectivity significantly.

IV. Solid-state extrusion of polymers and polymer composites

1. Crystallisable polymers

Porter and coworkers were some of the first investigators who studied solid-state extrusion.^{108, 109} They achieved the extrusion of PE through a capillary viscometer at temperatures close to the melting point. The transparent ultraoriented fibre thus obtained was characterised by high moduli of elasticity. In order to obtain a continuous oriented thread with the aid of a capillary rheometer, in a later study¹¹⁰ PE was crystallised under pressure, after which it was extruded at $T < T_m$. This resulted in the appearance of a rigid strengthened fibre.

The structure of the polyethylene fibres obtained by solid-state extrusion is microfibrillar and is in the main similar to the structure produced in the usual stretching. The main bunch of microfibrils (fibrilla) is ribbon-shaped. The microfibrils are linked sideways by penetrating chains, which has been confirmed by X-ray investigations.¹¹¹ The amorphous component of the extruded specimens is also oriented, although to a lesser extent than the crystalline component. The maximum orientation of the amorphous phase is attained at extrusion temperatures close to the α -relaxation temperature.¹¹²

The properties of the extruded fibres depend both on the extrusion conditions (extrusion temperature; draw ratio $\lambda = d_b^2/d_d^2$, where d_b^2 and d_d^2 are respectively the diameters of the billet and the calibrating aperture of the die; the geometry of the deforming instrument) and on the original morphology of the polymer. It has been shown for HDPE that there is an optimum ratio between the CEC and CFC in the original material, which makes it possible to obtain the best set of mechanical properties. On the other hand, the maximum tensile modulus of elasticity is attained on extrusion in the vicinity of the α -process temperatures.²⁵ An increase in external pressure also corresponds to an increase in the modulus of elasticity.¹¹³ The tensile strength is determined mainly by the value of λ .²⁵

The solid-state extrusion method, used to obtain ultraoriented fibres, may be employed also for the preparation of films, which are likewise characterised by effective mechanical properties.¹¹⁴ The solid-state coextrusion process has been frequently used in recent years for the uniaxial stretching of films.^{115–117} HDPE is usually the material of the shell in which the film is placed. The choice of HDPE is determined primarily by its satisfactory deformability.

The characteristic features of the solid-state extrusion of block specimens of isotactic polypropylene have been investigated.^{118, 119} The authors proposed a scheme for the process dynamics, incorporating nonstationary and stationary extrusion. The description of the process includes relations agreeing satisfactorily with experimental data. Within the framework of the chosen approach,¹¹⁸ taking into account the occurrence of the marked orientational strengthening of polymers, the formation of spiral defects on extrusion with high draw ratios λ becomes understandable.¹²⁰ For such values of λ , the yield point (σ_y) becomes close to the ultimate tensile strength (σ_t) and any local inhomogeneity in the flow leads to the rupture of the extrudate.

A new series of publications on this question appeared in connection with the development of the hydrostatic extrusion method. When a liquid is used to transmit a high pressure, the most favourable conditions are created for solid-state moulding and it is possible to obtain rod-like and tubular articles with different profiles and a satisfactory quality of the surface and performance properties.¹²¹

The vast majority of studies on hydroextrusion have been carried out in relation to PE (see, for example, Refs 120 and 122–132). The very significant role of the technological process parameters, particularly extrusion temperature, the rate of deformation, and the angle of the drawing die (α) has been noted. It has been established^{126, 128} that the most favourable deformation regime is the creep regime, in which the rate of emergence of the extrudate is $\sim 1 \times 10^{-3} \text{ m s}^{-1}$. The extrusion temperature range may be fairly broad but not unduly close to the melting point, where there is a possibility of the sticking of the material on the deforming instrument owing to its local fusion. At the same time, there is an optimum extrusion temperature for each draw ratio λ , which makes it possible to achieve the maximum effect (improvement of mechanical properties) due to orientation.

The data for the optimum value of α are contradictory,^{123, 128, 133} but it is at least clear that it is in the range $20^\circ \leq \alpha \leq 60^\circ$. For low conical angles of the discontinuity, the nonuniformity of the distribution of deformations on the cross-section of the extrudate is small, but, owing to the increase in the contact area, there is an increase in the friction of the billet against the die, which increases the extrusion pressure. For large angles, there is an increase in the nonuniformity of the distribution of the deformations, which promotes an increase in the extrusion pressure and has an unfavourable effect on the distribution of properties over the cross-section of the extrudate.

With increase in λ , the variation of the density of the extruded PE passes through a minimum,^{124, 126} the modulus of elasticity, the strength, and the hardness increase, while the plasticity diminishes.^{25, 31, 124, 128} It is noteworthy that the increment in the tensile modulus of elasticity induced by hydroextrusion with high draw ratios, may exceed two orders of magnitude, while the stress may exceed one order of magnitude.¹²⁸ The capacity for strengthening is determined to a large extent by the molecular mass: in high-molecular PE, the increment in the modulus of elasticity is smaller than in low-molecular PE for the same technical parameters of the hydroextrusion process.^{31, 124, 128} Together with the change in mechanical properties, an improvement of dielectric parameters has been noted for extrudates. Thus it has been observed¹²⁸ that the extruded HDPE is characterised by a greater resistance to the formation of incomplete electrical breakdown channels compared with the original material. This parameter increases with increasing draw ratio.

The study of the structures and properties of PE made it possible to put forward the following mechanism of the structural transformations in the hydroextrusion process.^{120, 127} For low values of λ , the material has a typical fibrillar structure with slightly skewed crystallites and intra- and inter-fibrillar layers. With increase in λ , the crystallites become thinner in a transverse direction, are displaced relative to one another in the direction of the extrusion axis, the fraction of the interfibrillar amorphous layers diminishes, and the layers are partly drawn into the fibrils. On further increase in λ , the interfibrillar layers vanish and a structure made up of layers perpendicular to the extrusion axis arises. Dense interfibrillar strands of the type of CEC appear in the amorphous sections. The increase in the modulus of elasticity for small and moderate draw ratios is due to the increase in the degree of orientation of the structural elements considered and in the degree of crystallinity, but for high values of λ it is caused by the uniform distribution of the mechanical load over all the fibrils and by the growing role of the increasing number of intercrystallite strands. Overall, the proposed mechanism agrees with that discussed by Ciferri and Ward.³¹

Fairly numerous studies have been carried out on the hydroextrusion of PP. Features in the main similar to those characteristic of PE have been established for this material.^{134, 135} In contrast to PE, the limiting draw ratios are significantly smaller for PP ($\lambda < 6$). A high degree of die swell (elastic recovery), characteristic of PP, reaching more than 30% for low values of λ , has also been noted.¹³⁴

The characteristic features of the hydroextrusion process and the properties of the extrudates have been investigated to a lesser extent for other representatives of the class of amorphous-crystalline polymers. The results of studies carried out on PTFE have been published.^{136, 137} The variation of the strength and elastic properties of fluoro-plastics as a function of the extrusion conditions obeys the same rules as in the case of other polyolefins, but the limiting degree of deformation on hydroextrusion does not exceed 4. The elastic and strength parameters for extension in the direction of the extrusion axis increase by a factor of 1.2–3.5. The breaking stress and tensile strength in the transverse direction also increase compared with the undeformed material. Extruded fluoro-polymers virtually lack cold fluidity.

The density, the mechanical properties in extension, and the linear coefficient of thermal expansion along the extrusion axis of hydroextruded poly- ϵ -caproamide have been investigated as a function of ratio.¹³⁸ The distribution of the densities of the axial and shear deformations has been obtained and comparative analysis of the experimental and calculated data on the extrusion pressure and the distribution of the deformations in the extrudates has been carried out.

An important performance characteristic of the oriented polymers is thermal shrinkage or the degree of recovery of the original dimensions (the shape memory effect). For HDPE, it does not exceed 10% and diminishes with increase in λ .¹²⁸ In the case of low-density polyethylene (LDPE), the degree of recovery is much greater: for low values of λ , it can reach $> 50\%$.¹²⁰ Numerous studies of the characteristic features of the thermal shrinkage of oriented specimens of crystallisable polymers have been carried out, but they were virtually all performed on films or fibres. The shrinkage characteristics and the shrinkage mechanism have been examined in detail for block specimens¹³⁹ in relation to LDPE deformed by hydroextrusion.

It was established that the thermal shrinkage of extruded LDPE specimens is a relatively rapid process in which the degree of shrinkage (ψ) increases with increase in the annealing temperature and with decrease in the extrusion temperature. Comparison of the maximum values of ψ for oriented PE films and specimens obtained by the hydroextrusion method showed that the latter exhibit a greater shape stability.^{140–143} The changes in the maximum shrinkage stresses ($\sigma_{m.sh}$) and linear dimensions of LDPE as a function of λ and extrusion temperature are similar (Fig. 11). The shrinkage stresses vanish completely at temperatures corresponding to the fusion of the crystallites in the oriented LDPE.

Figure 11. Relations between the draw ratio λ , the extrusion temperature T_e , and the maximum shrinkage stresses $\sigma_{m.sh}$ for LDPE. (1) $\sigma_{m.sh}(\lambda)$, $T_e = 313 \text{ K}$; (2) $\sigma_{m.sh}(T_e)$, $\lambda = 4$.

During the orientation of LDPE, layered structures consisting of crystalline lamellae arranged perpendicular to the direction of stretching, arise in the extrudates. Stressed tied chains or clusters also appear as a result of the orientation. Heating of the oriented specimens shortens the extended macromolecules or parts of them: under the influence of entropy factors, the crystalline framework is transformed, which makes possible the shortening of the molecules.^{140, 142, 144} The higher the temperature, the easier is the slip of individual sections of the macromolecules in the amorphous-crystalline polymer. With increase in extrusion temperatures, the number of stressed tied chains therefore diminishes, which decreases the stress and the degree of shrinkage. The decrease is caused primarily by the disappearance of the stressed tied chains in the defective crystallites, the disruption of which requires a low activation energy. At the same time, the displacement of the maximum on the temperature dependence of the shrinkage stress towards higher temperatures, which occurs with increase in the extrusion temperature,¹³⁹ is induced by the appearance of layers consisting of crystallites with increased transverse dimensions, the disruption of which requires a higher activation energy.

Yet another factor determining the structural rearrangement on heating of the extruded LDPE is the increase in the thickness of the lamellae during the annealing process. Individual segments are then 'drawn' into the body of the lamella, which induces the deorientation of the crystalline blocks and the appearance of internal stresses.^{145, 146}

All the results examined above for the solid-state extrusion of crystallisable polymers were obtained in the extrusion of low-porosity monolithic billets. When highly-porous polymeric billets are employed, a kind of anisotropic structure, which makes it possible to achieve a state with a negative Poisson ratio (μ), may be formed in the extrudates.^{147–149} The microstructure of such materials consists of grains joined by fibrils. These materials are interesting for a number of reasons: firstly, the effect of the negative μ may be used directly in clamps and seals; secondly, the presence of this effect influences favourably other mechanical properties, for example, the modulus of shear, the resistance to indentation, *etc.*^{150, 151} Finally, the complex microstructures responsible for the establishment of a negative μ may induce also other unusual phenomena associated with internal rotational degrees of freedom.^{152, 153}

Not only monolithic but also powder billet may be subjected to solid-state extrusion. Strips, which were subsequently placed in HDPE were prepared from superhigh-molecular polyethylene (SHMPE) powder^{154, 155} by pressing at elevated temperatures ($T < T_m$). Next the coextrusion process was carried out. Thus a highly modular high-strength state was achieved for the SHMPE. For example, the tensile modulus of elasticity achieved in one of the above investigations¹⁵⁵ amounted to ~ 60 GPa.

An even greater rigidity was attained on further stretching of the extruded materials by uniaxial extension. According to the data of Kanamoto *et al.*,¹⁵⁶ the modulus of elasticity of such films exceeded 100 GPa. Porter¹⁵⁷ obtained from powdered PTFE by the solid-state coextrusion method strips having a modulus of elasticity and an ultimate tensile strength of 3.2×10^4 and 3×10^3 MPa respectively. Oriented films have been obtained similarly¹⁵⁸ from polyacrylonitrile powder. They had effective strain–strength characteristics.

The difficulty of the process in which a polymeric billet is converted into a monolithic material, to be subjected to extrusion may in many instances render solid-state extrusion economically unjustified. This concerns particularly polymers with a high viscosity of the melt or reinforced compositions for which traditional highly productive processing methods (conversion of the billet into a monolithic material) are unsuitable. The solid-state extrusion method proposed in two investigations^{159, 160} makes it possible to solve this problem. The procedure includes the following operations: compaction of the powder billet at room temperature, free heating of the billet, and extrusion using a heated high-

pressure container and die. The process is fairly productive, since it can be made quasi-continuous, whereupon each successive billet, expels the mould residue from the preceding one.

It has been established empirically that the optimum extrusion temperature range for the extrusion of materials such as SHMPE is $(0.94–0.96)T_m$,¹⁶¹ while for the polyetherketone based on isophthalic and terephthalic acids (brand PKIT) it is $(0.95–0.98)T_m$. At lower temperatures, the extrudates are obtained in a nonmonolithic form whilst at higher temperatures the polymer sticks to the deforming instrument, inducing an increase in the extrusion pressure and the formation of an uneven surface on the articles obtained (SHMPE) or the cracking of the extrudates (PKIT).

With increase in the degree of extrusion, the moduli of elasticity of the polymers considered increase and the increment in the modulus of elasticity for the flexible-chain polymer (SHMPE) is greater than for the semirigid-chain polymer (PKIT) (Table 8). The extrusion-induced changes in σ_t are small in both cases. At the same time, the plasticity diminishes with increase in the draw ratio. The results of mechanical tests on extruded SHMPE specimens are consistent with the familiar rules established for flexible chain crystallisable polymers,^{126, 128} namely the increase in the modulus of elasticity is faster than the increase in the strength parameters associated with orientational extrusion. The conditions in the plunger extrusion of a polymeric powder billet differ fundamentally from the conditions in the traditional variants of solid-state extrusion and we shall therefore consider in greater detail the dynamics of the formation of the oriented structure in the extruded SHMPE specimens.

Figure 12 presents the dependence of the degree of crystallinity of SHMPE specimens on the draw ratio, obtained from

Table 8. The properties of polymer specimens obtained by the plunger extrusion of a powder billet.

Figure 12. Dependences of the degrees of crystallinity K_d (1) and K_x (2) on the draw ratio λ (a) for SHMPE and of ΔK on the increment in the crystalline phase α_{or} (b).

X-ray data (K_x) and from density measurements (K_d).¹⁶² Evidently the absolute values of the X-ray degree of crystallinity are smaller than those found from the measurements of ρ . The observed difference between the values of K_x and K_d agrees with the available literature data^{163,164} and can have two explanations. According to Egorov *et al.*,¹⁶³ X-ray diffraction analysis yields the so called 'geometrical' degree of crystallinity, because the macromolecules arranged parallel to one another but without a three-dimensional order are detected by this method as disordered regions. On the other hand, in dilatometric measurements they can contribute to the crystalline phase. Mandelkern¹⁶⁴ expressed a different view, according to which the difference under discussion is caused by the presence of interfacial regions possessing a partial degree of order. In these regions, there is a smooth transition from long-range order (crystalline phase) to disorder (amorphous layers). Thus the quantity $\Delta K = K_d - K_x$ defines the fraction of either oriented macromolecules in the noncrystalline regions or the fraction of interfacial regions.

An increase in λ leads to an increase in the degree of crystallinity of SHMPE (Fig. 12), *i.e.* crystallisation due to orientation take place. The increment in the crystalline phase (α_{or}) can be expressed by the difference between the degrees of crystallinity (ΔK) corresponding to an arbitrary λ and $\lambda = 1$. The quantity K_x yields the true characteristic of the orthorhombic crystalline phase without taking into account the partial order in the noncrystalline regions and, by virtue of this factor, is accurate. It is therefore used to determine α_{or} . The parameter ΔK may be treated as the decrease in the fraction of oriented macromolecules in the noncrystalline regions¹⁶³ or in the volume of the interfacial regions.¹⁶⁴ Comparison of the data presented in Fig. 12 supports the second version, since, firstly, a decrease in the fraction of stretched through chains with increase in λ is unlikely; secondly, the values of ΔK for the undeformed SHMPE specimens are close to those established earlier by Mandelkern.¹⁶⁴

The $E(\lambda)$ relations for SHMPE¹⁵⁶ and HDPE,¹²⁴ obtained in compressive, bending, and tensile tests, are similar (Fig. 13). Without dwelling on the discussion of the differences between the absolute values of E , we may note that, with increase in λ , one

Figure 13. Dependence of the modulus of elasticity E for SHMPE and HDPE on the draw ratio λ (a) and of β on $\Delta\alpha$ for SHMPE (b). (1) SHMPE, compression; (2) SHMPE, bending; (3) HDPE, extension.

observes an increase in E which is steeper than a linear increase. There exist two limiting models describing the distribution of stresses in the oriented amorphous-crystalline monomers.³¹ In the first, one postulates a uniform distribution of stresses in the crystalline block, where the tied chains are fairly uniformly distributed among the microfibrils formed in the stretching process. In the second, one postulates the complete independence of the tied chains and the crystalline blocks, the internal regions of the crystals alternating with amorphous layers which do not contain tied chains. The $K(\lambda)$ relations of the type presented in Fig. 12a correspond to the first model.³¹ In this case, the volume fraction of the volume (β) occupied by tied chains is calculated by means of the simplified Takayanaga formula³¹

$$\beta = \frac{E}{E_{ax}(1 - K_x)},$$

where E_{ax} is the axial modulus of elasticity of the crystalline component.

Figure 13b presents the dependence of β on the fraction of the crystallised interfacial regions $\Delta\alpha$. The moduli of elasticity calculated from the results of compressive tests were adopted as E . A linear relation, passing through the origin of coordinates, is observed between β and $\Delta\alpha$. This means that the interfacial regions participate actively in the formation of the system of tied chains in the extruded SHMPE. The $\beta(\Delta\alpha)$ relation shows that $\sim 45\%$ of the macromolecules in the interfacial regions become tied chains. The result obtained agrees well with theoretical¹⁶⁵ and experimental¹⁶⁶ estimates.

Two components of the crystalline phase may be differentiated for the extruded SHMPE (taking into account the results examined above): the original crystalline phase transformed by deformation and the phase arising as a result of orientational crystallisation. The latter consists of crystallised amorphous sections and crystallised interfacial regions. Analysis of data on

the thermal shrinkage of extruded SHMPE specimens showed¹⁶⁷ that ψ increases with increase in α_{or} and $\Delta\alpha$, the absolute values of ψ and the corresponding α_{or} and $\Delta\alpha$ being similar. The above factors made it possible to postulate the fusion sequence for the components of the crystalline phase. The least perfect crystalline formations, obtained by the orientational crystallisation of the interfacial regions, melt initially. Their relatively high degree of imperfection can be explained by the presence in the interfacial regions of a large number of irregularities in the chains torn away from the crystallites. The next to melt are amorphous regions crystallised in the orientation process in which the number of irregularities is appreciably smaller. Finally, at higher temperatures the original crystalline phase melts. Thus the evolution of different structural components of SHMPE during the extrusion of a powder billet are described satisfactorily within the framework of the model of the three-component structure of the amorphous-crystalline monomer. The mechanism of this process has been examined in greater detail (resorting to fractal analysis and the cluster model of the structure of amorphous polymers) in another study.¹⁶⁸

X-Ray diffraction investigations carried out on extruded PKIT specimens showed that the degree of crystallinity of all the specimens studied is $\sim 40\%$ and changes little with increase in λ from 1 to 3. The specimens are characterised mainly by reflections which correspond to interplanar spacings of 5.71, 3.87, 3.19, and 4.79 Å. This state of PKIT is characteristic of an unstable crystalline modification,¹⁶⁹ *i.e.* the processing conditions are insufficient for a transition to the stable crystalline form having four principal reflections with interplanar spacings of 4.79, 3.91, 3.86, and 3.08 Å. Experiments showed that such an equilibrium form is formed on pressing at 623 K. It may be that the retention of the instability of the crystalline modification on extrusion in the temperature range 533–593 K is one of the causes of the insignificant change in the strain–strength characteristics of PKIT.

Porter and coworkers^{157, 170} investigated the processes involved in the solid-state extrusion of a high-molecular PTFE powder billet. The extrusion was carried out in the temperature range 373–613 K until the attainment of the maximum values of λ . It was established that at a temperature below 373 K or above 613 K (this is higher than the melting point, which amounts to 607 K), the process under consideration cannot be achieved. In the range 373 K $< T_e < 553$ K, the maximum value of λ is 10 and depends only slightly on T_e . On further increase in temperature, the limiting value of λ increases rapidly and amounts to 60 for $T_e = 603$ –613 K. The structure and properties of PTFE are determined by the values of λ and T_e . In particular, the dimensions of the crystallites in both parallel and perpendicular directions relative to the extrusion axis increase with increase in λ . The presence of microfibrils, having a transverse dimension (~ 45 nm) greatly exceeding that usually observed for oriented monomers (6–20 nm), is characteristic of the highly oriented PTFE. The maximum value of the flexural modulus elasticity, corresponding to the optimum extrusion conditions ($T_e = 613$ K, $\lambda = 40$) reaches 20 GPa.

The method involving the solid-state extrusion of a powder billet proved to be fairly effective also in the case of thermoplastic polyimides.¹⁷¹ The transition of the polymers to the molten state induces cross-linking of the macromolecules, which hinders their further processing. On the other hand, if the extrusion is carried out below T_m , using billets made up of powders pressed into discs beforehand, then for 563 K $\leq T_e \leq 593$ K it is possible to obtain high-quality articles with a high degree of crystallinity.

2. Glassy polymers

There have been few studies of the properties of flexible-chain amorphous polymers extruded in the solid state. An increase in E and σ_t with increase in λ is observed for polymeric materials of this class, as for the amorphous-crystalline polymers, although it is not quite so pronounced. A distinctive feature of the flexible-chain amorphous polymers is that their plastic characteristics increase

appreciably as a result of extrusion. For example, the deformation at the rupture point (ε_r) of poly(methyl methacrylate) subjected to tensile tests increased from several per cent for the control specimens to tens per cent for the extrudates.¹⁷² A severalfold increase in impact strength has been noted for impact-resistant polystyrene.¹⁷³ The sharp increase in the plasticity of these polymers is attributed to the orientation of the molecular chains along the extrusion axis and the breaking away of side chains.^{172–174}

The mechanical properties of polymers extruded in the solid state and of low-molecular substances, for example, metals, differ. The dependence of the strain–strength characteristic of oriented polymers on λ is determined to an appreciable extent by the scheme underlying the stressed state chosen in the test. Whereas on extension of polymers many investigators have noted an increase in the elastic and strength parameters with increase in the degree of orientation of the specimens, on compression the reverse effect is frequently observed or there are relations with a minimum. This applies both to crystallisable and flexible-chain amorphous polymers (Fig. 14).¹⁷⁵

Figure 14. Dependence of the yield point σ_y in compression on the degree of deformation (ε) for polyethylene (1), polypropylene (2), poly(vinyl-chloride) (3), and poly(methyl methacrylate) (4).

The characteristic features of the solid-state extrusion of rigid-chain amorphous polymers have been scarcely investigated. In this connection, a definite interest attaches to data obtained in a study¹⁷⁶ of the influence of the deformation by hydroextrusion on the structure and properties of such materials in relation to the polyketones PAEKN (the product of the polycondensation of 4,4'-difluorobenzophenone and bisphenol A) and PAEKF (the product of the polycondensation of 4,4'-difluorobenzophenone and phenolphthalein, a card polymer). Table 9 presents the parameters of the hydroextrusion process: λ , T_e , the extrusion pressure P , and the properties of the extruded polyketones in compressive and microhardness tests. Evidently the pressure diminishes with increase in the extrusion temperature and increases with increase in the extrusion draw ratio. In the case of extrusion at room temperature, the extrusion pressure reaches such high values already at $\lambda > 3$ that the extruded materials are 'shot out' and break up.

Hydroextrusion improves the elastic characteristics of polyketones. For example, the modulus of elasticity of PAEKN increases with increase in λ and diminishes with increase in T_e . In the case of PAEKN, the highest value of E is observed at $T_e = 488$ K. The dependence of the characteristics σ_t and H_μ on

the conditions in orientational extrusion is more complex. For PAEKN deformed at room temperature, these characteristics were lower than for the cast polymer ($\lambda = 1$). On the other hand, the extrusion of this material at an elevated temperature improves significantly the properties indicated. The values of σ_t and H_μ for PAEKF initially fall and then increase as λ increases, but the maximum values of these parameters for the deformed polyketone are smaller (H_μ) or of the same order of magnitude (σ_t) than for the original material. The measurements of the density of PAEKF indicate the compaction of the polymer on deformation. This factor is associated primarily with the decrease in the volume of the pores, which are present in large numbers in the cast PAEKF according to optical microscope data.

The pattern in the scattering of X-rays by specimens of the original PAEKF consists of an amorphous halo. Annealing of the specimens for 2 h at 488 or 523 K with subsequent slow cooling does not alter it. Hydroextrusion at room temperature also does not change the pattern. At $T_e = 488$ K, the separation of the centre of the amorphous halo into two broad low-intensity reflections is observed, which indicates the onset of the crystallisation of the polymer. Cast PAEKF specimens are amorphous. Analysis of the X-ray diffraction data showed that hydroextrusion does not lead to any appreciable changes in the structure of the specimens.

Comparison of the results of mechanical tests and X-ray diffraction studies makes it possible to understand the characteristic features of the changes in the strain–strength properties of the aromatic polyketones studied. The slight increase in E and the nonmonotonic variation of H_μ observed with increase in λ (Table 9) for specimens subjected to hydroextrusion¹⁷⁵ are induced (as for flexible-chain amorphous polymers) by the orientation of polymer chains and the values of these quantities are determined by the degree of orientation and the structure of the polymer. The higher the extrusion temperature, the lower the degree of orientation, other conditions being equal. This is responsible for the low-slope of the $E(\lambda)$ and $H_\mu(\lambda)$ relations observed for PAEKF as T_e increases.

The strength of the polymer is to a large extent determined by the presence of different kinds of defects in it. The presence of a large number of micropores in cast PAEKF specimens and their ‘healing’ (elimination of microdefects) during hydroextrusion probably account for the nature of the $\sigma_t(T_e)$ relation. The effectiveness of the ‘healing’ increases with increase in pressure,⁵⁴ so that σ_t increases with decrease in T_e (this is accompanied by an increase in pressure) (Table 9). The $\sigma_t(\lambda)$ relation corresponds to

the variation of the strength properties of flexible-chain amorphous polymers established by Nakayama and Inoue.¹⁷⁵

It was noted above that the creation of oriented order in crystallisable polymers enhances more significantly their elastic and strength properties than in the case of amorphous polymers. Extrusion with $\lambda = 2.5$ and $T = 488$ K entails the transformation of the amorphous modification of PAEKN into a semi-crystalline modification. This tends to improve the mechanical characteristics of the given material.

The relaxation properties are well correlated with the results of mechanical tests and structural studies. Hydroextrusion increases the original and equilibrium values of the relaxing modulus (E_r) and stress (σ). The highest values of E_r and σ characteristic of PAEKN correspond to the modification with a partially crystalline structure. With the aid of the ideas developed by Askadskii¹⁷⁷ it has been possible to describe in detail the kinetics of the relaxation processes in the extruded aromatic polyketones. In particular, it has been established that the rate of interaction of the relaxators in the extrudates is higher than in the cast materials. This is quite reasonable if relaxators are understood as different kinds of microheterogeneities which are converted into nonrelaxing structures faster the higher the level of internal stresses (the latter naturally increases on deformation).

Large single deformations occurring without the disruption of brittle materials such as network polymers have been achieved as a result of the plasticisation effect during hydrostatic extrusion after the attainment of the oriented state.^{68,75,178–180} EP — characteristic representatives of the class of network polymers — were selected as the object of study in the above investigations. It was established that the solid-state extrusion of EP induces a rearrangement of the structure at different levels of the structural arrangement, which is indicated by the results of NMR studies and optical-microscope studies.⁶⁸ Fig. 15 illustrates the variation of the molecular mobility of the structural fragments of high-crosslinked network EP, characterised by the nuclear magnetic transverse relaxation times T_2 for the mobile (T_{2b}) and more rigid (T_{2c}) ‘kinetic phases’ and also the variation of the fraction of relatively immobile protons (the p_c populations of the relatively

Figure 15. Temperature dependences of the nuclear magnetic relaxation times (a) and the proton population (b) for EP-7. (1)–(4) T_{2b} ; (5)–(8) T_{2c} ; ε (%): (1) and (5) original specimen; (2) and (6) 15; (3) and (7) 30; (4) and (8) 40.

immobile 'kinetic phase') as a function of the degree of deformation (ε) and temperature.

The differences between the kinetic properties of the fragments of the topological structure are induced by the differences between the numbers of degrees of freedom.¹⁸¹ From these standpoints, the more mobile protons (characterised by the values of T_{2b} and p_b) belong to the linear chains between the cross-links and defective fragments of the network — the trifunctional cross-links CL_3 and chain branches. The less mobile protons (characterised by T_{2c} and $p_c = 1 - p_b$) belong to the tetrafunctional cross-links CL_4 . The hierarchy of these fragments in order of decreasing mobility is as follows: linear chains between the cross-links and branches — CL_3 — CL_4 . Mainly the molecular mobility of the more mobile structural elements changes on hydroextrusion (Fig. 15). The decrease in T_{2b} in the case of $\varepsilon = 15\%$ compared with the control specimen may be a consequence of the occurrence of orientational processes. Some of the mobile fragments are converted into the less mobile 'kinetic phase', which is manifested by an increase in p_c at $T > 410$ K compared with p_c for the original material.

For $\varepsilon \geq 30\%$, an increase in T_{2b} and a decrease in p_c are observed. This is apparently associated with the predominance of disordering processes over orientational processes. However, the significant decrease in the 'nuclear' glass transition temperature indicates that the disordering processes are accompanied by the mechanodegradation of the network, in the first place of CL_3 and CL_4 cross-links. The results of thermomechanical studies agree well with NMR data.¹⁷⁸

The microstructure of the undeformed high-crosslinked network EP consists of globule-like formations made up of smaller elements. Hydroextrusion leads to characteristic changes in the morphology of the polymer. For $\varepsilon = 15\%$, the distinct boundaries separating the globules in the original material already vanish. A further increase in ε promotes the obliteration of the relief, which is observed on the etched surfaces of the specimens, bending, crushing, and twisting of the structural elements, and the formation of what resembles an 'eddy' structure.¹⁴

With increase in ε , the modulus of elasticity of the high-crosslinked network EP-7 ($v = 9 \times 10^{20} \text{ cm}^{-3}$) increases strongly in tensile tests and diminishes in compressive tests.¹⁷⁸ For individual specimens, deformed to the extent of 45%, the values of E obtained in extension exceed those for the control specimens by a factor greater than 2. The density varies nonmonotonically, reaching a maximum at $\varepsilon \approx 25\%$. The dependence of the strength parameters on ε , like the dependence on ρ , passes through an extremum (Fig. 16); on extension, σ_y and σ_t vary in parallel. In

Figure 16. Dependence of the yield point σ_y (1, 3) and the breaking (tensile) stress σ_t (2, 4) on the degree of deformation ε for EP-7. (1) and (2) extension; (3) and (4) compression.

Figure 17. Dependence of the microhardness H_μ on the degree of deformation for EP-7 (1) and EP-5 (2, 3). T_c (K): (1) and (2) 293; (3) 358.

compressive tests, σ_y and σ_t reach minimum and maximum values respectively at $\varepsilon = 25\%$. In both types of tests, ε_r increases and then decreases with increase in ε to 25%, while H_μ decreases monotonically for EP-7 as ε increases (Fig. 17).

The nonmonotonic variation of the $\rho(\varepsilon)$ relation for hydroextrusion is associated with the following factors. Deformation under a high hydrostatic pressure promotes the 'healing' of the micropores formed in the EP curing stage^{25,80} and the orientation of the polymer chains in the direction of the application of force leads under these conditions to the greater ordering of the structure compared with the original structure. All these features are responsible for the increase in ρ . At the same time, as ε increases, the material becomes loosened with formation of interfaces and microcavities and the intramolecular and intermolecular bonds are broken,^{25,182,183} which leads in its turn to the appearance of cracks and a decrease in ρ . The changes in ρ noted above are undoubtedly reflected in the level of the mechanical properties of the hydroextruded polymer. This is indicated by the variation of σ_t and ε_r which is identical with that of ρ in both types of tests. The healing of the microcavities, predetermining to a large extent the strength of the continuous medium, leads to an increase in σ_t and ε_r , while the increase in porosity for $\varepsilon > 25\%$ induces an appreciable decrease in these quantities.

At the same time, the results of mechanical tests cannot be accounted for solely by the change in ρ . As already mentioned, processes involving the orientation of the chains of the macromolecules and mechanodegradation develop in EP on hydroextrusion. The orientation is probably achieved *via* the rotation of the elementary network, leading to the arrangement parallel to the direction of extrusion of the individual sections of the chains between the cross-links. For low values of ε , orientation processes predominate. They are responsible for the appearance in the polymer of internal microstresses, influencing the nature of the subsequent deformation of the specimen in tensile and compressive tests. As a result of the operation of the microstresses, the Bauschinger effect is observed:¹⁸⁴ the preliminary plastic deformation, induced by the extension, decreases the resistance to plastic deformation on compression. The moulding process during hydroextrusion can be regarded to a first approximation as deformation by extension (especially for a small angle of the die cone).³¹ Therefore the decrease in σ_y , observed in compressive tests for specimens with $\varepsilon = 25\%$ compared with the original specimen, may be induced by the identity of the signs of the microstresses in the extrudates caused by the tension in the linear chains between the cross-links, and of the applied stresses. It is noteworthy that the changes established in the mechanical properties of the deformed high-crosslinked polymer network are similar

to the changes in the strain–strength properties of oriented crystallisable and amorphous polymers,¹⁷⁵ which indicates the similarity of the mechanisms of their deformation.

The study of the relaxation properties of the high-crosslinked network EP carried out on the original specimens and the extrudates has shown that, for $\varepsilon = 35\%$ and 45% , there is a sharp increase in molecular mobility induced by the loosening of the material and the partial mechanodegradation of the network.¹⁷⁸ The relaxation of the stress in the deformed polymer proceeds more vigorously than in the control specimen with increase in ε , the stress required for the maintenance of the specified deformation diminishes, the rate of relaxation increases, and the relaxation continues until the attainment of lower stresses. The fitting of the experimental relations with the aid of new relaxation memory functions¹⁷⁷ made it possible to establish that the stress relaxation process in the extruded high-crosslinked network EP is determined with equal probability by the kinetics of the interaction of the relaxators (microheterogeneities) and the kinetics of the diffusion of the nonrelaxators.¹⁷⁸ Compared with the original material, the number of microheterogeneities in the extrudates diminishes.

In order to increase the probability of breaks in the network, experiments have been carried out⁷¹ on the hydroextrusion of an incompletely cured EP-1 epoxide composition. The curing of the specimens was completed after hydroextrusion. It was established that the elastic and strength properties depend only slightly on the degree of the preliminary deformation of the specimens. If the curing processes are not taken to completion, it is possible to detect at $\varepsilon = 50\%$ an increase in E by an order of magnitude compared with the undeformed specimens. Such an increase is induced by the orientation of the EP macrochain along the deformation axis. Probably a state with a high level of elastic and strength characteristics may be achieved for EP under appropriate experimental conditions when the time required for the completion of the curing of the extrudates is significantly shorter than the relaxation time of the oriented structure.

A study of the behaviour of the extruded EP having an open network ($v = 4 \times 10^{20} \text{ cm}^{-3}$) showed¹⁷⁹ that the nature of the dependences for σ_y and ε_r on ε in these materials is the same as for the high-crosslinked network EP. The difference consists only in the absolute values of σ_y and ε_r as well as the values of ε for which a change in the type of variation of σ_y and ε_r is observed; in the open network polymer (EP-5), the increase in σ_y and the fall of ε_r begin for higher values of ε . On the other hand, the dependences of E , σ_y and ρ on ε are qualitatively different. They increase over the entire range of ε . The microstructures of the original EP-5 specimens consist of globule-like formations of different dimensions. Deformation by hydroextrusion homogenises the microstructure and renders it finely disperse. On the other hand, an eddy structure is not formed up to $\varepsilon = 45\%$.

The observed differences between the changes in the microstructure, ρ , and the mechanical properties of the EP compared are associated with the different network densities and mobilities of the linear chains between the cross-links. In the more rigid polymer (EP-7), the plastic deformation processes accompanied by the rupture of the network of chemical bonds begin sooner and proceed more vigorously. In the case of EP with an open network (EP-5), they are scarcely manifested (for the range of ε investigated) in the behaviour of the integral macroscopic characteristics (ρ , E , σ_y , σ_t , ε_r). On the other hand, the use of a local method such as the procedure involving the measurement of microhardness made it possible to follow the evolution of network disruption processes even for low values of ε .¹⁷⁹ Fig. 17 (curve 2) illustrates the variation of H_μ in the extrusion of EP-5 in the glassy state. The nonmonotonic variation of H_μ with increase in ε indicates competition between the orientational strengthening and disordering processes caused by the loosening of the network. In the case of EP-7, in which the degradation phenomena develop sooner, such a maximum in H_μ is probably displaced towards $\varepsilon < 15\%$, and for this reason one observes on the experimental curve only its right-

hand (descending) branch (curve 1). It is logical to suppose that, in creating more favourable conditions for the orientation of the internodal fragments in EP, the maximum under consideration should be observed for larger values of ε . The $H_\mu(\varepsilon)$ relation, presented in Fig. 17 (curve 3), confirms this hypothesis. It was obtained for the EP-5 polymer deformed in the rubbery (non-equilibrium) state with subsequent ‘freezing’ of this state. Under conditions where the mobility of the linear chains between the cross-links increases significantly compared with the mobility of such chains in glassy polymers and the values of ε for which the disruption of the network is possible increase, this is reflected by the displacement of the maximum in the $H_\mu(\varepsilon)$ relation towards higher values of ε .

The behaviour in hydroextrusion of polymers of the IPN type with components differing appreciably in their rigidity is unusual. The results of studies^{179, 180} carried out on the polyurethane–polyesteracrylate (PU–PEA) system suggest that mainly the elastic component (PU) undergoes orientational strengthening. The strengthening effect is achieved because the rigid network (PEA) prevents the relaxation of the stressed PU chains, creating constraints in the form of macromolecular entanglements. At a low PEA concentration, the deformation-induced strengthening, caused by hydroextrusion, is insignificant, because the density of such entanglements is low and the elastic component relaxes readily. With increase in the PEA concentration, the degree of orientational strengthening increases, but mechanodegradation processes begin to be manifested already for a PEA content of 30%. Both elastic and rigid chains are probably disrupted. The latter follows from the fact that, for PU:PEA $\geq 50:50$, the possibility of the deformation of the IPN is reduced sharply.

The proposed explanation is supported by the following features. When the PU:PEA ratio changes from 90:10 to 70:30, the system undergoes phase separation.¹⁸⁵ This makes it possible to consider separately the evolution of the rigid and elastic networks during orientational stretching. It is known that in the solid-state extrusion of materials incorporating plastic and brittle (stronger) components with the former predominating, the weaker and more plastic component undergoes strengthening.¹⁸⁶ Under these conditions the brittle phase may be disrupted with increase in ε . The role of such phases in the PU–PEA composition is assumed by the PU and PEA networks respectively.

The characteristic features of the thermal shrinkage of network polymers have been investigated^{179, 180} in relation to EP and the PU–PEA system. It was established that the recovery of the original dimensions of the extruded EP when they are heated in a free state begins near the glass transition temperature ($T < T_g$) and terminates at $T \simeq T_g$ with attainment of the 100% effect. With increase in ε , the temperature of the onset of shrinkage diminishes. In contrast to linear amorphous and crystallisable polymers, network polymers have a narrower shrinkage temperature range and are characterised by the ability to retain the restored form at temperatures significantly exceeding T_g . The latter is known to be due to the presence of a network of chemical cross-links preventing the transition to the viscous flow state. The temperature of the onset of shrinkage is correlated with T_g (Fig. 18).

When extruded specimens with fixed ends are heated, the shrinkage stresses originally increase and then fall, this being accompanied by the disruption of the specimens in the vicinity of the clamps (Fig. 19). The maximum shrinkage stresses increase with increase in ε and v . The latter fact reflects the $\sigma_{m,sh}(T_g)$ relation (Fig. 18), since v and T_g vary in parallel in the case under consideration.¹⁸⁰ It is remarkable that the values of $\sigma_{m,sh}$ are approximately the same as for oriented block specimens of amorphous-crystalline polymers.

The characteristic features of the variation of the size of the oriented PU–PEA specimens during heating are on the whole similar to those established for EP: the shrinkage temperature range is comparatively narrow, the recovery of the original dimensions reaches 100%, and $T_{o,sh}$ diminishes with increase in ε . The temperature range in which the characteristic $\sigma_{sh}(T)$

Figure 18. Dependence of the temperature of the onset of shrinkage $T_{o.sh}$ (1) and of the maximum shrinkage stresses $\sigma_{m.sh}$ (2) on the glass transition temperature T_g for EP-1.

relations for the IPN investigated have an extremum (Fig. 20) indicates the dominant role of the elastic component, while the decrease in the half-width of the $\sigma_{sh}(T)$ maximum with increase in ϵ indicates an increase in the contribution of destructive processes (the specimens are disrupted earlier for the material with a defective structure in measurements of σ_{sh}) under these conditions. The fact that $\sigma_{m.sh}$ varies nonmonotonically (the relation has a maximum) with increase in ϵ is also striking. Such variation of σ_{sh} may be caused by the loosening of the network and hence by the partial relaxation of the stresses in the extrudate. The breaks on the right-hand branch of the $\sigma_{sh}(T)$ maximum for the

Figure 20. Temperature dependence of the shrinkage stresses for the PU-PEA IPN system containing 30 mass% of PEA, ϵ (%): (1) 25; (2) 30; (3) 40; $T_c = 358$ K.

PU-PEA system, preceding the disruption of the specimens, may be associated with the contribution of the rigid component.

The 'driving forces' of the thermal shrinkage of network and linear amorphous polymers^{187, 188} are apparently the same. The difference consists in the fact that in the case of network polymers the twisting process involves not molecular chains but internodal fragments oriented along the deformation axis during extrusion. Evidently, depending on the nature of the molecular mass distribution, the nature of the thermal shrinkage spectrum, especially its width, should also vary in these materials. For IPN with a high degree of segregation of the components, the stress relaxation processes in different networks are separated by a temperature range. This makes it possible to identify them on the basis of the $\sigma_{sh}(T)$ relation (Fig. 20): by varying the composition and ratio of the components, it is possible to control the form of the relation, obtaining different versions of the shrinkage spectrum.

For amorphous polymers (in contrast to crystallisable ones), the version of solid-state extrusion involving the use of a powder billet has not so far come to be widely employed. Nevertheless, individual investigations indicate that this processing procedure is promising for the establishment of an oriented structure. The extrusion process and the properties of extruded DF-10 (an aromatic polyester), consisting of a composition based on a polyarylate and a copolsulfoneformal, have been investigated.¹⁸⁹ The results of these studies have shown that the optimum process is achieved if the extrusion temperature is 0.95–0.98 of the temperature corresponding to the transition of the polymer to the viscous flow state and $\lambda \approx 6$ –7. Table 10 presents the strain–strength characteristics of DF-10 in tests involving compression and three-point bending (nicked specimens). Evidently, with increase in λ , the modulus of elasticity changes only slightly, whereas σ_y and σ_t increase appreciably. At the same time the plasticity of the material increases. These features are correlated with those established earlier for hydroextruded amorphous polymers.^{172–175}

Table 10. The properties of DF-10 specimens obtained by the plunger extrusion of a powder billet.

3. Polymer blends and reinforced compositions

Polymer systems consisting of polymer blends and reinforced compositions have been vigorously investigated in recent years. One of the reasons for the increased interest of investigators in these materials is their great potential possibilities as regards regulation of mechanical properties. However, there have been extremely few studies on the solid-state extrusion of polymer blends and reinforced compositions. The possibility of obtaining oriented block specimens of the LDPE-PP system by the hydrostatic extrusion method has been examined.¹⁹⁰ Uniaxial solid-state extrusion of such compositions is difficult owing to the weak interfacial interaction of the components caused by their thermodynamic incompatibility. In order to eliminate this obstacle, various procedures are resorted to, for example, radiation-induced or photochemical cross-linking.^{191, 192} Deformation under the conditions of a high hydrostatic pressure made it

possible to abandon these procedures and to achieve higher values of λ without disruption of the material.¹⁹⁰

The change in the mechanical properties of polymer blend specimens on compression and extrusion as a function of λ corresponds to the change in these properties established for extruded PE and PP specimens.^{135, 175} The thermal shrinkage characteristics of the blends have a number of unusual features. An increase in the content of PP increases the shape stability of the extrudates (the residual deformation). At the same time there is an increase in the values of σ_{sh} and in the width of the shrinkage temperature range (Fig. 21). For all the PP concentrations, the increase in λ entails also an increase in $\sigma_{m,sh}$.

Figure 21. Temperature dependences of the shrinkage stresses σ_{sh} for the LDPE–PP blends. LDPE content (mass%): (1) 90; (2) 80; (3) 40; $\lambda = 3$

Analysis of the results of the study of Beloshenko *et al.*¹⁹⁰ established that the thermal shrinkage mechanisms in the LDPE–PP compositions and in LDPE are similar. At low PP concentrations, the stressed LDPE chains play the main role in the shrinkage process. With increase in the content of PP, the contribution of this phase to the establishment of the thermal shrinkage effect increases, which is manifested by the increase in $\sigma_{m,sh}$ and in the shape stability of the extrudates. The PP phase hinders the relaxation processes in the material: the temperatures at which the internal stresses are fully relaxed are displaced towards the region of higher T_m for the polyethylene phase. However, owing to the occurrence of phase separation, the observed changes are relatively small. The $\sigma_{sh}(T)$ relations for the blends in the region of the descending branch of the maximum differ from the relations established¹⁹¹ for crosslinked compositions: at $T < T_m$ for polypropylene, the right-hand branch of the maximum passes to a plateau. This fact can be explained by the formation during cross-linking of a network of chemical cross-links intensifying the interfacial interaction. In the hydroextrusion of noncrosslinked compositions, one is dealing merely with the appearance of additional physical cross-links, the network of which is unstable during annealing, and also with a decrease in the stresses at the interfaces compared with the stresses in the course of uniaxial extrusion as a result of the favourable deformation scheme. Nevertheless the result obtained is of definite practical interest, since the expansion of the range of σ_{sh} increases the functional possibilities of the material.

The behaviour of amorphous and crystalline films specimens of the polyether-ether-ketone–polyester-imide (PEEK–PEI) system subjected to uniaxial extrusion by the coextrusion method has been studied.¹¹⁶ The latter was achieved at temperatures below T_g (amorphous films) or below and above the crystallisation temperature (crystallisable films). The influence of extrusion on T_g , crystallisation and the degree of orientation was noted. In the case of amorphous films of the PEEK–PEI system, extrusion lowers the glass transition temperature of the polymer blend, although the density of the specimens increases somewhat under

these conditions. The degree of orientation of these films increases with increase in the PEEK concentration. In the crystallisable films, the density diminishes monotonically with increase in λ and extrusion intensifies the crystallisation process during the subsequent annealing of the films.

The traditional method for the preparation of reinforced polymer compositions is mechanical blending of the components. In the 1970s, a fundamentally new method for the introduction of fillers was proposed — the polymerisation filling method, which makes it possible to obtain polymer compositions directly in the course of the synthesis of the polymer.^{193, 194} One of the promising aspects of the polymerisation filling method involves the creation of compositions based on SHMPE. Such materials have strain–strength parameters similar to those of SHMPE, but are harder, have a higher modulus of elasticity, and are more resistant to wear.¹⁹⁵ At the same time they are greatly superior to activation-reinforced compositions as regards deformability and impact strength.¹⁹⁵ The characteristic features of the solid-state extrusion process and the mechanical properties of extrudates of reinforced compositions based on SHMPE have been investigated.^{161, 167, 196–200} The extrusion was carried out with the aid of the method proposed in a patent,¹⁵⁹ using polymer powder billets.

The extrusion parameters and the properties of the extrudates for a series of compositions investigated, measured in compressive tests, are presented in Table 8. The variation of E , σ_t , and ε_r for the SHMPE–kaolin system is analogous to that observed for SHMPE with the sole difference that the introduction of kaolin increases the limiting value of λ , the rigidity, and the strength, but reduces the deformability of the material. For other compositions, dependences of E and σ_t on λ with an extremum are observed, the values of λ corresponding to the maxima in the characteristics diminishing in the sequence kaolin $\rightarrow$ Al $\rightarrow$ Al(OH)₃. The last composition has the lowest level of strain–strength properties.

Comparison of the properties of the extruded compositions with those of control specimens obtained by hot pressing revealed an increase in rigidity and strength during solid-state extrusion for all the compositions investigated. The deformability diminishes at the same time. This feature is manifested even more strikingly in tensile tests.¹⁹⁶ Appreciable changes in ρ during the variation of λ have not been observed for the SHMPE–kaolin systems. For other compositions, ρ diminishes with increase in λ .

The extrusion draw ratio is known²⁰¹ not to reflect the real deformation of the macromolecules (λ'_m) in oriented polymers. For reinforced compositions, the discrepancy between λ and λ'_m is greater than for unreinforced ones, because the former quantity is calculated in relation to the entire volume of the polymer, whereas only part of it (the polymer matrix) is actually deformed. In order to eliminate this, a corrected molecular draw ratio has been introduced:¹⁶⁷

$$\lambda'_m = \frac{\lambda_m}{1 - \varphi},$$

where φ is the volume degree of filling. The inequality $\lambda'_m < \lambda$ holds for SHMPE and $\lambda'_m > \lambda$ is valid for reinforced compositions. This relation between the parameters considered reflects the differences in the mechanisms of the deformation of SHMPE and the compositions based on it. For higher values of λ , the polymer macromolecules are disrupted at the polymer–filler boundary, which lowers the effective density of the network of macromolecular entanglements. This tends to increase λ'_m and has a positive effect on E . However, owing to the loosening of the interfaces, the fraction of free cavities increases with increase in λ , which leads to a decrease in E . For $\lambda > 5$, the second effect predominates and this induces a decrease in E for the reinforced compositions (Table 8).

The above conclusion has been confirmed by measurements of ρ and by the results of a study of the rupture surfaces of the extrudates.¹⁹⁸ For low values of λ , the surface relief of the break is homogeneous, which indicates a satisfactory adhesion between

SHMPE and the filler. In the case where $\lambda \geq 7$, the inhomogeneity of the relief, induced by the loss of adhesion at the polymer–filler boundary and hence by the rupture of the material at this boundary, can be easily seen.

For the majority of the compositions investigated, σ_r varies with λ in parallel with E and reaches the maximum values in the region $\lambda = 4–6$ (Table 8). Fig. 22 presents the dependences of the limiting extrusion draw ratio corresponding to the rupture of the specimen in mechanical tests (λ_r) as a function of the extrusion draw ratio. The values of λ_r were determined from the formula²⁰²

$$\lambda_r = 1 + \varepsilon_r.$$

Evidently λ_r increases with increase in λ (for oriented polymers, an increase in λ diminishes λ_r as a consequence of the exhaustion of the mobility of the molecular chains).³¹ On the basis of the above findings, one can also postulate that the rupture of the extruded compositions is related directly to the presence of fillers, namely to the breakdown of the continuity of the specimens owing to the loosening of the polymer–filler boundaries and the formation of numerous microcracks. On deformation of the specimen in the course of mechanical tests, the microcracks formed during extrusion aggregate and the specimen is ruptured.

Figure 22. Dependence of the limiting draw ratio λ_r on the draw ratio λ for the SHMPE–70 mass% Al (1) and SHMPE–45 mass% of bauxite (2) systems.

The difference between the strain–strength properties of the SHMPE–kaolin compositions and the analogous properties of other compositions is caused primarily by the shape of the filler particles. The kaolin particles have the shape of plates, while the Al and $\text{Al}(\text{OH})_3$ particles are spherical. The presence of particles anisotropic as regards shape promotes the appearance of an intense interfacial interaction, manifested in the partially cohesive mechanism of the destruction of the SHMPE–kaolin compositions.²⁰³ At the same time, owing to the weak interaction at the polymer–filler interface, the fully adhesive rupture mechanism operates for the SHMPE– $\text{Al}(\text{OH})_3$ system.

A mathematical model has been proposed for the solid-state extrusion of polymer composites.²⁰⁴ It is based on the idea that the formation and ‘healing’ of microcavities are possible on deformation under conditions of high pressure. Relations have been obtained which make it possible to calculate the density of the extrudate and to plot it against λ . Comparison of the calculated and experimental values of ρ showed that the model describes adequately the plunger extrusion of a powder billet comprising polymerisation-reinforced compositions. At the same time, it can be used to predict the defectiveness of polymeric materials also in other processing schemes involving high pressures.

V. Conclusion

The data presented show that a high pressure is frequently used in theoretical and technological research and that its role in the structure modification of polymers is considerable and varied.

The methods involving treatment with pressure examined in the review may be used for the effective control of shaping processes and of the structure and properties of polymeric materials with different structures. However, the functional possibilities of the different ways of achieving the modifying effect of pressure are not the same. Thus crystallisation or curing under pressure make it possible to obtain objects in the form of a block, as a rule cylindrical in shape, which limits the range of their practical applications. On the other hand, the substances formed in series-connected IPN (preparation of a prepolymer) or in oligomeric products serve as starting components for more complex compounds. The latter are manufactured under traditional conditions, which tends to expand their applications. For example, the IPN can be used as adhesives and also for the preparation of bulky polymeric articles of different shape and for different purposes. Finished articles, which do not require further mechanical treatment, can be usefully subjected to annealing under pressure, because favourable changes in the material take place to the greatest extent in its surface layer.

The results of the study of solid-state extrusion indicate the considerable potential possibilities of this method in the processing of not only flexible-chain polymers but also of rigid-chain network polymers, polymer blends, and reinforced compositions. As a result of the plasticising effect under the influence of high hydrostatic pressure, it is possible to achieve an orientational order in polymers and polymer composites which are brittle and difficult to work. The appearance of such order is accompanied by an improvement in the strain–strength properties of the materials or by the establishment in the latter of a qualitatively new state (the shape memory effect, a negative Poisson ratio).

One may hope that further studies of the application of the isostatic treatment or solid-state extrusion for the structural modification of polymers will help in discovering new aspects of the influence of high pressure which are of interest from both theoretical and practical points of view.

VI. Conclusion	996

Abstract. The synthesis and structure–activity relationships of inhibitors of steroid aromatase which catalyses the last stage of a multistep biotransformation of cholesterol into estrogens, *viz.*, aromatisation of C₁₉-steroids into C₁₈-phenolic steroids, are discussed. Compounds of the androstane series which are structurally related to the natural substrate, *viz.*, androst-4-ene-3,17-dione, are the subjects of consideration. The review encompasses problems of synthesis of various substituted androstanes and their aromatase-inhibiting activities and structural requirements for selective specific aromatase inhibitors based on *in vitro* and *in vivo* structure–activity studies of compounds synthesised, their biological properties and the results of clinical trials. Special attention is paid to practical applications of aromatase inhibitors in the treatment of hormone-dependent mammary and ovarian tumours as well as benign prostatic tumours. In writing this report, the author has used all the information currently available in the chemical, biochemical, endocrinological and medicinal literature as well as in patents. The bibliography includes 173 references.

I. Introduction

The search for selective and specific therapeutic steroid agents in the past few decades has given the main impetus to the development of synthesis of modified steroids. It is commonly known that many physiological processes occurring in the organism are controlled by a relatively small set of steroid hormones produced upon cholesterol biosynthesis. These compounds represent small hydrophobic molecules which penetrate easily through membranes and interact with their specific receptors thus regulating gene transcription. One most important factor that stimulated studies of steroids was the discovery that analogues of some endogenous hormones can be used for controlling the synthesis and modifications of steroids involved in proliferation of malignant tumours.

In many clinical situations, estrogens produced in normal or excess quantities play a prominent role in the pathogenesis of various diseases. Therefore, suppression of estrogen biosynthesis

is one of the ways to achieve progress in the treatment of such diseases as mammary and ovarian tumours, endometriosis, *etc.*^{1–4} The main efforts in the design of therapeutic preparations of the androstane series which are aromatase (estrogen synthase) inhibitors in their pharmacological effect have been directed at the synthesis of drugs against hormone-dependent mammary tumours. This approach has indisputable advantages over cytotoxic therapy which often causes serious complications.^{3,5}

At present, mammary tumours represent the most widespread type of malignant neoplasms and are the second major cause of mortality in women. In the USA alone, casuality of this disease amounts to about 130 000 annually.⁶ About a half of these malignant tumours require a source of estrogens for their growth and development. The present-day endocrine therapy relies upon the use of either antiestrogens which act on tumour cells directly, *via* their specific receptors, or high doses of progestins the mechanism of action of which has not been finally established. An alternative strategy consists in the application of aromatase inhibitors (AI) which suppress production of estrogens in the organism.

Aromatase represents an enzyme complex made up of two major components: a flavoprotein (NADPH-cytochrome P-450 reductase) which transfers electrons from NADPH to the terminal enzyme and a specific form of cytochrome P-450 commonly known as aromatase cytochrome P-450. This protein is involved in the binding of the C(19) atom of the steroid substrate and catalyses the multistep reaction resulting in the aromatisation of the ring A of the steroid.^{7–9} The conversion of Δ^4 -3-ketoandrogens into phenolic estrogens is the ultimate stage in the multi-enzyme transformation of cholesterol into female sex hormones. Although the details of this mechanism are still questionable, it is believed^{10,11} that aromatase performs three successive steps of the androgen oxidation. The first two steps yield 19-hydroxy- and 19-oxo-androgens. However, the site of incorporation of the third hydroxy group is not established. Presumably, hydroxylation occurs at C(2),¹² which results in aromatisation of the ring A of androst-4-ene-3,17-dione (AD). The loss of the angular C(19)-methyl group and *cis*-elimination of the hydrogen atoms from positions 1 and 2 give estrone and formic acid.^{3,12–19}

Received 3 October 1997

Uspekhi Khimii 67 (11) 1068–1093 (1998); translated by R L Birnova

The enzymic oxidation described above yields an enzyme-bound derivative, which in turn gives the aromatic steroid by virtue of rapid elimination and simultaneous recovery of the unchanged, active enzyme. It is obvious that various structural modifications of the natural substrate (AD) can alter this elimination in such a way that the steroid intermediate will remain covalently bound with the enzyme rather than undergo conversion into the aromatic steroid. Elucidation of the mechanism of androgen aromatisation and demonstration of its possible inhibition has led to successful design and development of a broad range of AI.

Since aromatisation is a unique reaction of steroid biosynthesis and estrogens are its final products, *in vivo* inhibition of aromatase does not affect other essential enzymes involved in this process. This is an important advantage of AI over other inhibitors recommended for therapeutic use (see Refs 4, 20).

Studies of the mechanism of aromatisation of the natural substrate (AD) have specified the type of its structural modification required for the design of AI. It consists in the introduction of substituents into the ring A or at adjacent positions with simultaneous preservation, in the majority of cases, of polar functional groups at C(3) and C(17). The sites for substitution have been identified as C(1), C(4), C(6), C(7), and C(19). The nature of the substituents varies widely depending on the substitution site.

Syntheses of AI often pose serious problems and are as such a considerable progress in both the design of synthetic approaches and their practical implementation. In each particular case, the synthesis of steroid AI employs original approaches which are based on modern methods of synthetic organic chemistry or a combination of several methods. Syntheses of structures with 2,19-bridges or a series of androsta-4,9(11)-diene-3,17-diones carrying a sulfur-containing group at C(10) (Section III.1) provide illustrative examples. Stereochemical aspects of the reactions are very important; modern physicochemical methods are employed for establishing the structure and stereochemistry of the reaction products.

From the standpoint of their chemical structure, AI can be classified according to the site of substitution in the AD molecule. It is this principle that is used in the description of AI syntheses in Section III of the present review. However, it should be remembered that classification of AI according to the mechanism of their action may be different. In this review, this classification was used to analyse the relationships between the structure of AI and their inhibitory activity.

The reviews on steroid AI that cover simultaneously the problems of their synthesis, relationships between their structures and biological properties and pharmacological data are virtually absent. One can mention the book by Zeelen 'Medicinal Chemistry of Steroids',²⁰ which includes the analysis of steroid and nonsteroid AI, as well as the surveys^{9,15,21} devoted predominantly to the mechanisms of action of AI and their inhibitory activity *in vitro*.

The present review describes the methods for the synthesis of substituted androstanes active as aromatase inhibitors, the relationships between the structure of AI and the extent of their binding with the enzyme as a criterion for directed search for selective AI, as well as biological properties and practical applications of the most potent steroid preparations currently available.

II. Classification of steroid aromatase inhibitors and methods for assessment of their activities *in vitro* and *in vivo*

Steroid AI have come under the scrutiny of science with the publication of the pioneering work by Brodie *et al.*²² in 1973. In the subsequent two decades, a vast variety of steroid compounds have been synthesised and assayed for AI activity.

In vitro inhibition of human placenta aromatase is the most common procedure used in the study of modified androgens.²³ This method is used primarily for testing steroids as candidates for AI. The inhibition is evaluated by several parameters. The most important of them are the inhibition constant, K_i , which is determined in experiments where both AI and a steroid substrate (AD) are introduced, and the concentration of AI that results in 50% inhibition (IC_{50}). The analysis of inhibition kinetics, which allows determination of the type of inhibitory activity for the given steroid compound, is also important.

The following methods are used for *in vivo* studies of AI: (1) inhibition of ovarian estrogen secretion; (2) inhibition of peripheral (extraovarian) aromatisation which is the main source of estrogens in post-menopausal women; (3) evaluation of the antitumour effect of AI in an experimental model of a 7,12-dimethylbenzo[*a*]anthracene (DMBA)-induced mammary tumour.

According to the mechanism of their action, AI are classified into reversible and irreversible ones. Compounds which, like usual androgenic substrates, reversibly bind with the active centre of aromatase to form a complex that does not undergo rapid dissociation can serve as rather efficient AI. Competitive aromatase inhibitors that are capable of binding with iron of the cytochrome P-450 heme (*e.g.*, due to the presence of a hetero atom with a specific stereochemical environment in their molecule) can sometimes manifest inhibitory activities both *in vitro* and *in vivo*. A great number of steroid AI are irreversible. Irreversible inhibition of the enzyme implies the conversion of a steroid substrate into an active complex which can irreversibly bind with the enzyme. These compounds are also referred to as 'suicide inhibitors'.^{9,24–26} The latter have a number of salient advantages over competitive reversible AI owing to their high specificity and the ability for irreversible inhibition. Thus, irreversible AI produce long-term inactivation of aromatase *in vivo*.

III. Methods for the synthesis of aromatase inhibitors of the androstane series and their activities

1. 19-Substituted androstanes

19-Substituted androstanes are the most numerous and diverse aromatase inhibitors. It is quite natural because many investigators consider the angular 19-methyl group to be the site of the primary enzyme attack leading to aromatisation.

Formally, the functionalisation of the 19-methyl group of the steroid molecule is a very difficult task. This class of steroids are synthesised mostly from compounds having a 5(10) double bond or from 19-hydroxy(oxo)androstanes using diverse methods of synthetic organic chemistry for their further transformations, such as epoxidation followed by oxirane ring opening with appropriate reagents; substitution of 19-mesyl(tosyl)oxy- and 19-halogeno-derivatives; fluorination; the Wittig, Corey, and Mitsunobu ethynylations, and other sophisticated approaches. All the known methods for the synthesis of 19-substituted androstanes are discussed below in detail.

10 β -Propynyl-steroids (19-ethynylandrostanes) synthesised in the 80's simultaneously and independently in several laboratories^{14,27–31} pertain to irreversible suicide inhibitors. Some 19-ethynyl-steroids of the androstane series have been described in patents.^{32–35}

19-Ethynylandrost-4-ene-3,17-dione **1** was obtained from commercially available estr-5(10)-ene-3,17-dione **2**. Diketal **3** formed upon protection of the carbonyl groups reacted with *N*-bromosuccinimide to give the bromohydrin **4** which was easily converted into the 5 α ,10 α -epoxide **5**. Epoxide opening with an alkynylcuprate reagent gave the 5 α ,10 β -disubstituted derivative **6** in 60% yield. Deprotection and elimination of the hydroxy group from position 5 of the 3,17-diketone **7** yielded the target androstane **1** in 23% yield starting from the oxirane **5**.¹⁴

(a) HO(CH₂)₂OH, H⁺, PhH; (b) *N*-bromosuccinimide (NBS), DMF; (c) NaOMe, MeOH; (d) [Me₃SiC $\equiv$ CCH₂]₂CuLi, Et₂O; (e) H⁺, Me₂CO.

Structurally related diastereomeric 19-ethynyl-19-hydroxy derivatives **10a,b** were obtained from the bisketal-aldehyde **8**. The latter reacted with ethynylmagnesium bromide to give a chromatographically separable mixture of (19*S*)-**9a** and (19*R*)-**9b** derivatives in a 3 : 2 ratio (> 90% yield). The authors²⁷ ascribed the (19*S*)-configuration to the main product by analogy with the stereoselectivity of the reaction of the diketal-aldehyde **8** with methyl lithium. After removal of the ketal protection, the diketones **10a,b** were obtained in the individual state and further oxidised into the triketone **11**²⁷ (Scheme 1).

The acetate **12** prepared from 19-ethynyl-19-hydroxy-steroids **9a,b** served as the starting compound in the synthesis of an analogous allenic AI (**14**)²⁹ based on cuprate-initiated reductive elimination of acetic acid. The allene **13** was converted into the final product **14** after deprotection (see Scheme 1).

Yoshida *et al.*²⁹ have also developed an original procedure for the synthesis of 19-ethynyl-AD **1** using 6 β -hydroxystrenedione bisketal **15** as the starting compound. The vinyl ether **16** obtained

Scheme 1

(a) HC $\equiv$ CMgBr, Δ , THF, 2 h, 94%; (b) 10% H₂SO₄, Me₂CO; (c) CrO₃, H₂SO₄; (d) Ac₂O, Py; (e) MeLi, CuI, Et₂O, -78 °C, 50%; (f) *p*-TsOH, Me₂CO, 70%.

from it was subjected to the Claisen rearrangement (66% yield). The Wittig reaction of the aldehyde **17** with chloromethylene-phosphorane gave a mixture of *cis*- and *trans*-vinyl chlorides **18**, which were dehydrochlorinated with lithium diisopropylamide at

(a) H₂C=CHOEt, Hg(OAc)₂, 78%; (b) collidine, 165 °C, 4 h, 66%; (c) ClCH=PPH₃, 84%; (d) lithium diisopropylamide (LDA), -70 °C, 1 h, 95%.

–70 °C to yield the ethynyl derivative **19** in 95% yield. Removal of the ketal protection gave the final product, *viz.*, 19-ethynyl-AD **1**, in high yield.

The steroid **1** and its derivatives have been extensively assayed as AI. It was found that 19-ethynyl-AD **1** and its 19-hydroxy- (**10a,b**) and 19-oxo-derivatives (**11**) are irreversible suicide inhibitors of aromatase and manifest high specificity^{14, 15, 26, 28, 29, 31, 36} (the data on their inhibitory activities are summarised in Table 1). The steroid **1** possessed high activity on oral administration with respect to the inhibition of ovarian aromatase. It is noteworthy that 19-ethynyl-17-propionyloxyandrost-4-ene-3-one manifests only *in vivo* inhibitory activity.³⁷ The allenic derivative AD **14** also pertains to irreversible AI and has rather high K_i value.²⁹

Several 19-halogeno-substituted androstanes **22** were obtained from the bisketal **21** by substitution of 19-methanesulfonates, which is well known in the series of Δ^5 -3-acetoxysteroids; 19-mesyloxy diketone **20** being used as the starting compound.³⁸

X = Cl (**a**), Br (**b**), I (**c**), CN (**d**), N₃ (**e**), SMe (**f**).

19-Difluoroandrostane **25** was obtained by selective fluorination of 17-benzoyloxy-3-oxoestr-4-en-19-al (**23**) with an excess of diethylaminosulfur trifluoride in a mixture of dichloromethane and trichlorofluoromethane. Removal of the benzoyl protection and oxidation of the resulting alcohol gave 19-difluoro-AD (**25**) which manifested moderate inhibitory activity^{39, 40} (see Table 1).

(a) excess Et₂NSF₃ (DAST), CH₂Cl₂–CCl₃ (1 : 1), 20 °C, 48 h;
(b) OH[–]; (c) CrO₃, H₂SO₄.

The synthesis of androstanes with functional groups at position 19 containing sulfur or nitrogen exploited the ability of 19-iodo derivatives **26a,b** for nucleophilic substitution without homoallylic rearrangement.⁴¹ This approach was used to obtain a series of 19-substituted androstanes **27a,b** and **22d–f**. It is appropriate to mention in this connection the synthesis of 19-azido-AD **22e** described in a patent.⁴² Compound **22e** was obtained by esterification of 19-hydroxy-AD **28** with trifluoroacetic anhydride with subsequent treatment of the ester **29** with sodium azide in DMF.

R¹ = OAc, R² = H (**a**); R¹, R² = O(CH₂)₂O (**b**);
X = CN, N₃, SSO₂Me;
(a) NaCN (X = CN); NaN₃, HMPA (X = N₃); NH₄SSO₂Me (X = SSO₂Me); (b) KOH, MeOH; (c) CrO₃, H₂SO₄; (d) Al(OPrⁱ)₃, cyclohexanone (CHex) (**27a**, X = CN, N₃); (e) (COOH)₂, EtOH (**27b**, X = CN, N₃); (f) LAH, THF; (g) MeI; (h) K₂CO₃; (i) Al(OPrⁱ)₃, CHex (**27a**, X = SSO₂Me); (j) (CF₃CO)₂O, Py; (k) NaN₃, DMF.

19-Substituted AD **22d–f** competitively inhibit aromatase.^{38, 42} Of special interest is the 19-methylthio derivative **22f** which is the first highly efficient AI (K_i = 1 nM); its inhibitory effect is determined not only by its interaction with the steroid-binding site of aromatase but also by coordination of the steroid sulfur atom with the heme iron of cytochrome P-450.⁴¹

The attention of several research groups was focussed on 10 β - and 19-sulfur-containing AD derivatives as aromatase inhibitors. Compounds with the sulfur atom linked directly with C(10) or separated from the C(10) atom by one or several methylene groups have been synthesised and assayed. Thus the introduction of the SH group at position 10 of estr-4-ene-3,17-dione resulted in an efficient suicide AI **32**. The opening of the 5 α ,10 α -epoxide ring of estrane **5** with potassium sulfide in ethylene glycol in the presence of 18-crown-6 gave 5 α ,10 β -disubstituted estrane **30** in 70% yield. The latter was converted in two steps into 10 β -mercaptoestr-4-ene-3,17-dione (**32**) via 5 α -hydroxy diketone **31**. The yield of the final product was 10% with respect to estr-5(10)-ene-3,17-dione **2**.¹⁴ The corresponding 17 β -hydroxy derivative possessing aromatase-inhibiting activity was synthesised by Bednarski and Nelson¹⁴ following an analogous scheme.⁴³ *In vitro* studies of the biological activity of the thiol **32** revealed that the free thiol group is required for the binding to the enzyme, because the corresponding acetylthio derivative was inactive.^{19, 43}

^a Symbols + and — denote the presence and absence of the double bond in this position, respectively.

(a) KSH, HO(CH₂)₂OH, 18-crown-6, 70%; (b) H⁺, Me₂CO, 78%;
(c) NaOH, MeOH, 32%.

The homologous 19-mercapto-AD **35** was obtained by the reaction of the 19-triflate **33** with potassium ethyl xanthate in the presence of 18-crown-6 with subsequent cleavage of the thio derivative **34**.⁴³

(a) (CF₃SO₂)₂O, Py; (b) EtOCSK, 18-crown-6, THF, 20 °C, 20 h;
(c) H₂N(CH₂)₂NH₂, THF.

The inhibition constant of the steroid **35** is 34 nM.⁴³ It represents an irreversible AI; its activity is 16 times as high as that of formestane both *in vitro* and *in vivo* (see Section II). However, the thiol **35** has a limited use because of its insufficient pharmacological stability due to the presence of a free thiol group. To overcome this limitation, its ethylthio derivative, *viz.*, 19-ethylthio-AD, has been synthesised⁴⁴ (for the relevant patent, see Ref. 45).

One of recent papers devoted to 19-functionalised androstanes presents the results of extensive studies on the synthesis and structure–aromatase affinity relationships of several series of androstane-4,9(11)-diene-3,17-diones carrying a sulfur-containing group, [(CH₂)_{*n*}SR], at the C(10) atom, where *n* = 0–3 and R stands for various alkyl, acyl and aryl substituents.⁴⁶ 19-Ethoxycarbonylandrosta-4,9(11)-diene-3,17-dione **37** obtained from the allylic alcohol **36** by the [3.3]-Claisen rearrangement was used as the starting compound in these syntheses (Scheme 2).

R = Me (**a**), Et (**b**), Ac (**c**), Ph (**d**), (CH₂)₂OH (**e**), CHF₂ (**f**), 2,4-

(NO₂)₂C₆H₃S (**g**), CH₂C≡CH (**h**), CH₂SMe (**i**), CH₂CH=CH₂ (**j**);
(a) (EtO)₃CMe, EtCO₂H, 137 °C, 4 h, 81%; (b) HO(CH₂)₂OH, CH₂Cl₂, Δ, 8 h, 71%; (c) LAH, THF, –50 to 20 °C, 2 h, 85%; (d) MsCl, Et₃N, CH₂Cl₂, 0 °C, 100%; (e) RNa, DMF; (f) HCl; (g) AcSH, PPh₃, diethylazodicarboxylate (DEAD), THF, 20 °C, 2.5 h, 60%; (h) NH₂NH₂, THF, –30 °C, 72 h, 97%; (i) Bu^tOK, THF, RHal; (j) (COCl)₂, DMSO, CH₂Cl₂, –50 °C; (k) RSH, BF₃·Et₂O, –78 to 20 °C.

Thus the reaction of steroid **36** with triethyl orthoacetate in the presence of propionic acid gave the ethoxycarbonyl derivative **37** in > 80% yield.⁴⁷ The latter was reduced to alcohol **38** via the biscetal. Several methods presented in Scheme 2 have been elaborated for its conversion into various 19-thiomethyl androstane derivatives. One of them consists in conversion of the alcohol **38** into the corresponding mesylate **39**, subsequent substitution of the mesyloxy group by various thiolates and deprotection to give compounds **40a–e**. The first member of this series, *viz.*, 3,17-diketo analogue of compound **41**, could not be obtained using this approach; various attempts at its deprotection gave compound **46**, which is the product of intramolecular Michael addition (Scheme 3).

40: R = C≡CSiMe₃ (**k**), CH=CH₂ (**l**), SMe (**m**), SPh (**n**), cyclo-C₃H₅ (**o**), C≡CH (**p**);
 (a) KOH, MeOH, 18 h, 95%; (b) ClCO₂Et, Et₃N, 20 °C, 1 h; (c) MeSNa, DMF, 2 h; (d) HCl; (e) 2,4-(NO₂)₂C₆H₃SCl, Py, CH₂Cl₂, 20 °C, 0.5 h; (f) RM, THF.

The thiol **41** was used as the starting compound in the synthesis of thio derivatives **40f–j**. This has been obtained by the Mitsunobu reaction from the alcohol **38** and thioacetic acid in the presence of PPh₃ and diethyl azodicarboxylate followed by hydrazinolysis. Alkylation of the thiol group of compound **41** with alkyl halides or 2,4-dinitrophenylsulfenyl chloride gave compounds **40f–j** in good yields (see Scheme 2). Thioacetals **43a,b** were prepared by the reaction of the aldehyde **42** obtained by the Swern oxidation of the alcohol **38** with methane- or ethanethiol, respectively, in the presence of boron trifluoride etherate. Compounds **40k–p** were synthesised by the reaction of the disulfide **40g** with various organometallic reagents. The methyl thiocarboxylate **45** was obtained from the key compound **37** in three steps which included hydrolysis of the ester function, activation of the resulting acid **44** with ethyl chloroformate and reaction with sodium methanethiolate (Scheme 3).

Methylthiovinyl steroids **48** and **50** have also been described.⁴⁶ The acetoxy derivative **47** was deacetylated into the corresponding 3,17-diol which was introduced into the reaction with diethyl methylthiomethylphosphonate and butyllithium. The thus prepared (10*E*)-methylthiovinyl derivative was further oxidised into steroid **48**.

(a) KOH, MeOH (78%); (b) MeSCH₂PO(OEt)₂, BuLi (76%); (c) Al(OPr)₃, CHex (74%).

An analogous reaction of the homologous aldehyde **49** with (methylthiomethyl)triphenylphosphorane gave a 1 : 1 mixture of chromatographically separable *E*- and *Z*-isomers **50** in total yield 76%. Hydrogenation of this mixture in the presence of the Wilkinson catalyst gave compound **51** in 80% yield which contained a 3-methylthiopropyl residue at C(10).

And, finally, the opening of the 5 α ,10 α -epoxide ring of estrane **52** with lithium methanethiolate which is analogous to that described above for compound **5**,^{14,43} and subsequent deketalisation and elimination of the 5 α -hydroxy group resulted in $\Delta^{4,9(11)}$ -steroid **53** (17%).

(a) MeSLi, THF, 1 h, 20 °C; (b) 6 N HCl; (c) 0.1 N NaOH (17%).

The opening of the 5 α ,10 α -epoxide ring of the estrane **5** with monolithium acetylide with subsequent partial hydrogenation of the hydroxy alkyne and hydroboration of the resulting alkene gave the diol **54**. Its mesylation and subsequent reaction of the mesylate with sodium methanethiolate followed by acid hydrolysis gave the ring C-saturated analogue of the steroid **40a**, *viz.*, 19-methylthiomethyl-AD **55**.

(a) $\text{LiC}\equiv\text{CH}$, ethylenediamine (EDA), 50 °C, 96 h, 81%; (b) H_2 –10% $\text{Pd}(\text{OH})_2/\text{BaSO}_4$, EtOAc-Py ; (c) $\text{BH}_3\cdot\text{Me}_2\text{S}$, THF, 35 °C, 4 h; (d) 30% H_2O_2 , NaOH, 0 to 20 °C, 12 h, 67%; (e) MsCl , Et_3N , CH_2Cl_2 , 0 °C, 45 min; (f) MeSNa , DMF, 20 °C, 1 h; (g) HCl , EtOH, 20 °C, 3 h.

The results of *in vitro* and *in vivo* studies of activities of the majority of compounds synthesised by Lesuisse *et al.*⁴⁶ suggest that the steroids with one- or two-carbon chains having a terminal thioether function at position 10 (e.g., **22f**, **40a,b**, **55**) are the most efficient AI. The presence or the absence of the 9(11)-double bond does not practically affect their inhibitory activity.⁴⁸ Compound **40a** was the most reactive among other compounds assayed and was considered⁴⁶ to be one of the best AI available to date. On the contrary, the steroids with the sulfur atom attached directly to the steroid skeleton (**53**) or separated from it by three carbon atoms (**51**) have practically no affinity for the enzyme. The key property of the efficient AI of this series is the ability of the sulfur atom to react with the heme iron of the porphyrin moiety of the enzyme (compounds **22f**, **40a** and **55**), whereas compound **53** reacts only with the lipophilic steroid-binding centre of the enzyme. This behaviour is consistent with the hypothesis^{14,41} that the incorporation of one methylene group between the sulfur atom and position 10 of the steroid skeleton alters the character of the interaction of the steroid substrate with the enzyme. The fact that AI with a two-carbon chain at C(10) react most efficiently with the heme $\text{Fe}(\text{III})$ allowed Lesuisse *et al.*⁴⁶ to suppose that the iron atom is separated from the 19-methyl group of the substrate by a distance equivalent to two methylene groups at the oxidation steps of AD. This hypothesis is consistent with the generally accepted mechanisms of aromatisation.^{15,16} The effect of the substituent at the sulfur atom in the molecule of AD analogues on the inhibition of aromatase has also been studied. Sulfur-containing steroids with methyl, vinyl or ethynyl substituents at the sulfur atom (compounds **40a**, **1** and **p**, respectively) possessed the highest affinity for the enzyme. Substitution of the ethyl group (**40b**) for the methyl group (**40a**) decreases the activity of the steroid substrate 72-fold. Compounds with hydroxyethyl (**40e**) and cyclopropyl groups (**40o**) are completely devoid of activity, while compounds with allyl (**40j**), phenyl (**40d**), prop-2-ynyl (**40h**) and methylthiomethyl (**40i**) groups possess certain activity. Disulfides **40g,m,n**, thioacetals **43a,b** and analogues **48** and **50** with a double bond in the side chain at C(10) are also inactive as AI.

Compound **40a**, which is the most active in this series, decreases the estradiol level and inhibits the growth of endocrine tumours *in vivo* when used at a dose of 0.4 mg kg^{-1} .⁴⁹

Yet another type of 19-substituted androstanes, *viz.*, 10 β -(oxiran-2-yl)- and -(thiiran-2-yl)-steroids, represent competitive reversible AI. The synthesis of diastereomeric 10 β -(epoxyethyl)estr-4-ene-3,17-diones (19*S*)-**59** and (19*R*)-**59** was carried out in four steps.^{50–52}

(a) Me_2SCH_2 (or Me_2SOCH_2), THF or DMSO; (b) $\text{Py}\cdot\text{HSO}_3\text{C}_6\text{H}_4\text{Me}$, 20 °C, 4 h; (c) $\text{Al}(\text{OPr})_3$, CHex; (d) Ph_3PS is picric acid, PhH, 80 °C, 16 h.

Reaction of the tetrahydropyranyl derivative of 19-aldehyde **56** with dimethylsulfonium methylide (or dimethylsulfoxonium methylide) in THF gives a mixture of oxiranes (19*R*)-**57** and (19*S*)-**57** in 26% and 74% yields, respectively. Under other reaction conditions, *i.e.*, in DMSO in the presence of dimethylsulfonium methylide at 0 °C, the ratio of diastereomeric products is changed: the (19*R*)-**57** isomer becomes predominant.⁵¹ Deprotection and chromatographic separation of diols (19*R*)-**58** and (19*S*)-**58** with subsequent Oppenauer oxidation of each of the diastereomeric alcohols gave individual isomers (19*R*)-**59** and (19*S*)-**59**, respectively. Steroid thio analogues (19*R*)-**60** and (19*S*)-**60** were obtained from oxiranes **59** by reaction of the latter with excess of triphenylphosphine sulfide and picric acid in benzene.⁵³

The configuration of isomeric 10 β -oxiranes **59** (*R* or *S*) was established from X-ray analysis. It was shown that the oxirane ring in the stereoisomer (19*R*)-**59** is positioned over the ring *A* in the direction towards C(1) and C(2) in a manner similar to that of the 19-hydroxy group in 19-hydroxy-AD **28**. On the contrary, the three-membered ring in the molecule of (19*S*)-**59** is positioned over the ring *B* and directed toward C(6).^{31,51,54} Presumably, it is these stereochemical peculiarities that are responsible for the difference in the binding and inhibitory activities of these compounds. Both of them are potent competitive AI with K_i 7 and 75 nM, respectively. Thiiranes (19*R*)-**60** and (19*S*)-**60** manifest an even greater stereoselectivity of binding: K_i for (19*R*)-**60** is 1–2 nM and that for (19*S*)-**60** is 75 nM.⁵¹ In another study⁵⁴ it was shown that (19*R*)-isomers of oxiranes and thiiranes are more active (36-fold and 80-fold, respectively) than the corresponding (19*S*)-diastereomers. Spectroscopic studies with purified aromatase showed that the inhibition involved reversible binding of the oxygen (or sulfur) atom of the oxirane (or thiirane) with the heme iron of the enzyme.^{15,51,54} The knowledge of the spatial structure of these compounds made it possible to assume that the modified steroid inhibitor is bound in exactly the same way as does the natural substrate (AD) and that the heme iron is localised in close proximity to the 19-methyl group of the androgen molecule.⁵⁴ It is of note that with neither 19-hydroxy, nor 19-methoxy derivatives of AD is such coordination possible.¹⁵ Thus, coordination with the heme iron of the enzyme, together with the binding selectivity inherent in 10 β -(oxiran-2-yl)- and -(thiiran-2-yl)-steroids make these AD analogues highly specific aromatase inhibitors.

The synthesis of homologous 19-(oxiran-2-yl)- (**63**) and 19-(thiiran-2-yl)-AD (**64**) continued the series of investigations aimed at establishing the localisation of the aromatase heme iron during its binding with the steroid substrate.⁵⁵

(a) $\text{Me}_2\text{SCH}_2^+$ (or $\text{Me}_2\text{SOCH}_2^+$), THF, 4 °C (75%); (b) $\text{CrO}_3 \cdot \text{Py}$, CH_2Cl_2 , 25 °C, 20 min; (c) diazabicyclononene (DBN), CH_2Cl_2 , 25 °C, 18 h; (d) Ph_3PS , PhH , Δ , 18 h.

The methodology of the synthesis of these compounds is analogous to those used in the synthesis of 10 β -(oxiran-2-yl) and -(thiiran-2-yl) steroids⁵² with 3 β ,17 β -dihydroxyandrost-5-ene 19-carbaldehyde **61** as the starting compound.³⁰ Unlike the 10-formyl analogue **56**, this reacted with both dimethylsulfonium and dimethylsulfoxonium methylide to give a chromatographically separable mixture of diastereomeric oxiranes (2'*R*)-**62** and (2'*S*)-**62** of the same composition (3 : 1) in 75% yield. This result is rationalised by higher spatial accessibility of the aldehyde group in the molecule of compound **61**. After separation into individual diastereomers, epoxy diols **62** were converted into diketones (2'*R*)-**63** and (2'*S*)-**63** by the Collins oxidation with subsequent isomerisation of resulting Δ^5 -3,17-diketones with diazabicyclonene. The configuration of epoxide (2'*R*)-**63** was established by X-ray analysis. Reaction of this oxirane with triphenylphosphine sulfide and picric acid gave thiirane (2'*S*)-**64** in 76% yield. Analogously, thiirane (2'*R*)-**64** was obtained from (2'*S*)-**63** in 79% yield. The *R*- and *S*-configuration of thiiranes **64** was ascribed on the basis of the established stereochemistry of the oxirane precursors and the known stereochemical regulation of thiirane formation.⁵⁵ Oxiranes **63** and thiiranes **64** are competitive AI; the latter possess higher activity than the corresponding oxiranes. (2'*S*)-Isomers of both compounds are more efficient inhibitors than 2'*R*-diastereomers. The inhibition constant of the strongest inhibitor, *viz.*, the thiirane (2'*S*)-**64**, is 22 nM. The oxygen and sulfur atoms in the oxirane (2'*S*)-**63** and the thiirane (2'*S*)-**64** molecules coordinate with the aromatase heme iron during their interaction with the enzyme similarly to the corresponding (19*S*)-diastereomers **59** and **60**. Here, the weaker inhibitor possesses weaker affinity for the heme iron of cytochrome P-450. The configuration of the 2'-centre of the three-carbon chain at C(10) is crucial for the stereoselectivity of inhibition.⁵⁵ Thus, strong competitive inhibition of aromatase and coordination of the heteroatom in the steroid substrate are observed even in those cases where the oxygen or the sulfur atom in the three-membered ring are separated from C(10) by a methylene group (*cf.* Ref. 46).

Having considered the AD analogues containing an oxygen or a sulfur atom at positions 10 or 19, one may conclude that sulfur-containing steroids are the most potent inhibitors and that compounds with a methylene group between the steroid skeleton and the heteroatom manifest higher inhibitory activity. A characteristic feature of compounds of this series is the stereoselectivity of their interaction with the enzyme.

Synthesis of AD derivatives containing nitrogen at position 19, which bind with iron of the aromatase heme by virtue of coordination similarly to sulfur-containing steroids was described by Robinson in 1993,⁵⁶ although attempts to synthesise such derivatives were undertaken earlier.⁵⁷ Thus 10 β -aminoestr-4-ene-3,17-dione **66** was obtained by the Curtius rearrangement of the corresponding derivative of 19-acid **65**. However, all the attempts to obtain its homologue, *viz.*, 19-aminomethyl-AD **69**, failed, although its diketal derivative **68** was obtained in high yield from 19-hydroxy-AD **28**. Compounds **66** and acetamido and trifluoroacetamido derivatives of diketone **69** displayed low AI activity.⁵⁷

(a) $\text{CrO}_3 - \text{H}_2\text{SO}_4$; (b) $\text{Py} \cdot \text{CrO}_3$ (93%); (c) $\text{NH}_2\text{OH} \cdot \text{HCl}$ (88%); (d) Ni/Ra , EtOH, 2 M NaOH (89%).

Oxime **74** obtained from the accessible 3,17-diacetate of the triol **70** in seven steps (Scheme 4) was the key compound in the synthesis of 10 β -(aziridin-2-yl)-steroids.⁵⁶ Oxidation of compound **70** with tetrapropylammonium perruthenate in the presence of *N*-methylmorpholine *N*-oxide as a co-oxidant gave 19-aldehyde diacetate **71** in high yield; the latter was further converted into diol and then into bis-*tert*-butyldimethylsilyl ether **72**. Methylation of the aldehyde **72** with methyl lithium occurred in quantitative yield. Oxidation of the 19-hydroxy-19-methyl derivative and selective desilylation of the thus obtained 10 β -acetyl derivative gave 17-silyl ether **73**. The latter was refluxed with hydroxylamine hydrochloride in pyridine to give a mixture of key oximes **74a,b** in 70% yield. On treatment with lithium aluminium hydride in THF, the oxime **74b** was converted into a mixture of (aziridin-2-yl)-steroids (19*R*)-**75** and (19*S*)-**75** isolated in the individual states with 35% and 53% yields, respectively. Each of them was further converted into (19*R*)- and (19*S*)-10 β -(aziridin-2-yl) diketones **76** (in 39% and 41% yields, respectively) *via* the corresponding diols. 17 β -Hydroxy analogues (19*R*)- and

Scheme 4

(a) Tetrapropylammonium perruthenate (TPAP), *N*-methylmorpholine *N*-oxide (NMO), CH₂Cl₂, 20 °C; (b) 10% KOH, MeOH, 90%; (c) Bu^tMe₂SiCl ((TBDMS)Cl), DMF; (d) MeLi, Et₂O; (e) TBAF, THF; (f) NH₂OH·HCl, Py, Δ; (g) LAH, THF, Δ, 18 h; (h) HF, H₂O, EtOH, 20 °C, 2.5 h; (i) Al(OPrⁱ)₃, LAH; (j) Al(OPrⁱ)₃, 4-methylpiperidone; (k) HF, H₂O, MeCN, 20 °C, 2 h.

(19*S*)-**78** were synthesised from the aziridines (19*R*)- and (19*S*)-**75** via intermediate Δ⁴-3-ketones **77**. The stereochemistry of these compounds was established by deamination of diastereomeric aziridines **76** and **78** with sodium nitrite in aqueous acetic acid into the known 10β-vinylestr-4-ene-3,17-diones and the corresponding 17β-alcohols. The configuration of the (aziridin-2-yl)-steroid (19*R*)-**78** was also confirmed by X-ray analysis.

Compounds (19*R*)- and (19*S*)-**76** as well as (19*R*)- and (19*S*)-**78** are potent stereoselective AI with *K*_i = 3.4, 56.0, 30.0 and 693 nM, respectively. 10β-(Aziridin-2-yl)-steroid (19*R*)-**76** manifested the highest efficiency. Spectroscopic analysis of its interaction with preparations of microsomal aromatase have shown the coordination of the nitrogen atom of the aziridine ring with the iron atom of the cytochrome P-450 heme. Earlier, such a coordination was established for 19-azido-AD **22e**.¹⁷ These results suggest that the orientation and accessibility of the nitrogen

atom are crucial for efficient coordination.⁵⁶ It should be noted that *N*-acetylation of compounds **76** strongly decreases their inhibitory activity.⁵⁶

The recently described 10β-aziridinoestr-4-ene-3,17 dione was less active in comparison with the 10β-aziridine (19*R*)-**76**.⁵⁸

The synthesis of hydroxylated 2,19-bridged structures related to AD was described in 1991.¹¹ The key compound in this synthesis was 10β-epoxide **79** [a mixture of (19*R*)- and (19*S*)-isomers] obtained by reaction of the aldehyde **8** with dimethylsulfonium methylide.

The opening of the epoxide ring and removal of the ketal protection with 48% HBr in acetone gave a mixture of bromohydrins **80** [the (19*R*)-**80**/(19*S*)-**80** ratio was 7 : 1]. Chromatographically separable trimethylsilyl derivatives **81a** and **81b** were obtained by the action of bis(trimethylsilyl)-acetamide in DMF. Intramolecular alkylation at C(2) under the action of lithium bis(trimethylsilyl)amide in THF and subsequent treatment of the reaction mixture with an acid complete the synthesis of diastereomeric alcohols **82a,b**.

(a) Me₃Si⁺, NaCH₂SOCH₃, DMSO, THF, 98%; (b) HBr, H₂O, Me₂CO; (c) CH₃C(=NSiMe₃)OSiMe₃ (BSA), DMF; (d) LiN(SiMe₃)₂, HCl, THF.

The synthesis of diketone **86**, which is homologous to these bridge structures, was carried out in five steps.^{59, 60}

(a) (EtO)₂P(O)CH₂CO₂Et; (b) Mg, MeOH; (c) LAH (93%); (d) TsCl, Py, 60%; (e) H⁺ (60%); (f) LiN(SiMe₃)₂, THF, -78 °C (62%).

In this case, too, the same bisketal **8** was used as the starting compound. Its reaction with triethyl phosphonoacetate gave the unsaturated derivative **83** in high yield, and the double bond was reduced with magnesium in methanol. The ester function in the thus prepared compound **84** was reduced into the alcohol function which was then tosylated. Removal of 3,17-diketal protection in the tosylate **85** and cyclisation of 19-(2-tosyloxyethyl)-AD with lithium bis(trimethylsilyl)amide in THF gave the final product, 2 β ,19-ethylene-AD **86**.

The section devoted to bridge structures can be completed by the description of a synthesis of 2 β ,19-methyleneoxy-AD **89**.

The methoxyethoxymethyl ether (MEM) **87** prepared from 19-hydroxymethyl-AD **28** was converted into the homoannular dienol **88** silyl ether. The latter underwent Lewis acid-catalysed intramolecular alkoxyalkylation at C(2) involving the acetal carbon atom of the MEM-protective group to give the bridge steroid **89**. It is noteworthy that the MEM ether group played the role of both the protective group and the reagent in these conversions.

(a) $\text{ClCH}_2\text{OCH}_2\text{CH}_2\text{OMe}$, $(\text{Me}_2\text{CH})_2\text{NEt}$, CH_2Cl_2 , 20 °C, 20 h;

(b) LDA, Me_3SiCl , THF, -20 °C, 0.5 h; (c) TiCl_4 , CH_2Cl_2 , -20 °C, 0.5 h.

Some sulfur-containing analogues of the steroid **89** have been recently patented.⁵⁹

2 β ,19-Bridged steroids **82a,b**, **86** and **89** appeared to be sufficiently active AI.^{11, 59–61} Bromohydrins **80** also manifested a certain AI activity (see Table 1).¹¹

2. 4-Substituted androstanes

Of all substituted androstanes, particularly of those substituted at position 4, 4-hydroxyandrost-4-ene-3,17-dione (4-OHA) **91** is the most popular and well-studied. It was first described in 1977⁶² as a competitive AI. Later, it was shown to represent a suicide irreversible AI; according to different estimates, its K_i ranges from 1 to 50 nM.^{19, 55, 62–64} This steroid is the basis of one of a few (if not the only) steroid inhibitors of aromatase that is already used in clinical practice.⁶⁵ This compound is known under the trade name 'formestane' and is used for the treatment of hormone-dependent mammary tumours in women in the post-menopausal period.^{8, 15, 48, 66–71}

All the syntheses of 4-OHA **91** described in the literature involved acid- or base-catalysed opening of 4,5-epoxides **90a,b**. The latter are obtained by treatment of AD with hydrogen peroxide in an alkaline medium.

Epoxidation of conjugated steroid ketones is a well-known reaction. In the case of Δ^4 -3-ketones, it affords a mixture of 4 α ,5 α - and 4 β ,5 β -oxides in which the latter predominates. The conditions for this reaction have not practically changed since the publication by Bible *et al.*⁷² in 1957. However, the overall yields described therein were rather low and poorly reproducible. Various modifications of reaction conditions failed to increase the yields considerably,^{73–75} although a successful synthesis of epoxides **90a** and **90b** (1 : 5, total yield 90%) is documented.⁴⁸

The opening of the epoxide ring in compounds **90a,b** results in 4-hydroxy-substituted AD **91** in up to 50% yields.^{14, 48, 74–78} The

steroid **91** was also obtained in a satisfactory yield by opening of the isomeric epoxides **90a,b** and hydrolysis of the ether **92**.¹³ Rearrangement of the epoxides **90a,b** in the presence of boron trifluoride etherate in benzene and chromatographic separation of side products (*e.g.*, 4-nor-3-oxo-5 α -carbaldehyde) gave the target steroid **91** in 34% yield.¹⁴ The ether **92** was synthesised in 25% yield by treatment of AD with *o*-iodosylbenzoic acid and alkali in methanol.⁷⁹ Special mention should also be made of a recently developed procedure for the synthesis of 4-OHA **91** (47% yield) which involves hydroxylation of AD with $\text{OsO}_4/\text{H}_2\text{O}_2$ with subsequent dehydration of the resulting mixture of 4,5-diols in an alkaline medium.⁷⁰

(a) H_2O_2 , OH^- ; (b) AcOH, H_2SO_4 , or Me_2CO , H_2O , H_2SO_4 , or HF, Py, or $\text{BF}_3 \cdot \text{Et}_2\text{O}$, PhH; (c) MeOH, NaOH (62%); (d) HCl, dioxane, Δ (53%); (e) OsO_4 , H_2O_2 , Bu^tOH, 20 °C; (f) $\text{OIC}_6\text{H}_4\text{CO}_2\text{H}$, MeOH, KOH (25%).

Introduction of 4-OHA **91** into the clinical practice and the steadily increasing number of publications devoted to the analysis of the topography of the active site of aromatase using various analogues of 4-OHA **91** (see, *e.g.*, Refs 80 and 81) have stimulated the search for alternative efficient methods of its synthesis. A recent publication,⁸² which describes a new approach to the synthesis of 4-OHA **91** by oxidation of easily accessible 5 α -androst-3-en-17-one (**93**), is an example. The latter was obtained by reduction of AD with zinc in acetic acid.⁸³ Treatment of steroid **93** with performic acid generated *in situ* gives *trans*-diaxial diol **95** in 96% yield. Oxidation of androst-4-ene-3-one **93** in dichloromethane resulted in 3 α ,4 α -epoxide **94** as the only identified and isolated reaction product. Further oxidation of the diol **95** with dimethyl sulfoxide activated with trifluoroacetic anhydride gives hydroxy ketone **96** in quantitative yield. The latter is isomerised into the final steroid **91** on treatment with a base.

(a) H_2O_2 , HCO_2H , CH_2Cl_2 , 20 °C, 6 h; (b) H_2O_2 , HCO_2H , 20 °C, 1 h;
(c) DMSO, $(\text{CF}_3\text{CO})_2\text{O}$, -60 °C, 3 h; (d) Et_3N , -60 °C, 15 min;
(e) NaOMe , 20 °C, 1 h.

High yields in all the stages of this synthesis and the accessibility of the starting steroid **93** (the authors propose to use a mixture of 5 α - and 5 β -isomers) illustrate the high outlook of this approach.

The mechanism of the inhibitory effect of 4-OHA **91** on aromatase has not been completely elucidated. An inactivation mechanism, which involves the formation of a covalent bond between the enzyme and position 4 of the steroid substrate (which, in turn, changes the direction of the final stage of elimination), has been proposed by Covey.²⁴ Protonation of the hydroxy group at position 4 of the substrate and its elimination as a water molecule occurs in the enzyme-bound intermediate **A** (instead of removal of the enzyme as the nucleophile, which normally takes place).

Nu is the nucleophile, E is the enzyme.

Inactivation of the enzyme, which cannot 'kick off' the steroid substrate, follows aromatisation of the steroid ring **A** with the formation of structure **B**. A great number of 4-OHA **91** analogues have been synthesised aimed at elucidating the mechanism of its action and obtaining more efficient aromatase inhibitors. Thus its 6 α -methyl analogue obtained by hydrolysis of the corresponding 4,5-epoxide in a mixture of acetic and sulfuric acids has been described.⁸⁴ 4-Acetoxy-AD^{63,64,85} possessed inhibitory properties, whereas 4-methoxy-AD **92** was inactive.⁷⁴ However, recent *in vitro* studies have shown that 4-methoxy-AD **92** suppressed the proliferative activity of cancer cells.⁸⁶

Although 4-OHA **91** is an active AI, it is characterised by low bioavailability and short-term action and manifests *in vivo* activity only on subcutaneous administration, which is due to the ease of its glucuronidation.^{67,87,88} The quest for the synthesis and analysis of its various analogues thus becomes understandable. Besides, these studies were aimed at establishing the structural demands for the design of novel AI.

A prominent role among formestane **91** analogues belongs to 4-alkylthio- and 4-arylthio-AD. Several compounds of this series (**98a–e**) were obtained in the 80's^{89,90} by the opening of epoxides **90a,b** with the corresponding thiol reagents. All of them appeared to be efficient competitive AI with K_i ranging from 36 to 73 nM.⁹⁰ It was found that the chain length at C(4) of alkylthio analogues of such steroids should not exceed three carbon atoms in order to preserve a sufficiently high inhibitory activity.⁹⁰ 4-Phenylthio-AD **98d** (25 and 50 mg per kg per day) inhibited the growth of mammary tumours in rats.⁹¹

The thiol **97** was synthesised in high yield by the opening of epoxides **90a,b** with thioacetic acid in dioxane. Its subsequent alkylation with various functionalised alkyl halides gave a series of

(a) AcSH , dioxane, MeOH , HCl ; (b) RX , Bu^tOK , THF ; (c) RSH ; $\text{R} = \text{Me}$ (**a**), Et (**b**), Pr (**c**), Ph (**d**), CH_2Ph (**e**), CH_2F (**f**), CH_2Cl (**g**), CHF_2 (**h**), CH_2CN (**i**), CH_2OMe (**j**), CH_2SMe (**k**).

4-alkylthio-AD **98f–k** containing hetero atoms in the substituent at C(4).^{48,92}

4-Thio-substituted **98f–h** were comparable in activity with 4-OHA **91** (see Table 2). The difluoromethyl analogue **98h** was found to be a reversible AI, whereas the fluoromethyl and chloromethyl analogues **98f** and **98g** are suicide AI with $K_i = 30$ nM (*cf.* K_i for 4-OHA **91** is 27 nM⁴⁸). *In vivo* activity of compound **98f** is comparable with that of 4-OHA **91** and, like the latter, it is inactive on *per os* administration.⁴⁸ It is noteworthy that the presence of an additional 9(11)-double bond in these analogues, like in 19-sulfur-containing steroids **40a–o**, does not influence their affinity and inhibitory activity with respect to aromatase. A similar conclusion was made from the biochemical analysis^{48,88} of some 4-alkyl(aryl)thio- $\Delta^{9(11)}$ -AD **102–106** (their synthesis is shown below). The most active compound of this series is the steroid **104** ($\text{R} = \text{CH}_2\text{Cl}$) ($K_i = 27$ nM).⁴⁸

(a) H_2O_2 , NaOH , CH_2Cl_2 , MeOH , 4 °C, 1 h; (b) H_2SO_4 , AcOH , 4 h, 20 °C; (c) AcSH -dioxane, MeOH , HCl ; (d) RX , Bu^tOK , THF ; (e) $\text{HC}(\text{OEt})_3$, EtOH , *p*-TsOH; (f) chloranil; (g) MCPBA; (h) DAST, CHCl_3 , Δ .

Table 2. Data on *in vitro* inhibition of aromatase from human placenta by 4-substituted androstanes.

SCH ₂ F (98f)	—	30		48
SCH ₂ CN (98i)	—	169		48

Other 4-substituted AD have been also obtained and assayed as AI. Thus 4-fluoro-AD **109** has been recently prepared from 4-bromo-AD **107**.⁹³ Conversion of bromide **107** into the 4-trimethylstannylated steroid **108** by hexamethyldistannane catalysed by tetrakis(triphenylphosphine)palladium and its subsequent treatment with cesium fluorosulfate gave 4-fluoro-AD **109** in high yield.

(a) Br₂, AcOH, Δ , –30 °C; (b) Pd(PPh₃)₄, (Me₃Sn)₂, PhMe; (c) FOSO₃Cs, CH₂Cl₂, MeOH, N₂, 0 to 20 °C.

4-Fluoro-AD **109** is comparable with 4-OHA **91** in its inhibitory activity; however, its practical application is limited due to its low bioavailability.⁹⁴ The synthesis of 4-chloro-AD is given in a patent.⁹⁵

Among other 4-substituted AD, special mention should be made of 4-azido-AD **111** and 4-amino-AD **112** prepared from 4-mesyloxy-AD **110** according to patent data.⁹⁶

(a) NaN₃, H₂O, 60 °C, 1 h; (b) NaN₃, 100 °C, 1.5 h.

Highly active 4-amino-androstenediones **114** and **119** present special interest. One of them, 4-aminoandrosta-1,4,6-triene-3,17-dione **119**, appeared to be an efficient AI and was recommended for treatment of mammary tumours. This compound has passed successfully clinical trials under the trade name of 'minamestane'.^{97–99}

4-Aminoandrosta-1,4-diene-3,17-dione (**114**) was obtained by ammonolysis of the corresponding 4-chloro derivative **113**⁹⁵ in dioxane (Scheme 5).

(a) 30% NH₄OH, dioxane, 24 h; (b) 2 KSO₅ · KHSO₄ · K₂SO₄ – phosphate buffer, Me₂CO, 5–10 °C, 15 min; (c) KSCN; (d) DMF, 110–135 °C, 1.5 h; (e) dioxane–H₂O, 35% NaOH, 0.5 h.

The oxirane **116** obtained by selective epoxidation of the trienedione **115** was the key compound in the synthesis of minamestane **119**. Its reaction with potassium thiocyanate gave the 6-thiocyanate derivative **117**. Heating of the latter in DMF resulted in 4-isothionate **118** and its alkaline hydrolysis yielded the target compound, 4-aminotrienedione **119** (see Scheme 5).¹⁰⁰ Its 6- and 7-substituted analogues have been described in the patent.¹⁰¹

Studies of structure–activity relationships revealed the enhanced rate and selectivity of aromatase inhibition upon introduction of additional 1,2- and 6,7-double bonds into the molecule of 4-amino-AD **112**.⁹⁸ Steroids **114** and **119** are highly efficient and manifest *in vivo* antitumour activity both on subcutaneous and oral administration.^{9, 81, 97–99}

Thus, the majority of 4-substituted AD described above represent highly active irreversible AI with K_i ranging from 30 to 200 nM.¹⁰⁰

3. 1-Substituted androstanes

1-Methylandrosta-1,4-diene-3,17-dione (**121**) is the most valuable and perhaps the only steroid AI of this series. It was synthesised in 1983¹⁰² and patented under the trade name atamestane in more than a dozen countries. Atamestane is an irreversible inhibitor of estrogen biosynthesis *in vitro* and *in vivo*.^{102–105}

Androsta-1,4-diene-3,17-dione (ADD) is the starting compound in the synthesis of atamestane **121**. This synthesis required two principal problems to be solved, *viz.*, introduction of a methyl group into position 1 of the steroid skeleton and regeneration of

the 1,2-double bond in the resulting 1 α -methyl- Δ^4 -3-oxo derivative **120**. The first problem can be solved through selective 1,4-addition of organometallic compounds (*e.g.*, methyl lithium cuprates) to ADD.¹⁰⁶ However, the high cost of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) employed in 1,2-dehydrogenation of Δ^4 -4-ketosteroid **120** and the formation of a 4,6-dehydro derivative as a side product are the limiting factors.^{107, 108}

Early patents applied by the 'Schering AG' company dealt with the synthesis of atamestane **121** by oxidation of its 17 β -hydroxy derivative **126**¹⁰² or by microbiological dehydrogenation of the 1-methyl- Δ^1 -5 α -derivative **127** in up to 65% yields.^{109, 110} Compounds **126** and **127** were prepared in a multistep procedure (see below) and in unsatisfactory yields.

Thus the 4,5-double bond in the 1 α -methyl derivative **123** obtained from the dienone **122**¹⁰⁶ was reduced and the resulting compound **124** was brominated to give the 2,4-dibromosteroid **125**. Elimination of two HBr molecules from the dibromide **125** gave the dienone **126**.^{111, 112} Oxidation of the 17 β -hydroxy group in compound **126** gave the target product **121**. The characteristic feature of this synthetic scheme is that the 4,5-double bond in the intermediate compounds is first reduced and then recovered together with the formation of the 1,2-double bond. Obvious disadvantages of this scheme consist in the formation of an undesirable side product, *viz.*, 17 β -hydroxy-1 α -methylandrosterane-4,6-dien-3-one, and the necessity of tedious chromatographic purification following dehydrobromination. Nevertheless, this scheme has recently been applied¹¹³ in the synthesis of atamestane **121** from 1 α -methyl dihydrotestosterone acetate (**128**)¹¹⁴ with satisfactory yields at all steps.

(a) 2 equiv. Br₂, 4N HBr, AcOH, THF, 50 °C, 0.5 h; (b) LiBr, Li₂CO₃, DMF, 80 °C, 18 h; (c) MeOH, NaOH, Δ , 1.5 h; (d) TPAP–NMO, CH₂Cl₂, 20 °C.

Dibromination has led to the epimeric dibromides **129a,b** isolated in the individual state, and their configuration was established by ¹H NMR. However, dehydrobromination of compounds **129a,b** with lithium carbonate and lithium bromide occurred in only 66% yields. No formation of side products has been reported. The alcohol **126** prepared by deacetylation of the 17 β -acetoxy derivative **130** was oxidised into atamestane **121** using a tetrapropylammonium perruthenate–*N*-methylmorpholine *N*-oxide system in quantitative yield. The overall yield was 60%.¹¹³

A shorter and more efficient method for the synthesis of atamestane **121** which does not require chromatographic procedures has been patented.¹¹⁵

(a) MeLi, CuI, Cl(CH₂)₂Cl, –30 to 0 °C; (b) Ac₂O, Cl(CH₂)₂Cl, 20 °C; (c) NH₄Cl, H₂O, 20 °C; (d) 1,3-bromo-5,5-dimethylimidazolidin-2-one (dibromantin), dioxane, H₂O, 20 °C; (e) MgO, DMF, 110 °C, 2 h; (f) NaOAc, ICl, Me₂CO, –10 °C, 99% (2 β -I-isomer); (g) (CH₂CO)₂Ni, abs. MeOH, N₂, 20 °C, 55% (2 α -I-isomer); (h) Li₂CO₃, DMF, 130 °C, 1.5 h; (i) Me₃Al, 1 mol.% – 5 mol.% CuBr, Me₃SiCl, THF–PhMe, 20 °C; (j) I₂, CuO, glacial AcOH, N₂, 60 °C, 24 h.

The intermediate 1 α -methylenolate formed upon 1,4-addition of dimethylolithium cuprate to ADD in the presence of acetic anhydride is converted into the crystalline dienol acetate **131**. Bromination of the latter in aqueous dioxane gave a mixture of epimeric 2 ξ -bromo-1 α -methylandrosta-4-en-17-ones (**132**) in which the 2 β -isomer was predominant. Dehydrobromination of the bromo ketone **132** with magnesium oxide resulted in the target product **121** in 70% yield.

Dehydroiodination of the 2-iodo derivative **133** is a modification of the above-described procedure.¹¹⁶ This compound is formed from dienol acetate **131** and monochloroiodine in acetone in quantitative yield. When *N*-iodosuccinimide was used, the yield of the iodide **133** dropped to 55%. The 2-iodosteroid **131** was also obtained by iodination of 1 α -methyl- Δ^4 -3-ketone **120** with elementary iodine in glacial acetic acid. Dehydroiodination proceeded smoothly on boiling of the iodo derivative **131** with lithium carbonate in DMF.

Yet another method for obtaining the intermediate **120** for the synthesis of atamestane **121** was the use of trimethylaluminium in the presence of catalytic amounts (1 mol.% – 5 mol.%) of monovalent copper salts for the introduction of the 1 α -methyl group into ADD.¹¹⁷ Various modifications of this approach, in particular, the use of Lewis acids for acceleration of the reaction and suppression of competitive 1,2-addition and the mechanism of these reactions are discussed in detail with steroid 1,4-dien-3-ones and 1-en-3-ones as examples.¹¹⁴ It was shown that selective 1,4-addition of trimethylaluminium to ADD occurs in the presence of equimolar amounts of chlorotrimethylsilane and catalytic amounts of copper(I) bromide, the yield of 1 α -methylandrosta-4-en-3,17-dione **120** being 90%.

Finally, a single-step procedure for the synthesis of atamestane **121** from ADD has been patented.¹¹⁸ This method consists in successive treatment of ADD with trimethylaluminium in hexane with a stoichiometric amount of sterically hindered di-*tert*-butylphenol in the presence of catalytic amounts of nickel(II) acetylacetonate. The yield of steroid **121** was 42%.

(a) Me₃Al, *n*-C₆H₁₄; (b) 3,5-(Bu^t)₂C₆H₃OH, EtOAc, Ni(acac)₂, 58 °C, 2 h.

Syntheses of 15 α -alkyl atamestane analogues^{107, 119, 120} and 1 β ,2 β -cyclopropano-4-OHA have been patented.¹²¹

4. 6-Substituted androstanes

6-Methyleneandrost-1,4-diene-3,17-dione (**136**) synthesised in the late 80's as an anticancer drug known under the trade name 'exemestane' is the most well-known aromatase inhibitor of the 6-substituted androstane series. It represents an orally active irreversible selective AI.^{9, 122–124} Exemestane **137** is shown to be 2.5 times more active than formestane **91**.¹²⁴

Exemestane can be synthesised from both AD and ADD (Scheme 6). The key stage in this synthesis is methylenation of a steroid at position 6. When AD is used as the starting compound, the methylene group at position 6 is introduced by direct methylenation of 3-oxo-4,5-dehydrosteroid using the method of Annen *et al.*¹²⁵ The yields in this stage do not exceed 45%; the penultimate stage consists in 1,2-dehydrogenation of 6-methylene-AD **138** by boiling either with DDQ in anhydrous dioxane or with selenium dioxide in *tert*-butyl alcohol. The yields in the second stage are 40% – 50%.¹¹⁷ Thus, the overall yield of exemestane was as low as 20% – 25%. This scheme involves tedious chromatographic purification of reaction products in both stages and the use of an expensive reagent (DDQ). An

Scheme 6

(a) HCHO, PhH, EtOH, 90%; (b) MeOH, HCl, 20 °C, 5 h (80%); (c) HCHO, Me₂NH·HCl, AmⁱOH, 131 °C (31%); (d) CrO₃, H₂SO₄ (79%); (e) HC(OEt)₃, *p*-TsOH, THF – EtOH, 40 °C, 2 h; (f) PhNHMe, HCHO, 40 °C, 2 h; (g) conc. HCl, 1 h (73%); (h) Br₂, Et₂O, HBr, AcOH, 2–3 °C (84%); (i) NaI, Me₂CO, Δ , 15 min; (j) Li₂CO₃, LiCl, DMF, 120 °C, 2.5 h; (k) H₂C(OR)₂, POCl₃, CHCl₃, NaOAc, Δ (40% – 50%).

improved procedure for the synthesis of the steroid **136** has been patented. Although this requires a larger number of steps, it yields only crystalline intermediates and is suitable for large-scale syntheses. It includes the Mannich aminomethylation of a 3,5-dien-3-ol ester prepared from AD (see Scheme 6). The 6-methylene steroid **138** is obtained in > 70% yield. Compound **138** is then brominated with bromine in acetic acid. Dehydrobromination of the tribromide thus formed is carried out in two steps. At first, the 6-methylene group is regenerated by treatment of the tribromide with sodium iodide in acetone. The resulting 2-bromo-6-methylene steroid (not shown in Scheme 6) is further dehydrobrominated without purification by boiling with lithium salts in DMF to give exemestane **136** in 47% yield for the last two stages.¹²⁶

Two approaches for the synthesis of exemestane **136** from 3-oxo-1,4-didehydrosteroids are shown in Scheme 6. Direct γ -methylenation, which is applicable for a wide range of substrates,¹²⁵ has failed in the case of ADD. However, the 17 β -hydroxy derivative **122**, which is an accessible industrial raw material, can participate in the Mannich reaction. The resulting product **137** formed in 31% yield is oxidised to exemestane **136**.¹²⁷ And, finally, ADD was used directly as the starting material for introducing the 6-methylene group *via* the 1,3-bispyrrolidino derivative **134** which was converted into 6 β -hydroxymethyl ste-

roid **135** by standard procedures.¹²⁸ Dehydration of the latter gave exemestane **136** in 80% yield.¹²⁹

A series of exemestane analogues modified at position 6 and its 17 β -hydroxy derivatives have been synthesised in order to investigate the structure–activity relationships.¹²⁴ The reason for these studies was the experimental evidence about a wide set of exemestane metabolites. The design of its analogues was based on the hypothesis according to which exemestane metabolism results in modification of not only the carbonyl group at C(17) but also the exocyclic double bond.¹²⁴

Synthesis of exemestane **136** analogues is considered below. Epoxidation of exemestane **136** or its 17 β -hydroxy derivative **137** with a peroxy acid gave epimeric mixtures of spirooxiranes **139a,b**, respectively. Their subsequent hydrolysis with aqueous perchloric acid gave 6-hydroxymethyl-1,4,6-trienes **141a,b** along with epimeric 6-hydroxy-6-hydroxymethyl derivatives **140a,b**.¹²⁴

$R^1, R^2 = \text{O}$ (**136**, **139a–141a**); $R^1 = \beta\text{-OH}$, $R^2 = \text{H}$ (**137**, **139b–141b**);
(a) MCPBA, CH_2Cl_2 , 20 °C, 48 h (80%); (b) HClO_4 , THF, 20 °C, 3 h.

The Jones oxidation of 6 β -hydroxymethyl-AD **135** gave 6 β -carboxy-AD **142**, while selective reduction of the diketone **135** with sodium borohydride gave the 17 β -hydroxy derivative **143**.¹²⁴

(a) CrO_3 , H_2SO_4 ; (b) NaBH_4 , MeOH.

A series of 6-methyl-substituted AD and ADD have been synthesised. Thus 6-methylene-AD **138** was isomerised over Pd/C into a 4,6-didehydro-6-methyl analogue. Its dehydrogenation with DDQ gave 1,4,6-triene **144** in 50% yield, while reduction over Pd/C in the presence of cyclohexene as a hydrogen donor yielded 6 α -methyl-AD **145**. The latter was further dehydrogenated into 6 α -methyl-1,4-diene steroid **146**. Finally, oxidation of ADD with oxygen in the presence of alkali gave androsta-1,4-diene-3,6,17-trione **147**.¹²⁴ Preparation of the 2-fluoro derivative of exemestane is patented.¹³⁰

(a) $\text{CH}_2(\text{OEt})_2$, POCl_3 , CHCl_3 (60%); (b) 5% Pd/C, EtOH, Δ , PhCH_2OH (90%); (c) DDQ, dioxane, Δ , 15 h; (d) Pd/C, cyclohexene (60%); (e) O_2 , KOBu^t , Bu^tOH (15%).

Exemestane **136** is a highly selective irreversible AI. The irreversibility of its inhibitory action is assigned to the presence of a 1,2-double bond in the molecule;¹²³ the corresponding 1,2-hydrogenated analogues represent reversible AI. It is these properties rather than pharmacokinetic ones that account for the prolonged action of exemestane on the organism.¹²³

None of the synthetic exemestane analogues displays *in vitro* activity which would be equal or greater than that of exemestane itself. Thus the 17 β -hydroxy derivative **137** is active *in vitro*, but its activity is 2.6-fold less than that of compound **136**. According to their inhibitory activity, exemestane analogues modified at C(6) and having a 17-keto group can be arranged in the following order: 6-methylene (**136**) > 6-spirooxirane (**139a**) > 6 β -hydroxymethyl (**135**) > 6-hydroxy-6-hydroxymethyl (**140a**) > 6 β -carboxy derivative (**142**). 17 β -Hydroxy analogues of some of these compounds, e.g., **139b**, **140b** and **143**, manifest 3–8-fold lower activity than the corresponding 17-oxo compounds. Isomerisation or reduction of the double bond (leading to compounds **144** and **146**) decreases their inhibitory activity threefold in comparison with exemestane itself.¹²⁴

A series of 6-alkyl- and 6-aryl-substituted AD has been described and their inhibitory activity has been studied with the view of determining the topography of the hydrophobic binding pocket in the active site of the enzyme.^{131–134} The key compound in this synthesis was a mixture of isomers of 5,6-epoxide **149** obtained by epoxidation of androst-5-ene-3,17-dione diketal **148**. The opening of the oxirane ring with Grignard reagents gave 5 α -hydroxy-6 β -substituted androstanes **150**. Treatment of the latter with HClO_4 in THF gave the corresponding 3,17-diketones **151** in high yields. Dehydration of these hydroxy diketones with thionyl chloride in pyridine has led to a series of 6 β -substituted AD **152a–i**. Epimerisation of the 6 β -centre in 6 β -substituted Δ^4 -3-ketones **152** into thermodynamically more stable 6 α -isomers **145a–g** occurred in 16%–56% yields.^{131,132}

R = Me (a), Et (b), Prⁿ (c), Bu (d), Prⁱ (e), Ph (f), CH₂Ph (g),
CH=CH₂ (h), C≡CH (i).

(a) MCPBA, CH₂Cl₂, 20 °C, 4 h (a mixture of isomers ~ 1 : 1);
(b) RMgBr, THF, Δ (86%–98%); (c) 3M HClO₄, THF, 20 °C, 3 h;

Biochemical assessment of both 6 α -(**145**) and 6 β -(**152**) substituted AD has been carried out (Table 3). These compounds appeared to be competitive aromatase inhibitors with K_i ranging from 1.4 to 63 nM. Introduction of a methyl group into 6 α - and 6 β -positions of AD increases its affinity for aromatase. Introduction of an additional methylene group into position 6 of the steroid molecule changes its inhibitory properties. Thus 6 β -ethyl-AD **152b** had the highest K_i value (1.4 nM) in this series of compounds. Further elongation of the chain does not result in any significant alteration in the inhibitory activity. 6 α -Benzyl-AD **145g** and 6 β -vinyl-AD **152h** also manifest high activity. Bulky substituents, such as 6-isopropyl (**152e** and **145e**) or polar substituents, like 6 β -ethynyl-(**152i**), decrease the inhibitory activity (K_i = 21–63 nM). The activity of 6 β -substituted AD decreases in the following order: Et > Pr > CH=CH₂ > Bu > Me > Prⁱ > Ph > C≡CH > CH₂Ph, while that of 6 α -substituted AD decreases in the order: Et > Me > Prⁿ > CH₂Ph > Bu > Ph > Prⁱ. The stereochemistry of the C(6) atom affects the inhibitory activity. Thus 6 β -alkyl isomers possess greater affinity for the enzyme than the corresponding 6 α -isomers with the exception of 6 α - and 6 β -methyl analogues **145a** and **152a**. Exchange of the 6 β -ethyl substituent by the 6 β -vinyl substituent decreases the affinity of compound **152h** compared to that of compound **152b**. It was shown that there is a hydrophobic binding pocket in the active site of the enzyme in the β -region of position 6 of the steroid substrate. Judging by the data on the crystal structure of cytochrome P-450 and the inhibitory activity of steroid substrates of this series, the following sizes for the pocket have been proposed: length 6.27 Å, width 5.25 Å, height 7.74 Å.¹³¹ In 1995, Numazawa and Oshibe¹³¹ synthesised and assayed 6 α - and 6 β -alkyl-substituted AD with 5–7 methylene groups in the side chains. Their K_i values varied from 2.8 to 80 nM. The earlier structure–activity regularities were also confirmed for compounds of this series. Thus 6 β -pentyl-AD manifested the highest activity; further elongation of the chain sharply decreased the affinity.¹³³

The analysis of effects of the chain length and configuration of the alkyl substituent at position 6 of ADD analogues¹³⁵ on their inhibitory activity is an extension of earlier studies.^{131, 133}

Table 3. Data on *in vitro* inhibition of aromatase from human placenta by 6-substituted androstanes.

^a Symbols + and — denote the presence and absence of the double bond in this position, respectively.

The 6 α - and 6 β -alkyl-substituted ADD **146a–g** and **153a–g** were obtained by dehydrogenation of their Δ^4 -3-keto precursors.

Compounds **146a–g** and **153a–g** appeared to be competitive AI with K_i ranging from 4.7 to 54 nM (see Table 3). Among those, only 6 α -ethyl-ADD **146b** is the suicide AI. 6 β -Isomers manifest greater activity than 6 α -analogues. However, there was no correlation between the length of the alkyl chain and the affinity for the enzyme. The ability of 6 β -alkyl isomers to inhibit aromatase decreases in the following order: Et > (CH₂)₄Me > Pr > (CH₂)₆Me > (CH₂)₅Me > Bu > Me, which is consistent with the results obtained for 6 β -alkyl derivatives of AD.¹³³ The activity of 6 α -isomers of alkyl-substituted ADD **146a–g**

decreases in the order: (CH₂)₄Me > Bu > Et > (CH₂)₆Me > Pr > (CH₂)₅Me > Me, which does not match that for 6 α -alkyl-AD.¹³³ Based on the experimental data and the results of molecular modelling studies, Numazawa *et al.*¹³⁵ assumed that at least 6 β -alkyl-ADD **153** can bind with the same hydrophobic pocket in the active centre of aromatase as does the corresponding 6 β -alkyl-AD **152**.

6-Hydroxyimino-AD **160** and its 17 β -hydroxy analogue **161** are competitive AI.¹³⁶ The key derivative **158** was obtained by standard methods from 3,17-diacetate **154** via 5 α ,6 α -epoxide **155** with its subsequent oxidative conversion into 5 α -hydroxy-6-ketone **156** with chromic anhydride. Dehydration of the latter and hydrolysis of 3,17-acetoxy groups in Δ^4 -6-ketone **157** gave the dihydroxy derivative **158** in high yield. Treatment of the latter with hydroxylamine hydrochloride resulted in the (*E*)-oxime **159**; its oxidation with chromic anhydride in pyridine gave 6-hydroxyimino-AD **160** in 70% yield. Oxidation of oxime **159** with manganese dioxide under mild conditions resulted in the testosterone derivative **161**.

(a) MCPBA, CH₂Cl₂; (b) CrO₃, H₂O; (c) SOCl₂, Py (90%); (d) KOH, MeOH (82%); (e) NH₂OH·HCl (75%); (f) CrO₃–Py (70%); (g) MnO₂, CHCl₃, 20 °C (45%).

5. 7-Substituted and 6,7-disubstituted androstanes

The key stage in the synthesis of 7-substituted androstanes is 1,6-conjugate addition of the corresponding reagents to 6-dehydro derivatives of AD and ADD. Thus 7 α -thio-substituted ADD **162**, one of the first highly active 7 α -substituted androstanes, was obtained in 14% yield by addition of *p*-aminothiophenol to 6-dehydro-ADD **115**.¹³⁷

R = H (a), NH₂ (b), I (c), OMe (d), N₃ (e).

This is accompanied by the formation of its inactive 2 α -isomer **163** (yield ~ 40%). The attempts to improve the regioselectivity and to increase the yield of 7 α -substituted compound **162** by changing the reaction conditions (solvent, temperature and reagent ratio) failed.¹³⁷

Further transformations of 7 α -(*p*-aminophenylthio)-ADD **162** have led to its analogues with bromine or iodine atoms in the *para*-position of the aryl substituent. 7 α -Naphthalene derivatives **164** and **165** are also described.¹³⁸ All these steroids are irreversible suicide AI (*K*_i = 12–27 nM).¹³⁸ According to the patent,¹³⁹

7 α -alkyl(acyl)thio- and 7 α -mercapto-ADD are highly active preparations for *in vivo* treatment of mammary tumours.

7 α -Arylthio-substituted AD **166a–e** were obtained by analogous addition of substituted thiophenols to 6-dehydro-AD.²⁴ The activity of the steroid **166b** was twice as low as that of its ADD analogue **162**. The steroid **166e** (K_i = 1 nM) was the most efficient in this series (Table 4).^{25, 140}

The compounds described above contain an aryl substituent which is linked to the steroid skeleton by the C–S bond. It was found, however, that the presence of a sulfur atom and the stereochemistry of the C(7) atom are not essential for the manifestation of activity, since 7 α - and 7 β -substituted AD **170a,b**, **171a,b** and **173a,b** with one or several methylene groups between the steroid skeleton and the phenyl substituent appear to be efficient AI.¹⁴¹

These androgens with arylaliphatic substituents were obtained by the same approach as that used for 7 α -thio-substituted compounds described above. The silylated testosterone derivative **167** was used as the starting compound. Introduction of a phenylethyl or a phenylpropyl substituent was carried out by addition of the cuprate reagent prepared from the corresponding lithium reagent and 1 equiv. of copper(I) tetrakis(tributylphosphine) iodide. Subsequent addition of 0.2 equiv. of the steroid **167** and deprotection gave the desired 1,6-addition products as mixtures of α,β -diastereomers **168a** and **169a** (71%, $\alpha:\beta$ = 2 : 1) or **168b** and **169b** (50%, $\alpha:\beta$ = 1 : 1) isolated in the individual state by chromatography. The structure of the 7 α -isomer **168a** was additionally confirmed by X-ray analysis. Oxidation of 17 β -alcohols **168a**, **169a**, **168b** and **169b** gave 17-ketones **170a**, **171a** and **171b**, respectively. 7 α - And 7 β -benzyl derivatives **172** and **173** were obtained in a similar way.

7 α -Substituted AD **170a,b** and **173a** are efficient competitive AI with K_i 13–19 nM. The corresponding 17 β -alcohols **168a,b** and **172** as well as 7 β -substituted AD **171a,b** and **173b** are less active (K_i = 36–44 nM). Thus, introduction of bulky aryl-aliphatic substituents into position 7 of AD favours high inhibitory activity. It was found that the length of the carbon chain between the steroid and the aryl group does not significantly affect the activity, thus indicating the presence of a bulky pocket in the active site of the enzyme near position 7 of the steroid substrate.

According to patent data,¹⁴² 7 α -allyl-AD **174** synthesised from the corresponding 17 β -acetoxy-androsta-4,6-dien-3-one is a rather active AI.

(a) $\text{H}_2\text{C}=\text{CHCH}_2\text{SiMe}_3$, TiCl_4 , CH_2Cl_2 , -70°C ; (b) HC/MeOH ; (c) PCC.

Disubstituted 4-phenoxy-7 α -phenylthio-AD **179** has been synthesised in order to explore the nature of the binding site of aromatase in the vicinity of the C(4), C(6) and C(7) atoms of AD.⁸⁰

(a) CuI , Bu_2S , MeLi , Et_2O , -78 to 20°C ; (b) Et_2O , THF , Py , -78°C ; (c) PhI , Δ (55%); (d) $\text{CH}(\text{OEt})_3$, $p\text{-TsOH}$, 20°C , 24 h; (e) DDQ (5%) aqueous Me_2CO , 20°C , 3 min (50%); (f) PhSH , Na , dioxane, 60°C , 8 h (40%).

The starting compound in this synthesis, 4-OHA **91**, was converted into the 4-phenoxy derivative **176** via the intermediate copper enolate **175** (yield > 50%).⁸¹ The formation of the necessary 6,7-double bond was achieved by treating the ether **177** with an equimolar amount of DDQ in aqueous acetone. Addition of thiophenol to $\Delta^{4,6}$ -4-phenoxy-AD formed completes the synthesis of the 4-phenoxy-7-phenylthio-substituted compound **179**. However, its inhibitory activity was much lower than that of the monosubstituted analogues, viz., 4-phenylthio- (**98d**) and 7 α -phenylthio-AD **166a**. These results together with molecular modelling data for all the three compounds have led Liu *et al.*^{80,81} to infer the existence of a single hydrophobic pocket in the active site of aromatase in the vicinity of the C(4) and C(7) atoms of the steroid substrate.

In conclusion, it is appropriate to mention the synthesis of 6,7-disubstituted androstanes. Thus 6,7-epimino-AD¹⁴³ represent a practically novel class of derivatives. The key compounds in this synthesis are 7 α -azido-6 β -hydroxy- (**181**) and 6 β -azido-7 α -hydroxy-AD **184** (Scheme 7). Treatment of 4,6-dienedione **180** with sodium azide and chromic anhydride in acetic acid gives the azido alcohol **181**, which was converted into 6 α ,7 α -aziridine **182** in 80% yield upon heating with 2 equiv. of triphenylphosphine in toluene. Epoxidation of 6-dehydro-AD **180** with *m*-chloroperbenzoic acid in boiling chloroform gave the 6 α ,7 α -oxide **183**; its diaxial opening in 6 β -azido-7 α -hydroxy-AD **184** occurred in high yield and was performed by treatment of an equimolar mixture of sodium azide and concentrated sulfuric acid in DMSO. Reaction of the azide **184** with triphenylphosphine in toluene gives 6 β ,7 β -epimino-AD **185**.

The β -configuration of its three-membered ring was confirmed by ^1H NMR spectral data and by independent synthesis,

Scheme 7

H_2SO_4 , DMSO , 20°C (84%); (e) $\text{ClF}_2\text{CCO}_2\text{Na}$, diglyme Δ , 5 h; (f) $(\text{CH}_2)_2\text{SH}$, $p\text{-TsOH}$, AcOH , 20°C , 24 h (77%); (g) $\text{Na}-\text{NH}_3$, THF , 0.5 h (40%).

viz., by reduction of 7-mesylate **190a** with lithium aluminium hydride. The stereochemical aspect of the formation of steroids **182** and **185** deserves mention: in each case, the corresponding azido alcohol yields only one isomer with the aziridine ring configuration identical with that of the azido group.

The compounds obtained appeared to be weak aromatase inhibitors; only 6 β -azido-7 α -acetate **190b** manifested moderate inhibitory activity.^{143, 144}

This section is finished with a description of a series of 6 α ,7 α -cyclopropaandrost-4-en-17-ones.^{145, 146} Addition of difluorocarbene generated from sodium difluorochloroacetate to 6-dehydro-AD **180** gave 6 α ,7 α -difluorocyclopropane-AD **186**. Reduction of its 3-ethylenedithio derivative **187** with lithium in ammonia gave a mixture of 3-deoxy-6 α ,7 α -cyclopropaandrost-4-en-17-one **188** and its 17 β -hydroxy derivative **189**. These compounds proved to be efficient competitive AI,¹⁴⁵ the cyclopropane derivative **188** ($K_i = 5$ nM) being the most active one. However, introduction of a 6 α ,7 α -difluorocyclopropane group into the AD molecule (compound **186**) did not affect considerably its affinity for the enzyme. This suggests that it is the keto group at position 17 of AD that plays the crucial role in the binding of the steroid with aromatase.

A recent study¹⁴⁷ devoted to the synthesis and biochemical assay of compound **191**, yet another representative of substituted androstanes obtained by the base-catalysed Michael addition of 2-aminothiophenol to 3,17-diacetoxyandrost-4-en-6-one with subsequent cyclisation, is also worth mentioning. Compound **191** manifested weak inhibitory activity of a competitive type ($K_i = 42$ 300 nM).

IV. Structure–activity relationships in substituted androstanes as aromatase inhibitors

The data considered in Section III and those listed in Tables 1–4 allow one to make certain conclusions about the structural requirements for steroid substrates to act as aromatase inhibitors. Although the substituted androstanes described above are rather diverse in nature and mechanisms of their inhibitory action have hitherto been studied relatively little, one may note some general regularities concerning the relationships between their structure and inhibitory activity judging mainly by the affinity for the enzyme and inhibitory properties of a series of similarly substituted androstanes. According to Cole and Robinson,¹⁵ efficient AI have two domains which play an important role in binding of the steroid substrate with the enzyme, namely, an iron-coordinating domain and a hydrophobic domain. The structural requirements for the latter are considered to be a crucial factor, although chemical details of its specificity are unknown.

The introduction into, or removal from, certain positions of the AD molecule of definite substituents and/or additional double bonds affect the inhibitory activity as indicated by arrows in Fig. 1.

The steroid molecule must contain at least one keto group, specifically at position 17 to manifest aromatase-inhibiting activity. All substituted androstanes sharply decrease their activity as AI upon reduction of the 17-keto group to the hydroxy group and especially following its esterification. Evidently, in some cases the carbonyl function at position 3 is not strictly required as a structural element, because, as has been shown in the preceding

Figure 1. The functional groups affecting the inhibitory activity and their position in the AD molecule. The arrows directed towards a specific position denote enhancement of activity, those directed from this position denote decrease in activity.

section, some 3-deoxy analogues retain high inhibitory activity.^{14, 33, 35, 36, 145} Moreover, replacement of the 3-keto group in AD or in 19-substituted AD by a 3-methylene group (or a halogenomethylene group) affords compounds possessing high competitive inhibitory activity.^{148, 149} The study of inhibitory activity of androst-4-ene-3,6,17-trione and its 3-hydroxy analogue revealed that both of them can irreversibly bind with aromatase.^{150, 151}

An important role in manifestation of biological activity is played by the conformation of the ring A. For example, androst-2-ene-3,17-dione binds with aromatase very weakly, whereas its 4-dehydro isomer is an efficient AI with $K_i = 37$ nM.^{15, 145, 152} The presence of a substituent at position 10 of the steroid skeleton of AD is indispensable for activity. As has been shown in Section III, this substituent plays an essential role in the oxidation of the steroid substrate by the enzyme. Thus 19-nor-4-hydroxyandrost-4-ene-3,17-dione binds with aromatase but is devoid of inhibitory activity.^{15, 64}

Introduction of additional double bonds into the molecule of AD and its substituted analogues enhances their inhibitory activity. It is particularly true for 1,2- and 6,7-double bonds. It is assumed¹²³ that the presence of a 1,2-double bond in a steroid molecule is responsible for the irreversible type of inhibition and, correspondingly, for the long-lasting effect of AI *in vivo*.

Introduction of various substituents into the rings A and B (positions 1, 4, 6, 7 and 19) as well as alkylation or arylation of 4-amino-, -mercapto- or -hydroxy-androstanes are the most common structural modifications. High affinity for the enzyme has been noted for steroid AI with small substituents at C(1), C(4) and C(19) and with bulky substituents at C(7). Introduction of hydrophobic substituents is a general trend in the design of efficient AI, although the optimal volume and position of functional groups are often difficult to predict.

2 α -Substitution and involvement of the C(6) and C(7) atoms in the formation of a three-membered heterocycle have a negative effect.^{14, 19}

Thus, studies of structure–activity relationships of steroid AI and their interactions with the active site of aromatase provides valuable information about the nature of the enzyme and allows one to gain better insight into the mechanism of action of this enzyme. Investigation of this mechanism is far beyond the scope of the present review; it is evident, however, that the synthesis and analysis of activity of various series of steroid AI represent a step on the way to its elucidation.

V. *In vivo* activities and applications of major steroid aromatase inhibitors

As can be seen from Tables 1–4, highly efficient AI usually have similar K_i which are close to the lower limits of sensitivity (0.5–1.0 nM). The possibility of their practical application will further be determined by their biological properties *in vivo*, pharmacological and pharmacokinetic characteristics, the pres-

ence or absence of side hormonal effects typical of some steroids of the androstane series, and, naturally, by the methods of their synthesis and the possibility of scaling.

This section considers pharmacological activities and clinical applications of several major substituted androstanes the properties of which have been studied in sufficiently great detail. Owing to their antitumour activity, some of these steroid compounds, *viz.*, 4-hydroxy-AD **91**, 1-methyl-ADD **121** and 6-methylene-ADD **136**, have found wide use in the clinical practice. The former known under the trade name formestane is already used in the therapeutic practice, while the other two are undergoing clinical trials. Besides, there is ample literature evidence concerning the pharmacological activity of another two AI. The first of them, 19-ethynyl-AD **1** (promestane), manifests high activity in inhibiting ovarian aromatase on oral administration and efficiently reduces mammary and ovarian tumours in both experimental models and the clinic.^{15, 36, 37} The synthetic 'Organon' product, 19-ethyldithio-AD, possesses very weak androgenic activity but very efficiently inhibits estrogen biosynthesis *in vivo*.^{43, 44} Antitumour activities of these AI have been surveyed recently.^{21, 153, 154}

4-Hydroxy-AD (**91**, formestane) was designed in 1984 by the 'Ciba-Geigy' company for treatment of post-menopausal mammary tumours in women and is now commercially available in Great Britain, Germany, Austria and some other countries.⁷¹ Some patents issued by the 'Schering AG' company deal with their application in the therapy of benign prostatic hyperplasia.^{65, 155}

Studies of formestane effects on human placenta aromatase revealed its high inhibitory activity.^{62, 64} Formestane produced a significant antitumour effect in rats with experimental mammary tumours.^{36, 70, 87} This inhibition is highly selective.⁶³ However, there is evidence that formestane also inhibits 5 α -reductase.^{69, 156}

One main disadvantage of formestane reported by some authors^{48, 67, 88, 98, 157} is its low bioavailability and short-term effect. Since this drug is highly active on subcutaneous administration,⁹ it is normally used in the form of injections. The results of clinical trials of this drug in patients with mammary tumours (500–1000 mg weekly, *i.m.*) testify to its high efficiency.^{157–160} According to the experimental protocol elaborated for IIInd phase of clinical trials, formestane injected once or twice a week causes partial or complete remission of the tumour.^{66, 68, 158, 159} This drug is generally well tolerated and produces only nonspecific side effects. One should mention in this connection that replacement hydrocortisone therapy was necessary for patients receiving formestane for a prolonged period, since this drug inhibits pregnenolone biosynthesis and, as a consequence, biosynthesis of corticosteroids.^{67, 161}

According to the literature data, atamestane and exemestane have no such shortcomings. Comparative characteristics of *in vivo* activities of formestane, atamestane and exemestane and analysis of mechanisms of their action in animals have been documented.^{9, 69}

1-Methyl-ADD or atamestane was designed by the 'Schering AG' company in 1983¹⁰² and patented in more than 30 countries. The main objective of its clinical trials initiated in 1986 in Europe and Japan was to estimate its efficiency in the treatment of mammary tumours and endometriosis in women and of benign prostatic hyperplasia in men. As mentioned above, atamestane is a selective irreversible inhibitor of estrogen biosynthesis *in vitro* and *in vivo*. Studies in rats revealed that its activity exceeds that of formestane almost 1.5-fold;^{102, 162} according to other data, its effect is weaker than those of formestane and exemestane.⁹ DMBA-induced mammary tumours in rats reduced appreciably after subcutaneous administration of atamestane (30 or 150 mg per kg per day).¹⁰³ Neither atamestane nor its main metabolites, *viz.*, 5 β - and 17 β -reduced compounds, manifest any affinity for steroid receptors, which correlates with the endocrine-pharmacological profile of this drug.¹⁰⁴ *In vivo* studies failed to detect estrogen, anti-estrogen, androgen, progestane or antigonadotropic activities in atamestane.¹⁰⁵ As the affinity of atamestane for enzymes responsible for steroid biosynthesis in adrenal glands

is negligibly small in comparison with its affinity for aromatase, it does not exert any appreciable influence on these glands even when used in high doses and upon prolonged administration. This finding has been confirmed experimentally.¹⁰⁵

As has been mentioned above, atamestane has been recommended for treatment of benign prostatic hyperplasia.^{154, 163} Along with other factors, estrogens play an important role in the etiology of this disease. Apart from the finding that the incidence of this disease correlates with a shift of the androgens/estrogens ratio towards estrogens upon ageing in males, the presence of the estrogen receptor meeting the classical criteria has also been demonstrated by Habenicht *et al.*^{164, 165} The role of estrogens in the pathogenesis of this disease revealed in animals has been confirmed by clinical tests.¹⁶⁴ The results of successful clinical trials of atamestane administered in an oral dose of 200 mg 3 times daily for 3 months in the endocrine therapy of benign prostatic hyperplasia were published several years ago.¹⁶⁶ The use of atamestane in the form of tablets for increasing testosterone content in the organism has been patented.¹⁶²

Exemestane **136** has also been recommended for clinical use. This preparation was designed in 1988 by the Italian company 'Farmitalia Carlo Erba' and tested in many countries of the world as an independent therapeutic agent for treating estrogen-dependent tumours, especially post-menopausal mammary tumours in women. The choice of exemestane is based on its pharmacological properties which characterise this drug as a highly active (on oral administration) selective AI.^{9, 97} Studies in animals revealed long-term inhibition of ovarian aromatase on subcutaneous and oral administration.^{9, 97, 167} The activity of exemestane exceeds that of formestane twofold on subcutaneous administration and 27-fold on oral administration.¹²³ This drug does not manifest any affinity for the majority of steroid receptors with the exception of its weak binding with the androgenic receptor; the androgenic activity of exemestane was as low as 10% of the testosterone activity.^{98, 123} The results of endocrinological clinical trials of small doses of exemestane published in 1995 testify to a long-term selective decrease in estrogen levels and good tolerance of this drug.^{168, 169} The antitumour effect of exemestane has been studied in a model of DMBA-induced rat mammary tumours.¹⁶⁷ Subcutaneous or oral administration of exemestane caused partial or complete remission of the tumour.^{123, 124} Exemestane has a specific action on women: it does not influence the levels of hydrocortisone, aldosterone, 17-hydroxyprogesterone and luteinising and follicle-stimulating hormones even when used in very high doses.¹²³ The composition of tablets containing exemestane¹⁷⁰ and designed for the treatment of mammary tumours and the use of this AI as a component of a combined preparation for prophylaxis and treatment of benign prostatic hyperplasia have been patented.¹⁵⁵

VI. Conclusion

Thus, substituted androstanes are aromatase inhibitors in their pharmacological effect and antitumour agents in the mode of action. They may compete successfully with other drugs and are sometimes indispensable in the treatment of hormone-dependent tumours. Special mention should be made of the relative simplicity of synthesis of these preparations from industrially available steroid sources.

Analysis of methods used for the synthesis of AI together with detailed studies of their activity *in vitro* and *in vivo* give a strong impetus to the design of new efficient drugs and the development of methods for their synthesis and offers a possibility to choose the most efficient drug in each concrete case.

Abstract. Data on catalytic antibodies as a new generation of biocatalysts are reviewed. The principles used in the design, and the methods for the preparation of all presently known classes of catalytic antibodies, which catalyse particular conversions of organic compounds, are discussed. Data on the efficiency, regio- and stereospecificity and mechanisms of action of catalytic antibodies are presented and their possible applications in fine organic synthesis are considered. The bibliography includes 124 references.

I. Introduction

Elaboration of an immense variety of methods designed for the formation of the carbon skeleton and its directed functionalisation makes it possible currently to obtain organic compounds of virtually any degree of complexity. Usually, the synthesis of structurally complex compounds is accomplished in several steps. The efficiency and unambiguity of each of these steps are the two crucial factors that determine the success of the synthesis. The efficiency of the reaction is characterised by its rate and the product yield, while its unambiguity is characterised by its regio- and stereospecificity. This enables one to achieve the maximum degree of purity of the target compound and to avoid tedious isolation and purification procedures. The progress in fine organic synthesis and the access to more and more complex structures necessitates enhancement in reaction efficiency and specificity. However, the use of purely chemical approaches in multistep syntheses is often insufficient. Recent trends are towards the use of enzymic reactions for the formation of the carbon skeleton and its functionalisation at particular stages of the synthesis.

The use of enzymes often makes it possible to carry out the reaction at higher rates and to achieve higher degree of purity of the reaction products due to high regio- and stereoselectivity of

enzymes. Therefore, the methods of enzymic and chemoenzymic synthesis are becoming more and more popular in the routine practice of fine organic synthesis. However, low availability of natural enzymes endowed with the desired activity and specificity is an obstacle for the wide application of biosynthetic procedures. This demands additional tedious work aimed at a search for suitable and accessible enzyme sources, elaboration of methods for isolation and purification of the enzymes and detailed analysis of their specificity. Therefore, the laboratory and industrial use of natural enzymes that catalyse definite chemical conversions is rather limited.

Preparation of artificial enzymes with high efficiency and, which is the most important, with high predetermined selectivity has long been the dream of organic chemists. Such enzymes have to be prepared in a laboratory to be used for accomplishment of a particular reaction. Such artificial enzymes, which are endowed with predetermined specificity (the so-called 'tailor-made enzymes'), would make it possible to enhance considerably the efficiency of organic synthesis and open up new ways to the synthesis of novel classes of organic compounds.

Natural enzymes are high-molecular-weight proteins possessing a unique structure. Their catalytic activity and the selectivity of their action are determined by the strictly specific amino acid sequence of the protein chain. This, in turn, predetermines the conformation of the protein molecule and, ultimately, the formation of the spatial structure of the active site of the enzyme.

Directed synthesis might be considered as the simplest way to obtain an artificial enzyme. However, despite the generally acknowledged progress in synthetic protein chemistry, this approach is fairly inefficient not only because it is labour-consuming but because it requires information about the primary structure of the target enzyme. However, determination of an amino acid sequence is by itself a complicated and labour-consuming task.

The solution of this problem came from the use of a different approach to the preparation of artificial enzymes with predetermined specificity. This is based on the biosynthesis and rests on tremendous potentialities of the cell immunological apparatus, which can produce a great variety of protein molecules.

It is well known that a specific feature of the immune system of animals is its ability to synthesise antibodies, *i.e.*, protective

proteins that 'neutralise' alien molecules and more complex entities (the so-called antigens) getting into the organism. The immune system generates a protein molecule of an antibody the structure of which relates to the structure of the antigen in such a way that the active site of the antibody appears to be complementary to the specific part of the antigen called the hapten. The antibody forms a rather stable complex with the antigen and thus 'neutralises' its effect. In other words, the biosynthetic apparatus of the immune system provides the synthesis of the protein molecule in which the active site is formed, the structure and spatial configuration of which are predetermined by the structure of the antigen administered to the organism. It is this principle that is being employed in the synthesis of artificial enzymes.

According to the current views, the catalytic effect of a natural enzyme consists primarily in the facilitation of the transition of the reaction substrate from the ground state to the excited transition state. The latter is stabilised in the active site of the enzyme to be further converted to reaction product(s). Therefore, the formation of an active site promoting the generation and stabilisation of the transition state of the substrate is a prerequisite for manifestation of catalytic activity by the protein molecule. Thus, the biosynthesis of the antibody possessing catalytic activity by the immune apparatus requires the use of an antigen the structure of which mimics the transition state formed in the catalytic reaction. It is impossible, however, to obtain a stable molecule corresponding to the transition state, since the latter represents an unstable complex. For this reason, only compounds the molecules of which mimicked the spatial and electronic structure of the transition state were used as antigens generating catalytically active antibodies. Being incorporated into immune cells, such antigens ought to generate antibodies that stabilise the transition state and, hence, manifest catalytic properties like the natural enzymes.

Although this idea was first forwarded long ago,^{1,2} its practical implementation faced serious difficulties because immune cells synthesise a great number of antibodies ('polyclonal antibodies') in response to antigens. Isolation of an antibody manifesting the highest catalytic activity and selectivity from a complex mixture of structurally similar proteins is very problematic, which made this method impracticable.

The situation has changed totally with the discovery and detailed development of the method of synthesis of the so-called 'monoclonal antibodies' that are fewer in number and less diverse.³ The antibodies isolated with recourse to this method did manifest catalytic activity.

Such antibodies, which were named 'catalytic antibodies' (CA) or 'abzymes' (abbreviated from 'antibody enzymes'), were first synthesised about 10 years ago.^{4,5} This area continues to develop rapidly since that time. By now, nearly a hundred CA that accelerate and specifically direct various reactions have been generated and the basic principles underlying the preparation of CA with predetermined specificity have been formulated. Their physicochemical characteristics appeared to be similar to those of the natural enzymes.

In some cases, the activity of CA was close to that of the natural enzymes. As a rule, these CA manifested high specificity and stereoselectivity which might be predetermined. Moreover, several CA were prepared that catalysed reactions (e.g., the Diels–Alder reaction) for which natural enzymes had not been found. What is most remarkable and promising for synthetic chemistry is that CA could be obtained which made it possible to change the direction of a known reaction and to channel it through a route which is energetically forbidden under normal non-catalysed conditions. In other words, it was possible to change chemo-, regio- and stereospecificity of the reaction and to implement conversions unattainable with conventional chemical methods.

Hence, 'catalytic antibodies' represent a new generation of protein biocatalysts, and their preparation is a considerable step forward in theoretical and practical aspects of biocatalysis.

In this review, which encompasses the literature up to 1997, the main attention is given to the chemical aspects of the problem and the prospects of application of CA for the solution of current tasks of synthetic chemistry. As for other aspects, such as enzymic kinetics of CA and some other physicochemical problems, they are reviewed only briefly and where appropriate, e.g., in relation to the specificity of CA, the structure of their active sites and the mechanisms of their catalytic action. The readers who are interested in this problem as well as in the problems of immunochemistry and molecular biology of the catalytic antibodies may be referred to the original literature.

II. The basic principles and techniques used in the synthesis of catalytic antibodies

The essence of action of catalytic antibodies, like that of ordinary enzymes, is facilitation of the formation of the transition state of the substrate molecule to favour its conversion into the reaction products. This is accompanied by a decrease in the energy barrier on the reaction coordinate during the formation of the transition state, so that the reaction rate increases. This is a result of several specific interactions occurring in the active site of the enzyme. The cavity of the latter matches the spatial structure of the substrate. The active site contains active groups in its surface favouring the corresponding conversions of the substrate molecule. The spatial and electronic complementarity of the active site and the substrate favours the 'recognition' of the substrate by the enzyme and the formation of the enzyme–substrate complex, while the active groups enable the conversion of substrate molecules into the reaction products which involves acid–base catalysis, nucleophilic or electrophilic interactions, etc.

As the enzyme–substrate complex is formed, the mobility of the substrate molecule is restricted, and the latter becomes 'fixed' in a conformation which is the most favourable for further conversions. This provides a significant gain in energy and creates the so-called 'entropic trap'. This catalytic effect is especially important for bimolecular reactions, where both interacting molecules are fixed in a reciprocal position favourable for the reaction. Other factors, such as the presence in the active site of hydrophobic zones favouring substrate conversions in non-polar aprotic ('non-aqueous') media, also play a substantial role in the manifestation of the catalytic effect.

In order to obtain an effective catalytic antibody (CA), it is necessary that its active site possesses the properties characteristic of the active site of the enzyme (see above), which ensures the manifestation of the catalytic effect.⁶ This task is accomplished by an antigen, which induces the formation of the active site of a desired structure during the biosynthesis of the protein molecule by the immune apparatus of the cell in response to administration of the antigen.

The antigen used to obtain CA usually consists of two main fragments: a low-molecular-weight hapten and a high-molecular-weight carrier, usually, an available natural protein. It is the hapten that represents the fragment of the antigen molecule which is directly involved in the formation of the active site of CA. Its spatial and electronic structures must correspond to the transition state of this reaction and enable the formation of active groups, hydrophobic zones, etc., in the active site.

The protein fragment of the antigen (the so-called 'immunogen') is a high-molecular-weight carrier that ensures the generation of antibodies by the immune apparatus. Some available natural proteins, such as hemocyanin from the mollusc *Megatura crenulata* (keyhole limpet hemocyanin, KLH) or bovine serum albumin (BSA), are the most popular immunogens.

It is the proper choice of the hapten that is the key factor determining success in the preparation of CA. Naturally, the correct design of a hapten requires knowledge of the structure of the transition state, the pathways of its induction and subsequent decomposition, in short, a knowledge of the reaction mechanism. A number of CA catalysing many reactions which occur by

different mechanisms have been prepared. However, it is impossible to formulate general recommendations concerning the design of a hapten. The reasoning behind the choice of a hapten structure will be given below for each concrete case.

Sometimes, the choice of a hapten is semi-empirical because of the lack of exact knowledge of the reaction mechanism. In such cases, researcher's experience and even intuition come to the foreground. Thus in the early studies, a somewhat simplified concept of the correlation between the spatial and electronic structures of the hapten and the structure of the transition state have played a crucial role. This sufficed to prepare the first efficient CA. Mimicking of the transition state in the hydrolysis of the ester group by phosphoric or phosphonic acid groups provides an example (see Section III).

In addition to the main 'reactive' fragment, which is responsible for the formation of the active site of CA, the hapten must contain fragments providing the 'recognition' of the substrate by the antibody. This is achieved by incorporation into the hapten of groups analogous to those in the substrate. In addition, the hapten must contain a group which enables its immobilisation on the protein, so that the hapten fragment in the antigen is located at some distance from the protein chain. The role of such 'spacer' or 'linker' groups may be played by a short aliphatic chain having a terminal reactive functional group (*e.g.*, a carboxy group). In the immobilisation, the carboxy group of the spacer reacts with the amino group of the lysine residue of a protein and binds the hapten to the protein by a strong amide bond.

Normally, immobilisation of the hapten on the protein is performed under mild conditions that do not affect either the hapten or the immunogenic protein. The number of hapten molecules bound to the protein molecule depends on the immobilisation conditions. As a rule, the antigen synthesis is conducted so as to achieve binding of not less than 10–20 hapten residues per one protein molecule.

The antigen thus prepared is used for immunisation of animals (usually, inbred mice) using standard procedures⁷ which differ from one another in some details for different CA. As a rule, two or three immunisations (as intramuscular injections) are performed in the presence of an adjuvant (most commonly, Freund's adjuvant) followed by one intravenous injection without the adjuvant in order to enhance the immune response. After the lapse of a definite time, spleen cells of the immunised animal are removed to prepare monoclonal antibodies by the classical hybridoma technology.⁸ To this end, the spleen cells are 'fused' with myeloma cells in a polyethylene glycol solution. The hybridomas thus obtained are able to produce monoclonal antibodies against various fragments of the antigen molecule. From the total bulk of monoclonal antibodies, those generated against particular structural fragments of the hapten and able to form complexes with it due to complementarity of their structures are selected using the so-called enzyme-linked immunosorbent assay (ELISA).⁹ The hapten immobilised on BSA is used as a specific reagent. The formation of a hapten–antibody complex points to the complementarity of the structure of the active site of the antibody to that of the hapten (and, correspondingly, to that of the transition state of the substrate which had been mimicked by the given hapten). Such antibodies are likely to manifest catalytic activity. The ability of the selected antibody to catalyse a specific reaction is assayed in direct experiments.

In order to obtain large quantities of CA for further analysis, the appropriate hybridoma selected by the ELISA technique is repeatedly injected into experimental mice after which the target CA is isolated from the ascites fluid where it is present in a high concentration. The CA thus obtained is further purified by conventional methods of protein chemistry (precipitation, chromatography and electrophoresis).

Being a protein, CA completely loses its activity upon thermal treatment (denaturation) or this is changed following treatment with typical protein modifiers (iodoacetamide, diethyl carbonate, tetranitromethane, *etc.*).

Sometimes, the preparation of active CA requires more sophisticated and specific procedures. These may include sequential immunisation of mice with two antigens differing in the hapten structure (the so-called 'heterologous immunisation').¹⁰ This provides the formation of an active site which matches the features of both haptens and thus imparts a required specificity on CA. An alternative approach consists of the use of an antigen whose hapten not only is a stable model of the transition state generated in the course of the substrate conversion but can also interact with the active site of the CA formed in this process, thus reproducing the dynamics of conversion of the substrate molecule in the course of the catalytic reaction (the so-called 'reactive immunisation').¹¹

In their properties and behaviour, CA are typical proteins pertaining to the class of immunoglobulins. Their physico-chemical characteristics are close to those of natural enzymes. Thus the behaviour of CA in a catalytic process follows saturation kinetics and is described by the Michaelis–Menten equation. It thus follows that the catalytic effect of CA is based on the formation of the enzyme–substrate complex, which has been directly confirmed in mass spectrometric studies.¹²

The inhibition of the CA activity by the hapten or its analogues suggests that the cavity in the active site of CA is in fact complementary to the hapten used for its generation. Inhibitory analysis of CA is widely employed in the studies on the structure of the active site of CA and the mechanism of its catalytic effect. Quantitatively, the catalytic effect of CA is estimated by the ratio of the rate constants of the catalytic and non-catalytic (basic) reactions.

An important feature of CA is its specificity, which also includes stereoselectivity. Specificity of CA is established using a traditional approach, *viz.*, in reactions of structural analogues of the substrate, where the rates of their conversions and/or inhibitory effect in catalysis are determined.

In some cases, the structure of CA or its active site has been studied in more detail using X-ray structural analysis of CA itself or its complex with the substrate. These studies were mainly undertaken in order to elucidate the mechanism of action of CA at the molecular level, to compare the structure and mechanism of action of CA with those of the natural enzyme and to solve other enzymological problems with CA as the models.

In the subsequent sections, we shall consider the procedures used to prepare CA catalysing reactions of various types which are classified according to the principle conventionally employed in organic chemistry and familiar to organic chemists. The chronological order may not be strictly followed.

III. Hydrolysis of the ester bond and other transacylation reactions

Hydrolysis of the ester bond is the first example of a chemical conversion for which catalytic antibodies have been specially raised and the principles of selection of haptens, which are the 'active' parts of the artificial antigens used in generation of specific CA by biosynthesis in the immune apparatus of an animal, have been considered.

Success in the synthesis of these CA was achieved primarily due to the correct choice of a group mimicking the transition state **1** formed in the hapten in the cleavage of the ester bond (Scheme 1).

The RP(O)(OR')O group (**2**) in phosphoric or phosphonic acid derivatives, which contains a tetrahedral phosphorus(V) atom and bears a negative charge, mimicked the transition state **1** of the reaction of cleavage of the ester bond containing a tetrahedral carbon atom and bearing a negative charge.^{4,5}

R = Ar, OAlk, OAr.

The idea to use phosphoric or phosphonic acid derivatives came about also from the consideration of the known data on the structure of synthetic inhibitors of natural esterases, particularly of choline esterases.¹³ These inhibitors represent phosphate (or phosphonate) analogues of the corresponding substrates (*e.g.*, acetylcholine) with a phosphorus-containing group in place of the ester bond. They form complexes with choline esterase, which points to the complementarity of the phosphate group to the enzyme active site. It was found that some antibodies raised against such inhibitors manifested catalytic properties, *i.e.*, they enhanced the hydrolysis of the ester bond in the corresponding substrate. This confirmed the presence of the active site favouring hydrolysis. Thus the MOPS 167 antibody raised against the inhibitor of *O*-(4-nitrophenoxy)carbonylcholine (**3**) esterase formed a complex with this inhibitor (4-nitrophenylphosphorylcholine) (**4**) and possessed noticeable catalytic activity, *viz.*, it accelerated manifold the hydrolysis of the choline derivative **3**.⁵

This antibody manifested the features of natural esterases (Michaelis–Menten kinetics, inhibition by compound **4**, characteristic dependence of its activity on pH, *etc.*). Its catalytic effect was regiospecific, *viz.*, the hydrolysis of substrate **3** analogues with an altered structure of the aliphatic chain or devoid of the quaternary nitrogen atom was accelerated in a much lesser degree or not at all. These data suggest that the phosphorus-containing group efficiently mimics the transition state which appears in the hydrolysis of the ester bond and can generate the active site in the CA possessing esterase activity. This circumstance has been widely employed in further preparation of this type of CA.

Thus a 4-nitrophenyl phosphonate derivative (**6**) containing a tetramethylene fragment with a carboxy group as a spacer was used as a hapten[†] to raise a CA catalysing the hydrolysis of 4-nitrophenyl carbonate (**5**).¹⁴

Immobilisation of phosphonate **6** through this carboxy group made it possible to obtain an artificial antigen containing, on the average, 15 hapten residues per one protein molecule. This antigen was used for immunisation, and a CA was isolated which accelerated the hydrolysis of carbonate **5** 800-fold in comparison with the non-catalysed reaction. This CA manifested the properties of an esterase, *viz.*, its hydrolysis followed Michaelis–Menten kinetics, suggesting the formation of an enzyme–substrate com-

plex, and its activity showed a typical pH-dependence. This CA was inhibited by 4-nitrophenyl phosphate, the phosphate analogue of the substrate. Its effect was regiospecific, *viz.*, the rate of hydrolysis of 3-methyl-4-nitrophenyl carbonate was 10-fold smaller in comparison with the original compound, while the hydrolysis of isomeric 2-nitrophenyl carbonate was not catalysed at all.

Haptens with similar structures were used to obtain CA catalysing the hydrolysis of phenol esters. Thus the hapten **8** was used to raise CA catalysing the hydrolysis of the simplest *O*-acylphenols of the type **7**.

One of the CA prepared accelerated the hydrolysis of acylphenols more than 10⁴-fold.¹⁵ The hydrolysis of the ester bonds in nitrophenols **9** acylated with *N*-carboxyalkyl glutaramide, such as compound **9**, was accelerated 10⁴-fold in the presence of CA raised against the hapten **10**.¹⁶

The hydrolysis of structurally more complex substrates **11** (aminophenol esters with substituted aminophenylacetic acids) would be accelerated in the presence of CA raised against phosphorus-containing haptens, *viz.*, a benzylphosphonate derivative **12**.¹⁷

The structural similarity of the benzylphosphonic acid derivative to the acid moiety of the substrate allows more precise mimicking of the transition state of hydrolysis of the esters **11**. Several CA have been isolated from a mixture of antibodies raised against the hapten **12**. The most efficient of them accelerated the hydrolysis of the esters **11** 10⁶-fold and manifested all the features of the enzyme. Thus its activity changed after treatment with specific protein modifiers (diethyl carbonate, tetranitromethane, *etc.*). The activity of this CA strongly depended on the nature of substituents in the aromatic nuclei of the substrate **11**. It was inactive in the hydrolysis of carbonate **13** structurally similar to the esters **11**.

The problem of specificity of the CA of the esterase type is of considerable importance for their practical applications in the solution of synthetic tasks. This problem and the factors determining the specificity have been studied with the hydrolysis of nitrophenylacetates **14** as an example.¹⁸

[†] For the synthesis of this hapten and other compounds mentioned in this review, see the original papers.

R = Alk, Bn, O₂NC₆H₄CH₂, ClC₆H₄CH₂ etc.

To this end, the hapten **15** containing a 4-hydroxypiperidine residue (enhancing the antigen immunogenicity) and a spacer was synthesised.

A catalytic antibody raised against the hapten **15** appeared to be highly efficient. It accelerated the hydrolysis of the esters **14** (3×10^4 -fold, on average). The results of the kinetic analysis of hydrolysis of structurally different esters **14** revealed that the catalytic effect of CA was manifested only in the case of 4-nitro-substituted derivatives. The hydrolysis of the corresponding 3-nitro derivatives was not catalysed at all, which confirmed the previously established regularity.[‡]

This specificity allowed the hydrolysis of a mixed ester of 1,3-propylene glycol **16** to occur in a strictly selective manner.

The effect of the nature of the alcoholic component is much less pronounced. Thus CA catalyse the hydrolysis of esters **14** containing residues of various primary alcohols, although the rates of this hydrolysis vary from 10^4 to 10^6 . In contrast, the hydrolysis of the esters **14** containing residues of secondary alcohols is not catalysed at all, with the exception of 1,1,1,3,3,3-hexafluoropropan-2-ol derivatives.

High stereospecificity is one of the most distinguishing and important features of enzymic catalysis. This problem has received much attention in the studies of CA, and the generation of the first highly stereospecific CA has been a considerable achievement. For the first time, this has been studied in the preparation of a CA catalysing the hydrolysis of esters of substituted phenylacetic acid with α -methylbenzyl alcohol (**17**) containing a chiral carbon atom.²⁰ The hapten **18**, which is a phosphonate analogue of the substrate **17** and also contains an asymmetric carbon atom, was used to raise a specific CA.

The ester **18** was used as a racemate. Eleven active CA catalysing the hydrolysis of the esters **17** were obtained. Study of the hydrolysis of pure enantiomers **17a** and **17b** in the presence of these CA showed that nine of them catalysed the hydrolysis of the *R*-isomer, while the other two catalysed the hydrolysis of the *S*-isomer. A detailed analysis revealed that all of these CA manifested the characteristic properties of esterases and high

stereoselectivity. Thus the degree of hydrolysis of the enantiomer which corresponds to the specificity of the CA is 98%, while that of the other enantiomer is only 2%. The catalytic activity of stereospecific CA catalysing the hydrolysis of the *R*- and *S*-isomers is different. The catalytic antibody, which catalyses the cleavage of the *R*-isomer, accelerates the reaction 8×10^4 -fold (vs. 1.6×10^3 -fold increase in the case of the CA specific toward the *S*-isomer). Thus, the racemic hapten **18** generates CA manifesting two different stereospecificities and each of the enantiomers of **18** 'forges' the active site of CA with the complementary spatial structure. As has been mentioned above, the number of antibodies raised against each enantiomer of the hapten **18** is different due to the peculiarities of the protein chain biosynthesis in the immune apparatus.

Catalytic antibodies of different stereospecificities can be isolated in the individual state or be specifically generated using the corresponding optically pure hapten enantiomers. Such CA manifest high stereoselectivity and are used successfully in the synthetic practice, e.g., for kinetic resolution of mixtures of stereoisomeric alcohols by selective hydrolysis of their esters. For example, racemates of the fluorine-containing alcohols **19a** were resolved by hydrolysis of the corresponding phenylacetates **19b**.²¹ CA with predetermined stereoselectivity were generated using enantiomers of the hapten **20** having an *R*- or *S*-configuration.

R = H (**a**), COBn (**b**);

Alk = C₆H₁₃, C₇H₁₅, C₈H₁₇;

Alk_F = CHF₂, CF₃.

The hydrolysis of the racemic phenylacetates **19b** in the presence of these CA yielded the *R*- and *S*-isomers of the alcohols **19a** with optical purity 98%. It is noteworthy that the stereoselectivity of the resolution did not depend on the length of the aliphatic chain.

Kinetic resolution of the stereoisomeric alcohols **19a** containing the allylic group (Alk = CH=CHC₆H₁₃) was carried out in a similar way. With the use of CA against the enantiomers of the hapten **21** it was possible to isolate all the four isomers of the corresponding alcohols **19a** of high optical purity from a mixture of phenylacetates **19b** (Alk = CH=CHC₆H₁₃, Alk_F = CF₃).

The diastereomeric alcohols **22a** were resolved by the hydrolysis of their phenylacetates **22b** catalysed by the catalytic antibodies raised against the haptens **23** having *syn*- and *anti*-configurations.²²

R = H (**a**), COBn (**b**).

The catalytic antibody against the *syn*-isomer of **23** hydrolysed the *syn*-isomer of **22b** to yield the alcohol with optical purity 99% (the degree of hydrolysis was 49%), while CA against the *anti*-isomer of **23** hydrolysed the *anti*-isomer of **22b** with the same high degree of purity. The resolution of the alcohols HOCH(R_F)C(F)(Alk)CH₂OBn, which differed from compounds **22a** in the length of the aliphatic chain (Et, Pr and Bu substituents instead of the methyl substituent), occurred in a similar way. After

[‡] The specificity of antibodies against nitro-substituted substrates was established by Landsteiner¹⁹ at the dawn of development of immunochemistry.

X = O, NH; R¹, R² = H, Bn.

This CA hydrolysed only the ester bond (X = O) without affecting the peptide bond (X = NH) (chemoselectivity). It is noteworthy that this antibody exclusively catalysed the hydrolysis of the depsipeptide **35** containing the D-phenylalanine residue, whereas the depsipeptide containing the L-isomer was hydrolysed by no more than 0.5% (stereoselectivity). Evidence for the high regiospecificity of this CA followed from its inability to catalyse the hydrolysis of the depsipeptide **35** analogues in which leucine or tryptophan was substituted for the phenylalanine residue.[§]

All the above examples of preparation of CA are based on the use of substrate analogues as the haptens in which the ester bond was replaced by a residue of phosphoric or phosphonic acid and which mimic the transition state of ester hydrolysis. Catalytic antibodies against these haptens manifested chemo-, regio- and stereoselectivity. Haptens of this type are used in the synthetic practice most often and most successfully.

However, haptens of a different structure, among which haptens containing secondary alcoholic groups instead of the ester group in the substrate molecule are the most popular, can also be used for the preparation of CA possessing esterase activity.[¶] Although the mechanism of action of such haptens is not clearly understood, several active CA were raised against them. For the first time, a hapten of this type was designed by analogy with pepstatin, a well-known inhibitor of pepsin.²⁸ Thus preparation of CA catalysing the hydrolysis of 4-nitrophenyl carbonate **5** or the corresponding acetate **37** was based on the use of 7-(4-nitrophenyl)-6-hydroxyheptanoic acid (**38**) as a hapten.

The acid **38** contains the structural elements of the substrates **5** and **37**; its structure resembles that of the phosphorus-containing hapten **6** used to obtain CA with the same character of action (see p. 1002).

The catalytic antibody against the acid **38** accelerated the hydrolysis of the esters **5** and **37** 930- and 1225-fold, respectively. This CA displayed all the typical features of esterases, although its activity was much lower than that of CA generated against the phosphorus-containing hapten **6**. Nevertheless, this finding confirmed the possibility of using the secondary alcoholic group for mimicking the transition state of the hydrolytic reaction.

§ For the preparation of CA catalysing the hydrolysis of carbamates, see D van Vranken, D Panomitros, P G Schulz *Tetrahedron Lett.* **35** 3873 (1994); P Wentworth, A Datta, S Smith, A Marshall, L Partridge, G M Blackburn *J. Am. Chem. Soc.* **119** 2315 (1997).

¶ For attempts to use haptens of a different structure (e.g., containing the isosteric and isoelectronic CF₂ group) for preparing CA of the esterase type, see Ref. 27.

The use of haptens containing a positively charged group together with a secondary alcoholic group appeared to be more successful.²⁹ Thus a CA catalysing the hydrolysis of the ester bond in the benzoate **39** was raised against the hapten **40**.

It was assumed that the positive charge of *N*-methylpyridinium generated an acidic group (presumably, a carboxy group) in the appropriate position of the active site of the antibody, while the tetrahedral carbon atom of the secondary alcoholic group provided the formation of its spatial structure. The catalytic antibody raised against the hapten **40** was found to be highly efficient; it manifested activity close to that of natural esterases and accelerated the hydrolysis of the benzoate **39** 10⁶-fold. This was attributed to the fact that, in addition to the formation of the spatial structure of the active site, the hapten **40** induced the generation of a carboxy group which, in turn, facilitated the conversion of the substrate with the involvement of general acid–base catalysis. Indirect evidence for the presence of a carboxy group in CA and its role in the hydrolysis of the ester bond can be derived from the fact that the hapten **41**, the pyridine analogue of compound **40**, which is deprived of the positive charge, does not generate active CA.

Thus, the preparation of efficient CA requires not only the formation of an active site complementary to the transition state, but also the generation in the active site of groups favouring the very conversion of the transition state into the reaction products, e.g., involving general acid–base catalysis. This view was confirmed³⁰ in studies of the hydrolysis of the ester bond in compound **42** catalysed by CA raised against the haptens **43**. These CA accelerated the ester hydrolysis 3 × 10³-fold.

43a: R¹ = NH₂, R² = OH;

43b: R¹ = N⁺Alk₃, R² = OH;

43c: R¹ = N⁺Alk₃, R² = O—P(=O)(OH)₂.

A detailed study of CA generated against the haptens **43a–c** having different substituents using enzymic kinetics and, especially, inhibitory analysis has led to an important conclusion, viz., that the lack of catalytic activity in CA depends not only on insufficient binding of the substrate because of insufficient matching of the active site but, rather, on the arrangement of groups responsible for the dynamics of conversion of the transition state into the reaction products in the active site. Thus the number of active CA raised against the hapten **43a** containing an amino

group (it virtually functions as the H_3N^+ group) exceeds that of CA raised against the hapten **43b** containing a bulkier Alk_3N^+ group, because the access to the positively charged centre of the hapten is hindered, which impedes the formation of the carboxy group in the appropriate position of the active site. The presence of an additional charged phosphorus group in the hapten **43c** also impedes the formation of the active centre, which results in less active CA. Thus the activity of CA against the haptens **43a–c** is believed³⁰ to depend primarily on the reciprocal position of the charged groups in the 1,2-amino-alcohol fragment of the molecule. This circumstance must be taken into consideration in the design of haptens for highly efficient CA.

Attempts have been made to introduce certain groups aimed at increasing the efficiency of CA by the methods common for natural enzymes, *viz.*, by chemical modification and site-directed mutagenesis. The incorporation of a covalently bound imidazole residue into the active site of the antibody MOPS 315 possessing esterase activity³¹ is an example of such a modification, which resulted in an increase in the activity of the CA 10^3 -fold in comparison with that observed after mere addition of imidazole to the reaction medium in the same hydrolytic reaction.

All the examples cited above are related to the preparation of CA catalysing the simplest transacylation reaction, *i.e.*, the hydrolysis of esters where the acyl group is transferred to the water molecule present in huge excess. This reaction is of the pseudo-first order. In a wider sense, *O*-transacylation implies the transfer of an acyl residue to any hydroxy-containing compound and occurs according to a more complex mechanism.

The intramolecular transfer of the acyl group in the phenyl ester of the hydroxy acid **44** to the hydroxy group to yield the lactone **45** is the simplest example of the *O*-transacylation reaction.³²

The hapten **46**, which is a phosphate analogue of the lactone **45**, was used to obtain CA catalysing this reaction. Like other haptens used to raise CA of the esterase type, the phosphonate **46** used (in the form of one enantiomer) mimicked the transition state which appears in the lactonisation of the ester **44**. In the presence of a CA obtained, the reaction was accelerated 167-fold in comparison with the non-catalysed process; this occurred with high stereoselectivity and followed the Michaelis–Menten kinetics.

The cyclisation of the racemic ester **44** was terminated after conversion of 50% of the substrate to yield only one of stereoisomers of the lactone **45**, since only one enantiomer of compound **44** underwent conversion. The second enantiomer did not enter into the reaction. Thus, the enantiomer of the hapten **46** used has created the active site of CA complementary to only one of the enantiomers of the substrate. This CA can be regarded simultaneously as an enzyme promoting the formation of a new ester (lactone) bond and as a synthase.

In addition to CA catalysing the intramolecular transfer of an acyl group within the same substrate, some CA of the transferase type have also been obtained. These CA catalysed the intermolecular transfer of acyl groups from one substrate to another. The reactions occurring in aqueous media, *i.e.*, in the presence of large excess of water as the competing acceptor, present special interest.

The preparation and examination of CA catalysing such reactions were performed mostly with the view of investigating the reaction mechanisms, the practical aspect of their use for the solution of problems of organic synthesis was studied relatively little. The complexity of catalysis of two-substrate reactions lies in that they can follow two fundamentally different mechanisms, *viz.*, through the formation of a ternary complex ($\text{CA} + \text{substrate 1} + \text{substrate 2}$) or in a more complex way which involves several steps. Realisation of such reactions in aqueous media implies the formation of an additional active site in CA responsible for 'ejection' of a competing water molecule from the reaction sphere, *e.g.*, due to the presence of hydrophobic groups. This property must be 'preset' in the structure of the hapten mimicking the transition state.

A detailed study of one of such reactions, *viz.*, the selective transfer of 4-acetylaminophenylacetic acid from the esters **47** to substituted benzyl (**48**) and α -methylbenzyl alcohols (**49**) in the water–DMSO system (10 : 1), has been carried out.³³

$\text{R} = \text{Alk, Ar, Bn, CH}_2=\text{CH}.$

48: $\text{R}'' = \text{H}$, **49:** $\text{R}'' = \text{Me}.$

The corresponding CA was raised against the hapten **18**. This CA efficiently catalysed the transfer of the acyl residue not only to the water molecule (hydrolysis) (see p. 1003) but also to alcohols. The latter reaction is selective and unaccompanied by the hydrolysis of the ester **47** despite the presence of a large excess of water. Transacylation in a system of various acyl donors **47** ($\text{R} = \text{Alk, CH}_2=\text{CH, Ar, Bn}$) and acceptors (alcohols **48** and **49**) is highly efficient; the catalysed reaction occurs 10^4 – 10^6 times faster, even in the case of the secondary alcohols **49** the hydroxy group of which is much more sterically hindered than that of water. Interestingly, the vinyl ester **47** as an acyl donor proved to be especially efficient and convenient, since vinyl alcohol produced upon transacylation is isomerised into acetaldehyde and eliminated from the reaction.

Detailed studies of the catalytic effect of CA raised against the hapten **18** using the methods of enzymic kinetics and inhibitory analysis as well as X-ray analysis of several CA complexes with substrates have prompted important conclusions about the mechanisms of two-substrate transacylation reactions which can be briefly summarised as follows.^{34,35} The transfer of the acyl residue from the ester **47** onto the alcohol occurs *via* the intermediate formation of an acyl derivative of the CA. Subsequent transfer of the acyl group onto the acceptor alcohol follows the so-called 'ping-pong' kinetics where the entering of the first substrate (the ester) into the active site of the CA, the removal of the leaving group with the concomitant formation of the acyl derivative of the CA, the entering of the second substrate (the acyl group acceptor) and the liberation of the transacylation product accompanied by the recovery of the catalyst (CA) regularly alternate. The whole sequence of reactions is then repeated. The active site of CA undergoes certain conformational changes in the course of the reaction depending on the structure of the second reaction substrate. For molecular mechanisms of the acyl transfer see Refs 36, 37

The reactions of the acyl transfer catalysed by natural transferases are widely represented in various biochemical processes occurring in living organisms. In this connection, the preparation of CA catalysing one of the most important reactions of this kind, *viz.*, aminoacylation, which consists in the transfer of the amino acid residue onto a nucleotide residue is of considerable interest. In a cell, this reaction is catalysed by the natural enzyme (aminoacyl-tRNA synthase) and is the key stage in protein biosynthesis.

The transfer of the *N*-acylalanine residue onto the hydroxy group of the thymidine derivative **50** from the ester **51** resulting in the derivative **52** has been studied (Scheme 3).³⁸

Scheme 3

$R^1 = \text{Ph}, 4\text{-FC}_6\text{H}_4, \text{CH}_2\text{CN}$; $R^2, R^3 = \text{H}, \text{Me}$.

$R^2, R^3 = \text{H}, \text{Me}$.

The corresponding CA was raised against the haptin **53**, the phosphate analogue of the aminoacylation product **52**.

This haptin structure enables the formation of the active site of CA which ensures the mutually advantageous arrangement of the reaction substrates and gives a considerable gain in entropy in the formation of the transition state of this bimolecular reaction. The tetrahedral structure of the phosphonate group differs from the trigonal structure of the reaction product, which prevents the inhibition of the aminoacylation reaction by the reaction products.

The aminoacylation of thymidine **50** took place in the case of phenyl ($R^1 = \text{C}_6\text{H}_5$), 4-fluorophenyl ($R^1 = 4\text{-FC}_6\text{H}_4$) and cyanomethyl ($R^1 = \text{CH}_2\text{CN}$) esters **51**, but not for the ethyl ($R^1 = \text{C}_2\text{H}_5$) esters **51**. Four of the CA raised against the haptin **53** catalysed the transesterification of L-alanine esters and three CA catalysed the transesterification of D-alanine esters. The most active of these CA accelerated the aminoacylation reaction more than 10^8 -fold. A kinetic analysis showed that these CA only weakly recognised the alcoholic component but were more selective with respect to substrate stereochemistry, *i.e.*, the reaction was highly stereospecific.

IV. Hydrolysis and formation of the amide bond

The search for CA endowed with the ability to catalyse hydrolytic cleavage of the amide bond in a way similar to that of natural proteolytic enzymes is of considerable importance, because it opens up new ways to selective hydrolysis of a polypeptide chain of the protein molecule, which represents one of the basic challenges to bioorganic chemistry. This problem is much more difficult than hydrolysis of the ester bond, and achievements in this area are far more modest. Since the hydrolysis of the $\text{NH}-\text{CO}$ bond is a more energy-consuming process and occurs according to a more complex mechanism, a more accurate choice

of a haptin that would initiate the biosynthesis of highly specific CA able to lower the energy barrier of this reaction is required. Only CA efficiently catalysing the hydrolysis of only the simplest amides have been obtained so far.

The hydrolysis of the amide bond occurs through the transition state **54** which is further decomposed to give an amine and an acid (Scheme 4).

Scheme 4

The catalytic antibody must stabilise the ionic site in the transition state **54** and induce simultaneously protonation of the nitrogen atom as the amine is split off. Amide analogues in which the carboxamide bond was replaced by the sterically and electronically similar phosphamide bond were used as haptens mimicking the transition state **54** and forming the active site of CA.

For example, the hydrolysis of 4-nitroanilides of phenylacetic acids **55** was catalysed by CA raised against the haptin **56**.

$R = (\text{CH}_2)_2\text{COOH}$ (**56**), Me (**57**).

The haptin **56** contained a phosphonamide group as well as functional groups analogous to the corresponding groups of the substrate **55** and essential for its 'recognition' and a spacer.³⁹ The most active of the CA obtained accelerated 2.5×10^5 -fold the hydrolysis of the amide **55** at pH 9.0 compared to the non-catalysed reaction and manifested the features typical of natural amidases (Michaelis–Menten kinetics, inhibition with phosphonamide **57**, which is an analogue of the haptin **56**, *etc.*). The effect of this CA was highly specific, *viz.*, in contrast with 4-nitroanilide **55**, it did not catalyse the hydrolysis of 2- and 3-nitroanilides. Similar specificity was observed for CA of the esterase type (see Section III). The narrow specificity of CA against the acyl fragment of the substrate is the most essential.

Unfortunately, the hydrolysis of 4-nitroanilides of various α -amino acids and some di- and tripeptides was not catalysed by these CA. Therefore, they are not suitable for the catalytic hydrolysis of the peptide bond.

Certain success has been achieved in the synthesis of CA catalysing hydrolysis of the simplest non-substituted amides of *N*-acylated phenylalanines **58**. The corresponding CA was generated using the haptin **59**, which is an analogue of the amides **58**; the carboxamide group in this haptin was replaced by the methylphosphinic acid residue, and the alkyl spacer had a terminal maleimide residue essential for immobilisation.⁴⁰

$R = \text{Me}$ (**a**), $(\text{CH}_2)_5\text{NHSO}_2$ -[maleimide ring]- NMe_2 (**b**)

This CA accelerated the hydrolysis of the amide **58b** only 130-fold and catalysed the hydrolysis of D-phenylalanine derivatives only; it did not possess esterase activity. High regiospecificity of this CA was manifested in that it catalysed hydrolysis of only the non-substituted amide group, while the acylamide bond in the amides **58a,b** was unaffected. Although the practical application of this CA is impeded due to its narrow specificity, it turned out to be a useful tool in the study of the mechanism of the acyl transfer reaction (see p. 1006).

An alternative approach has also been used to obtain CA catalysing the cleavage of peptide bonds. Considering that many natural peptidases are metalloenzymes (*i.e.*, their active site contains a metal ion), it was suggested to use an amide complex containing a metal ion with the corresponding ligand as a hapten. It was assumed that this complex hapten will form a cavity in the active site which might accommodate the amide bond of the substrate coordinated with the metal ion. An attempt to obtain CA selectively hydrolysing the peptide bond of glycylphenylalanine is an example.⁴¹ A hapten containing the trien (tri-ethylenetetraamine) complex of cobalt(III) in addition to the substrate residue was used to raise CA. One of them was found to be active and specific with respect to the peptide structure. Unfortunately, this study was not apparently continued and the CA obtained did not find any practical application. However, the fundamental importance of using metal complexes as haptens is indubitable.

The reverse reaction, *i.e.*, the CA-catalysed synthesis of the peptide bond, especially if this is efficient and selective under mild conditions, is no less interesting than the CA-catalysed cleavage of the amide bond. Although a great number of natural enzymes catalysing this reaction are known, interest in the preparation of CA with predetermined specificity is quite justified.

The chemical methods used in the formation of the amide bond are based on aminolysis of certain carboxylic acid derivatives, *i.e.*, the transfer of the acyl residue onto an amine. The specific function of CA consists in the facilitation of this transfer. Actually, the effect of this CA is close to that of CA of the esterase type catalysing the transfer of the acyl group to the water molecule. The essential difference is that in this case the concentration of the amine is commensurable with that of the acyl donor. This is a second-order reaction and occurs according to a more complex mechanism which may involve the formation of the intermediate acyl group carrier, *viz.*, the acylated derivative of CA (*cf.* Section III).^{34–37} This must be taken into consideration in the design of the hapten mimicking the transition state arising in the synthesis of the peptide bond. The simplest aminolysis reaction, *viz.*, direct attack of the nucleophilic nitrogen atom on the ester bond (the transition state of this reaction is analogous to that existing in the hydrolysis of the ester or amide bonds) was used as a model. The transition state was mimicked with a hapten, a substrate analogue, in which the ester bond was replaced by the phosphamide bond. Thus in the preparation of a CA catalysing aminolysis of aryl esters of substituted phenylacetic acids (**60**) with the amines (**61**) (benzylamine, in particular), the 8-aminoquinoline derivative (**62**) containing a phosphonamide group was used as a hapten.⁴²

Like natural enzymes, the CA obtained noticeably accelerated the aminolysis which followed Michaelis–Menten kinetics with respect to both reaction components and was inhibited by the hapten analogue (**63**). The effect of CA was specific as regards the amine structure, which has been established in competitive reactions. The ratio of the rates of the CA-catalysed aminolysis with 8-aminoquinoline, benzylamine and butylamine was 30:3.12:1, whereas in the absence of CA the reaction rate was practically independent of the amine structure (the ratio was 0.9:0.7:1). In the presence of CA, the reaction was stereoselective: the rates of aminolysis of the ester **60** with epimers of α -methylbenzylamine were different ($R:S = 2.2:1$).

A CA catalysing aminolysis of the lactone **64** with *p*-phenylenediamine was obtained in a similar way (Scheme 5). This reaction results in the ring opening and the formation of the amino alcohol **65**.⁴³

Scheme 5

A catalytic antibody raised against the hapten **66**, the phosphonate analogue of lactone **64**, increased the rate of this reaction severalfold and produced a stereospecific effect by catalysing the aminolysis of only the (–)-epimer of the lactone **64**.

Initially, these studies were important for a comparison of the mechanisms of action of CA in similar reactions of hydrolysis and aminolysis (see Section III)^{34–37} but did not present any interest for synthetic chemistry. However, recently these reactions have again attracted attention of investigators. The reason is that the design of efficient catalysts allowing selective formation of the peptide bond may facilitate the solution of a problem of synthesis of large proteins by directed coupling of peptide blocks that have now become available owing to solid-phase synthesis. The first steps in this direction have already been undertaken aimed at the preparation of CA the effect of which would be similar to that of such natural enzymes as ligases. Using phosphorus-containing compounds as haptens mimicking the transition state, the first representatives of CA catalysing the formation of the peptide bond between amino acids have been obtained. Thus CA efficiently catalysing synthesis of dipeptides **67**⁴⁴ from *p*-nitrophenyl

esters of the corresponding *N*-acetyl amino acids **68** with tryptophan amide (**69**) were raised against the hapten **70**.[†]

R = Pri, Buⁱ, CH₂Ph.

Compound **70** is a phosphonate analogue of the peptides **67** and contains all their characteristic groups. It is assumed⁴⁴ that the *p*-nitrobenzyl residue favours the removal, from the active site of the CA, of *p*-nitrophenol that is split off in the condensation, and the cyclohexyl residue mimics the aliphatic chain of α -amino acids. Two CA of approximately equal efficiency accelerated the synthesis of AcVal-Trp, AcIle-Trp and AcPhe-Trp peptides 220-, 380-, and more than 1000-fold, respectively, in comparison with the non-catalysed reactions. Thus, the CA manifested broad specificity essential for their synthetic application.[‡] Very low racemisation of the original amino acids (0%–4%) (vs. 25% in the non-catalysed reaction) is an important advantage of conducting the condensation in the presence of CA. Interestingly, the configuration of the amino acid has little effect on the efficiency of CA.

A similar approach was used to obtain CA catalysing the formation of a dipeptide (alanylphenylalanine) derivative **71**.⁴⁶

N-Benzyloxycarbonyl-L- or -D-alanine azide (**72**) prepared *in situ* from the corresponding phenyl ester and sodium azide was used as a peptidyl donor in the condensation reaction. The amino group of phenylalanine the C-terminus of which was protected as the amide with *N*-(4-nitrobenzoyl)-1,3-diaminopropane has served as an acceptor.

A phosphonate analogue of the dipeptide **71** to be synthesised containing protective groups of the original amino acids (compound **74**) was used as a hapten.

[†] The hapten **70** with the P–O bond has been employed instead of a less accessible phosphamide analogue.

[‡] One of these CA has been used in the synthesis of tri- and tetrapeptides.⁴⁵

The CA obtained accelerated the condensation of the amino acids **72** and **73** 10⁴-fold in comparison with the non-catalysed reaction. The effect of the CA was stereoselective, *viz.*, the reaction with the L-alanine derivative occurred 7 times faster than that with the D-isomer.

These studies^{44–46} present substantial interest, since they can be regarded as the first steps en route to protein synthesis by coupling peptide fragments.[§]

V. Hydrolytic cleavage of the carbon–oxygen bond in enol ethers and acetals

A great number of papers have been devoted to the synthesis and investigation of CA catalysing the hydrolysis of the C–O bond in enol ethers and acetals to recover the parent carbonyl compounds. These reactions follow similar mechanisms and are involved in many synthetic schemes. Enhancement of the efficiency and selectivity (stereoselectivity, in particular) of these reactions would favour the solution of many synthetic problems.

Hydrolysis of alkyl vinyl ethers with recovery of the corresponding aldehyde or ketone is the simplest example of hydrolysis of enol ethers. This reaction occurs in the presence of an acid catalyst (Scheme 6).

Scheme 6

Protonation of the β -carbon atom of the vinyl group of the ether is the rate-limiting stage. If the β -carbon atom of the vinyl ether is prochiral ($R^1 \neq R^2$), the reaction may yield a mixture of two stereoisomers. The stereochemical outcome of the reaction is important for its synthetic application, in particular, in asymmetric synthesis.

Hydrolysis of *O*-alkylenols normally occurs under relatively drastic conditions with moderate stereoselectivity. Therefore, preparation of CA catalysing this conversion under mild conditions and with satisfactory stereochemical control is of considerable interest. These CA will favour the formation of the oxonium centre in the substrate and the protonation of the β -carbon atom concomitantly with its sp^3 -hybridisation ('pyramidalisation'), while it is the spatial direction of the proton attack that will determine the enantioselectivity of this reaction.

The preparation of CA catalysing the hydrolysis of the vinyl ethers **75** and **76** has been described.⁴⁸

Ar = C₆H₄CONH(CH₂)₃OH

The *N,N*-dialkylpiperidinium derivatives **77** have been used as haptens.

The positive charge on the nitrogen atom in the hapten **77** induces the formation of a negatively charged group in the active site of CA responsible for the formation of the oxonium site and

[§] For the preparation of a CA catalysing rearrangement of the peptide bond in aspartylglycine, see Ref. 47.

the protonation of the substrate. In turn, the tetrahedral structure of the nitrogen atom favours the formation of a cavity in the active site facilitating pyramidalisation of the β -carbon atom. The substituent at the C(3) atom of the piperidine ring stabilises the conformation of the ring in the molecule **77** and serves as a linker employed for coupling of the hapten to the protein in the immobilisation.

Several haptens differing in the nature and spatial arrangement of substituents at the nitrogen atom (R^1 and $R^2 = H, Me, CH_2Ar$) have been synthesised to study the relationship between the efficiency and stereoselectivity of the CA action. Active CA have been raised against all of these haptens. One of those, 14D9 raised against the hapten **77** ($R^1 = Me, R^2 = CH_2Ar$) has been selected for a more detailed examination. This CA manifested all the specific features of an enzyme and possessed relatively high efficiency, which strongly depended on the substrate structure. Thus, under comparable reaction conditions (pH 6.0), it accelerated the hydrolysis of the *trans*-isomer **75** 2500-fold and of the *cis*-isomer **76** only 290-fold. Further investigations into this CA revealed⁴⁹ that this antibody manifested broad substrate specificity, although its efficiency was not very high and varied within a very broad range. Thus the hydrolysis of the vinyl ethers **78**, which do not contain alkyl β -substituents, was accelerated 180-fold, while that of the vinyl ether **79** was accelerated only 110-fold. In contrast, this catalytic antibody manifested high activity in the hydrolysis of cyclic vinyl ethers and accelerated the hydrolysis of the methoxycyclopentene derivative (**80**) and methoxycyclohexene derivative (**81**) 12 500- and 370-fold, respectively.

High enantioselectivity is the most essential property of this CA: it catalysed hydrolysis of the vinyl ethers **75** and **76** to yield the same *S*-enantiomer of the aldehyde **82** with very high enantioselectivity (93%–96% *ee*).[†]

The hydrolysis of the cyclic vinyl ether **80** was also highly enantioselective and the cyclic ketone was obtained with 93% *ee* in the presence of this CA. Such a high enantioselectivity, which was comparable with that attainable with the most efficient chemical methods, was rather unexpected and was extensively investigated^{49,50} using numerous substrate analogues and structurally related inhibitors (including deuterated ones) by the enzymic kinetics method. The correlation between the enantioselectivity of the effect of the CA and the spatial structure of the hapten used for its generation as well as the origin of the enantioselective effect of the CA (which is the reason for the *S*- or *R*-configuration of the newly formed chiral centre) are of particular interest. The conformation of the hapten **77** ($R^1 = Me, R^2 = CH_2Ar$), which determines the peculiarities of the cavity formed in the active site of CA in the course of its biosynthesis by the immune apparatus of the cell, was established with the use of inhibitory analysis.⁵⁰ It was shown that the piperidine ring in the molecule **77** has a chair conformation with the *N*-benzyl group in the axial position and

the *N*-methyl group in the equatorial position. The presence of a substituent at the C(3) atom of the piperidine ring, which also occupies the equatorial position, favours this conformation. The substrate molecule (the ether **75**) is arranged in the newly formed active site of CA to 'copy' the conformation of the hapten which had determined the steric configuration of the cavity in the active site of the CA. The position of the benzyl residue of the substrate responsible for its 'recognition' by the active site and fixation in the cavity of the active site of CA is similar to that of the benzyl residue of the hapten **77**. The presence of an anionoid (presumably, carboxy) group in the active site of the substrate induces the formation of a positively charged oxonium site, as a result of which the excited molecule of the substrate accepts the conformation **A**.

It is arranged in the active site as if it mimics the configuration of the hapten, making the β -carbon atom of the substrate accessible for enantioselective protonation on the *r,e*-site and providing the formation of the *S*-aldehyde **82**. Consequently, the enantioselectivity of protonation and the formation of the *S*-aldehyde are predetermined by the configuration of the hapten **77**.

It was emphasised⁵⁰ that the most characteristic feature of the enantioselective formation of the new chiral centre is that the hapten shapes the active site of CA which is complementary to the excited substrate molecule predisposed to the attack by the proton rather than to the neutral substrate molecule. This determines strict spatial directionality of this attack and high enantioselectivity of this process. Thus, the choice of the hapten structure mimicking the excited state of the substrate molecule is considered to be of crucial importance in the design of a CA endowed with high enantioselectivity.^{49,50}

Such catalytic antibodies may acquire great importance in the development of asymmetric synthesis, *i.e.*, the introduction of the first chiral centre with a predetermined absolute configuration into an achiral molecule.⁵¹ The use of CA in the synthesis of the pheromone (–)- α -multistratin (**83**) is an example.

The key stage in this synthesis is the enantioselective introduction of a chiral centre into the molecule of a substrate (the vinyl ether **84**) using CA.⁵² Hydrolytic cleavage of the ether **84** was accelerated 6.5×10^4 -fold by the CA 14D9 and was highly enantioselective (95% *ee*). The ketone **85** obtained in 85% yield was further converted into the ketal **86** and then into (–)- α -multistratin (**83**).

A simple laboratory technique⁵³ specially developed for the synthesis of gram quantities of compounds catalysed by CA consists in the removal of the reaction product by dialysis. Since CA remaining in the dialysis sack are reusable, it is possible to use them in small quantities. A small semi-automatic laboratory unit has been designed for conducting the reaction in the presence of CA.⁵⁴

[†]In order to avoid partial racemisation of the carbonyl compound, which may occur under reaction conditions and obscure the stereochemical result, the CA-catalysed conversion of enol ethers was carried out in the presence of cyanide. The latter converts the carbonyl compound into cyanohydrin and stabilises its configuration.

The use of CA in the hydrolysis of vinyl ethers permits one to interfere with the course of the reaction and to perform conversions that are unattainable under ordinary conditions. An amazing result was obtained in the hydrolysis of the vinyl ether **87** in the presence of the CA 14D9 (Scheme 7). This reaction can yield either the ketone **88** or the cyclic ketal **89**.⁵²

Scheme 7

In an aqueous medium (in the absence of the CA 14D9), the acid-catalysed reaction gives only the ketone **88**, because the hydroxy group of the vinyl ether **87** cannot compete with excess water present in the reaction medium. In contrast, the cyclic ketal **89** is formed in organic solvents. However, when the reaction is carried out in an aqueous medium in the presence of CA, 12% of the cyclic ketal **89** is formed in addition to the ketone **88**. The formation of both products obeys the Michaelis–Menten kinetics, they have the *S*-configuration and are formed with very high enantioselectivity (99.5% *ee*), which testifies to the involvement of the active site of CA in their formation *via* the common transition state **90**. Thus, the ketal **89** is formed in a CA-catalysed reaction occurring in aqueous media. The involvement of water is excluded in this reaction because of the hydrophobic environment created in the cavity of the active site of CA where the reaction occurs.

The mechanism of hydrolysis of the acetal bond in the presence of an acidic reagent differs only slightly from that of vinyl ethers. In both cases, the reaction occurs through protonation. However, in contrast with the hydrolysis of vinyl ethers, it is the oxygen atom of the acetal group that undergoes protonation.

It was found that CA efficiently catalysing hydrolysis of vinyl ethers manifest catalytic activity in the hydrolysis of acetals.⁵⁵ This is apparent from comparative hydrolysis of the vinyl ether **91** and the ketal **92** in the presence of the same CA (Scheme 8).

Scheme 8

Both reactions occur *via* the same transition state **93** and result in the ketone **94**. In an aqueous medium and in the absence of CA,

acid-catalysed hydrolysis of the acetal **92** usually proceeds at a substantially higher rate than that of the ether **91** (the ratio of hydrolysis rates is 0.09 : 1). In the presence of the CA 14D9, the ratio of the reaction rates changes drastically to the opposite (**91** : **92** = 1100 : 1). The dependence of the reactivities of acetals on their structure was studied under conditions of a hydrolytic reaction. It was found that the acyclic ketals **95** and **96**, which are hydrolysed more slowly in the absence of the CA than the cyclic ketal **92** (the rate ratio is **95** : **96** : **92** = 0.23 : 0.38 : 1), demonstrate the opposite reactivities in the presence of the CA (the rate ratio is **95** : **96** : **92** = 90 : 8 : 1).

Presumably, the differences in reactivities are due to the fact that the role of steric tensions generated in the cavity of the active site of the CA in the protonation and further decomposition of the acetal is higher in the case of the conformationally more rigid cyclic ketal **92** than in the case of its conformationally flexible acyclic analogues **95** and **96**.

However, this is not the only reason. Recently, the relative effectiveness of the same CA (14D9) has been studied in the hydrolysis of other cyclic ketals (compounds **97–99**) with different ring sizes.⁵⁶ It was found that the effectiveness of the CA decreased with the increase in the ring size (the rate ratio was **97** : **98** : **99** = 1 : 0.37 : 0.04). These data and comparison of the binding constants of these acetals with those of the complementary azaalicyclic analogues in which the ammonium nitrogen atom corresponded to the acetal carbon atom led the authors to conclude that the effectiveness of the CA largely depended primarily on the electrostatic complementarity of its active site with the substrate, while the conformational tension generated during the reaction was of lesser importance.

In conclusion, let us dwell briefly on attempts to prepare CA catalysing hydrolysis of mixed acetals (particularly, cleavage of the glycosidic bond).

The hydrolysis of the glycosidic bond under conditions of acid catalysis occurs through the transition state **100** with the oxocarbenium ion in the six-membered ring which has a half-chair conformation (Scheme 9).

Scheme 9

An attempt has been made^{57,58} to obtain CA catalysing the hydrolysis of the simplest model compound, *viz.*, 2-aryloxypyran **101**.

This was achieved using the haptens **102**, analogous to the hapten **77** and containing the CH_2NH_3^+ group at the C(3) atom, and the haptens **103** containing a substituted amino group at the C(2) atom. In both cases, the CA obtained moderately accelerated hydrolysis of the model substrate **101** but were ineffective in hydrolysis of more complex compounds.

These results show that it is possible, in principle, to obtain CA catalysing the hydrolysis of the glycosidic bond. However, the preparation of sufficiently active and selective artificial glycosidases poses the problem of choice of a hapten mimicking the half-chair transition state with a positive charge as well as a polysubstituted, polychiral molecule of a real monosaccharide.

VI. The formation of carbon–carbon bonds

Apparently, preparation of CA that would catalyse the formation of new carbon–carbon bonds making the skeleton of organic molecules is of prime interest in preparative organic synthesis. These include CA that would increase the efficiency of the known reactions and enhances their regio- and stereospecificity and CA able to change the direction of certain reactions in comparison with the non-catalysed processes. This may eventually lead to the discovery of novel reactions that cannot be carried out by conventional chemical methods (the so-called ‘unfavourable transformations’).

Among a great multitude of reactions that result in the formation of the C–C-bond, only very few are known for which the corresponding CA have been obtained. In particular, several CA catalysing cationic cyclisations, sigmatropic rearrangements and pericyclic reactions as well as aldol condensation, which is one of the most common reactions of carbon–carbon bond formation, have been obtained thus far.

1. Cationic cyclisation

Cationic cyclisation is widely used in the synthesis of carbocyclic systems. Cyclisation of aryl sulfonates of unsaturated alcohols, which occurs in their solvolysis and gives cyclohexane derivatives (the Johnson reaction), has long been known.

This reaction proceeds through intramolecular electrophilic attack, by the carbocation formed upon solvolysis of the C–O bond, at the double bond of the sulfonate **104**. The resulting cyclic carbocation **105** can be further stabilised either by addition of an external nucleophile to give, *e.g.*, the alcohol **106**, or by elimination of a proton to give the alkene **107**. Under ordinary conditions, this reaction is normally accompanied by the formation of a complex mixture of compounds, which strongly impedes its practical application. Therefore, a search for CA which would not only catalyse the reaction but also enhance its specificity is of considerable interest.

The cyclisation of the sulfonate **108** into the cyclohexanol derivative **109** was studied (Scheme 10).⁵⁹ It was assumed that this reaction occurs *via* the transition state **110** where the original substrate acquires a chair configuration, whereas the C–O bond of the sulfonate becomes polarised, which is accompanied by the appearance of an excess positive charge on the carbon atom. Thus the active site of CA would promote the formation and stabilisation of the carbocation and the formation of a chair conformation of the substrate and thus alleviate sterically the cyclisation.

The piperidine *N*-oxide derivative **111** was used as a hapten aimed at the formation of the active site of a CA which matches

spatially and electronically the transition state. This derivative contains a spacer with a succinic acid residue needed for immobilisation.

In addition to the six-membered ring, which is spatially close to the transition state, compound **111** contains the $^+\text{N}-\text{O}^-$ fragment, which mimics sterically and electronically the formation and cleavage of bonds in the conversion of the sulfonate **108** into the cyclohexane derivative. The dimethylphenylsilyl group was introduced into the substrate **108** and, correspondingly, into the hapten **111** for convenience of monitoring the course of cyclisation. The authors assumed also that the silyl group occupying the quasi-equatorial position favoured the fixation of the chair conformation of the substrate ring in the transition state and the formation of a cyclic carbocation, the primary product of this cyclisation, owing to the β -effect of the silicon atom.

The hapten **111** was used to raise several CA which could catalyse the solvolysis of the sulfonate **108**. One of these, CA 4C6, catalysed the cyclisation of the substrate **108** to give the alcohol **109** and was studied in more detail.⁵⁹ The solvolysis of the sulfonate **108** in a biphasic system (pH 7.0) in the presence of the CA followed Michaelis–Menten kinetics and was accelerated several thousand-fold in comparison with the non-catalysed reaction. However, the most important feature is that this reaction was strictly stereospecific in the presence of the CA. The reaction mixture contained 98% of the *trans*-cyclohexanol **109** and only 2% of the elimination product, *viz.*, the cyclohexene derivative. Other side products were absent. It should be noted that in the absence of the CA the solvolysis of the sulfonate **108** yields a complex mixture of products with less than 30% content of the alcohol **109**.

It is noteworthy that the catalytic antibody 4C6 manifests high substrate specificity. The conversions of compounds **112** and **113**, which are analogues of the sulfonate **108**, is not catalysed by this CA, whereas the sulfonate **114**, which has an additional methyl group and produces a secondary carbocation upon solvolysis instead of the primary one, yields a complex mixture of reaction products.⁵⁹

These findings have led the authors to conclude that the CA-catalysed cyclisation reaction occurs by a concerted mechanism: the double bond in the sulfonate **108** anchimerically assists the formation of the carbocation, while the cyclic cation that formed (of the type **105**) undergoes immediately attack by the external nucleophile. Thus, the catalytic antibody 4C6 not only initiates the reaction by generating a carbocation but also promotes its further conversions (cyclisation) due to matching of the active site of the CA to the substrate. Additional evidence in favour of this

hypothesis can be derived from the fact that of all CA against the hapten **111** tested in this study only 4C6 induced the cyclisation, while other CA could merely accelerate the solvolysis of the sulfonate **108**, *i.e.*, they favour the formation of the carbocation without subsequent cyclisation (see below).

The nature and the ratio of the cyclisation products of unsaturated sulfonates of the type **108** depend also on the nature of CA, *i.e.*, on the structure of the hapten that had induced the CA. Thus it was found that the ratio of the cyclisation products of the sulfonate **108** could be fully reversed when CA 87D7 against the hapten **115**, very close to the analogue of the hapten **111**, was used instead of CA 4C6.

Compound **115** contains the $N^+ - Me$ group instead of the $N \rightarrow O$ group.⁶⁰ The cyclisation of the sulfonate **108** in the presence of this CA gives 90% of the cyclohexene derivative and only 10% of the cyclohexanol **109**. It was shown that the substrate **108** virtually adopts the same conformation in the active sites of both CA (4C6 and 87D7). Therefore, the difference in the ratios of the cyclisation products should be ascribed to the difference in the charge on the nitrogen atom rather than to the conformational effect, since the ammonium group induces a higher negative charge in the active site of CA than does the nitrogen atom of the $N - O$ group.

Replacement of the substrate **108** by its analogue **116a** containing the CMe_2Ph group instead of the silyl group changes the direction of the cyclisation reaction catalysed by the CA 87D7. In this case, the reaction affords the corresponding cyclohexanol in 60% yield.

The direction of cyclisation of the sulfonate **116b** with the propenyl group instead of the vinyl group changes even more significantly.⁶¹

116a,b

R = H (**116a**), Me (**116b**).

In the presence of CA 87D7, solvolysis of the *cis*-isomer of the sulfonate **116b** gives the alcohol **117** in 80% yield, whereas solvolysis of the *trans*-isomer yields the bicyclo[3.1.0]hexane derivative **118** as the main product. This unexpected result can be explained by the fact that the β -effect underlying the stabilisation of the six-membered carbocation is not manifested in the absence of the silyl group. This results in the carbocation **119**, which is further stabilised either by the attack of the external nucleophile to give the alcohol **117** or by the formation of the bicyclic compound **118** upon deprotonation.

As mentioned above, antibodies against the hapten **111** contain those which catalyse solvolysis and favour generation of the carbocation but not cyclisation. One of them, CA 16B5, was used as a convenient tool in elucidation of the mechanism of formation of carbocations in the solvolysis of arylsulfonates.⁶² To this end, the conversion of the sulfonate **120** into the iodide **121** was studied under solvolysis conditions.

The catalytic antibody 16B5 was found to be an efficient catalyst of this reaction and accelerated it more than 500-fold.

Analysis of reaction kinetics and performance of this reaction in the presence of other nucleophiles (NaSCN, NaN₃) revealed that this CA favoured the formation of the carbocationic centre in the transition state. This conclusion was also confirmed by measurements of the secondary isotope effects of α - and β -deuteriated analogues of the sulfonate **120**. Analysis of the CA-catalysed solvolysis of the deuteriated analogues revealed that substitution of the iodine for the sulfonyloxy group occurred with inversion of its configuration, which can be explained by the fact that the carbocation was generated as a tight ion pair in an equilibrium with the covalent sulfonate.

It may be concluded that the direction of the reaction of cationic cyclisation is determined by the peculiarities of both the active site of CA and the structural features of the substrate. These peculiarities affect all the stages of this reaction, such as generation of the carbocation, its stabilisation, the 'positive' charge value, possible ways of carbocation conversions and stabilisation of the secondary carbocation.

The examples of carbocationic cyclisation considered above[†] demonstrate high potentialities of the use of CA in directed synthesis of cyclic compounds and the possibility of their subtle modification by changing the type of the hapten and the structure of the substrate.

2. The Claisen rearrangement of enol ethers

The Claisen rearrangement of enol ethers, which consists in the cleavage of the $O - C$ bond and the transfer of the enol residue and results in the formation of a new carbon-carbon bond, is widely used in the synthesis of complex organic structures, particularly, natural compounds. The possibility of preparing CA that would catalyse this reaction was examined⁶⁴⁻⁶⁶ with the rearrangement of chorismic acid (**122**) into prephenic acid (**123**) as an example. This rearrangement is one key step in the biosynthesis of aromatic amino acids by bacterial or plant cells where this reaction is catalysed by the natural enzyme, *viz.*, chorismate mutase. The preparation of a CA catalysing this reaction was the first case of preparation of an artificial enzyme catalysing the formation of the $C - C$ bond in a pericyclic reaction. The rearrangement of the acid **122** into the acid **123** is a [3,3]-sigmatropic concerted process and occurs *via* the transition state **124**, which is similar to the spatial structure of oxabicyclo[3.3.1]nonene with one six-membered ring in a boat conformation (Scheme 11).

Scheme 11

The bonds corresponding to the structure of the substrate **122** in the transition state **124** are weakened, while the bonds of the future rearrangement product have just been outlined. The hapten derivative of the oxabicyclononene **125** containing a spacer (R) with the active succinimide group needed for its immobilisation on the protein was used to obtain CA the active site of which must promote the generation of a transition state with this spatial

[†]A recent report describes an attempt to obtain a CA catalysing carbanionic cyclisation, one of the versions of the Dieckman reaction.⁶³ Although the catalytic effect was observed in this case, data on the preparation of CA and its characteristics were absent.

structure. It is of note that the dicarboxylic acid **125** ($R = H$) is an inhibitor of the natural enzyme (chorismate mutase).

The resulting CA accelerated the conversion of chorismic acid (**122**) into prephenic acid (**123**) $2 \times 10^2 - 10^4$ -fold in comparison with the non-catalysed rearrangement (data from two independent laboratories). This reaction proceeded with high regioselectivity at $10^\circ C$ and pH 7.0 and gave prephenic acid alone. (About 5% of hydroxybenzoic acid was formed in the absence of CA). The stereospecificity of this reaction is also very high. Experiments with (+)- and (–)-isomers of chorismic acid revealed that only the (–)-isomer was a substrate for the reaction. Only 50% of the substrate was consumed in the reaction with racemate. The kinetic measurements establish the enantioselectivity of this reaction in the presence of CA as 90 : 1.

X-Ray structural analysis of a complex of the hapten **125** with the CA ⁶⁷ confirmed the complementarity of the spatial structure of the active site of CA to the structure of the hapten and, correspondingly, to the structure of the transition state **124**. The lack of pH dependence of the Claisen rearrangement in the presence of CA and the absence of ionic groups in the active site testify to the fact that this rearrangement in the presence of the CA represents a pericyclic reaction. The role of the active site amino acid residues has been established in this reaction and the catalytic role of CA in this process has been suggested.⁶⁸ Although the effectiveness of the CA studied is inferior to that of the natural enzyme, the preparation and detailed analysis of this first CA catalysing a pericyclic reaction was a considerable breakthrough en route to artificial enzymes.

3. The Cope rearrangement

The Cope rearrangement is also related to pericyclic reactions and occurs as a [3,3]-sigmatropic rearrangement. No natural enzyme for this reaction has been found thus far.

The possibility to obtain CA catalysing this reaction was studied in the example of conversion of a diphenylhexadienol derivative **126** into the unsaturated aldehyde **127** (Scheme 12).⁶⁹

It is suggested that this rearrangement occurs *via* the transition state **128** in which the central six-membered ring has a chair conformation. The enol **129**, which is formed first, is further converted into the aldehyde **127** fixed as an oxime.

With consideration of the accepted reaction mechanism, the diphenylcyclohexanol derivative **130** with a spacer group was used as a hapten. The specific role of this hapten consisted in the formation of the active site of CA and fixation there of the substrate in a conformation most closely matching the transition state. This active site would thus act as an 'entropic trap' (see Section II). The absence of a natural enzyme catalysing the Cope rearrangement made the preparation of this catalytic antibody especially attractive because it provided rationale for the general

principles of design of haptens for the CA catalysing pericyclic reactions.

The most reactive catalytic antibody (AZ-28) raised against the hapten **130** accelerated this rearrangement 5300-fold. Of the two enantiomers of the original alcohol **130**, only the *S*-isomer and not the *R*-isomer entered into the reaction. The kinetic and inhibitory analyses of all the CA catalysing this reaction confirmed that they do generate the transition state **128** in the reaction.

The Fab fragment isolated from the CA AZ-28 was prepared in considerable quantity by genetic engineering methods.⁷⁰ This important experiment illustrates the possibility to use the catalytic antibodies generated in small quantities under laboratory conditions for large-scale productions using the most advanced biotechnological techniques.

An attempt has been made to establish the mechanism of the catalytic action of the CA AZ-28 and its spatial structure by molecular genetics methods and X-ray analysis.

4. The Diels–Alder reaction

The Diels–Alder reaction is the basis for one of the main synthetic procedures used to obtain six-membered alicyclic systems by condensation of a diene with an alkene (dienophile). It represents a $4\pi + 2\pi$ -cycloaddition reaction. The cleavage of particular bonds in the reaction components and the formation of other bonds occur as a single concerted process and conform to the regularities of pericyclic reactions. The success in the condensation depends on the mutual arrangement of the diene and the dienophile, which must be in the appropriate conformation in the transition state enabling the pericyclic process.

No natural enzyme has been found as a catalyst of the Diels–Alder reaction; therefore the preparation of an effective CA is of fundamental interest. Since the Diels–Alder condensation often occurs as a spontaneous exothermic process, the main function of the CA would be to alter its regio- and stereoselectivity rather than to increase the reaction rate.

The catalytic effect of the active site of the CA is reduced to the restriction of mobility of the diene and the dienophile and their fixation in the necessary conformation. Thus, the active site of the CA should primarily act as an 'entropic trap' (see Section II), while the presence of reactive groups in this site is less significant. In the design of a hapten for generation of the CA, one had to keep in mind that the CA prepared must not be inhibited by the reaction product. Otherwise, this would reduce the enzyme 'turnover number' and its effectiveness. Therefore, the spatial structure of the active site of the CA must be close to that of the transition state but differ, wherever possible, from the structure of the reaction product.

Several CA catalysing the Diels–Alder reaction have been obtained (Scheme 13).

The first of these CA catalysed the condensation of tetrachlorothiophene dioxide **131** with *N*-ethylmaleimide **132** which occurs *via* intermediate formation of the tricyclic sulfone **133**. Spontaneous elimination of SO₂ results in the dihydrophthalimide derivative **134** (Scheme 13).⁷¹

The tricyclic derivative **135** structurally analogous to the intermediate product **133** and containing a hexanoic acid residue essential for immobilisation was used as a hapten. At the same time, the structure of the hapten **135** differs from that of the final product, *viz.*, the imide **134**.

The reaction between the reactive sulfonyl group in the molecule **131** with the amino groups of lysine in CA might irreversibly change its function. To avoid this, the amino groups of lysine were methylated by reaction first with CH₂O followed by reduction with NaBH₃CN. The methylated CA thus obtained was found to be sufficiently active and accelerated the Diels–Alder condensation of the sulfone **131** with the imide **132** manifold. Its effect was substrate-specific. No catalytic effect of CA was manifested when maleimide was used instead of *N*-ethylmaleimide.

Preparation of a CA catalysing the condensation of the acyclic diene **136** with the maleimide derivative **137** is of certain interest. This reaction yields a derivative of *cis*-tetrahydrophthalimide **138**⁷² and proceeds *via* the transition state **139** in which the diene acquires a *cisoid* conformation, while its complex with the dienophile **137** adopts a boat conformation. This favours the pericyclic reaction and ensures *cis*-fusion of the rings in the reaction product **138** (Scheme 14).

Scheme 14

The hapten **140** containing a cyclohexane ring fixed in a boat conformation by an ethylene bridge and the isothiocyanate group necessary for its immobilisation was chosen for raising CA with the active site mimicking this transition state. The most active CA accelerated the condensation of the diene **136** with the imide **137** approximately 500-fold and followed Michaelis–Menten kinetics. The reaction product **138** was found to bind with the CA ~ 100 times weaker than the original compounds **136** and **137**. Thus, the CA is practically uninhibited by the reaction product.

Preparation of a CA catalysing a similar reaction, *viz.*, the condensation of 1-acetoxybutadiene **141** with *N*-methyl- and *N*-benzylmaleimides **142** to give the *N*-substituted tetrahydrophthalimides **143**, is documented.^{73, 74}

R = Me, Bn.

It was shown^{73, 74} that the CA raised against the hapten **144** accelerated the condensation of the diene **141** with the dienophile **142** more than 1000-fold. It manifested substrate specificity, since it was inactive when more reactive methoxybutadiene or piperylene were used instead of the diene **141**.

It was found also that the activity of this CA depended on pH, which was never observed with other CA catalysing the Diels–Alder reaction. This was rationalised as being due to the fact that this CA also manifested esterase activity and is a unique example of CA possessing dual activity. However, this explanation does not seem to be convincing enough, although the side product of this reaction, *viz.*, alcohol **143a**, has been isolated.

The problem of stereospecificity of the Diels–Alder reaction is the key problem. It was specially studied in the condensation of two acyclic compounds, *viz.*, *trans*-1-*N*-(alkoxycarbonyl)amino-butadiene **145** and *N,N*-dimethylacrylamide **146**, resulting in the cyclohexene derivative **147**.⁷⁵

This reaction may, in principle, yield four compounds, *viz.*, two 1,2-isomers with *cis(endo)*- and *trans(exo)*-configurations and two 1,3-isomers with *cis(endo)* and *trans(exo)* configurations. In the absence of CA, the condensation of compounds **145** and **146** yields only the 1,2-isomers in the *cis*:*trans* ratio 66:34 (thermal condensation) or 85:15 (condensation in a phosphate buffer). Thus, this reaction is not stereospecific. Analysis of molecular models and calculation of the transition states leading to the formation of each of these isomers[‡] revealed that the energy of the transition state for the 1,2 isomers was 2–4 kcal mol^{–1} lower than that for the 1,3-isomers. It is noteworthy that the energy barrier for the 1,2-isomer having the *cis*-configuration is lower than for the *trans*-isomer, *i.e.*, the formation of the *trans*-isomer (an 'unfavourable' reaction) is energetically less favourable.

[‡] The calculation was performed with the use of a simplified model of the diene component of the reaction.

Catalytic antibodies able to selectively direct the condensation of compounds **145** and **146** towards the formation of either *cis*- or *trans*-isomers have been obtained. The haptens **148a** and **148b** with a rigidly fixed ethane bridge where the CONMe₂ and NHCOR groups corresponding to the groups of the reactants ('recognition groups') are in the *cis*- or *trans*-positions relative to each other were used to mimic the transition states.

Two groups of CA were raised against these haptens. One CA, each from both groups, were selected that catalysed the condensation of compounds **145** and **146** in an aqueous medium at pH 7.0 to give the *cis*- (CA 7D4, *endo*-‘Diels–Alder’ase) and *trans*-isomers (CA 22C8, *exo*-‘Diels–Alder’ase). The effectiveness of these CA was not very high: they accelerated the reaction 960- (CA 22C8) and 740-fold (CA 7D4) in comparison with the non-catalysed reaction. It is noteworthy that the *exo*-CA catalysed the ‘unfavourable’ reaction of the *trans*-isomer formation more efficiently than the *endo*-CA. Both CA ensured complete stereoselectivity of the reaction: the isomer **147** was formed in the presence of the CA 7D4, whereas the *trans*-isomer **147** was formed in the presence of the CA 28C8 with the stereoselectivity exceeding 98%. Thus, artificial enzymes (*endo*- and *exo*-‘Diels–Alder’ase’) manifesting high stereoselectivity have been obtained.

A very interesting and a basically new approach to the preparation of stereospecific CA for the Diels–Alder reaction has been recently demonstrated.⁷⁶ In contrast to the above-described, traditional approach based on the use of conformationally rigid haptens, it was suggested to use conformationally flexible haptens. The authors proceeded from the opposite idea that the immune apparatus can produce antibodies against individual conformers of a conformationally flexible hapten including those the ‘frozen’ conformation of which would correspond to the transition state observed in the formation of certain stereoisomers. Thus, biosynthesis can yield a set of antibodies from which CA with the required specificity can be selected.

This idea was examined in the example of condensation of compounds **145** and **146**. The ferrocene derivatives **149a,b** were used as haptens to mimic the transition state of the reaction. They contained the substrate ‘recognition groups’ one of which served as a spacer. This is the first example of the use of organometallic compounds for such a purpose.

It was taken into account that the π -delocalised system and two planar cyclopentadiene rings of ferrocene at a distance 3.3 Å rotating freely around the common axis can form a cavity in the active site of a CA the size and spatial configuration of which would favour the approach and the necessary mutual arrangement of the diene and the dienophile. The rotation of five-membered rings gives the desired steric combinations of the hapten which mimic various transition states that appear in the formation of the stereoisomeric reaction products.

Two most active and stereospecific CA, viz., *endo*-CA (4D5) and *exo*-CA (13G5), were selected from a large group of antibodies raised against compounds **149a** and **149b**. Examination of these CA revealed that they accelerated the condensation only insignificantly and were inferior to the CA raised against ‘rigid’

haptens. However, the specificity of reactions was very high: the condensation of the substrates **145** and **146** catalysed by these CA yielded only the 1,2-isomers: *endo*-CA (4D5) gave the *cis*-isomer **147**, while *exo*-CA (13G5) gave the *trans*-isomer **147** with high diastereoselectivity (98% *de*) and enantioselectivity (95% *ee*). Thus, the concept on the possible use of conformationally flexible haptens that correspond in the geometric and electronic parameters to the transition state of the Diels–Alder reaction for the preparation of stereospecific CA has been fully confirmed.

Comparative characteristics of CA raised against ‘rigid’ haptens (e.g., bicyclo[2.2.2]octenes **148**) and conformationally flexible haptens **149** suggest that the ‘antiferrocene’ CA have a bulkier cavity in their active site, since the ferrocene molecule is larger than the bicyclo[2.2.2]octene molecule, and can react therefore with the ‘rigid’ haptens, whereas CA raised against ‘rigid’ haptens does not react with the conformationally flexible haptens.

Although the ‘antiferrocene’ CA are not yet practically valuable, this result is very essential for it offers a fundamentally new approach to the preparation of CA endowed with stereospecific activity through selection of CA from the group of antibodies raised against a conformationally flexible hapten.

In addition to the CA that catalyse the classical Diels–Alder reaction, the first CA catalysing the hetero-Diels–Alder condensation of *cis*-piperylene **150** with 4-nitrosobenzamide derivative **151** to give isomeric dihydro-1,2-oxazines **152** and **153** has been obtained (Scheme 15).⁷⁷

This CA was raised against the ‘rigid’ hapten **155** which mimics the hypothetical transition state **154** with a boat conformation.

This catalytic antibody accelerates the condensation of *cis*-piperylene **150** (R¹ = Me, R² = H) 2600-fold; however, its effectiveness in condensation of *trans*-piperylene (**150**) (R¹ = H, R² = Me) is much lower.⁷⁸ The regioselectivity of this reaction in the presence of the CA is also enhanced: the non-catalysed reaction of the diene **150** with an excess of the nitroso compound **151** gives the oxazines **152** and **153** in the ratio 48:52. In the presence of 10% CA, this ratio alters to 32:68, whereas in the presence of an equimolar amount of CA, 95% of the isomer **153** with high enantioselectivity (82% *ee*) is formed. Apparently, this results from inhibition of the sluggish parallel non-catalysed reaction. The action of the CA is fully inhibited by the hapten analogue **155** in which the *n*-propyl group is used instead of the (CH₂)₅COOH group. This proves that the catalytic reaction occurs in the cavity of the active site of CA.

5. Aldol condensation

Aldol condensation is one of the most well-studied reactions. It occurs under conditions of acid–base catalysis and results in the formation of a new C–C-bond and a β -hydroxycarbonyl (aldol) system. This reaction occupies a prominent position among the

processes occurring in living cells. Despite numerous multiple modifications and versions allowing for this reaction to be carried out efficiently and in a highly regio- and stereoselective way by purely chemical methods, interest in specific CA with enabling enhanced selectivity is never lost. A great number of natural enzymes (aldolases) catalysing this reaction are presently known; however, all of them manifest relatively narrow specificity which prevents their practical use. The preparation of CA manifesting broader and/or 'predetermined' specificity might be very useful in organic synthesis.

Several approaches are currently used to obtain CA catalysing aldol condensation. One of them is based on general chemical concepts on the mechanism of formation of the β -hydroxycarbonyl system in the condensation of two carbonyl compounds under conditions of acid–base catalysis. Others reproduce, to a certain extent, the catalytic process catalysed by natural enzymes, *viz.*, aldolases.

The first approach can be exemplified by the preparation of a CA catalysing intramolecular cyclisation of the oxo aldehyde **156**, which occurs *via* the formation of two stereoisomeric cyclic aldols **157a** and **157b**. The latter are at equilibrium, and elimination of the water molecule eventually results in the cyclohexenone derivative **158** (Scheme 16).⁷⁹

Scheme 16

$\text{Ar} = \text{C}_6\text{H}_4\text{CONH}(\text{CH}_2)_2\text{OH-p}$

Preparation of a CA catalysing this reaction seems to be a more complicated task than those described above, because this concerns a multistep process. The overall acceleration of the cyclisation of the oxo aldehyde **156** into the enone **158** requires a catalyst which stabilises several transition states by lowering the energetic barrier on the common coordinate of this reaction.

This problem has been solved successfully owing to the fact that all the steps of this reaction occurred under the conditions of acid–base catalysis and the intermediate products (as well as the corresponding transition states) were similar as regards their spatial and electronic structures. This made it possible to raise CA using a single hapten **77** responsible for the formation of the active site of the CA, which exerted a catalytic effect at all the steps of this reaction. The hapten **77** is structurally similar to the cyclic aldols **157a** and **157b** and the final product **158**. The positive charge on the nitrogen atom in the hapten **77** generates a carboxy group in the complementary position of the active site of the CA and thus provides for acid–base catalysis in enolisation (Scheme 16, stage *a*) and elimination (Scheme 16, stages *c* and *d*).

Among other antibodies against the hapten **77**, two CA were catalytically active in the cyclisation of the oxo aldehyde **156**. This reaction followed Michaelis–Menten kinetics and was inhibited by one of the hapten analogues, which testified to its occurrence in the active site of the CA. One of these CA (**78H6**) was studied in

more detail. It was found that general base catalysis takes place and the CA **78H6** is its very potent catalyst. It is of note that the dehydration stages (*c* and *d*) represent energetically less favourable ('adverse') *trans*-elimination reactions in the intermediate aldol **157a** and are regio- and stereospecific. Kinetic studies showed that this reaction was accelerated more than 10^5 -fold in aldolisation (stages *a* and *b*) and more than 10^4 -fold in elimination (stages *c* and *d*) as compared to the reaction carried out under ordinary conditions, *viz.*, in the presence of acetate. This example illustrates the possibility to obtain a unified CA that catalyses a multistage intramolecular process in those cases where the catalytic mechanism and the intermediate products (and, correspondingly, transition states) formed at all stages are sufficiently close.

Another approach to the preparation of a CA the mechanism of action of which is similar to that of natural aldolases seems to be more interesting and versatile.⁸⁰ According to the present concepts of the mechanism of the catalytic action of aldolases, this may be represented by Scheme 17.

Scheme 17

The ϵ -amino group of lysine in the enzyme molecule reacts with the carbonyl group of the aldol donor **159** to yield the hemiaminal **160**, which is further converted into the enamine **162** *via* the immonium ion **161**. It is the enamine **162** that is the genuine aldol donor (the nucleophile) and the key intermediate of the overall reaction. The enamine **162** attacks the aldol acceptor **163** to form a new C–C bond and the immonium ion **164**. Its subsequent hydrolysis gives the aldol **165** and results in the regeneration of the amino group of lysine in the aldolase. Since all the reactions in this chain are reversible, aldolase can also catalyse the reverse reaction, *i.e.*, retroaldol degradation.

The active site of a CA catalysing this complex chain of reversible reactions must be able to lower the energy barriers in all the stages of this process. It is difficult to imagine the generation of such a CA in a traditional way where a stable and nonreactive hapten does not virtually react with the antibody raised against itself but, rather, merely mimics the transition state.

A fundamentally new approach, which is named 'reactive immunisation', has been proposed. In this case, the hapten reacts with the antibody to form a covalent bond. The active site of the CA that formed acquires the ability to 'perceive' and favour these conversions. Such a hapten not only favours the formation of the transition state of the CA but virtually mimics the reaction itself. Here, structural elements favouring the whole chain of conversions involved in this multistage process are generated in the active site of the CA.

Condensation of 3-(4-acetamidophenyl)propionaldehyde (**166**) with acetone resulting in 4-hydroxy-6-(4-acetamidophenyl)-hexanone (**167**) was used as a model reaction aimed at obtaining CA of the aldolase type.^{80, 81}

A β -diketone derivative **168**, which is structurally similar to compounds **166** and **167** and contains the substrate 'recognition groups' and a spacer, $[\text{CO}(\text{CH}_2)_3\text{COOH}]$, was used as a hapten.

The hapten **168** induced the formation of structural elements that favoured the appearance of a lysine residue in the active site of the CA and the interaction of the NH_2 group of this lysine residue with the substrate to give the key intermediate **169** with an enamine structure.

$\text{Ar} = \text{C}_6\text{H}_4\text{NHCO}(\text{CH}_2)_3\text{COOH}-p$

The stabilisation of the intermediate **169** was achieved owing to the equilibrium $\text{169a} \rightleftharpoons \text{169b}$ and the formation of a conjugated system, *viz.*, carboximide vinyllogue.

In addition, this hapten favoured the necessary mutual arrangement of the aldehyde **166** and acetone and thus lowered the entropic barrier to the bimolecular reaction. Thus, owing to its conversions in the active site of the CA that is formed, the hapten **168** generated all the elements needed for this reaction to occur. The formation of the enamine, the main driving force of aldol condensation, is crucial for this reaction. It is the formation of the enamine structure of the type **169** that indicated that the reaction of the antigen with the antibody generated against it did occur. This circumstance was taken into consideration in primary monitoring of reactive antibodies by chemical methods [instead of commonly employed monitoring by immunoenzymic methods (see p. 1001)].

The antibodies against the hapten **168** were studied by spectral analysis as complexes with the hapten. It was assumed that all the complexes having absorption bands at 316 nm characteristic of the carboximide vinyllogue **169b** and, correspondingly, capable of forming enamines possessed catalytic properties. The two CA (38C2 and 33F12) thus selected did manifest high activity and catalysed the aldol condensation of the aldehyde **166** with acetone. This catalytic reaction followed Michaelis–Menten kinetics and was inhibited by the hapten analogue or acetylacetone. These and some other data suggest that the CA in fact functions as a natural aldolase. Kinetic measurements showed that these CA accelerate the reaction 10^9 -fold; their activities were close to that of the natural enzyme.

It is essential that both CA manifest broader substrate specificity than the natural aldolase, which catalyses an analogous conversion and thus demonstrates the benefits of the artificial enzyme. Thus the CA 38C2 catalyses the condensation of **166** not only with acetone but also with other ketones (fluoro- and chloroacetone, butan-2-one, pentan-3-one, pentan-2-one, dihydroxyacetone), although its efficiency is lower in this case. The condensation with asymmetrical butan-2-one and pentan-2-one was regioselective, *viz.*, the reaction occurred predominantly at the CH_2 group of the ketone to give branched aldols. The catalytic effect of the CA in the reaction of the aldehyde **166** was manifested

only towards ketones, the reaction with acetaldehyde was not accelerated. However, the CA 38C2 catalysed reactions of acetone with branched analogues of the aldehyde **166** (e.g., with 3-aryl-2-methylpropionaldehyde derivative **170**) with even higher efficiency.

The action of the CA was highly stereoselective. Thus the addition of acetone to the stereoisomeric aldehydes **170** occurred with high diastereoselectivity: the *S*-isomer yielded the 4*S*,5*S*-isomer of the aldol (**171a**) (*de* > 95%), while the *R*-isomer gave the 4*S*,5*R*-aldol **171b** (*de* > 83%).

a: $\text{R}^1 = \text{Me}$, $\text{R}^2 = \text{H}$; **b:** $\text{R}^1 = \text{H}$, $\text{R}^2 = \text{Me}$.

It is noteworthy that in both cases the addition of the acetone molecule occurs from the *re*-side irrespective of the configuration of the chiral centre in the aldehyde **170**. The rate of this addition is the same for the both isomers **170**. Therefore it cannot be used for kinetic resolution of the racemate of the aldehyde **170**.

Yet another possibility of catalysis of aldol condensation with CA has been studied.⁸² Since the catalytic effect of aldolases is based on the acceleration of the reaction of the carbonyl group of an aldol donor with the amino group of the lysine residue with subsequent formation of a nucleophilic enamine, it was decided to carry out aldol condensation in the presence of a CA against the hapten of the type **77** using an amine with the appropriate pK_a as a cofactor. This amine would react with the CA in its active site to yield a 'modified' CA the mechanism of action of which would be then typical of that of the natural aldolase.

This possibility has been examined in the condensation of 3-aryl-2-methylpropionaldehyde **170** with acetone in the presence of a CA against the hapten **77** and a benzylamine derivative *p*- $\text{H}_2\text{NCH}_2\text{C}_6\text{H}_4\text{CONH}(\text{CH}_2)_2\text{OH} **172** as a cofactor. This amine is structurally similar to the hapten **77** and has the corresponding value of pK_a (8.5). It may therefore be assumed that it will react with CA against this hapten and modify it in the appropriate way; the reaction of aldol condensation will occur *via* the formation of the immonium ion **173**, the enamine **174** and the product of its condensation with the aldol acceptor **175** (Scheme 18).$

$\text{Ar} = \text{C}_6\text{H}_4\text{CONH}(\text{CH}_2)_2\text{OH}-p$

Indeed, the condensation of the aldehyde **170** with acetone in the presence of the CA 72D4 and a cofactor (amine **172**) at

pH 7–9 occurs with high efficiency and follows Michaelis–Menten kinetics with respect to each component. Evidence was obtained that this reaction involves the formation of the intermediates **173** and **175**. The use of the tertiary amine as a cofactor does not result in a catalytic effect.

This reaction is stereoselective: the racemate of the aldehyde **170** gives *S,S*- and *R,S*-diastereomers of the aldol **171** with *de* 95% and 65%, respectively in 1 : 2.8 ratio.[§]

The aforementioned examples of the preparation of artificial aldolases possessing high stereoselectivity and a broader specificity than natural enzymes illustrate one of the most remarkable achievement in the design of a new generation of biocatalysts.

VII. 1,2-Elimination reactions (β -elimination)

Reactions of 1,2-elimination (dehydrohalogenation, dehydration, *etc.*) underlie many synthetic procedures that are used for introduction of multiple bonds into the carbon skeleton of a molecule. Catalytic antibodies which catalyse these conversions are mostly of interest because they can alter the stereochemical result of some reactions resulting in alkene isomers that are inaccessible in energetically forbidden reactions of non-catalysed elimination. Most frequently, elimination of hydrogen halide, water and other small molecules from the vicinal carbon atoms with the formation of a multiple bond occurs as a concerted process.

Several examples of preparation of CA catalysing 1,2-elimination are presently known. The action of these CA is based on promotion of the reaction by introduction, into the active site of CA, of a group favouring removal of either a proton or a substituent (*e.g.*, the OH group in the dehydration), thereby initiating a concerted elimination process.

The preparation of a CA catalysing elimination of HF from the fluoroketone **176** to give the benzylideneacetone derivative **177** is an example.^{84, 85}

The design of a hapten aimed at generation of the active site of CA was based on an assumption that facilitation of α -deprotonation would accelerate the reaction. Therefore, compound **178** was selected as a hapten, which contained the groups similar to those in the ketone **176**. The CH₂ group in this ketone was replaced by the ammonium group. It was assumed that the latter would generate a group (presumably, a carboxy group) in the complementary position of the active site of CA which would facilitate deprotonation of the CH₂ group of the substrate **176**.

Indeed, compound **178** immobilised on the protein through a (CH₂)₄COOH spacer group generated a CA that accelerated the elimination of HF from the fluoro ketone **176** 10⁴-fold. This reaction followed Michaelis–Menten kinetics and was inhibited by the hapten and its analogues. Modification of the CA with chemical reagents and the character of the pH dependence of the CA activity confirmed the presence of a carboxy group (in the form of aspartate or glutamate) in the active site of the CA. This was confirmed by isolation of the corresponding peptide upon hydrolysis with trypsin of a CA modified with diazoacetamide. The effect of CA was substrate-specific, *viz.*, the elimination from

the *meta*-isomer of the ketone **176** was activated less strongly than from the *para*-isomer. It was found that the racemate of the substrate **176** yielded a mixture of *cis*- and *trans*-isomers of the unsaturated ketone **177**.

The stereochemical outcome of the elimination reaction is of particular interest. The reactions of all four diastereomers of the ketone **176** containing one deuterium atom in the CH₂ group were studied. Because of free rotation around the CHF–CH₂ bond in the molecule of the ketone **176**, the stereochemistry of β -elimination could be judged from the ratio and the structure of the *cis*- and *trans*-isomers of the unsaturated ketone **177** formed. The experimental results suggest that β -elimination takes place when the fluoro ketone molecule **176** is in the staggered conformation, *i.e.*, when the F and H (or, correspondingly, D) atoms are in the *anti*-periplanar position (*anti*-elimination). It thus follows that the active site of the CA favours *anti*-elimination without discriminating considerably between the *R*- and *S*-isomers of the substrate. This suggests that the carboxy group in the active site of the CA is conformationally flexible and can approach that particular proton the splitting of which is most favourable for the elimination from the *anti*-periplanar position.

In this context, the preparation of CA catalysing elimination of two 'eclipsed' atoms (or groups), *i.e.*, promoting '*syn*-elimination', is of special interest.⁸⁶ In the absence of a catalyst, this reaction is impeded, since the 'eclipsed' conformation is energetically most unfavourable because of the strong steric and/or electronic interaction of the neighbouring groups. Thus *syn*-elimination leading to a *cis*-alkene is an example of the so-called 'unfavourable' reaction and can hardly be realised by purely chemical methods. In order to perform this energetically unfavourable (or even forbidden) reaction, the active site of the CA must fix the substrate molecule in an unfavourable, 'eclipsed' conformation. Then the group facilitating deprotonation (*e.g.*, the carboxy group) present in the active site of the CA must be fixed in a position close to the proton to be eliminated from the substrate.

This idea has been successfully materialised in the preparation of a CA catalysing *syn*-elimination of HF from the ketone **179a** to yield the *cis*-isomer. In the absence of CA, this reaction cannot be performed, since the molecule **179a** adopts the staggered conformation **A**, as a result of which the H and F atoms in the *anti*-periplanar position are eliminated to give the *trans*-alkene **180a**.

A CA raised against the hapten **181** with a rigid bicycloheptane skeleton was used to direct the reaction towards the formation of the *cis*-alkene **180b**.

The hapten **181** forms such a cavity in the active site of the CA, where the PhCO and Ph groups of **179a** are fixed in an 'eclipsed' position relative to the central C–C bond (the conformation **B**). This determines their *cis*-position in the elimination product.

The position of the NH₂ group in the hapten **181** corresponds to the eclipsed position of the proton in the molecule **179a** relative to the fluorine atom that is eliminated. The NH₂ group, which is

[§]This reaction is reversible; the aldol formed can undergo retroaldol degradation or be converted into an unsaturated ketone. For the effect of spatial structure of the aldol on its further conversions, see Ref. 83.

converted into the NH_3^+ group in the CA biosynthesis, generates a carboxy group ensuring the catalysis in a strictly specific position of the active site of the CA.

The catalytic antibody against the hapten **181** catalyses the elimination of HF from the ketone **179a** to give only the *cis*-alkene **180b**, i.e., ensures 'syn-elimination' with high stereospecificity and fully changes the stereochemical result of this reaction in comparison with the non-catalysed process. The catalytic reaction follows Michaelis – Menten kinetics and is inhibited by the hapten **181** and its structural analogues which points to its occurrence in the active site of the CA. Thus, conditions exist which compensate for the consumption of additional energy ($\sim 5 \text{ kcal mol}^{-1}$) needed for the 'unfavourable' *syn*-elimination reaction to take place.

It is of note that this CA catalyses the conversion of the ketone **179a** into the *cis*-alkene **180b** more effectively than the conversion of the diastereomeric ketone **179b**.

The conversion **179b** $\rightarrow$ **180b** occurs as the *anti*-elimination, which suggests that the active site of the CA binds specifically with the conformer where the PhCO and Ph groups (and, correspondingly, the H and F atoms) are 'eclipsed' and is less suitable for the fixation of the conformers with the *anti*-periplanar position of these substituents.

The reaction of 1,2-dehydration is yet another type of β -elimination. One plausible mechanism of dehydration of hydroxy ketones involves protonation of the hydroxy group, the formation of an oxonium intermediate in the transition state and subsequent elimination of the substituent as the water molecule, which is energetically more favourable.

The possibility to obtain a CA catalysing this reaction was studied using the dehydration of the β -hydroxy ketone **182** into the unsaturated ketone **183** as an example (Scheme 19).⁸⁷

The hapten **185** used to obtain such a CA contained the ammonium group instead of the hydroxy group in the ketone **182**. The ammonium group would induce the formation, in the complementary position of the active site, of a group responsible for the protonation of the hydroxy group in the molecule **182** and stabilisation of the transition state **184**. The disulfide group was used in a spacer to provide binding of the hapten **185** with the protein.

This CA accelerated the elimination more than 1000-fold. It is specific to the substrate structure, since it does not catalyse the dehydration of the *meta*-isomer of the ketone **182**. The nature of the group in the active site of CA that stabilises the oxonium centre in the transition state remains obscure.

It is of note that the same CA catalyses stereoselective transformation of 4-nitroacetophenone **186** into the oxime **187**, which occurs as a consecutive addition and dehydration.⁸⁸

The dehydration of the intermediate **188** in the absence of the CA is not stereochemically unambiguous and yields a mixture of *syn*- and *anti*-oximes **187** in a 3 : 1 ratio. The reaction conducted under identical conditions but in the presence of the CA is accelerated 10⁴-fold and gives predominantly the *syn*-oxime (the *syn* : *anti* ratio is 9 : 1). It is remarkable that the same CA induces the elimination of small molecules not only from the C – C bond, but also from the C – N bond, if the substrate molecules are structurally close to each other.

Transformation of benzoisoxazole **189** into the *o*-cyano-phenol derivative **190** is another example of dehydration for which a highly effective CA has been obtained.⁸⁹

This reaction is initiated by deprotonation to give a partially delocalised transition state **191**. This reaction occurs as a concerted *E2*-elimination.

In order to initiate this reaction, the active site of a CA must contain a group favouring deprotonation. Obviously, a carboxy group with appropriate acidity ($\text{pK}_a = 7.8$) matching the proton to be split off meets this demand.

The benzimidazole derivative **192**, which is planar like benzoisoxazole and bears a spacer providing its immobilisation on the protein, was used as a hapten. The N(3) atom in the hapten **192** is protonated and is positively charged, which induces the formation of the carboxylate ion in the active site of a CA.

The most active CA raised against the hapten **192** accelerated the reaction $\sim 10^8$ -fold compared to the reaction catalysed by the acetate ion. Such efficiency is one of the highest attained with CA so far.

The results of kinetic and inhibitory analyses and the character of pH dependence of the CA effectiveness suggest that initially the CA forms a complex with the substrate. It is followed by deprotonation under the action of the carboxylate ion in the cavity of the active site, resulting in the ring opening. Such a high catalytic effect is attributed⁸⁹ to the correct choice of the hapten stimulating the formation of a carboxy group of proper acidity and at the necessary place of the active site of the CA.

A recent study⁹⁰ describes the preparation of CA catalysing β -elimination of *p*-nitrobenzeneselenenic acid from the selenoxide **193** to yield the unsaturated derivative **194** (Scheme 20).

This reaction, which has recently attracted considerable attention of synthetic chemists, occurs as a [2,3]-sigmatropic process. It is believed that the planar five-membered pericyclic transition state **195**, which is less polar than the original molecule **193**, is formed in the first stage.

The proline derivative **196**, which was deemed to form a relatively low-polar medium in the active site of a CA,⁹⁰ was used as a hapten. Such a medium favours the pericyclic reaction; the carboxy group and the benzene rings form a cavity in which the substrate is fixed in a conformation favourable for the reaction.

$\text{R}^1, \text{R}^2 = \text{H, COOH.}$

Two CA against the *cis*-isomer of the hapten **196** ($\text{R}^1 = \text{H}$, $\text{R}^2 = \text{COOH}$) and one CA against its *trans*-isomer ($\text{R}^1 = \text{COOH}$, $\text{R}^2 = \text{H}$) have been obtained. All of them accelerated the elimination reaction several hundred times (2000-fold in case of the most active CA). The reaction rate increased with a decrease in the size of the substituent R in the molecule of the original selenoxide **193** ($\text{COOH} < \text{CH}_2\text{OH} < \text{Me} < \text{H}$).

Of particular interest is the stereochemical result of this reaction, which opens up new opportunities for its application in organic synthesis. The non-catalysed elimination of selenenic acid from the selenoxide **193** results in *trans*-alkenes for steric reasons. If the reaction is performed in the presence of a CA raised against the *trans*-hapten **196** ($\text{R}^1 = \text{COOH}$, $\text{R}^2 = \text{H}$), the racemic selenoxide is converted into the *trans*-alkene **194** (90%), while the *cis*-isomer is formed in insignificant amounts (10%).

On the contrary, in the presence of catalytic antibodies against the *cis*-hapten ($\text{R}^1 = \text{H}$, $\text{R}^2 = \text{COOH}$) only a half of the racemate **193** (*i.e.*, one stereoisomer) undergoes conversion. It is noteworthy that whereas one CA gives exclusively *trans*-alkenes, while the other yields both *cis*- and *trans*-isomers **194** in the 45:55 ratio. This unusual result was rationalised as being due to the fact that the cavity of the active site of this CA was split into two parts, so that the CA could interact with both stereoisomers. Detailed analysis of the reaction kinetics revealed strong effects of the medium polarity and solvation on the catalytic activity of the CA.

There is a single study⁹¹ devoted to the preparation of CA which catalyse *cis*–*trans*-isomerisation of a double bond. These CA effect the conversion of the *cis*-isomer of the α,β -unsaturated ketone **197** into the *trans*-isomer **198** (Scheme 21).⁹¹

It is believed that the isomerisation occurs by addition of a basic (or a nucleophilic) group to the double bond to give the transition state **199**. After rotation around the ordinary bond that

formed, the substrate acquires a more favourable *transoid* conformation, while elimination of X^- gives the *trans*-isomer **198**.

Such an isomerisation could take place provided that the active site of the CA contained a group X that could add to the double bond and the spatial configuration of the cavity in the active site of the CA favoured subsequent conformational transition.

The hapten **200** was used to obtain a CA in which the nitrogen atom of the piperidine ring generated a carboxy group (a carboxylate ion) in the active site of the CA, while the benzene rings in the molecule **200** form a cavity favouring the conformational transition of the substrate by lowering the energy barrier to this reaction.

The catalytic antibody against the hapten **200** accelerated the isomerisation of the alkene **197** into the alkene **198** 1.5×10^4 -fold. This reaction was inhibited by the *trans*-isomer of the hapten **200** but not by its *cis*-isomer. The presence of a carboxy group in the active site of the CA was confirmed by chemical modification of this CA. Thus, the CA plays the role of an ordinary acid which lowers the energy barrier to isomerisation.

VIII. Formation and opening of the oxirane ring

Several papers^{92–97} devoted to the preparation of CA catalysing the formation and opening of the oxirane ring present special interest for synthetic chemists.

Thus a CA catalysing synthesis of oxiranes by epoxidation of a non-activated double bond of alkenes under the action of oxidants has been prepared.⁹² This study was focussed mainly not on the acceleration of this well-known reaction but on the possibility of its stereochemical control, *i.e.*, an increase in its enantioselectivity. The catalytic effect of the CA was studied with the conversion of alkenes of the type **201** into the oxiranes **202** as an example.⁹²

Hydrogen peroxide in acetonitrile was found to be the most suitable oxidant; in this case, the real oxidant is peroxyacetimidic acid $\text{CH}_3\text{C}(=\text{NH})\text{OOH}$. It is essential that the effectiveness of this oxidant is combined with its mild action; it did not destroy the protein.

Ar = C₆H₄CONH(CH₂)₂OH-*p*

Compound	R ¹	R ²	R ³
a	Me	H	Me
b	H	–(CH ₂) ₃ –	
c	H	Me	Me
d	H	H	Me
e	Me	Me	Me

The catalytic antibody must favour the pyramidalisation of carbon atoms, *i.e.*, their transition from *sp*²- to *sp*³-hybridisation. The active site of the CA was formed under the action of the hapten **203** with a positively charged tetrahedral nitrogen atom, which ensured the formation of a negatively charged group that facilitated acid catalysis.

L = spacer; Ar = C₆H₄CONH(CH₂)₂OH-*p*.

One of the catalytic antibodies raised against this hapten was relatively effective in the conversion of the alkenes **201** into the oxiranes **202**. It was found that epoxidation of trisubstituted alkenes (**201a–c**) was accelerated 40–125-fold, epoxidation of the disubstituted alkene **201d** and the tetrasubstituted alkene **201e** was accelerated 60- and 15-fold, respectively. High enantioselectivity of this oxidation presents substantial interest, although it depends on the alkene structure. The alkenes **201b** and **201c** yielded the corresponding oxiranes **202** with optical purity 98% (with allowance made for the reaction product formed in the parallel non-catalysed reaction). Enantioselectivity of the oxidation of the alkene **201a** was 67%, which can probably be ascribed to the ability of this alkene to react in two different conformations.

Catalytic epoxidation of styrene in the presence of a CA raised against a metalloporphyrin derivative with iodosobenzene as an oxygen source has been described.⁹³ This study was undertaken with the view of elucidating the mechanism of action of natural oxidases of the cytochrome type.

Studies aimed at the synthesis of CA that accelerate the opening of the oxirane ring are of considerable interest. Such CA enable a control over the regioselectivity and enantioselectivity of this reaction.

A catalytic antibody of this type was used⁹⁴ to catalyse the hydrolytic opening of the oxirane ring in the alicyclic oxirane **204** (Scheme 22).

Scheme 22

Ar = C₆H₄CONH(CH₂)₂COOH.

This acid-catalysed reaction occurs *via* the transition state **206** in which the tertiary carbon atom bears an excess positive charge and is subject to a nucleophilic attack, in this case, by the OH[–] ion. The catalytic function of the active site of the CA is reduced to the promotion and stabilisation of this positively charged centre and facilitation of ‘pyramidalisation’ of the corresponding carbon atom.

The hapten **203** was used to generate the CA. This hapten is thought⁹⁴ to form a cavity in the CA complementary to the transition state and the positive charge on the nitrogen atom favours the formation of a negatively charged group stabilising the excess positive charge of the transition state.

This antibody accelerated the conversion of the oxirane **204** into the 1,2-diol **205** 440-fold in comparison with the reaction carried out under identical conditions but in the absence of the CA and, which is especially important, with high enantioselectivity: the racemate of the epoxide **204** yields only the *R,S*-diol **205** (*ee* 87%). This reaction obeys Michaelis–Menten kinetics and is inhibited by an analogue of the hapten **203**, which confirms its localisation in the active site of the CA.

The catalytic antibody raised against the hapten **203** manifests broad substrate specificity and accelerates 100-fold the ring opening in simple epoxides of the aliphatic series, for example, the conversion of the epoxide **207** into the diol **208**. However, in this case the reaction is devoid of enantioselectivity, *viz.*, the *R*- and *S*-isomers of **207** are hydrolysed at the same rate, while hydrolysis of the corresponding racemate does not yield an excess of the *R*- or the *S*-enantiomer.

The difference in the behaviour of the oxiranes **204** and **207** is ascribed to the presence of an additional five-membered ring in the molecule **204**. In this case, the substrate and the active site of the CA created against the cyclic hapten are in a tighter contact.

Of particular interest is the use of CA in the catalysis of intramolecular opening of the oxirane ring in epoxy alcohols where a CA can change the regioselectivity of the reaction. The opening of the oxirane ring in the epoxy alcohol **209**, which culminates in the formation of a heterocyclic system, is an example.

This reaction may proceed by two different routes. In the absence of CA, it proceeds only by a route (*a*) as the nucleophilic attack at the C(4) atom of the epoxide ring and gives the tetrahydrofuran derivative **210** in accordance with the so-called ‘Baldwin rule’.⁹⁶ Apparently, the reaction occurs *via* the transition state **211** with a partial positive charge on C(4) (Scheme 23).

Ar = C₆H₄NHAc-*p*, C₆H₄OMe-*p*.

It was found that this reaction can be fully reversed in the presence of the corresponding CA and channeled through the energetically less favourable route (*b*) to give the tetrahydropyran **212**, which requires special conditions, that would direct the reaction *via* the transition state **213**. This demand was met with the use of a CA the active site of which corresponded to the transition state **213** different from the transition state **211**. The piperidine *N*-oxide derivative **214** the geometry of which is close to that of the transition state **213** was used as a hapten.

The haptin **214** has the $N^+ - O^-$ group which matches the carbon and oxygen atoms bearing excess charges in the transition state **213**. All this promoted the formation of groups stabilising this transition state in the active site of the CA.

Indeed, one of the CA obtained (26D9) favoured the strictly regiospecific opening of the oxirane ring to give the tetrahydropyran **212** alone. The action of this CA was also highly stereoselective: only the *S,S*-isomer of the epoxy alcohol **209** was converted into the *S,R*-isomer **212**. This alteration in the reaction course in the presence of the CA was due to the formation of a complex between the transition state **213** and the complementary active site of the CA, which decreased the free energy of the transition state **213** and lowered the energy barrier to this reaction. Route (b) proved to be energetically more favourable than route (a).

An analogous CA-induced change in the regiospecificity of the reaction of intramolecular opening of the epoxy alcohol **215** has been reported.⁵⁴ Under conditions of ordinary acid catalysis, only a tetrahydrofuran derivative is formed, whereas in the presence of the CA tetrahydropyran **216** is exclusively formed.⁵⁴

This reaction is highly stereoselective: the racemate **215** gives the *S,R*-isomer **216**, while the *R,R*-isomer of the epoxy alcohol **215** does not enter into the reaction.

Further experiments showed that such changes in regiospecificity are common for the cyclisation of epoxy alcohols. Thus it was found unexpectedly that the cyclisation of the epoxy alcohol **217**, which under normal conditions is converted into the tetrahydropyran derivative **218** in accordance with the Baldwin rule, yields exclusively the oxepane **219** in the presence of the same CA (26D9).

Thus, in this case, too, the CA channels the reaction through an energetically 'unfavourable' route.⁹⁷ Since the geometry of the haptin involved in the formation of the active site of the CA corresponded to the transition state with a six-membered ring, the formation of the oxepane **219** is unexpected at first glance. The authors interpret this phenomenon by the fact that the role of the CA consists primarily in the formation of a group in the appropriate position of the active site which facilitates the strictly specific opening of the oxirane ring. The size of the heterocyclic ring formed in the process depends on the length and conformation of the aliphatic chain (tether) in the epoxy alcohol **217**.

The above examples demonstrate various applications of CA in directed organic synthesis and elaboration of new synthetic procedures.

IX. Redox reactions

Studies aimed at the search for CA catalysing redox reactions have been neither extensive, nor systematic, apparently because of the existence of numerous chemical and biochemical methods for

their efficient realisation. Nevertheless, several CA catalysing the reduction of carbonyl groups have been prepared. The use of artificial CA pursued the objective to make reduction more selective.

Some CA catalysed the reduction of the α -oxo amide **220** into the α -hydroxy amide **221**⁹⁸ and the reduction of the ketones **222** into the corresponding alcohols **223** with NaBH_3CN .⁹⁹

R = Et, Prⁱ, Bn.

In the former case, the corresponding phosphonic acid derivative **224** was used as a haptin.

The phosphorus atom in the haptin **224** is in the same position as the oxo group in the substrate **220** to be reduced. The haptin **224** ensured the formation of a group, in the active site of CA, responsible for the polarisation of the oxo group and the tetrahedral structure of the phosphorus atom provided the stereoselectivity of the nucleophilic attack on the carbon carbonyl atom by the hydride ion in the transition state. The resulting CA accelerated the reduction of the oxo amide **220** 300-fold in comparison with the non-catalysed reaction. High stereoselectivity is the main merit of this reduction, because the alcohol **221** with the *S*-configuration formed in the presence of the CA was of 99% purity, whereas the *R*- and *S*-isomers were formed in approximately equal amounts in the absence of the CA.

Since the oxo group in the ketone **222** is less reactive than that in the oxo amide **220**, a more effective CA raised against the haptin **225** was used to catalyse this reaction.

The $N^+ - O^-$ group in the molecule **225** ensured the formation of the CA. Its active site ensured both the stabilisation of the tetrahedral transition state and enhancement of the substrate polarisation, which are essential for the nucleophilic attack of the reducing agent.

This CA accelerated the reduction of the oxo group in the ketones **222** approximately 100-fold; the alcohols **223** having the *S*-configuration were formed with high stereoselectivity (88%–95% *ee*) irrespective of the size of the alkyl substituent. The effect of CA was also highly regiospecific. The reduction of the unsymmetrical diketone **226** in the presence of this CA afforded the *S*-enantiomer of the hydroxy ketone **227** in 95% yield, whereas other probable reaction products (compounds **228** and **229**) were formed in insignificant amounts. The regiospeci-

ficity of the CA is determined by the structure of the initiating hapten **225**, viz., by the presence of the NO₂ group.

Among oxidation reactions for which effective CA have been obtained, special mention should be made of the oxidation of the sulfide **230** into the sulfoxide **231** (Scheme 24).

Scheme 24

It is believed that this reaction involves the attack at the sulfur atom of the sulfide **230** with the oxygen of the periodate ion which occurs *via* the transition state **232**.

Based on these concepts, the hapten **233**, a benzylaminophosphonic acid derivative, the amino group of which was transformed into the ammonium group under conditions of the CA biosynthesis, was used to generate the CA. The ammonium group favoured the formation of a negatively charged group stabilising the positive charge on the sulfur atom in the transition state, whereas the phosphonic acid residue formed a cavity binding the periodate ion in the active site of the CA.¹⁰⁰

One of the CA raised against this hapten accelerated the oxidation of the sulfide **230** 2×10^5 -fold; its effectiveness was close to that of natural oxidases, although it differed from the latter by low enantioselectivity ($\sim 15\%$ ee). This CA was practically inert with respect to periodate. The mechanism of its catalytic action and the structure of its active site were established by X-ray analysis of a CA-hapten complex.¹⁰¹

It can also be noted that CA catalysing redox reactions have been used to solve some problems of biochemistry and enzymic catalysis, e.g., for determining the reduction potential of flavin¹⁰² and for estimating the contribution of two fluorescein fragments to the free energy of binding in the active site of CA.¹⁰³

X. Miscellaneous reactions

The catalytic antibodies described below have not found general use; yet they present certain interest since they demonstrate not only the broad range of conversions for which active CA can be obtained but also the high potentialities of these artificial enzymes.

1. Hydrolysis of phosphotriesters

The interest in the synthesis of CA catalysing hydrolysis of phosphotriesters¹⁰⁴ arose in connection with medicinal and environmental problems, since phosphotriesters and their derivatives are the basis for many pesticides and war gases and intermediate products for large-tonnage chemical industry. Preparation of CA providing mild hydrolysis of these toxic compounds and their practical application might become useful in curing poisoning with pesticides, war gases, etc.

Thus the preparation of a CA catalysing hydrolysis of a well-known pesticide paraoxon (**234**), which occurs with the elimination of 4-nitrophenol, was undertaken with compound (**235**) as a hapten.

The charges on the N⁺—O[−] group of the molecule **235** generate specific groups in the cavity of the active site of the CA, which favour protonation and/or stabilisation of the negative charge on the oxygen atom of the phosphate group, whereas the spatial structure of the hapten forms a cavity which corresponds to the optimum structure of the transition state.

The CA obtained accelerated hydrolysis of the phosphate **234** ~ 1000 -fold. The linear dependence of the reaction rate on the concentration of the hydroxide ion suggests¹⁰⁴ that the catalytic effect of this CA is most probably associated with the stabilisation of the transition state. The CA possessed rather narrow substrate specificity. Hydrolysis of phosphate **234** analogues with a methoxy or an acetamino group in the benzene ring and of cyclic phosphates was practically not accelerated by this CA.

2. Cleavage of triphenylmethyl ethers

Selective splitting of the triphenylmethyl (trityl) group presents certain practical interest, since this group is widely employed in synthetic practice for temporary protection of the hydroxy group, especially in the synthesis of nucleosides and carbohydrates. Detritylation is usually performed under rather drastic conditions of acid hydrolysis. Preparation of CA which would permit one to perform detritylation under neutral conditions and with required selectivity presents substantial interest.

Detritylation of the ether **236** served as an example.¹⁰⁵

R = (CH₂)₂O(CH₂)₂O(CH₂)₂OH.

The protonation of the oxygen atom possessing enhanced nucleophilicity is the rate-determining step in the detritylation of tris(4-methoxyphenyl)methyl ether **236**. The resulting transition state **237** is further decomposed to give tris(4-methoxyphenyl)methanol.

The triphenylphosphonium derivative **238** containing a spacer was used to obtain the CA catalysing this reaction.

This hapten was structurally similar to the substrate **236**. The positive charge on the phosphorus atom of this hapten favoured the formation of a negatively charged group in the CA.

The CA obtained accelerated the hydrolysis of the ether **236** 270-fold in comparison with the non-catalysed reaction at pH 6.0 and manifested broad specificity as it was active in detritylation of analogues of the ether **236**, *e.g.*, such compounds as $(p\text{-MeOC}_6\text{H}_4)_2\text{C(Ph)O(CH}_2)_5\text{COOH}$ and $(p\text{-MeOC}_6\text{H}_4)\text{-C(Ph)}_2\text{O(CH}_2)_5\text{COOH}$, by accelerating their hydrolysis 200- and 230-fold, respectively. It is of note that hydrolysis of the thio analogue of the ether **236** was also accelerated 70-fold by this CA, whereas that of the amine Ar_3CNHR was not catalysed.

The effect of pH on the detritylation of compound **236** in the presence of the CA suggested¹⁰⁵ that its catalytic action was not owing to the direct effect of the carboxy group but rather due to electrostatic stabilisation of the oxonium centre of the transition state **237** in the cavity of the active site of the CA. This study on the preparation of a CA catalysing detritylation, was not explored further but it gave an impetus to the preparation of CA for other reactions associated with the cleavage of oxygen–carbon bonds (see Section V).

3. Decarboxylation reactions

Preparation of CA catalysing one specific reaction, *viz.*, the decarboxylation of 5-nitrobenzo[d]isoxazole-3-carboxylic acid **239** resulting in 4-nitro-2-cyanophenol, has been described (Scheme 25).¹⁰⁶

Scheme 25

This first-order reaction[¶] occurs as a concerted process. It is known that it is not associated with acid–base catalysis but its rate depends critically on the reaction medium. This reaction is accelerated by several orders of magnitude in aprotic solvents, in micelles and in the presence of organic polymers. Presumably, it

[¶] For an analogous CA-catalysed conversion of nitrobenzoxazole into a cyano phenol derivative, see Section VII.

proceeds *via* the transition state **240** in which the bonds are partially delocalised. A CA catalysing this reaction must contain a hydrophobic active site with polar groups favouring the splitting of CO_2 .

The hapten **241** with a spacer group (R) was used to generate CA.

It was suggested¹⁰⁶ that the naphthalene nucleus of the hapten provides the formation of a cavity complementary to the substrate in the active site of the CA, while the sulfo groups induce the appearance of positively charged groups, which facilitate splitting of CO_2 . The authors' arguments in favour of this hapten are not completely clear; nevertheless, a highly effective CA able to accelerate the reaction 2×10^4 -fold in comparison with non-catalysed decarboxylation has been raised. It is of note that no active CA could be raised against the hapten **242**, which matches more closely the substrate but is devoid of polar sulfo groups.

This reaction has been studied in detail using inhibitory analysis, fluorescence spectra and the kinetic isotope effect.¹⁰⁷ It was shown that the active site of the CA is very hydrophobic, and that the catalytic effect of the CA is achieved owing to the formation of a hydrophobic environment around the substrate. This conclusion was confirmed, in particular, by comparison of the rates of CA-catalysed reactions occurring in solvents of different polarity.¹⁰⁸

Preparation of a CA catalysing decarboxylation of 4-pyridylacetic acid has been reported.¹⁰⁹

Compound **243** with a cyclopentyl substituent, which was introduced to form a hydrophobic cavity in the active site of the CA, was used as a hapten.

The CA obtained accelerated the decarboxylation of 4-pyridylacetic acid and some of its methyl-substituted analogues 10^4 – 10^5 -fold. It was shown that the catalytic effect of such CA was largely due to the formation of a hydrophobic environment around the substrate in the complementary region of the active site of the CA. The main role in the formation of such a hydrophobic environment is played by the cyclopentyl substituent in the hapten **243**. Preparation of this kind of CA is of fundamental importance, since it demonstrates the possibility to attain a catalytic effect by the formation of hydrophobic zones in CA. This allows one to gain more insight into the mechanisms of action of natural decarboxylases.

4. Isomerisation of cyclic biphenyl derivatives

Isomerisation of the biphenyl derivative **244** incorporated in a cyclic system into its diastereomer **245** requires rather high (~ 20 – 26 kcal mol^{-1}) activation energy (Scheme 26).¹¹⁰

At room temperature, this reaction proceeds very slowly, because the rotation of phenyl nuclei around the common axis is

impeded due to the presence of methylene groups in *ortho*-positions.

Presumably, the effect of a CA is associated exclusively with the geometric factors favouring isomerisation rather than with stereoelectronic effects or acid–base catalysis. Assuming that this isomerisation occurs *via* the planar transition state **246**, a dihydrophenanthrene derivative **247** with fixed coplanar benzene rings was used in the preparation of CA as a hapten.

The most active CA obtained accelerated the isomerisation **244** → **245** approximately 3000-fold. This CA was subjected to a more detailed physicochemical analysis. It was demonstrated that the transition state **246** actually has a step-like conformation but its phenyl nuclei lie in the same plane.

5. The formation of metal–porphyrin complexes

The formation of metal–porphyrin complexes is the key step in many vital processes. Thus, Fe^{2+} incorporates into protoporphyrin IX at the final step of heme (**248**, $\text{R} = \text{CH}=\text{CH}_2$) biosynthesis.

This reaction is catalysed by a natural enzyme, ferrochelatase, and inhibited by *N*-methylprotoporphyrin IX. It is assumed that the inhibiting effect of the latter is due to the non-planar structure, which resembles that of the transition state formed in the reaction **249** → **248**. Therefore, *N*-methylprotoporphyrin IX competes with the transition state for binding with the active site of the enzyme.

N-Methylmesoporphyrin **250** in which propionic acid residues served as a spacer for immobilisation was used to generate an active CA catalysing the formation of metal–porphyrin complexes.¹¹¹

In this case, the choice of a hapten was based on the principle of mimicking the 'strained transition state'.

The most active CA obtained accelerated the formation of complexes of dihydroporphyrin **249** ($\text{R} = \text{C}_2\text{H}_5$) with Zn^{2+} and Cu^{2+} 2600- and 1700-fold, respectively. This reaction followed Michaelis–Menten kinetics and was inhibited by the hapten **250**. The catalytic effect of this CA varied for different metals and depended specifically on the porphyrin structure. Thus complex formation of protoporphyrin **249** ($\text{R} = \text{CH}=\text{CH}_2$) and its analogue ($\text{R} = \text{H}$) was not catalysed by this CA. This makes the effect of CA strongly different from that of ferrochelatase, which also catalyses the reactions of these analogues.

6. Photochemical reactions

Several CA affecting UV-induced reactions (*e.g.*, dimerisation of methyl 4-nitrocinnamate in acetone) have been obtained.¹¹² Under ordinary conditions, this reaction gives a mixture of the dimers **251**–**254**.

$\text{Ar} = p\text{-O}_2\text{NC}_6\text{H}_4$, $\text{R} = \text{COOMe}$.

With the use of a CA it was possible to change the ratio of the two main isomers **251** and **253** (0.45 : 1).

In order to increase the yield of the isomer **251**, it is necessary that the cavity of the active site of the CA matched the spatial structure of the dimer **251**. Therefore, the hapten **255** was used to generate the CA.

Irradiation of methyl 4-nitrocinnamate in the presence of the CA raised against the hapten **255** gave the dimers **251** and **253** in a 1.13 : 1 ratio. The reaction was accelerated by the CA. Thus, the formation of the active site favouring the appropriate configuration of the transition state directs the reaction towards the formation of the corresponding isomer. The structure of the group catalysing the dimerisation itself is still unknown.

Preparation of a CA catalysing UV-induced dissociation of the thymine dimer **256** ($\text{R}^1 = \text{R}^2 = \text{H}$, $\text{R}^3 = \text{Me}$) presents certain interest.¹¹³

UV-Induced dimerisation of the thymine residue of DNA is a cause of structural disturbances in this biopolymer, which has profound biological consequences. This reaction is reversible and DNA can be 'repaired' by irradiation in the presence of natural enzymes (DNA-photolyases).

The dissociation of the dimer **256** seems to occur through electron transfer with subsequent dissociation by a radical mechanism. Indole, quinone and flavin derivatives are sensitisers of the electron transfer. It was speculated that catalytic antibodies that catalyse effectively the dissociation of the dimer **256** ought to contain a group that sensitises the electron transfer in the cavity of the active site matching the substrate. The hapten **256** ($R^1 = \text{NHCH}_2\text{COOH}$, $R^2 = \text{H}$, $R^3 = \text{Me}$), which is the substrate analogue, was used to raise such CA. The efficiency of a CA raised against this hapten was comparable with that of the natural enzyme (DNA-photolyase from *E. coli*). The effect of the CA was specific: dissociation of the dimer **256** ($R^1 = \text{H}$, $R^2 = R^3 = \text{Me}$) was not catalysed. The changes in the fluorescence spectra during this reaction provide evidence that a tryptophan residue is responsible for sensitisation of this reaction in the active site of the CA.

The dissociation of the N_1 -carboxymethyluracil dimer **256** ($R^1 = R^2 = R^3 = \text{H}$) was studied in order to elucidate the mechanism of photochemical dissociation of nucleic bases.¹¹⁴ The corresponding CA was raised against the hapten **256** ($R^1 = \text{NHCH}_2\text{COOH}$, $R^2 = R^3 = \text{H}$), which is a structural analogue of the hapten used to obtain the CA catalysing the dissociation of the thymine dimer. The resulting CA accelerated the photodissociation of the uracil dimer 380-fold. A study of the effect of the wavelength of UV irradiation revealed the crucial role of a tryptophan residue on the electron transfer. Analysis of the isotope effect in the irradiation of C(5)- and C(6)-deuteriated uracil dimers has made it possible to suggest a general scheme for the photodissociation of nucleic base dimers.

XI. Conclusion

The creation of artificial catalysts having a protein structure and endowed with a predetermined specificity is one of the most impressive accomplishments in chemistry and biology. Considerable progress has been achieved over the decade elapsed since the preparation of the first catalytic antibody. A great number of such biocatalysts of a new generation have already been obtained. But what is most important is that the main principles of the design of catalytic antibodies of targeted action have been elucidated and the strategy of their preparation has been elaborated.

The design of a hapten determining the specificity of the antibody and the structure of its active site is the crucial step in the generation of a CA.

At present, the choice of a hapten is governed by different principles which reflect the diversity of mechanisms of conversion of organic compounds.¹¹⁵ In the simplest case, a compound the structure of which is spatially and electronically similar to that of the transition state, is used as a hapten, which stabilises this transition state in the active site of the CA. Haptens generating active groups responsible for acid–base or nucleophilic catalysis in substrate conversions in the active site of CA are also used for this purpose. Catalytic antibodies that are effective in sigmatropic and pericyclic reactions are raised against haptens which form a cavity in the active site of a CA that enables optimum reciprocal arrangement of the reactants (in bimolecular reactions) or a required stereoelectronic state of the substrate. This lowers the entropy barrier to a chemical conversion (the 'entropic trap' principle). In some cases, the purpose of the hapten is to create local or more extended hydrophobic zones in the CA mimicking conversion of the substrate in a 'non-aqueous' medium. In practice, haptens meeting simultaneously two or several requirements have been employed, which made it possible to form an active site which acted on the substrate in several directions at once.

The most recent approaches make use of haptens which directly interact with the antibodies raised against them. In this way, CA acquire the ability not only to stabilise the transition state but also to mimic the very process of conversion of the substrate (the so-called 'reactive immunisation').¹¹ Yet another approach consists in catalysis in the presence of a cofactor which acts simultaneously with the antibody (and actually modifies it in the course of the reaction) and channels the catalytic reaction in the necessary direction.⁸²

Further progress in this area will depend first of all on new efficient approaches to the design of haptens. It is due, primarily, to the development of theoretical chemistry and the use of computation and computer modelling for gaining a deeper insight into molecular mechanisms of biocatalysis and elucidation of mechanisms of catalytic reactions.

Great diversity of reactions for which catalytic antibodies have been already obtained testify to the high potentialities of this novel field. At first glance, it may seem that a catalytic antibody can be generated for virtually any conversion of an organic compound. However, it is still too premature to prognosticate and outline the real scope of the method.

The 'exploration' period in this area seems to be over. In addition to purely academic research, studies devoted to the preparation of artificial enzymes for practical purposes are currently under way. Yet, many general problems still await their solution.¹¹⁶ Here it seems appropriate to mention two of such problems which present special importance from the point of view of a synthetic chemist.

In most cases, the activity of synthetic CA is inferior to that of natural enzymes. The inhibitory effect of reaction products on catalytic antibodies is one main reason for the low activity of CA which reduces their 'turnover' number and decreases their efficiency. The understanding of the mechanism of this phenomenon and the ability to overcome the problem through the correct choice of a hapten is the urgent task.

All in all, catalytic antibodies differ strongly from each other in their substrate specificity: some CA have narrow specificity and are effective with respect to only one substrate, while others are effective with respect to a vast variety of structurally close compounds. The former ensure high chemo-, regio-, and stereo-specificity of a specific reaction and exclude parallel and side processes. The latter are more suitable for wide application and elaboration of a versatile synthetic procedure. As a matter of fact, both types of CA may coexist, and it would be important to learn how to control the range of their substrate specificity in the targeted preparation. This requires knowledge of mechanisms of the catalytic effect and the role of the fine structure of the active site in manifestation of specificity, and hence the correct choice of a hapten determining these properties.

Further improvement of the primary monitoring of CA raised and the procedure for the choice of the most efficient catalysts (see Ref. 117) are problems of substantial importance facing specialists in biological sciences. One may also hope that the efficiency of antibody biosynthesis in the immune apparatus will also be enhanced as a result of fundamental or methodological modifications of the existing immunisation protocols and further utilisation of the hybridomas obtained.

However, CA have already proved to be a very helpful tool in organic synthesis not only in enhancement of well-known reactions but, which is even more important, in increasing the specificity and stereoselectivity. It is therefore very tempting to obtain CA catalysing the reactions for which natural enzymes have not yet been found. Apparently, CA acquired the greatest importance in conversions of organic compounds which cannot be performed by purely chemical methods because of energetic and/or steric hindrances. In some cases, CA facilitate the formation of a required transition state and channel the reaction through a 'forbidden' route by changing its chemo-, regio- or stereospecificity, *i.e.*, opening up a way for a new synthetic method.

For chemists, the use of CA opens up new opportunities in the studies of the 'intimate' aspects of mechanisms of many reactions, the role of thermodynamic and kinetic factors, acid–base catalysis, effects of the medium, *etc.*

Catalytic antibodies may hold a particular position in bioorganic chemistry, specifically, in the chemistry of biopolymers where enzymes find especially wide uses.

Studies of CA are of considerable importance for the understanding of basic principles of biocatalysis.¹¹⁵ The possibility to obtain CA with targeted action and their comparison with natural enzymes of analogous action patterns, studies of the molecular structure of the active site of CA by X-ray analysis and other physicochemical methods, the use of targeted chemical modification or selective mutagenesis and many other features make catalytic antibodies an indispensable tool in studies on the mechanisms of enzymic catalysis, the structure of enzyme–substrate complexes and their role in the catalytic process. The problem of specificity of natural enzymes can be followed by preparing a series of CA with analogous action, elucidating their molecular structures, structure–specificity relationships and so on. Studies in this area are currently under way and have been briefly mentioned in this review.

Investigations of CA will probably make a significant contribution to the elucidation of other problems related to immunochemistry, immunology, protein biosynthesis, *etc.* Thus it is known that CA have already been used to study such specific problems as the formation and alteration of the structures of natural enzymes in the course of chemical evolution.¹¹⁸

Attempts have been made to use CA in medicinal practice (see a review¹¹⁹), *e.g.*, as preparations neutralising the effects of certain toxins, narcotics, *etc.* Their application in the creation of 'prodrugs' is another perspective trend.^{120–122}

This creates a problem of a large-scale preparation of CA. The first steps in this direction aimed at obtaining large batches of CA and their utilisation in the synthesis of gram quantities of compounds as well as the design and construction of a laboratory unit operating in a semi-automatic regime have already been undertaken.^{53,54} In the state-of-the-art biotechnology and protein engineering, preparation of large amounts of highly purified catalytic antibodies does not face any serious problems. Of course, their practical application on a large laboratory or industrial scale will require the solution of many other problems including technological ones. One problem is related to the most rational form of their application, *viz.*, in solution, in biphasic systems,¹²³ immobilised on carriers¹²⁴ or under conditions of micellar catalysis.¹⁵ Many of these problems connected with the use of natural enzymes have been successfully solved, which facilitates their solution in the case of CA.

As far as the economical aspect is concerned, the benefits of CA applications (*e.g.*, in asymmetric synthesis) may have fully paid off despite the labouriousness and expensiveness of the technological procedures involved in the preparation of these biocatalysts. However, their application in large-tonnage processes is still premature.

IV. Reactions of Δ^1 -piperideines	1040
V. Conclusion	1057

Abstract. The data on the synthesis and transformations of 2,3,4,5-tetrahydropyridine and its derivatives published after 1970 are surveyed and described systematically. The bibliography includes 251 references.

I. Introduction

The enhanced interest in the pyridine derivatives is due to some specific chemical and physical properties peculiar to this class of compound. The fact that pyridine bases exhibit a broad spectrum of biological activities is equally important. 2,3,4,5-Tetrahydropyridine (Δ^1 -piperidine) and its derivatives also attract attention. Δ^1 -Piperidine itself is a key compound participating in the biosynthesis of some alkaloids (for example, alkaloids of the coniine and lobeline groups). Substituted 2,3,4,5-tetrahydropyridines are convenient starting compounds for the synthesis of other families of alkaloids, the structures of which are often fairly complex.

Published data on the chemistry of tetrahydropyridines were surveyed for the first time in a volume.¹ This volume contains only one mention of Δ^1 -piperideines, namely, it presents a scheme for the synthesis of 3,5-dimethyl-2-phenyl- Δ^1 -piperidine. More recent volumes^{2,3} contain data on the methods of synthesis and properties of 1,2,3,4-tetrahydropyridines, 2,3,4,5-tetrahydropyridines and 1,2,5,6-tetrahydropyridines, mostly published before 1971. The chemistry of 2-alkoxy-3,4,5,6-tetrahydropyridines has been discussed in a review⁴ devoted to the lactim ethers containing heterocyclic nuclei of various sizes.

In the present review, we consider systematically the data on the chemistry of Δ^1 -piperideines published from 1970 to the present time. Among the compounds synthesised, the products belonging to one or another family of alkaloids are mentioned, and their biological activities are discussed.

II. Structure of Δ^1 -piperideines

The unsubstituted 2,3,4,5-tetrahydropyridine (**1**) stands out in the series of Δ^1 -piperideines. In fact, almost all 2,3,4,5-tetrahydropyr-

idine derivatives are monomers under ordinary conditions, whereas unsubstituted 2,3,4,5-tetrahydropyridine (**1a**) exists at pH ≥ 7 as three isomeric trimers, α -isomer **2**, β -isomer **3** and isotripiperidine **4**.⁵

The structures, configurations and conformations of these three trimers were determined by ^{13}C NMR spectroscopy.^{5,6} It was established that at low temperatures, the compound occurs as the trimer **3**, while at room temperature, it is converted into the trimer **2**. The trimer **4** can also exist at room temperature. The trimer **2** has C_3 symmetry and exists as a racemic mixture of the *RRR* and *SSS* configurations, while the trimer **3** is characterised by C_1 symmetry and is a racemic mixture of the *RRS* and *SSR* configurations. The most favourable conformations for all the three isomers are shown below.⁵

The monomer – trimer equilibrium has been studied by NMR, UV and IR spectroscopy.⁷ It was found that at pH 7, the compound **1a** occurs as a trimer, while in solutions in anhydrous acids, aqueous acids and aqueous alcohols, the equilibrium shifts towards the monomer. In strongly acidic solutions 2,3,4,5-tetrahydropyridine exists only as the monomer **1a**.

All the bond lengths and the internal angles in the six-membered ring of 2,3,4,5-tetrahydropyridine (**1a**) have been determined by *ab initio* quantum-chemical calculations.^{8,9}

Bond	Length / Å	Angle	Magnitude / deg.
a	1.5080	1	111.5
b	1.5242	2	108.6
c	1.5233	3	109.5
d	1.5241	4	115.5
e	1.4670	5	118.2
f	1.2830	6	128.0

The cyclic imine **1** exists in a half-chair conformation, having the lowest energy. Of the three piperideines, Δ^1 -piperidine **1a** is

Received 24 February 1997

Uspekhi Khimii 67 (12) 1133–1163 (1998); translated by Z P Bobkova

characterised by the minimum energy; if the relative energy of the compound **1a** is taken to be zero, the energy of 1,2,3,4-tetrahydropyridines is 6.39 kcal mol⁻¹ and that of 1,2,5,6-tetrahydropyridine is 11.9 kcal mol⁻¹. The calculated bond lengths and internal angles are in good agreement with the corresponding values determined for substituted Δ^1 -piperideines by X-ray diffraction analysis.^{8,9}

Some derivatives of the imine **1a** containing substituents at the 2-position exist as two tautomers. Thus 2-methyl-3,4,5,6-tetrahydropyridine **1b** is readily converted into the lithium derivative of 2-methylenepiperidine (**5**) on treatment with lithium diisopropylamide (LDA).¹⁰ In the presence of perchloric acid, the compound **1b** also reacts as 2-methylenepiperidine.¹¹

2-Methoxy-3,4,5,6-tetrahydropyridine **6**^{12–14} and 2-methylthio-3,4,5,6-tetrahydropyridine **7**¹⁴ can participate in reactions as the enamine forms **8** and **9**.

X = O (**6, 8**), S (**7, 9**).

In the case of 2-acetyl-3,4,5,6-tetrahydropyridine **10**, the equilibrium is shifted towards the enamine form **10a**. Having been formed, the compound **10** first exists as the less stable tautomer **10b**, which is then partially converted into the more stable tautomer **10a** (the **10a** : **10b** ratio is 2 : 1).^{15,16}

When 2-cyano-3,4,5,6-tetrahydropyridine **11** is made to react with MeMgI and then the reaction mixture is treated with an aqueous solution of ammonium chloride, a mixture of the tautomers **10a** and **10b** in 1 : 4 ratio is formed. During storage, the content of **10a** increases (**10a** : **10b** = 2 : 1).¹⁷

On distillation, the nitrile **11** is partially converted into 6-cyano-1,2,3,4-tetrahydropyridine **12** (ratio **11** : **12** = 1 : 1.3).¹⁷ The compound **11** isomerises to **12** upon the reaction with MeLi and subsequent treatment with water.

3-Cyano-2-methoxy-3,4,5,6-tetrahydropyridine **13** exists as two tautomers **13a** and **13b**, which is confirmed by the presence of two absorption bands in its IR spectrum, at 2180 cm⁻¹ (for the

conjugated CN group) and 2260 cm⁻¹ (for the non-conjugated CN group).¹³

It was found by ion cyclotron resonance that in the series of alkylated derivatives, tautomers **14b** are stronger bases than **14a**.¹⁸

R = H, Me.

III. Methods of synthesis of Δ^1 -piperideines

1. Synthesis from piperidine and its derivatives

The unsubstituted imine **1a** is commonly prepared by a two-stage procedure which includes treatment of piperidine with chlorinating agents and reaction of the resulting 1-chloropiperidine with nucleophilic reagents.

Treatment of amine **15a** with calcium hypochlorite in acetic acid gave the chloro-derivative **16a**, which was converted into the trimerised compound **1a** (yields 39% – 64%) by treatment with an ethanolic solution of KOH .^{19–21}

In other studies,^{22,23} piperidine and 2-methylpiperidine were converted into the cyclic imines **1a, b** on treatment with sodium hypochlorite in water followed by refluxing of the resulting *N*-chlorinated derivatives **16a, b** in a 10% ethanolic solution of potassium hydroxide²² or in a solution of sodium methoxide in methanol.²³

R = H (a), Me (b).

On treatment with Bu^tOCl in ether¹⁷ or THF,²⁴ the derivatives **15c, d** are transformed into the *N*-chlorinated compounds **16c, d**, which react with MeONa in MeOH , triethylamine in Et_2O ¹⁷ or KOH in EtOH and THF²⁴ to give the Δ^1 -piperideines **1c, d**.

R¹ = H, R² = CN (c); R¹ = R² = Ph (d).

In several studies,^{25–27} *N*-chlorosuccinimide in Et_2O was used to convert the amine **15a** into 1-chloropiperidine **16a**, and dehydrochlorination of the chloro-derivative was carried out using potassium hydroxide.

Gas-phase chlorination of piperidine **15a** with *N*-chlorosuccinimide (47°C , 10^{-1} – 10^{-2} mm Hg) and gas-phase dehydrochlorination of the resulting *N*-chloropiperidine **16a** (which is formed in 90% yield) over AdOK (Ad is 1-adamantyl) at 2°C ²² or over Bu^tOK at -97 to -77°C ^{22,28} have been reported.

N-Chlorosuccinimide (NCIS) has been used to chlorinate the substituted piperidines **15**; the resulting chlorinated derivatives **16** were converted into the Δ^1 -piperideines **1** using KOH in an alcohol.^{29–32}

Heating of tetramethylpiperidinium chloride **17** in trifluoroacetic acid in the presence of azobisisobutyronitrile yields radical cation **18**, which is converted into cation **19** with elimination of Me[•]. Treatment of the reaction mixture with an aqueous solution of sodium carbonate affords 2,6,6-trimethyl- Δ^1 -piperidine (yield 67%).³³

AIBN is azoisobutyronitrile.

The piperidine trimer is formed in a relatively low yield upon anodic oxidation of piperidine derivatives **20** under an inert atmosphere.³⁴

X	Anolyte	Current density /A dm ⁻²	The charge passed /F mol ⁻¹	Yield (%)
Li	LiClO ₄	0.21	1	6
MgBr	—	0.84	1	15

The transformation of piperidine **15a** into the piperidine trimer (yield 58%) upon oxidation with chloroiron(III) mesoporphyrin IX dimethyl ester has been reported.³⁵

The piperidines **15** react with sodium hyposulfite in the presence of catalytic amounts of silver nitrate giving a mixture of 1-(1-piperidyl)piperidines **21** and piperidine trimers.³⁶

A popular method for the synthesis of Δ^1 -piperideines is treatment of piperidin-2-one **22a** or piperidine-2-thione or their substituted derivatives with various reagents.

Thus heating of the lactam **22a** with dimethyl sulfate in benzene or toluene gives 2-methoxy-3,4,5,6-tetrahydropyridine **6a** in 70%–90% yield.^{37–42} 2-Methoxy-6-methyl-3,4,5,6-tetrahydropyridine **6b** was prepared by treatment of methylpiperidone **22b** with dimethyl sulfate.⁴⁰

The imide **6a** is produced in 78% yield in the reaction of the lactam **22a** with methyl fluorosulfonate followed by treatment of the resulting salt **23a** with aqueous sodium hydroxide.⁴³

The imideate **6a** and 2-ethoxy-3,4,5,6-tetrahydropyridine **24** have been synthesised in 92% and 89% yields, respectively, by the reaction of lactam **22a** with trimethyloxonium or triethyloxonium tetrafluoroborate.⁴¹

A method for the synthesis of the methoxy-derivative **6a** consisting in the reaction of the lactam **22a** with diazomethane in ether in the presence of silica gel and sodium bicarbonate has been patented⁴⁴

When piperidin-2-one **22a** reacts with POCl₃ at 20 °C, 2-chloro-3,4,5,6-tetrahydropyridine is formed.⁴⁵

Heating of iodo-derivative **25** with the lactam **22a** in a sealed tube affords salt **26**, which reacts with a second molecule of the lactam **22a** yielding lactim ether **27** and the hydroiodide of the lactam **22a**.⁴⁶

The reaction of piperidine-2-thione **28** with methyl iodide in anhydrous ether at 20 °C gives rise to 2-methylthio-3,4,5,6-tetrahydropyridine **7**.⁴⁷

The synthesis of piperidine **29** from the lactam **22b** and methyl nicotinate has been patented.⁴⁸

In the presence of TiCl_3 , 1-hydroxypiperidines **30**, substituted at the 2-position, are rapidly converted into the Δ^1 -piperidines **1e–g**, which are formed in high yields.^{49, 50}

Compound	R	Yield (%)	Ref.
1e	Pr	83	49
1f	CH = CH ₂	73	49

		70	50

1-Trimethylsilylpiperidin-2-one is converted into 2-methyl-3,4,5,6-tetrahydropyridine **1b** on treatment with methyl lithium under an inert atmosphere.⁵¹

2-Butylthio-3,4,5,6-tetrahydropyridine **31** has been synthesised in 59% yield by heating 1-trimethylsilylpiperidine-2-thione with butyl bromide.⁵²

When piperidine derivatives **32**, containing an acyl group at the nitrogen atom, are heated with calcium oxide, carbon monoxide is removed and the R¹ radical migrates to the α-position of the heterocyclic ring to give the piperideines **1**.^{53–55}

R ¹	R ²	Yield (%)	Ref.
Pr	H	69	53
	H	62	53
CH ₂ =CH(CH ₂) ₃	Me	39	54

Methods for the preparation of Δ¹-piperideines from N-substituted Δ²-piperideine derivatives have been reported. Thus the reaction of 1-lithio-2-methoxy-Δ²-piperideine **33** with alkyl halides resulted in the synthesis of imideate **34**, substituted at the 3-position of the heterocyclic centre; the reactions of **33** with methyl vinyl ketone and diphenyl sulfide yielded the corresponding ethers **34d** and **34e**.⁵⁶

Compound	R ¹	X	Temperature / °C (time / h)	Yield (%)
34a		I	20(4)	56
34b	CH ₂ =C(Me)CH ₂ CH ₂	I	–78(3) to 22(0.3)	60
34c	Me(Cl)C=CHCH ₂	Cl	–78(2) to 20(12)	37
34d			–78(0.1) to 20(0.3)	31
34e			–78(0.05) to 20(0.3)	66

The Δ²-piperideine derivatives **35** lose the methoxycarbonyl group when heated with iodotrimethylsilane and are thus converted into Δ¹-piperideines **1** in almost quantitative yields.^{57, 58}

R = C₁₁H₂₃, C₈H₁₇.

Hydrazinolysis of the C–N bond in the Schiff's bases **36** affords the Δ¹-piperideines **1** in almost quantitative yields.⁵⁹

R¹, R² = H, C₁₁H₂₃; H, CH₂Ph; Me, C₁₁H₂₃.

Methyl 1-tosyl-1,4,5,6-tetrahydronicotinate has been found to undergo an unexpected transformation on heating with thiourea yielding acid **37**.⁶⁰

2. Synthesis from primary amines and their derivatives

Primary amines **38** react with HBF₄ to give the corresponding salts **39**, which are converted into the imines **1** upon reaction with methyl(trifluoromethyl)dioxirane at 0 °C followed by treatment with sodium carbonate. Presumably, this reaction yields initially amino ketones **40**.^{61, 62} The reaction can be carried out either with or without isolation of the intermediate salts **39**.

(a) H₂O, MeCN, pH 2–3; (b) methyl(trifluoromethyl)dioxirane, CH₂Cl₂; (c) Na₂CO₃; n = 5–7, R = Me (90%), Et (95%), Pr (92%).

Oxidative cyclisation of aminoalkenes **41** and **42** in the presence of palladium(II) chloride and copper(II) chloride gives rise to a mixture of the imine **1b** and 2-ethyl-Δ¹-pyrroline in 66 : 34 ratio and in a total yield of 75% and 71%, respectively.⁶³

Alkynylamines **44** have been converted into the Δ¹-piperideines **1** by refluxing in acetonitrile or THF in the presence of NaAuCl₂·2 H₂O for 1–2 h (yield 64%–90%)⁶⁴ or by refluxing in propionitrile in the presence of PdCl₂·(MeCN)₂ for 10–20 h (yield 42%–92%).⁶⁵

R¹ = H, Et, C₅H₁₁, C₆H₁₃, C₇H₁₅, CH₂=CH(CH₂)₂, Ph;
R² = H, Me, C₁₁H₂₃.

Cyclisation of the amines **44** ($R^1 = \text{Ph}, \text{Me}_3\text{Si}; R^2 = \text{H}$) in the presence of catalytic amounts of the samarium complex ($\eta^5\text{-Me}_5\text{C}_5\text{SmCH}(\text{SiMe}_3)_2$) also results in the formation of the Δ^1 -piperidines **1** ($R^1 = \text{Ph}, \text{Me}_3\text{Si}; R^2 = \text{H}$).⁶⁶

The synthesis of the Δ^1 -piperidines **1** from alkynylamines **45** in the presence of Group IV metal complexes occurs as intramolecular [2+2]-cycloaddition with the intermediate formation of metalocyclic compounds **46**.⁶⁷

The transformation of the alkynylamine **45** ($R = \text{C}_7\text{H}_8$) into the corresponding Δ^1 -piperidine **1** ($R = \text{C}_7\text{H}_8$) was carried out in *N,N*-dimethylaniline in the presence of CpTiCl₃ at 80 °C.⁶⁷

In the presence of PdCl₂·(MeCN)₂ as a catalyst, alkynylamines **47** are converted into mixtures of the Δ^1 -piperidines **1** and Δ^1 -pyrrolines **48**, which are formed in a quantitative yield in 4:1 ratio.⁶⁵

Three procedures have been proposed for the synthesis of 2-methyl-6-phenyl-3,4,5,6-tetrahydropyridine,⁶⁸ namely, heating of 6-amino-6-phenylhex-1-yne **49** with formic and hydrochloric acids, Kucherov hydration of its *N*-formyl derivative **50** and cyclisation of keto amide **51** in boiling hydrochloric acid.

Heating of unsaturated amides **52** with P₂O₅ in CCl₄ in the presence of hexamethyldisiloxane is accompanied by their cyclisation to give Δ^1 -piperidines **53**.⁶⁹

$R = \text{Me}, (\text{CH}_2)_2\text{CH}(\text{CH}_2\text{Ph})\text{COOEt}.$

The transformation of the amino alcohol **54** into Δ^1 -piperidine **1a** in the presence of various catalysts and at a temperature of 200, 225, 250 or 300 °C (in some cases, under a hydrogen atmosphere) has been studied. The process was shown⁷⁰ to occur in two stages comprising cyclodehydration of the amino alcohol **54** and dehydration of the piperidine **15a** thus formed. The highest yields of the piperidine **15a** were attained in the presence of Cu/Al₂O₃ at 200 °C or Cu/MgO at 225 °C (99% and 62%, respectively). The yield of piperidine **1a** at 250 °C was not greater than 20%–22%, while at 300 °C, it was only 5%.

On treatment with 20% sulfuric acid, 5-aminopentanal acetal **55** is converted into sulfate **56a** in 92% yield.⁷¹ A similar cyclisation of the acetal **55b** induced by hydrochloric acid gives hydrochloride **56b**.⁷¹

$R_2 = \text{Me}_2$ (**a**), CH_2CH_2 (**b**); $X = \text{HSO}_4$ (**a**), Cl (**b**).

3,3-Disubstituted Δ^1 -piperidines **58** have been synthesised by heating amino aldehyde acetals **57** with hydrochloric acid followed by treatment with NaOH.⁷²

$R^1 = \text{H}; R^2 = \text{Me, Et}; R^1 = R^2 = \text{Me}.$

Treatment of amino ketone ketals **59** with dilute hydrochloric acid in ether⁷³ or THF⁷⁴ as well as treatment with toluene-*p*-sulfonic acid in acetone⁷⁵ gives the Δ^1 -piperidines **1** in 70%–90% yields.

$R^1, R^2 = \text{C}_5\text{H}_{11}, \text{Me, Br, C}_{11}\text{H}_{23}, (\text{MeO})_2\text{CH}(\text{CH}_2)_3.$

The 2-substituted 3,4,5,6-tetrahydropyridines **1** are formed upon cyclisation of oxo amides **60** in the presence of trifluoroacetic acid.⁷⁶

$R = \text{C}_6\text{H}_{13}$ (74%), Ph (71%), Pr (44%), $\text{C}_{11}\text{H}_{23}$ (48%), 3-pyridyl (56%).

2,6-Diaminocaproic acid (lysine **61**) serves as the starting compound in the biosynthesis of about 150 alkaloids, which are produced from this acid *via* oxidative rearrangements occurring in plants with the intermediate formation of the imine **1a**.

In nature, 2,3,4,5-tetrahydropyridine **1a** can arise from lysine **61** *via* two routes, namely, Strecker degradation to 5-aminopentanal followed by intramolecular dehydration (a) and decarboxylation of the acid **61** to give 1,5-diaminopentane (cadaverine) and its subsequent cyclisation (b).^{77, 78}

In order to identify the intermediate compounds which may form in these reactions, 2,3,4,5-tetrahydropyridines labeled by ^{14}C at the 2- or 6-position have been synthesised^{79,80} by the reaction of the corresponding labelled D,L-lysine hydrochlorides with *N*-bromosuccinimide.

In another study,⁷⁷ ^{14}C -labelled ($\pm$)-[2- ^{14}C]-lysine, [1,5- ^{14}C]-cadaverine and [2- ^{14}C]- Δ^1 -piperidine were introduced into the *Lobelia inflata* plant, together with non-labelled lobeline **62**. After some time, ^{14}C -containing lobeline **62** was found in the plant. Based on the ratio of the introduced to recovered ^{14}C , it was concluded that biosynthesis of the alkaloid **62** involves the intermediate formation of 5-aminopentanal. A probable scheme for the formation of lobeline **62** was proposed.

3,3-Diethyl- Δ^1 -piperidine **65** was prepared in 53% yield by the reaction of amine **63** with bis-silylated aminobromopropane **64** in the presence of LDA followed by desilylation of the intermediate compound.

2-(3-Pyridyl)-3,4,5,6-tetrahydropyridine was synthesised from imine **66** and bromide **64** in 88% yield.⁸¹

(a) LDA, THF, 0 °C, 2 h; (b) **64**, THF, 0–20 °C, 15 h; (c) K_2CO_3 , MeOH, Δ , 3 h.

The hydrobromides of selenium-containing Δ^1 -piperideines **68** are formed in the reaction of *O*-benzoyloximes **67** with PhSeBr at room temperature.⁸²

$n = 3, 4$.

3. Synthesis from nitriles

Nitriles containing functional groups such as carbonyl or alkoxy-carbonyl groups, halogen atoms or a multiple bond in their molecules are convenient starting compounds for the synthesis of Δ^1 -piperideines. The reduction of oxo nitriles **69** over Raney nickel in ethanol or methanol results in the formation of compound **70** as a mixture of equal amounts of enantiomers in 65% and 83% total yield, respectively.

R = Me, Et.

During hydrogenation of trinitrile **71** in the presence of the G49A catalyst (manufactured by Gierdler company), all the three nitrile groups are reduced to CH_2NH_2 ; after that, cyclisation giving a tetrahydropyridine nucleus occurs. The reaction affords 3,3-bis(2-aminopropyl)-2-phenyl- Δ^1 -piperideine **72** (yield 22%).⁷²

Compounds **74** have been synthesised by reductive cyclisation of acetals or ketals **73** on treatment with lithium aluminium hydride in boiling THF. The piperideine **74** [$\text{R}^1-\text{R}^2 = (\text{CH}_2)_5$] was patented as a repellent.^{85,86}

$\text{R}^1-\text{R}^2 = (\text{CH}_2)_2\text{CH}=\text{CHCH}_2$, $\text{CH}(\text{Me})\text{CH}_2\text{CH}=\text{CHCH}_2$, $(\text{CH}_2)_5$, $(\text{CH}_2)_6$, $(\text{CH}_2)_{10}$, $(\text{CH}_2)_3\text{CH}(\text{OH})\text{CH}_2$, $(\text{CH}_2)_2\text{C}(\text{Me})=\text{C}(\text{Me})\text{CH}_2$; $\text{R}^1, \text{R}^2 = \text{H, Me, Et, Pr, Ph, CH}(\text{Me})\text{Et, C}_9\text{H}_{19}, \text{cyclo-C}_5\text{H}_9$.

2-Methoxy-4-methyl-3,4,5,6-tetrahydropyridine **6b** has been prepared by reductive cyclisation of nitrile **75** on a rhodium catalyst followed by treatment of the resulting 4-methylpiperidin-2-one with dimethyl sulfate.⁸⁷

Cyclisation of 5-halo-substituted nitriles induced by organo-metallic compounds is used quite often to synthesise Δ^1 -piperideines.

French investigators⁸⁸ established that the transformation of 5-chloro-substituted nitriles into the corresponding Δ^1 -piperidines on treatment with lithium reagents occurs successfully only when no hydrogen atoms are present in the α -position relative to the nitrile group. Otherwise, the reaction results in the formation of cyclobutane derivatives.

The reaction of nitriles **76** with organolithium compounds was carried out in ether under an inert atmosphere for 0.5 h at 0–5 °C and then for 4 h at 20 °C (in the case of phenyllithium, the reaction mixture should be refluxed for 4 h). After hydrolysis, compounds **77** were isolated in 48%–93% yields.⁸⁸

$\text{R}^1 = \text{Me, Bu, Ph}$; $\text{R}^2 = \text{Me}_2, (\text{CH}_2)_5$; $\text{R}^3 = \text{H, Me}$.

2,3,3,5,5-Pentamethyl- Δ^1 -piperidine was also synthesised from bromo-derivative **78** and methylolithium (yield 84%).⁸⁸

The following scheme was proposed⁸⁸ for the formation of Δ^1 -piperidines from 5-halo-substituted nitriles:

When studying cyclisation of 5-halo-substituted nitriles **79** induced by organolithium compounds on refluxing in benzene, Gallulo *et al.*⁸⁹ found that with bromo-substituted nitriles **79** the reaction time is shorter and the yields of the piperidines **1** are higher than those attained with chloro-derivatives. In another study,⁹⁰ the piperidine **1** ($\text{R} = \text{Ph}$) was prepared in 37% yield in a similar way by refluxing 5-chloropentanenitrile and PhLi in an Et_2O –cyclohexane mixture.

$\text{X} = \text{Cl, Br}$; $\text{R} = \text{Bu, Ph, Me}$.

The reaction of 5-bromopentanenitrile with Grignard reagents in a THF– C_6H_6 mixture affords the corresponding Δ^1 -piperidines **1** in good yields.⁹¹

$\text{X} = \text{Cl, Br}$; $\text{R} = \text{Bu}$ (75%), Ph (85%), Bu^i (58%), PhCH_2 (64%), Me (34%), Pr^n (84%).

The modified Favorsky reaction between 5-chloropentanenitrile and brominated esters **80** was used to prepare alkyl 2-(3,4,5,6-tetrahydropyridin-2-yl)-2-methylpropanoates **81**. On boiling in sulfuric acid, these products are hydrolysed with decarboxylation to give 2-isopropyl-3,4,5,6-tetrahydropyridine.⁹²

$\text{R} = \text{Me, Et}$.

Imide **82**, prepared from the corresponding nitrile, cyclises in the presence of iodine and 4,4'-thiobis(2-*tert*-butyl-6-methylphenol) (TBP) in the dark giving rise to Δ^1 -piperidine **83** (yield 83%).⁹³

(a) I_2 , TBP, NaHCO_3 , CH_2Cl_2 , H_2O , 25 °C, 24 h.

The rates of cyclisation in the CH_2Cl_2 – H_2O and CHCl_3 – H_2O biphasic systems are higher than that in the CCl_4 – H_2O system; the lowest reaction rates were observed in THF and MeCN. The compound **83** is produced in 75%–80% yield upon ultrasonic treatment of the imide **82** in a nonaqueous medium (Bransonic 221 bath).⁹³

4. Synthesis from azides

When selenium-substituted azido ketones **84** are heated with triphenylphosphine in benzene, they cyclise to give the corresponding 2,5-disubstituted Δ^1 -piperidines **85**.⁹⁴

$\text{R} = \text{Me}$ (74%), Ph (83%), 2-thienyl (67%).

Δ^1 -Piperidines containing a cyclopropane ring at the 2-position are prepared by cyclisation of methylenecyclopropane azides. Heating of azides **86** in DMF affords cyclopropane-substituted piperidines **87** (yield ~60%).⁹⁵

$\text{R} = \text{H, Me}$ (a 3 : 1 mixture of isomers).

To synthesise compound **92**, the starting compound in the synthesis of the alkaloid (–)-8*a*-*epi*-desacetoxyslaframine, azide **88** was made to react with cyclopropyllithium, and the resulting alcohol **89** (yield 89%) was converted into methylenecyclopropane azide **90** (yield 85%) by treatment with oxalyl chloride in the presence of triethylamine. Cyclisation of the azide was induced by triphenylphosphine. The reaction proceeds *via* unstable ylide **91**.⁹⁵

The intramolecular Wittig aza reaction has been used⁹⁶ in the synthesis of several Δ^1 -piperideines **1** from oxo ylides **93**.

The Δ^1 -piperideines **1** were synthesised by the reaction of δ -azido ketones **94**, containing one more carbonyl group (either free or as acetal), with triphenylphosphine without isolation of the intermediate ylides.^{15, 97}

5. Synthesis by recyclisation reactions

1-Azido-1-alkylcyclopentanes **95** recyclise on treatment with sulfuric acid in chloroform to give the cyclic imines **1** in good yields.⁹⁸

1,1-Bis(methylthio)cyclopentane **96** reacts with sodium azide in the presence of tin chloride giving 2-methylthio-3,4,5,6-tetrahydropyridine **7** in 95% yield.⁹⁰

When L-proline is heated with monosaccharides or aldehydes of the furan series for 1.5 h at 150 °C, the corresponding Δ^1 -piperideines are produced.¹⁰⁰

Recyclisation of aminocyclopentane derivatives **98**, formed in the reaction of amines **97** with arylsulfonyl peroxides, occurs at room temperature to give 2,6-disubstituted- Δ^1 -piperideines **1** (yields 43%–79%).¹⁰¹

R = Me, Bu, PhCH₂; Ar = 3-F₃CC₆H₄, 4-O₂NC₆H₄.

If the compound **97** contains a substituent at the 2-position, recyclisation does not occur. This fact was explained¹⁰¹ by assuming that salts **100**, formed from amines **99** in the first stage of the process, are unable to recyclise if R² ≠ H.

On treatment with trimethylaluminium, 2-undecylcyclopentanone oxime mesylate **101** is converted into 2-methyl-6-undecyl-3,4,5,6-tetrahydropyridine in 54%–57% yield.^{102, 103}

Transformation of oxime tosylates **102** into Δ^1 -piperideines **7a,b** was attained by heating these substrates in the presence of diisobutyl(methylthio)aluminium.¹⁰³

R = H (**a**, 5%), Me (**b**, 46%).

2-(Pyrrolidin-1-yl)-3,3,5,6-tetrahydropyridine picrate **104** was obtained in 88% yield by the pyrolysis of 7,7-bis(pyrrolidin-1-yl)bicyclo[4.1.0]heptane **103** followed by treatment of the reaction product with picric acid.¹⁰⁴

Exposure of 3,3,3,6-tetramethyl-1,2-diazacyclohex-1-ene **105** to radiation ($\lambda = 420$ nm) in the presence of 9,10-dicyanoanthracene in acetonitrile gives 2,3,3,6,6-pentamethyl- Δ^1 -piperideine **108** in 75% yield. Evidently, this reaction occurs *via* the successive formation of radical anion **106** and radical cation **107**.¹⁰⁵

DCA is 9,10-dicyanoanthracene.

6. Other methods

To synthesise the substituted piperidine **111** from the 2,5-dihydropyridine derivative **109**, the modified Zelinsky method of irreversible catalysis has been used.¹⁰⁶ In the presence of Pd/C under an inert atmosphere, the compound **109** undergoes an exothermic reaction with cyclohexene giving a mixture of the pyridine derivative **110** (yield 68.4%) and the piperidine derivative **111** (yield 10.6%).

The reaction of 2,6-diphenylpyridine with metallic potassium gives rise to a mixture of *cis*-2,6-diphenylpiperidine **112a**, *trans*-2,6-diphenylpiperidine **112b** and 2,6-diphenyl-3,4,5,6-tetrahydropyridine **1d**.¹⁰⁷

At 25 °C, the compounds **112** are the main reaction products (total yield 34%, **112a**:**112b** ratio ~1:2), while the imine **1d** is formed in 11% yield. At -75 °C, the yield of **1d** increases to 31%, while the compounds **112** are formed in 21% yield (the **112a**:**112b** ratio is ~1.5:1).¹⁰⁷

When substituted piperideines **113** are heated with boric acid, hydrolysis of the ester group, decarboxylation and subsequent isomerisation with double bond migration occur to give the Δ^1 -piperideines **1** in good yields.^{10, 108}

R = H (70%), Me (65%), PhCH₂ (70%), CH₂=CH(CH₂)₈ (70%), Me(CH₂)₉ (80%).

Under the same conditions, compound **114** is converted into 2-methyl-3,4,5,6-tetrahydropyridine **1b** in a yield of only 47%.¹⁰⁹

The reaction of compound **115** with isopropyl alcohol gives 2,6-dimethyl-3,4,5,6-tetrahydropyridine, in addition to the piperidine derivatives.¹¹⁰

Under conditions of vacuum flash pyrolysis, *N*-allylpiperidine is converted into 2,3,4,5-tetrahydropyridine **1a**.¹¹¹

Under similar conditions, 2-methyl-1-(propyn-3-yl)piperidine is converted into a mixture of the imine **1b** and 2-methyl-2,3,4,5-tetrahydropyridine (quantitative yield; ratio 5:1). The imine **1b** was isolated in a pure state in 54% yield using preparative TLC.¹¹²

On treatment with the Meerwein reagent, spiro compounds **116** (R' = tetrahydropyran-2-yl) are converted into thioimides, which react with organolithium compounds in the presence of diisobutylaluminium hydride giving 1-azaspiro[5.5]undec-1-ene derivatives **117**. The protection of the hydroxyl group is removed by boron bromide; this gives compounds **118**.^{113, 114}

R¹, R², R³ = C₅H₁₁, Prⁱ, Buⁿ; CH₂=CH(CH₂)₃, tetrahydropyran-2-yl, CH₂=CH(CH₂)₂.

It was found that fragmentation of bicyclic compounds **119** under the action of the electron impact yields cation **120**.¹¹⁵

IV. Reactions of Δ^1 -piperideines

1. Reduction

Addition of hydrogen to the double bonds of Δ^1 -piperideine can be attained by catalytic hydrogenation and also by other reduction techniques.

The addition of hydrogen to the C=N bond in 4,4-disubstituted Δ^1 -piperideines in the presence of the Raney nickel (2–8 atm; 2 h) gives piperidine derivatives **121**.⁸⁵

$R^1-R^2 = (CH_2)_5$ (90%), $CH_2CH=CH(CH_2)_2$, $CH(Me)CH_2CH=CHCH_2$, $(CH_2)_6$, $(CH_2)_{10}$, $CH_2O(CH_2)_3$, $CH_2C(Me)C=C(Me)(CH_2)_2$, $CH_2CH(OH)(CH_2)_3$;
 $R^1, R^2 = H, Me, Et, Pr, Ph, Bu, C_9H_{19}, cyclo-C_5H_9$.

2,6,6-Trimethyl-3,4,5,6-tetrahydropyridine was converted into 2,6,6-trimethylpiperidine (yield 87%) by hydrogenation over the Raney nickel at 80 °C and 100 atm.³³

2,6-Disubstituted Δ^1 -piperideines **1** are hydrogenated to the corresponding piperidine derivatives **122** in the presence of palladium supported on carbon.⁹⁸

$R^1, R^2 = H, Me, Pr, Bu, Ph$.

2,6-Dimethyl-3,4,5,6-tetrahydropyridine is hydrogenated over Pd/C in the presence of 10% hydrochloric acid over a period of 35 h to give 2,6-dimethylpiperidine in 74.5% yield.⁵⁵

The heat of hydrogenation of the piperideine trimer to piperidine over Pd/C was found to be $-30.2 \pm 0.5 \text{ kcal mol}^{-1}$; this value was used to estimate the enthalpy of hydrogenation of monomeric piperideine **1a**, $\Delta H^0 = -20.8 \text{ kcal mol}^{-1}$.¹¹⁶

Hydrogenation of 2,3-dimethyl-3-(4-methoxyphenyl)- Δ^1 -piperideine **70** over Pd/C in methanol affords equal amounts of diastereoisomeric 2,3-dimethyl-3-(4-methoxyphenyl)piperidines.⁸⁴

Stepwise hydrogenation of 2-(pent-4-en-1-yl)-3,4,5,6-tetrahydropyridine to 2-pentylpiperidine has been reported.⁵⁴ Hydrogenation was carried out in the presence of PtO_2 . In the first stage, a hydrogen molecule adds to the double bond of the substituent to give 2-pentyl-3,4,5,6-tetrahydropyridine, which is subsequently converted into 2-pentylpiperidine by hydrogenation over PtO_2 in acetic acid.

During hydrogenation of 2-(penta-1,3-dien-1-yl)-3,4,5,6-tetrahydropyridine over PtO_2 in ethanol at room temperature and atmospheric pressure, hydrogen adds to the three double bonds, and 2-pentylpiperidine is formed.¹¹⁷

Catalytic deuteration of 2-methyl-3,4,5,6-tetrahydropyridine **1b** was carried out over PtO_2 in methyl acetate. This yielded a complex mixture of products with different deuterium contents.¹¹⁷

The last two compounds result presumably from deuteration of 6-methyl-3,4,5,6-tetrahydropyridine, a tautomer of the imine **1b**.¹¹⁸

Most often, Δ^1 -piperideines are reduced by complex metal hydrides, lithium aluminium hydride or sodium borohydride.

Treatment of the imine **1b** with $NaBD_4$ in aqueous methanol gives 2-deuterio-2-methylpiperidine in 80% yield.¹¹⁸

If the reaction of the imine **1b** with $NaBD_4$ is carried out in the presence of D_2O , a mixture of deuterated compounds, **123** and **124**, is produced.¹¹⁷

Reduction of the Δ^1 -piperideines **1** to the corresponding piperidine derivatives **122** has been attained by treatment with lithium aluminium hydride in ether at room temperature.⁵⁹

$R^1, R^2 = H, Me, C_{11}H_{23}, PhCH_2$.

2-Methyl-6-octyl-3,4,5,6-tetrahydropyridine is reduced by lithium aluminium hydride in THF at -78 to 0 °C giving rise to a mixture of *cis*- and *trans*-isomers of the corresponding piperidine in 5 : 7 ratio; their overall yield is 70%.^{57, 58}

On treatment with lithium aluminium hydride and trimethylaluminium in hexane, 2-methyl-6-undecyl-3,4,5,6-tetrahydropyridine is reduced to give 2-methyl-6-undecylpiperidine [alkaloid ($\pm$)-solenopsine] as a mixture of diastereoisomers *trans*-**122a** and *cis*-**122a** in 95 : 5 ratio.^{57, 58, 119}

When the benzylidene derivative of piperidine is treated with lithium aluminium hydride in ether or with sodium borohydride in methanol, only the C=N bond is reduced to give 3-benzylidene-piperidine **125**.¹²⁰

The reduction of compounds **126** by sodium borohydride occurs regioselectively, only the intracyclic bond being involved in the reaction. This affords a mixture of diastereoisomeric piperidines in which the *cis*-isomers **127a** predominates.⁸²

$n = 3, 4$.

The reduction of Δ^1 -piperidine **70** with sodium borohydride in methanol gives rise to a mixture of diastereoisomers of 2,3-dimethyl-3-(4-methoxyphenyl)piperidine (yield 70%).⁸³

The reduction of Δ^1 -piperidines **128a,b**, containing a furyl substituent at the 2-position, has been studied.¹²¹ The compound **128a** is converted into one reaction product, while the imine **128b** gives two isomeric products, **129a** and **129b**, in 91:9 ratio. Piperidine **130** is reduced by sodium borohydride yielding three isomeric piperidines [ratio **131a** : (**131b** + **131c**) = 85:15].

R = H (**128a**), Me (**128b**).

$R^1 = Me_2C=CHCH_2$, $R^2 = Me$, $R^3 = 3\text{-furyl}$.

The structure of the products of reduction of the compounds **53**, containing an intracyclic C=N bond and an exocyclic C=C bond at the 3-position, depends on the nature of the substituent. When $R = (CH_2)_2CH(OCH_2Ph)COOEt$, reduction of the C=N bond and subsequent cyclisation occur over a period of 2 h to give bicyclic derivative **132** (yield 70%). When $R = Me$, both double bonds are reduced over a period of 72 h affording substituted piperidine **133** (yield 66%).⁶⁹

Alkaloids of the nicotoin group have been prepared by selective hydrogenation of the C=N bond in the Δ^1 -piperidines **118** by aluminium hydride in cyclohexane.^{113, 114}

$R^1 = Bu$, $R^2 = C_5H_{11}$ (**a**);
 $R^1 = (CH_2)_2CH=CH_2$, $R^2 = (CH_2)_3CH=CH_2$ (**b**).

6-Alkyl-2-methyl-3,4,5,6-tetrahydropyridines are reduced on treatment with sodium cyanoborohydride in THF in a citrate-phosphate buffer solution to give piperidines **135** in high yields.⁷⁴

R = Pr (81%), $C_{11}H_{23}$ (95%), $(MeO)_2CH(CH_2)_3$ (82%).

Study of the reduction of 2-methyl-6-undecyl-3,4,5,6-tetrahydropyridine by various reducing reagents and solvents has demonstrated that, depending on the reaction conditions, the ratio of the resulting *cis*- and *trans*-2-methyl-6-undecylpiperidines varies from 99:1 to 5:95. The results are summarised in Table 1.¹⁰²

Table 1. Reduction of 2-methyl-6-undecyl-3,4,5,6-tetrahydropyridine.¹⁰²

Reducing agent	Solvent	Ratio <i>cis</i> - 122a : <i>trans</i> - 122a
Bu ₂ AlH	CH ₂ Cl ₂	99 : 1
LiAlH ₄ –NaOMe	THF	99 : 1
NaCNBH ₃ –HCl	MeOH	98 : 2
LiAlH ₄ –Ti(OPr ⁱ) ₄	THF	90 : 10

When 2-alkyl-Δ¹-piperideines react with lithium alkyl(or phenyl)bis(isopinocampyl)borates **136**, compounds **137** of the (+)-(*S*)- or (–)-(*R*)-series are formed, depending on the stereochemistry of the substituent R³ in the borate.³⁰ The results obtained are listed in Table 2.

**Table 2.** Hydroboration of Δ¹-piperideines.

R ¹	R ²	R ³	Isomer [<i>ee</i> (%)]	Yield (%)
Me	Bu		<i>R</i> (25)	37
Me	Ph		<i>R</i> (10)	32
Et	Bu		<i>R</i> (5)	48
Pr	Bu		<i>R</i> (4)	75
Pr	Me		<i>R</i> (11)	82
Me	Bu		<i>S</i> (22)	32
Me	Ph		<i>S</i> (10)	30

Catalytic hydrogenation of 2-phenyl-3,4,5,6-tetrahydropyridine is highly enantioselective. The catalyst was prepared by treating (*R,R*)-ethylene-1,2-bis(η⁵-4,5,6,7-tetrahydroinden-1-yl)-titanium-(*R*)-1,1'-bisnaphthalene-2,2'-diolate with butyllithium and phenylsilane. The *R*-isomer of 2-phenylpiperidine was obtained in 70%–81% yield with *ee* 95%–98%.^{90, 122, 123}

The irradiation of a mixture of 2-methyl-3,4,5,6-tetrahydropyridine **1b** and propan-2-ol with the light of a Hanovia-450W high-pressure mercury lamp through a quartz filter results in a redox process giving 2-methylpiperidine (yield 72%), acetone and the product of reductive dimerisation of acetone, 2,3-dimethylbutane-2,3-diol.¹²⁴

2. Oxidation

On treatment with 3-chloroperbenzoic acid at –60 °C, 2-methoxypiperidine **6** is oxidised to 1-hydroxypiperid-2-one **138** (yield 87%).¹²⁵

3-Acetoxy-2-methoxy-3,4,5,6-tetrahydropyridine **139** was obtained (yield 79%) upon oxidation of the imine **6** with lead tetraacetate in the presence of the polymer of 4-vinylpyridine.¹²⁶

(a) 3-ClC₆H₄COOH, CH₂Cl₂, –60 °C;

(b) Pb(OAc)₄, (N₂CH=CH₂)_n, THF, 20 °C, 2 h; 50 °C, 1 h.

1-Aza-7-oxabicyclo[4.1.0]heptanes **140** are formed in almost quantitative yields when the Δ¹-piperideines **1** are treated with 4-nitroperbenzoic acid on exposure to the light of a low-pressure mercury lamp (λ = 2537 Å) under an inert atmosphere.²⁹

R = H, Me.

Passing oxygen through the piperidine **15a** for 16 h at 40 °C in the presence of a platinum catalyst (according to Adams) affords 2,3,4,5-tetrahydropyridine **1a**, which is further oxidised to give a broad range of products, as shown in the scheme

The following compounds were isolated from the oxidation products: piperidine (**1a**, 6%), pyridine (**141**, 8%), pentane-1,5-dioic acid (**142**, 10%), 3-(2-piperidyl)pyridine (**143**, 3%), pyrroli-

din-2-one (**144**, 7%), *N*-acetylpiperidine (8%) and *N*-formylpiperidine, resulting from acylation of piperidine with formic acid.¹²⁷

3. Reactions with organometallic compounds

When unsubstituted piperidine **1a** is made to react with organolithium compounds, these reagents add to the C=N double bonds giving 2-substituted pyridine derivatives.³¹

The Δ^1 -piperidine **1g** is formed in 50% yield in the reaction of the imidate **6a** with phenyllithium or thioimide **7** with phenyllithium in the presence of diisobutylaluminium hydride.¹²¹

Piperidine derivative **145**, used as the initial compound in a total synthesis of the alkaloid ($\pm$)-porantherine, was prepared by the reaction of the imidate **6a** with two moles of organolithium derivative **146**; the yield of **145** varied over a wide range depending on the reaction conditions.¹²⁸

^a The reaction was carried out under argon.

2-Methylthio-3,4,5,6-tetrahydropyridine **7** reacts with 2-methoxyphenyllithium at room temperature to give the bisarylation product, 2,2-bis(2-methoxyphenyl)piperidine **147**, its yield being only 2%.¹²⁹

When the imidate **6a** and thioimide **7** react with one equivalent of 2-methoxyphenylmagnesium iodide under the same conditions, the monoarylation product, 2-(2-methoxyphenyl)-3,4,5,6-tetrahydropyridine **148**, is formed.¹²⁹

X = O (**6a**), S (**7**).

By varying the ratios of the reactants in the reaction of the imidate **6a** with organolithium compounds, one can synthesise selectively either only monosubstituted piperidines **1** or disubstituted piperidines **149**.¹³⁰

3-Benzylidene- Δ^1 -piperidine **124** was made to react with butyllithium or with phenylmagnesium bromide; after quenching of the reaction mixtures, the corresponding 2-substituted compounds **150** (yield 95%) or **151** (yield 56%) were isolated.¹²⁰

The reaction of 2-cyano-3,4,5,6-tetrahydropyridine with methylmagnesium iodide involves the C≡N bond and gives a mixture of 2-acetyl-3,4,5,6-tetrahydropyridine **10b** and 2-acetyl-1,2,3,4-tetrahydropyridine **10a** (ratio 4 : 1, total yield 44%).¹⁷

2-Allylpiperidine **152** has been prepared in 90% yield from the piperidine trimer and allyldimethoxyborane in the presence of triethanolamine.¹³¹

4. Reactions with amines and their derivatives

When the imidates **6** react with excess methylamine at room temperature, the methoxy group is substituted yielding amino-derivatives **153**.⁸⁷

Treatment of 2-methoxy-3,4,5,6-tetrahydropyridine **6a** with diethylamine hydrochloride in methanol results in the formation of 2-dimethylamino-3,4,5,6-tetrahydropyridine.¹³²

When the imide **6a** is heated with aminoalkanesulfonic acids **154** in DMSO, compounds **155a,b**, resulting from substitution of the methoxy group, are formed (yields 79% and 90%, respectively). On treatment with POCl_3 and PCl_5 , these products are converted into either bicyclic compound **156** or Δ^1 -piperidine **157**, depending on the number of methylene units in the initial amine.¹³³

The imide **6a** reacts with pyrrolidine for 2 days at $20 ^\circ\text{C}$ to give 2-(pyrrolidin-1-yl)-3,4,5,6-tetrahydropyridine **158** in 94% yield.¹²⁰

Refluxing of phosphorus-containing primary amines **159** with the imide **6a** in benzene gives rise to Δ^1 -piperidine **160**.¹³⁴

The reaction of 2-methylthiopiperidine hydroiodide with cyclic hydrazine derivative **161** in boiling pentyl alcohol yields compound **162**, which has been patented as a hypotensor.¹³⁵

The reactions of the imide **6a** with *O*-alkyl phosphorothioic acid hydrazides **163** occur as substitution of the methoxy group by the hydrazide residue and give *N,N'*-disubstituted hydrazine derivatives **164**.¹³⁶

The reaction of the imide **6a** with *cis*-2-aminocyclohexane-carboxylic acid in boiling ethanol affords the product of substitution of the methoxy group **165** in 84% yield.¹³⁷

Compounds **166** and **167**, patented as animal growth stimulators, have been prepared by the reaction of the imide **6a** with primary or secondary amines.¹³⁸

On refluxing in ethanol, the imide **6a** reacts with hydrochlorides of primary (**168**) or secondary (**169**) amines being thus converted into compounds **170** or **171**.^{139, 140}

2-Phenyliminopiperidine has been synthesised from the lactone **22a**; first, the lactone was converted into the imide **6a** by treatment with dimethyl sulfoxide, and then the latter was made to condense with aniline. A large number of analogous aryliminopiperidines **172** were prepared directly from the lactone **22a** by its condensation with arylamines in the presence of POCl_3 .¹⁴¹

$\text{Ar} = 2\text{-ClC}_6\text{H}_4 \text{ (44.7\%)}, 4\text{-ClC}_6\text{H}_4 \text{ (50.9\%)}, 4\text{-BrC}_6\text{H}_4 \text{ (75.9\%)}, 4\text{-MeOC}_6\text{H}_4 \text{ (39.2\%)}, 2,4\text{-Cl}_2\text{C}_6\text{H}_3 \text{ (62.6\%)}, 3,4\text{-Cl}_2\text{C}_6\text{H}_3 \text{ (78.9\%)}, 3\text{-Cl-4-Me-C}_6\text{H}_3 \text{ (28.8\%)}, 3\text{-F}_3\text{CC}_6\text{H}_4 \text{ (63.2\%).}$

Penicillamine **173** reacts with the imide **6a** at room temperature to give Schiff's base **174** in 48% yield.¹⁴²

Piperidine derivatives **176** have been synthesised by the reaction of the imide **6a** with hydrochlorides of alicyclic amines **175**.¹⁴³

$n = 1-3$; $R = \text{Ph, 4-ClC}_6\text{H}_4, \text{cyclohexyl, 2-thienyl}$.

Adamantyliminopiperidine hydrochlorides **177**, which exhibit antiviral and antidiabetic activities, are produced by the reaction of the imide **6a** with adamantylamine hydrochlorides.^{144, 145}

Ad is 1-adamantyl or 2-adamantyl.

The condensation of 9-aminofluorene (**178a**)^{146, 147} or 5-aminoindibenzocycloheptane (**178b**)^{147, 148} hydrochlorides with the Δ^1 -piperidines **6** gives compounds **179a,b**, possessing hypoglycemic,^{146, 147} antiphlogistic,^{147, 148} anticoagulant and diuretic¹⁴⁶⁻¹⁴⁸ properties.

$n = 0$ (**a**), 2 (**b**); $R = \text{H, Bu}$.

Amidines **180**, which have been recommended as anticoagulants and diuretics^{147, 149-151} and also possess hypoglycemic activity^{152, 153} or are used in the synthesis of hypoglycemic preparations,¹⁴⁷ are obtained by the reaction of the imide **6a** with alkylaromatic amines.

$R^1 = \text{H, Pr}$; $R^2 = \text{Ph, 4-ClC}_6\text{H}_4, 3-\text{F}_3\text{CC}_6\text{H}_4, \text{cyclo-C}_3\text{H}_5$;
 $\text{Ar} = \text{Ph, 4-FC}_6\text{H}_4, 2-\text{ClC}_6\text{H}_4, 3-\text{ClC}_6\text{H}_4, 4-\text{ClC}_6\text{H}_4, 4-\text{Pr}^i\text{C}_6\text{H}_4,$
 $3-\text{F}_3\text{CC}_6\text{H}_4, 4-\text{F}_3\text{CC}_6\text{H}_4, 2-\text{MeOC}_6\text{H}_4, 3-\text{MeOC}_6\text{H}_4, 4-\text{MeOC}_6\text{H}_4,$
 $4-\text{BuOC}_6\text{H}_4, 4-\text{PhOC}_6\text{H}_4, 3,4-(\text{MeO})_2\text{C}_6\text{H}_3, 3,4,5-(\text{MeO})_3\text{C}_6\text{H}_2$;
 $n = 0, 1, 2$.

A series of piperidine derivatives **182** have been synthesised from the piperidines **6** and primary (1-naphthyl)alkylamines **181** or their hydrochlorides.¹⁵⁴

$R^1 = \text{H, Bu}^i$; $R^2 = \text{H}$; $R^3 = \text{H, 2-Me, 4-Cl, 4-F}$; $R^4 = 5-\text{Me, 8-Me}$; $R^4 = \text{H, Me, Pr}^i, \text{Bu}^n, \text{Ph, 2-MeC}_6\text{H}_4$.

The compounds **182** exhibit hypoglycemic, diuretic and anti-coagulant activities.¹⁵⁴

Condensation of substituted imides with hydrochlorides of primary amines **183**, containing a furyl or a thienyl substituent, results in the synthesis of amidine hydrochlorides **184**, which possess hypoglycemic activity.^{38, 155}

$X = \text{O, R} = \text{H, Z} = \text{CHCH}_2\text{Ph}$;
 $X = \text{S, R} = \text{H, Z} = \text{cyclo-C}_3\text{H}_5, \text{C(Me)Et}$;
 $X = \text{O, S, R} = \text{H, Me, Z} = \text{CH}_2, \text{CHPh, (CH}_2\text{)}_3, \text{CH}_2\text{CH(Et), cyclo-C}_3\text{H}_5, \text{CH}_2\text{CH(Me), CH(Me)CH}_2\text{CH}_2$.

On heating without a solvent, α -(4-pyridyl)benzylamine reacts with the imide **6a** to give 2-[α -(4-pyridyl)benzylimino]piperidine in 48% yield.¹⁵⁶

Compounds **185** have been synthesised by the condensation of **6a** with the corresponding primary amines under similar conditions.¹⁵⁶

2-Cyanoiminopiperidine **186** has been prepared in 91% yield by the reaction of the imide **6a** with cyanamide at room temperature.¹⁵⁷ Piperidine derivative **187** is formed in 72% yield upon condensation of **6a** with thiourea.¹⁵⁸

Compounds containing a primary amino group and a triple carbon-carbon bond or a carbonyl group at the 1- and 3-posi-

tions react with the imide **6a** with cyclisation giving five-membered heterocycles.

The product of condensation of the imide **6a** with prop-2-ynylamine, which exists as two tautomers, cyclises *in situ* to give 8-methyl-1,7-diazabicyclo[4.3.0]nona-6,8-diene **188** (yield 52%).¹⁵⁹

The product of condensation of **6a** and aminoacetophenone undergoes spontaneous cyclodehydration yielding bicyclic derivative of 2-imidazoline **189**.¹⁶⁰

Refluxing of benzoic acid hydrazide with the imide **6a** in xylene affords 9-phenyl-1,7,8-triazabicyclo[4.3.0]nona-6,8-diene **190**.¹⁶¹

Synthesis of 1,7,8-triazabicyclo[4.3.0]nona-6,8-diene derivatives **191** from acylhydrazides and the imide **6a** has been patented.^{162, 163}

R = ArN(CH₂)_nN(X)_m; X = alkylene; n = 1–5.

The compounds **191** are recommended as tranquilizers,¹⁶³ remedies against glaucoma^{162, 163} and schizophrenia.¹⁶²

Cyclocondensation of Δ¹-piperidine with compounds containing NH₂ (or NH) and carboxy (or alkoxy carbonyl, or nitrile) groups at neighbouring positions has been studied in detail. Polycyclic pyrimidine derivatives were synthesised in this way.

Thus heating of 2-aminocyclohexanecarboxylic acid with the imide **6a** in chlorobenzene gives 1,2,3,4,4a,6,7,8,9,11a-decahydropyrido[2,1-b]quinazolin-11-one **192** in 88% yield.¹³⁷ A similar reaction with 2-chloropiperidine affords the compound **192** in a yield of only 8.7%.¹⁶⁴ Several more methods for the synthesis of the compound **192** from 2-aminocyclohexanecarboxylic acid or its lactam are described.¹⁶⁴

The cyclocondensation of the imide **6a** with *cis*- and *trans*-2-aminocyclohex-4-enecarboxylic acids **193** occurs enantioselectively to give *cis*- and *trans*-1,4,4a,6,7,8,9,11a-octahydroquinazolin-11-ones **194a** and **194b**, respectively.¹⁶⁵

Tricyclic compounds **195** have been prepared in 64%–82% yields by heating the imides **6** with anthranilic acid or its derivatives in benzene,^{45, 166} ethanol⁴⁵ or DMF.⁴⁵

R¹ = H, Me; R² = H, 2-COOH, 2-COOEt.

Deoxyvasicinone analogues **197** have been prepared in relatively low yields by condensation of heterocyclic amino acids **196** with the imide **6a** in boiling DMF.¹⁶⁷

X	Y	Z	W	Time /min	Yield (%)
N	CH	CH	CH	10	12
CH	N	CH	CH	210	38
CH	CH	CH	N	150	20
N	CH	CH	N	120	12

The reaction of 2-chloro-3,4,5,6-tetrahydropyridine with methyl anthranilate derivatives **198** gives compounds **199**.^{45, 168}

R ¹	R ²	Solvent	Time /h	Yield (%)	Ref.
H	COOMe	PhH	5	53	45
NO ₂	H	dioxane	1	94	168

The imide **6a** reacts with 5-amino-4-ethoxycarbonyl-1-phenyl-1,2,3-triazole to give compound **200** in 25% yield.¹⁶⁹

1,2,3,4,7,8,9,10-Octahydro-5*H*-dipyrido[1,2-*a*:2',3'-*d'*]pyrimidin-5-one **201** has been synthesised in 66% yield by heating the imide **6a** with 6-amino-5-ethoxycarbonyl-1,2,3,4-tetrahydropyridine.¹⁷⁰

Tetracyclic compounds **203** are formed in 75%–85% yield as a result of cyclocondensation of 2-methoxy-3,4,5,6-tetrahydropyridine **6a** with 2-amino-3-ethoxycarbonyl-4,5-polymethylene-thiophenes **202** in the presence of polyphosphoric acid (PPA).¹⁷¹

Cyclocondensation of the imide **6a** with 2-amino-3-ethoxycarbonylindole gives rise to 5,7,8,9,10,12-hexahydropyrido[1',2':1,2]pyrimido[4,5-*b*]indol-12-one **204** in 39% yield.¹⁷²

On heating in 2-methoxyethanol, compounds **205**, containing amino and nitrile groups in vicinal positions, enter into condensation with the imide **6a** to give pyrimidin-4-one derivatives **206**.¹⁷³

R	n	X	Yield (%)
Me	1	O	25
H	1	S	71
H	2	O	39

A well-studied synthesis of angular polynuclear heterocyclic compounds is cyclocondensation of Δ^1 -piperideines with cyclic compounds containing NH and CH_2COOEt groups in vicinal positions.

Thus prolonged heating of the imide **6a** with 2-ethoxycarbonylpiperidine in a sealed tube affords 1,2,3,4,6,7,8,9,9*a*,10-decahydro-13*H*-isoquino[2,1-*a*]-[1,8]naphthiridin-13-one **207** in 54% yield.^{13, 174}

The yield of compound **209** formed in the condensation of the imide **6a** with compound **208** under similar conditions is only 20%.^{14, 174}

When the compound **208** is heated with methylthiopiperidine **7** in a tube at 100 °C, cyclic diamide **210** (yield 20.5%) is formed in addition to the condensation product **209** (yield 9%).¹⁴

If the mixture formed upon the reaction of the compounds **7** and **208** is treated with 5% hydrochloric acid and then with sodium iodide and the reaction product is reduced with sodium borohydride in methanol (20 °C, 12 h), tetracyclic compound **211** is formed (yield 14%).¹⁴ The following scheme was proposed for the formation of the compounds **209**–**211**:

The reaction of 1-(ethoxycarbonylmethyl)-1,2,3,4-tetrahydroisoquinoline **213** with 2-methylthiopiperidine **7** on heating in a sealed tube affords compound **214** (yield 81.1%).⁴⁷ When the isoquinoline derivative **213** reacts with 2-methoxypiperidine **6a** under similar conditions, isomeric tetracyclic product **215** is produced.^{13, 174} The reaction between **6a** and **213** carried out in the presence of triethylamine affords tricyclic product **216** (yield 19%), together with the compounds **214** (yield 14%) and **215** (yield 21%).¹³

2-Methoxy-3-cyano-3,4,5,6-tetrahydropyridine **13** exists as a mixture of two tautomers, **13a** and **13b**, and can be converted into different products depending on which tautomer is involved in the reaction. Since only compound **217** was isolated (yield 36%) upon the reaction of the Δ^1 -piperidine **13** with the isoquinoline derivative **213**, it is clear that in this case the imide **13** reacts as the tautomer **13a**.

Treatment of the Δ^1 -piperidines **1** with *O*-hydroxylaminosulfonic acid in the presence of potassium carbonate and benzyltriethylammonium chloride results in the formation of 1,7-diazabicyclo[4.1.0]heptanes **218**.^{23, 175}

The formation of tricyclic compound **220** (yield 32%) from 3-benzylidene-3,4,5,6-tetrahydropyridine and pyrrole can be represented as two consecutive reactions — addition to the C=C bond in the benzylidene derivative owing to the C—H group at the 2-position of pyrrole and cycloaddition, involving pyrrole nitrogen, to the C=N bond in the intermediate compound **219**.¹²⁰

Some reactions of Δ^1 -piperidines with primary amines occur with opening of the heterocyclic ring.

Thus heating of the piperidine trimer with 2-aminobenzaldehyde in a citrate buffer solution gives 3-(3-aminopropyl)quinoline in 70% yield.⁸⁰

When the imide **6a** is refluxed with thioethanolamine in ethanol, the heterocyclic ring is cleaved and 1,3-thiazoline derivative **221** is formed as the reaction product (yield 69%).¹⁷⁶

Compounds **223**, serving as the starting compounds in syntheses of medicines and pesticides, were prepared by condensation

of the imide **6a** with aniline derivatives **222** under an inert atmosphere. This reaction also proceeds with opening of the Δ^1 -piperidine ring.¹⁷⁶

R = H, Me; X = O, S.

The reaction of the imide **6a** with *o*-phenylenediamine in boiling ethanol in the presence of hydrogen chloride gives rise to compound **224** in 74% yield.¹⁷⁷

The piperidine **1a** reacts with 3-(2-aminoethyl)indole in the presence of trifluoroacetic acid with opening of the imine heterocycle to give the alkaloid nazlinin **225** in 72% yield.¹⁷⁸

Arylhydrazines **226** and the piperidine trimer react in the presence of hydrogen chloride as salts **227** and **228** to give aminoalkylindole salts **229**. On treatment with aqueous ammonia, these products are converted into amines **230**.¹⁷⁹

R¹ = H: R² = H (18%), Me (33%), Ph (23%), CH₂Ph (52%);
R¹–R² = CH(Me)CH₂CH₂ (26%).

The reaction of 2-methoxypiperidine **6a** with *S*-methylisothiosemicarbazide hydroiodides **231** yields 1,3,5-triazole derivatives **232**.¹⁸⁰

R = H, Ph.

5. Reactions with isocyanates

2-Methylthio-3,4,5,6-tetrahydropyridine **7** reacts with aryl isocyanates ArNCO giving rise to compounds **233**.¹⁸¹

Ar = Ph (77%), 4-ClC₆H₄ (73%), 4-EtOC₆H₄ (82%).

Urea derivatives **235**, which exhibit high antiglycemic activity and decrease the level of glucose in blood, have been synthesised by the reaction of 2-amino-3,4,5,6-tetrahydropyridine with sulfonyl isocyanates **234**.¹⁸²

R = H (42%), Me (49%), Cl (44%).

2-Methoxy-3,4,5,6-tetrahydropyridine **6a** reacts with aryl isocyanates to give piperideines **236**, containing an arylamide group.¹²

Ar = Ph (68%), 4-ClC₆H₄ (65%), 4-EtOC₆H₄ (70%).

6. Reactions with nitriles

Treatment of 2-methyl-3,4,5,6-tetrahydropyridine **1b** with LDA^{183, 184} and subsequent reaction of the lithiated product with nitriles RCN results in the formation of heterodienes **237**. If allyl bromide is added to the reaction mixture together with benzonitrile, compound **238** is formed in 32% yield.

R = C₅H₁₁ (94%), Ph (66%), cyclo-C₆H₁₁ (56%).

By heating lithium derivatives of the imidates **6** with nitriles, bicyclic pyrimidine derivatives **239** have been synthesised in 17%–26% yield.¹⁸⁵

R¹ = H, Me; R² = Ph, 2-furyl, 2-thienyl, 2-pyridyl, 4-pyridyl.

Indolizine derivatives **240** have been obtained by the reaction of lithium derivatives of the imine **1b** with nitriles followed by treatment of the product with propargyl bromide.¹⁸⁶

R = Ph (70%), cyclo-C₃H₅ (75%), 2-thienyl (71%);(a) LDA, THF, -78°C ; (b) RCN, 3.5 h;(c) HC $\equiv$ CCH₂Br, -78°C to -20°C , 14 h.

The dianion **241**, generated on treatment of 5-methylisoxazole with LDA in THF, reacts with the imide **6a** giving rise to 2-amino-1-azabicyclo[4.4.0]deca-2,5-dien-4-one **242** (yield 40%).¹⁸⁷

7. Reactions with aldehydes and ketones

Alcohols **243** have been synthesised (yields 56%–88%) by treatment of 2-methyl-3,4,5,6-tetrahydropyridine **1b** with LDA and subsequent condensation of the resulting lithium derivative with carbonyl compounds.^{188, 189} Treatment of the imine **1b** with LDA followed by the reaction with cinnamaldehyde gave secondary unsaturated alcohol **244**.¹⁹⁰

R¹ = H; R² = Me, Et, Prⁱ, Bu^t, Ph; R¹ = R² = Me

The piperidine trimer readily reacts with aromatic aldehydes according to the crotonic condensation route to give arylmethylenes derivatives.^{120, 191, 192}

R = Ph, 4-MeC₆H₄, 4-MeOC₆H₄, 4-ClC₆H₄, 4-NCC₆H₄,

An interesting method for the synthesis of ketones **246**, containing a 2-piperidyl fragment, has been developed. The method consists in the reaction of methyl ketones RCOMe with magnesium methyl carbonate **245** and the imide **6a**.^{19,20,193} Methyl ketones and the salt **245** were kept in DMF in a flow of CO₂ at 120 °C, then CO₂ was displaced by nitrogen and the reaction mixture was held at 120 °C under nitrogen, the MeOH evolved being evaporated. After cooling the reaction mixture, the imine **6a**¹⁹³ or its α-trimer^{19,20} was added, and the mixture was kept at 20 °C in an atmosphere of CO₂ for several days.

R = 2,5-(MeO)₂C₆H₃ (75%), 4-PhSC₆H₄ (50%), dibenzofuran-2-yl (32%), Ph₂CH (37%), 4-MeOC₆H₄CH=CH (43%), PhCH=C(Me)CH=CH (48%), PhCH=CHC₆H₄ (57%), 4-pyridyl, (8%) 1-adamantyl (6%), Ph, 4-MeOC₆H₄, 4-BuⁿC₆H₄, 4-BuⁿOC₆H₄, 3,4,5-(MeO)₃C₆H₂, 4-PhC₆H₄, 3,4-(MeO)₂C₆H₃CH=CH, PhCH=CMe, PhCH=CH, 4-MeSC₆H₄, 4-(fluoren-9-ylidenemethyl)-phenylene (73%).

When the reaction between the imide **6a** and 1-acetyladamantane is conducted for 28 h at 120 °C and then for 120 h at 20 °C, the yield of the ketone **246** (R = 1-adamantyl) increases to 37%.¹⁹ The compounds **246** were obtained in low yields from ketones RCOMe with R = 4-NCC₆H₄ or 4-Me₂NSO₂C₆H₄. In the case of R = 4-HOC₆H₄, 4-H₂NCC₆H₄, 4-O₂NC₆H₄, 4-HOOC₆H₄ or 4-HO₃SC₆H₄, these products did not form at all.¹⁹

A similar procedure for the preparation of the ketones **246** at 20 °C over a period of 70 h has been described in a patent.²⁰ The synthesised compounds [R = 4-MeOC₆H₄CH=CH, PhCH=CH, 4-BuⁿC₆H₄CH=CH, 4-BuⁿOC₆H₄CH=CH, 3,4-(MeO)₂C₆H₃CH=CHCH=CH, 3,4,5-(MeO)₃C₆H₂CH=CH, 4-PhC₆H₄CH=CH, PhCH=CHCH=CH, 4-MeSC₆H₄CH=CH, PhCH=C(Me)CH=CH] were claimed to be anticoagulants.

Ketone **247** was introduced into the reaction with the salt **245** in an atmosphere of CO₂; then the piperidine trimer was added and condensation product **248** was obtained in 73% yield.¹⁹

(a) **245**, CO₂, DMF, 120 °C, 4 h; (b) [piperidine]₃, CO₂, 24 h.

The reaction of the imide **6a** with unsaturated ketone **249** at 20 °C for 24 h affords piperidin-2-one derivative **250** in 46% yield. At a low temperature (−15 °C for 62 h), the yield increases to 65%.¹⁹⁴

Condensation of acetylacetone with the imide **6a** results in the formation of a mixture of compounds **251** and **252** (yields 26% and 25%, respectively).¹⁹⁵

8. Reactions with acids and their derivatives

Carboxylic acids and their derivatives can be used as the methylene components in the condensation of Δ¹-piperidine.

Thus the imide **6a** condenses with methyl¹⁹⁶ or ethyl¹⁹⁷ nitroacetate giving rise to piperidine derivatives **253a,b**, which are used to synthesise insecticides.¹⁹⁶

R = Me (**a**), Et (**b**).

The compound **253b** can also be synthesised by heating 2-methylthio-3,4,5,6-tetrahydropyridine **7** and ethyl nitroacetate in the presence of zinc chloride.¹⁹⁸

Condensation products **254** have been prepared in good yields from cyanoacetic acid derivatives and the imide **6a** or the thioimide **7**.^{199–202}

X	R	Reaction conditions	Yield (%)	Ref.
O	CONH ₂	DMF, refluxing for 3 h	77	199

^a Refluxing in CHCl₃ in the presence of Ni(OAc)₂; ^b refluxing in PhH in the presence of triethylamine and piperidine; ^c refluxing in the presence of triethylamine.

In the previous Section, we considered the reactions of the imine **1a** with ketones in the presence of magnesium methyl carbonate **245** to give the compounds **246**. These reactions involve the intermediate formation of magnesium enolates of β -oxo acids, which react with Δ^1 -piperidine **1a** to give, after decarboxylation,

the compounds **246**. It is quite natural that in several other studies, it has been proposed to prepare the piperidine derivatives **246** by the condensation of the imine **1a** with β -oxo acids^{77, 79, 208–210} or their sodium salts.^{26, 27}

($\pm$)-Isopelletierine (**246**, R = Me) was synthesised in a higher yield (42%–51%) by condensation of the imide **1a** with sodium acetoacetate on refluxing in water for 4 h.^{26, 27}

R	Reaction conditions	Yield (%)	Ref.
Pr	20 °C, 24 h, H ₂ O, pH 7	—	77

Me	Et	Et	100 ^a	50	—	211
2,4-Cl ₂ -5-FC ₆ H ₂	Et	Me	80	48	63 ^b	212

^a The reaction was carried out in a tube; ^b a mixture of the methyl and ethyl ester **260** in 1 : 2 ratio was obtained.

5-Methoxycarbonyl-1-azabicyclo[4.4.0]dec-5-en-4-one **262**, the initial compound in the synthesis of ($\pm$)-epilupinine, has been prepared from 3-oxopent-4-enoic acid **261** and the imide **6a** (yield 54%)¹⁹⁴ or the thioimide **7** (yield 62%).²¹³

At room temperature, the dicarbonyl compound **261** reacts with 2-methoxy-5-phenyl-3,4,5,6-tetrahydropyridine to give 5-methoxycarbonyl-9-phenyl-1-azabicyclo[4.4.0]dec-5-en-4-one **263** (yield 65%).²¹⁴

When developing approaches to the synthesis of alkaloids of the *Lythraceae* family, Rosazza *et al.*²¹⁵ synthesised compound **265** (yield 84%) by cyclocondensation of the imine **1a** with unsaturated oxo ester **264**.

In the presence of nickel acetylacetonate, the imide **6a** enters into the reaction with oxo lactones **266** to give compounds **267**.²¹⁶

R = H (56%), Et (33%).

1-Azabicyclo[4.3.0]nonane-8,9-dione derivatives **269** have been synthesised from 2,3,4,5-tetrahydropyridine **1a** and esters of oxo dicarboxylic acids **268**.^{217, 218}

The reaction of the imine **1a** with alkyl oxalylacetates (**268**, R¹ = H) affords tautomers of the compounds **269**, 7-alkoxycarbonyl-8-hydroxy-1-azabicyclo[4.3.0]non-7-en-9-ones.²⁵

R² = Bu^t (60%), Et (48%).

N-Lithio-2-methylenepiperidine **5**, formed on treatment of 2-methyl-3,4,5,6-tetrahydropyridine **1b** with LDA, reacts *in situ* with diethyl carbonate to give 2-ethoxycarbonylmethylenepiperidine **270** in 59% yield.¹⁰

Cyclocondensation of the imide **6a** with esters of oxo dicarboxylic acid **271** in the presence of Et₃N affords quinolizine derivatives **272**.²¹⁹

R = Me (57%), Et (92%).

9. Reactions with ketenes

Δ¹-Piperideines and ketenes react according to the [2 + 2] cycloaddition pattern yielding bicyclic compounds — 1-azabicyclo[4.2.0]octane derivatives.

Thus treatment of potassium *N*-(2-methoxycarbonylpropen-2-yl)glycinate **273** with PhPOCl₂ and Et₃N gives ketene **274**, which enters *in situ* into the cycloaddition reaction with 3,3-dimethyl-2-phenyl-3,4,5,6-tetrahydropyridine giving rise to 7-(2-methoxycarbonylpropen-2-yl)amino-5,5-dimethyl-6-phenyl-1-azabicyclo[4.2.0]octan-8-one **276** in 74% yield.²²⁰

Synthesis of 1-azabicyclo[4.2.0]octane derivatives **278a–g** (yields 42%–87%) by the reaction of the imine **275** with the ketenes formed on treatment of acyl chlorides **277** with triethylamine has been reported.²²¹

R = N₃ (a), MeO (b), PhO (c), PhCH₂O (d), 4-ClC₆H₄SO₃ (e), phthalimid-1-yl (f), Cl (g).

The azido-derivative **278a** is formed over a period of 2 h, while in the majority of cases, completion of the reaction requires 12 h. In the case of the synthesis of **278g** (yield 61%), more drastic conditions were used: the reaction mixture was refluxed for 1.5 h and then kept at room temperature for 16 h.²²¹

The imide **6a** reacts with diketene even at 0 °C according to two pathways — giving quinolizine derivative **279** (yield 10%) and pyrido[2.1-*b*]oxazine **280** (yield 43%).²²²

When the reaction is carried out in acetic acid at 20 °C, only the tetracyclic compound **281** is formed; this product results from condensation of two molecules of **6a** with two diketene molecules. The following scheme has been proposed for this reaction:²²³

In some cases, ketenes synthesised by other methods have also been introduced in reactions with Δ^1 -piperideines. Thus on refluxing in toluene, homophthalic anhydride **282a** and 4,5-dimethoxyhomophthalic anhydride **282b** eliminate a CO_2 molecule being thus converted into the corresponding ketenes **283**, which react with 2-methoxy-3,4,5,6-tetrahydropyridine **6a** to give tricyclic compounds **284**.²²⁴

R = H (52%), OMe (55%).

Compound **285**, formed from anthranilic acid under the action of thionyl chloride, eliminates an SO_2 molecule even at room temperature and is thus converted into ketene **286**, which enters into cyclocondensation with imidates to give quinazoline derivatives **287** (yields 71%–82%).^{225, 226}

R¹ = Me, Et; R² = H, OMe.

Benzo[*b*]-1,8-naphthiridine derivatives **293** have been prepared by the reaction of 2-methylthio-3,4,5,6-tetrahydropyridines **7** with N-substituted isatic anhydrides **288** in the presence of LDA. Evidently, the anhydrides **288** lose a CO_2 molecule under the reaction conditions giving rise to ketenes **289**, which react according to the [4 + 2] cycloaddition pattern with the lithium derivative **290**, resulting from the reaction of the thioimide **7** with LDA. The salts **291** thus formed are converted into salts **292** upon

elimination of an MeSH molecule. The latter give the final products **293** upon treatment with an aqueous solution of ammonium chloride.²²⁷

R ¹	R ²	R ³	Yield (%)
Me	H	H	64
PhCH ₂	H	H	53
Me	Me	H	42
Me	H	Cl	62
Ph	H	Cl	14

Ketene chromium tricarbonyl complexes **295**, which are produced upon photolysis of the carbene complexes **294**, react *in situ* with 2,3,4,5-tetrahydropyridine **1a** yielding 1-azabicyclo[4.2.0]octan-8-one **296**.^{228, 229}

R ¹	de	Yield (%)	Ref.
Ph	97	91	228, 229
Me ₂ CH	97	55	228

When a mixture of 2-phenyl-3,4,5,6-tetrahydropyridine and carbene complex **297** is exposed to sunlight under an argon atmosphere and then oxidised by atmospheric oxygen, 7-methoxy-7-methyl-6-phenyl-1-azabicyclo[4.2.0]octan-8-one **298** is formed in 63% yield.²³⁰

10. Reactions with alkyl halides

Piperidine-2-thione in the thiol tautomeric form reacts with ethyl 2-bromobut-3-enoate **299** to give salt **300**. Subsequent treatment of the compound **300** with ethyldiisopropylamine affords N-substituted piperidine-2-thione **302** (yield 70%); the formation of this product was explained by the S,N-allyl rearrangement of intermediate **301** under the reaction conditions.²³¹

Treatment of the imide **6a** with LDA and then with halogenated compounds results in the formation of product **303**, alkylated at the 3-position.^{56, 194}

When Δ^1 -piperideines **304** ($R^1 = \text{COOEt}$) are treated successively with sodium hydride and halo-derivatives R^2X , alkylation of the side-chain methylene group occurs and compounds **305** are formed in 35%–80% yields.¹⁰⁹

The compounds **305** ($R^1 = \text{H, Me; } R^2 = \text{Me}$) have been synthesised in >95% yields by the reaction of the Δ^1 -piperideines **304** ($R^1 = \text{H, Me}$) with methyl iodide in the presence of LDA in THF at -78 to 20 °C for 1 h.²³²

When imidates **306** are heated with halo-containing compounds, the nitrogen atom in the heterocyclic nucleus is alkylated giving substituted piperidones **307**.^{39, 233} The reaction conditions and the product yields are listed in Table 4.

Table 4. Alkylation of the imidates **306**.

R ¹	R ²	R ³	X	Temperature / °C	Time / h	Yield (%)	Ref.
Me	H	Me	I	60	6	93	39

11. N-Acylation reactions

N-Acylation of 3-substituted Δ^1 -piperideines with acylating agents is accompanied by isomerisation of the double bond.

Thus treatment of 3-ethyl- Δ^1 -piperideine with acetic anhydride affords compound **308** (yield 57%). Under the same conditions, 3,3-dimethyl- Δ^1 -piperideine is converted into diacetyl derivative **309** in 78% yield.⁷²

N-Acylation of the imine **1a** with polyunsaturated acid chlorides was carried out by refluxing in benzene.^{234, 235} 2,6-Dimethyl-3,4,5,6-tetrahydropyridine was N-acylated with acryloyl chloride in the presence of triethylamine at room temperature.²³⁶

$R = \text{Me(CH}_2)_2\text{C}\equiv\text{C(CH=CH)}_2$ (60%), Me(CH=CH)_4 (35%).

Compound **311** was synthesised in 76% yield by the reaction of the imine **1a** with chloride **310** in the presence of Et₃N in DMF.²³⁷

The thioimide **7** reacts with acetyl or benzoyl chloride at room temperature to give N-acylated derivatives **312**.²³⁸

R = Me (73%), Ph (83%).

Ethyl chlorocarbonate reacts with the imine **1b** in the presence of potassium carbonate to give N-acylated product **313** (yield 79%).²³⁹

When the Δ^1 -piperideines **6** are heated with lithium hydride in THF and the resulting organolithium compounds are treated with acyl chlorides, N-acylation products **314** are formed in low yields, acyclic compounds **315** being the main products (yields 72%–77%). Treatment of the Δ^1 -piperideines **6** with lithium or sodium hydride or lithium hydroxide in benzene and subsequent reaction with acid chlorides give the N-acylated derivatives **314** as the main reaction products (see Table 5).¹⁸⁵

Table 5. N-Acylation of the piperideines **6**.

R ¹	R ²	Base	Solvent	Reaction conditions		Yield of 314 (%)
				1st stage	2nd stage	
Me	3-furyl	LiH	THF	Δ , 3 h	25 °C, 88 h	4
H		LiH	THF	Δ , 3 h	25 °C, 88 h	6
Me		LiOH	C ₆ H ₆	Δ , 3 h	25 °C, 19 h	75
H		NaH	C ₆ H ₆	Δ , 3 h	25 °C, 19 h	70
H	Ph	LiH	C ₆ H ₆	Δ , 3 h	25 °C, 19 h	67

Heating of the imide **6a** with lithium hydride in benzene for 3 h followed by treatment of the reaction product with benzoyl chloride also gives compound of the type **315** (R¹ = H, R² = Ph) in 32% yield.¹⁸⁵

Later the investigation of the reaction of Δ^1 -piperideines with lithium hydride and the chloride of furan-3-carboxylic acid has been continued. The formation of only the product of piperidine ring opening in this reaction has been reported.¹²¹

The reaction of the imide **6a** with sulfonyl chlorides in the presence of Bu₄N⁺Cl[−] in CH₂Cl₂ at room temperature results in the formation of N-sulfonyl-substituted derivatives **316**.⁴¹

R = Me (73%), Ph (66%), 4-C₆H₄ (66%).

12. Reactions with labile cyclic systems

In this Section, we discuss the reactions of Δ^1 -piperideines with labile cyclic systems accompanied by ring opening or recyclisation.

Thus 2,3,4,5-tetrahydropyridine **1a** enters into the reaction with thiiranes **317** on heating to 100 °C; these reactions yield 1-aza-7-thiabicyclo[4.3.0]nonane **318**.²⁴⁰

R¹ = R² = H (63%); R¹ = H, R² = Me (67%); R¹ = R² = Me (32%).

Bicyclic compounds **320** have been synthesised by heating the Δ^1 -piperideines **1** with diphenylcyclopropenone **319a**²⁴¹ or methylenecyclopropene derivative **319b**.²⁴²

Y = O: R = Me (79%), Et (76%), 2,5-(MeO)₂C₆H₃ (80%).

Y = : R = MeSC₆H₄ (60%), 2,5-(MeO)₂C₆H₃ (77%).

The reaction of 2-(4-methylthio)phenyl-3,4,5,6-tetrahydropyridine with the methylenecyclopropene **319c** follows a different pathway.²⁴²

The reaction of the Δ^1 -piperideines **1** with diphenylcyclopropenone **319a** or with the cyclopropenethione **319d** giving tricyclic compounds **321** (yields 46%–82%) is evidently a two-stage process. The first stage gives bicyclic compounds of the type **320**; under the reaction conditions, these products undergo intramolecular cyclisation involving the CH₂ group at the 5-position of the piperidine ring and the C=C bond of the five-membered ring.²⁴¹

Y = O: R = Ph, 4-MeSC₆H₄; Y = S: R = Me, Et, Ph, 4-MeSC₆H₄, 2,5-(MeO)₂C₆H₃.

Δ^1 -Piperideines **322**, containing a cyclopropyl substituent at the 2-position, isomerise on heating in the presence of ammonium chloride to give 1-azabicyclo[4.3.0]non-6-ene derivatives; the imines **322** (R² = H) are converted into individual compounds **323**, whereas the imine **322** (R¹ = H, R² = Me) gives two isomeric reaction products **324** and **325**.⁹⁵

10-Acetyl-7-phenyl-2,8-diazabicyclo[4.4.0]deca-6,10-dien-9-one **327** is formed in 56% yield in the reaction of the imide **6a** with 6-methyl-2-phenyl-1,3-oxazin-4-one **326**.²⁴³

Heating of 2-amino-3,4,5,6-tetrahydropyridine hydrochloride **328** with 1,3,5-triazine or its 2,4,6-tris(triethoxycarbonyl) derivative **329** in DMF gives rise to bicyclic compounds **330** in 63%–75% yields. The reaction of 2-methylthio-3,4,5,6-tetrahydropyridine hydroiodide **328** ($X = \text{SMe}$, $Y = \text{I}$) with triazines follows a similar pathway; however, the corresponding derivatives **330** are formed in low yields.²⁴⁴

$X = \text{NH}_2$, $Y = \text{Cl}$; $X = \text{SMe}$, $Y = \text{I}$; $R = \text{H}$, COOEt .

It was shown that the first stage in the reaction of 2-amino-3,4,5,6-tetrahydropyridine with 1,3,5-triazine is [2 + 4] cycloaddition giving tricyclic compound **331**; this product loses an NH_3 molecule and undergoes the retro Diels–Alder reaction to give the final product **330**.²⁴⁴

Neither interaction of the imide **6a** with the triazines **329** ($R = \text{H}$, COOEt) nor the reaction of the hydrochloride **328**

($X = \text{NH}_2$, $Y = \text{Cl}$) with 2,4,6-tris(methylthio)triazine gives products of the type **330**.²⁴⁴

13. Isomerisation

When the imide **6a** is heated with a catalytic amount of dimethyl sulfate, it is converted into *N*-methylpiperidin-2-one in a yield of $>90\%$.³⁷

N-Methylpiperidone is also formed (yield 76%) in the absence of dimethyl sulfate when the imide **6a** is heated in boiling benzene for 6 h.²⁴⁵

In a study of the isomerisation of imides into *N*-methylated lactams, it has been found that the rate of formation of the intermediate adducts **331** decreases as the size of the ring increases.²⁴⁶

$n = 1$ – 3 .

On heating in THF in the presence of $\text{PdCl}_2 \cdot (\text{PhCN})_2$, allyl thioimides **332** isomerise to allyl-substituted piperidinethiones **333**.²³¹

$R^1 = R^2 = \text{H}$ (**a**, 74%), $R^1 = \text{H}$, $R^2 = \text{Ph}$ (**b**, 58%), $R^1 = \text{Me}$, $R^2 = \text{H}$ (**c**, 25%).

When the rearrangement of the compound **332a** is carried out without a catalyst for 40 h, the yield of the product **333a** is 60%.²³¹

14. Other reactions

The reaction of the imide **6a** with chloroform in the presence of 50% aqueous sodium hydroxide and tributylamine at 30°C is accompanied by opening of the tetrahydropyridine ring and gives isonitrile **334** in 41% yield.²⁴⁷

Compounds **335**, serving as the initial compounds in the synthesis of insecticides, have been prepared by condensation of 2-methoxy-3,4,5,6-tetrahydropyridine or 2-ethoxy-3,4,5,6-tetrahydropyridine with nitromethane or nitroethane.^{42, 248}

$R^1 = \text{Me}$, Et ; $R^2 = \text{H}$, Me .

Nitrosyl chloride adds to the $\text{C}=\text{N}$ bond of 2,3,4,5-tetrahydropyridine **1a** at -30°C yielding unstable product **336**. Subsequent treatment of this product with methanol or acetic acid in the presence of triethylamine affords relatively stable methoxy-derivative **337** (yield 30%) or acetoxy-derivative **338** (yield 20%).²⁴⁹

Spiro compound **341** has been synthesised by condensation of 2,3,3-trimethyl-3,4,5,6-tetrahydropyridine tosylate **339** with 1-hydroxy-2-nitronaphthalene **340** in the presence of Et_3N .²⁵⁰

The cyclocondensations of 2-methyl-3,4,5,6-tetrahydropyridine **1b** with 9-methyl-2-azabicyclo[4.4.0]deca-1,7-diene **342** in the presence of trimethylacetic and perchloric acid give different products.¹¹

The reaction of the imine **1b** with (–)-(1*R*,2*S*,5*R*)-menthyl-(*S*)-*p*-tolylsulfate **343** in THF in the presence of LDA gives (+)-2,3,4,5-tetrahydro-6-(*R*)-(–)-*p*-tolylsulfonylethylmethylpyridine **344**.²⁵¹

On heating, imide **345** is cleaved to give piperidin-2-one and the corresponding alkene **346**.⁴⁶

V. Conclusion

The data considered above demonstrate that piperidine and its derivatives arouse obvious and continuing interest. At the same time, some aspects of the chemistry of these highly reactive compounds receive undeservedly little attention. For example, addition to the endocyclic $\text{C}=\text{N}$ bond has not been adequately studied. Virtually no data on the cycloaddition involving the piperidine $\text{C}=\text{N}$ bond, except for the reactions with ketenes, have been reported, although these reactions would provide the possibility of preparing starting compounds for the synthesis of other interesting heterocyclic systems.

VII. Conclusion	1069

Abstract. The main results concerning the immobilisation of hydroxyl-containing stationary phases in capillary gas chromatography are surveyed and treated systematically. Attention is concentrated on the influence of the chemical reactions occurring during immobilisation and on the characteristics of the capillary column. It is noted that, together with the improvement of the methods for the immobilisation of known phases, the syntheses of new stationary liquid phases, the properties and the immobilisation conditions of which have been optimised taking into account the characteristics of the objects analysed, are promising. The bibliography includes 176 references.

I. Introduction

Capillary chromatographic methods are mainly employed in modern gas chromatography. This situation became possible as a consequence of the development of a fundamentally new technology for the preparation of open capillary columns with a stationary liquid phase immobilised within the capillary.

The idea of immobilising the stationary liquid phase on the inner surface of a capillary column appeared at the junction of the 1960s–1970s^{1,2} and acquired its present form a decade later as a consequence of the studies by K Grob and G Grob,^{3–7} Blomberg *et al.*,⁸ and Sandra *et al.*⁹

Immobilisation constitutes a method for the stabilisation of a film of a polymeric stationary phase as a result of its structuring (cross-linking) and (in certain cases) grafting to the walls of the capillary column. Immobilisation differs from the traditional methods for the stabilisation of a stationary phase employing different versions of the geometrical and/or chemical modification of the surface of the capillary column^{10–17} by the fact that not only the walls of the column but also the stationary phase film are acted upon directly.

As a result of the immobilisation, the macromolecules of the stationary phase lose their ability to migrate along the inner surface of the column and to form significant local thickened regions. At the same time, the stationary phase acquires a new important property — nonextractibility, which appreciably simplifies the use and regeneration of capillary columns. On comparing the properties of the phase before and after immobilisation, an increase in the reproducibility and stability of the chromatographic characteristics of the column and the expansion of the range of working temperatures were noted and the possibility of obtaining thick (up to 100 μm)^{18,19} and multilayer films of the stationary phase was discovered.^{20,21}

The evident practical advantages of capillary columns with immobilised stationary phases promoted very vigorous research in this field in recent years and led to the rapid practical application of the advances made. Effective methods have been developed to date for the immobilisation of nonpolar and moderately polar polysiloxanes (PS).^{16,22–33} As a rule, the immobilisation of stationary phases of this class is accompanied by minimal changes in their chemical nature and chromatographic characteristics. The methods for the immobilisation of polar stationary phases are associated with considerable difficulties and are being improved.

The review gives a systematic account of experimental data on the immobilisation of hydroxyl-containing stationary phases. Compounds such as di- and poly-ols are of special interest in connection with their unique selectivity in the separation of polar and polarisable sorbates.^{34–40} Poly(ethylene glycols) (PEG) with a high molecular mass (not less than 2×10^4) comprising the commercial brands Carbowax, Superox, CP-WAX, DB-WAX, *etc.* are most often employed as hydroxyl-containing stationary phases in capillary gas chromatographic practice.^{41–44} The chemical structure of the polymer macromolecules corresponds to the general formula $\text{HO}(\text{CH}_2\text{CH}_2\text{O})_m\text{H}$.⁴⁵

Together with organic hydroxyl-containing stationary phases, α,ω -dihydroxypolysiloxanes are considered in the review.

It is noteworthy that the studies on the method of preparation of capillary columns are within the sphere of commercial interests of the firms manufacturing chromatographic equipment. For this reason, many publications are concerned with advertising, which hinders the interpretation of the results. Although the questions which we have considered have been described to some extent in a series of reviews (see, for example, Refs 12, 28, 46, and 47), new experimental data, which need to be surveyed, have accumulated in recent years.

II. Radiation-induced initiation

The essential feature of the radiation-induced initiation of the immobilisation of stationary phases is that high-energy radiation is employed for the formation of the initial active centres.

The possibility of the immobilisation of a series of hydroxyl-containing stationary phases, such as Carbowax 20M, CP-WAX 51 ($M = 2 \times 10^4$), Superox 0.1 ($M = 1 \times 10^5$), and Superox 6 ($M = 6 \times 10^6$), under the influence of ^{60}Co γ -radiation^{27, 41, 42, 46–51} and low-temperature argon plasma⁵² has been investigated.

The efficiency of γ -quanta as initiators of the immobilisation of PEG is low. For example it has been possible to immobilise Carbowax 20M to the extent of 90% for an irradiation dose of 24 Mrad,^{49, 51} whereas methylpolysiloxane is 80%–100% cross-linked already after the absorption of 2–10 Mrad.^{28, 29, 50, 53–55} Such results may be regarded as evidence indicating the complexity of the radiation-chemical transformations in the PEG. However, this question has been scarcely investigated.^{56–62} On the basis of the results obtained by capillary gas chromatographic, IR spectroscopic, and ^{13}C NMR methods, it is claimed in a brief communication⁵¹ that hard radiation does not influence appreciably the chemical nature and the permeability of the PEG to diffusion. In our view, this conclusion requires additional confirmation.

Ideas according to which the mechanism of structure formation in polymers under the influence of radiation is of a radical character are most widespread,^{58–60, 63, 64} but one cannot rule out^{43, 60, 63} the possibility of the involvement of ions and radical-ions in cross-linking processes.

The effect of radiation on PEG depends not only on the overall dose absorbed but also on factors such as the average molecular mass of the polymeric stationary phase and the presence in the latter of impurities or specially introduced additives. Thus, for an irradiation dose of 10 Mrad, the degree of immobilisation of the Carbowax 20M and CP-WAX 51 fractions is 10%–14%,^{48, 65} whilst that of the Superox 6 fraction is 25%.⁶⁵ If 5 mass%–10 mass% of cumenyl peroxide is added to CP-WAX 51 under these conditions, the degree of immobilisation of the stationary phase increases to 50%–52%. In the latter case, the polymer is subjected to direct and indirect action of the radiation, the latter consisting in the initiation of the homolysis of the peroxide.

Springston and Dezero⁵² used a low-temperature argon plasma as the initiator of the immobilisation of the PEG of the Superox 0.1 brand. The degree of immobilisation of the stationary phase did not exceed 12% and the capillary columns acquired in addition an adsorption activity.

III. Material initiation

The material initiation of the immobilisation of stationary phases is based on the use of individual compounds capable of decomposing into free radicals in a certain temperature range.

The material initiators of the immobilisation of PEG employed are usually cumenyl peroxide and, more rarely, benzoyl peroxide and aliphatic azo-compounds.

Compared with the nonpolar polysiloxanes, PEG exhibits an appreciably smaller (at least by a factor of 10) capacity for immobilisation under the influence of organic peroxides and azo-compounds, the process being extremely sensitive to experimental conditions. For example, Etler and Vigh⁶⁵ investigated the immobilisation of the PEG of the brand CP-WAX 51, initiated by cumenyl peroxide, on the walls of glass capillaries modified by BaCO_3 crystals. For a ratio of the masses of the stationary phase and cumenyl peroxide of 10:1 and a process temperature of 160–180 °C, the degree of immobilisation of the phase did not exceed 19%. Russo *et al.*⁶⁶ used graphitised lamp black as the modifying agent for the inner surface of the capillaries. For the same content of the initiator at 150 °C, it was possible to

immobilise PEG 20M ($M = 2 \times 10^4$) to the extent of 75%. According to the authors, this entailed grafting the stationary phase to the layer of carbon black adsorbed on the glass. If account is taken of the chemical properties of the surface of the graphitised thermal black^{36, 67} and the inefficiency of the immobilisation of the relatively low-molecular PEG (for example PEG-600 and PEG-1500), it appears unlikely that grafting was the dominant process in the immobilisation of this phase. The degree of immobilisation of the higher-molecular PEG of the brand Superox 4 ($M = 4 \times 10^6$) on the surfaces of capillaries deactivated by tetramethyldiphenyl disilazene (when grafting is impossible in principle) was only 45% under similar conditions.⁶⁸

Glass capillaries with an active (not deactivated) surface have been used in certain experiments.^{69, 70} Thus Yakabe *et al.*⁶⁹ achieved 80% immobilisation of the PEG-20M fraction in the presence of 15% of cumenyl peroxide at a process temperature of 160 °C. Bystricky⁷⁰ required 20%–40% of this initiator in order to achieve the 65%–97% immobilisation of Carbowax 20M at 150 °C.

It is difficult to explain the experimental results obtained in the above studies.^{69, 71} According to Yakabe *et al.*,⁶⁹ when the cumenyl peroxide content is 2%–3% the degree of immobilisation of PEG 20M on glass is 60% whilst according to Buijten *et al.*⁷¹ the degree of immobilisation on PEG of the brand CPTM-WAX 40M ($M = 4 \times 10^4$) on quartz deactivated by PEG 20M is only 3%.⁷¹

Thus it is evident that the immobilisation of PEG under the influence of cumenyl peroxide is affected also by uncontrollable objective and subjective factors. For example PEG 20M specimens of different origin can differ in the degree of polydispersity and in the amount and nature of the admixture of the polymerisation catalyst.⁷²

According to the results of the studies examined above, the use of higher concentrations of cumenyl peroxide does ultimately lead to the desired result namely the immobilisation of PEG, but according to the view of the majority of the investigators it impairs the efficiency^{66, 69, 73} and the adsorption inertness^{66, 71, 73–75} of the capillary columns. Furthermore, immobilisation under the influence of this initiator alters the polarity of the PEG^{69, 71, 73, 75, 76} and imparts acid properties to the stationary phase.^{68, 69, 73, 77, 78} Martinez de la Gandara *et al.*⁷³ concluded that the classical immobilisation method in which the initiator is introduced into the solution of the phase before depositing it onto the walls of the capillary is partly a source of such problems. The authors developed a two-stage method providing for the deposition of cumenyl peroxide as a separate layer onto a film of the stationary phase. However, this technical procedure did not afford appreciable advantages: an adequate degree of immobilisation (80%–90%) of Carbowax 20M was attained after the addition of 20% of the peroxide, but the immobilised phase manifested acid properties as before. Blomberg and Markides⁷⁹ also used a two-stage method but noted a low reproducibility of the results.

It was noted above that PEG is immobilised under the influence of organic peroxides appreciably less effectively than polysiloxanes. We shall consider in greater detail the causes of this phenomenon. Blum⁸⁰ believes that, in the immobilisation of PEG, an appreciable proportion of the peroxide is consumed on the side reaction involving the oxidation of the terminal hydroxy groups. There is no doubt that this process does occur. However, the number of OH groups in high-molecular PEG is small. For example, the proportion is $\sim 0.17\%$ in Carbowax 20M.⁸¹ Furthermore it is known^{43, 82} that alkyl peroxides are capable of inducing not only the polymerisation but also the depolymerisation of PEG. In addition, the radicals arising in the thermolysis of the peroxide are capable of being incorporated in the chemical structure of the polymer,^{23, 29, 83} which undoubtedly influences the immobilisation process. Finally, the macroradicals formed from the PEG and responsible for this cross-linking are capable of decomposing with dissociation of the polymer chain.^{84–86} Bearing

this in mind, one can assume that the immobilisation of PEG under the influence of cumenyl peroxide includes the following stages:

(1) Initiation of the free-radical reaction

(2) The formation of the macroradicals **A–E** and others as a result of the occurrence of various reactions, for example $\text{S}_{\text{N}}2$ substitution reactions (abstraction of hydrogen), addition reactions, and β -cleavage (Scheme 1):

Scheme 1

R' is any free radical present in the system: methyl, cumenyl, etc., a macroradical.

(3) The recombination and disproportionation of macroradicals, which leads to the termination of the kinetic chain, for example with participation of the radical **A**:

If R' is a macroradical, then recombination leads to the cross-linking of the macrochains and to a gradual development of immobilisation.

One cannot rule out the possibility of the occurrence also of other reactions, in particular those associated with the heterolytic decomposition of cumenyl peroxide and the presence of traces of O_2 , H_2O , etc.

Thus the cause of the comparatively low efficiency of the immobilisation of PEG under the influence of peroxides is apparently that the macroradicals of many types (and especially of type **A**) undergo unimolecular β -decomposition (degradation of the polymer), leading, to a decrease in the degree of polymerisation of the PEG. This effect may be compensated by the high rate of generation of radicals obtained at a high initial peroxide concentration when the competition between radical–radical interactions (second order with respect to the radical) and the decomposition reaction (first order with respect to the radical) does not have an outcome in favour of the latter. There is also the possibility of other ways of solving the problem. For example, the radical immobilisation of PEG is facilitated by the introduction of vinyl groups⁸⁴ into the polymer structure or by employing special active additives (see below).

Comparison of the radiation-induced and chemical initiations of the immobilisation of hydroxyl-containing stationary phases has shown that the efficiency of both procedures is low, but the radiation method has experimental advantages: firstly, the heating of the capillary column before the immobilisation of the stationary phase is eliminated and, secondly, the process initiator (the source of radiation) is outside the column. Consequently the film of the stationary phase is acted upon not thermally and is not

contaminated by the initiator decomposition products as in material initiation.

IV. Composite immobilisation

In order to increase the efficiency of the immobilisation of hydroxyl-containing stationary phases, cross-linking and cross-linking-grafting polyfunctional agents are frequently employed. The main function of the former is to form chemical cross-links between the macromolecules of the stationary phase; together with this feature, the latter are capable of grafting the phase to the walls of the column. Incidentally, when the inner surface of the column is modified appropriately, cross-linking agent can also induce the grafting of the phase to the wall of the column. At the same time, the cross-linking-grafting agent can itself act as a modifying agent, generating on the walls of the column an intermediate mono- or poly-molecular layer capable of interacting with the stationary phase. Since cross-linking and cross-linking-grafting agents usually constitute an appreciable proportion of the mass of the immobilised stationary phase, the immobilisation with their participation may be referred to as composite immobilisation. Polyfunctional alkoxy- and acetoxy-silanes are most widely employed as cross-linking-grafting agents: γ -glycidyloxypropyltrimethoxysilane **1**,^{87–90} trimethoxyvinylsilane **2**,⁸⁷ triethoxymethylsilane **3**,^{88,89} and tetraacetoxysilane **4**.⁹¹

Traitler *et al.*⁸⁷ were the first to suggest that alkoxy-silanes (**1** or **2**) be used for the immobilisation of Carbowax 20M. A mixture of cumenyl peroxide and dibutyltin dilaurate (DBTL) served as the process initiator. The silane **1** makes it possible to obtain more thermally stable and adsorption-inert capillary columns. For a mass ratio of the stationary phase and compound **1** of 2 : 1, the degree of immobilisation of Carbowax 20M on the surface of borosilicate glass was 70%–75%, which is lower by 10%–25% than on quartz. According to the authors, this is a result of the catalytic action of the alkali and alkaline earth metals entering into the composition of the glass. Since a strong catalyst is present in sufficient amount (1.34% of DBTL) in the immobilised mixture, we suggest that other causes may also exist. It may be that the hydroxylated surface of the glass ensures more effective grafting of the stationary phase. On the basis of the ideas developed in a number of studies,^{92–95} the immobilisation of PEG with participation of the silane **1** can be represented as follows:

(1) Chemical modification of the column walls.^{92–94}

(2) Chemical modification of the stationary phase.⁹⁵

(3) Structure formation and grafting of the stationary phase to the column walls. This stage is difficult to describe in the form of a scheme, since it is a complex set of inter-related and parallel homolytic and heterolytic reactions.

It follows from the schemes presented that the transesterification of the alkoxy groups of the silane by the silanol groups on the surface of the capillary columns and the aliphatic OH groups of the stationary phase makes an important contribution to the immobilisation of PEG in the presence of the silane **1**. In practice, certain stages of the immobilisation process coincide. Thus, a version of the combination of (2) + (3) stages has been developed,⁸⁷ whilst in other investigations^{88–90} the (1) + (2) + (3)

version was devised. It is noteworthy that, as a consequence of the high reactivity of alkoxysilanes, the structures of the immobilised stationary phase is extremely sensitive to the presence of impurities in the reaction medium. Thus at an elevated temperature traces of H_2O and O_2 induce the polymerisation of the silane **1** and also of the products of its interaction with glass and PEG. The polymerisation leads to the formation of siloxane polyethers.

Traitler's idea was developed further in Blum's investigations,^{88,89} devoted to the immobilisation of a series of block copolymers of ethylene and propylene oxides (UCON 50HB 2000, 2800 and 5100, LB 550X, Pluronic P-94, as well as N,N,N',N' -tetrasubstituted ethylenediamines (Sinperonik T/904, T/908). Blum abandoned the use of cumenyl peroxide and DBTL, because the role of the cumenyl peroxide-initiated radical processes in the immobilisation of PEG in the presence of alkoxysilanes is slight, while DBTL may impart an undesirable catalytic activity to the capillary column.

Alkoxy- and acetoxy-silanes and siloxanes have been used successfully also in the immobilisation of other hydroxyl-containing stationary phases, for example α,ω -dihydroxypolysiloxanes.^{91,96–99}

Certain organic compounds containing more than one non-conjugated double bond have found an application as cross-linking agents for PEG and its analogues: 2,4,6,8-tetramethyl-2,4,6,8-tetravinylcyclotetrasiloxane **5**,¹⁰⁰ 2,4,6,8,10-pentamethyl-2,4,6,8,10-pentavinylcyclopentasiloxane **6**,⁷¹ 1,1,3,5,5-pentamethyl-1,3,5-trivinyltrisiloxane **7**,¹⁰⁰ and triallyl isocyanurate **8**.⁶⁹ The detailed mechanism of the cumenyl peroxide-initiated immobilisation of PEG with participation of the above compounds has not been established. The attempt to use NMR spectroscopy for this purpose was unsuccessful as a consequence of the low sensitivity of the method.⁷⁹

Buijten *et al.*⁷¹ proposed a method for the immobilisation of the PEG of the CP™-WAX 40M brand with the aid of methylvinylcyclopentasiloxane. They suggest that the process begins with the opening of the siloxane ring and its condensation with the PEG. The immobilisation proper of the phase is attained as a result of the cumenyl peroxide-initiated structure formation involving the siloxane fragments in the copolymer obtained. The following process mechanism has been put forward:

CP = cumenyl peroxide.

However, this route for the process is possible only in the presence of certain substances — acids, bases, and certain salts — capable of cleaving the siloxane linkage and of catalysing the polycondensation.⁴⁵ Organic peroxides induce structure formation in cyclosiloxanes without ring opening.^{83,101} For this reason, in the presence of cumenyl peroxide the development of radical chain processes is most probable in the system under consideration, whereupon the polymerisation of methylvinylcyclopentasiloxane, its grafting to a PEG macromolecule, as well as structure formation in the PEG and in the copolymer formed take

place simultaneously. The mechanism proposed by the authors can operate as a side process when the stationary liquid phase contains an appreciable amount of an admixture of a polymerisation catalyst or the inner surface of the capillary column is insufficiently deactivated.

Siloxanes without vinyl groups also possess the properties of cross-linking agents but they are less reactive. Thus, when the cyclosiloxane **6** is replaced by octamethylcyclotetrasiloxane **9**, the degree of immobilisation of CP™-WAX 40M diminishes by a factor of 2.⁷¹

Schomburg *et al.*¹⁰² immobilised Carbowax 20M using acryloylvaline-(*S*)- α -phenylethyl amide **10** containing one vinyl group. However, the latter is not a cross-linking agent. It is a chiral modifying agent which is grafted to the Carbowax 20M macromolecules in the course of the radical immobilisation. As a result, the immobilised phase acquires the property of enantioselectivity. In the study under consideration, the possibility of a deliberate alteration of the selectivity of the stationary phase in the course of immobilisation was first demonstrated. The structural fragments incorporating the immobilised phase are always chosen so that they resemble the sorbates being separated.^{103,104}

Aliphatic and aromatic di- and poly-isocyanates constitute a special group of cross-linking agents: $\text{OCN}(\text{CH}_2)_6\text{NCO}$ **11**, $\text{OCN}(\text{CH}_2)_6\text{N}[\text{CONH}(\text{CH}_2)_6\text{NCO}]_2$ **12**, and $\text{MeCH}_2\text{C}[\text{CH}_2\text{O}-\text{CONHC}_6\text{H}_3(\text{NCO})\text{Me}]_3$ **13**.

The method for the immobilisation of PEG, its analogues, and acid derivatives (Carbowax 20M, Castorwax DD-026, Carbowax 20M-TPA, OV-351, FFAP) under consideration was developed further in the studies of Horka and coworkers.^{105–111}

The immobilisation of hydroxyl-containing stationary phase with participation of isocyanates proceeds in the following manner.^{45,47,112,113} In the presence of the DBTL catalyst or 1,4-diazabicyclo[2,2,2]octane (DABCO), the CO group of the isocyanate reacts with the OH groups of the phase with formation of urethane groups [process (1)]. The latter are extremely reactive and interact with the excess isocyanate and the silane **1** — the agent modifying the inner surface of the capillary column. Allophanate fragments, cross-linking the copolymer [process (2)] arise under these conditions, and the copolymer is also grafted to the walls of the capillary column [process (3)]:

According to the data of Horka and coworkers,^{47,105,106} the immobilisation of PEG with participation of the isocyanates **11–13** makes it possible to obtain stationary phases which are thermally stable up to 305–320 °C. However, these data are inconsistent with the known facts. Thus it has been established^{43,114} that above 200 °C the urethane fragments dissociate *via* a depolymerisation mechanism. There is a possibility of the dissociation of bonds with formation of an olefin and a primary amine.⁶³ The thermal degradation of the allophanate groups

begins already at 120 °C. In the range 300–320 °C, PEG decomposes at an appreciable rate.⁴³ Evidently, in characterising the thermal stability of the stationary phase, it is insufficient to determine the maximum working temperature on attainment of which the properties of the phase are still not significantly impaired. One should also have an idea about the 'lifetime' of the column (or the magnitude of the background flow) at this temperature and about the chemical inertness of the phase in the region of high temperatures.

The immobilisation of acid derivatives of PEG by the method of Horka and coworker^{105–111} is distinguished by the fact that, together with the isocyanate, 3,5-dinitrosalicylic acid (3,5-DNSA) is introduced into the reaction mixture. Apparently the acid is necessary to compensate for the loss of carboxy groups and hence of the specific properties of the phase in the course of immobilisation. Furthermore, if one considers the possible interactions in the PEG–isocyanate–3,5-DNSA system, it becomes evident that the carboxy group is retained only by the part of the acid which does not enter into the structure of the stationary phase. This conclusion is confirmed by data concerning the loss of acid properties after the extraction of the phase by a series of organic solvents.⁴⁷

There have been few studies devoted to the immobilisation of relatively low-molecular PEG ($M < 10^4$). This is evidently associated with the limited stability of films of such stationary phases on the surfaces of glass and quartz and with the narrow range of working temperatures.³⁷ However, low-molecular PEG is characterised by a high functional selectivity.^{36, 37} Thus, on passing from PEG 20M to PEG 600, the McReynolds constants (indices) $y-z$ increase by 60–95 units. In capillary gas chromatography, the requirement for phases with a high functional selectivity has not so far been satisfied,^{115–122} so that the development of methods for the immobilisation of low-molecular glycols appears of very great current interest.

A novel method for the immobilisation of PEG 2500 and PEG 10 000 has been proposed by Sandra *et al.*⁷² The composition comprising PEG and 3-triethoxysilylpropyl isocyanate **14** is immobilised on the walls of a quartz capillary by treatment with water, which is injected in pulses into the flow of carrier gas. The development of the process begins with the hydrolysis of the isocyanate **14**, whereupon a siloxane polyisocyanate is formed¹²³ and its action is subsequently similar to that of the organic isocyanates examined above.

The method of the immobilisation of low-molecular PEG 400 proposed by Mukhina and coworkers^{124, 125} is based on the interaction with the bisphenol A epoxide resin (BE):

$\text{Z} = \text{OCH}_2\text{CH}(\text{OH})\text{CH}_2\text{OC}_6\text{H}_4\text{CMe}_2\text{C}_6\text{H}_4$, $p = 0-3$.

According to the ideas developed in a number of investigations,^{95, 126–130} the stationary phase is in this case immobilised in the following manner. Under the influence of the catalyst (triethylamine), the hydroxy groups of the PEG react with the epoxide groups of BE, which results in the formation of a linear copolymer.

$\text{A} = \text{OCH}_2\text{CH}(\text{OH})\text{CH}_2(\text{OCH}_2\text{CH}_2)_m\text{OH}$.

In the presence of an excess of BE (for the molar ratio PEG:BE < 1), structure formation involving secondary OH groups takes place in the copolymer. There is a possibility of grafting the phase to the surface of glass *via* the both epoxide¹³¹ and hydroxy groups.¹³² Out of the multiplicity of compounds capable of accelerating the interaction of PEG 400 and BE, the

authors gave preference to triethylamine taking into account not only its activity as a catalyst but also its possible influence on the chemical inertness as well as the catalytic and adsorption properties of the stationary phase. As a cross-linking agent, the BE resin also has a series of advantages: firstly, it exhibits a satisfactory adhesion to the surface of glass and quartz, which stabilises the stationary phase film on the walls of the capillary column; secondly, the BE macromolecules contain no functional groups other than the terminal epoxide and aliphatic OH groups and the resin is a polyether like PEG, *i.e.* the characteristics of their thermal and chemical stabilities are comparable;¹³³ thirdly, the loss of hydroxy groups by the PEG on interaction with BE is compensated by the formation of new OH groups.

Thus the use of the agents **1–15** generally promotes an increase in the efficiency of the immobilisation of hydroxyl-containing stationary phases (Table 1). However the problem of increasing the quality of the immobilised phase remains. Thus the copolymer of the PEG of the Superox 4TM brand and the siloxane **7** has basic and acid adsorption centres;⁷⁵ the PEG of the brand CPTTM-WAX 40M, immobilised with the aid of the siloxane **6**, exhibits weak acid properties;⁷¹ Carbowax 20M, immobilised in the presence of the isocyanates **11–13**, is distimety.⁴² Triallyl isocyanurate, used in an amount of 10% relative to the mass of PEG 20M, induces an asymmetry in the chromatographic peaks of all of Grob's test sorbates.⁶⁹ This is probably a consequence of the high functionality of the agents employed.

Regardless of the way in which it is carried out, immobilisation disturbs the molecular order in PEG,^{134, 135} which lowers the degree of crystallinity and the melting point of the stationary phase. This effect is less pronounced in the radiation-induced immobilisation of PEG and is most marked for composite immobilisation. Fernandez-Sanchez *et al.*¹³⁴ established that at 40 °C the degree of crystallinity of PEG of the Superox 20M brand is 83%–86%, while after immobilisation by means of cumenyl peroxide using Bystricky's method⁷⁰ it is 47%–53%. On the other hand, the fraction of the crystalline phase of the polymer immobilised with participation of the silane **1** by the method of Trautler *et al.*⁸⁷ is only 24%–31%. The minimum working temperature of the immobilised high-molecular PEG is reduced in most cases by 20–30 °C.^{49, 51, 65, 70, 71, 77, 134–137} This effect is well illustrated by the temperature dependence of the retention of the sorbate on a column containing PEG 20M before and after immobilisation (Fig. 1). However, the use of large amounts of reagents leads to the opposite result — an increase in the lower limit of the working temperatures owing to the high density of structure formation in the stationary phase.^{87, 107, 110}

It is noteworthy that composite immobilisation leads in most cases to the formation of new phases which may be characterised as statistical copolymers of the initial phases and the cross-linking agents.

Figure 1. Temperature dependence of the retention of 1-butanol on capillary columns containing PEG 20M before (*1*) and after immobilisation by treatment with cumenyl peroxide (*2*) or a mixture of cumenyl peroxide with γ -glycidyloxypropyltrimethoxysilane (*3*).¹³⁴

Note. The following designations have been adopted: *I* — initiator or catalyst; *II* — concentration of initiator or catalyst (mass %) [the irradiation dose (Mrad) is indicated in brackets]; *III* — cross-linking or cross-linking-grafting agent; *IV* — concentration of cross-linking or cross-linking-grafting agent (mass %); SP — stationary phase; st — static immobilisation regime (in a sealed column); dn — dynamic immobilisation regime (in a stream of carrier gas); *Z* — immobilisation efficiency equal to the ratio of the capacity factors of the capillary columns before (*K*) and after (*K'*) extraction of the immobilised stationary phase: $Z = (K/K')100$; DPS — diphenyltetramethylsilazane; Irganox — pentaerythritol tetrakis-3,5-di-*tert*-butylphenyl-β-4-hydroxypropionate; GTB — graphitised thermal black; BP — benzoyl peroxide; AIBN — azobisisobutyronitrile; 3,5-DNSA — 3,5-dinitrosalicylic acid; AtO — azo-*tert*-octane; SE-54 — methylsiloxane containing 5% of phenylpolysiloxane units. Cross-linking and cross-linking-grafting agents: **1–15** — see text. The isocyanates **12** and **13** tend to undergo oligomerisation; the corresponding oligomers are known under the commercial names Desmodur N75 (the number of functional groups is 5–6) and Desmodur L75 (the number of functional groups is 6–7). The main properties of the stationary phases of the commercial brands indicated are quoted in chromatographic handbooks and Company Catalogues.

V. Thermal immobilisation

In the majority of methods for the immobilisation of the stationary phase, use is made of the activating effect of thermal energy. Furthermore, in the case of polymeric stationary phases with a specific structure, the thermal energy can function as the principal initiator of the immobilisation process. This was illustrated for the first time in relation to the immobilisation of α,ω-dihydroxypolysiloxanes^{97, 99, 138–140} and α,ω-dihydroxysilarenes.^{141, 142}

R = Me, Ph, (CH₂)₃CN, (CH₂)₃CF₃; R' = Me, Ph.

On the basis of the analysis of the volatile products formed on thermal immobilisation of α,ω-dihydroxypolysiloxanes, Welsch and Teichmann¹⁴³ proposed the following process mechanism. Under the influence of temperature and catalytically active impurities (traces of O₂, H₂O and the basic catalyst for the polymerisation of the stationary phases), present in the column, siloxide ions are formed and attack the Si–C bond of the polymer and/or the silanised surface of the column. The corresponding hydrocarbon is then evolved and the cross-linking and grafting of the stationary phase take place.

Polycondensation *via* silanol groups makes an appreciably smaller contribution to the immobilisation of α,ω -dihydroxypolysiloxanes than was postulated initially.^{138, 139, 144–149} The application of the thermal method for the immobilisation of polysiloxanes improves significantly the inertness and thermal stability of the capillary column. As a consequence of this, the possibilities of capillary gas chromatography for high-temperature analysis have expanded. Using thermally immobilised α,ω -dihydroxypolysiloxanes, Blum and coworkers^{98, 150, 151} developed methods for the direct gas-chromatographic determination of petroleum porphyrin bases, their metal complexes, and other organic compounds with molecular masses up to 1196 (the traditional applications of gas chromatography involve compounds with molecular masses up to 500).¹⁵² However, on increase in the content of functional groups, the capacity of α,ω -dihydroxypolysiloxanes for immobilisation under the influence of temperature diminishes. Thus the degree of thermal immobilisation of α,ω -dihydroxypolysiloxane containing 60% of cyanopropyl groups does not exceed 40%.¹⁴⁰ For this reason, the polar α,ω -dihydroxypolysiloxanes are usually immobilised with the aid of cross-linking-grafting agents.^{91, 98, 99}

The thermal method has been used by ourselves in the immobilisation of a hydroxyl-containing stationary phase with a polyglycidol (PG) structure.^{153, 154}

It was proposed to use the capacity of polyalcohols for structure formation on heating as a result of dehydration.¹⁵⁵ Evidently the main condition governing the application of this approach in chromatography is an optimum hydroxyl functionality of the initial polymer, ensuring not only its capacity for structure formation but also the permeability of the structured polymer film to sorbate molecules over a sufficiently wide temperature range. The range of working temperatures of the PG-based thermally immobilised phase (PGTM) is from 80 to 300 °C. The chromatographic characteristics of PG change only slightly in the thermal immobilisation process. This makes it possible to postulate that the chemical nature of the bulk of the stationary phase, accessible to sorbate molecules, also hardly changes, *i.e.* an appreciable proportion of the OH groups are retained, although the phases are in fact immobilised *via* these groups. The PGTM-based thermally immobilised phase is characterised by a high resistance to the action of organic solvents and water even at an elevated temperature.

The resistance of immobilised polar phases to the action of solvents is known^{7, 24, 28, 29} to be determined to a large extent by the presence of chemical bonds between the stationary phase and the walls of the capillary column. However, in the case under

consideration the multicentre sorption of the hydroxyl-containing PGTM macromolecules on the dehydrated surface of the glass column is apparently of decisive importance. Among the disadvantages of PGTM one should note the low permeability of this phase to diffusion, which is largely caused by the low segmental mobility of the polymer macromolecules owing to the high density of the hydrogen bonds. When PGTM is used under the conditions of steam chromatography, water loosens the supermolecular structure of the stationary phase films and hence the HETP is reduced by a factor of 2.8, while the minimum working temperature falls by 40–45 °C. On the other hand, the functional selectivity of PGTM increases by only 5%. It is of interest that the corresponding characteristics of PEG 20M under analogous conditions vary in a different way: the selectivity of the phase changes most appreciably (it increases on average by 20%), whereas the efficiency of the separation increases only by a factor of 1.1. By virtue of the high content of the reactive OH groups and the resistance to the action of solvents, PGTM may be used as a matrix for the preparation of new polar immobilised stationary phases *via* their chemical modification *in situ*.¹⁵⁶

Thus the thermal method for the immobilisation of hydroxyl-containing stationary phases makes it possible to obtain the most inert and thermally stable capillary columns and also leads to new possibilities in the synthesis of polar immobilised phases.

VI. Design of hydroxyl-containing stationary phases to be immobilised

Until recently polymeric materials obtained for other purposes have been used as the stationary phases in capillary gas chromatography.^{36, 37} However, it was found that the properties of many stationary phases do not meet the necessary set of requirements most fully formulated by Blomberg.³⁹ According to these requirements, the stationary phases must possess a definite type of selectivity, chemical inertness, thermal stability, reproducibility of properties, an adequate diffusional permeability, and the capacity for immobilisation *in situ*. The experimental data accumulated towards the middle of the 1980s made it possible to proceed to the deliberate synthesis of phases specially designed for capillary gas chromatography.^{115, 116, 120, 157–160} Computer modelling has been used in recent years to determine the composition, structure, and immobilisation conditions for new phases employed in the analysis of specific objects.^{23, 120, 161–164} For example, the stationary phase DB-Dioxin, described by Lautamo *et al.*¹⁶² and Jennings and Nikelly,¹⁶³ represents the application of a computer model of a selective stationary phase for the separation of a series of isomers of polychlorinated dibenzo-*p*-dioxins and dibenzofurans.

The search for phases comparable to PEG in their selectivity but having a wider range of working temperatures and more readily immobilised, is being prosecuted. For this purpose, studies are made on block copolymers of dimethylpolysiloxane and PEG¹⁶⁵ and on copolymers of ethylene glycol and siloxane (brand OV-330 phase).⁷¹ However, polysiloxanes of grafted oligo(ethylene oxide) fragments (PS-OEO) exhibited the best chromatographic characteristics.^{166–169}

$R = (CH_2)_3C_6H_4O(CH_2)_2(OCH_2CH_2)_{2-3}OMe$,
 $m = 0.02–0.05$, $n = 0.45–0.48$.

The composition and structure of the copolymer were optimised taking into account the requirements, listed above, which must be met by the phases: thermal stability, satisfactory adhesion to glass and quartz, and excellent permeability to diffusion are characteristic of the polysiloxane; oligo(ethylene oxide) ensures the required type of selectivity, while the octyl substituent simplifies

the immobilisation by treatment with radical process initiators. This type of 'brush' structure, which successfully combines the advantages of the siloxane skeleton and functional-selective substituents, is characteristic of the majority of new generation stationary phases.^{170–175} Certain characteristics of such phases are presented in Table 2.

Table 2. The capacity factor (k'), the retention index (I), the number of effective theoretical plates (N), and the range of working temperatures of a quartz capillary column (20 m × 200 µm) with different stationary phases.¹⁶⁸

Stationary phase	Dodecanol		Biphenyl		N /tp m ⁻¹	Range of working temperatures /°C
	k'	I	k'	I		
PS–OEO	16.0	1800	15.2	1920	5700	20–280
Carbo-wax 20M	15.4	1756	15.5	1925	5400	60–220
Bondable PEG	17.1	1985	14.2	1740	5600	40–260

It must be emphasised that the advances in the practical realisation of the possibilities of capillary gas chromatography are determined to a large extent by the high quality and diversity of the properties of the capillary columns. The synthesis of new stationary phases, the composition and structural parameters of which have been optimised taking into account the general requirements and characteristics of the objects to be analysed, is therefore one of the principal aspects of the development of capillary gas chromatography.

VII. Conclusion

Hydroxyl-containing stationary liquid phases are nowadays the commonest selective phases in capillary gas chromatography. The polarity of such phases varies within fairly wide limits. The methods for the preparation of immobilised phases examined in the present review make it possible to create the optimal stationary phase of this type for the given variety of separation.

The further development of the methods for the preparation of hydroxyl-containing stationary phases should in our view take place in the following principal directions (1) preparation of hydroxyl-containing chiral phases; (2) increase in the thermal stability of the hydroxyl-containing phases; (3) deliberate alteration of the properties of the hydroxyl-containing phases by dissolving organic and inorganic solvents in them.

In conclusion we may note that the immobilised phases are of interest also for employment in packed columns.¹⁷⁶

Abstract. The interaction of hydrocarbons having different structures with catalysts for their partial oxidation is considered. The activation of the hydrocarbon molecules on the surface can lead to the formation of adsorption complexes or radicals. This process depends on the structure of the hydrocarbons and the energy of the bonds in them, the temperature and nature of the surface of the solid (structure, the valence state of the elements entering into its composition, and the form of oxygen and its mobility). The possible mechanism of the activation of hydrocarbons on different catalytic systems is discussed. The bibliography includes 149 references.

I. Introduction

The catalytic oxidation of organic substances is a complex multi-stage process. Numerous studies have been devoted to its mechanism. The interaction of organic substances and solids, in particular catalysts, is known to be accompanied by the formation of intermediate surface compounds which are converted into reaction products on further oxidation. The composition of the products, *i.e.* the direction of the process, are determined to a large extent by the nature of the intermediate compounds and also by the active form of oxygen participating in the oxidation process. The first stage of the catalytic oxidation is the activation of the molecules of organic compounds. Unfortunately, little attention has been devoted to the study of this stage, although in our view it exerts a significant influence on the subsequent oxidation stages.

The interaction of hydrocarbons with the catalyst is accompanied by the formation on its surface of adsorption complexes or radicals. The role of radicals in the oxidation reactions and their influence on the selectivity have been examined in a review.¹ The formation of surface compounds in the interaction of hydrocarbons with various heterogeneous catalysts has been described.² Questions of the interaction of hydrocarbons with partial oxidation catalysts have been examined in a monograph,³ but only the

results published up to 1975 were discussed. It is useful to analyse the current literature data on the oxidation mechanism. Evidently such a task cannot be performed within the framework of a single communication. In the present review, attention is concentrated on the nature of the activation of hydrocarbons and the influence of the chemical properties and structure of the catalysts on the activation.

The development of new spectroscopic methods, such as IR Fourier spectroscopy, laser Raman spectroscopy, *etc.*, made it possible to determine the structures of many surface compounds formed in the interaction of hydrocarbons with the catalyst.³ The energies of the bonds in the intermediate compounds formed when hydrocarbons are adsorbed on the active surface centres have been calculated by quantum-chemical methods.⁴ In the calculations of the structures of the surface compounds and of the nature of the bonds between the adsorbed hydrocarbons and the catalysts, many properties of the surfaces of the solids are usually disregarded,^{5, 6} so that an appreciable proportion of the mechanisms of the catalytic reactions and of the activation of hydrocarbons are of a formal character.

The interaction of hydrocarbons with the active centres of the catalysts is accompanied by the deformation^{7–11} and the subsequent dissociation of individual bonds in the reacting molecules. The C–H bond in hydrocarbons may be dissociated homolytically or heterolytically. In the homolytic dissociation, a surface OH group and a free radical are formed on the catalyst surface:

where O_s is surface oxygen.

The heterolytic reaction is accompanied by the binding of a proton on an alkaline surface centre:

The heterolytic dissociation of the hydrocarbon molecule with formation of a hydride on the acid surface centre (Lewis centre) is also possible:

where M^{n+} is the Lewis centre.

In the homolytic dissociation of a C–H bond, the radicals formed on the catalyst surface can be desorbed into the gas phase, initiating the homogeneous propagation of the process, or can remain on the surface and participate in the stages leading to the formation of the reaction products.¹² The characteristics of the

Received 18 November 1997

Uspekhi Khimii 67 (12) 1175–1185 (1998); translated by A K Grzybowski

heterogeneous-homogeneous oxidation reactions of hydrocarbons have been described in a review.¹

In considering the dependence of the reactivity of hydrocarbons on their structure, the activation energies (E_a) for the dissociation of various bonds can be compared.⁷ For example:

Bond	E_a /kJ mol ⁻¹	Bond	E_a /kJ mol ⁻¹
CH ₃ –H	456.7	CH ₂ =CHCH ₂ –H	368.7
CH ₃ CH ₂ –H	410.6	C ₆ H ₅ –H	460.9
(CH ₃) ₂ CH–H	398.0		

Alkenes exhibit a higher reactivity than alkanes. Comparative study of the oxidation of various alkenes on a palladium single crystal showed that the allyl C–H bond in the hydrocarbon molecule is less reactive than the vinyl bond.

Saturated hydrocarbons may be activated in two ways:²

(1) cleavage of a C–H bond by electrophiles with formation of a carbonium ion or a carbanion and subsequent dissociation of a C–C bond;

(2) dissociation of a C–C bond in the interaction with a low-valence metal.

The ability to cleave a C–C bond depends on the oxidation state of the transition metal. In redox processes, there is a possibility of the formation of catalytic *ensembles* and the role of the catalyst then consists in transforming one-electron processes into processes involving two and more electrons. Thus the structure of the hydrocarbons and the nature of the bonds in the molecules constitute one of the main factors influencing the way in which they are activated on interaction with catalysts.

Various mechanisms of the activation of butane have been considered in a review.⁷ The dissociation energies of the bonds between hydrogen and the primary, secondary, and tertiary carbon atoms have been compared with the rates of abstraction of one or two hydrogen atoms from the hydrocarbon. Various mechanisms of the activation of hydrocarbons and of the formation in this process of radicals and complexes (carbonium ions and carbanions) have been described in communications^{7–9} devoted to the study of the partial oxidation of alkanes, in particular propane.

The composition of the catalyst exerts a major influence on the activation of hydrocarbons. For example, on the V₂O₅ catalyst one hydrogen atom is abstracted from the CH₃ group of toluene, whereas following the introduction of the PO₄ group into the catalyst a new active centre (V^{δ+}···O^{δ-}···P) is formed on the surface and this time two hydrogen atoms are abstracted simultaneously from the hydrocarbon molecule on this centre. Under these conditions, a surface compound different from that on vanadium pentoxide is formed and a different reaction product is therefore obtained. The activation mechanism depends on the nature of the active surface centres, on which different forms of oxygen may be present. The centres for the adsorption and activation of hydrocarbons consist of cations, acid–base centres, free electrons, and defects and vacancies in the solid. The possible versions of the interaction of hydrocarbons with catalysts will be examined below in relation to olefins (ethene and propene), alkanes (ethane, propane, and butane), and aromatic compounds (benzene and toluene).

II. Activation of hydrocarbons by the oxygen of the surface

It is very difficult to discover a process in which only the oxygen of the catalyst surface participates. One of the few examples for which it is possible to trace the activation of hydrocarbons by precisely such oxygen is the oxidation of ethene on silver.^{13,14} Ethene is known not to be sorbed on pure silver.

Korchak and Tret'yakov's study¹⁴ was devoted to the kinetics of the oxidation of ethene on silver foil cleaned in an ultrahigh vacuum. The formation of an oxide phase on the surface of silver during the experiment can be virtually completely avoided if the

oxygen pressure is below 10⁻² mm Hg while the catalyst temperature does not exceed 523 K. In order to obtain reproducible kinetic data, the catalyst had to be treated in hydrogen at 773 K to eliminate traces of the oxide phase. Under these conditions, the oxidation of ethene afforded only CO₂ and H₂O.

By observing the above conditions, it was possible to investigate in detail the kinetics of the oxidation of ethene on silver free from a surface oxide phase. At an oxygen pressure of 2 × 10⁻⁴–10⁻² mm Hg and a catalyst temperature of 400–523 K, the principal stages of the mechanism of the extensive oxidation of ethene are described satisfactorily by the following scheme:

where a is the adsorption coefficient and Z a catalyst active centre. Stage (4) represents the overall complete oxidation reaction of acetaldehyde, which proceeds at a high rate and does not limit the overall process.

Korchak and Tret'yakov¹⁴ established that silver free from an oxide layer or oxygen dissolved in the bulk phase is 2 × 10⁴ times more active in the extensive oxidation of ethene than the oxidised form of the catalyst. When the catalyst is saturated with oxygen, the rate of the extensive oxidation falls, which leads to the equalisation of the rates of the extensive and mild oxidation and hence to an increase in the selectivity in the formation of epoxyethane.

In order to increase the process selectivity, in industry the catalyst is activated in a stream of air. Taking into account the data presented above, one can postulate that the activation takes place as a result of the saturation of the catalyst with oxygen and the formation of an active phase on the surface.

The specific catalytic properties of pure silver can be explained by the fact that the dissociative adsorption of oxygen proceeds at a high rate on this metal. Because of this, extensive coating of the surface by oxygen atoms is achieved, such atoms oxidising ethene rapidly to CO₂ and water.

When oxygen is dissolved in silver, the strength of its bond with the metal diminishes and there is a sharp increase in the activation energy for the dissociative adsorption of oxygen (from 14 to 28 kcal mol⁻¹).¹⁵ As a result, the coating of the surface by atomic oxygen decreases in the course of the reaction, which actually entails a fall in the rate of the extensive oxidation of ethene.

The decrease in the amount of atomically adsorbed oxygen is accompanied by an increase in its molecular adsorption, particularly at elevated O₂ pressures, which should increase the rate of formation of epoxyethane. The principal conclusions reached as a result of the study of the kinetics and mechanism of the oxidation of ethene on pure silver have been confirmed by the results of other investigations. Thus it has been established that the adsorption of ethene on silver becomes possible only after the latter has been treated with oxygen.¹³

The mechanism of the formation of surface oxygen has been described in detail in a series of communications and monographs (see, for example, Margolis³). The oxygen on the surfaces of oxide systems is known to undergo consecutive transformations:

The oxygen ion formed (O⁻) is inserted in the lattice of the solid in the form of O²⁻. The oxygen may dissolve in the near-surface layers of metals.

In the adsorption of oxygen on the surface of silver, the quasi-oxides Ag₂O and Ag₂O₃ are formed, *i.e.* metallic silver is converted into the Ag⁺ cations. The study of the interaction of silver

with oxygen also enabled investigators^{16–18} to reach the following conclusions:

1. Depending on the conditions, the oxygen on the surface of silver is adsorbed in different forms. The dimeric oxide Ag_2O with ionic type of bonding is formed at temperatures below 470 K and this form participates in the extensive oxidation of ethene.

2. If silver is treated with a mixture of ethene with oxygen, weakly bound covalent oxygen appears on the surface of the metal in the form of single atoms, such form corresponding to the structure $\text{Ag}-\text{Ag}-\text{O}$.

It has been suggested that the 'ionic' oxygen creates surface sites for the adsorption of ethene, while the 'covalent' oxygen participates in the formation of epoxyethane. The disposition of oxygen on different faces of the silver lattice depends on the structure of the catalyst surface. This influences the catalyst activity and the selectivity in the ethene oxidation reaction and hence also the structure of the surface compounds.

It has been shown by IR spectroscopy that the adsorption of ethene entails the dissociation of the double bond in the ethene molecule and the formation of various surface compounds.^{19,20} With the aid of improved IR Fourier spectroscopy, strongly bound acetaldehyde and the complex $\text{Ag}\cdot\text{CO}$ have been detected on the $\text{Ag}/\text{Al}_2\text{O}_3$ catalyst.²¹ It has been established^{22–24} that ethene is activated with participation of the atomic surface oxygen. When ethene is oxidised on silver, acetaldehyde, formate, oxalate, and CO_2 are formed in addition to epoxyethane.²⁵ The epoxyethane conversion products have been investigated by IR spectroscopy and NMR and also by an isotope method involving the use of ^{13}C .²⁶

The degree of dispersion of silver on various supports (SiO_2 , Al_2O_3 , TiO_2) is very important for the conversion of ethene into epoxyethane.^{27,28} However, since the heats of adsorption of the reaction components on silver with different degrees of dispersion have not been determined and the coexistence on silver of various adsorbed forms of oxygen has not been confirmed, the question of the influence of the degree of dispersion on the activation of ethene remains open.

The atomic structure of the silver surface (nanoclusters) has been discovered with the aid of a tunnelling microscope and the migration of the metal particles on the surfaces of supports has been observed.²⁹

There is no information in the literature about the influence of the rearrangement of the silver surface on the activation of ethene and the formation of surface complexes. In quantum-mechanical calculations of the energy parameters of the ethene conversion process, simplified models are therefore used³⁰ in which a stationary silver atom bound to oxygen or entering into the composition of the cluster is considered. The calculation has been performed³¹ for the interaction of oxygen, hydrogen, chlorine, hydroxy groups, and ethene with silver clusters on supports. Depending on the mode of coordination to a silver atom, the chemisorbed oxygen (an atomic oxy-radical) can participate in the formation of epoxyethane or can be converted into an inactive form. Additives introduced into the silver influence the ratio of the radical forms of oxygen.

Thus ethene is activated with participation of different forms of oxygen. The oxygen dissolved in the silver lattice influences the process occurring the catalyst surface.

Data concerning the migration of silver atoms on the catalyst surface under the influence of the medium (the formation of clusters of different size, surface diffusion) are not taken into account in the models employed in calculations for the ethene activation process. The mechanisms of the conversion of ethene into epoxyethane are therefore formal in character: although they are in fact used in kinetic analysis, they do not reflect the true reaction mechanism.

III. Activation of hydrocarbons by the oxygen and cations of metal oxides

1. Olefins

The most thoroughly investigated stage in the process involving the oxidation of hydrocarbons is their adsorption on oxide systems. Depending on the structure, olefins can be adsorbed in the following forms on the surface of the catalyst:^{32,33}

(a) two-centre forms with σ -bonds:

(b) associative π -complex:

(c) dissociative π -allyl complex:

Extensive experimental data on the formation of σ -, π -, and allyl complexes on the surfaces of various oxide systems in the adsorption of propane have been accumulated.^{32–35}

Formal mechanisms have been proposed for the adsorption and the reactions, in which it is postulated that such surface compounds are formed when olefins are activated on the cations of the metal oxide lattices. For example, when propene is adsorbed on MoO_3 it forms a bond with Mo^{6+} , as a result of which a π -complex is formed and the Mo^{6+} ion is simultaneously converted into Mo^{5+} . The structure of molybdenum oxide has been investigated with the aid of an electron microscope and also by X-ray phase analysis and UV and Raman spectroscopy.^{36,37} In the course of the oxidation of propene, MoO_3 is reduced to MoO_2 and MoO . More complex structures — Mo_8O_{20} and Mo_9O_{26} — have also been detected. When MoO_3 was deposited on silica gel, the formation of molybdates was observed.³⁶ The structure of MoO_3 has been investigated in detail^{37,38} and the existence of different forms of oxygen on its various faces has been demonstrated.^{39–42}

Particular attention has been devoted to the $\text{Bi}-\text{Mo}-\text{O}$ system,^{32,33} consisting of three different phases: $\text{Bi}_2\text{O}_3 \cdot 3\text{MoO}_3$ (α -phase), $\text{Bi}_4\text{O}_3 \cdot 2\text{MoO}_3$ (β -phase), and $\text{Bi}_2\text{O}_3 \cdot \text{MoO}_3$ (γ -phase).⁴³ The study of the structures of these phases and of their catalytic activities in the oxidation of propene led investigators to the conclusion that, when propene interacts with the catalyst surface, the abstraction of a hydrogen atom from the methyl group is followed by the formation of π - and σ -complexes. The olefin molecule is activated by a bismuth cation. It has been demonstrated in numerous experiments that the active oxygen necessary for the conversion of these complexes into acrolein originates from MoO_3 . The characteristic features of the transport of the active oxygen in a $\text{Bi}-\text{Mo}-\text{O}$ catalyst have been investigated.⁴²

In order to increase the rate and selectivity of the oxidation of olefins, catalysts with more complex compositions have been used. Several molybdates (multiphase systems) may be present in them, for example $\text{CoMoO}_4 + \text{Bi}_2\text{MoO}_4 + \text{Fe}_2(\text{MoO}_4)_3$.

The mechanism of the action of such complex catalysts has been established with the aid of various methods (IR, UV, EPR, and Mössbauer spectroscopy).^{44,45} The fundamental principle is the separation of the functions of the separate system components. Propene is adsorbed on the $\text{Bi}-\text{Mo}-\text{O}$ component and is activated on bismuth ions, while the oxygen necessary for the conversion of the complexes is supplied by the iron molybdate phase $\text{Fe}_2(\text{MoO}_4)_3$. This phase is converted into the divalent iron molybdate FeMoO_4 .

The propene and oxygen adsorption and activation centres are separated. The study of complex systems showed that, when bismuth molybdate is mixed with the Fe–Co–Mo solid solution, epitaxy of the crystals of one phase on another is observed and the transport of oxygen participating in the oxidation of propene is facilitated.^{46,47} Unfortunately there are no literature data on the adsorption and activation of propene on other complex systems and it is not clear which of the cations ‘abstract’ a hydrogen atom from the olefin molecule.

If an alkene (for example, isobutene) is adsorbed on a complex multiphase catalyst, it is not possible to establish by the thermogrammed desorption (TPD) method which of the phases participates in the process.⁴⁸ The interaction of isobutene with oxygen on the Co–Mo–Bi–Fe catalyst has been investigated by IR Fourier spectroscopy and it has been shown that an anhydride-like compound is formed in the adsorption process. Other forms of the interaction of the olefin with the catalyst have not been observed. Unfortunately, the mechanism of the activation of an alkene on such complex systems could not be elucidated.

A model has been developed for the action of catalysts consisting of several phases (Bi–Mo, Sn–Sb, Mo–Fe), among which oxygen donors and acceptors are present.^{49,50} Oxygen migrates from the donor to the acceptor *via* spill-over. The reaction mechanism on such systems has been called ‘remote control’. It has been suggested that hydrocarbons are adsorbed on the acceptor phase, but there is no experimental confirmation of this. Unfortunately, the elementary mechanism of the activation of alkenes on multicomponent systems still remains unelucidated.

2. Alkanes

The activation of alkanes on oxide catalysts occurs in many cases *via* a heterogeneous-homogeneous mechanism. This applies particularly to the oxidation of methane, which, in contrast to other hydrocarbons, is not adsorbed on the catalyst surface at the reaction temperature. It is activated on impact against the surface, being converted into a methyl radical, which is desorbed and forms a methoxy-compound as a result of a secondary interaction with various forms of oxygen on the surface or with a OH group. The mechanism of the activation of methane, the kinetics of the process, and its energy characteristics have been described in a series of communications (see, for example, Refs 51–57) and will not therefore be considered in the present review.

The oxidation of C₂–C₅ alkanes can proceed *via* two mechanisms — heterogeneous-homogeneous and heterogeneous.⁵³ Ethane, propane, and butane are adsorbed on catalysts and are either oxidised to aldehydes, anhydrides, and acids or are dehydrogenated to alkenes.^{8,9} The alkane oxidation catalysts are molybdenum and vanadium oxides, compounds of the type of molybdates or vanadates, or V–P–O systems.^{7–9,58–60}

The activation of alkanes is ensured by the ability of the catalysts to propagate redox processes and by the presence on their surfaces of atomic oxygen and acid–base centres. The conversion of alkanes into various adsorbed forms — radicals, complexes, and carbonium ions — is possible by virtue of these properties of the catalysts.

A mechanism has been proposed^{61,62} for the activation of ethane on MoO₃ and alkali metal molybdates. The interaction of ethane with atomic oxygen and the Mo⁵⁺ and Mo⁶⁺–O[–] (ethane activation centre) active centres entails the abstraction of a hydrogen atom and the conversion of the hydrocarbon molecule into the C₂H₅· radical. The interaction of C₂H₅· and O[–] leads to the formation of the ethoxide C₂H₅O[–], which is converted into acetaldehyde with participation of a hydroxy group of the catalyst surface. Ethene is formed on decomposition of this ethoxide (oxidative dehydrogenation).

The activity of alkali metal vanadates in the oxidation of ethene depends on the catalyst structure.⁶² The influence of vanadium pentoxide on the activation of ethane has been inves-

tigated and a relation has been demonstrated between characteristics such as the degree of dispersion of the oxide and the yield of acetaldehyde.⁶¹ The oxidation of methane and ethane on iron phosphate has also been studied.⁶³

Numerous studies have been devoted to the oxidative dehydrogenation of propane and the results have been surveyed in reviews.^{8,9} Following adsorption and activation, propane is converted into propene or oxidation products (acrolein, acetaldehyde, *etc.*). These two aspects of the conversion of propane have a common stage — the abstraction of a hydrogen atom from the methyl group of the molecule. According to Michalakos *et al.*,⁶⁴ in the activation of propane a propyl radical is formed and is then converted into propene. The vanadium-containing catalysts Mg–V–O, V–Sb–O, *etc.* are used to effect this process.

Mechanisms for the conversion of propane on Bi–Mo–O, Sn–Sb–O, and other catalytic systems have been proposed in a review.⁹ According to these mechanisms, the oxidation of the intermediate reactive forms, which are the products of the interaction of propane with the catalyst, involves the formation of oxygen-containing surface complexes.

Investigators have devoted much attention to the study of oxidation reactions and oxidative dehydrogenation of butane.^{6,7} It has been established that the mechanism of the activation of butane with participation of different forms of oxygen on the surface of the catalysts is similar to the mechanism of the oxidation of propane.^{65–67}

The oxidation of butane on the V–P–O catalysts leads to the formation of a centre (V⁵⁺ ··· O) on which the hydrocarbon is activated,^{68,69} some of the V⁵⁺ ions being reduced to V⁴⁺. If there are no V⁴⁺ ions in the catalyst, butane is not activated. It has been found^{70–72} that, in the activation of a butane molecule on the V^V = O active centre, two hydrogen atoms are abstracted from it.

On the V–P–O catalyst, butane is converted into oxygen-containing products,⁷³ whilst on other vanadium systems, for example on V–Mg–O, it gives rise to butadiene (oxidative dehydrogenation).⁷⁴

Thus the activation of C₂–C₄ alkanes on various catalysts entails the formation of various surface forms of these compounds (radicals, complexes).

3. Aromatic hydrocarbons

The oxidation reactions of aromatic hydrocarbons may be of two kinds: oxidation of the side chain of alkyl-substituted aromatic compounds without disruption of the structure of the ring and oxidation with degradation of the aromatic ring. Different forms of oxygen — electrophilic and nucleophilic — participate in these processes. Diverse vanadium systems, containing added molybdenum oxide and alkali metals in addition to the vanadium ions, are used as the catalysts.

The catalytic oxidation of aromatic hydrocarbons to maleic and phthalic anhydrides has been studied in fair detail using modern experimental methods. Quantum-mechanical calculations for these systems have also been carried out.⁴ A series of studies have been devoted to the structure, the nature of the surface, and the valence state of the vanadium ion in vanadium catalysts.^{75–78}

Much attention has been devoted to the investigation of supported vanadium catalysts. The role of supports (for example a zeolite, quartz, SiO₂, and aerosil) in the state of the vanadium ion has been investigated resorting to the EPR method. The formation of polyvanadates and oligomers as well as bridges comprising vanadium ions has been observed on silica gel and aluminium oxide.⁷⁷ The structure of vanadium oxide depends on the type of support.⁷⁹ Meta- and deca-vanadates are formed on aluminium oxide, while octahedral vanadium pentoxide is formed on silica gel. The V₂O₅–TiO₂ system merits special attention. Monolayer catalysts are the most active in the partial oxidation of aromatic hydrocarbons.

Bond and Tahir⁸⁰ examined the properties of catalysts obtained by different methods. The state of vanadium ions was

investigated by various spectroscopic methods (IR Fourier spectroscopy, laser Raman spectroscopy, EPR, XPS, NMR). The following types of active centres on the surfaces of vanadium catalysts were established by analysing the data obtained:

The structure of the V_2O_5/TiO_2 catalysts has been investigated by NMR using the ^{129}Xe isotope and it has been shown that vanadium ions form large domains and individual V_2O_5 crystals contain large pores.⁸¹

Analysis of the ^{51}V NMR data obtained in a study of vanadium catalysts deposited on aluminium and titanium oxides showed that the structure of vanadium oxide depends on the degree of coverage of the support and the nature of the latter.⁸² The symmetry of the octahedra in the layers on the outer surface of the support is disturbed to a greater extent than the symmetry of the tetrahedra in the crystal. When vanadium oxide is inserted in titanium oxide, surface defects are formed and the specific surface of the catalyst changes.⁸³ Particularly interesting data have been obtained in a study of the influence of the support (titanium oxide) on the state of the vanadium ion.⁸⁴ In this system, vanadium can exist in the following forms: V^{4+} (forms a solid solution with rutile); V^{5+} (is inserted in the rutile surface and forms a monolayer); VO^{2+} (is formed during the reaction on reduction of V^{5+} in the monolayer); deformed V_2O_5 crystals.

The EPR study of V–Ti catalysts showed that the number of spins and the g -factor depend on the degree of surface coverage of the support by vanadium ions.⁸⁵ Two types of ions were discovered: the tetrahedral V^{4+} and the vanadyl ion. The structure of the active centre of a vanadium catalyst has been described.^{86,87} The vanadium ions on TiO_2 (rutile and anatase) are in different states: an amorphous vanadium layer is formed on anatase, whereas separate regions with partly reduced vanadium ions are produced on rutile.⁸⁸ Analysis of data on the state of vanadium ions on the surface of the catalyst showed⁸⁹ that, depending on the concentration and the method of preparation of the catalyst, mono- or poly-layers are formed and the ratio of the V^{4+} and V^{5+} ions changes.

The wide variety of the possible states of vanadium on TiO_2 led to special interest of investigators in the mechanism of the activation of aromatic hydrocarbons having different structures. A cluster incorporating vanadium ions was chosen as the model. The changes in the energy of the C–H bonds in the methyl group on activation were discovered from the results of a quantum-mechanical calculation for the interaction of toluene with isolated vanadium cluster^{90–92} and it was shown that oxygen plays the role of an adsorption centre if it adjoins the vanadium ion. The approach of the CH_3 group to the cluster results in the deformation of the C–H bonds. The structure of the surface compound and its further transformation into different products depend on the orientation of the toluene molecule relative to the cluster (*via* the ring or the CH_3 group).

The following mechanism of the oxidation of toluene has been proposed on the basis of an IR spectroscopic study: (1) abstraction of a hydrogen atom from the CH_3 group on chemisorption of the hydrocarbon; (2) dissociation of a C–H bond and the formation of a surface complex linked to the metal ion *via* the carbon atom; (3) abstraction of a hydrogen atom from a CH_2 group not linked to the surface.

A comparative study has been made⁹³ of the oxidation of toluene and xylene on the V_2O_5/TiO_2 catalyst and a possible reaction mechanism was discussed.

In a study of the oxidation of benzene to maleic anhydride on vanadium catalysts, especially on vanadium–molybdenum catalytic systems, data were obtained on the phase composition of the catalyst and the state of oxygen on their surfaces and in the bulk phase.³³ Quantum-mechanical calculation for the interaction of

benzene with a vanadium catalyst (a cluster made up of vanadium ions) showed that there is a likelihood of the abstraction of a hydrogen ion from the benzene ring under the influence of the catalyst oxygen and the formation of an intermediate peroxide complex. Depending on the disposition of the benzene molecule on the surface, π - and σ -complexes may be formed.

Thus different forms of oxygen and cations having different valences participate in the activation of hydrocarbons of different classes. The acid–base centres on the catalyst surfaces exert a significant influence on these processes.

IV. The influence of the acid–base properties of catalysts on the activation of hydrocarbons

The catalysts for the partial oxidation of hydrocarbons possess acidic or basic properties. The methods for the determination of these properties, the nature of the surface acid centres, and the link between the type of such centres and the selectivities in various processes have been described in detail in a monograph.⁹⁴ Two types of acid centres are distinguished: Brønsted and Lewis (aprotic). Modern spectroscopic methods have made it possible to discover the surface compounds formed on different acid centres. It has been suggested that the Brønsted centres are bifunctional.^{95–100} They are capable of being proton donors and of altering the basicity of the neighbouring oxygen atoms.

The influence of the acidity of the catalyst surfaces on the oxidation of various organic substances has been examined in a series of publications.^{3,7,96,101} Acetone is formed on oxidation of propene on the Brønsted centres of the MoO_3/Al_2O_3 catalyst.¹⁰¹ Intermediate forms of the type $CH_2-CH^+-CH_3$ (enolate) have been detected by IR spectroscopy on the surface of a tin–molybdenum catalyst. The Lewis centres on oxides can adsorb hydrocarbons in two ways: by abstracting a hydride ion from the alkane with formation of a carbonium ion or from the olefin with formation of a radical-cation.¹⁰²

The interaction of hydrocarbons with Lewis and Brønsted centres has been examined, the mechanism of the activation of propene on bismuth molybdate has been discussed, and the role of the acid centres in the activation of the olefin has been demonstrated.^{9,11,102,103}

The role of the acid centres in the oxidation of propene on the $MoO_3-Sb_2O_4$ system has been investigated by a spectroscopic method and by the method involving the adsorption of pyridine and ammonia.¹⁰⁴ The relation between the degree of conversion of propene on Brønsted centres and between the selectivity and the ratio of the concentrations of the Lewis (N_L) and Brønsted (N_B) centres has been demonstrated. The dissociation of the vinyl C–H bond leads to the formation of an intermediate oxygen-containing propene compound. The intensity of this process depends on N_L and N_B . Detailed quantitative analysis using the adsorption of pyridine and ammonia demonstrated a correlation between the ratio N_B/N_L and the selectivity of the oxidation of propane on molybdenum oxide and on the $MoO_3 + Sb_2O_4$ mixture; the greater this ratio, the higher the selectivity.

Activation in the presence of water vapour on the acid centres of V_2O_5 leads to the dehydration of propene and its dehydrogenation.¹⁰⁵ The activation of propene on copper molybdate results in the formation of an intermediate carbonium ion species.¹⁰³ Acidity influences also the oxidative dehydrogenation of ethane on vanadium oxide deposited on silica gel.¹⁰⁶ It has been shown by the method involving the adsorption of pyridine and ammonia that the higher the degree of acidity, the greater the degree of conversion of ethane.

There are strong acid centres on the $(VO)_2P_2O_4$ catalyst. They consist of V^{5+} ions involved in octahedral coordination and surrounded by the PO_4 group (tetrahedron). The acidity of the catalyst surface influences the oxidation of aromatic compounds.^{107,108} The acid centres also participate in the oxidative dehydrogenation and oxidation of butane.^{108–110} The properties of the acid–base centres may change significantly when additives

are introduced.³ For example, after the addition of Group I elements (K, Na, Li) to MoO₃ deposited on TiO₂ and Al₂O₃, the rates of oxidation of propene and butene on the catalyst change; the introduction of acid (P₂O₅) and basic (Na₂O) additives into SnO₂ alters the mode of oxidation of propene: in the presence of the acid additive, propene is oxidised to acrolein, whereas modification with alkaline additives results in its dehydrogenation to benzene.

The effect of additives promotes the appearance in the vanadium catalyst of new compounds with the vanadium ion. When potassium sulfate is introduced into V₂O₅, vanadyl sulfate containing V⁴⁺ is formed. This is accompanied by a change in the acidity of the catalyst and in the rate of conversion of butadiene. The introduction of acid additives (tellurium and selenium ions) into bismuth molybdate accelerates the formation of acrolein. The addition of phosphorus ions to bismuth molybdate promotes the formation of π -allyl complex from butene. Thus modification of vanadium catalysts alters their acid properties and influences the activation of alkenes.

The structure of the vanadium–molybdenum catalyst for the oxidation of benzene changes when PO₄²⁻ ions are introduced into it: the lattice rearranges and the V–O and Mo–O bonds are disturbed. With increase in the PO₄²⁻ concentration, new compounds (bronzes) appear. These data indicate the influence of the modification on the structure and acidity of the catalyst and hence also on the adsorption of hydrocarbons and their activation.

The study of Blasco *et al.*¹¹² was devoted to the acid–base properties of vanadium catalysts deposited on various supports and to the influence of these properties on the oxidative dehydrogenation of butane. The acidity of the catalysts on different supports was determined from the degree of adsorption of pyridine and ammonia, the concentrations of the acid centres were determined, and it was shown that the selectivity in the conversion of butane depends on the acid properties of the surface. The introduction of additives also alters the acidity of the catalyst and its redox properties and it is therefore difficult to separate the influences of the nature of the support and the additives on the activation of hydrocarbons.

Lewis acid centres capable of activating butane by converting it into a radical have been identified in the V–P–O system.⁸ The oxidative dehydrogenation of ethane on the V/SiO₂ catalyst has been described¹⁰ and the redox reaction mechanism has been examined. It was shown that the activities of the catalysts depend on their acidity.

Thus the acid–base properties of oxide systems influence significantly the activation and conversion of hydrocarbons with different structures, while the alteration of these properties is accompanied by a rearrangement of the structure of the solid and the disturbance of the valence state of certain ions in the catalyst composition. It is therefore difficult to discover the influence of acidity or basicity alone on the mechanism of the activation of hydrocarbons.

V. The influence of structural defects in the catalysts on the activation of hydrocarbons

The nature of the defects in solids, especially in oxides, has been discussed in numerous communications (see, for example, Tret'yakov¹¹³ and Tomlinson *et al.*¹¹⁴). The conditions in the preparation of the catalysts, the effect of the medium, and impurities alter the structures of solids and influence the type of defects and the distribution of additives which may interact with the basic elements. This may result in the local reconstruction of the initial oxides. Furthermore, clusters may be formed from the structural components and additives.

Defects alter the electronic characteristics of the surface and of the bulk of the solid^{5,6} and thereby influence the activation of the components of the reaction mixtures.^{114,115} The partial oxidation of hydrocarbons is achieved with participation of the oxygen in the oxide lattices. Oxygen vacancies are formed in the course of

this process and oxygen migrates *via* the lattice and interacts with the oxygen from the gas phase.^{30,32} Anionic vacancies influence the abstraction of a hydrogen atom from the propene molecule when the latter is oxidised on various spinels and solid solutions.^{30,33} The structural sensitivity of oxidation reactions has been discussed.^{115,116} Several types of defects in metal oxides have been examined: 'genetic' and impurity defects as well as oxygen vacancies.

Defects and vacancies may arise in complex oxide systems when additives are introduced.¹¹⁷ For example, the modified Co–Mo–Bi–Fe catalyst contains the molybdate Fe₂(MoO₄)₃, which has a garnet-like structure with a vacant dodecahedral sublattice. When alkali elements, especially the potassium ion, the ionic radius of which is optimal for this structure, are introduced, the vacant sublattice is partly filled and the degree of defectiveness of iron molybdate increases. The latter acquires the structure of a nonstoichiometric garnet containing oxygen vacancies:

$\square^0$ — vacancy in the dodecahedral sublattice, $\square^-$ — anionic oxygen vacancy.

Such structural changes influence the mobility of oxygen in the catalyst lattice.

A process involving the appearance of defects in catalysts has been described in a review.¹¹⁷ The adsorption of various substances on catalysts can also induce the appearance of defects in the lattice of the solid. Thus defects are formed after the adsorption of chloride ions on a silver single crystal,¹¹⁸ oxygen from the gas phase being adsorbed on these centres. This type of centre–oxygen associated species is called a 'B defect' and serves as a kind of 'gate' for the permeation of atomic oxygen into the layers of the silver lattice. A model of the structure of silver, on the surface of which chloride ions are sorbed, has been proposed.¹¹⁸

The perovskites ABO₃ have begun to be used recently in oxidative catalysis.^{119–121} Vacancies and defects are formed in the structures of these compounds owing to the nonstoichiometric amounts of the elements A and B. The same vacancies and defects appear when additives are introduced.^{120,121} The properties of the lattice oxygen and adsorbed oxygen have been investigated for the pure and modified lanthanum oxides and the nature of the defects has been established.¹²¹ A calculation has been carried out for a model of the defect and its diffusion from the bulk phase and on the surface.^{122,123} The addition of strontium ions to the perovskite increases the mobility of oxygen and the number of oxygen vacancies.¹²⁴ The interaction of ethene, propene, and isobutene with a defect-containing catalyst, the composition of which is described by the formula Bi_{1-x/3}□_{x/3}Mo_y(V_{1-x}Mo_{x-y}Fe_x)O_y, where □ is a cationic vacancy and $x = 0.13–0.60$, has been investigated.^{124–126} Schemes for the disposition of oxygen around different cations have been proposed and the view has been expressed that the coordinated cation participates in the dissociation of a C–H bond of the hydrocarbon with formation of the allyl group. The rate of oxidation depends on the number of vacancies in the catalyst. Theoretical calculations have been performed for the interaction of hydrocarbons with clusters and structural defects.

The modern experimental methods make it possible to investigate the transformations in a solid, occurring under the influence of the medium, and the structure of the surface compound *in situ*. However, the results of such studies have not been duly employed in establishing the mechanism of the activation of hydrocarbons, which is therefore purely formal.

In considering the questions concerning the influence of the chemical and structural properties of the catalyst on the activation, it is essential to take into account, apart from the factors indicated above, the electronic transitions between the solid and the hydrocarbons being adsorbed. In the electronic theory of catalysis, much attention has been devoted to the establishment of the signs of the charges of the substances adsorbed on metal oxides

and the charge on the surface of the metal.¹²⁷ As a rule, the molecular and atomic oxygen on oxides has a negative charge, while organic substances have a positive charge.^{3,28}

Adsorption on metals entails the formation of dipoles with different directions of the charge relative to the catalyst surface.¹²⁸ According to the electronic theory of catalysis, the activity of the catalyst depends on the position of the Fermi level for the lattice of the solid and electron exchange takes place between the adsorbed molecule of the given substance and the catalyst. The search for the relation between the electronic properties of a solid catalyst, on the one hand, and the charged reacting molecules, on the other, was therefore believed to be a problem of current interest. However, the electronic theory of catalysis was not developed further. The characteristics of the electron exchange process are determined from the change in the electron work function on adsorption and from the electrical conductivity. The change in the electron work function on the V_2O_5/TiO_2 catalysts, pure and modified with potassium ions, has been studied.¹²⁹ The presence of potassium facilitates electron exchange in the solid. The vacancies in oxide lattices may be charged and, when hydrocarbons are adsorbed and interact with oxygen, they may transfer electrons to the surface compounds formed.

The electron exchange between the charged forms of the hydrocarbon and the surface oxygen, observed on various oxides, has been considered in the analysis of the selectivity in the partial oxidation. The catalytic properties of many catalysts are influenced by the charge transfer between the surface and the bulk of the catalyst.^{130–133} This is particularly notable on supported catalysts, the activity of which is related to the electrical conductivity.^{131,132} The electronic characteristics of the catalysts influence the rate of interaction of hydrocarbons with surface oxygen but do not alter the type of activation.

Thus analysis of the activation of hydrocarbon molecules on partial oxidation of catalysts has shown that this is a complex process which includes diverse interactions depending on the structure and energy parameters of the molecules being adsorbed and also on the characteristics of the catalyst surface (the form of oxygen, the valence state of ions, vacancies, and defects).

VI. The selectivity of the partial oxidation and activation of hydrocarbons

The principal characteristics of the partial oxidation are the rate and selectivity of the reaction.^{134–138}

The partial oxidation processes are almost always accompanied by extensive oxidation. There are two mechanisms of the extensive oxidation of hydrocarbons: the consecutive mechanism, where the partial oxidation product is converted into CO_2 and water, and the parallel mechanism where CO_2 and water are formed from the hydrocarbon *via* other intermediate species (surface compounds, radicals). The selectivity of the oxidation depends on the process mechanism.¹³⁹

The extensive oxidation of hydrocarbons of different classes on the $MgCr_2O_4$ catalyst typical for this process has been studied.¹⁴⁰ The spectroscopic investigation showed that hydrocarbons react with chromium ions functioning as active centres. The weakest C–H bond is then ruptured and C–O bond is formed, while further oxidation leads to the formation of carboxylates and carbonates.

The activation of hydrocarbon molecules on partial oxidation catalysts is the first and probably the rate-determining stage of the process. Further reactions of the surface forms produced with participation of oxygen determine the type and structure of the oxidation products. In the elucidation of the activation mechanism, one of the main questions is that of the role in this process of the structure and energy of the bonds in the hydrocarbon molecule and also the question of the form of oxygen capable of participating in the formation of the partial oxidation product. Comparative study of hydrocarbons of several classes makes it possible to establish the influence of their structure on the activation.

Among all the alkenes, only ethene is converted into epoxyethane on a silver catalyst. The attempt to obtain epoxypropane on this catalyst proved unsuccessful: propene is activated by involvement of the methyl group, from which a hydrogen atom is abstracted and this results in the formation of the allyl group.^{140,141} Ethene is activated as a consequence of the rupture of the double bond by oxygen, which leads to the formation of a complex preceding the formation of epoxyethane.

Aldehydes and acids or alkenes appear as a result of the activation of alkanes (oxidative dehydrogenation). For example, two hydrogen atoms may be split off from the hydrocarbon molecule on activation of butane. The products of this reaction are maleic anhydride, maleic aldehyde, or butadiene. Still more significant differences are observed in the activation of aromatic hydrocarbons. One hydrogen atom is split off in this case from the ring (benzene is formed), two hydrogen atoms are split off from the side chain (alkyl-substituted aromatic hydrocarbons are formed), or the ring is ruptured. In a study devoted to the selective oxidation of light alkanes,¹⁴² the view has been expressed that the choice of catalytic systems for these reactions must be determined by the structure of the active centres and their redox and acid–base properties. Particular attention was devoted in this investigation to the reaction products, their stability, and the strength of the bond with the solid (ease of desorption). The adsorption mechanism and the mechanism of the insertion of oxygen in oxide catalysts were examined.

The interaction of hydrocarbons with the surface of an oxide catalyst is accompanied by its reduction, *i.e.* by a change in the valence state of the cations. This process influences the mode of activation of the hydrocarbon molecules. In a number of instances, the rate of activation and its mechanism are determined by the redox properties of the catalyst. The lack of capacity for reduction (for example, in the vanadium–phosphorus catalyst) prevents the formation of oxygen-containing products from butane and the process proceeds on other surface centres (for example, acid centres). Oxidative dehydrogenation then takes place. The rates and selectivities of the oxidation of various hydrocarbons on the same catalysts may differ as a consequence of the formation of various intermediate forms. For example, on bismuth molybdate propene gives rise to an allyl complex, whilst butene produces a π -complex with elimination of two hydrogen atoms.

The V–Mo–Ti catalytic system is the most active in the oxidation of aromatic hydrocarbons, while propene is oxidised on it with a low selectivity.¹⁴³

Oxidative dehydrogenation takes place preferentially on the $Mg_2(VO_4)_2$ catalyst. On other vanadium systems, the rates of partial oxidation and oxidative dehydrogenation depend on the ratio of V^{4+} and V^{5+} (see Refs 55, 64). As a consequence of the removal of oxygen from the lattice of the catalyst in the interaction of its surface with a hydrocarbon, vacancies (defects) arise and electron exchange processes take place within the lattice.

The influence of the nucleophilicity and electrophilicity of oxygen on the mechanism of the oxidation of hydrocarbons has been examined in numerous studies.^{4,33,137–140} The abilities of Bi–Mo–O and V_2O_5 to oxidise hydrocarbons of different classes have been compared on the basis of the analysis of the interaction of electrophilic oxygen with the C–C and C–H bonds in the hydrocarbon molecule. For example, bismuth molybdate is incapable of oxidising aromatic hydrocarbons, while V_2O_5 cannot oxidise olefins. The diversity of the mechanisms of the activation of hydrocarbons on different catalytic systems is determined not only by the state of the organic molecule and oxygen but also by the properties of the catalyst surface. We have already considered the influence of the structure and redox properties of the solid on the activation of hydrocarbons. However, the characteristic features of the acid centres of the catalyst are no less important.^{134,136}

In the activation of hydrocarbons on the surfaces of catalysts, the complexes or radicals formed interact with oxygen almost simultaneously with the dissociation of the C–H bond. The lattice

oxygen of the oxide or the atomic oxygen adsorbed on the metal surface are known to participate in the partial oxidation reaction. The molecular oxygen adsorbed from the gas phase participates in the extensive oxidation. The structure of the surface and the valence state of the ions influence the bond energy of the oxygen in the lattice and its mobility. Numerous studies, in which the mechanism of the interaction of the adsorbed hydrocarbon with different forms of oxygen is discussed, have been devoted to these questions (see, for example, Refs 3, 7, and 31). In essence, the activation step involves the adsorption of a hydrocarbon molecule and its interaction with oxygen. The selectivity in the formation of the reaction products depends on the structure of the oxygen--hydrocarbon complex which has appeared and also on its mobility and reactivity.

It has been suggested that the mechanism of the partial oxidation is determined by the interaction of the mobile activated hydrocarbon complex or radical with the stationary lattice oxygen:¹³⁶

At a low temperature there is a possibility of the formation of peroxides (as a result of the interaction with O_2^-) and their subsequent decomposition with formation of oxygen-containing products.

On extensive oxidation, the activated mobile oxygen interacts with the stationary hydrocarbon complex:

The mobile oxygen may consist of an adsorbed atom or molecule. The continuation of the reaction in the gas phase is possible (a homogeneous-heterogeneous mechanism).¹

Sokolovsky¹⁴¹ carried out a kinetic analysis and proposed models for the extensive oxidation of hydrocarbons. The selectivity and the partial oxidation of hydrocarbons are determined not only by the structure of the molecules of hydrocarbons of different classes and the C-H bond energies but also by the valence state of the components of the catalyst surface. One of the stages in the activation of hydrocarbons consists of redox reactions in the catalyst. The cations in the lattice of the solid undergo a change in their valence state as a result of the adsorption of hydrocarbons. There is also a corresponding change in the mode of oxidation. For example, in vanadium catalysts, oxygen bridges may be formed on the vanadium ions. These are readily reduced when the hydrocarbon is adsorbed, as a result of which oxygen is removed and a C-O bond is formed. The reaction products contain oxygen.

The acid-base properties of the catalyst as well as the redox reactions influence the conversion of hydrocarbons and the process selectivity. When the reaction is carried out on complex oxide systems (for example, $\text{MoO}_3\text{-Sb}_2\text{O}_4$),¹⁰⁴ a relation is observed between the ratio of the number of Brønsted and Lewis centres and the selectivity in the conversion of propene into acrolein. On the other hand, a change in the ratio of the molybdenum and antimony oxides alters the concentration of the oxidation-reduction centres on the surface and influences the migration of oxygen *via* the lattice. The combined operation of these factors promotes the dissociation of oxygen, the enhancement of oxygen spill-over between the phases, and the adsorption of the protons split off from the propene molecule. Such is the complex mechanism of the influence on the activation of the hydrocarbon by various processes occurring on the catalyst surface.

The oxidation kinetics have been considered in a large number of publications, both review publications¹³⁸ and those devoted to the investigation of individual catalytic reactions in the extensive and partial oxidation of hydrocarbons. Apart from the dependences of the reaction rate and selectivity on the pressure, temper-

ature, and contact time, models of the process, corresponding to the observed parameters, are presented in these communications.

In order to choose a model, it is essential to elucidate which stage of the oxidation process determines its rate. Almost all investigators believe that this stage is the activation of the hydrocarbon on the catalyst surface with formation of various surface compounds. Formal schemes, which do not always correspond to the true reaction mechanism, have been proposed in many investigations.

The foundations for the construction of a kinetic model of the methane oxidative condensation reaction on the $\text{PbO}/\text{Al}_2\text{O}_3$ catalyst have been described.¹⁴⁴ Ethene, ethane, and extensive oxidation products are formed in this process from methane. The reaction proceeds *via* a heterogeneous-homogeneous mechanism. Characteristic features of the process at different temperatures, oxygen pressures, and for other parameters have been investigated. The proposed model includes the formation of the methyl radical from methane, its dimerisation to ethane, and the reaction with oxygen to form a peroxide. The dependence of the limiting selectivity and of the rate of formation of the products on various parameters has been established on the basis of this model and it has also been shown that the process proceeds *via* a redox mechanism. It is postulated that ethane is activated and the extensive oxidation products are formed on different centres.

Albonetti *et al.*⁸ investigated the kinetics of the oxidation of ethane and ethene. Kinetic analysis showed that this reaction has a redox mechanism. The rate constants for the formation of methyl radicals and the extensive oxidation products were found, equations were proposed for the rates of formation of different products, and the limiting selectivities were established.

A similar approach to the elucidation of the mechanisms of catalytic partial oxidation processes, based on a profound kinetic analysis and the establishment of a relation between the physicochemical properties of the catalysts and the selectivity of the oxidation process, has also been used in other studies.^{143, 144} A two-centre model has been proposed for the oxide catalyst as well as kinetic models for the partial oxidation of olefins (propene, isobutene) and unsaturated aldehydes. It is postulated that the hydrocarbon and oxygen are adsorbed on centres of different types and that the interaction between them occurs as a result of the diffusion of oxygen from its adsorption centres to the reaction centres, which function simultaneously as the hydrocarbon adsorption centres.

Kinetic analysis of the two-centre model and the active surfaces of oxide catalysts has been carried out.¹⁴⁵⁻¹⁴⁹ Apart from a detailed mechanism of the transfer of oxygen from its adsorption centres to the reaction centres, it proved possible to describe the principal kinetic features of the oxidation of propene, isobutene, and methacrolein to acrolein, methacrolein, and methacrylic acid respectively under stationary conditions.

VII. Conclusion

The activation of hydrocarbons on the surfaces of catalysts is the first and rate-determining stage of their partial and extensive oxidation. The hydrocarbons are converted into active radicals or complexes, which form different surface compounds, affording different oxidation products.

The way in which the hydrocarbon interacts with the surface of the solid depends on the structure of the organic molecule (bond energy) and the nature of the catalyst surface (structure, valence state of its constituent ions, and the forms of oxygen and its mobility).

In the structure of the catalyst there are defects, which can also serve as activation centres. Electron exchange takes place between the solid and the adsorbed hydrocarbon. The interaction of the hydrocarbon with oxide systems is accompanied by redox processes in the solid involving a change in the valence state of the lattice cations. Brønsted and Lewis acid centres also participate in the activation of the hydrocarbon. The mode of oxidation of

hydrocarbons, namely to oxygen-containing products or to hydrocarbons with a different structure (oxidative dehydrogenation), depends on the activation mechanism.
